In immunosuppressed patients, especially those with AIDS, management of molluscum can be very difficult. Aggressive treatment of the HIV infection with HAART, if it leads to improvement of the helper T-cell count, is often associated with a dramatic resolution of the lesions. This response is delayed 6 to 8 months from the institution of the treatment. Molluscum occurs frequently in the beard area, so shaving with a blade razor should be discontinued to prevent its spread. If lesions are few, curettage or core removal with a blade and comedo extractor are most effective. EMLA application may permit treatment without local anesthesia. Cantharone or 100% trichloroacetic acid may be applied to individual lesions. Temporary dyspigmentation and slight surface irregularities may occur. Cryotherapy may be effective but must be used with caution in persons of pigment. Subcutaneous IFN- α has been anecdotally effective. When lesions are numerous or confluent, treatment of the whole affected area may be required because of the possibility of latent infection. Trichloroacetic acid peels above 35% concentration (medium depth) or daily applications of 5fluorouracil (5-FU) to the point of skin erosion may eradicate lesions, at least temporarily. At times, removal by curette is required. Electron beam has been effective. In patients with HIV infection, continuous application of tretinoin cream once nightly at the highest concentration tolerated seems to reduce the rate of appearance of new lesions. Topical 1% to 3% cidofovir application and systemic infusion of this agent have been reported to lead to dramatic resolution of molluscum in patients with AIDS. -

PICORNAVIRUS GROUP

Picornavirus designates viruses that were originally called *enteroviruses* (polioviruses, coxsackieviruses, and echoviruses), plus the rhinoviruses. The picornaviruses are small, single-stranded RNA, icosahedral viruses varying in size from 24 to 30 nm. Only the coxsackieviruses, echoviruses, and enterovirus types 70 and 71 are significant causes of skin disease.

Enterovirus Infections

Person-to-person transmission occurs by the intestinal-oral route and less commonly the oral-oral or respiratory routes. Enteroviruses are identified by type-specific antigens. The type-specific antibodies appear in the blood about 1 week after infection has occurred and attain their maximum titer in 3 weeks. Viral cultures obtained from the rectum, pharynx, eye, and nose may isolate the infecting agent. Usually the diagnosis is by clinical characteristics, and except in specific clinical settings, the causative virus is not identified. Enteroviral infections particularly occur in children between the ages of 6 months and 6 years.

Many nonspecific exanthems and exanthems that occur during the summer and early fall are caused by coxsackievirus or echovirus (Fig. 19-38). The exanthems are most typically diffuse macular or morbilliform erythemas, which sometimes also contain vesicular lesions, or petechial or purpuric areas. Echovirus 9 has caused an eruption resembling acute meningococcemia. Each type of exanthem has been associated with many subtypes of coxsackievirus or echovirus (one exanthem, many possible viral causes). Echovirus 9, the most prevalent enterovirus, causes a morbilliform exanthem initially on the face and neck, then the trunk and extremities. Only occasionally is there an eruption on the palms and soles. Small red or white lesions on the soft palate may occur. The most common specific eruptions due to enteroviruses are hand-foot-and-mouth disease, herpangina, and roseola-like illnesses. Rare reported presentations of enterovirus infection include a unilateral vesicular eruption simulating herpes zoster, caused by echovirus 6; a fatal dermatomyositis-like illness in a patient with hypogammaglobulinemia, caused by echovirus 24; and a widespread vesicular eruption in atopic dermatitis that simulated Kaposi varicelliform eruption, caused by coxsackievitus A-16. Pleconaril and other future antienteroviral agents may be useful in severe enteroviral infections.

While the cutaneous eruptions due to these viruses are quite benign, infections with enterovirus 71 can be quite severe with the development of brainstem encephalitis and fatal neurogenic pulmonary edema, as well as ascending flaccid paralysis resembling poliomyelitis. Epidemics with severe disease have been reported in Bulgaria, Hungary, Hong Kong, Japan, Australia, Malaysia, Singapore, and

Fig. 19-38 Viral exanthema, photodistributed.

F**ig. 19-39** Herpangina.

Taiwan; the latter had the worst epidemic affecting more than 1 million people with 78 deaths in 1998.

Herpangina Herpangina, a disease of children worldwide, is caused by multiple types of coxsackieviruses (most frequently A8, A10, and A16), echoviruses, and enterovirus 71. In the severe outbreaks in Taiwan, 10% of the fatal cases had herpangina. It begins with acute onset of fever, headache, sore throat, dysphagia, anorexia, and sometimes, stiff neck. The most significant finding, which is present in all cases, is of one or more yellowish-white, slightly raised 2-mm vesicles in the throat, usually surrounded by an intense areola (Fig. 19-39). The lesions are found most frequently on the anterior faucial pillars, tonsils, uvula, or soft palate. Only one or two lesions might appear during the course of the illness or the entire visible pharynx may be studded with them. The lesions often occur in small clusters and later coalesce. Usually, the individual or coalescent vesicles ulcerate, leaving a shallow, punched-out, grayish-yellow crater 2 to 4 mm in diameter. The lesions disappear in 5 to 10 days. Treatment is supportive, consisting of topical anesthetics.

Herpangina is differentiated from aphthosis and primary herpetic gingivostomatitis by the location of the lesions in the posterior oropharynx and by isolation of an enterovirus. Coxsackievirus A-10 causes acute lymphonodular pharyngitis, a variant of herpangina, characterized by discrete yellow-white papules in the same distribution as herpangina.

Hand-Foot-and-Mouth Disease Hand-foot-andmouth disease (HFMD) is usually a mild illness. It primarily affects children from 2 to 10, but exposed adults may also develop disease. Infection begins with a fever and sore mouth. In 90% of cases oral lesions develop; these consist of small (4-8 mm), rapidly ulcerating vesicles surrounded by a red areola on the buccal mucosa, tongue, soft palate, and gingiva. Lesions on the hands and feet are asymptomatic red papules that quickly become small, gray, 3- to 7-mm vesicles surrounded by a red halo. They are often oval, linear, or crescentic and run parallel to the skin lines on the fingers and toes (Fig. 19-40). They are distributed sparsely on the dorsa of the fingers and toes and more frequently on the palms and soles. Especially in children who wear diapers, vesicles and erythematous, edematous papules may occur on the buttocks (Fig. 19-41). The infection is usually mild and seldom lasts more than a week. Treatment is supportive, with the use of oral topical anesthetics.

Fig. 19-40 Handfoot-and-mouth disease. (Courtesy of James Fitzpatrick, MD)

Fig. 19-41 Hand-foot-and-mouth disease.

HFMD is most frequently caused by coxsackievirus A-16 and less commonly by other coxsackie viruses (A5, A7, A9, A10, B1, B3, and B5) as well as enterovirus 71. In the severe Taiwanese enterovirus 71 outbreak, 80% of cases with CNS disease had HFMD. No cases of HFMD associated with CNS disease were due to coxsackie A16, so the rapid discrimination of viral types may be vital in outbreaks of HFMD. The virus may be recovered from the skin vesicles. Histopathologic findings are those of an intraepidermal blister formed by vacuolar and reticular degeneration of keratinocytes similar to other viral blisters. Inclusion bodies and multinucleated giant cells are absent. HFMD is distinguished from herpangina by the distribution of the oral lesions and the presence of skin lesions. It is differentiated from erythema multiforme minor by the skin lesions, which are oval and gray, as opposed to targetoid, as in erythema multiforme. HFMD usually requires no treatment. Although the coxsackieviruses lack thymidine kinase, acyclovir has anecdotally been reported to hasten resolution of the eruption in two reports.

Boston Exanthem Disease The so-called Boston exanthem disease occurred as an epidemic in Boston and was caused by echovirus 16, a now uncommon cause of viral exanthems. The eruption consisted of sparsely scattered pale red macules and papules. In severe cases, the lesions were

morbilliform and even vesicular. The eruption was chiefly on the face, chest, and back and in some cases on the extremities. On the soft palate and tonsils, small ulcerations like those of herpangina were noted. There was little or no adenopathy. The incubation period was 3 to 8 days.

Eruptive Pseudoangiomatosis Eruptive pseudoangiomatosis describes the sudden appearance of 2- to 4-mm blanchable red papules that resemble angiomas. In children it is usually associated with a viral syndrome, but most affected adults have no viral symptoms. The red papules blanch on pressure and are often surrounded by a 1- to 2-mm pale halo. Lesions often number about 10, but may be much more numerous. Most lesions appear on the face and extremities, but the trunk may also be affected. In children, lesions are short-lived, virtually always resolving within 10 days. Lesions may last slightly longer in adults. Recrudescences may occur. Epidemics have been described in adults and even healthcare workers caring for patients with eruptive pseudoangiomatosis have developed lesions. Histologically, dilated upper dermal vessels, but not increased numbers of blood vessels, with prominent endothelial cells are seen. Echoviruses 25 and 32 have been implicated in the initial reports, and more recently EBV. The occurrence in young children and the presence of miniepidemic outbreaks strongly suggest an infectious trigger.

PARAMYXOVIRUS GROUP

The paramyxoviruses are RNA viruses that range in size from 100 to 300 nm. In this group, the viral diseases of dermatologic interest are measles (nubeola) and German measles (rubella). Others viruses of this group are mumps virus, parainfluenza virus, Newcastle disease virus, and respiratory syncytial virus.

Measles

Also known as *rubeola* and *morbilli*, measles is a worldwide disease that in developed countries most commonly affects children under 15 months of age. It is spread by respiratory droplets and has an incubation period of 9 to 12 days. Currently, available immunizations are highly effective, with the US being the largest country to have eradicated all endemic cases. Imported cases continue to occur, however, with the highest number coming from China and Japan. In Japan, vaccination is not required and is recommended only after age 2, which are two factors in the failure of that advanced nation to eradicate this viral disease. There is no link between vaccination against measles or rubella and the development of epilepsy.

The prodrome consists of fever, malaise, conjunctivitis, and prominent upper respiratory symptoms (nasal congestion, sneezing, coryza, and cough). After 1 to 7 days, the exanthem appears, usually as macular or morbilliform lesions on the anterior scalp line and behind the ears. Lesions begin as discrete erythematous papules that gradually coalesce. The rash spreads quickly over the face, then by the second or third day (unlike the more rapid spread of rubella) extends down the trunk to the extremities. By the third day, the whole body is involved. Lesions are most prominent and confluent in the initially involved areas and may be more discrete on the extremities. Purpura may be present, especially on the extremities, and should not be confused with "black measles," a rare, disseminated intravascular coagulation-like complication of measles. Koplik spots, which are pathognomonic, appear during the prodrome. They appear first on the buccal mucosa nearest to the lower molars as 1-mm white papules on an erythematous base. They may spread to involve other areas of the buccal mucosa and pharynx. After 6 to 7 days the exanthem clears, with simultaneous subsidence of the fever.

Complications include otitis media, pneumonia, encephalitis, and thrombocytopenic purpura. Infection in pregnant patients is associated with fetal death. Complications and fatalities are more common in children who are undernourished or have T-cell deficiencies. In HIV-infected children the exanthem may be less prominent.

Modified measles occurs in a partially immune host as a result of prior infection, persistent maternal antibodies, or immunization, and is a milder disease. The course is shorter, the exanthem less confluent, and Koplik spots may be absent. It is difficult to differentiate it from other viral exanthems.

Atypical measles was seen in patients who received killed measles vaccine in the early to mid 1960s. The syndrome consists of fever, cough, headache, abdominal pain, myalgia, edema of the extremities, pleural effusion, pneumonia, and hilar adenopathy. Morbilliform lesions occur on the skin, occasionally with intermingled petechiae and/or vesicles, beginning on the hands and feet and spreading centripetally. The main differential diagnosis is Rocky Mountain spotted fever.

A diagnosis of measles is established by the presence of a high fever, Koplik spots, the characteristic conjunctivitis, upper respiratory symptoms, and typical exanthem. Lymphopenia is common, with a decreased white blood cell count. Biopsies of skin lesions may show syncytial keratinocytic giant cells, similar to those seen in respiratory secretions. Laboratory confirmation is usually with acute and convalescent serologic tests. Rubella, scarlet fever, secondary syphilis, enterovirus infections, and drug eruptions are in the differential diagnosis. Administration of high doses of vitamin A will reduce the morbidity and mortality of hospitalized children with measles. Two doses of retinyl palmitate, 200,000 IU 24 h apart, are recommended for all children 6 months to 24 months of age, immunodeficient children, children with malnutrition or evidence of vitamin A deficiency, and recent immigrants from areas of high measles mortality. Otherwise, treatment is symptomatic, with bed rest, analgesics, and antipyretics.

Live virus vaccination is recommended at 15 months with a booster at 5 years. A faint maculopapular exanthem may occur 7 to 10 days after immunization. When given up to 5 days after exposure, vaccination may prevent infection. Children under 1 year of age who are exposed to measles should be treated with immune serum globulin.

Rubella

Rubella, commonly known as *German measles*, is caused by a togavirus and probably spreads by respiratory secretions. The incubation period is 12 to 23 days (usually 15 to 21). Live virus vaccination is highly effective, providing lifelong immunity. There is no association between measles, mumps, and rubella (MMR) vaccination and autism.

There is a prodrome of 1 to 5 days consisting of fever, malaise, sore throat, eye pain, headache, red eyes, runny nose, and adenopathy. Pain on lateral and upward eye movement is characteristic. The exanthem begins on the face and progresses caudad, covering the entire body in 24 h and resolving by the third day. The lesions are typically pale pink morbilliform macules, smaller than those of rubeola. The eruption may resemble roseola or erythema infectiosum. An exanthem of pinhead-sized red macules or petechiae on the soft palate and uvula (Forscheimer's sign) may be seen. Posterior cervical, suboccipital, and postauricular lymphadenitis occurs in more than half of cases. Rubella is in general a much milder disease than rubeola is. Arthritis and arthralgias are common complications, especially in adult women. These last a month or longer.

Congenital Rubella Syndrome Infants born to mothers who have had rubella during the first trimester of pregnancy may have congenital cataracts, cardiac defects, and deafness. Numerous other manifestations, such as glaucoma, microcephaly, and various visceral abnormalities, may emerge. Among the cutaneous expressions are thrombocytopenic purpura; hyperpigmentation of the navel, fore-head, and cheeks; bluish ted infiltrated 2- to 8-mm lesions ("blueberry muffin" type), which represent dermal erythropoiesis; chronic urticaria; and reticulated erythema of the face and extremities.

Asymmetric Periflexural Exanthem of Childhood

This clinical syndrome, also known as unilateral laterothoracic exanthem, occurs primarily in the late winter and early spring, and appears to be most common in Europe. It affects girls more often than boys (1.2-2:1). It occurs in children 8 months to 10 years of age, but most cases are between 2 and 3 years of age. Multiple cases have been reported in adults from Europe and China. Its cause is unknown, but a viral origin has been proposed, since it occurs in young children and is seasonal, and secondary cases in families have been reported. No reproducible viral etiology has been implicated, however. Clinically, two-thirds to threefourths of affected children have symptoms of a mild upper respiratory or gastrointestinal infection, usually preceding the eruption. The lesions are usually discrete 1-mm erythematous papules that coalesce to poorly marginated morbilliform plaques. Pruritus is usually present, but mild. Lesions begin unilaterally close to a flexural area, usually the axilla (75% of cases). Spread is centrifugal with new lesions appearing on the adjacent trunk and extremity. Normal skin may intervene between lesions. The contralateral side is involved in 70% of cases after 5 to 15 days, but the asymmetrical nature is maintained throughout the illness. Lymphadenopathy of the nodes on the initially affected side occurs in about 70% of cases. The syndrome lasts 2 to 6 weeks on average, but may last more than 2 months, and resolves spontaneously. Topical steroids and oral antibiotics are of no benefit, but oral antihistamines may help associated pruritus. Histologically, a mild-to-moderate lymphocytic (CD8+ T-cell) infiltrate surrounds and involves the eccrine ducts but not the secretory coils. There may be an accompanying interface dermatitis of the upper eccrine duct and adjacent epidermis.

PARVOVIRUS GROUP

Parvovirus B19 is the most common agent in this erythrovirus genus to cause human disease. Infection is worldwide, occurring in 50% of persons by age 15. The vast majority of elderly adults are seropositive. Infections are more common in the spring in temperate climates. Epidemics in communities occur every few years. The virus is spread via the respiratory route and infection rates are very high within households. Most infections are asymptomatic. Erythema infectiosum, papular purpuric gloves and socks syndrome, arthropathy (especially in middle-aged females), aplastic crisis in hereditary spherocytosis and sickle cell disease, and chronic anemia in immunosuppressed patients are clearly related to parvovirus B19 infection. Hydrops fetalis and fetal demise may result if infection occurs during pregnancy, with 30% of fetuses infected and 5% to 9% of affected pregnancies suffering letal loss.

Erythema Infectiosum (Fifth Disease)

Erythema infectiosum is a worldwide benign infectious exanthem that occurs in epidemics in the late winter and early spring. In normal hosts (but not immunosuppressed or sickle-cell patients in crisis), viral shedding has stopped by the time the exanthem appears, making isolation unnecessary. The incubation period is 4 to 14 days (average 7 days). Uncommonly, a mild prodrome of headache, runny nose, and low-grade fever may precede the rash by 1 or 2 days.

Erythema infectiosum has three phases. It begins abruptly with an asymptomatic erythema of the cheeks, referred to as *slapped cheek* (Fig. 19-42). The erythema is typically diffuse

Fig. 19-42 Erythema infectiosum.

and macular, but tiny translucent papules may be present. It is most intense beneath the eyes and may extend over the cheeks in a butterfly-wing pattern. The perioral area, lids, and chin are usually unaffected. After 1 to 4 days the second phase begins, consisting of discrete erythematous macules and papules on the proximal extremities and later the trunk. This evolves into a reticulate or lacy pattern. These two phases typically last 5 to 9 days. A characteristic third phase is the recurring stage. The eruption is markedly reduced or invisible, only to recur after the patient is exposed to heat (especially when bathing) or sunlight, or in response to crying or exercise. About 7% of children with erythema infectiosum have arthralgias, whereas 80% of adults have joint involvement. Necrotizing lymphadenitis may also occur in the cervical, epitrochlear, supraclavicular, and intraabdominal lymph nodes. Children with aplastic crisis due to parvovirus B19 usually do not have a rash. However, even healthy children can develop significant bone marrow complications, albeit transient and self-limited (Fig. 19-43).

Papular Purpuric Gloves and Socks Syndrome

This syndrome, which is less common than erythema infectiosum, occurs primarily in teenagers and young adults. Pruritus, edema, and erythema of the hands and feet appear and a fever is present. The lesions are sharply cut off at the wrists and ankles. Over a few days they become purpuric. There is a mild eigthema of the cheeks, elbows, knees, and groin folds. Lesions in the groin may become purpuric. Oral erosions, shallow ulcerations, aphthous ulcers on the labial mucosa, erythema of the pharynx, Koplik spots, or petechial lesions may be seen on the buccal or labial mucosa. The lips may be red and swollen. Vulvar edema and erythema accompanied by dysuria may be seen. An unusual variant is a unilateral petechial and erythematous eruption of the axilla. The acral erythema may rarely move proximally along lymphatics, simulating a lymphangitis. Transient lymphocytopenia, a drop in platelet count, and elevation of liver function tests may be seen. The syndrome resolves within 2 weeks. Evidence of seroconversion for parvovirus B19 has been found in most reported patients. Histologically, there is a dermal infiltrate of CD30+T-lymphocytes surrounding the upper dermal vessels. There is an interface component and prominent extravasation of red blood cells in petechial lesions. Parvovirus B19 antigen has been found in the endothelial cells, sweat glands and ducts, and epidermis in three

Fig. 19-43 Erythema infectiosum, acral papular eruption and purpura induced by blood pressure cuff and due to the associated thrombocytopenia.

patients. In HIV-infected patients who develop papular purpuric gloves and socks syndrome (PPGSS), the eruption is more persistent (lasting 3 weeks to 4 months) and is associated with anemia.

Not all cases of PPGSS are caused by parvovirus B19. In adults it may be associated with HBV infection. In children the syndrome occurs at an average age of 23 months. The eruption lasts an average of 5 weeks. In children CMV and EBV are the most common documented causes in Taiwan where this syndrome appears to be very common in the last quarter of the year.

ARBOVIRUS GROUP

The arboviruses comprise the numerous arthropod-borne RNA viruses. These viruses multiply in vertebrates as well as in arthropods. The vertebrates usually act as reservoirs and the arthropods as vectors of the various diseases.

West Nile Fever

West Nile virus (WNV) is a flavavirus which is endemic in East Africa. It first appeared in eastern North America in 1999 and reached California by 2004. It is primarily an infection of the crow family (crows, ravens, magpies and bluejays). It is spread by *Culex* mosquitoes. Approximately 80% of infected persons will have no symptoms. After an incubation period of 3 to 15 days, a febrile illness of sudden onset occurs. The primary complications are neurologic disease, including seizures (10% of symptomatic adults), ascending flaccid paralysis (like poliomyelitis), ataxia, and reduced level of consciousness. A significant percentage of affected persons are left with permanent neurologic sequelae. A morbilliform eruption of the neck, trunk, arms or legs occurs in 20% of patients.

Sandfly Fever

Sandfly fever is also known as phlebotomus fever and pappataci fever. The vector, Phlebotomus papatasii, is found in the Mediterranean area (Sicilian, Naples and Toscana virus), Russia, China, and India. While Sicilian and Naples sandfly fever viral infections disappeared or dramatically decreased with mosquito eradication programs, Toscana virus infection is still common. While most infected persons are asymptomatic, 80% of aseptic meningitis cases in the summer in endemic areas are due to this agent. Small pruritic papules appear on the skin after the sandfly bite and persist for 5 days. After an incubation period of another 5 days, fever, headache, malaise, nausea, conjunctival injection, stiff neck, and abdominal pains suddenly develop. The skin manifestations consist of a scarlatiniform eruption on the face and neck. Recovery is slow, with recurring bouts of fever. No specific treatment is available.

Dengue

Dengue, also known as break-bone fever, is a common disease of tropical regions throughout the world, but especially in Southeast Asia. It is spread by the Aedes aegypti mosquito. Two to 15 days after the bite of an infected inosquito the disease begins with a sudden high fever, headache, backache, retroorbital pain, bone and joint pain, weakness, depression, and malaise. A scarlatiniform or morbilliform exanthem, especially on the thorax and joint flexors, may accompany these symptoms. The patient may recover completely at this stage. On about the fourth day, after a brief remission of fever, another scarlatiniform exanthem may appear, most vividly over the trunk, face, and extremities. It may be petechial or purpuric (Fig. 19-44). Sinall spared areas of normal skin (white islands in a sea of red) are characteristic.

In 1% to 7% of cases, dengue hemorthagic fever (DHF) develops. It usually begins with similar symptoms, but thrombocytopenia and hemoconcentration develop. Spontaneous bleeding may occur in the skin, conjunctiva, and gastrointestinal tract. Up to 30% of patients with DHF may progress to Dengue shock syndrome (DSS) with increased vascular permeability, hypovolemia, and hypotension. Mortality rates are 10% or higher if untreated, but less than 1% if adequate care is provided. The disease is not modified by high doses of systemic corticosteroids.

Fig. 19-44 Dengue.

Alphavirus

In Finland, Sindbis virus infection is transmitted by the *Culiseta* mosquito. An eruption of multiple, erythematous, 2to 4-mm papules with a surrounding halo is associated with fever and prominent arthralgias. The eruption and symptoms resolve over a few weeks. Histologically, the skin lesions show a perivascular lymphocytic infiltrate with large atypical cells, simulating lymphomatoid papulosis. CD30 does not stain the large cells, however, allowing their distinction.

PAPOVAVIRUS GROUP

Papovaviruses are double-stranded, naked DNA viruses characterized as slow growing. They replicate inside the nucleus. Because they contain no envelope, they are resistant to drying, freezing, and solvents. In addition to the human papillomaviruses (HPVs), which cause warts, papillomaviruses of rabbits and cattle, polyomaviruses of mice, and vacuolating viruses of monkeys are some of the other viruses in this group.

Warts (Verruca)

There are more than 100 types of HPVs. The genome of HPV consists of early genes (E 1, 2, 4, 5, 6, and 7), two late genes (L1 and L2), and in between an upstream regulatory region (URR). L1 and L2 code for the major and minor capsid proteins. A new HPV type is defined when there is less than 90% DNA homology with any other known type in the L1 and E6 genes. Viruses with 90% to 98% homologies are classified as subtypes. The gene sequences from HPVs

throughout the world are similar. Most HPV types cause specific types of warts and favor certain anatomic locations, such as plantar warts, common warts, genital warts, and so on. Some wart types, e.g. HPV-27, may be found in several different locations. A large proportion of the HPV types rarely cause warts and appear to be pathogenic only in immunosuppressed patients or those with epidermodysplasia verruciformis. However, many persons may carry or be latently infected with these rare wart types, explaining the uniformity of gene sequence and clinical presentation all over the world. In the setting of immunosuppression, HPV types may cause warty lesions of a different clinical morphology than they would cause in an immunocompetent host.

Infection with HPV may be clinical, subclinical, or latent. Clinical lesions are visible by gross inspection. Subclinical lesions may be seen only by aided examination (e.g. the use of acetic acid soaking). Latent infection describes the presence of HPV virus or viral genome in apparently normal skin. Latent infection is thought to be common, especially in genital warts, and explains in part the failure of destructive methods to eradicate warts.

HPV infection is very common, as most people will experience infection during their lifetime. In school children in Australia, 22% were found to have nongenital cutaneous warts, with 16% having common warts, 6% having plantar warts, and 2% having flat (plane) warts. In the UK, the prevalence has been reported at between 4% and 5%. The peak age for cutaneous warts is in the teenage and early adult years where infection rates reach 25% in some studies. White persons have visible cutaneous warts twice as frequently as other ethnicities. Genital warts begin to appear with sexual activity and infection rates, including latent infection, exceed 50% in sexually-active populations in many parts of the world.

Management of warts is based on their clinical appearance, location, and the immune status of the patient. In general, warts of all types are more common and more difficult to treat in persons with suppressed immune systems. Because warts in some settings are important cofactors in cancer, histologic evaluation of warty lesions in these situations may be important.

Verruca Vulgaris Common warts are a significant cause of concern and frustration on the part of the patient (Figs 19-45 to 19-47). Social activities can be affected, lesions can be uncomfortable or bleed, and treatment is often painful and frustratingly ineffective. HPV-1, -2, -4, -27, -57, and -63 cause common warts. Common warts occur largely between the ages of 5 and 20 and only 15% occur after the age of 35. Frequent immersion of hands in water is a risk factor for common warts. Meat handlers (butchers), fish handlers, and other abattoir workers have a high incidence of common warts of the hands. The prevalence reaches 50% in those persons with direct contact with meat. Warts in butchers are caused by HPV-2 and -4 and up to 27% of hand warts from butchers are due to HPV-7. HPV-7 is very rarely found in warts in the general population (<0.3%), and in butchers it is found only on the hands where there is direct contact with meat. The source of HPV-7 is unknown, but HPV-7 is not bovine papilloma virus and does not come from the slaughtered animals. HPV-57 has been reported to cause dystrophy of all 10 fingernails with marked subungual

Autio P, et al: An eruption associated with alphavirus infection, Br J Dermatol 1996;135:320.

Fig. 19-46 Verruca vulgaris, wart at site of trauma.

Fig. 19-47 Verruca, nail biter with periungual warts.

hyperkeratosis and destruction of the nail plate without periungual involvement.

The natural history of common warts is for them to spontaneously resolve. Reported clearance rates in children are 23% at 2 months, 30% at 3 months, 65% to 78% at 2 years, and 90% over 5 years. Common warts are usually located on the hands; they favor the fingers and palms. Periungual warts are more common in nail biters and may be confluent, involving the proximal and lateral nailfolds. Fissuring may lead to bleeding and tendemess. Lesions range in size from pinpoint to more than 1 cm, most averaging about 5 mm. They grow in size for weeks to months and usually present as elevated, rounded papules with a rough, gravish surface, which is so characteristic that it has given us the word verticous, used to describe lesions with similar surface character (e.g. seborrheic keratosis). In some instances a single wart (mother wart) appears and grows slowly for a long time and then suddenly many new warts erupt. On the surface of the wart, tiny black dots may be visible, representing thrombosed, dilated capillaries. Trimming the surface keratin makes the capillaries more prominent and may be used as an aid in diagnosis. Warts do not have dermatoglyphics (fingerprint folds), as opposed to calluses, in which these lines are accentuated.

Common warts may occur anywhere on the skin, apparently spreading from the hands by autoinoculation. In nail biters, warts may be seen on the lips and tongue, usually in the middle half, and uncommonly in the commissures. Digitate or filiform warts tend to occur on the face and scalp and present as single or multiple spikes stuck on the surface of the skin.

Pigmented Warts Pigmented warts have been reported commonly in Japan. They appear on the hands or feet and resemble common warts or plantar warts except for their hyperpigmentation. They are caused by HPV-4, -65, and -60. The pigmentation is due to melanocytes in the basal cell layer of the HPV-infected tissue containing large amounts of melanin. This is proposed to be caused by "melanocyte blockade" or the inability of the melanocytes to transfer melanin to the HPV-infected cells.

Fig. 19-48 Verruca plana.

Flat Warts (Verruca Plana) HPV-3, -10, -28, and -41 most often cause flat warts. Children and young adults are primarily affected. Flat warts present most typically as 2- to 4-mm flat-topped papules that are slightly erythematous or brown on pale skin and hyperpigmented on darker skin. They are generally multiple and are grouped on the face, neck, dorsa of the hands, wrists, elbows, or knees (Figs 19-48 and 19-49). The forehead, cheeks, and nose, and particularly the area around the mouth and the backs of the hands, are the favorite locations. In men who shave their beards and in women who shave their legs, numerous flat warts may develop as a result of autoinoculation. A useful finding is the tendency for the warts to Koebneríze, forming linear, slightly raised, papular lesions (Fig. 19-50). Hyperpigmented lesions occur and when scarcely elevated, they may be confused with lentigines or ephelides. Plaque-like lesions may be confused with verrucous nevus, lichen planus, and molluscum contagiosum. When lesions occur only on the central face and are erythematous, they can be easily confused with papular acre

Fig. 19-50 Verruca plana, linear lesions (Koebner).

Fig. 19-51 Verruca plantaris.

Fig. 19-49 Verruca plana, atopic dermatitis infected with numerous flat warts.

vulgaris. Of all clinical HPV infections, flat warts have the highest rate of spontaneous remission.

Plantar Warts (Verruca Plantaris) HPV-1, -2, -4, -27 and -57 cause plantar warts. These warts generally appear at pressure points on the ball of the foot, especially over the mid-metatarsal area. They may, however, be anywhere on the sole. Frequently there are several lesions on one foot (Fig. 19-51). Sometimes they are grouped or several contiguous warts fuse so that they appear as one. Such a plaque is known as a mosaic wart. The soft, pulpy cores are surrounded by a firm, horny ring. Over the surface of the plantar wart, most clearly if the top is shaved off, multiple small black points may be seen that represent dilated capillary loops within elongated dermal papillae. Plantar warts may be confused with corns or calluses, but have a soft central core and black or bleeding points when pared down, features that calluses do not have.

The myrmecia type of vertuca occurs as smooth-surfaced, deep, often inflamed and tender papules or plaques, mostly on the palms or soles, but also beside or beneath the nails, or, less often, on the pulp of the digits. They are distinctively dome-shaped and much bulkier beneath the surface than they appear. Myrmecia are caused by HPV-1. They can be mistaken for a paronychia or digital mucinous cyst.

HPV-60 causes a peculiar type of plantar wart called a *ridged wart* because of the persistence of the dermatoglyphics across the surface of the lesion. Typically, the warts are slightly elevated, skin colored, 3- to 5-mm papules. They occur on non-weight-bearing areas and lack the typical features of plantar warts. HPV-60 also causes plantar verrucous cysts, 1.5- to 2-cm epithelium-lined cysts on the plantar surface. These cysts tend to occur on weight-bearing areas, suggesting that HPV-infected epidermis is implanted into the dermis, forming the cyst. It is common to see ridged warts near plantar vertucous cysts.

Histologic Features

Typical nongenital warts rarely require histologic confirmation. A biopsy may be useful in several settings, however. Histology can be used to distinguish warts from corns and other keratotic lesions that they resemble. This is enhanced by immunoperoxidase staining for HPV capsid antigen. Cytologic atypia and penetration into the dermis suggest the diagnosis of an HPV-induced squamous cell carcinoma. There is a correlation between HPV type and the histologic features of the wart, allowing identification of the HPV types that cause specific lesions, a useful feature in the diagnosis of epidermodysplasia veruciformis, for example.

Treatment

The form of therapy used depends on the type of wart being treated, age of the patient, and previous therapies used and their success or failure. With any treatment modality at least 2 or 3 months of sustained management by that method is considered a reasonable therapeutic trial. Do not abandon any treatment too quickly. Since many nongenital warts will spontaneously regress, the treatment algorithm should allow for nonaggressive options and the patient should be offered the option of no treatment. Indications for treatment are pain, interference with function, social embarrassment, and risk of malignancy. Aims of therapy are 1) to remove the wart; 2) not to produce scarring; and 3) to induce lifelong immunity to prevent recurrence. There are very few controlled studies on the treatment of cutaneous warts, so the evidence for all forms of treatment except cryotherapy-is fair to poor.

Flat Warts

Flat warts frequently undergo spontaneous remission, so therapy should be as mild as possible, and potentially scarring therapies should be avoided. If lesions are few, light cryotherapy is a reasonable consideration. Topical salicylic acid products can also be used. Treatment with topical tretinoin once or twice a day in the highest concentration tolerated to produce mild erythema of the warts without frank dermatitis can be effective over several months. Tazarotene cream or gel may also be effective. Imiquimod 5% cream used up to once a day can be effective. If the warts fail to react initially to the imiguimod, tretinoin may be used in conjunction. Should this fail, 5-FU cream 5% applied twice a day may be very effective. Anthralin, although staining, could be similarly used for its irritant effect. For refractory lesions, laser therapy in very low fluences or photodynamic therapy might be considered before electrodesiccation because of the reduced risk of scarring. Ranitidine 300 mg twice a day cleared 56% of refractory flat warts in one study. Cimetidine alone or with levamisole may be considered. Topical immunotherapy with dinitrochlorobenzene (DNCB), squaric acid, or dyphencyprone can be used on limited areas of flat warts. The induced dermatitis requires careful dose monitoring when treating facial lesions.

Common Warts

Treatments for common warts involve two basic approaches: destruction of the wart and induction of local immune reactions (immunotherapy). Destructive methods are most commonly used as initial therapy by most practitioners. Cryotherapy is a reasonable first-line therapy for most common warts. The wart should be frozen adequately to produce a blister after 1 or 2 days. This correlates with a thaw time of 30 to 45 s for most common warts. A sustained 10-s freeze with a spray gun was found more effective than simply freezing to obtain a 2- to 3-mm halo around the wart. Aggressive cryotherapy can produce significant blistering and may be complicated by significant post-procedural pain for several days. Berth-Jones et al found that a single freezethaw cycle was as effective as two cycles. The ideal frequency of treatment is every 2 or 3 weeks, just as the old blister peels off. A spray device, while more costly, is quicker, and cannot spread infectious diseases (especially viral hepatitis) from one patient to the next. Children may be frightened by such a device, so a cotton-tipped swab is an option for them. Cryotherapy can be effective for periungual warts. Damage to the matrix is unusual or rare, since periungual warts usually affect the lateral nailfolds, not the proximal one. Complications of cryotherapy include hypopigmentation, uncommonly scarring, and rarely, damage to the digital nerve from freezing too deeply on the side of the digit. Patients with Fanconi anemia, cryoglobulinemia, poor peripheral circulation, and Raynaud may develop severe blisters when cryotherapy is used to treat their warts. Doughnut warts, with central clearing and an annular recurrence, may complicate cryotherapy (Fig. 19-52).

Products containing salicylic acid with or without lactic acid are effective patient-applied treatments; these have an efficacy comparable to that of cryotherapy. After the wartaffected area is soaked in water for 5 to 10 min, the topical medication is applied, allowed to dry, and covered with a strip bandage for 24 h. This is repeated daily. The superficial

Fig. 19-52 Verruca vulgaris, doughnut wart.

keratinous debris may be removed by scraping with a table knife, pumice stone, or emery board.

A small amount of cantharone (0.7% cantharidin) is applied to the wart, allowed to dry, and covered for 24 h. A blister, similar to that produced by cryotherapy, develops in 24 to 72 h. These blisters may be as painful as or more painful than those following cryotherapy. Treatment is repeated every 2 to 3 weeks. Perhaps more than any other method, there is a tendency for cantharidin to produce doughnut warts, a round wart with a central clear zone at the site of the original wart (see Fig. 19-52). Nonetheless, this agent is a very useful adjunct in the management of difficultto-treat verruca.

Simple occlusion with a relatively impermeable tape can be effective in eradicating warts. The key appears to be to keep the wart occluded as much of the time as possible. Duct tape or transparent tapes (Blenderm) are practical options. Fenestrated and semipermeable dressings have not been studied and may not be effective. This is a good initial option for children and others unwilling to have other forms of treatment.

Bleomycin has high efficacy and is an important treatment for recalcitiant common warts. It is used at a concentration of 1 U/mL, which is injected into and immediately beneath the wart until it blanches. The multiple-puncture technique of Shelley-delivering the medication into the wart by multiple punctures of the wart with a needle through a drop of bleomycin-may also be used, as may an airject injector. For small warts (<5 mm), 0.1 mL is used and 0.2 mL for larger warts. The injection is painful enough to require local anesthesia in some patients. Pain for up to 1 week can occur. The wart becomes black and the black eschar separates in 2 to 4 weeks. Treatment may be repeated every 3 weeks, but it is unusual for common warts to require more than one or two treatments. Scarring is rare. Response rates vary by location, but average 90% with two treatments for most common, nonplantar warts, even periungual ones. Treatment of finger warts with bleomycin may uncommonly be complicated by localized Raynaud phenomenon of treated fingers. Bleomycin treatment of digital warts may rarely result in digital necrosis and permanent nail dystrophy, so extreme caution should be used in treating warts around the nailfolds. Lymphangitis/cellulitis is a rare complication. In a patient receiving a total of 14 U for plantar warts, flagellate

urticaria followed by characteristic bleomycin flagellate hyperpigmentation occurred.

Surgical ablation of warts can be effective treatment, but even complete destruction of a wart and the surrounding skin does not guarantee the wart will not recur. Surgical methods should be reserved for warts that are refractory to more conservative approaches. Pulsed dye laser therapy appears to have similar efficacy to cryotherapy. With pulsed dye laser therapy less plume is produced than with CO_2 laser therapy. Depending on the fluences used, the treatment can be performed in two-thirds of patients without anesthesia, although some pain occurs. The energy setting is dependent on the particular device being used. The energy may be as low as 7 J/cm² for thinner lesions and up to 15 J/cm² for more hyperkeratotic ones. A short pulse duration (0.45 ms) is most effective. A 5- or 7-mm spot size is used and treatment is extended 2 mm beyond the visible wart. Immediately after treatment, the skin has a gray-black discoloration, which evolves to an eschar over 10 to 14 days. Treatment is repeated every 2 to 4 weeks and up to five treatments may be required. In immunocompetent patients, response rates for refractory warts range from 70% to 90%. CO₂ laser destruction requires local anesthesia, causes scarring, and may lead to nail dystrophy. Its efficacy is between 56% and 81% in refractory warts. A potentially infectious plume is produced. Frequency doubled Nd:YAG and 532-nm KTP lasers are also reported to be effective, but there is less evidence for their use. Photodynamic therapy with aninolevulinic acid 20% applied for 5 h prior to irradiation with broad-band sources (400-700 nm, 50 mW/cm²) produces a clearance rate of 55% to 75% for recalcitrant warts. Several treatments at 3-weekly intervals may be required. Significant pain can occur during treatment and lasts for up to 24 h, which limits its use in children.

Oral cimetidine, 30 to 40 mg/kg/day, has been anecdotally reported to lead to resolution of common warts, perhaps because of its immunomodulatory effects. When used as a single agent, however, in both children and adults, the efficacy is low (30%), comparable with a placebo. It may be beneficial as an adjunct to other methods, however, or for treatment of refractory warts. Heat treatment, either localized to the wart and delivered by radiofrequency or by application to the affected part by soaking it in a hot bath, have been reported to be effective. Treatment for 15 min at 43° C to 50° C (107.6-122° F) to as short as 30 s at higher temperatures has been used. Extreme caution must be exercised to avoid scalding. Oral administration of acitretin or isotretinoin may also be used in refractory cases. Hypnotic suggestion and hypnoanalysis for warts have been reviewed by Shenefelt.

Immunotherapy with topical and intralesional agents has become a mainstay of wart therapy. The hope is that not only will the wart be eradicated, but the immune reaction induced in the wart may also induce widespread and permanent immunity against warts. The commonly used agents are topical dinitrochlorobenzene, squaric acid dibutyl ester, and diphencyprone, as well as intralesional candida or mumps antigen. Patients may be initially sensitized at a distant site (usually the inner upper arm) with the topical agents or the agent may be applied initially to the warts directly. Two treatment approaches are used and their efficacies have not been compared. Some practitioners apply topical agents in

the office in higher concentrations (2-5%), but only every 2 weeks or so. Others give their patients take-home prescriptions to use on a daily basis, albeit at lower concentrations to start with (0.2-0.5%). In most cases the agents are dissolved in acetone. The treated wart should be kept covered for 24 h after application. If the reaction is overly severe, the strength of the application may be reduced. Wart tenderness may indicate the need to reduce treatment concentration. Warts may begin to resolve within a week or two, but on average, 2 to 3 months of treatment or more are required. For intralesional candida antigen, treatments are repeated weekly. Overall cure rates for all three topical sensitizers and for intralesional antigen injection is 60% to 80%. Side effects of treatment include local pruritus, local pain, and a mild eczematous dermatitis. Most patients have no limitation of activities or function with topical immunotherapy. Scarring has not been reported.

Imiquimod has been reported to be effective for common warts in small series or single cases. With twice a day treatment for up to 24 weeks (average 19 weeks), 27% of patients cleared their warts. The efficacy of imiquimod for common warts appears to be significantly less than cryotherapy or topical immunotherapy and it is considerably more expensive. The routine use of imiquimod in the treatment of common or plantar warts cannot be recommended. Topical cidofovir has been used in desperate situations.

Plantar Warts

In general, plantar warts are more refractory to any form of treatment than are common warts. Initial treatment usually involves daily application of salicylic acid in liquid, film, or plaster form after soaking. In failures, cryotherapy or cantharidin application may be attempted, alone or in combination. A second freeze-thaw cycle is beneficial when treating plantar warts with cryotherapy. Bleomycin injections, laser therapy, or topical immunotherapy, as discussed above, may be used in refractory cases. Surgical destruction with cautery or blunt dissection should be reserved for failures with nonscarring techniques, since a plantar scar may be persistently painful. CO_2 laser may also result in plantar scars.

Genital Warts Genital warts are the most common STD. Among sexually-active young adults in the US and Europe, infection rates as high as 50% in some cohorts have been found using sensitive PCR techniques. It is estimated that the lifetime risk for infection in sexually-active young adults may be as high as 80%. The number of new cases of genital wart infection diagnosed in the US yearly may approach 1 million. In the vast majority of couples in whom one has evidence of HPV infection, the partner will be found to be concordantly infected. The risk of transmission is not known, however. A large portion of genital HPV infection is either subclinical or latent. Unfortunately, the infectivity of subclinical and latent infection is unknown. Subclinical and latent infection are probably responsible for most "recurrences" following treatment of genital warts. Since the methodology for determining HPV infection in males is less accurate and since women suffer the major complication of HPV infection -cervical cancer, virtually all data on HPV infection rates and epidemiology are derived from studies of women.

Genital HPV infection is closely linked with cancer of the cervix, glans penis, anus, vulvovaginal area, and periungual skin. Cancer occurs when there is integration of the HPV genome into the host DNA. In high-risk genital HPV types, E6 and E7 gene products bind to and inactivate p53 and retinoblastoma protein (pRb), respectively. This is felt to be important in their ability to cause cancer. In most persons, genital HPV infection appears to be transient, lasting about 1 to 2 years, and results in no sequelae. In a small proportion, infection persists and in a small proportion of persons with persistent HPV infection cancer may develop. Certain cofactors, such as the HPV type causing the infection, location of infection, cigarette smoking, uncircumcised status, and immunosuppressed status are associated with progression to cancer. The transition zones of the cervix and anus are at highest risk for the development of cancer.

More than 30 HPV types are associated with genital warts. Patients are commonly infected with multiple HPV types. The HPV types producing genital infection are divided into two broad categories—those that produce benign lesions, or low-risk types (at least 12 types), and those associated with cancer, the so-called high-risk or oncogenic types (at least 15 types). The most common low-risk genital HPV types are HPV-6 and -11, and most HPV-induced genital dysplasias are caused by HPV-16 and -18. There is a strong correlation between the HPV type and the clinical appearance of HPVinduced genital lesions. Virtually all condylomata acuminata are caused by "benign" HPV-6 and -11. High-risk HPV-16 and -18 produce flat or sessile, often hyperpigmented lesions. For this reason, biopsy and HPV typing of external genital warts is rarely necessary.

Genital HPV infection is strongly associated with sexual intercourse. Female virgins rarely harbor HPV (about 1%). For women, insertive vaginal intercourse is strongly associated with acquiring genital HPV infection, with 50% of women testing positive for genital HPV within 5 years of the time of first sexual intercourse. However, sexual contact does not need to be penile-vaginal, as the risk of acquiring genital HPV infection was 10% in women who had nonpenetrative sexual exposure as compared to 1% of women who had no such exposure. Infection may occur at the introitus and then be spread to other sites by self inoculation. Women who have sex with women may have genital HPV infection and still require regular gynecologic evaluations. Condom use may be partly, but not completely, protective for acquisition of genital HPV infection. In men the risk of genital HPV infection is associated with being uncircumcised, having had sex before age 17, having had more than six lifetime sexual partners, and having had sex with professional sex workers.

Condylomata Acuminata

Condylomata on the skin surface appear as lobulated papules that average 2 to 5 mm in size, but they may range from microscopic to several centimeters in diameter and height. Lesions are frequently multifocal. Numerous genital warts may appear during pregnancy. Condylomata accuminata occur in men anywhere on the penis or about the anus. Scrotal condylomata occur in only 1% of immunocompetent male patients with warts (Figs 19-53 and 19-54). Intraurethral condylomata may present with terminal hematuria, altered urinary stream, or urethral bleeding. In women, lesions appear on the mucosal surfaces of the vulva, cervix, on the

Fig. 19-54 Genital warts, keratotic type.

perineum, or about the anus. Cauliflower-like masses may develop in moist, occluded areas such as the perianal skin, vulva, and inguinal folds. As a result of accumulation of purulent material in the clefts, these may be malodorous. Their color is generally gray, pale yellow, or pink. When perianal lesions occur, a prior history of receptive anal intercourse will usually predict whether intra-anal warts are present and will help to determine the need for anoscopy. Inmunosuppressed individuals and those with known highrisk HPV types should have routine anal pap smears to detect malignant change.

Genital warts are sexually transmitted and other STDs may be found in patients with genital warts. A complete history should be taken and the patient screened for other STDs as appropriate. Women with external genital warts should have a routine cervical cytologic screening to detect cervical dysplasia.

Bowenoid Papulosis and HPV-Induced Genital Dysplasias

Bowenoid papulosis is characterized by flat, often hyperpigmented papules a few millimeters to several centimeters

Fig. 19-53 Genital warts, condyloma accuminata.

Fig. 19-55 Genital warts, bowenoid papulosis. Recurrence after radiation therapy may be associated with a more aggressive course.

Diagnosis

Even in women with confirmed cervical HPV infection, serologic tests are positive in only 50%, making serologic diagnosis of HPV infection of no use to the practicing clinician. HPV cannot be cultured. HPV typing via in situ hybridization or PCR is useful in managing HPV infection of the cervix and in some cases of prepubertal HPV infection, but not in the management of most cases of external genital warts. Virtually all condylomata can be diagnosed by inspection. Bright lighting and magnification should be used when examining for genital HPV infection. Flat, sessile and pigmented lesions are suggestive of bowenoid papulosis and may require a biopsy. Subclinical and latent infections are no longer sought or investigated because they are very common and there is no management strategy known to eradicate these forms of HPV infection. Soaking with acetic acid is not generally necessary, but may be helpful to detect early lesions under the foreskin. In patients with multiple recurrences, acetic acid soaking may determine the extent of infection, helping to define the area for application of topical therapies. The procedure is performed by soaking the external genitalia in men and the vagina and cervix in women with 3% to 5% acetic acid for up to 10 min. Genital warts turn white (acetowhitening), making them easily identifiable. Any process that alters the epidermal barrier will be acetowhite, however (dermatitis, for example), so only typical acetowhite lesions should be treated as warts. In atypical cases, a 2-week trial is attempted with a 1% hydrocortisone preparation plus a topical anticandidal imidazole cream. If the acetowhitening persists, a biopsy is performed and histologic evidence of HPV infection sought. Immunoperoxidase or in situ hybridization methods may aid in evaluation. PCR should probably not be performed on such biopsied specimens, except possibly in childhood cases. The high background rate of latent infection (up to 50%) makes interpretation of a positive PCR impossible. In contrast, chromogenic in situ hybridization clearing demonstrates the localization of positive nuclei within the lesion.

Treatment

Because no effective virus-specific agent exists for the treatment of genital warts, their recurrence is frequent. Treatment is not proven to reduce transmission to sexual partners or to prevent progression to dysplasia or cancer. Specifically the treatment of male sexual partners of women with genital warts does not reduce the recurrence rate of warts in these women. Therefore, the goals of treatment must first be discussed with the patient, and perhaps with his/her sexual partner. Observation represents an acceptable option for some patients with typical condylomata acuminata. In some patients, only wart-free periods are achieved. Because genital warts may cause discomfort, genital pruritus, malodor, bleeding, and substantial emotional distress, treatment is indicated if the patient desires it. Bleeding genital warts may increase the sexual transmission of HIV and hepatitis B and C. Bowenoid papulosis may be treated as discussed below when it occurs on the external genitalia. Lesions with atypical histology (squamous intraepithial lesion) on mucosal surfaces and periungually are special cases and treatment

Fig. 19-56 Genital Bowen's disease.

in multiples on the penis, near the vulva, or perianally (Fig. 19-55). At times similar lesions are seen outside the genital area in the absence of genital bowenoid papulosis. They occur most commonly on the neck or face and are more common in men. They contain HPV-16, -18, or other highrisk HPV types. Histologically, bowenoid papulosis demonstrates abnormal epithelial maturation and cellular atypia closely resembling Bowen's disease. It is usually caused by HPV-16. On the glabrous external genitalia, bowenoid papulosis usually behaves similarly to other external genital warts, but may progress to squamous cell carcinoma (SCC). On the glans penis of an uncircumcised male, and on the cervical, vaginal, or rectal mucosa, progression to invasive SCC is more likely (Fig. 19-56). Female partners of men with bowenoid papulosis and women with bowenoid papulosis have an increased risk of cervical dysplasia.

in diameter. These occur singly, or more often, may be found

Giant Condyloma Acuminatum (Buschke-Lowenstein Tumor)

Giant condyloma acuminatum is a rare, aggressive, wart-like growth that is a verrucous carcinoma. Unlike other HPVinduced genital carcinomas, this tumor is usually caused by HPV-6. It occurs most often on the glans or prepuce of an uncircumcised male; less often it may occur on perianal skin or the vulva. Despite its bland histologic picture, it may invade deeply and uncommonly it may metastasize to regional lymph nodes. Treatment is by complete surgical excision. must be associated with histologic confirmation of eradication in cases where topical methods are used.

The treatment chosen is in part dictated by the size of the warts and their location. Podophyllin is more effective in treating warts on occluded or moist surfaces, such as the mucosa or under the prepuce. It is available as a crude extract, usually in 25% concentration in fincture of benzoin. It is applied weekly by the physician and is washed off 4 to 8 h later by the patient, depending on the severity of the reaction. After six consecutive weekly treatments, approximately 40% of patients are free of warts and 17% are free of warts at 3 months after treatment. Purified podophyllotoxin 0.5% solution or gel is applied by the patient twice a day for 3 consecutive days of each week in 4- to 6-week treatment cycles. Efficacy approaches 60% for typical condylomata and side effects are less than with standard, physician-applied podophyllin preparations. Therefore, whenever possible, podophyllotoxin should be used instead of classic podophyllin solutions.

Imiquimod, an immune response modifier which induces IFN locally at the site of application, has an efficacy similar to cryotherapy (about 50%) and yields a low recurrence rate (22%). It is available in a 250 mg sachet containing a 5% cream formulation. One sachet can cover up to 350 cm² when applied appropriately, allowing for several treatments with a single sachet if the treatment area is limited. It is more effective than podophyllotoxin in treating women with external genital warts, but it is only equally or slightly less effective in men, especially for warts on the penile shaft. Response is slow, requiring 10 or more weeks in some patients to see a response. It is patient applied, once a day for 3 alternate days per week (usually Monday, Wednesday, and Friday). Treatment results in mild-to-moderate irritation (less than with podophyllin or cryotherapy in men, but with a similar side effect profile in women). Rare complications include flaring of psoriasis and psoriatic arthritis, vitiligo-like hypopigmentation and the production of a local neuropathy. Imiguimod should be used cautiously in persons with psoriasis. Neuropathy is associated with application of excessive amounts, occlusion of the medication, and application to an eroded mucosa.

Imiquimod may be used to treat penile condyloma in circumcised and uncircumcised men, anal and perianal condyloma, and vulvar condyloma. It may be used as the initial treatment or in cases in which recurrence has been frequent after other forms of treatment were attempted. Initial therapy with imiquimod for 16 weeks, followed by surgical removal of residual external genital warts is associated with a reduced tisk of recurrence when compared to surgical removal alone (20% vs 65%), suggesting that imiquimod might even be beneficial for patients who do not respond and require other subsequent treatments. Suppositories containing about 5 mg of imiquimod appear to reduce the risk of recurrence of anal condyloma in immunocompetent men after surgical ablation of extensive anal disease. Imiquimod has been effective in the treatment of bowenoid papulosis in scattered case reports.

Bichloroacetic or trichloroacetic acid (TCA) 35% to 85% can be applied to condylomata weekly or biweekly. TCA is safe for use in pregnant patients. When compared with cryotherapy, TCA has the same or lower efficacy and causes more ulcerations and pain. It is not generally recommended

for external genital warts as other available treatments are more effective and cause less morbidity.

Cryotherapy with liquid nitrogen is more effective than podophyllin, approaching 80% resolution during treatment and 55% 3 months after treatment. One or two freeze-thaw cycles are applied to each wart every 1 to 3 weeks. A zone of 2 mm beyond the lesion is frozen. Cryotherapy is effective in dry as well as moist areas. Perianal lesions are more difficult to treat than other genital sites and two freeze-thaw cycles are recommended in this location. Cryotherapy is safe to use in pregnant patients. EMLA cream with or without subsequent lidoaine infiltration may be beneficial in reducing the pain of cryotherapy.

Electrofulguration or electrocauterization with or without snip removal of the condyloma is more effective than TCA, cryotherapy, or podophyllin. Wart clearance during therapy is nearly 95% and wart cure at 3 months exceeds 70%. Local anesthesia is required and scarring may occur. Surgical removal is ideal for large exophytic warts that might require multiple treatments with other methods. It has high acceptance in patients who have had recurrences from other methods because results are immediate and cure rates higher.

The use of CO_2 laser in the treatment of genital warts has not been demonstrated to be more effective than simpler sutgical methods. Although visible warts are eradicated by the laser, HPV DNA can still be detected at the previous site of the wart. The CO_2 laser has the advantage of being bloodless, but it is costlier and requires more technical skill on the part of the surgeon to avoid complications. It should be reserved for treatment of extensive lesions in which more cost-effective methods have been attempted and failed.

Any surgical method that generates a smoke plume is potentially infectious to the surgeon. HPV DNA is detected in the plumes generated during CO_2 laser or electrocoagulation treatment of genital warts. The laser-generated plume results in longer-duration HPV aerosol contamination and wider spread of detectable HPV DNA. If these methods of wart treatment are used, an approved face mask should be worn, a smoke evacuator should be operated at the surgical site during the procedure to remove the plume and decontamination of the equipment after the surgery should be carried out.

Photodynamic therapy with 20% 5-aminolaevulinic acid (ALA) and irradiation with 70 to 100 J/cm² (FORTH-IESL) 6 to 10 h after ALA application lead to clearance of condyloma accuminata in 73% of treated men.

5-FU 5% cream applied twice a day may be effective, especially in the treatment of flat, hyperpigmented lesions, such as those in bowenoid papulosis. Care must be taken to avoid application to the scrotum, as scrotal skin is prone to painful erosions. Twice a day instillation of 5-FU into the urethra can be used to treat intraurethral condylomata. The cone from a tube of xylocaine jelly will fit onto the thread of the 5-FU tube, or the cream may be instilled with a syringe. It is typically left in place for 1 h before the patient voids. Care should be taken that drips of urine containing the medication do not contact the scrotum. 5-FU may also be used to treat intravaginal warts by instillation in the vagina, but is often associated with severe irritation. Intermittent therapy (twice a week for 10 weeks) is better tolerated than daily therapy. 5-FU is not commonly recommended for the treatment of typical external genital warts because other methods of treatment are available.

The efficacy of systemic and intralesional IFN- α therapy has been found to be relatively low in eradicating genital warts. Intralesional therapy eradicates 40% to 60% of warts and systemic IFN treatment will eradicate warts in only about 20% of patients. IFN treatment of genital warts in patients with AIDS has even lower efficacy rates. Response rates to IFN have never reached the levels achieved with electrosurgical methods. Because of the high cost, frequent side effects, and low efficacy associated with IFN therapy, the CDC no longer recommends the use of IFN for the treatment of genital warts.

Human Papillovirus Vaccination

HPV virus-like particles (VLPs) composed of spontaneous assembling L1 molecules have been used as a vaccine against HPV-16. This vaccine was highly effective in preventing HPV-16 infection and the development of HPV-16 associated squamous intraepithelial lesions (dysplasia). The protection was type specific and did not prevent squamous intraepithelial lesions from other HPV types. Since HPV-16 and -18 are the primary HPV types associated with cervical cancer, it is hoped that the rate of cancers induced by high-risk genital HPV types (especially HPV-16 and -18) can be reduced by vaccination.

Genital Warts in Children

Children can acquire genital warts through vertical transmission perinatally, and through digital inoculation or autoinoculation, fomite or social nonsexual contact, and sexual abuse. HPV typing has demonstrated that most warts in the genital area of children are "genital" HPV types and most children with genital warts have family members with a genital HPV infection.

HPV typing can be performed; however, the presence of genital types of HPV does not prove abuse and a finding of a nongenital HPV type does not exclude the possibility of sexual abuse. In children younger than 1 year of age, vertical transmission is possible and is probably the most common means of acquisition. The risk for sexual abuse is highest in children older than 3 years of age. When abuse is suspected, children should be referred to child protection services if the practitioner is not skilled in evaluating children for sexual abuse. Children between 1 and 3 years of age are primarily nonverbal and are difficult to evaluate. Management of such patients is on a case-by-case basis. Other STDs should be screened for in children who have a genital HPV infection. Usually the management of children with anogenital warts requires a multidisciplinary team which should include a pediatrician. Genital warts in children often spontaneously resolve (75%), so nonintervention may be a reasonable consideration. Genital warts in children usually respond quickly to topical therapy, such as podophyllotoxin, imiquimod, or light cryotherapy. In refractory cases, surgical removal or electrocautery may be used. The use of a topical anesthetic is recommended before treatment.

Recurrent Respiratory (Laryngeal) Papillomatosis

HPV-associated papillomas may occur throughout the respiratory tract, from the nose to the lungs. Recurrent respiratory papillomatosis has a bimodal distribution—in children under 5, and after the age of 15. Affected young children are born to mothers with genital condylomata and they present with hoarseness. The HPV types found in these lesions, HPV-6 and -11, are the types seen in genital condylomata. Treatment is with CO_2 laser surgery and IFN. Carcinoma that is often fatal develops in 14% of patients, even in young children. The incidence of carcinoma is higher in those treated with radiation therapy.

Heck's Disease Small white to pinkish papules occur diffusely in the oral cavity in this disease, also known as *focal epithelial hyperplasia*. It occurs most commonly in Native Americans, in Greenland, and in Turkey. HPV-13, -24, and -32 have been associated. Lesions may spontaneously resolve. Treatment options include cryosurgery, CO_2 laser, electrosurgery, and topical (β), intralesional, and systemic IFN.

Epidermodysplasia Verruciformis

Epidermodysplasia vertuciformis is a rare, inherited disorder characterized by widespread HPV infection and cutaneous SCCs. Most commonly it is inherited as an autosomalrecessive trait. HPV types associated with this syndrome include those infecting normal hosts, such as HPV-3 and -10, as well as many "unique" HPV types. These HPV types are called EV HPVs and include HPV-5, -8, -9, -12, -14, -15, -17, -19 through -25, and -36 through -38. The pathogenesis of this syndrome is unknown, but is felt to be a specific defect of cell-mediated immunity. Patients with epidermodysplasia verruciformis cannot be sensitized to topical immunosensitizers.

The condition presents in childhood and continues throughout life. Skin lesions include flat wart-like lesions of the dorsal hands, extremities, face, and neck. These are flatter than typical flat warts and may be quite abundant, growing to confluence (Fig. 19-57). Typical HPV-3- and -10-induced

Fig. 19-57 Epidermodysplasia verruciformis.

Fig. 19-58 Epidermodysplasia verruciformis.

flat warts may be admixed. In addition, on the trunk are lesions which are red, tan, or brown patch/plaques or hypopigmented, very slightly scaly plaques resembling tinea versicolor (Fig. 19-58). Plaques on the elbows may resemble psoriasis. Seborrheic keratosis-like lesions may also be seen on the forehead, neck, and trunk.

The histologic features of an epidermodysplasia vertuciformis-specific HPV infection are very characteristic. The cells of the upper epidermis have a clear, smoky or lightblue pale cytoplasm and a central pyknotic nucleus.

SCCs develop in 30% to 60% of patients. Most often skin cancers appear on sun-exposed surfaces, but they can appear on any part of the body. They begin to appear at the age of 20 to 40. Skin cancers are less common in African patients, suggesting a protective effect of skin pigmentation. HPV-5, -8, and -47 are found in more than 90% of epidermodysplasia veruciformis skin cancers. The SCCs may appear de novo, but usually appear on the background of numerous actinic keratoses and lesions of Bowen's disease. Surgical treatment is recommended. Radiation therapy is contraindicated. If skin grafting is required, the grafts should be taken from sun-protected skin, such as the buttocks or inner upper arm.

Aside from surgical intervention for skin cancer, treatment for epidermodysplasia vertruciformis consists largely of preventive measures. Strict sun avoidance and protection should be started as soon as the syndrome is diagnosed. An approach similar to that for children with xeroderma pigmentosa could be instituted.

The mechanism by which cancer occurs in patients with epidermodysplasia vertuciformis is unclear. HPV-5 proteins do not bind to p53 or pRb. The p53 mutations present in the SCCs of patients with epidermodysplasia vertuciformis are characteristic of those induced by UVB, confirming the close association of UV exposure and the development of cancer in patients with epidermodysplasia vertuciformis. EV HPV DNA has been reported to be found in a large percentage (35%) of the general population in very low copy number. EV HPV DNA is reported to be present on the skin in up to 80% of patients with psoriasis. The genetic loci for epidermodysplasia vertuciformis colocalize to two known psoriasis susceptibility loci on chromosomes 17q and 2p, supporting a putative relationship between EV HPV infection and psoriasis.

Immunosuppressed Patients

Patients with defects in their cell-mediated immunity may have an increased frequency of HPV infection. Predisposing conditions include organ transplantation, immunosuppressive medications, congenital immunodeficiency diseases, lymphoma, and HIV infection.

Organ transplant recipients begin to develop warts soon after transplantation and by 5 years up to 90% of transplant patients have warts. Initially these are common and plantar warts, but later numerous flat warts appear, particularly in sun-exposed areas. Depending on the background level of UV radiation, the lifetime risk for cutaneous carcinomas may exceed 40%. Skin cancers begin to appear 5 years or more after transplantation, occur in sun-exposed sites, and are more common in persons with skin types I and II. The duration and intensity of immunosuppression appear more important in causing the skin cancers than are the specific immunosuppressive agents used. Malignant lesions may resemble Bowen's disease, keratoacanthomas, SCCs, or warts. Genital warts are also increased and, especially in women, genital dysplasias are more frequent.

Epidermodysplasia vertuciformis types and some unique HPV types are frequently found in the nongenital dysplasias among organ transplant recipients. The skin of organ transplant patients should be examined closely and once skin cancers begin to appear, regular dermatologic examinations should be performed.

In HIV disease, common, plantar, flat, oral and genital warts are all very common. Warty keratoses at the angle of the mouth, often bilateral, are a characteristic, and perhaps unique, manifestation of HPV infection in patients with AIDS (Fig. 19-59). The warts are caused predominantly by HPV-2, -27, and -57. HPV-7 can be found in cutaneous, oral, and perioral warts in non-butchers with HIV infection. HPV-6 may be found in common warts. Genital warts are increased 15-fold among HIV-infected women. Fifty percent or more of HIV-infected homosexual men have evidence of anal HPV infection. Genital neoplasia associated with HPV-16 and -18 occur much more frequently in HIV-infected women and homosexual men. Uncommonly, HIV-infected patients develop HPV-5- and -8-induced epidermodysplasia verruciformis-like lesions. Although nongenital skin cancers are also common in some fair-skinned HIV-infected patients, HPV has not been demonstrated in the nongenital SCCs of these patients. With HAART therapy, warts may disappear. Paradoxically, increased rates of genital and oral warts are seen in HIV-infected persons with adequate control of their HIV infection. The likelihood of clearance of common warts in persons with HIV is related to the nadir of their helper T-cell count. HIV-infected persons whose helper T-cell count never falls below 200 are more likely to have sustained remission of their warts.

The treatment of warts in immunosuppressed hosts is very difficult. Although standard methods are used, their efficacy may be reduced. Imiquimod has low efficacy in this setting, but can be attempted. The addition of a second modality (podophyllin, 5% 5-FU, or surgery) to the imiquimod treatment may lead to improvement. Topical cidofovir (in concentrations from 0.4% to 3%) and systemic cidofovir have been effective in refractory anogenital and common wart cases. Topical cidofovir is very expensive, is irritating, and can cause skin erosion and ulceration: Usually short treatment

Fig. 19-59 Oral warts.

courses of 5 to 14 days, with 1- to 4-week rest periods to allow healing, have been used. Cidofovir treatment may be combined with destructive methods in refractory cases.

It is especially important in immunosuppressed patients to regularly monitor the genital and anal areas for changing lesions and to have a low threshold for performing a biopsy.

Viral-Associated Trichodysplasia (Cyclosporin-Induced Folliculodystrophy)

Organ transplant recipients on immunosuppressive regimens rarely develop a characteristic eruption of erythematous 1- to 3-mm facial papules. The midface, glabella, and chin are primarily affected. Lesions are numerous, may reach confluence, and can cause nasal distortion similar to that seen in rosacea and sarcoidosis (Fig. 19-60). Some papules have a central, keratotic white excrescence. Alopecia of the eyebrows and eyelashes may occur, but the scalp is spared. Histology is characteristic, showing massively distended,

Fig. 19-60 Trichodysplasia. (Courtesy of Len Sperling MD)

bulbous follicles with expansion of the inner root sheath cells containing numerous trichohyaline granules. Abrupt inner root sheath-type cornification is present. No hair shafts (or hair cortex) are present in the affected follicles. Electron microscopy demonstrates numerous viral particles about 40 nm in size with features suggestive of a papovavirus. Topical cidofovir 3% cream slowly improved one patient.

RETROVIRUSES

These oncoviruses are unique in that they contain RNA, which is converted by a virally coded reverse transcriptase to DNA in the host cell. The target cell population is primarily CD4+ lymphocytes (primarily helper T cells), but also, in some cases, macrophages. For this reason they are called human T-lymphotropic viruses (HTLV). Transmission may be by sexual intercourse, blood products/intravenous drug use, and from mother to child during childbirth and breast-feeding. There is often a very long "latent" period from the time of infection until presentation with clinical disease.

Human T-Lymphotropic Virus-1

HTLV-1 is endemic in Japan, the Caribbean, South America (Brazil), sub-Saharan Africa, among Australian Aborigines, and in the southeastern US. In endemic areas infection rates may be quite high, with only a small percentage of infected patients ever developing clinical disease. HTLV-1 is responsible for several clinical syndromes. About 1% of persons who are infected will develop adult T-cell leukemia-lymphoma (ATLL). HTLV-1-associated myelopathy or tropical spastic paraparesis (HAM/TSP) is a less common degenerative neurologic syndrome.

There are four forms of ATLL: smoldering, chronic, acute, and lymphomatous, usually progressing in that order. ATLL is characterized by lymphadenopathy, hepatosplenomegaly, hypercalcemia, and skin lesions. Skin lesions in ATLL include erythematous papules or nodules. Prurigo may be a prodrome to the development of ATLL. Histologically, the cutaneous infiltrates are pleomorphic, atypical lymphocytes with characteristic "flower cells" representing HTLV-1 infected lymphocytes. Epidermotropism may be present, mimicking mycosis fungoides.

HTLV-1 infected patients often have an abnormal skin examination. If they are seropositive but asymptomatic, dermatophytosis (34%), seborrheic dermatitis (6%), xerosis/ acquired icthyosis (7%), are most commonly found. Xerosis occurs in 82% of patients with HAM/TSP, seborrheic dermatitis in 33%, candidiasis and palmar erythema in 15%, and chronic eczema/photosensitivity in up to 20%. Biopsies from the areas of chronic eczema/photosensitivity may show features of ATLL in up to 25% of these patients (smoldering ATLL). Areas of positive biopsies are described as "atrophic." Scabies is seen in 2% of asymptomatic HTLV-1 infected patients and in 5% of those with HAM/TSP. The scabies may be of the hyperkeratotic (crusted) type and the finding of this pattern of scabies in a person from an HTLV-1 endemic region should trigger serologic testing for HTLV-1. The spectrum of skin disease seen in symptomatic HTLV-1 infected patients is remarkably similar to that seen in HIV-infected patients with CNS disease (xerosis/eczema, seborrheic dermatitis, and scabies).

"Infective dermatitis" occurs in Jamaican children infected with HTLV-1. It is diagnosed by major and minor criteria as delineated by La Grenade et al. Clinically, the children present at an early age (on average, about 7 years) with a chronic eczema of the scalp, axilla, groin, external auditory canal, retroauricular area, eyelid margins, paranasal areas, and neck. There is a chronic nasal discharge. Cultures from the skin and nares are positive for *S. aureus* or beta-hemolytic streptococcus, and the condition responds rapidly to antibiotics. Flowever, the condition is relapsing and recurrent. Skin biopsies show a nonspecific dermatitis.

Human Immunodeficiency Virus (HTLV-3)

HIV infects human helper T-cells, leading to a progressive immunodeficiency disease. In its end stages it is called *acquired immunodeficiency syndrome* (AIDS). Cutaneous manifestations are prominent, affecting up to 90% of HIVinfected persons. Many patients have multiple skin lesions of different kinds. The skin lesions or combinations of skin conditions are so unique that the diagnosis of HIV infection or AIDS can often be suspected from the skin examination alone. The skin findings can be classified into three broad categories: infections, inflammatory dermatoses, and neoplasms. The skin conditions also tend to appear at a specific stage in the progression of HIV disease, making them useful markers of the stage of HIV disease.

The natural history of HIV infection in the vast majority of patients is a gradual loss of helper T-cells. The rate of this decline is variable, with some patients progressing rapidly and others very slowly or not at all (long-term nonprogressors). Soon after infection there is a seroconversion syndrome called primary HIV infection, or acute infection (group 1). Patients recover from this syndrome and enter a relatively long latent period (asymptomatic infection or group II), which averages about 10 years. During this period patients may have persistent generalized lymphadenopathy (group III). When symptoms begin to appear they are often nonspecific and include fever, weight loss, chronic diarrhea, and mucocutaneous disease (group IV A). Helper T-cell counts in group II, III, and IV A patients usually range from 200 to 500. The skin findings at this stage (originally called ARC [AIDS-related complex]) include seborrheic dermatitis, psoriasis, Reiter syndrome, atopic dermatitis, herpes zoster, acne rosacea, oral hairy leukoplakia, onychomycosis, warts, recurrent *S. aureus* folliculitis, and mucocutaneous candidiasis.

Once the helper T-cell count is 200 or less the patient is defined as having AIDS. In this stage of HIV disease the skin lesions are more characteristic of immunodeficiency and include characteristic opportunistic infections: chronic herpes simplex, molluscum contagiosum, bartonellosis (bacillary angiomatosis), systemic fungal infections (cryptococcosis, histoplasmosis, coccidioidomycosis, and penicilliosis), and mycobacterial infection. Paradoxically, patients at this stage also have hyper-reactive skin and, (requently, inflammatory, often pruritic skin diseases. These skin conditions include eosinophilic folficulitis, granuloma annulare, drug reactions, enhanced reactions to insect bites, and photodermatitis.

When the T-cell count falls below 50, the patient is often said to have "advanced AIDS." These patients may have very unusual presentations of their opportunistic infections, including multicentric, refractory molluscum contagiosum; chronic herpes simplex; chronic cutaneous varicella zoster infection; cutaneous acanthamebiasis, cutaneous atypical mycobacterial infections (including Mycobacterium avium complex and Mycobacterium haemophilum), and crusted scabies. Treatment of their infections is often very difficult because of the significant chronic immunosuppression.

It is now clear that HIV itself is the cause of the loss of helper T-cells and that effective treatment of HIV infection may halt or reverse the natural history of HIV disease. There are numerous antiretroviral agents and they are usually used in combinations called "cocktails." This combination treatment is called highly active antiretroviral therapy (HAART). A significant percentage of HIV-infected patients respond to HAART and may show dramatic improvement of their HIV disease. HIV virus disappears from the blood and helper T-cell counts rise. As expected, in patients who respond to HAART, opportunistic infections no longer occur, and subsequently mortality decreases. This is also true of cutaneous infectious conditions. HIV-associated psoriasis usually improves substantially, especially if the patient did not have psoriasis prior to HIV infection.

HAART is typically associated with resolution of all forms of HIV-related cutaneous complications. However, some conditions may initially appear or be exacerbated by the sudden improvement of the immune status that occurs with eradication of HIV viremia. This complex of manifestations has been termed the "immune reconstitution" or "immune restoration" syndrome. Eosinophilic folliculitis, drug eruptions, at times HPV infections (especially oral and genital), tattoo and foreign body granulomas, and sarcoidosis may exacerbate during this period. The enhancement of T-cell function may activate granulomatous infectious disease, with new lesions of cutaneous tuberculosis and atypical mycobacterial infections appearing after institution of HAART.

Primary HIV Infection (Acute Seroconversion Syndrome) Several weeks after infection with HIV, an acute illness develops in a large proportion of individuals. The clinical syndrome is much like EBV infection, with fever, sore throat, cervical adenopathy, a rash, and oral, genital, and

Fig. 19-61 Primary HIV infection.

Fig. 19-62 Primary HIV infection. (Courtesy of Ginat Mirowski, MD)

rectal ulceration. The skin eruption can be polymorphous (Figs 19-61 and 19-62). Most characteristic is a papular eruption of discrete, slightly scaly, oval lesions of the upper trunk. The lesions have a superficial resemblance to pityriasis rosea, but the peripheral scale is not prominent, and there is focal hemorrhage in the lesions. A Gianotti-Crosti-like papular eruption may also occur. Purpuric lesions along the margins of the palms and soles, as seen in immune complex disease, have been reported. The mucosal erosions resemble aphthae but are larger and can affect all parts of the mouth, pharynx, esophagus, and anal mucosa. Dysphagia may be prominent. The helper T-cell count falls abruptly during seroconversion. The level of immune impairment may be adequate to allow oral candidiasis or even Pneumocystis carinii pneumonia to develop. The diagnosis should be suspected in any at-risk individual with the correct constellation of symptoms. A direct measurement of HIV viral load will confirm the diagnosis. Combination antiviral therapy is instituted immediately in these patients with the hope of improving the natural history of their disease.

HIV-Associated Pruritus From early in the HIV epidemic, it was clear that pruritus was a marker of HIV infection throughout the world, occurring in up to 30% of patients. Pruritus is not caused by HIV disease itself but is related to inflammatory dermatoses associated with the

disease. "Papular pruritic eruption" is not a specific disease, but a wastebasket diagnosis used to encompass patients with many forms of HIV-associated pruritus. These pruritic eruptions are best subdivided into follicular and nonfollicular eruptions. The relative prevalence of these two patterns of pruritic eruptions is geographically distinct. In tropical and semi-tropical regions where biting insects are prominent, nonfollicular eruptions are most common, and probably represent insect bite hypersensitivity. In temperate regions, follicular pruritic eruptions are more common.

Eosinophilic folliculitis is the most common pruritic follicular eruption. It is seen in patients with a helper T-cell count of about 200. Clinically, it presents with urticarial follicular papules on the upper trunk, face, scalp, and neck. Pustular lesions are uncommon; pustules are usually smaller than in bacterial folliculitis and represent end-stage lesions. They are uncommonly seen, since the pruritus is so severe that they are excoriated before the lesion evolves to this degree. Ninety percent of lesions occur above the nipple line on the anterior trunk, and lesions typically extend down the midline of the back to the lumbar spine. The disease waxes and wanes in severity and may spontaneously clear, only to flare unpredictably. A peripheral eosinophilia may be present and the serum IgE level may be elevated, suggesting this is a disorder mediated by T-helper 2 cells. Histologically, an infiltrate of mononuclear cells and eosinophils is seen around the upper portion of the hair follicle at the level of the sebaceous gland. As lesions evolve, eosinophils and lymphocytes enter the follicular structure and the sebaceous glands. Pustules are formed late and represent aggregates of eosinophils in the uppermost part of the follicle.

Initial treatment of eosinophilic folliculitis is topical steroids and antihistamines. If the patient fails to respond, phototherapy (UVB or PUVA) or itraconazole 200 mg twice a day may be effective. In some patients repeated applications of permethrin (every other night for up to 6 weeks) may be of benefit. This latter therapy is directed at *Demodex* mites, which may be the antigenic trigger of this condition. Isotretinoin is also effective, often after a few months, in a dose of about 0.5 to 1 mg/kg/day. Staphylococcal folliculitis, which may be severely pruritic in patients with HIV disease, and pityrosporum folliculitis should be included in the differential diagnosis. These are excluded by bacterial culture and skin biopsy, respectively.

The other pruritic dermatoses that are not follicular can be divided into the primarily papular eruptions and the eczematous ones. The papular eruptions include scabies, insect bites, transient acantholytic dermatosis, granuloma annulare, and prurigo nodularis. The eczematous dermatoses include atopic-like dermatitis, seborrheic dermatitis, nummular eczema, xerotic eczema, photodermatitis, and drug eruptions. Patients may have multiple eruptions simultaneously, making differential diagnosis difficult. A skin biopsy from a representative lesion of every morphologic type on the patient may elucidate the true diagnoses. Treatment is determined by the diagnosis and is similar to treatment in persons without HIV infection with these same dermatoses. Special considerations in AIDS patients include the use of topical therapy plus ivermeetin for crusted scabies and thalidomide for prurigo nodularis and photodermatitis. Both of these systemic agents are very effective if used appropriately.

HIV-Associated Neoplasia Neoplasia is prominent in HIV infection and in some cases is highly suggestive of HIV infection. Kaposi sarcoma is an example. Other common neoplasms seen in patients with HIV infection include superficial basal cell carcinomas of the trunk, SCCs in sunexposed areas, genital HPV-induced SCC, and extranodal B- and T-cell lymphomas. Less common neoplasms include lung cancer, leiomyomas and leiomyosarcomas, germ cell tumors, conjunctival cancer, multiple myeloma, and leukaemia. Lipomas and angiolipomas may occur in association with HAART therapy, perhaps more commonly in patients taking protease inhibitors.

Nonmelanoma skin cancers are very common in HIVinfected persons and usually occur as superficial multicentric basal cell carcinomas on the trunk in fair-skinned males in their 20s to 50s. The ratio of basal cell carcinoma to SCC is not reversed in HIV disease, as it is in organ transplant recipients. Basal cell carcinomas behave in the same manner as they do in the immunocompetent host and standard management is usually adequate.

Actinically-induced SCCs are also quite common and present in the standard manner as nodules, keratotic papules, or ulcerations. In most cases their behavior is relatively benign and standard management is adequate. Removal of SCCs in sun-exposed areas by curettage and desiccation in patients with HIV infection is associated with an unacceptably high recurrence rate of about 15%. Complete excision is therefore recommended. The use of imiquimod to treat SCC in situ in the setting of HIV infection should be considered experimental, and if undertaken, very close follow-up is recommended. In a small subset of patients with AIDS, actinic SCCs can be very aggressive—they may double in size over weeks and may metastasize to regional lymph nodes or viscerally, leading to the death of the patient.

Genital SCCs, including cervical, vaginal, anal, penile, and nailbed SCC, all occur in patients with HIV infection. These neoplasms are increased in frequency and the progression from HPV infection to neoplasia appears to be accelerated. This is analogous to the situation in organ transplant and other immunosuppressed patients. It appears that these cancers are associated with primarily "high-risk" HPV types.

For the dermatologist, there are three important manifestations of high-risk genital HPV infection in patients with HIV. Most common is perianal dysplasia, seen most frequently in homosexual men with a history of receptive anal intercourse. Dysplasia in this area may present as velvety white or hyperpigmented plaques involving the whole anal area and extending into the anal canal. These lesions may erode or ulcerate. Histology will demonstrate SCC in situ. The risk of progression of the lesions to anal SCC is unknown but is estimated to be at least 10 times higher than the rate of cervical cancer in women in the general population. The management of such lesions is unclear, but regular follow-up is clearly indicated and any masses in the anal canal should be immediately referred for biopsy. At some centers Pap smear equivalents are performed. Imiquimod has been used as an adjunct in the management of genital warts and HPV-associated genital in situ dysplasias (not genital SCC). While it may be of benefit in patients with reconstituted immune systems on HAART, especially in combination with surgical ablation, the response rate is much lower than in immunocompetent patients. In the only placebo

controlled trial, done before standard HAART was available, imiquimod was no more effective than placebo in clearing genital warts in HIV infection (11% of genital warts cleared). Small case series of patients on HAART suggest clearance rates of about 30% to 50%.

The vulvar and penile skin may develop flat white or hyperpigmented macules from a few millimeters to several centimeters in diameter. These show SCC in situ and are analogous to bowenoid papulosis in the immunocompetent host. Rare cases of progression to SCC have occurred. Such lesions are best managed conservatively as warts and watched closely. Lesions of the penis and vulva, not at a transition zone or on mucosal surfaces, have a low risk of progressing to invasive SCC. Lesions of the glans penis that are red and fixed should be biopsied. If the changes of SCC in situ are found, these should be managed aggressively as erythroplasia of Queyrat. Topical 5-FU and superficial radiation therapy are effective. Close clinical follow-up is indicated. Peniungual SCC has also been seen in patients with HIV infection. Any persistent keratotic or hyperpigmented lesion in the periungual area must be carefully evaluated. Management is surgical excision.

Extranodal B-cell and, less commonly, T-cell lymphomas are associated with the advanced immunosuppression of AIDS. The B-cell lymphomas and some of the T-cell lymphomas present as violaceous or plum-colored papules, nodules, or tumors. Once the diagnosis is established by biopsy. systemic chemotherapy is required. EBV is found in some cases. HAART therapy is both protective against the development of non-Hodgkin lymphoma (NHL) and Hodgkin's disease in HIV and substantially improves prognosis of HIVinfected patients with NHL. Mycosis fungoides can also be seen in patients with HIV infection, often in patients who have not yet developed AIDS. It presents with pruvitic patches or plaques and may progress to tumor stage. EBV in not found in these cases. CD8+ pseudolymphoma is also seen in patients with untreated HIV infection, and may resolve with HAART.

Malignant melanoma is occasionally seen in persons with HIV infection. These patients demonstrate the same risk factors as do other melanoma patients—multiple nevi, fair skin type, and prior intermittent intense sun exposure. HIVinfected patients with melanoma in the era prior to HAART had a significantly shorter disease-free survival and a reduced overall survival. Many fair-skinned patients infected with HIV complain of the new onset of atypical moles (analogous to organ transplant patients). Whether these confer an increased risk of melanoma is unknown.

AIDS and Kaposi Sarcoma Kaposi sarcoma was, along with pneumocystis pneumonia, the harbinger of the AIDS epidemic. Many homosexual and bisexual men presented with this tumor in the early 1980s, with a prevalence of up to 25% in some cohorts. HHV-8, a gamma herpesvirus, has been identified in these lesions and appears to be pathogenically related. The clinical features of Kaposi sarcoma in patients with AIDS are different than those seen in elderly men who do not have AIDS. Patients with AIDS present with symmetrical widespread lesions, often numerous. Lesions begin as macules that may progress to tumors of nodules. Any mucocutaneous surface may be involved, but areas of predilection include the hard palate, trunk, penis, and lower legs and soles. Visceral disease may be present, and progressive. Edema may accompany lower leg lesions, and if it is significant, it is often associated with lymph node involvement in the inguinal area.

A diagnosis of Kaposi sarcoma is established by skin biopsy, which should be taken from the center of the most infiltrated plaque. Excessive bleeding is not usually a problem. Early macular lesions show atypical, angulated, ectatic vessels in the upper dermis associated with an inflammatory infiltrate containing plasma cells. Plaque lesions show aggregates of small vessels and endothelial cells in the upper dermis, and surrounding adnexal structures. Nodules and tumors show the classic pattern of a spindle cell neoplasm with prominent extravasation of red blood cells.

HAART has reduced the incidence of Kaposi sarcoma in HIV-infected patients by 10-fold. The treatment of AIDSassociated Kaposi sarcoma depends on the extent and aggressiveness of the disease. Effective HAART after about 6 months is associated with involution of Kaposi sarcoma lesions in 50% of patients. This should be the initial management in most patients with mild-to-moderate disease (<50 lesions and <10 new lesions/month) who are not receiving anti-HIV treatment. Intralesional vinblastine 0.2 to 0.4 mg/ mL can be infiltrated into lesions (as for a hypertrophic scar) and they will involute over several weeks. Hyperpigmentation usually remains. Cryotherapy is also effective but will leave postinflammatory hypopigmentation in pigmented persons. Persistent individual lesions and lesions of the soles and penis respond well to local irradiation therapy (one single treatment of 80 Gy or fractionated treatments to 150 Gy). For patients with moderate disease (>10 lesions or mucosal or visceral involvement) HAART alone may not be adequate in controlling Kaposi sarcoma, and liposomal doxorubicin may need to be added to their treatment. For patients with symptomatic visceral disease, aggressive skin disease, marked edema, and pulmonary disease, systemic chemotherapy is indicated. Options include IFN-a, vinca alkaloids, bleomycin, and liposomal doxorubicin as first-line therapies and taxol for treatment failures.

CHAPTER

20 Parasitic Infestations, Stings, and Bites

The major groups of animals responsible for bites, stings and parasitic infections in humans belong to the phyla Arthropoda, Chordata, Cnidaria (formerly Coelenterata), Nemathelminthes, Platyhelminthes, Annelida, and Protozoa. Vector-borne disease continues to be a major worldwide public health threat. Mosquito-borne diseases, such as malaría, West Nile fever, and equine encephalitis present risks for the resident population as well as travelers. Tick-borne diseases include Lyme disease, Rocky Mountain spotted fever, ehrlichiosis, tick-borne relapsing fever, tularemia, babesiosis, and Colorado tick fever. Children and those who work outdoors are at higher risk for contracting arthropod-borne diseases. Protection of children is complicated by the potential toxicity of agents used as repellents. This chapter will review parasitic diseases and the major causes of bites and stings, as well as strategies for prevention.

PHYLUM PROTOZOA

The protozoa are one-celled organisms, divided into classes according to the nature of their locomotion. Class Sarcodina organisms move by temporary projections of cytoplasm (pseudopods); class Mastigophora by means of one or more flagella; and class Ciliata by short, hairlike projections of cytoplasm (cilia); class Sporozoa have no special organs of locomotion.

CLASS SARCODINA

The amebas are the best known organisms in this class. Of medical significance is *Entamoeba histolytica*.

Amebiasis Cutis

E. hisolytica is an intestinal parasite transmitted by the fecal-oral route or by sexual contact. Cutaneous ulcers usually result from extension of an underlying amebic abscess: the most common sites are the trunk, abdomen, buttocks, or perineum. Those on the abdomen may result from hepatic abscesses. Penile lesions are usually sexually acquired. Most lesions begin as deep abscesses that rupture and form ulcerations with distinct, raised, cordlike edges, and an erythematous halo approximately 2 cm wide. The base is covered with necrotic tissue and hemopurulent, glairy, pus-containing amebae. These lesions are from a few centimeters to 20 cm wide. Without treatment slow progression of the ulcer occurs in an increasingly debilitated patient until death ensues.

The sole manifestation of early amebiasis may be chronic urticaria.

Worldwide, an estimated 10% of the population is infected with *E. histolytica*. An estimated 10 million invasive cases occur annually, most of them in the tropics. Infection may be asymptomatic or bloody diarrhea and hepatic abscesses may be present. In the US, the disease occurs chiefly in institutionalized patients, world travelers, recent immigrants, migrant workers, and male homosexuals.

The histologic findings are those of a necrotic ulceration with many lymphocytes, neutrophils, plasma cells, and eosinophils. *E. histolytica* is found in the tissue, within blood and lymph vessels. The organism measures 50 to 60 μ m in diameter, has basophilic cytoplasm, and a single eccentric nucleus with a central karyosome.

The organism is frequently demonstrable in fresh material from the base of the ulcer by direct smear. Culture of the protozoa confirms the diagnosis. Indirect hemagglutination test results remain elevated for years after the initial invasive disease's onset, whereas the results of gel diffusion precipitation tests and counterimmunoelectrophoresis become negative at 6 months; this property can be used to test for recurrent or active disease in persons coming from endemic areas.

When the perianal or perineal areas are involved, granuloma inguinale, lymphogranuloma venereum, deep mycosis, and syphilis must be considered. In chronic urticaria, fresh stool examinations by a trained technician are necessary.

The treatment of choice is metronidazole (Flagyl), 750 mg orally three times a day for 10 days. Abscesses may require surgical drainage, but there is no need for resection of lesions.

Albanese G, et al: Albendazole: a new drug for human parsitoses. Dermatol Clin 2003;21:283.
Other Ameba

Amebas of the genera Acanthamoeba and Balamuthia may also cause skin lesions in infected hosts. These organisms are ubiquitous in the environment and are found in soil, water and air. Granulomatous amebic encephalitis is the most common manifestation of infection with these amebas. nearly always in immunocompromised individuals, such as acquired immunodeficiency syndrome (AIDS) or organ transplant patients. Disseminated infection occurs and skin lesions are the most common sign, occurring in 90% of such severely ill individuals. They initially present as pink or violaceous nodules that then enlarge, suppurate, and form ulcers with a necrotic eschar (Fig. 20-1). Other findings include fever, nasal congestion or discharge, epistaxis, cough, headaches, lethargy, altered mental status, and seizures. In patients infected with acanthamoeba who have disease of the central nervous system (CNS), death is nearly universal within days to weeks. The organisms are visible on skin biopsy and culture is definitive. In patients without CNS involvement, the mortality rate is 75%, with successfully treated cases often treated with a combination of 5-flurocyosine and sulfadiazine. In patients infected with Balamuthia mandrillaris pentamidine is favored. Chlorhexidine topically and surgical debridement are local adjunctive measures which may prove beneficial.

CLASS MASTIGOPHORA

Organisms belonging to this class are known as *flagellates*. Many have an undulating membrane with flagella along their crest.

Trichomoniasis

Trichomonas vulvovaginitis is a common cause of vaginal pruritus, with burning and a frothy leukorrhea. The vaginal mucosa appears bright red from inflammation and may be mottled with pseudomembranous patches. The male urethra may also harbor the organism; in the male it causes urethritis and prostatitis. Occasionally, men may develop balanoposthitis. Erosive lesions on the glans and penis or abscesses of the median raphae may occur. Neonates may acquire the infection during passage through the birth canal, but they require treatment only if symptomatic or colonization lasts more than 4 weeks. As this is otherwise nearly exclusively a sexually-transmitted disorder (STD), trichomonas vulvovaginitis in a child should prompt suspicion of sexual abuse.

Trichomoniasis is caused by Trichomonas vaginalis, a colorless pyriform flagellate 5 to 15 μ m long. T. vaginalis is demonstrated in smears from affected areas. Testing by direct immunofluorescence is sensitive and specific.

Metronidazole, 2 g in a single oral dose, is the treatment of choice. Alternatively, 500 mg twice a day for 7 days may be given. Patients should be warned not to drink alcohol for 24 h after the last dose because of the disulfiram type of effects of this medication. Male sex partners should also be treated. The use of metronidazole is contraindicated in pregnant women, and clotrimazole, applied intravaginally, at a dosage of 100 mg a night for 2 weeks may be used in instead.

Leishmaniasis

Cutaneous leishmaniasis, American mucocutaneous leishmamiasis, and visceral leishmaniasis (kala-azar), which includes infantile leishmaniasis and post-kala-azar dermal leishmaniasis, are all caused by morphologically indistinguishable protozoa of the family Trypanosomidae, called *Leishmania* (pronounced leesh-may-nea). The clinical features of these diseases differ and they have, in general, different geographic distributions. The reason for the variable clinical manifestations may reside with diversity of the organism, the immune status of the patient, and the genetic ability to initiate effective cell-mediated immune response to the specific infecting organism. It is known that the antigen-specificT-cell responses, which lead to the production of interferon (IFN) and

Fig. 20-2 Old World leishmaniasis.

Fig. 20-3 Leishmaniasis recidivans.

where there is high humidity. This form is a more chronic ulcer that may persist for years, destroying the ear cartilage and leading to deformity. The etiologic agent is *Leishmania*

> Uta is a term used by Peruvians for leishmaniasis occurring in mountainous territory at 1200 to 1800 m above sea level. The ulcerating lesions are found on exposed sites and mucosal lesions do not occur.

> mexicana and the sandfly vector, Lutzomyia flaviscutellata.

Disseminated cutaneous leishmaniasis may be seen in both New and Old World disease. Multiple nonulcerated papules and plaques, chiefly on exposed surfaces, characterize this type (Fig. 20-6). The disease begins with a single ulcer, nodule, or plaque from which satellite lesions may develop and disseminate to cover the entire body. The disease is progressive and treatment is usually ineffective. It is characterized by anergy to the organism. This type of leishmaniasis must be differentiated from lepromatous leprosy, xanthoma tuberosum, paracoccidioidal granuloma, Lobo's disease, and malignant lymphoma.

Etiologic Factors

L. tropica, Leishmania major, Leishmania aethiopia, and Leishmania infantum, the cause of Mediterranean visceral leishmaniasis, may cause cutaneous leishmaniasis. Purely cutaneous leishmaniasis is also caused by several species present in the New World. L. mexicana does not induce mucosal disease. Leishmania braziliensis guyanensis produces cutaneous disease, as does Leishmania braziliensis braziliensis and Leishmania braziliensis panamensis; however, the latter two may also result in mucocutaneous disease.

Epidemiology

Cutaneous leishmaniasis is endemic in Asia Minor and to a lesser extent in many countries around the Mediterranean. Iran and Saudi Arabia have a high occurrence rate. In endemic areas, deliberate inoculation on the thigh is sometimes practiced so that scarring on the face—a frequent site for Oriental sore—may be avoided. Purely cutaneous lesions may also be found in the Americas. In the US, leishmaniasis is largely restricted to South Texas, although rare reports of human cutaneous disease have occurred as far north as Pennsylvania, and visceral leishmaniasis in immunosuppressed humans is being recognized as an emerging infection in areas not previously thought to be endemic for the disease.

interleukin (IL)-12, are important for healing of the lesions and the induction of lifelong, species-specific immunity to reinfection which results after natural infection.

Cutaneous Leishmaniasis There are several types of lesions. All tend to occur on exposed parts as all are transmitted by the sandfly. Old World leishmaniasis manifests mainly in the skin and has also been called *Baghdad boil*, *Oriental sore*, *leishmaniasis tropica*, *Biskra button*, *Delhi boil*, *Aleppo boil*, *Kandahar sore*, and *Lahore sore*. Mild visceral disease may occur. Skin lesions of New World infection have been termed *uta*, *pian bois*, and *bay sore* or *chiclero ulcer*.

Clinical Features

In Old World leishmaniasis lesions may present in two distinct type. One is the moist or rural type, a slowly growing, indurated, livid, indolent papule (Fig. 20-2), which enlarges in a few months to form a nodule that may ulcerate in a few weeks to form an ulcer as large as 5 cm in diameter. Spontaneous healing usually takes place within 6 months, leaving a characteristic scar. This type is contracted from rodent reservoirs such as gerbils via the sandfly vector. The incubation period is relatively short—1 to 4 weeks. The dry or urban type has a longer incubation period (2–8 months or longer), develops much more slowly, and heals more slowly than the rural type.

Rarely, after the initial or "mother" lesion is healed, at the borders of the healed area, a few soft red papules may appear that are covered with whitish scales and have the "apple jelly" characteristics of granulomatous diseases such as lupus vulgaris. These spread peripherally on a common erythematous base and are the lupoid type. This is also known as leishmaniasis recidivans (Fig. 20-3) and occurs mostcommonly with the urban type of disease, caused by Leishmania tropica. New World disease may also induce purely cutaneous lesions, of varied morphology. The primary papule may become nodular, verrucous, furuncular, or ulcerated, with an infiltrated red border (Fig. 20-4). Subcutaneous peripheral nodules, which eventually ulcerate, may signal extension of the disease. A linear or radial lymphangitic (sporotrichoid) pattern may occur with lymphadenopathy, and the nodes may rarely yield organisms. Recidivans lesions are unusual in the New World form of disease. In Yucatan and Guatemala, a subtype of New World disease exists: the chiclero ulcer. The most frequent site of infection is the ear (Fig. 20-5). The lesions ulcerate and occur most frequently in workers who harvest chicle for chewing gum in forests,

Fig. 20-4 A–C, New World leishmaniasis.

Flg. 20-5 Chiclero ulcer in leishmanlasis.

Fig. 20-6 Disseminated cutaneous leishmaniasis.

Philebotomus sandflies for the Old World type and Philebotomus perniciosus and Lutzomyia sandflies for the New World cutaneous leishmaniasis. After the insect has fed on blood, the flagellates (leptomonad, promastigote) develop in the gut in 8 to 20 days, after which migration occurs into the mouth parts; from here transmission into humans occurs by a bite. In humans, the flagella are lost and a leishmanial form (amastigote) is assumed.

Pathogenesis

The organism has an alternate life in vertebrates and in insect hosts. Man and other mammals, such as dogs and rodents, are the natural reservoir hosts. The vector hosts are

Histopathology

An ulcer with a heavy infiltrate of histiocytes, lymphocytes, plasma cells, and polymorphonuclear leukocytes is seen. The parasitized histiocytes form tuberculoid granulomas in the dermis. Pseudoepitheliomatous hyperplasia may occur in the edges of the ulcer. Numerous organisms are present (mostly in histiocytes), which are nonencapsulated and contain a nucleus and a paranucleus. Wright, Giemsa, and monoclonal antibody staining may be helpful in identifying the organisms. Polymerase chain reaction (PCR) primers are available for a variety of species. The organisms are seen within histiocytes and often line up at the periphery of a vacuole like the bulbs surrounding a movie marquee.

Diagnosis

In endemic areas, the diagnosis is not difficult. In other localities, cutaneous leishmaniasis may be confused with syphilis, yaws, lupus vulgaris, and pyogenic granulomas. The diagnosis is established by demonstration of the organism in smears. A punch biopsy specimen from the active edge of the ulcer is ideal for culture. It can be placed in Nicolle-Novy-MacNeal (NNN) medium and shipped at room temperature. Parasites can also be cultured from tissue fluid. A hypodermic needle is inserted into the normal skin and to the edge of the ulcer base. The needle is rotated to work loose some material and serum, which is then aspirated. A culture on NNN medium at 22° to 35° C (71.6–95° F) is recommended to demonstrate the leptomonads. As expected, PCR is the most sensitive diagnostic test for cutaneous leishmaniasis.

Treatment

Spontaneous healing of primary cutaneous lesions occurs, usually within 12 to 18 months, shorter for Old World disease. The rationale of treating an ordinarily self-limited infection include avoiding disfiguring scars in exposed areas, notably the face; avoiding secondary infection; controlling disease in the population; and failure of spontaneous healing: in the diffuse cutaneous and recidivans types, the disease may persist for 20 to 40 years if not treated.

In areas in which localized cutaneous leishmaniasis is not complicated by recidivans or sporotrichoid forms, or mucocutaneous disease, treatment with such topical modalities as paromycin sulfate 15% plus methylbenzethonium chloride 12%, ketoconazole cream under occlusion, cryotherapy, local heat, and laser ablation, or with intralesional sodium stibogluconate antimony or emetine hydrochloride, may be effective and safe. Perilesional injections of IFN-y have also been reported to be effective but are expensive.

In patients who are immunosuppressed or who acquire disease in areas where mucocutaneous disease may occur, systemic therapy is recommended. As with topical treatment, many alternatives have been reported effective. Sodium antimony gluconate (sodium stibogluconate) solution is given intramuscularly or intravenously 20 mg/kg/day in two divided doses for 28 days. It can be obtained from the CDC Drug Service (Atlanta, GA 30333). Repeated courses may be given. Antimony *n*-methyl glutamine (Glucantime) is used more often in Central and South America because of its local availability.

Other systemic medications reported to be effective include fluconazole (200 mg per day for six weeks), ketoconazole, dapsone, rifampicin, and allopurinol. Some of these have not been subjected to controlled clinical trials, as is true of most topical treatments. The recidivans and disseminated cutaneous types may require prolonged courses or adjuvant IFN therapy. Amphotericin B may be used in antimonyresistant disease. Lipid formulations of amphotericin B are highly effective in short courses but are expensive.

Control depends chiefly on the success of antifly measures taken by health authorities and personal protection with protective clothing, screening, and repellents. Vaccines are being investigated but are not available.

Mucocutaneous Leishmaniasis (Leishmaniasis Americana, Espundia)

Clinical Features

The initial infection, which occurs at the site of the fly bite, is a cutaneous ulcer. Secondary lesions on the mucosa usually occur at some time during the next 5 years (Fig. 20-7). The earliest mucosal lesion is usually hyperemia of the nasal septum with subsequent ulceration, which progresses to invade the septum and later the paranasal fossae. Perforation of the septum eventually takes place. For some time the nose remains unchanged externally, despite the internal destruction.

At first only a dry crust is observed, or a bright red infiltration or vegetation on the nasal septum, with symptoms of obstruction and small hemorrhages. Despite the mutilating and destructive character of leishmaniasis, it never involves the nasal bones. When the septum is destroyed, the nasal

Fig. 20-7 A and B, Mucocutaneous lelshmaniasis. (Courtesy of James Fitzpatrick, MD)

bridge and tip of the nose collapse, giving the appearance of a parrot beak, camel nose, or tapir nose.

It is important to recall that the four great chronic infections (syphilis, tuberculosis, leprosy, and leishmaniasis) have a predilection for the nose. The ulcer may extend to the lips (Fig. 20-8) and continue to advance to the pharynx, attacking the soft palate, uvula, tonsils, gingiva, and tongue. The eventual mutilation is called *espundia*. Two perpendicular grooves at the union of the osseous palate and soft tissues, in the midst of the vegetative infiltration of the entire pharynx, is called the *palate cross of espundia*.

Only in exceptional cases does American leishmaniasis invade the genital or ocular mucous membranes. The frequency of mucous membrane involvement is variable. In Yucatan and Guatemala it is an exception; in other countries, such as Brazil, it may occur in 80% of cases.

Etiologic Factors

Mucocutaneous leishmaniasis is caused by L. braziliensis braziliensis and L. braziliensis panamensis. Leishmania has two forms, the nonflagellated form or leishmania, which is found in the tissues of humans and animals susceptible to the inoculation of the parasite, and the flagellated form or leptomonad, which is found in the digestive tract of the vector insect (Lutzomyia in mucocutaneous disease) and in

Fig. 20-8 Severe destructive mucocutaneous leishmanlasis. (Courtesy of Debra Kalter, MD)

cultures. The typical morphology of leishmania, as found in vertebrates, is round or oval, usually with one extremity more rounded than the other, measuring 2 to 4 μ m × 1.5 to 2.5 μ m, with cytoplasm, nucleus, and blepharoplast or kinetoplast.

Epidemiology

Mucocutaneous leishmaniasis is predominantly a rural and jungle disease. It most often occurs in damp and forested regions. The disease can be contracted at any time of the year, but the risk is highest just after the rainy season. All ages and races, and both sexes are equally affected.

Histopathology

In the ulcerous type, marked irregular acanthosis and sometimes pseudoepitheliomatous hyperplasia can be found. The dermis shows a dense infiltration of histiocytes, lymphocytes, and plasma cells. In new lesions some neutrophils are observed. Large Langerhans giant cells or typical tubercles are occasionally seen. Numerous organisms are present (mostly in histiocytes), which are nonencapsulated and contain a nucleus and a paranucleus. Wright, Giemsa, and monoclonal antibody staining may be helpful in identifying the organisms. In patients with granulomatous infiltrates containing intracellular parasites within histiocytes, leishmaniasis is one of several diseases to be considered, including rhinoscleroma, histoplasmosis, granuloma inguinale, Chagas' disease, *Penicillium manneffei* infection, and toxoplasmosis. Touch smears stained with Giemsa are helpful in many cases of cutaneous and mucocutaneous leishmaniasis.

Laboratory Findings

Leishmania is demonstrated in the cutaneous and mucous membrane lesions by direct smears or cultures. In biopsy material stained with Wright stain, intracellular and extracellular organisms are seen with typical morphology of two chromatic structures: nucleus and parabasal body. In later mucosal lesions the scarcity of parasites makes the identification difficult. The culture is done on NNN medium for leptomonads.

Prophylaxis

Although it is impractical to eliminate the insect vector, it is still the only valid measure for the control of this prevalent disease. Effective vaccines are not available.

Treatment

Treatment is the same as described for cutaneous leishmaniasis except that antimony resistance is common in mucocutaneous disease. Combination therapy using antimonials with drugs such as rifampin or azithromycin, or adding immunomodulators such as IFN- γ , IL-2, or imiquimod may result in cure. Amphotericin B treatment may be necessary.

Visceral Leishmaniasis (Kala-Azar, Dumdum Fever) Clinical Features

The earliest lesion is the cutaneous nodule or leishmanioma, which occurs at the site of the initial sandfly inoculation. *Kala-azar*, meaning "black fever," acquired its name because of the patchy macular darkening of the skin caused by deposits of melanin that develop in the later course of the disease. These patches are most marked over the forehead and temples, periorally, and on the midabdomen.

The primary target for the parasites is the reticuloendothelial system; the spleen, liver, bone marrow, and lymph nodes are attacked. The incubation period is 1 to 4 months. An intermittent fever, with temperatures ranging from 39° to 40° C ($102-104^{\circ}$ F) ushers in the disease. There are hepatosplenomegaly, agranulocytosis, anemia, and thrombocytopenia. Chills, fever, emaciation, weight loss, weakness, epistaxis, and purpura develop as the disease progresses. Susceptibility to secondary infection may produce pulmonary and gastrointestinal infection, ulcerations in the mouth (cancrum oris), and noma. Death occurs about 2 years from onset in untreated individuals.

Most infections are subclinical or asymptomatic. In patients with AIDS, papular and nodular skin lesions may occur. Dermatofibroma-type or Kaposi sarcoma-like brown to purple nodules are most commonly reported, although random biopsies of normal skin will reveal organisms; therefore, clinical correlation is necessary to attribute skin findings to leishmania specifically.

Etiologic Factors

L. donovani spp. donovani, infantum, and chagasi, cause visceral leishmaniasis and are parasites of rodents, canines, and humans. They are nonflagellate oval organisms some $3 \mu m$ in diameter, known as Leishman-Donovan bodies. In the sandfly it is a leptomonad form with flagella.

Epidemiology

L.d. donovani causes visceral leishmaniasis in India, with the major reservoir being humans and the vector being Phlebotomus argentipes. L.d. infantum occurs in China, Africa, the Near East and Middle East, and the Mediterranean littoral, where the major reservoirs are dogs, and Phlebotomus permiciosus and Phlebotomus ariasi are the vectors of the Mediterranean type. American visceral leishmaniasis is caused by L. donovani chagasi and is transmitted by the sandfly Lutzonyia longipalpis. American visceral leishmaniasis principally affects domestic dogs, although explosive outbreaks of the human infection occur sporadically, when the number of L. longipalpis builds up to a high level in the presence of infected dogs. Canine visceral infections with L. infantum have been reported in foxhounds in northern states and Canada.

Diagnosis

Leishman-Donovan bodies may be present in the blood in individuals with kala-azar of India. Specimens for examination, in descending order of utility, include spleen pulp, sternal marrow, liver tissue, and exudate from lymph nodes. Culturing on NNN medium may also reveal the organisms.

Treatment

General supportive measures are essential. Pentavalent antimony has long been the drug of choice. In areas of drug resistance, amphotericin B is usually effective, but expensive, toxic and it requires intravenous administration. Miltefosine is an oral alkyl-phosphocholine analog that has proven as effective as amphotericin B in Indian trials, and is being investigated in other regions and other populations. Post-Kala-Azar Dermal Leishmaniasis In kalaazar, the leishmanoid (amastigote) forms may be widely distributed throughout apparently normal skin. During and after recovery from the disease, a special form of dermal leishmaniasis known as post-kala-azar dermal leishmaniasis appears. This condition appears during or shortly after treatment in the African form, but its appearance may be delayed up to 10 years after treatment in the Indian form. It follows the treatment of visceral leishmaniasis in 50% of Sudanese patients and 5% to 10% of those seen in India. There are two constituents of the eruption: a macular, depigmented eruption found mainly on the face, arms, and upper part of the trunk; and a warty, papular eruption in which amastigotes can be found. Because it may persist for up to 20 years, these patients may act as a chronic reservoir of infection. This condition closely resembles leprosy. High concentrations of IL-10 in the blood of visceral leishmaniasis patients predict those who will be affected by post-kala-azar dermal leishmaniaisis.

Viscerotropic Leishmaniasis Twelve soldiers developed systemic infection with *L. tropica* while fighting in Operation Desert Storm in Saudi Arabia. None had symptoms of kala-azar, but most had fever, fatigue, malaise, cough, diarrhea, or abdominal pain. None had cutaneous disease. Diagnostic tests yielded positive results on bone marrow aspiration; lymph node involvement was also documented. Treatment with sodium stibogluconate led to improvement.

Human Trypanosomiasis

Three species of trypanosomes are pathogenic to humans: *Thypanosoma gambiense* and *Thypanosoma rhodesiense* in Africa, and *Thypanosoma cruzi* in America. The skin manifestations are usually observed in the earlier stages of the disease as evanescent erythema, erythema multiforme, and edema, especially angioedema.

In the early stage of African trypanosomiasis, a trypanosome chancre may occur at the site of a tsetse fly bite. Then erythema with circumscribed swellings of angioedema, enlargement of the lymph nodes, fever, malaise, headache, and joint pains ensue. In the West African (Gambian) form, the illness is chronic, lasting several years, with progressive deterioration, whereas the East African (Rhodesian) form is an acute illness, with a stormy, fatal course of weeks to months. The Rhodesian form is more often associated with cutaneous signs. Annular or deep erythema nodosum-like lesions are frequent manifestations (Fig. 20-9). Lymphadenopathy is generalized, but frequently there is a pronounced enlargement of the posterior cervical group (Winterbottom's sign).

In American trypanosomiasis (Chagas' disease), similar changes take place in the skin. The reduviid bug (kissing bug,

Fig. 20-9 African trypanosomiasis. (Courtesy of James Fitzpatrick, MD)

Fig. 20-10 Triatome reduviid bug.

assassin bug) (Fig. 20-10) usually bites at night, frequently at mucocutaneous junctions, where the bug's infected feces are deposited when it feeds. The unsuspecting sleeping person rubs the feces into the bite and becomes infected. If the bite of the infected bug occurs near the eye, Romana's sign develops; this consists of unilateral conjunctivitis and edema of the eyelids, with an ulceration or chagoma in the area. The bite of a "kissing bug" becomes markedly swollen and red, whether trypanosomes are involved or not. Acute Chagas' disease is usually a mild illness consisting of fever, malaise, edema of the face and lower extremities, and generalized lymphadenopathy. Skin lesions occurring in this phase include nodules at the site of inoculation, disseminated nodules or morbilliform and urticarial lesions. In chronic Chagas' disease, which occurs in 10% to 30% of infected persons years to decades later, the heart (myocarditis, arrhythmias, thromboembolism, and cardiac failure) and the gastrointestinal system (megaesophagus and megacolon) are the most commonly involved organs. During the remaining infected but asymptomatic indeterminate phase patients may transmit the disease through transfusion. When such patients become immunosuppressed (with AIDS or organ transplantation) reactivation skin lesions may occur.

Rhodesian trypanosomiasis is endemic among the cattleraising tribes of East Africa, with the savannah habitat of the vectors determining its geographic distribution. Wild game and livestock are reservoir hosts, in addition to humans. The tsetse fly, *Glossina morsitans*, is the principal vector.

For Gambian trypanosomiasis, humans are the only vertebrate host and the palpalis group of tsetse flies is the invertebrate host. These flies are found close to the water, and their fastidious biologic requirements restrict their distribution, and thus that of the disease. Incidence is seasonal, with humidity and temperature being determining factors. The highest incidence is in males aged 20 to 40 years in tropical areas of West and Central Africa.

Chagas' disease is prevalent in Central and South America from the US to Argentina and Chile; the highest incidence is in Venezuela, Brazil, Uruguay, Paraguay, and Argentina. Approximately 29% of all male deaths in the 29- to 44-yearold age group in Brazil are ascribed to Chagas' disease.

Before CNS involvement has occurred in the Rhodesian form, suramin, a complex, non-metal-containing, organic compound, is the treatment of choice. When the CNS is involved, melarsoprol is the drug of choice. Pentamidine isethionate is the drug of choice for the Gambian disease. For American trypanosomiasis, treatment is of limited efficacy. Nifurtimox and benzimidazole clear the parasitemia and reduce the severity of the acute illness. There is a high incidence of adverse effects, however. Conservative treatment is most appropriate for the patient with congestive heart failure from Chagas myocarditis. Gastrointestinal complications may be treated surgically.

CLASS SPOROZOA

Toxoplasmosis

Toxoplasmosis is a zoonosis caused by a parasitic protozoan, *Toxoplasma gondii*. Infection may be either congenital or acquired. Congenital infection occurs from placental transmission. Abortion or stillbirth may result. However, a fullterm child delivered to an infected mother may have a triad of hydrocephalus, chorioretinitis, and cerebral calcification. In addition, there may be hepatosplenomegaly and jaundice. Skin changes in toxoplasmosis are rare and clinically nonspecific.

In congenital toxoplasmosis, macular and hemorrhagic eruptions predominate. Blueberry muffin lesions, reflecting dermatoerythropoesis, may be seen. Occasionally, abnormal hair growth and exfoliative dermatitis have also been observed. The differential diagnosis of congenital toxoplasmosis is the TORCH syndrome (toxoplasmosis, rubella, cytomegalovirus, and herpes simplex). In acquired toxoplasmosis, early skin manifestations consist of cutaneous and subcutaneous nodules, and macular, papular, and hemorrhagic eruptions. These may be followed by scarlatiniform desquamation, eruptions mimicking roseola, erythema multiforme, dermatomyositis or lichen planus, as well as exfoliative dermatitis. As a rule, the exanthem is accompanied by high fever and general malaise.

Diagnosis of acquired toxoplasmosis is of special importance to three groups of adults: healthy pregnant women concerned about recent exposure; adults with lymphadenopathy, fever, and myalgia, who might have some other serious disease, such as lymphoma; and immunocompromised persons, such as patients with AIDS, in whom toxoplasmosis might be fatal. It is the most common cause of focal encephalitis in patients with AIDS and this may be accompanied by a widespread papular eruption.

Toxoplasma gondii is a crescent-shaped, oval, or round protozoan that can infect any mammalian or avian cell. The disease is often acquired through contact with animals, particularly cats. Reservoirs of infection have been reported in dogs, cats, cattle, sheep, pigs, rabbits, rats, pigeons, and chickens. The two major routes of transmission of *T. gondii* in humans are oral and congenital. Meats consumed by humans may contain tissue cysts, thus serving as a source of infection when eaten raw or undercooked. There is no evidence of direct human-to-human transmission, other than from mother to fetus.

The diagnosis cannot be made on clinical grounds alone. It may be established by isolation of *T. gondii*, demonstration of the protozoa in tissue sections, smears, or body fluids by Wright or Giemsa stain; characteristic lymph node histology; and serologic methods.

A combination of pyrimethamine (Daraprim) and sulfadiazine act synergistically and form an effective treatment. Dosages and total treatment time vary according to the age and immunologic competence of the infected patient.

PHYLUM CNIDARIA

The cnidarians include the jellyfish, hydroids, Portuguese man-of-war, corals, and sea anemones. These are all radial marine animals, living mostly in ocean water. When a swimmer's skin contacts these organisms, they release a toxin through small spicules.

Portuguese Man-of-War Dermatitis

Stings by the Portuguese man-of-war (*Physalia physalis* in the Atlantic, or the much smaller *Physalia utriculus* or "bluebottle" in the Pacific) are characterized by linear lesions that are erythematous, urticarial, and even hemorrhagic. The forearms, sides of the trunk, thighs, and feet are common sites of involvement. The usual local manifestation is sharp, stinging, and intense pain. Internally there may be severe dyspnea, prostration, nausea, abdominal cramps, lacrimation, and muscular pains. Death may occur if the areas stung are large in relation to the patient's size.

The fluid of the nematocysts contains toxin that is carried into the victim through barbs along the tentacle. The venom is a neurotoxic poison that can produce marked cardiac changes.

Each Portuguese man-of-war is a colony of symbiotic organisms consisting of a blue to red float or pneumatophore with a gas gland, several gastrozooids measuring 1 to 20 mm, reproductive polyps, and the fishing tentacles bearing the

Fig. 20-11 Jellyfish sting. (Courtesy of Anthony Slagel, MD)

Fig. 20-12 Seabather's eruption.

nematocysts from which the barbs are ejected. The hydroid is found most frequently along the southeastern Florida coastline and in the Gulf of Mexico, and on windward coasts throughout the mid-Pacific and South Pacific.

Jellyfish Dermatitis

This produces lesions similar to those of the Portuguese manof-war, except that the lesions are not so linear (Fig. 20-11). Immediate allergic reactions occur infrequently as urticaria, angioedema or anaphylaxis. Delayed and persistent lesions also rarely occur.

The Australian sea wasp, *Chironex fleckeri*, which is colorless and transparent, is the most dangerous of all, with a sting that is often fatal. Another sea wasp, *Carybdea marsupialis*, much less dangerous, occurs in the Caribbean.

Seabather's eruption is an acute dermatitis that begins a few hours after bathing in the waters along the coast of the Atlantic. It affects covered areas of the body as Cnidarian larvae become entrapped under the bathing suit and the nematocyst releases its toxin because of external pressure. Thus, the buttocks and waist are affected primarily, with the breast also involved in women (Fig. 20-12). Erythematous macules and papules appear and may develop into pustules

Fig. 20-13 Sea anemone.

or vesicles. Urticarial plaques are also present in a smaller number of patients. Crops of new lesions may occur for up to 72 h, and the eruption persists for 10 to 14 days on average. It is quite pruritic.

Outbreaks in Florida are usually caused by larvae of the thimble jellyfish *Linuche unguiculata* which patients report as "black dots" in the water or their bathing suits. The larvae of the sea anemone *Edwardstella lineata* caused one epidemic of seabather's eruption in Long Island, New York. This organism also has nematocysts; thus, the mechanism of the eruption is the same as with the jellyfish-induced eruption. It is likely that different cnidarian envenomations in different waters produce a similar clinical picture. Other reports focus on spring plants, dinoflagellates, protozoans, or crustaceans as potential causes. Since trapping of cnidarian larvae with their nematocysts or other toxic or irritant substances under the bathing suit accounts for this eruption, seabathers who take off their bathing suit and shower soon after leaving the water may limit it.

Hydroid, Sea Anemone, and Coral Dermatitis

Patients contacting the small marine hydroid *Halecium* may develop a dermatitis. The organism grows as a centimeterthick coat of moss on the submerged portions of vessels or pilings. Sea anemones (Fig. 20-13) produce reactions similar to those from jellyfish and hydroids. Coral cuts (Fig. 20-14) are injuries caused by the exoskeleton of the corals, Milleporina. They have a reputation for becoming inflamed and infected, and for delayed healing. The combination of implantation of fragments of coral skeleton and infection (since the cuts occur most commonly on the feet) probably accounts almost entirely for these symptoms. Detoxification as soon as possible after the injury is advisable for all these types of stings or cuts.

Treatment of Stings and Cuts

Hot water immersion may be an effective remedy for many stings, but scald injuries must be avoided. Undischarged nematocytes may be removed with sea water, but never with fresh water, as this may cause them to discharge. Pacific *Chironex* (box jellyfish) nematocytes should always be inactivated with 5% acetic acid (vinegar) when it is available, but pacific *Physalia* (blue bottle) nematocytes may discharge

Fig. 20-14 A and B, Coral cuts. (Courtesy of Curt Samlaska, MD)

on contact with vinegar. Large visible tentacles may be removed with forceps in a double-gloved hand. Remaining nematocysts may be removed by applying a layer of shaving cream and shaving the area gently. Meat tenderizer may cause tissue damage and has been shown to be no better than placebo in some studies.

Pressure dressings and abrasion will worsen the envenomation. Topical anesthetics or steroids may be applied after decontamination. Systemic reactions may occur either through large amounts of venom or a previously sensitizing exposure from which anaphylaxis may result, and systemic treatment with epinephrine, antihistamines, or corticosteroids may be needed. Specific antivenin is available for the box jellyfish, *Chironex fleckeri*. This should be administered intravenously to limit myonecrosis. MgSO₄ may also be of value in the setting of box jellyfish envenomation.

Sponges and Bristleworms

Sponges have horny spicules of silicon dioxide and calcium carbonate. Some sponges produce dermal irritants, such as halitoxin and okadaic acid, and others may be colonized by cnidaria. Allergic or irritant reactions may result. Bristleworms may also produce stinging. All of these may be treated by first using adhesive tape to remove the spicules, then applying vinegar soaks, as described above, and finally, applying topical corticosteroid agents.

Sea Urchin Injuries

Puncture wounds inflicted by the brittle, fragile spines of sea urchins, mainly of genus *Diadema* or *Echinothrix*, are stained blue-black by the black spines and may contain fragments of the spines. The spines consist of calcium carbonate crystals which most commonly induce an irritant reaction with pain and inflammation of several days' duration. Foreign-body or sarcoid-like granulomas may develop, as may a vesicular hypersensitivity reaction 10 days after exposure. Injuries by spines of the genus *Tripneustes* have been reported to cause fatal envenomation, but this genus is not found on US coasts. Starfish also have thorny spines that can sting and burn if they are stepped on or handled. Several different types of stinging fish also produce puncture wounds. Stingrays, scorpionfish, stonefish, catfish, and weaverfish may cause such envenomations.

These wounds should be immersed in nonscalding water $(45^{\circ} C [113^{\circ} F])$ for 30 to 90 min or until the pain subsides. Calcified fragments may be visible on x-ray evaluation, with fluoroscopy guiding extraction of spines, especially on the hands and feet. Sea urchin spines have been effectively removed using the erbium:YAG laser. Debridement and possibly antibiotic therapy for deep puncture wounds of the hands and feet are recommended. There is a specific antivenin for stonefish stings.

Seaweed Dermatitis

Although this is caused by a marine alga and not by an animal, it deserves mention with other problems associated with swimming or wading. The dermatitis occurs 3 to 8 h after the individual emerges from the ocean. The distribution is in parts covered by a bathing suit: scrotum, penis, perineum, and perianal area. The dermatitis is caused by a marine plant, *Lyngbya majuscula Gomont*. It has been observed only in bathers swimming off the windward shore of Oahu, Hawaií. Seabather's eruption, clamdígger's itch, and swimmer's itch must be differentiated from seaweed dermatitis caused by marine algae. Prophylaxis is achieved by refraining from swimming in waters that are turbid with such algae. Swimmers should shower within 5 min after swimming. Active treatment in severe cases is the same as for acute burns.

Dogger Bank Itch

Dogger Bank itch is an eczematous dermatitis caused by the sea chervil, *Alcyondium hirsutum*, a seaweed-like animal colony. These sea mosses or sea mats are found on the Dogger Bank, an immense shelflike elevation under the North Sea between Scotland and Denmark.

PHYLUM PLATYHELMINTHES

Phylum Platyhelminthes includes the flatworms, of which two classes, trematodes and cestodes, are parasitic to humans. The trematodes, or blood flukes, parasitize human skin or internal organs. The cestodes are segmented, ribbonshaped flatworms that inhabit the intestinal tract as adults and involve the subcutaneous tissue, heart, muscle, and eye in the farval form. This is encased in a sac that eventually becomes calcified.

CLASS TREMATODA

Schistosome Cercarial Dermatitis

Cercarial dermatitis is a severely pruritic, widespread, papular dermatitis caused by cercariae of schistosomes for which humans are not hosts (the usual animal hosts are waterfowl and rodents, such as muskrats).

The eggs in the excreta of these animals, when deposited in water, hatch into swimming miracidia. These enter a snail, where further development occurs. From the snail, the freeswimming cercariae emerge to invade human skin on accidental contact. The swimming, colorless, multicellular organisms are a little less than a millimeter long. Exposure to cercariae occurs when a person swims or, more often, wades in water containing them. They attack by burrowing into the skin, where they die. The species that causes this eruption cannot enter the bloodstream or deeper tissues.

Fig. 20-15 Swimmer's itch.

After coming out of the water, the bather begins to itch and a transient erythematous eruption appears, but after a few hours, the eruption subsides, together with the itching. Then, after a quiescent period of 10 to 15 h, the symptoms recur, and erythematous macules and papules develop throughout the exposed parts that were in the water (Fig. 20-15). After several days the dermatitis heals spontaneously. There are two types: the freshwater swimmer's itch, and the saltwater marine dermatitis or clam digger's itch. It is not communicable.

Various genera and species of organisms have been reported from various locations worldwide. An outbreak of cercarial dermatitis was reported from Delaware in 1991 in which the avian schistosome *Microbilharzia variglandis* was implicated as the causative organism. *Schistosoma spindale* cercaria caused a recent epidemic in southern Thailand.

Thoroughly washing, then drying with a towel after exposure can prevent the disease. Rubbing with alcohol is an additional preventive measure advocated by some. Snail populations can be controlled or waterfowl may be treated with medicated feedcorn to destroy the adult schistosomes and prevent outbreaks of swimmer's itch.

Visceral Schistosomiasis (Bilharziasis)

The cutaneous manifestation of bilharziasis may begin with mild itching and a papular dermatitis of the feet and other parts after swimming in polluted streams containing cercariae. The types of schistosomes causing this disease can penetrate into the bloodstream and eventually inhabit the venous system draining the urinary bladder (Schistosoma haematobium) or the intestines (Schistosoma mansoni or Schistosoma japonicum). After an asymptomatic incubation period, there may be a sudden illness with fever and chills, pneumonitis, and eosinophilia. Petechial hemorrhages may occur.

Cutaneous schistosomal granulomas most frequently involve the genitalia, perineum, and buttocks. The eggs of *S. haematobium* or *S. mansoni* usually cause these bilharziomas. Vegetating, soft, cauliflower-shaped masses, fistulous tracts and extensive hard masses occur; these are riddled by sinuses that exude a seropurulent discharge with a characteristic odor. Phagedenic ulcerations and pseudoelephantiasis of the scrotum, penis, or labia are sometimes encountered. Histologically, the nodules contain bilharzial ova undergoing

Fig. 20-16 Sparganosis is characterized histologically by a secretory tegument and loose stroma with smooth mucle and calcareous bodies.

degeneration, with calcification and a surrounding cellular reaction of histiocytes, eosinophils, and occasional giant cells. In some cases, eventual malignant changes have been noted in chronic lesions.

Infrequently, ectopic or extragenital lesions may occur, mainly on the trunk. This is a papular eruption tending to group in plaques and become darkly pigmented and scaly (Fig. 20-16).

A severe urticarial eruption known as *urticarial fever* or *Katayama fever* is frequently present along with a *S. japonicum* infection; it occurs with the beginning of oviposition, 4 to 8 weeks after infection. This condition occurs mainly in China, Japan, and the Philippines. In addition to the urticaria, fever, malaise, abdominal cramps, arthritis, and liver and spleen involvement are seen. This is felt to be a serum sickness-like reaction.

Preventive measures include reducing infection sources, preventing contamination by human excreta of snail-bearing waters, control of snail hosts, and avoiding exposure to cercaria-infested waters. Prophylactic measures are constantly sought to control one of the world's worst parasitic diseases, but as yet none has been found to be practical.

For both S. haematobium and S. mansoni, praziquantel (Biltricide) 40 mg/kg orally for each of two treatments in 1 day is the treatment of choice. S. japonicum treatment requires 60 mg/kg in three doses in 1 day.

Schistosomicides exhibit toxicity for the host as well as for the parasite, and the risk of undesirable side effects may be enhanced by concomitant cardiac, renal, or hepatosplenic disease.

Cysticercosis Cutis

The natural intermediate host of the pork tapeworm, Taenia solium, is the pig, but under some circumstances humans act in this role. The larval stage of *T. solium* is *Cysticercus cellulosae*. Infection takes place by the ingestion of food contaminated with the eggs, or by reverse peristalsis of eggs or proglottides from the intestine to the stomach. Here the eggs hatch, freeing the oncospheres. These enter the general circulation and form cysts in various parts of the body, such as striated muscles, brain, eye, heart, and lung.

In the subcutaneous tissues the lesions are usually painless nodules that contain cysticerci. They are more or less stationary, usually numerous, and often calcified, and are therefore demonstrable radiographically. Pain and ulceration may accompany the lesions. The disease is most prevalent in countries in which pigs feed on human feces. It may be confused with gumma, lipoma, and epithelioma. A positive diagnosis is established solely by incision and examination of the interior of the calcified tumor, where the parasite will be found.

Albendazole or praziquantel are effective; however, the status of the CNS, spinal and ocular involvement, needs to be thoroughly assessed prior to treatment. The length of therapy and use of concominant corticosteroids depends upon the location of the cysts. None of the regimens clear the calcified parasites, however, which need to be surgically removed.

Sparganosis

Sparganosis is caused by the larva of the tapeworm of the species *Spirometra*. The adult tapeworm lives in the intestines of dogs and cats. This is a rare tissue infection occurring in two forms. *Application sparganosis* occurs when an ulcer or infected eye is poulticed with the flesh of an infected intermediate host (such poultices are frequently used in the Orient). The larvae become encased in small nodules in the infected tissue. *Ingestion sparganosis* occurs when humans ingest inadequately cooked meat, such as snake or frog, or when a person drinks water that is contaminated with *Cyclops*, which are infected with plerocercoid larvae. One or two slightly pruritic or painful nodules may form in the subcutaneous tissue or on the trunk and legs.

Humans are the accidental intermediate host of the Sparganum, which is the alternative name for the plerocercoid larva. Treatment is surgical removal or ethanol injection of the infected nodules (Fig. 20-17). This may be difficult because of the swelling and extensive vascularity.

Echinococcosis

Echinococcosis is also known as *hydatid disease*. In humans, infection is produced by the ova reaching the mouth from the hands, in food, or from containers soiled by ovacontaminated feces from an infected dog. This leads to *Echinococcus granulosus* infestation of the liver and the lungs. Soft, fluctuating, semitranslucent, cystic tumors may occur in the skin, sometimes in the supraumbilical area as fistulas from underlying liver involvement. These tumors become fibrotic or calcified after the death of the larva. The treatment is excision, with care being taken to avoid rupturing the cyst. Albendazole combined with percutaneous drainage may also be used

Eosinophilia, intractable urticaria and pruritus, and even acute generalized exanthematous pustulosis may be present. Such reactive findings may be present as skin manifestations of many of the helminthic infections, including other types of tapeworms. *Hymenolepis nana* is a cosmopolitan dwarf tapeworm endemic in the tropics which may cause a treatmentresistant pruritic papular eruption associated with eosinophilia. Stool specimens for ova and parasites are definitive and praziquantel is curative.

PHYLUM ANNELIDA

LEECHES

Leeches, of the class Hirudinea, are of marine, freshwater, or terrestrial types. After attaching to the skin, they secrete an anticoagulant, *hirudin*, and then engorge themselves with blood. Local symptoms at the site of the bite may include bullae, hemorrhage, pruritus, whealing, necrosis, or ulceration. Allergic reactions, including anaphylaxis, may result. Leeches may be removed by applying salt, alcohol, or vinegar, or by use of a match flame. Bleeding may then be stopped by direct pressure or by applying a styptic pencil to the site. Leeches may be used medicinally to salvage tissue flaps that are threatened by venous congestion. However, aeromonas infection, anetoderma, and pseudolymphoma may be complications of their attachment.

PHYLUM NEMATHELMINTHES

Phylum Nemathelminthes includes the roundworms, both free-living and parasitic forms. Multiplication is usually outside the host. Both the larval and adult stages may infect humans.

CLASS NEMATODA

Enterobiasis (Pinworm Infection, Seatworm Infection, Oxyuriasis)

The chief symptom of pinworm infestation, which occurs most frequently in children, is nocturnal pruritus ani. There is intense itching accompanied by excoriations of the anus, perineum, and pubic area. The vagina may become infested with the gravid pinworms. A pruritic papular dermatosis of the trunk and extremities may be observed infrequently. Restlessness, insomnia, enuresis, and irritability are but a few of the many symptoms ascribed to this exceedingly common infestation.

Oxyuriasis is caused by the roundworm Enterobius vernicularis, which may infest the small intestines, cecum, and large intestine of humans. The worms, especially gravid ones, migrate toward the rectum and at night emerge to the perianal and perineal regions to deposit thousands of ova; then the worm dries and dies outside the intestine. These ova are then carried back to the mouth of the host on the hands. The larvae hatch in the duodenum and migrate into the jejunum and ileum, where they reach maturity. Fertilization occurs in the cecum, thus completing the life cycle.

Humans are the only known host of the pinworm, which probably has the widest distribution of all the helminths. Infection occurs from hand-to-mouth transmission, often from handling soiled clothes, bedsheets, and other household articles. Ova under the fingernails are a common source of autoinfection. Ova may also be airborne and collect in dust that may be on furniture and the floor. Investigation may show that all members of the family of an affected person also harbor the infection. It is common in orphanages and mental institutions and among people living in communal groups.

Rarely is it feasible to identify a dead pinworm in the stool. Diagnosis is best made by demonstration of ova in smears taken from the anal region early in the morning before the patient bathes or defecates. Such smears may obtained with a small eye curette and placed on a glass slide with a drop of saline solution. It is also possible to use Scotch tape, looping the tape sticky-side out over a tongue depressor and then pressing it several times against the perianal region. The tape is then smoothed out on a glass slide. A drop of a solution containing iodine in xylol may be placed on the slide before the tape is applied to facilitate detection of any ova. These tests should be repeated on 3 consecutive days to rule out infection. Ova may be detected under the fingernails of the infected person.

Albendazole, 400 mg, mebendazole, 100 mg, or pyrantel pamoate, 11 mg/kg (maximum 1 g) given once and repeated in 2 weeks, is effective. Personal hygiene and cleanliness at home are important. Fingernails should be cut short and scrubbed frequently; they should be thoroughly cleaned on arising, before each meal, and after using the toilet. Sheets, underwear, towels, pajamas, and other clothing of the affected person should be laundered thoroughly and separately.

Pack SC, et al: Pruritus vulvae in prepubertal children. J Am Acad Dermatol 2001;44:795.

Hookworm Disease (Ground Itch, Uncinariasis, Ancylostomiasis, Necatoriasis)

The earliest skin lesions (ground itch) are erythematous macules and papules, which in a few hours become vesicles. These itchy lesions usually occur on the soles, toe webs, and ankles; they may be scattered or in groups. The content of the vesicles rapidly becomes purulent. These lesions are produced by invasion of the skin by the *Ancylostoma* or *Necator* larvae, and precede the generalized symptoms of the disease by 2 or 3 months. The cutaneous lesions last less than 2 weeks before the larvae continue their human life cycle. There may be as high as 40% eosinophilia around the fifth day of infection.

The onset of the constitutional disease is insidious and is accompanied by progressive iron-deficiency anemia and debility. During the course of the disease urticaria often occurs. The skin ultimately becomes dry and pale or yellowish.

Hookworm is a specific communicable disease caused by Ancylostoma duodenale or Necator americanus. In the soil, under propitious circumstances, they attain the stage of infective larvae in 5 to 7 days. These tiny larvae (which can scarcely be seen with a small pocket lens), when they come into accidental contact with bare feet, penetrate the skin and reach the capillaries. They are carried in the circulation to the lungs, where they pass through the capillary walls into the bronchi. They move up the trachea to the pharynx and, after being swallowed, eventually reach their habitat in the small intestine. Here they bury their heads in the mucosa and begin their sexual life.

Hookworm is prevalent in most tropical and subtropical countries and is often endemic in swampy and sandy localities in temperate zones. In these latter regions the larvae are killed off each winter, but the soil is again contaminated from human sources the following summer. *Necator americanus* prevails in the western hemisphere, Central and South Africa, South Asia, Australia, and the Pacific islands.

The defecation habits of infected individuals in endemic areas are largely responsible for its widespread distribution, as is the use of human feces for fertilization in many parts of the world. In addition, the climate is usually such that people go barefoot because of the heat or because they cannot afford shoes. Infection is thereby facilitated, especially through the toes.

Finding the eggs in the feces of a suspected individual establishes the diagnosis. The ova appear in the feces about 5 weeks after the onset of infection. The eggs may be found in direct fecal films if the infection is heavy, but in light infections it may be necessary to resort to zinc sulfate centrifugal flotation or other concentration methods. Mixed infections frequently occur.

Albendazole, 400 mg once, or mebendazole, 100 mg twice a day for 3 days or 500 mg once, or pyrantel pamoate 11 mg/ kg (maximum 1 g) each day for 3 days is effective. Prophylaxis is largely a community problem and depends on preventing fecal contamination of the soil. This is best attained by proper sanitary disposal of feces, protecting individuals from exposure by educating them about sanitary procedures, and mass treatment through public health methods.

Nematode Dermatitis

Miller et al described a patient who developed a persistent widespread folliculitis caused by Ancyclosforma caninum. It was apparently acquired by his lying in grass contaminated by the droppings of his pet dogs and cats. A biopsy revealed hookworm larvae within the hair follicle. Oral thiabendazole was curative.

Creeping Eruption (Larva Migrans)

Creeping eruption is a term applied to twisting, winding linear skin lesions produced by the burrowing of larvae. People who go barefoot on the beach, children playing in sandboxes, carpenters and plumbers working under homes, and gardeners are often victims. The most common areas involved are the feet, buttocks, genitals, and hands.

Slight local itching and the appearance of papules at the sites of infection characterize the onset. Intermittent stinging pain occurs, and thin, red, tortuous lines are formed in the skin. The larval migrations begin 4 days after inoculation and progress at the rate of about 2 cm/day. However, they may remain quiescent for several days or even months before beginning to migrate. The linear lesions are often interrupted by papules that mark the sites of resting larvae (Fig. 20-18). As the eruption advances, the old parts tend to fade, but sometimes there are purulent manifestations caused by secondary infection; erosions and excoriations caused by scratching frequently occur. If the progress of the disease is not interrupted by treatment, the larvae usually die in 2 to 8 weeks, with resolution of the eruption, although rarely it has been reported to persist for up to 1 year. At times the larvae are removed from the skin by the fingernails in scratching. Eosinophilia may be present.

Loeffler syndrome, consisting of a patchy infiltrate of the lungs and eosinophilia as high as 50% in the blood and 90% in the sputum, may complicate creeping eruption.

The majority of cases in the US occur along the southeast coast and are caused by penetration by the larvae of a cat and dog hookworm, *Ancylostoma braziliense*. It is acquired from body contact with damp sand or earth that has been contaminated by the excreta of dogs and cats. The larvae of *Ancylostoma caninum*, which also infests the dog and the cat, rarely produce a similar dermatitis.

Elston DM: Enterobius vermicularis (pinworms, threadworms). Cutis 2003;71:268.

Fig. 20-18 A and B, Cutaneous larva migrans.

Ivermectin 200 μ g/kg, generally given as a single 12-mg dose and repeated the next day, or albendazole, 400 mg/day for 3 days, are effective treatments. Criteria for successful therapy are relief of symptoms and cessation of tract extension, which usually occurs within a week. Topical thiabendazole compounded as a 10% suspension or a 15% cream used four times a day will result in marked relief from pruritus in 3 days, and the tracts become inactive in 1 week. Topical metronidazole has also been reported to be effective.

Another condition, not to be confused with this helminthic disease, which also is called *creeping eruption* (or *sandworm*, as it is known in South Africa, particularly in Natal and Zululand), is caused by a small mite about 300 μ m long that tunnels into the superficial layers of the epidermis.

Gnathostomiasis

Migratory, intermittent, erythematous, urticarial plaques characterize human gnathostomiasis. Each episode of painless swelling lasts from 7 to 10 days and recurs every 2 to 6 weeks. Movement of the underlying parasite may be as much as 1 cm/h. The total duration of the illness may be 10 years. Histopathologic examination of the skin swelling will demonstrate eosinophilic panniculitis. The clinical manifestation has been called *larva migrans profundus*.

The nematode Gnathostoma dolorosi or spinigerum is the cause; most cases occur in Asia or South America. Eating raw flesh from the second intermediate host, most commonly freshwater fish, in such preparations as sashimi and ceviche, allows humans to become the definitive host. Eating raw squid or snake are other less common exposures. As the larval cyst in the flesh is digested, it becomes motile and penetrates the gastric mucosa, usually within 24 to 48 h of ingestion. Symptoms then occur as migration of the parasite continues. Surgical removal is the treatment of choice, if the parasite can be located. This may be combined with albendazole 400 mg/day or twice a day for 21 days, or ivermectin 200 μ g/kg/day for 2 days.

Creeping eruption in several reports from Japan has been found to be caused by a newly recognized causative parasite of the nematode superfamily Spiruroidea. Eating raw squid was associated with the onset of long, narrow lesions that were pruritic, linear, and migratory. Surgical removal is necessary; chemotherapy has been unsuccessful.

Larva Currens

Intestinal infections with Strongyloides stercoralis may be associated with a perianal larva migrans syndrome, called *larva currens*, because of the rapidity of larval migration (currens means "running" or "racing"). Larva currens is an autoinfection caused by penetration of the perianal skin by infectious larvae as they are excreted in the feces. An urticarial band is the prominent primary lesion of cutaneous strongyloidiasis. Strongyloidiasis, and the creeping eruption secondary to it, is often a chronic disease; infections may persist for more than 40 years. Approximately one-third of patients infected are asymptomatic.

Signs and symptoms of systemic strongyloidiasis include abdominal pain, diarrhea, constipation, nausea, vomiting, pneumonitis, urticaria, eosinophilic folliculitis, and a peripheral eosinophilia. The skin lesions originate within 30 cm of the anus and characteristically extend as much as 10 cm/day.

Fatal cases of hyperinfection occur in immunocompromised patients. In such patients the parasite load increases dramatically and can produce a fulminant illness. Widespread petechiae and purpura are helpful diagnostic signs of disseminated infection and chronic urticaria is a possible presenting sign. Periumbilical ecchymoses may appear as if they were caused by a thumbprint.

Administration of ivermectin, 200 μ g/kg/day for 2 days, or thiabendazole 50 mg/kg/day in two doses (maximum 3 g/ day) for 2 days, is the treatment of choice. Immunosuppressed hosts may be treated with thiabendazole 25 mg/kg twice a day for 7 to 10 days.

There are free-living strongyloides known as *Pelodera* that can produce a creeping eruption also. Jones et al reported a case of widespread follicular, erythematous, dome-shaped papules and pustules that began within 24 h of working under a house. This eruption persisted for 1 month before presentation. Scraping the lesions revealed live and dead larvae of the free-living soil nematode *Pelodera strongyloides*. Treatment with oral thiabendazole led to resolution.

Dracunculiasis (Guinea Worm Disease, Dracontiasis, Medina Worm)

Guinea worm disease is now limited to remote villages in several sub-Saharan African countries. It is caused by *Dracunculus medinensis* and is contracted through drinking water that has been contaminated with infected water fleas in which *Dracunculus* is parasitic. In the stomach, the larvae penetrate into the mesentery, where they mature sexually in 10 weeks. Then the female worm burrows to the cutaneous surface to deposit her larvae and thus causes the specific skin manifestations. As the worm approaches the surface, it may be felt as a cordlike thickening and forms an indurated cutaneous papule. The papule may vesiculate and a painful ulcer develops, usually on the leg. The worm is often visible (Fig. 20-19). When the parasite comes in contact with water, the worm rapidly discharges its larvae, which are ingested by water fleas (*Cyclops*), contaminating the water.

The cutaneous lesion is usually on the lower leg, but it may occur on the genitalia, buttocks, or arms (Fig. 20-20). In addition to the ulcers on the skin, there may be urticaria, gastrointestinal upsets, eosinophilia, and fever.

The disease may be prevented by boiling drinking water, providing safe drinking water through boreholes, or filtering the water through mesh fibers. Native treatment consists of gradually extracting the worm a little each day, with care not to rupture it; in the event of such an accident, the larvae escape into the tissues and produce fulminating inflammation. Surgical removal is the treatment of choice. Metronidazole 500 mg/day resolves the local inflammation and permits

Fig. 20-19 Dracunculosis.

Fig. 20-20 Dracunculosis.

easier removal of the worm. Immersion in warm water promotes emergence of the worm.

Geenaway C. Drancuculiasis. CMAJ 2004;170:495.

Filariasis

Elephantiasis Tropica (Elephantiasis Arabum) Filariasis is a widespread tropical disorder caused by infestation with filarial worms of *Wuchereria bancrofti*, *Brugia malayi*, or *Brugia timori*. It is characterized by lymphedeina, with resulting hypertrophy of the skin and subcutaneous tissues, and by enlargement and deformity of the affected parts, usually the legs, scrotum, or labia majora. The disease occurs more frequently in young men than in women.

The onset of elephantiasis is characterized by recurrent attacks of acute lymphangitis in the affected part, associated with chills and fever (elephantoid fever) that lasts for several days to several weeks. These episodes recur over several months to years. After each attack the swelling subsides only partially, and as recrudescences supervene, thickening and hypertrophy become increasingly pronounced. The overlying epidermis becomes stretched, thin, and shiny, and in the course of years, leathery, insensitive, and verrucous or papillomatous from secondary pyogenic infection. There may be a dozen or more attacks in a year.

In addition to involvement of the legs and scrotum, the scalp, vulva, penis, female breasts, and arms are at times affected, either alone or in association with the other regions. The manifestations vary according to the part involved. When the legs are attacked, both are usually affected in a somewhat symmetrical manner, the principal changes occurring on the posterior aspects above the ankles and on the dorsa of the feet. At first, the thickening may be slight and associated with edema that pits on pressure (Fig. 20-21). Later, the parts become massive and pachydermatous, the thickened integument hanging in apposing folds, between which there is a fetid exudate (Fig. 20-22).

When the scrotum is affected, it gradually reaches an enormous size and the penis becomes hidden in it. The skin, which at first is glazed, later is coarse and vertucous, or, in far-advanced cases, ulcerated or gangrenous. Resistant urticaria may occur. Filarial orchitis and hydrocele are common. A testicle may enlarge rapidly to the size of an apple and be extremely painful. The swelling may subside within a few days, or the enlargement may be permanent. As a result of obstruction and dilation of the thoracic duct or some of its lower abdominal tributaries into the urinary tract, chyle appears in the urine, which assumes a milky appearance. Lobulated swellings of the inguinal and axillary glands, called varicose glands, are caused by obstructive varix and dilation of the lymphatic vessels.

Filaria are transmitted person-to-person by the bites of a variety of mosquitoes of the *Culex*, *Aedes*, and *Anopheles* species. The adult worms are threadlike, cylindrical, and creamy white. The females are 4 to 10 cm long. Microfilarial embryos may be seen coiled each in its own membrane near the posterior tip. Fully grown, sheathed microfilariae are 130 to 320 μ m long. The adult worms live in the lymphatic system, where they produce microfilariae. These either

Fig. 20-21 Filarial elephantiasis.

Fig. 20-22 Filarial elephantiasis. (Courtesy of James Fitzpatrick, MD)

remain in the lymphatic vessels or enter the peripheral bloodstream. An intermediate host is necessary for the further development of the parasite.

It is important to realize that infestation by the filaria is often asymptomatic, and elephantiasis usually occurs only if hundreds of thousands of mosquito bites are suffered over a period of years, with episodes of intercurrent streptococcal lymphangitis. Filariasis was endemic in the considerable Samoan population of Hawaii for half a century, and only one case of elephantiasis has occurred among this group.

Search for the microfilariae should be made on fresh coverslip films of blood (collected at night), urine, or other body fluid and examined with a low-power objective lens. Calcified adult worms may be demonstrated on x-ray examination and ultrasound can detect adult worms. At times adult filariae are found in abscesses or in material taken for pathologic examination. Specific serologic tests and a simple card tests for filarial antigen are available. The prognosis in regard to life is good, but living becomes burdensome unless the condition is alleviated.

Fig. 20-23 A and B, Lolasis. (Courtesy of Curt Samlaska, MD)

Dithylcarbamazine in increasing doses over a 14-day period is the treatment of choice. This regimen clears microfilariae but not adult worms. A single dose of ivermectin may also be effective. Doxycycline kills the intracellular symbiotic bacteria Wolbachia. This leads to long-term sterility of adult female worms. It is being studied to determine its place in the treatment of both bancroftian filariasis and onchercerciasis. A worldwide effort to eliminate these diseases is underway. Surgical operations have been devised to remove the edematous subcutaneous tissue from the scrotum and breast. Prophylactic measures consist of appropriate mosquito control. Diethylcarbamazine has been effective in mass prophylaxis and if a trip of over 1 month is planned to areas with endemic W. bancrofti and extensive exposures to mosquitoes is likely, taking 500 mg/day for 2 days each month is recommended.

Loaiasis (*Loa Ioa*, Calabar Swelling, Tropical Swelling, Fugitive Swelling)

Infection with Loa loa is often asymptomatic. In infected persons, the parasite develops slowly and there may even be an interval of as much as 3 years between infection and the appearance of symptoms, although the usual interval is 1 year. The first sign is often painful localized subcutaneous nonpitting edema called calabar or fugitive swelling (Fig. 20-23A). These are one or more slightly inflamed, edematous, transient swellings, usually about the size of a hen's egg. They usually last a few days and then subside, although recurrent swellings at the same site may eventually lead to a permanent cystlike protuberance. These swellings may result from hypersensitivity to the adult worm or to materials elaborated by it. Eosinophilia may be as high as 90% and often is between 60% and 80%.

The filariae may be noticed subcutaneously in the fingers, breasts, eyelids, or submucosally under the conjunctivae.

The worm may be in the anterior chamber of the eye, the myocardium, or other sites. It has a predilection for loose tissues such as the eye region, the frenum of the tongue, and the genitalia. The wanderings of the adult parasite may be noticed by a tingling and creeping sensation. The death of the filaria in the skin may lead to the formation of fluctuant cystic lesions.

Loaiasis is a form of filariasis caused by Loa loa, widely distributed in west and central Africa. It is transmitted by the mango fly, *Chrysops dimidia* or *Chrysops silacea*. This fly bites only in the daytime. Humans are the only important reservoir for the parasite.

The observation of the worm under the conjunctiva, calabar swellings, and eosinophilia establish the diagnosis. Demonstration of the characteristic microfilariae in the blood during the day is possible in only some 20% of patients. Specific serologic tests are available.

Removal of the adult parasite whenever it comes to the surface of the skin is mandatory (Fig. 20-23B). This must be done quickly by seizing the worm with forceps and placing a suture under it before cutting down to it. Worms that are not securely and rapidly grasped quickly escape into the deeper tissues.

Diethylcarbamazine kills both adults and microfilariae and is given in increasing doses for 21 days.

In regions in which onchocerciasis and loaiasis are both endemic and ivermectin is used in a community-based elimination strategy for onchocerciasis, simultaneously infected patients with a high *Loa loa* load have a high risk of serious side effects. If ivermectin treatment of these patients is undertaken, proper monitoring and appropriate supportive treatment should be available in anticipation of this risk. Diethylcarbamazine is an effective chemopreventive, using 300 mg/week in temporary residents of regions of Africa where *Loa loa* is endemic.

Onchocerciasis

The skin lesions are characterized by pruritus, dermatitis, and onchocercomata. The dermatitis is variable in its appearance and probably relates to chronicity of infection, age of the patients, geographic area in which it was acquired, and relative immune responsiveness. Early in the course of the infection an itchy papular dermatitis may occur, and in visitors who acquire the infection this may be localized to one extremity (Fig. 20-24). In Central America, papules may appear only on the head and neck area. This unusual localization of insect bite-appearing papules with excoriations may lead to the diagnosis in travelers returning to their home countries. In Central America, another manifestation of the acute phase is acute swelling of the face with erythema and itching, known as erisipela de la costa. In Zaire and Central America, an acute urticarial eruption is seen. The inflammation, which is accompanied by hyperpigmentation, is known as mal morado.

As time passes, the dermatitis becomes chronic and remains papular; however, thickening, lichenification, and depigmentation occur (Fig. 20-25). Later, atrophy may supervene. When the depigmentation is spotted, it is known as *leopard skin*; when the skin is thickened, it is called *elephant skin*. When local edema and thickened, wrinkled, dry dermatitic changes predominate, it is sometimes called *lizard skin*.

In Saudi Arabia, Yemen, and East Africa, a localized type of onchocerciasis exists called *sowda*, which is Arabic for "black." It is characterized by localized, pruritic, asymmetrical, usually darkly pigmented, chronic lichenified dermatitis of one leg or one body region. It is also known as the chronic hyperreactive type, and an association with anti-

Fig. 20-25 Onchocerciasis. (Courtesy of Debra Kalter, MD)

definsin antibodies suggests a reason for this enhanced reactivity against the parasite.

After a time, firm subcutaneous nodules, pea-sized or larger, develop on various sites of the body. These nodules are onchocercomas containing myriad microfilariae. These occur in crops, are frequently painful, and their site varies. In parts of Africa, where natives are wholly or nearly unclothed, the lesions occur on the trunk, axillae, groin, and perineum. In Central and South America, the head, especially the scalp, is the usual site of involvement.

Firm, nontender lymphadenopathy is a common finding in patients with chronically infected onchocerciasis. "Hanging groin" describes the loose, atrophic skin sack that contains these large inguinal nodes (Fig. 20-26).

In about 5% of affected persons, serious eye lesions arise late in the disease, gradually leading to blindness.

Onchocerciasis is caused by Onchocerca volvulus, which is transmitted to humans by the bite of the black fly of the genus Simulium. It breeds in fast-flowing streams. When the black fly bites, it introduces larvae into the wound. The larvae reach adulthood in the subdermal connective tissue in about 1 year. Then millions of the progeny migrate back into the dermis and the aqueous humor of the eye.

Onchocerciasis occurs in Africa on the west coast, in the Sahara, Sudan, and the Victoria Nile division, where this disease is known as river blindness. In Central and South America, it is to be found in Guatemala, Brazil, Venezuela, and southern Mexico.

Fig. 20-26 Onchocerciasis.

The presence of eosinophilia, skin lesions, and onchocercomas with ocular lesions is highly suggestive in endemic areas. Frequently the microfilariae may be found in skin shavings or dermal lymph, even when no nodules are detectable. The scapular area is the favorite site for procuring specimens for examination by means of a skin snip. This is performed in the field or office by lifting the skin with an inserted needle and then clipping off a small, superficial portion of the skin with a sharp knife or scissors. The specimen is laid in a drop of normal saline solution on a slide, covered with a coverslip, and examined under the microscope. The filariae wriggle out at the edges of the skin slice.

Specific serologic and polymerase chain reaction-based diagnostic tests from blood and skin biopsies are available. Other filarial parasites can be detected in similar systems. When patients suspected of having onchocerciasis were given a single oral dose of 50 mg of diethylcarbamazine, a reaction consisting of edema, itching, fever, arthralgias, and an exacerbation of pruritus was described as a positive Mazzotti test reaction, which supported the diagnosis of onchocerciasis. The reaction may be related to Wolbachia organisms within the worms.

Onchocercomas may be surgically excised whenever feasible. Ivermectin as a single oral dose of 150 μ g/kg is the drug of choice. Skin microfilaria counts remain low at the end of 6 months' observation. Ivermectin should be repeated every 6 months to suppress the dermal and ocular microfilarial counts. Doxycycline kills the intracellular symbiotic bacteria Wolbachia which leads to nematode sterility, and inhibits larval development and adult worm viability. It is being tested for long-term effects and determination of its place in the treatment of onchocerciasis and bancroftian filariariasis. If there is eye involvement, prednisone 1 mg/kg

should be started several days before treatment with ivermectin.

There are community-based treatment protocols that have the objective of eliminating onchocerciasis from endemic areas. Severe reactions may occur in patients simultaneously infected with Loa loa.

Trichinosis

Ingestion of Trichinella spiralis larva-containing cysts in inadequately cooked pork, bear, or walrus meat may cause trichinosis. It usually causes a puffy edema of the eyelids (Fig. 20-27), redness of the conjunctivae, and sometimes urticaria associated with hyperpyrexia, headache, erythema, gastrointestinal symptoms, muscle pains, and neurologic signs and symptoms. Ten percent of patients develop a bilateral, asymptomatic hand swelling that is especially prominent over the digits, and erythema along the perimeters of the palms and volar surfaces of the digits, which progresses to desquamation. In 20% of cases a nonspecific macular or petechial eruption occurs and splinter hemorrhages are occasionally present. Eosinophilia is not constant, but may be as high as 80%. In the average patient, eosinophilia begins about 1 week after infection and attains its height by the fourth week.

The immunofluorescence antibody test has the greatest value in establishing early diagnosis. The bentonite flocculation test, an enzyme-linked immunosorbent assay (ELISA) test, and other serologic tests are limited by their inability to detect infection until the third or fourth week.

Diagnosis is confirmed by a muscle biopsy that demonstrates larvae of *Trichinella spiralis* in striated muscle. Unfortunately, trichinae cannot usually be demonstrated unless the infection is very heavy, of over a month's duration, and the biopsy specimen is very large. A 2-mm thick slice of the muscle biopsy may be compressed between two glass slides to demonstrate the cysts.

The condition is treated with albendazole 400 mg twice a day for 14 days. Corticosteroidal agents are effective as a means of controlling the often severe symptoms and should be given at doses of 40 to 60 mg/day.

PNEUMOCYSTOSIS

Pneumocystis carinii has features characteristic of both protozoa and fungi. It is an opportunistic infection, occurring primarily as a pulmonary infection in AIDS patients. Extrapulmonary involvement is uncommon and usually occurs in the reticuloendothelial system. Skin findings are uncommon. At least half of reported cases are of nodular growths in the auditory canal with the remainder having nonspecific pinkto-skin colored papules and nodules which may ulcerate. On biopsy the dermis contains foamy material within which Giemsa-positive organisms are identified. A 3-week course of trimethoprim-sulfamethoxazole combination is the treatment of choice.

PHYLUM ARTHROPODA

This phylum contains more species than all the other phyla put together. The following classes are of dermatologic significance: Myriapoda, Insecta, and Arachnida. Mosquitoes, flies, ticks, and fleas transmit diseases throughout the world.

Prevention of Arthropod-Related Disease

Mosquitoes remain the most important vectors of arthropodborne disease, and mosquito control programs are an essential component of the public health efforts of many states. Insect repellents are effective in preventing disease transmission and are especially important during travel to areas endemic for vector-borne disease. Most are based on DEET (N,N-diethyl-3-methylbenzamide, previously called N,N-diethyl-m-toluamide). DEET has been tested against a wide range of arthropods, including mosquitoes, sandflies, ticks, and chiggers. The American Academy of Pediatrics recommends concentrations of 30% or less in products intended for use in children. As this represents a major market share for these products, many formulations that comply with the recommendation are available. Some evidence suggests that children do not have a higher incidence of adverse reactions when compared to adults, but even in adults there have been occasional reports of neurotoxicity. High concentrations of DEET can also produce erythema

and irritation or bullous eruptions. Extended-release products reduce the need for repeated application, and appear to minimize the risk of complications. Overall, DEET has a good safety record in widespread use. Picaridin (KBR 3023) is a piperidine-derived repellent ingredient that is also effective against a range of arthropods. In some studies, it has been shown to be less irritating than DEET while providing comparable efficacy. The best studies for the evaluation of repellents are field trials that involve a range of arthropods. Arm box studies are still performed, but must be interpreted with caution. In a well designed arm box study, soybean oil (Bite Blocker for Kids) performed reasonably well, and was second only to DEET in efficacy. Citronella did not perform well. Citronella candles have little documented efficacy. Neem oil is an effective mosquito repellent that is used in many areas of the world that are endemic for malaria.

Travelers to malaria-endemic areas should follow Centers for Disease Control (CDC) guidelines for malaria prophylaxis. They should also avoid night-time outdoor exposure and use protective measures such as repellents and bed netting. The anopheline mosquitoes that carry malaria tend to bite at night, so bed nets and screens are important measures. Mosquitoes that carry Dengue mostly bite during the day. Repellents play a greater role in protection against Dengue as it is more difficult to limit daytime outdoor activity. Mosquito control programs depend largely on drainage of stagnant water and spraying of breeding areas. In developing countries, water barrels may be stocked with fish or turtles to consume mosquito larvae. Both can soil the water and the relative risks must be evaluated. In some studies, the risk has clearly favored stocking the barrel. Mosquito traps, including the Mosquito Magnet, have been shown to be effective for the control of mosquitoes in limited areas. Generally, mosquitoes fly upwind to bite, and downwind to return to their resting area. Mosquito traps must be positioned between the breeding and resting areas, and the area to be protected. Mosquito traps commonly use CO₂, heat, and chemical attractants. Some Culex mosquitoes are repelled by octenol, and the manufacturer may provide guidelines for areas where the attractant should not be used.

Prevention of Disease from Ticks and Chiggers

Tick-borne diseases include rickettsial fevers, ehrlichiosis, Lyme disease, babesiosis, relapsing fever, and tularemia. Most require a sustained tick attachment of more than 24 h for effective transmission, and frequent tick checks with prompt removal of ticks is an important strategy for the prevention of tick-borne illness. Unfortunately, tick inspections frequently fail to identify the tick in time for prompt removal. Some data suggest that adult ticks are found and removed only 60% of the time within 36 h of attachment. Nymphal ticks are even more difficult to detect, and may be removed in as few as 10% of patients within the first 24 h. Because of this, repellents and acaricides remain critical to prevent tickborne illness. Permethrin has cidal activity against a wide range of arthropods. Some North African Hyalomma ticks are resistant to permethrin, and may exhibit a paradoxical pheromone-like attachment response when exposed to the agent, but permethrin performs very well with other species of ticks, as well as mosquitoes and chiggers. It can be used to treat clothing, sleeping bags, mosquito netting, and tents. Permethrin-treated clothing, used in conjunction with a

repellent, provides exceptional protection against bites in most areas of the world. Permethrin has a good record of safety, although there is a single case report of congenital leukemia with 11q23/MLL rearrangement in a preterm female infant whose mother had abused permethrin because of a pathologic fear of spiders. Permethrin can induce cleavage of the MLL gene in cell culture, providing a plausible link between the agent and the leukemia. It should be emphasized that permethrin in this case was not used according to the manufacturer's instructions, and the theoretical risk of carcinogenicity should be weighed against the very real risk of death from arthropod-borne disease. Cardiac glycosides have also been used topically as acaricides and have performed well in limited studies.

Ixodes scapularis is the major North American vector for Lyme disease, human granulocytic ehrlichiosis, and human babesiosis. An effective Lyme vaccine was marketed in the US, but proved to be a commercial failure and was voluntarily withdrawn from the market. Prevention of Lyme disease now centers on prevention of tick attachments, and prompt tick removal. Back yards and recreational areas adjacent to wooded areas have higher rates of tick infestation. Tick numbers can be reduced by deer fencing, removal of leaf debris, application of an acaricide, and by creating border beds with wood chip mulch or gravel. Bait boxes and deer feeding stations have been devised that are capable of delivering a topical acaricide while the animal feeds. Parasitic wasps control tick numbers in nature, but wasp populations may fluctuate, and investment in wasp-control may be a risky venture compared with other forms of tick control. Other natural forms of tick control have been investigated, as they have the potential to become self-sustaining in the environment, at least for a period of time. Fungi and nematodes show some promise. In southern states, fire ants control tick populations by eating tick eggs.

Prevention of Flea-Borne Illness

Fleas are important vectors of plague, endemic typhus, and *Rickettsia felis* (a spotted fever organism). They may also be vectors of cat scratch disease. Lufenuron is a maturation inhibitor that prevents fleas from breeding. It is commonly used in oral and injectable forms for the prevention of flea infestation in cats and dogs. Fipronil is used topically for the prevention of flea and tick infestation. Other agents in use include imidacloprid, selamectin, and nitenpyram. House sprays often include pyrethroids or pyriproxyfen. Powdered boric acid may be helpful for the treatment of infested carpets or floor boards. A knowledgeable veterinarian and an exterminator should be consulted.

CLASS MYRIAPODA

Morphologically, and genetically, the class Myriapoda is distinct from other groups of arthropods. This group contains the centipedes and millipedes. Both are capable of producing significant skin manifestations.

Centipede Bites (Chilopoda)

Centipede bites are manifested by paired hemorrhagic marks that form a chevron shape caused by the large paired mouthparts (Fig. 20-28). The bite is surrounded by an erythematous swelling (Fig. 20-29) that may progress into a brawny edema

Fig. 20-28 Centipede.

Flg. 20-29 Centipede bite.

or lymphangitis. Locally there may be intense itching and pain, often associated with toxic constitutional symptoms. Most centipede bites run a benign self-limited course, and treatment is only supportive. Children are often bitten when they try to handle centipedes. As some species of *Scolopendra in the* western US will attain a length of 15 to 20 cm, the child may describe it as a snake. Recognition of the characteristic chevron shape is important to avoid inappropriate treatment with snake antivenin. In the eastern US, the common house centipede, *Scutigera coleopterata*, does not bite humans. *Scolopendra subspinipes*, in Hawaii, inflicts a painful bite. As exotic species appear more commonly at pet stores and swap meets, envenomation by them will become more common.

In some tropical and subtropical areas, centipede bites account for about 17% of all envenomations (compared to the 45% caused by snakes and 20% by scorpious). Most bites occur at home and involve an upper extremity. Local pain and edema occur in up to 96% of patients, depending on the species involved. Treatment is largely symptomatic. Rest, ice, and elevation may be sufficient, but topical or intralesional anesthetics may be required in some cases. Tetanus immunization should be considered if the patient has not been immunized within the past 10 years. Centipede bites can result in Wells syndrome, requiring topical or intralesional corticosteroids. Rarely, bites may produce more serious toxic responses, including rhabdomyolysis and acute renal failure. These have been reported following the bite of Scolopendra heros, the giant desert centipede. Although centipedes have sometimes been found in association with corpses, injuries from the centipede tend to be postmortem and are rarely the cause of death. Ingestion of centipedes by children is usually associated with transient, self-limited toxic manifestations.

Millipede Burns (Diplopoda)

Some millipedes secrete a toxic liquid that causes a brownish pigmentation or burn when it comes into contact with skin. Burns may progress to intense erythema and vesiculation. Millipedes may be found in laundry hung out to dry, and millipede burns in children have been misinterpreted as signs of child abuse. Recognition of the characteristic curved shape of the burn can be helpful in preventing misdiagnosis. Some millipedes can squirt their venom and ocular burns are reported. Washing off the toxin as soon as possible will limit the toxic effects. Other treatment is largely symptomatic.

Diplipods (Fig. 20-30) have evolved a complex array of chemicals for self-defense. Some primates take advantage of these chemicals. Two millipede compounds, 2-methyl-1,4benzoquinone and 2-methoxy-3-methyl-1,4-benzoquinone, demonstrate a repellent effect against *Aedes aegypti* mosquitoes. Tufted and white-faced capuchin monkeys anoint themselves with the secretions to ward off mosquitoes. Effective commercial repellents are available for human use and millipede juice is not recommended.

Weldon PJ, et al: Benzoquinones from millipedes deter mosquitoes and elicit self-anointing in capuchin monkeys (Cebus spp.). Naturwissenschaften 2003;90:301.

CLASS INSECTA

Order Lepidoptera

Order Lepidoptera includes butterflies and moths and their larval forms, caterpillars. Severe systemic reactions have occurred as the result of ingestion of some caterpillars, and with some species the sting alone can produce severe toxicity. Lonomia achelous, found in Latin America, can cause a fatal bleeding diathesis. The Spanish pine caterpillar, Thaumetopoea pityocampa, causes both dermatitis and anaphylactoid symptoms. Pine caterpillars are also an important cause of systemic reactions in China and Israel. The tussock moth, Orgyia pseudotsugata, causes respiratory symptoms in forestry workers in Oregon.

Caterpillar Dermatitis Irritation is produced by the hairs coming in contact with the skin. Toxins in the hairs can

Fig. 20-30 Millipede.

Fig. 20-31 Puss caterpillar.

Flg. 20-33 Saddleback caterpillar.

Fig. 20-32 Characteristic railroad track purpura of a puss caterpillar sting.

produce severe pain, local pruritic erythematous macules, and wheals, depending on the species. If the hairs get into the clothing, widespread persistent dermatitis may result. Not only the caterpillars, but their egg covers and cocoons also commonly contain stinging hairs. In the US the most common caterpillars of medical importance are the browntail moth caterpillar (Nygmia phoeorrhoea), puss caterpillar (Megalopyge opercularis) (Figs 20-31 and 20-32), saddleback caterpillar (Sibine stimulae) (Fig. 20-33), io moth caterpillar (Automeris io), crinkled flannel moth caterpillar (Megalopyge crispata), Oklahoma puss caterpillar (Lagoa crispate), buck moth caterpillar (Hemileuca maia), and flannel moth caterpillar (Norape cretata). The hairs of the European processionary caterpillar (Thaumetopoea processionea) are especially dangerous to the eyes, but ophthalmia nodosa (a papular reaction to embedded hairs) can be seen with a wide variety of caterpillars and moths.

Moth Dermatitis Moth dermatitis may be initiated by the hairs of the brown-tail moth (*Euproctis chrysorrhoea*), goat moth (*Cossus cossus*), puss moth (*Dicranura vinula*), gypsy moth (*Lymantria dispar*), and Douglas fir tussock moth (*Hemenocampa pseudotsugata*). In Latin America, the moths of the genus *Hylesia* are most frequently the cause of moth dermatitis. Severe conjunctivitis and pruritus are the first signs, and may persist for weeks aboard ships that have

docked in ports where the moth is common. Caripito itch is named after Caripito, Venezuela, a port city where the moth is found. Korean yellow moth dermatitis is caused by *Euproctis flava* Bremer.

Topical applications of various analgesics, antibiotics, and oral antihistaminics are of little help. Topical or oral corticosteroids are sometimes helpful, as is scrubbing and tape stripping of skin. Contaminated clothing may need to be discarded if derinatitis persists after the clothing is washed.

Order Hemiptera

The true bugs belong to the order Hemiptera. The order includes bedbugs, water bugs, chinch bugs, stink bugs, squash bugs, and reduviid bugs (kissing bugs, assassin bugs). The latter are vectors of South American trypanosomiasis. In most true bugs, the wings are half sclerotic and half membranous, and typically overlap. In bedbugs, the wings are vestigial.

Cimicosis (Bedbug Bites) Bedbugs have flat oval bodies and retroverted mouthparts used for taking blood meals (Fig. 20-34). *Cimex lectularius* is the most common

Fig. 20-35 Tropical bedbug.

Fig. 20-36 Bedbug.

species in temperate climates, and *Cimex hemipterus* in tropical climates. Both are reddish brown, and about the size of a tick. *C. hemipterus* (Fig. 20-35) is somewhat longer than *C. lectularius* (Fig. 20-36). They breed through a process referred to as traumatic insemination, where the male punctures the female and deposits sperm into her body cavity. Bedbugs hide in cracks and crevices, then descend to feed while the victim sleeps. It is common for bedbugs to inflict a series of bites in a row ("breakfast, lunch and dinner"). Bullous and urticarial reactions occur. In some refugee camps, almost 90% of residents suffer from bedbug bites. Bedbugs are suspected vectors for Chagas' disease and hepatitis B.

Bedbugs often infest bats and birds, and these hosts may be responsible for infestation in houses. Management of the infestation may require elimination of bird nests and bat roosts. Cracks and crevices should be eliminated, and the area treated with an insecticide such as dichlorvos or permethrin. As most insecticides have poor residual effect on mud bricks, wood, and fabric, frequent retreatment may be necessary. Microencapsulation of insecticides enhances persistence. Permethrin-impregnated bednets have been shown to be effective against bedbugs in tropical climates.

Fig. 20-37 Triatome bite.

Myamba J, et al: Pyrethroid resistance in tropical bedbugs, *Cimex hemipterus*, associated with use of treated bednets. Med Vet Entomol 2002;16:448.

Reduviid Bites Triatome reduviid bugs (kissing bugs, assassin bugs, conenose bugs) descend on their victims while they sleep, and feed on an exposed area of skin. The bite is typically painless, although they are capable of producing a more painful defensive bite. Swelling and itching occur within hours after the bite (Fig. 20-37). Many Latin American species have a pronounced gastrocolic reflex and defecate when they feed. Romana's sign is unilateral eye swelling after a night-time encounter with a triatome bug. Trypanosoma cruzi is transmitted by the feces and rubbed into the bite. American trypanosomiasis can produce heart failure and megacolon. Triatome bugs infest thatch, cracks and crevices, and infestation is associated with poor housing conditions. In nonendemic areas, bites are sporadic, and are often followed by a red swelling suggestive of cellulitis. Anaphylaxis has also occurred. Arilus cristalus, the wheal bug, is widely distributed and has an extremely painful defensive bite. It is not known to carry disease.

Elston DM, et al: What's eating you? Triatome reduviids Cutis 1999;63:63.

Order Anoplura

Pediculosis Three varieties of these flattened, wingless insects infest humans, *Pediculus humanus* var. *capitis* (the head louse), *P. humanus* var. *corporis* (the body louse), and *Phthirus pubis* (the pubic or crab louse) (Fig. 20-38). Rarely, zoonotic lice or louse-like psocids will cause infestation.

Pediculosis Capitis

Pediculosis capitis is more common in children, but occurs in adults also. Patients present with intense pruritus of the

Fig. 20-38 Crab louse.

scalp, and often have posterior cervical lymphadenopathy. Excoriations and small specks of louse dung are noted on the scalp, and secondary impetigo is common. Lice may be identified, especially when combing the hair. Nits may be present throughout the scalp, but are most common in the retroauricular region. Generally, only those ova close to the scalp are viable, and nits noted along the distal hair shaft are empty egg cases. In very humid climates, however, viable ova may be present along the entire length of the hair shaft. Peripilar keratin (hair) casts are remnants of the inner root sheath that encircle hair shafts. They may be mistaken for nits. While nits are firmly cemented to the hair, casts move freely along the hair shaft.

Effective therapeutic agents must kill or remove both lice and ova. Permethrin is the most widely used pediculicide in the US. It is available as an over-the-counter 1% cream rinse (Nix) and a 5% prescription cream (Elimite) that is marketed for the treatment of scabies. The 1% cream rinse must be applied after shampooing and drying the hair completely. Applying to dry hair lessens dilution of the medication. Product labeling states the medication should be applied for 10 min, then rinsed off, but longer applications may be required. Shampooing should not take place for 24 h afterward. Permethrin has a favorable safety profile, although as noted above congenital leukemia has been reported in a preterm infant whose mother had heavily abused aerosolized permethrin.

Pyrethrins, combined with piperonyl butoxide (RID, A-200, R+C Shampoo), are sold over the counter. Malathion 0.5% lotion (Ovide) is marketed as a prescription product in the US. The efficacy is partly dependent upon the vehicle, and the product is flammable and can be irritating to the eyes. As it has not been widely used in the US, resistance has not emerged. Lindane is also marketed as a prescription product. The efficacy is somewhat lower, and the product has potential neurotoxicity if abused. Carbaryl is used in many parts of the world, but not in the US. Various "natural" remedies are marketed that contain coconut oil, anise oil, and ylang ylang oil, but these agents are potential contact allergens, and there are few data regarding their safety and efficacy. Aliphatic alcohols show promise as pediculicides, and crotamiton (Eurax), an antiscabetic agent, has some efficacy in the treatment of pediculosis. As no treatment is reliably ovidical, retreatment in a week is reasonable for all patients. Combing with a metal or plastic nit comb is an important adjunctive measure. The hair should be wet, and nit removal is facilitated by a conditioner, 8% formic acid solution (Step 2), or an enzymatic nit removal system (Clear and others).

Resistance to pediculicides is an emerging problem in many parts of the world. The emergence of resistance to an agent is related to the frequency with which that agent is used. Knockdown resistance (KDR) is a common mechanism of resistance that manifests as lack of immobilization of the lice. Responsible gene mutations (T929I and L932F) have been identified and can be used to screen for KDR. In countries like the US, where permethrin is used commonly, permethrin-resistant lice have emerged. Cross-resistance among pyrethroids is typical. In the UK, resistance to malathion has been reported, and multidrug-resistant lice have been identified.

KDR results in slower killing of lice, but may be overcome to some degree by longer applications. Monooxygenase-based resistance to pyrethrins may be overcome by synergism with piperonyl butoxide. Sequential use of pediculicides may be useful in overcoming resistance, and systemic agents may play some role. Trimethoprim-sulfamethoxazole has been shown to be effective as an off-label oral agent, although data regarding efficacy are mixed. For practical purposes, physical modalities are useful only as adjunctive measures. Shaving the head will cure head lice, but has poor patient acceptance in most cultures. Wet combing produces a cure rate of only 38% when used alone. Occlusive agents that asphyxiate the louse have great appeal because of their lack of toxicity. Those currently available are best used as adjunctive therapy, together with a pediculicide. Simple public health measures are also of value when epidemics of louse infestation occur in schools. Hats, scarves, and jackets should be stored separately under each child's desk. Louse education and inspections by the school nurse facilitate targeted treatment of infested individuals.

Pediculosis Corporis

Pediculosis corporis (pediculosis vestimenti, "vagabond's disease") is caused by body lice that lay their eggs in the seams of clothing. The parasite obtains its nourishment by descending to the skin and taking a blood meal. Generalized itching is accompanied by erythematous and copper-colored macules, wheals, and lichenification. Secondary impetigo and furunculosis are common.

Body louse infestation is differentiated from scabies by the lack of involvement of the hands and feet. Infestation by both lice and scabies is common, and a given patient may suffer from lice, scabies and flea infestation.

Lice may live in clothing for 1 month without a blood meal. If discarding the clothing is feasible, this is best. Destruction of body lice can also be accomplished by laundering the clothing and bedding. Clothing placed in a dryer for 30 min at 65° C (149° F) is reliably disinfected. Pressing clothing with an iron, especially the seams, is also effective. Permethrin spray or 1% malathion powder can be used to treat clothing and reduce the risk of reinfestation.

Body lice are vectors for relapsing fever, trench fever, and epidemic typhus. These diseases are most prevalent among refugee populations. The trench fever organism is also an important cause of endocarditis among the homeless.

Pediculosis Pubis (Crabs)

Pthirius pubis, the crab louse, is found in the pubic region, as well as hairy areas of the legs, abdomen, chest, axillae, and arms. Pubic lice may also infest the eyelashes and scalp. The lice spread through close physical contact, and are commonly transmitted sexually. A diagnosis of pediculosis pubis should initiate a search for other STDs, including HIV disease. Contaminated bedding is also a source of infestation. Pubic louse nits are attached to the hairs at an acute angle. Other than the presence of lice and nits in the hair, the signs and symptoms are similar to those of body louse infestation.

Occasionally, blue or slate-colored macules occur in association with pediculosis publs. These macules, called *maculue cerulene*, are located chiefly on the sides of the trunk and on the inner aspects of the thighs. They are probably caused by altered blood pigments.

Treatment of pediculosis publis is similar to that for head lice. The affected person's sexual contacts should be treated simultaneously. For eyelash involvement, a thick coating of petrolatum can be applied twice daily for 8 days, followed by mechanical removal of any remaining nits. Fluorescein is also effective. Clothing and fomites should be washed and dried by machine or laundered and ironed.

Order Diptera

Order Diptera includes the two-winged biting flies and mosquitoes. Adult dipterids bite and spread disease, while larvae parasitize humans in the form of myiasis. Medically important families of flies include the *Tabanidae* (horsefly, deerfly, gadfly), which inflict extremely painful bites, and the *Muscidae* (housefly, stablefly, and tsetse fly). Tsetse fly bites transmit African trypanosomiasis. *Simulidae* include the black fly (buffalo gnat, turkey gnat), the vector of onchocerciasis. These flies are dark colored and "hunchbacked." They may produce extremely painful bites that may be associated with fever, chills, and lymphadenitis. Black flies are seasonal annoyances in the northern US and Canada.

Psychodidae sandflies (Diptera: Phlebotominae) are small, hairy-winged flies that transmit leishmaniasis, sandfly fever, and verruga peruana. Sandfly fever viruses are a problem in Africa, the Mediterranean basin, and Central Asia, and are carried by Phlebotomus flies. Lutzomyia flies are common in Latin America and South Texas. Culicidae, or mosquitoes, are vectors of many important diseases, such as filariasis, malaria, dengue, and yellow fever. Their bites may cause severe urticarial reactions. Ceratopogonidae, the biting midges or gnats, fly in swarms and produce erythematous, edematous lesions at the site of their bite.

Mosquito Bites Moisture, warmth, CO₂, estrogens, and lactic acid in sweat attract mosquitoes. Drinking alcohol also stimulates mosquito attraction. Mosquito bites are a common cause of papular urticaria. More severe local reactions are seen in young children, individuals with immunodeficiency, and those with new exposure to indigenous mosquitoes. Both necrotizing fascitis and the hemophagocytic syndrome have been reported following mosquito bites, and exaggerated hypersensitivity reactions to mosquito bites are noted in a wide variety of Epstein-Barr virus (EBV)-associated lymphoproliferative disorders, especially natural killer (NK) cell proliferations. Mosquito bites may play a key role in reactivation of latent EBV infection.

- Verma SB: Necrotizing fascitis induced by mosquito bite. J Eur Acad Dermatol Venereol 2003;17:591.

Ked ltch The sheep ked (*Melophagus ovinus*) feeds by thrusting its sharp mouth parts into the skin and sucking blood. Occasionally, it attacks woolsorters and sheepherders, causing pruritic, often hemorrhagic papules, nearly always with a central punctum. Deer keds attack humans in a similar way. The papules are very persistent and may last for up to 12 months. Favorite locations are the hips and the abdomen.

Myiasis Myiasis is the infestation of human tissue by fly larvae. Forms of infestation include wound myiasis, furuncular myiasis, plaque myiasis, creeping dermal myiasis and body cavity myiasis. Wound myiasis occurs when flies lay their eggs in an open wound. Furuncular myiasis often involves a mosquito vector that carries the fly egg. Plaque myiasis typically involves many maggots and occurs after flies lay their eggs on clothing. Creeping myiasis develops when the larvae of the Gasterophilus fly wander intradermally. The most common species are Gasterophilus nasalis and Gasterophilus intestinalis. An itching pink papule develops, followed by a tortuous line that extends by 1 to 30 cm a day. Body cavity myiais may involve the orbit, nasal cavity, gastrointestinal tract, or urogenital system.

The human botfly, Dermatobia hominis, is a common cause of furuncular myiasis (Fig. 20-39) in the neotropical regions of the New World. The female glues its eggs to the body of a mosquito, stablefly, or tick. When the unwitting vector punctures the skin by biting, the larva emerges from the egg and enters the skin through the puncture wound. Over a period of several days a painful furuncle develops in which the larva is present. Other larvae that frequently cause furuncular lesions in North America are the common

Fig. 20-39 Mylasis.

cattle grub (Hypoderma lineatum), rabbit botfly (Cuterebra cuniculi), and Wohlfahrtia vigil. This last fly can penetrate infant skin, but not adult skin. Thus, nearly all reported cases have occurred in infants. The New World screw worm, Cochliomyia hominivorax, often involves the head and neck region. Larvae of Calliphoridae flies, especially Phaenicia sericata, the green blowfly, cause wound myiasis. Other blowflies, flesh flies (Sarcophagidae), and humpbacked flies (Phoridae) are less common causes of wound myiasis. In tropical Africa the Tumbu fly (Cordylobia anthropophaga) deposits her eggs on the ground or on clothing. The young maggots penetrate the skin and often form a plaque with many furuncular-appearing lesions. Cordylobia ruandae and Cordylobia rodhaini are less frequent causes of plaque myiasis.

Removal of the maggots of furuncular myiasis can be accomplished by injection of a local anesthetic into the skin, which causes the larva to bulge outward. The opening of the furuncle can also be occluded with hair gel, surgical lubricant, lard, petrolatum, or bacon, causing the larva to migrate outward.

Order Coleoptera

Blister Beetle Dermatitis Blister beetle (Fig. 20-40) dermatitis occurs after contact with several groups of beetles. The Meloidae and Oedemeridae families produce injury to the skin by releasing a vesicating agent, cantharidin. Members of the family Staphylinidae (genus Paederus) contain a different vesicant, pederin. None of the beetles bites or stings; rather, they exude their blistering fluid if they are brushed against, pressed, or crushed on the skin. Many blister beetles are attracted at night by fluorescent lighting.

Slight burning and tingling of the skin occur within minutes, followed by the formation of bullae, often arranged in a linear fashion. "Kissing lesions" are observed when the blister beetle's excretion is deposited in the flexures of the elbows or other folds. Ingestion of beetles or cantharidin results in poisoning, presenting with hematuria and abdominal pain. In many tropical and subtropical habitats, rove beetles (genus *Paederus*) produce a patchy or linear erythematous vesicular eruption. In parts of South America, it is known as *podo*. It occurs frequently during the rainy season and appears predominantly on the neck and exposed parts. In the American southwest, outbreaks of rove beetle dermatitis have followed unusually rainy periods. In southeastern Australia, corneal erosions are caused by small Corylophidae beetles (*Orthoperus spp*).

Treatment consists of drainage of the bullae and application of cold wet compresses and topical antibiotic preparations. Early cleansing with acetone, ether, soap, or alcohol may be helpful to remove cantharidin.

Other Beetles Papulovesicular and urticarial dermatitis is caused by the common carpet beetle (Dermestidae: Anthrenus scrophulariae). The eruption involves the chest, neck, and forearms. The larvae inhabit warm houses throughout the winter months. They are reddish brown, fusiform, about 6 mm long, and covered by hairs. A generalized pruritic eruption has been attributed to the larvae of the carpet beetle Anthrenus verbasci. Bombardier beetles of the family Carabidae (subfamily Brachininae) can cause skin burns with a deep yellow-brown color. Chemicals released when these beetles are crushed include acids, phenols, hydrocarbons, and quinines. When the beetle is threatened, chemical reactions produce an explosive spray of boiling hot benzoquinones from the tip of the abdomen. Dermestidae (skin beetles) and Cleridae (bone beetles) infest exposed human remains and are useful in estimating the postmortem interval.

Order Hymenoptera

Hymenopterids include bees, wasps, hornets, and ants. Stings by any of these may manifest the characteristic clinical and histologic features of eosinophilic cellulitis (Wells syndrome) complete with flame figures.

Bees and Wasps Yellowjackets are the principal cause of allergic reaction to insect stings, because they nest in the ground or in walls and are disturbed by outdoor activity, such as gardening or lawn mowing. Bees are generally docile and sting only when provoked, although Africanized bees display aggressive behavior. The allergens in vespid venom are phospholipase, hyaluronidase, and a protein known as *antigen 5*. Bee venom contains histamine, mellitin, hyaluronidase, a high molecular weight substance with acid phosphatase activity, and phospholipase A. The barbed ovipositor of the honeybee is torn out of the bee and remains in the skin after stinging. The bumble bee, wasp, and hornet are *able to withdraw their stinger*.

The reaction to these stings ranges from pain and mild local edema to exaggerated reactions that may last for days. Serum sickness, characterized by fever, urticaria, and joint pain may occur 7 to 10 days after the sting. Severe anaphylactic shock and death may occur within minutes of the sting. Most hypersensitivity reactions have been shown to be mediated by specific IgE antibodies. Anaphylaxis to vespids may also be the presenting symptom of mastocytosis, with no demonstrable specific IgE against wasp venom.

Treatment of local reactions consists of immediate application of ice packs or topical anesthetics. Chronic reaction sites may be injected with triamcinolone suspension diluted to 5 mg/mL with 2% lidocaine. Oral prednisone may be required for severe local reactions.

For severe systemic reactions, 0.3 mL of epinephrine (1:1000 aqueous solution) is injected intramuscularly. This may need to be repeated after 10 min. Susceptible persons should carry a source of injectable epinephrine. Corticosteroids and epinephrine may be required for several days following severe reactions. Hyposensitization by means of venom immunotherapy can reduce the risk of anaphylaxis in people at risk. Those at risk should be evaluated by an allergist.

Ants The sting of most ants is painful, but that of the fire ants (*Solenopsis invicta, Solenopsis geminata, or Solenopsis richteri*) is especially painful. Fire ants are vicious and will produce many burning, painful stings within seconds if their mound is disturbed. The sting causes intense pain and whealing. Later, an intensely pruritic sterile pustule develops at the site (Fig. 20-41). Anaphylaxis, seizures, and mononeuropathy have been reported. The sting of harvester ants and soldier ants may produce similar reactions. Treatment options are similar to those for vespid stings.

Fig. 20-41 Sterile pustules at the site of fire ant stings.

Fig. 20-42 Cat flea.

Order Siphonaptera

Fleas are wingless, with highly developed legs for jumping. They are blood-sucking parasites, infesting most warmblooded animals. Fleas are important vectors of plague, endemic typhus, brucellosis, melioidosis, and erysipeloid.

Pulicosis (Flea Bites) The species of fleas that most commonly attack humans are the cat flea (*Ctenocephalides felis*) (Fig. 20-42), human flea (*Pulex irritans*) (Fig. 20-43), dog flea (*Ctenocephalides canis*), and oriental rat flea (*Xenopsylla cheopis*) (Fig. 20-44). The stick tight flea (*Echidnophaga gallinacea*) (Fig. 20-45), mouse flea, (*Leptopsylla segnis*), and chicken flea (*Ceratophyllus gallinae*) are sometimes implicated.

Fig. 20-43 Human flea.

Two hairs Flattened head Broad lacinia

Fig. 20-45 Stick-tight flea.

Fleas are small, brown insects about a 16th of an inch long, flat from side to side, with long hind legs. They slip into clothing or jump actively when disturbed. They bite about the legs and waist and may be troublesome in houses where there are dogs or cats. The lesions are often grouped and may be arranged in zigzag lines. Hypersensitivity reactions may appear as papular urticaria, nodules or bullae. Camphor and menthol preparations, topical corticosteroids, and topical anesthetics can be of benefit.

Vectors of Disease Xenopsylla cheopis and Xenopsylla braziliensis are vectors of plague and endemic typhus. The cat flea (*Ctenocephalides felis*) is the vector for *R. felis*. Plague and tularemia are transmitted by the squirrel flea, *Diamanus montanus*. Several species of flea are intermediate hosts of the dog tapeworm and rat tapeworm, which may be an incidental parasite of humans.

Tungiasis Tunga penetrans is also known as *nigua*, the chigoe, sand flea, or jigger. It is a reddish-brown flea about 1 mm long. It resides in the Caribbean, equatorial Africa, Central and South America, India, and Pakistan. It was first reported in crewmen who sailed with Christopher Columbus.

The impregnated female chigoe burrows into the skin, often adjacent to a toenail. The eggs develop and drop to the ground. These eggs develop into larvae, which form cocoons from which the insects emerge in about 10 days. Skin lesions are pruritic swellings the size of a small pea. These may occur on the ankles, feet, soles, as well as the anogenital areas. The lesions become extremely painful and secondarily infected.

Curettage or excision of the burrows is recommended. Topical ivermectin, metrifonate or thiabendazole can be used, and oral thiabendazole, 25 mg/kg/day, has been effective in heavily infested patients. Antibiotics should be used for the secondary infection and tetanus prophylaxis given. These lesions can be prevented by the wearing of shoes. Infested ground and buildings may be disinfected by the use of insecticides and growth inhibitors.

Fig. 20-46 Dermacentor variablilis.

CLASS ARACHNIDA

Arachnida includes the ticks, mites, spiders, and scorpions. Adult and nymph stages of arachnids have four pairs of legs, while larval forms have six legs. Their bodies consist of cephalothorax and abdomen, in contrast to insects which have three body segments.

Order Acarina

Tick Bite Several varieties of the family Ixodidae (hard ticks) and Argasidae (soft ticks) will attack human skin, but only hard ticks remain attached. In the US, the wood tick (Dermacentor andersoni) is an important disease vector in western states. It carries Rocky Mountain spotted fever, tularemia, ehrlichiosis, and Colorado tick fever. The dog tick (Dermacentor variabilis) (Fig. 20-46) is prevalent in the eastern states, and is the most common vector of Rocky Mountain spotted fever. It also carries tularemia. The brown dog tick (Rhipephalus sanguineus) (Fig. 20-47) is a vector of Rocky Mountain spotted fever, tularemia, and Boutonneuse fever. The lone star tick (Amblyomma americanum) (Fig. 20-48) carries Rocky Mountain spotted fever, tularemia, and human monocytic ehrlichiosis. Ixodes ricinus in Europe and Ixodes scapularis and Ixodes pacificus in the US transmit Borrelia burgdorferi, the cause of Lyme disease. Ixodes ticks also transmit human granulocytic ehrlichiosis and babesiosis.

The female hard tick attaches itself to the skin by sticking its proboscis into the flesh to suck blood from the superficial vessels. The insertion of the hypostome is generally unnoticed by the subject. The attached tick may be mistaken by the patient as a new mole. The parasite slowly becomes engorged and then falls off. During this time, which may last

Fig. 20-47 Rhipicephalus tick, engorged female. physiology and possibility of misdiagnosis. Neurology 2002;59:1088.

Mites

Scabies

Surcoptes scabiei, the itch mite, is an oval, ventrally flattened mite with dorsal spines. The fertilized female burrows into the stratum corneum and deposits her eggs. Scabies is characterized by pruritic papular lesions, excoriations, and burrows. Sites of predilection include the finger webs, wrists, axillae, areolae, umbilicus, lower abdomen, genitals, and buttocks. An imaginary circle intersecting the main sites of involvement-axillae, elbow flexures, wrists and hands, and crotch-has long been called the circle of Hebra. In adults, the scalp and face are usually spared, but in infants lesions are commonly present over the entire cutaneous surface. The burrows appear as slightly elevated, gravish, tortuous lines in the skin. A vesicle or pustule containing the mite may be noted at the end of the burrow, especially in infants and children. To identify burrows quickly, a drop of India ink or gentian violet can be applied to the infested area, then removed with alcohol. Thin threadlike burrows retain the ink.

The eruption varies considerably, depending on the length of infestation, previous sensitization, and previous treatment. It also varies with climate and the host's immunologic status. Lichenification, impetigo, and furunculosis may be present. Bullous lesions may contain many eosinophils, resembling bullous pemphigoid. Positive immunofluorescent findings may also be noted. Scabies may also resemble Langerhans cell histiocytosis clinically and histologically. Misdiagnosis has lead to systemic treatment with toxic agents.

Dull red nodules may appear during active scabies; these are 3 to 5 mm in diameter, may or may not itch, and persist on the scrotum, penis, and vulva. Intralesional steroids, tar, or excision are methods of treatment for this troublesome condition, termed *nodular scabies*. Histologically, the lesions may suggest lymphoma.

Crusted scabies (Norwegian, or hyperkeratotic, scabies) is found in immunocompromised or debilitated patients, including those with neurologic disorders, Down syndrome, organ transplants, graft-versus-host disease, adult T-cell leukemia, leprosy, or AIDS. In these patients, the infestation assumes a heavily scaling and crusted appearance. Crusts and scales teem with mites, and there is involvement of the face and especially the scalp. Itching may be slight. Psoriasislike scaling is noted around and under the nails. The tips of the fingers are swollen and crusted; the nails are distorted. Severe fissuring and scaling of the genitalia and buttocks may be present. Pressure-bearing areas are the sites of predilection for the heavy keratotic lesions, in which the mites may abound.

Scabies is usually contracted by close personal contact, although it may also be transmitted by contaminated linens and clothing. Screening for other STDs is appropriate. Sensitization begins about 2 to 4 weeks after onset of infection. During this time the parasites may be on the skin and may burrow into it without causing pruritus or discomfort. Severe itching begins with sensitization of the host. In reinfections, itching begins within days and the reaction may be clinically more intense. The itching is most intense at night, whereas during the daytime the pruritus is tolerable but persistent. The eruption does not involve the face or scalp in adults. In

Fig. 20-48 Lone star tick.

for 7 to 12 days, the patient may suffer from fever, chills, headache, abdominal pain, and vomiting. This is called *tick bite pyrexia*. Removal of the engorged tick causes a subsidence of the general symptoms in 12 to 36 h.

The bites may be followed by small, severely pruritic, fibrous nodules (tick bite granulomas) that persist for months, or by pruritic circinate and arciform localized erythemas that may continue for months.

Tick Paralysis Tick paralysis most commonly affects children, and carries a mortality rate of about 10%. Flaccid paralysis begins in the legs, then the arms, and finally the neck, resembling Landry-Guillain-Barré syndrome. Bulbar paralysis, dysarthria, dysphagia, and death from respiratory failure may occur. Prompt recovery occurs if the tick is found and removed before the terminal stage. *Dermacentor* ticks in North America and *Ixodes* ticks in Australia are the most important causes of tick paralysis. As *Dermacentor* ticks commonly attach to the scalp, the tick may go unnoticed.

Vedanarayanan VV, et al: Tick paralysis in children: electro-

Fig. 20-49 Scabies mite, ova, and feces.

women, itching of the nipples associated with a generalized pruritic papular eruption is characteristic; in men, itchy papules on the scrotum and penis are equally typical. When more than one member of the family has pruritus, a suspicion of scabies should be aroused. Whenever possible, though, it is advisable to identify the mite, as a diagnosis of scabies usually requires treatment of close physical contacts in addition to the patient. Because scabies cannot always be excluded by examination, treatment on presumption of scabies is sometimes necessary.

Positive diagnosis is made only by the demonstration of the mite under the microscope (Fig. 20-49). A burrow is sought and the position of the mite is determined. A surgical blade or sterile needle is used to remove the parasite. A drop of mineral or immersion oil can be placed on a lesion and gently scraped away with the epidermis beneath it. The majority of mites are found on the hands and wrists, less frequently (in decreasing order) at the elbows, genitalia, buttocks, and axillae. Children have often gathered mites and ova under the nails when scratching. A blunt curette can be used to gather material from under the nails for examination.

Permethrin 5% cream (Elimite) is the most widely used medication for scables. It is a synthetic pyrethroid that is lethal to mites and has low toxicity for humans. Lindane (y-benzene hexachloride) is also effective, with a low incidence of adverse effects when used properly. Because of the availability of less toxic agents, lindane is rarely used as a first-line agent. In much of the world, benzyl benzoate and 10% precipitated sulfur in white petrolatum are used to treat scabies. The scabicide should be thoroughly rubbed into the skin from the neck to the feet, with particular attention given to the creases, perianal areas, umbilicus, and free nail edge and folds. It is washed off 8 to 10 h later. Clothing and bed linen are changed and laundered thoroughly. Crotamiton (Eurax) has a lower cure rate than other available agents. When used, it should be applied on 5 successive nights and washed off 24 h after the last use.

Ivermectin has been used to control onchocerciasis since 1987, and is marketed in the US for the treatment of strongyloides. Numerous publications attest to its efficacy in treating scabies. It is supplied as 3- and 6-mg pills, and is usually given at a dose of $200 \mu g/kg$. Although an oral treatment is very convenient, it may not be any more effective than topical therapy. In the crusted type, it should be used in conjunction with a topical agent. It may need to be repeated two or three times at intervals of 1 to 2 weeks. The drug appears to have a good margin of safety, although neurotoxicity may be possible.

Individuals in close contact with the patient should be treated. Scabies in long-term healthcare institutions is an increasing problem. Other residents, staff, and visitors may be affected, and delays in treating close contacts may result in large numbers requiring treatment.

Animal Scabies. Zoonotic scabies and scab mites may affect humans who come in close contact with the animal. The reaction resembles scabies, but runs a self-limited course. Burrows are usually absent.

Other Mite Diseases

Demodex Mites. Demodex folliculorum is a vermiform mite that inhabits the pilosebaceous units of the nose, forehead, chin, and scalp. The mite has a flattened head, four pairs of short, peglike legs, and an elongated abdomen. Demodex brevis is shorter, and is more commonly found on the trunk.

In dogs, the lesions of demodectic mange contain numerous mites. In humans, numerous mites have been found in skin lesions, and yet demodectic disease has not been as well accepted. There are convincing reports of demodectic blepharitis, demodectic folliculitis, demodectic abscess, and demodectic alopecia that respond to eradication of the mites. Some rosacea-like lesions may also be caused by *Demodex*. Treatment of the emptions in which *Demodex* has been implicated consists of applying permethrin, sulfur, lindane, benzyl benzoate, or benzoyl peroxide. Oral ivermectin and metronidazole have also been used.

Cheyletiella Dermatitis. Cheyletiella yasguri, Cheyletiella blakei (Fig. 20-50), and Cheyletiella parasitovorax are three species of nonburrowing mites that are parasitic on dogs, cats, and rabbits, respectively, where they present as "walking dandruff." They may bite humans when there is close contact with the animals, producing an itchy dermatitis resembling scables or immunobullous disease. The mites are similar in diameter to Sarcoptes scabiei, but are elongated and have prominent anterior hooked palps. They may be found by brushing the animal's hair over a dark piece of paper. The brushings can be placed in alcohol, where the scales and hair sink while the mites float. The pet should by treated by a gualified veterinarian.

Chigger Bite. The trombiculid mites are known as chiggers, mower's mites, or red bugs. In North America Eutrombicula alfreddugesi attacks humans and animals. In Europe, the harvest mite, Neotrombicula autumnalis, is a common nuisance. Attacks occur chiefly during the summer

Flg. 20-50 Cheyletiella blakei.

and fall, when individuals have more frequent contact with mite-infested grass and bushes. The lesions occur chiefly on the legs, and at the belt line and other sites at which clothing causes constriction. Penile lesions are common in males. Lesions generally consist of severely pruritic hemorrhagic puncta surrounded by red swellings. On the ankles, intensely pruritic grouped excoriated papules are noted. Several varieties of trombiculid mites in East Asia and the South Pacific are vectors of scrub typhus (tsutsugamushi lever).

Gamasoidosis. Persons in contact with canaries, pigeons, and poultry are prone to develop gamasoidosis. The dermatosis occurs chiefly on the hands and arms, where the bite produces inflammatory, itchy papules. Any area on the body may be attacked and common additional sites are the groin, areolae, umbilicus, face, and scalp. The mites may wander from birds' nests as soon as the young birds begin to fly, and they may infest terrace cushions and furniture. In large metropolitan areas, especially where pigeons tend to gather, it is not unusual to see pigeons roosting on window ledges. Through the open windows or even through air conditioners the pigeon mites attack humans and cause urticarial and papular eruptions. The tropical fowl mite (Ornithonyssus bursa), widely prevalent in wild birds in both continental US and Hawaii, may do this as well.

Two genera of mites, Ornithonyssus and Dermanyssus, commonly infest birds. Ornithonyssus bursa and Ornithonyssus sylvarium are the two common species of leather mites. Dermanyssus gallinae, the red or chicken mite, is also a common parasite of birds. Dermanyssus mites may carry Erysipelothrix rhusiopathiae. Dermanyssus gallinae tends to leave the bird during the day and hide in cracks and crevices, and therefore can be killed without direct treatment of the bird. Thorough spraying of the surroundings with an agent such as malathion is effective. Mites of the Ornithonyssus group require treatment of the birds themselves.

Grocer's ltch. This is a pruritic dermatitis of the forearms, with occasional inflammatory and urticarial papules on the trunk. It results from the handling of figs, dates, and prunes when it is caused by *Carpoglyphus passularum*, or from exposure to the cheese mite (*Glyciphagus domesticus*). This must be distinguished from grocer's eczema caused by sensitization to flour, sugar, cinnamon, chocolate, and similar items.

Grain Itch. Grain itch is also known as straw itch, barley itch, mattress itch, and prairie itch. Causative mites include Pyemotes tritici, Pyemotes ventricosus, Cheyletus malaccensis, and Tyrophagus putrescentiae (the copra itch mite). Those chiefly affected are harvesters of wheat, hay, barley, oats, and other cereals, or farm hands and packers who have contact with straw. Grain itch has a typical lesion consisting of an urticarial papule on which is a small vesicle. There is intense pruritus, with lesions occurring predominantly on the trunk. Frequently, there is a central hemorrhagic punctum in the beginning that rapidly turns into an ecchymosis with hemosiderin pigmentation.

Other Mite-Related Dermatitis. Lepidoglyphus destructor is the hay mite. There have been outbreaks of Pyemotes boylei bites in homes furnigated for termites. Although mites do not appear capable of survival when forced to share an environment with termites, they thrive in locations in which there are termite carcasses. Vanillism is a dermatitis caused by Acarus siro and occurs in workers handling vanilla pods. Copra itch occurs on persons handling copra who are subject to Tyrophagus longior mite bites. Coolie itch is found in tea plantations in India and is caused by Rhizoglyphus parasiticus. It causes sore feet. Rat mite itch caused by Ornithonyssus bacoti, the tropical rat mite, may result in an intensely pruritic dermatitis. This papulovesicular urticarial eruption is seen in workers in stores, factories, warehouse, and stockyards. The rat mite may transmit endemic typhus, Rickettsial pox, equine encephalitis, tularemia, plague, and relapsing fever. Feather pillow dermatitis is a pruritic papular dermatitis traced to the Psoroptid carpet mite, Dermatophagoides scheremetewskyi, which may infest feather pillows. Finally, the house mouse mite, Allodermanyssus (Liponyssoides) sanguineus, is the vector of Rickettsia akari, the causative organism of rickettsialpox.

Order Scorpionidae

Scorpion Sting Scorpions (Fig. 20-51) are different from other arachnids in that they have an elongated abdomen

Flg. 20-51 Common Centruroides scorpion.

ending in a stinger. They also have a cephalothorax, four pairs of legs, pincers, and mouth pincers. Two poison glands in the back of the abdomen empty into the stinger. Scorpions are found all over the world, especially in the tropics. They are nocturnal and hide during the daytime under table tops, in closets, shoes, and folded blankets. Ground scorpions may burrow into gravel and children's sandboxes. The most venomous species include *Tityus serrulatus*, found in Brazil, *Buthotus tamulus*, found in India, *Leiurus quinquestriatus* and *Androctonus crassicauda*, found in North Africa and southwest Asia, and *Centruroides suffussus*, found in Mexico. *Centruroides exilicauda* and *sculpturatus* are the most toxic scorpion in the United States.

Scorpions sting only by accident or in self-defense. The venom causes pain, paresthesia, and variable swelling at the site of the sting. The sting of the Egyptian scorpion (Leiurus quinquestriatus) has a mortality rate of 50% in children. The neurotoxic venom may produce numbness at the sting site, laryngeal edema, profuse sweating and salivation, cyanosis, nausea, and paresthesia of the tongue. There is little or no visible change at the site of the sting. Death may occur from cardiac or respiratory failure, especially in children.

Treatment depends on the species and toxic symptoms. Antiarrhythmics, antiadrenegic agents, vasodilators, and calcium-channel blockers may be required. Antivenin is available for many species of scorpion.

Order Arachnidae

Arachnidism Spiders are prevalent throughout the world. Most are beneficial to humans, as they trap many insects, but a few species are dangerous to humans. Many spider venoms are not well characterized, and in most cases of envenomation, the responsible spider is never identified. The Brazilian armed spider (*Phoneutria nigriventer*) is well characterized. Its venom contains neurotoxins that may be fatal in children.

Latrodectism The various species of Latrodectus have similar toxins and cause similar reactions in humans. The black widow spider, Latrodectus mactans, is of chief concern in the continental US. It may also be found in the Caribbean. Black widows are web-building spiders, and are commonly found in woodpiles and under outhouse seats. Their venom is more potent than that of related brown widow spiders. Latrodectus curacavienis is native to South America, and Australia and New Zealand have related red-black spiders (Latrodectus mactans hasselti). Latrodectus indistinctus is found in Africa, and the brown widow, Latrodectus geometricus is native to southern Africa and Madagascar.

The female Latrodectus mactans (Fig. 20-52) spider is 13 mm long, shiny black, with a red hourglass-shaped marking on its abdomen. The legs are long, with a spread of up to 4 cm. The black widow spider is not aggressive, and bites only when disturbed. Severe pain usually develops within a few minutes and spreads throughout the extremities and

trunk. Within a few hours there may be chills, vomiting, violent cramps, delirium or partial paralysis, spasms, and abdominal rigidity. The abdominal pains are frequently most severe and may be mistaken for appendicitis, colic, or food poisoning. Toxic morbilliform erythema may occur.

Antivenin is indicated for severe symptoms of envenomation. Benzodiazepines reduce the associated tetany.

Loxoscelism The brown recluse spider (Loxosceles reclusa) (Fig. 20-53) is the major cause of necrotic arachnidism in the US. It is most common in the lower Midwest and Southwest. This reclusive spider may be identified by a dark, violin-shaped marking over the cephalothorax and three sets of eyes, rather than the usual four. It is light brown, about 1 cm long, with a small body and long delicate legs. It is found in storage closets, basements, cupboards, and among clothing. Outdoors it has been found in woodpiles, grass, on rocky bluffs, and in barns. It stings in self-defense. Loxosceles rufescens, Loxosceles desert, and Loxosceles arizonica cause lesser degrees of skin necrosis. Loxosceles laeta occurs throughout Latin America and produces changes similar to those of Loxosceles reclusa. The venom contains a phospholipase enzyme, sphingomyelinase D, which is the major toxin. Hyaluronidase contributes to a gravity-dependent spread of the necrotic lesions.

In the localized type of reaction, known as *necrotic* cutaneous loxoscelism, extensive local necrosis develops (Fig. 20-54). A painful severe edematous reaction occurs within the first 8 h, with development of a bulla with surrounding zones of erythema and ischemia. In about a week the central portion becomes dark, demarcated, and gangrenous. Systemic loxoscelism is rare, but may be associated with minor appearing bite reactions. Systemic toxic symptoms are associated with disseminated intravascular coagulation.

Fig. 20-54 Brown recluse spider bite.

Treatment

Treatment consists of rest, ice, and elevation. Tetanus toxoid should be given if the patient has not received the immunization within 10 years. Some data suggest a trend towards better outcome with injections of intralesional triamcinolone, and there are anecdotal reports of sparing of necrosis in the injected site, while the area above and below the injection site show necrosis. Antibiotics and conservative debridement may be needed for necrotic wounds. Dapsone has been used, but some studies show that it is no better than placebo, and it may be toxic, especially in the setting of venom-induced hemolysis.

Funnel web spiders Funnel web spiders include Tegenaria agrestis (the hobo spider or aggressive house spider of the Pacific Northwest) and Atrax robustus (the Sydney funnel web spider of Australia). Australian funnel web spiders are dangerous, but antivenin is available.

Tarantulas (Lycosoidae: Theraphosidae) Tarantulas are large hairy hunting spiders. American species have urticating hairs that produce cutaneous wheal and flare reactions and embed in the comea causing ophthalmia nodosa.

PHYLUM CHORDATA

Stingray Injury

The two stingray families (*Dasyatidae* and *Myliobatidae*) are among the most venomous fish known to man. Attacks generally occur as a result of an unwary victim stepping on a partially buried stingray. A puncture-type wound that later ulcerates occurs about the ankles or feet. Sharp, shooting pain develops immediately, with edema and cyanosis. Symptoms of shock may occur.

Persons wading in shallow, muddy waters where stingrays may be found should shuffle their feet through the mud to frighten the fish away. Successful treatment is usually attained by immersing the injured part in hot water for 30 to 60 min. The water should be as hot as can be tolerated, since the venom is detoxified by heat. Meperidine hydrochloride administered intravenously or intramuscularly may be necessary. If the ulcer remains unhealed after 8 weeks, excision is indicated.

Snake Bite

Venomous snake bites are a serious problem in some parts of the world. In the US the rattlesnake, cotton-mouth moccasin, copperhead and coral snake are the venomous snakes most Irequently encountered. Patients are usually young men, with 98% of bites on the extremities, most often the hands or arms (Fig. 20-55). Nearly 30 enzymes are found in snake venom, most of which are hydrolases. Snake venom has effects on the cardiovascular, hematologic, respiratory, and nervous systems. Local effects at the bite site include the rapid onset of swelling, erythema, and ecchymosis. In more severe reactions bullae and lymphangitis may appear. Fang marks are often visible and pain is common, except with Mojave rattlesnake bites. Antivenin is of great value. In addition antibiotics and antitetanus measures are often needed.

Lizard Bite

Heloderma suspectum (the Gila monster) is found chiefly in Arizona and New Mexico. Another venomous lizard is the beaded lizard of southwestern Mexico (Heloderma *horridum*). Bites from these poisonous lizards may cause paralysis, dyspnea, and convulsions. Systemic toxicity usually resolves spontaneously with supportive care within 1 or 2 days. Death is rare. There is no antivenom.

CHAPTER

21 Chronic Blistering Dermatoses

In the noninherited chronic blistering (vesicular or bullous) dermatoses, the cause of blistering is an autoimmune reaction, and the pattern of immunofluorescence is critical in establishing the diagnosis. Usually, antibodies are bound in perilesional skin and at the site of the earliest lesions. Lesional skin often fails to demonstrate deposits, and lower extremity skin may be prone to false-negative reactions. Salt-split skin preparations are useful in determining the site of deposition of the autoantibodies. A 1 M solution of NaCl predictably splits skin at the level of the lamina lucida. Localization of immune deposits to the roof or floor of this split is diagnostically useful. Immunoprecipitation and immunoblotting have helped to define the molecular targets of the autoantibodies.

Transient acantholytic dermatosis (Grover's disease) is an idiopathic nonimmune vesiculobullous disease that may mimic the histologic patterns of immunobullous disease, but shows no specific findings on direct immunofluorescence (DIF). Specific dermatoses of pregnancy are discussed under the differential diagnosis of herpes gestationis.

PEMPHIGUS VULGARIS

Clinical Features

Pemphigus vulgaris (PV) is characterized by mucosal erosions, and thin-walled, relatively flaccid, easily ruptured bullae that appear on apparently normal skin and mucous membranes or on erythematous bases. The fluid in the bulla is clear at first but may become hemorrhagic or even seropurulent. The bullae rupture to form erosions. The denuded areas soon become partially or totally covered with crusts that have little or no tendency to heal (Fig. 21-1). When they finally heal, lesions often leave hyperpigmented patches with no scarring.

PV usually appears first in the mouth (60% of cases) or at the site of a burn or other skin injury. Other common sites include the groin, scalp, face, neck, axillae, and genitals. The Nikolsky sign is present (intact epidermis shearing away from the underlying dermis leaving a moist surface). The sign is elicited by slight pressure, twisting or rubbing. The "bullaspread phenomenon" (Asboe-Hansen sign) is elicited by pressure on an intact bulla, gently forcing the fluid to spread under the adjacent skin.

Short-lived bullae quickly rupture to involve most of the mucosa with painful erosions. The lesions extend onto the lips and form heavy, fissured crusts on the vermilion. Involvement of the throat produces hoarseness and difficulty in swallowing. The mouth odor is offensive. The esophagus may be involved, and sloughing of its entire lining in the form of a cast (esophagitis dissecans superficialis) may occur, even when the cutaneous disease appears to be well controlled. The conjunctiva, nasal mucosa, vagina, penis, and anus may also be involved. Chronic lesions may involve the face, scalp or flexures (Fig. 21-2). Widespread cutaneous

Fig. 21-1 Nonhealing crusted lesions of pemphigus vulgaris.

Fig. 21-2 Nonhealing erosions of pemphigus vulgaris.

Fig. 21-3 Pemphigus vulgaris.

disease (Fig. 21-3) may cause death through sepsis or fluid and electrolyte imbalance.

The diagnosis is made by histology, immunofluorescence pattern of perilesional skin or plucked hairs, indirect immunofluorescence (IIF) testing of serum, or enzyme-linked immunosorbent assay (ELISA) testing for anti-desmoglein (Dsg)1 and -Dsg3 autoantibodies. As in other autoimmune diseases, specific antibodies may be present in relatives of patients with pemphigus who do not manifest any signs of disease.

Epidemiology

PV occurs with equal frequency in men and women, usually in their fifth and sixth decades. It is rare in young persons. The condition occurs more often in Jewish people and those of Mediterranean descent.

Etiologic Factors

Antibodies in PV are most commonly directed against Dsg3. The presence of antibodies to both Dsg1 and Dsg3 correlates with mucocutaneous disease. If autoantibodies are only directed against Dsg3, mucosal lesions predominate. Both humoral and cellular autoimmunity are important in the pathogenesis of skin lesions. Antibody alone can produce acantholysis, without complement or inflammatory cells. Both IgG1 and IgG4 autoantibodies to Dsg3 occur in patients with pemphigus, but some data suggest that the IgG4 antibodies are pathogenic. Plasminogen activator is associated with antibody-mediated acantholysis. Involved T-cells are usually CD4 α/β cells that secrete a T-helper 2 (Th2)-like cytokine profile, although. Th1 cells may also be involved in antibody production in chronic disease. IgG is found in both involved and clinically normal skin. C3 deposits are heavier in acantholytic areas. DIF may remain positive for years after clinical remission, and conversion to negative predicts sustained remission after withdrawal of therapy. Pemphigus may be associated with myasthenia gravis and thymoma.

The PV antigen (130-kD transmembrane desmosomal glycoprotein) shows homology with the cadherin family of calcium-dependent cell-adhesion molecules. With IIF, circulating antibodies can be demonstrated in 80% to 90% of patients. Circulating intercellular antibodies may also be present in patients with thermal or actinic burns, and in patients with drug eruptions. These antibodies are not directed against Dsg3. They do not bind to the epidermis in vivo and may be directed against ABO blood-group antigens.

Penicillamine treatment of rheumatoid arthritis has induced pemphigus, most often of the foliaceous type. Nearly all the reported cases have had a positive DIF and more than half have had a positive IIF. Penicillamine and captopril may induce acantholysis in organ explant cultures in the absence of autoantibody. The doses responsible for induction of disease have ranged from 250 to 1500 mg/day. and were taken for an average of 13 months before the onset of pemphigus. A long list of drugs, including captopril, enalapril, penicillin, thiopronine, interleukin (IL)-2, nifedipine, piroxicani, and rifampicin, have also been reported to induce pemphigus. Many drugs implicated in inducing pemphigus contain either a sulfhydryl or an amide group. Only 10% to 15% of patients with drug-induced pemphigus have had oral lesions. Most disease resolves when the medication is discontinued, but some have persisted for many months.

Many studies have indicated a genetic predisposition to pemphigus. Statistical analysis shows a skewed distribution of various HLA antigens. Most patients are of HLA phenotype DR4 or DR6. In addition, a HLA-DQ β restriction fragment has been identified in many patients with pemphigus. HLA-G is associated with pemphigus in Jewish patients. Thus, there may be a genetically inherited susceptibility to the disease. Additionally, a predisposition to develop other autoimmune diseases may occur in relatives of pemphigus patients.

Histopathology

The characteristic findings consist of suprabasilar acantholysis with intraepidermal blister formation. Acantholytic cells are round and show no intercellular bridges. Regeneration of the epidermis occurs, and may cause the split to appear to be higher as cells regenerate beneath the cleft. At least some areas generally still demonstrate the characteristic tombstone row of basal keratinocytes underneath the bulla. An early intact bulla shows the most characteristic histology. Asboe-Hansen modification of the Nikolsky test may be used to extend the bulla beyond its original margin to where secondary regenerative changes have not taken place.

In early disease, spongiosis with eosinophils may be noted in the epidermis, in the absence of acantholysis. In the setting of immunobullous disease, spongiosis with eosinophils is more likely to represent pemphigoid than pemphigus, and immunofluorescent findings readily distinguish the two.

DIF demonstrates a "chicken wire" pattern of intercellular IgG in perilesional skin or plucked hairs. C3 may also be present. The staining is uniform, not granular. IIF shows a similar pattern of staining. Prozone reactions occur, so the serum should be tested at a wide range of dilutions. Positive tests may be confirmed with ELISA assays for the antibody.

Treatment

Large-scale, prospective, double-blinded studies are lacking, and the management of PV is based largely on smaller open trials and clinical experience. A survey of 24 very experienced clinicians showed that half used prednisone in doses of 1 mg/kg/day, while half used higher doses. Adjuvant steroidsparing agents were commonly used, with almost half of the respondents reporting the use of azəthioprine. Because of its tolerability and simpler dosing schedule, mycophenolate mofetil is now used very commonly in place of azathioprine. Other agents used less commonly include cyclophosphamide and methotrexate. Almost 40% of the clinicians aimed to replace prednisone with a steroid-sparing agent, while others were content to continue a low dose of prednisone. The survey suggests that even among the world's experts, there is significant variation in how this difficult disease is managed.

Most agents used are immunosuppressive, although the mechanism of action may not merely be suppression of T-cells and antibody production. Methylprednisolone can directly block pemphigus antibody-induced acantholysis. It also upregulates expression of the genes encoding Dsg3 and periplakin, increases measurable levels of E-cadherin, Dsg1 and Dsg3, and interferes with phosphorylation of these adhesion molecules. Many of these effects antagonize those of pemphigus antibodies.

Topical Treatment

The skin lesions are extremely painful in advanced cases. When there are extensive raw surfaces, prolonged daily baths are helpful in removing the thickened crusts and reducing the foul odor. Silver sulfadiazine (Silvadene) 1%, widely used for local therapy of burns, is an effective topical antimicrobial agent, suitable for treatment of limited disease. Silver nitrate-impregnated cotton batting, manufactured for burn units, can be used in more extensive disease. Very localized areas can be treated with silver nitrate-impregnated dressings such as Acticoat 7 or Aquacell Ag. Painful ulcerations of the lips and mouth may benefit from topical application of a mixture of equal parts of Maalox and elixir of diphenhydramine hydrochloride (Benadryl) or viscous xylocaine, especially before meals. The various commercial antiseptic mouthwashes are helpful in alleviating discomfort and malodor. Potent topical corticosteroids and topical tacrolimus have been successful in some patients with limited disease.

Systemic Therapy

A common method of treatment for severe disease would be to begin with doses of prednisone adequate to control the disease. High doses of prednisone (100-150 mg) are sometimes needed, but prolonged high doses are associated with significant morbidity and mortality, so adjuvant therapy should be started early. During the early phase of therapy, if a prednisone dose of 1 mg/kg/day proves inadequate, the dose is commonly increased to a split dose of 1 mg/kg twice a day. Mycophenolate mofetil is commonly chosen as a steroid-sparing agent at a dose of 1 to 1.5 g twice a day. Gastrointestinal intolerance is the most common side effect, and blood counts must be monitored. If the disease does not respond, either plasmapheresis or intravenous immunoglobulin (IVIG) is added to the regimen. Azathioprine is less expensive than mycophenolate mofetil, and is commonly used as an alternative when cost is an overriding issue. It is best dosed based on measurement of the patient's thiopurine methyltransferase (TPMT) level. The majority of patients metabolizes the drug quickly, and may be underdosed if TPMT is not measured. Patients with high levels of the enzyme may require 2.5 to 5 mg/kg/day. Patients with midrange levels are treated with 1 to 3 mg/kg/day. Patients who are deficient in the enzyme may be treated with very low

doses, or with a different agent. Allopurinol interferes with metabolism of the drug and increased serum levels may lead to toxicity. Patients with refractory disease may be treated with cyclophosphamide, either alone or in conjunction with plasmapheresis. Plasmapheresis alone is followed by rebound of antibody production, but the rebounding clone of plasma cells is sensitized to the effects of cytotoxic agents. Both daily cyclophosphamide dosing and pulse dosing schedules can be used. Pulse dosing is usually given with MESNA rescue and is associated with less bladder toxicity. Both dosing schedules should be planned early in the day with vigorous hydration to minimize the risk of bladder toxicity. Blood counts must be monitored closely. Other risks of therapy with high doses of corticosteroids and immunosuppressants include diabetes, infection, hypertension, and cardiorespiratory disease. All of these risks must be monitored, and all patients must receive gentle wound care and fluid and electrolyte management. In patients who cannot tolerate cyclophosphamide, chlorambucil has been used, but is associated with a greater risk of hematologic malignancy. In addition to the use of IVIG as an adjuvant to conventional therapy, it has also been used as monotherapy. Onset of action is fairly rapid, and may be seen within 1 to 2 weeks.

The sooner the diagnosis is established and the sooner treatment is given, the more favorable the prognosis. The therapeutic effects are estimated by the number of new lesions per day and the rate of healing of the new lesions. In patients with and Dsg3 antibodies, mucosal disease may still be active when cutaneous disease appears to be in remission. Pemphigus antibody titers can be performed on esophageal substrate, watching for a fall in titer. If after 4 to 8 weeks of treatment new blister formation is not suppressed, prednisone dosage may be increased to 150 mg/day. Dosage adjustments are, of course, made more frequently and aggressively in severe, progressive disease. Dividing the daily dose will usually result in greater efficacy, but will also result in greater adrenal suppression. Additionally, intravenous pulse therapy with megadose corticosteroids (Solu-medrol) at a dose of 1 g/day over a period of 2 to 3 h, repeated daily for 5 days, may be employed for cases that are unresponsive to oral doses. Untreated disease is commonly fatal, but the clinician should remember that in treated patients, side effects of therapy are the most common cause of death. Adjuvant therapy to decrease steroid dependence has reduced mortality.

Medication is continued until clinical disease is suppressed and pemphigus antibody disappears from the serum. Once the antibody is no longer present, a DIF test is repeated. A negative DIF is predictive of sustained remission after withdrawal of therapy.

Immunosuppressant therapy alone has been reported as a successful treatment of early stable PV. If a contraindication to the use of corticosteroids exists or only limited disease is present, these may be used as single agents. In general, however, combined treatment with corticosteroids is superior in gaining early control of the disease.

Dexamethasone-cyclophosphamide therapy was studied in 32 patients with PV. Monthly pulses consisted of intravenous dexamethasone (136 mg) for 3 consecutive days monthly with intravenous cyclophosphamide (500 mg) on the second day. Daily oral cyclophosphamide (50 mg) and oral tapered courses of oral corticosteroids were given in the intervals between the pulses. All patients responded. Partial remissions were noted after two to eight pulses. From 8 to 32 pulses were required to achieve complete remission. The duration of pulsed therapy correlated with both the disease severity and the time to achieve remission.

Oral cyclophosphamide was successful in 17 of 20 patients who had failed therapy with prednisone and an antimetabolite. The median time to achieve complete remission was 8.5 months, and the median duration of treatment was 17 months. Plasmapheresis was used in nine patients. Hematuria developed in five patients and in six infections were noted. One patient developed bladder cancer 15 years after therapy.

Intramuscular or oral gold are no longer commonly used. Gold is less effective than immunosuppressive therapy, but its advantages include lack of carcinogenicity and infertility. A minimum of 6 months is required to judge the effectiveness of gold therapy. Infliximab or rituximab, an anti-CD20 monoclonal antibody, have been used successfully in several with refractory disease, but may be associated with serious infections. Extracorporeal photochemotherapy has been used in a few patients, and dapsone may have some value as a steroid-sparing agent. Nicotinamide and tetracycline can be tried in patients with milder disease. In one study, it was successful in two of six patients. In another study, it was only successful in 1 of 10 patients. Data on the effectiveness of cyclosporin have been mixed. Etanercept has also been used.

PEMPHIGUS VEGETANS

Pemphigus vegetans may present as localized plaques in the scalp, or in two classic forms, the Neumann type (which generally begins and ends as typical pemphigus) and Hallopeau type (which usually remains localized). Both types show pseudoepitheliomatous hyperplasia, and the Hallopeau type is characterized by eosinophil microabscesses within the epidemnis.

Pemphigus vegetans may begin with flaccid bullae that become erosions and form fungating vegetations or papillomatous proliferations, especially in body folds or on the scalp. The tongue often shows cerebriform morphologic features early in the course. At times there is a tendency for the lesions to coalesce to form large patches or to arrange themselves into groups or figurate patterns.

The laboratory findings, etiologic factors, epidemiology, pathogenesis, and treatment of pemphigus vegetans are the same as those for PV. Captopril-induced pemphigus vegetans has been reported.

Pemphigus vegetans must be differentiated from other conditions characterized by pseudoepitheliomatous hyperplasia and microabscesses, including halogenoderma, chromoblastomycosis, blastomycosis, granuloma inguinale, blastomycosislike pyoderma, conyloma lata, and amebic granulomas. The Hallopeau type is distinguished by the presence of eosinophils, and both types by immunofluorescent findings.

PEMPHIGUS FOLIACEUS

Pemphigus foliaceus (PF) is characterized by flaccid bullae and localized or generalized exfoliation. Antibodies target Dsg1. Lesions start as small, flaccid bullae that rupture almost as they evolve to form crusting, below which is a moist surface with a tendency to bleed. A Nikolsky sign may be easily elicited by rubbing the skin (Fig. 21-4). After a time, the exfoliative characteristics predominate, with few bullae (Fig. 21-5). Adherent scale crusts may resemble corn flakes.

Fig. 21-4 Pemphigus foliaceus.

Fig. 21-5 Pemphigus foliaceus. A variant of pemphigus that has clinical features suggestive of dermatitis herpetiformis but has immunologic features of pemphigus has been called *herpetiform pemphigus*. Most of these patients represent a clinical variant of PF, with the remainder being PV patients. A few have also demonstrated desmocollin antibodies.

The Nikolsky sign is present in PF. Oral lesions are rarely seen, and then only as superficial erosive stomatitis. This may be because Dsg3, present throughout the epithelium, is unaltered in PF and provides enough adherence to maintain clinical integrity. Several patients have been described whose clinical picture shifted from PF to PV or vice versa, with an accompanying change in antibody profile.

Most patients with PF are not severely ill. They complain of burning, pain, and pruritus. The lesions may persist for many years without affecting general health. PF occurs mostly in adults between 40 and 50 years of age, but has also been reported in children. The sexes are affected equally. Prevalence of PF in people of Jewish heritage is much less than with PV. The drugs listed under PV more commonly induce PF.

The principal histologic finding consists of acantholysis in the upper epidermis, usually in the granular layer. The stratum corneum may be missing entirely, or separated from the underlying epidermis. Individual elongated acantholytic cells are noted above the epidermis or clinging to the underside of the stratum corneum.

DIF demonstrates intercellular IgG throughout the epidennis, although the deposits may be somewhat more prominent in the upper epidermis. IIF is positive in most patients, although prozone reactions occur and a wide range of dilutions should be tested. A sensitive and specific ELISA for detecting antibodies to Dsg1 is now available to confirm positive IIF results. Patients with a distinct clinical picture of PF or PV may have a mix of antibodies. Western blot has shown Dsg1 in roughly 86% of PF patients and 25% of PV patients. ELISA has shown anti-Dsg1 antibodies in up to 71% of PF patients and in 62% of PV patients. In one study, antibodies to Dsg3 were detected in 19 of 276 patients with PF and fogo selvagem who had only cutaneous disease. The antibody was capable of producing disease in laboratory animals, suggesting they were pathogenic in the PF patients. Therefore, ELISA studies must always be interpreted in the context of clinical, histologic, and immunofluorescence findings. In PV, Dsg3 mediates mucosal disease and cutaneous disease is associated with antibodies to Dsg1. A shift to predominantly Dsg1 antibodies has accompanied a clinical shift from PV to PF.

Dsg1, the antigen in PF, was first identified by immunoprecipitation consisting of polypeptides of molecular weight 260, 160, and 85 kD. The 260-kD molecule is a complex of the 160- and 85-kD polypeptides. The PF antibody binds to a 160-kD glycoprotein extracted from normal epidermis. This glycoprotein is identical to Dsg1. The 85-kD glycoprotein is plakoglobulin, a desmosomal and adherens junction-associated molecule.

Desmogleins are cadherin-type adhesion molecules found in desmosomes. The N-terminal extracellular domain of Dsg1 contains the dominant autoimmune epitopes in both PF and PV. Antibodies include both IgG1 and IgG4 subclasses. IgG4 antibodies appear to be pathogenic in most patients. In a subset of patients, IgG1 autoantibodies are pathogenic.

Treatment

Treatment is similar to that for PV. In fact, many clinical trials include patients with both diseases. PF patients are generally less ill, and may not need oral corticosteroid therapy. Dapsone and hydroxychloroquine may be useful, either alone in mild cases or to reduce the steroid dose level. Nicotinamide and tetracycline may be more effective than in PV. Azathioprine, mycophenolate mofetil, or cyclophosphamide may be needed, just as in PV. Rituximab, IVIG, and immunoablative high-dose cyclophosphamide without stem cell rescue have been used for refractory disease. Immunoadsorption with tryptophan-linked polyvinylalcohol adsorbers or adsorption with plant lectins, such as wheat germ agglutinin, have been effective in animal models and hold promise as adjuvant therapy.

ENDEMIC PEMPHIGUS (FOGO SELVAGEM)

Endemic pemphigus is found in tropical regions, mostly in certain interior areas of Brazil. Fifteen percent of cases are familial. The disease is common in children, adolescents, and young adults, with about one-third of cases occurring before the age of 20 and two-thirds by the age of 40. The initial lesions may be flaccid bullae, but later lesions are eczematoid, psoriasiform, impetiginous, or seborrheic in appearance. The mid-facial areas may be involved. Melanoderma and vertucous vegetative lesions are not unusual, and exfoliative dermatitis may occur. The mucous membranes are not often involved. The Nikolsky sign is present. The disease is often seen in those with arthropod exposure, and may be initiated by an infectious agent, possibly carried by mosquitoes or black flies. Histologically and immunohistologically, fogo selvagem is identical to PF. Peripheral blood mononuclear cells from patients produce more IL-1ß than those from healthy controls. A strong Th2 bias is also observed.

A distinct subset has been described in a rural area in north-eastern Colombia. This subset differs from previously described forms of endemic pemphigus, and shares some immunoreactivity with paraneoplastic pemphigus. It is not, however, associated with malignant tumors. Clinically, the disease resembles Senear-Usher syndrome. A systemic form may affect internal organs and has a poorer prognosis. All patients appear to have antibodies to Dsg1. In addition, many sera react with desmoplakin I, envoplakin, and periplakin. A few Brazilian sera also react with plakins. None of the Colombian patients' sera reacted with Dsg3, but about half of Brazilian patients' sera react with Dsg3. This area of Colombia is a mining region and the population is exposed to high environmental levels of mercuric sulfides and selenides; these compounds have been found in the skin of patients with the disease.

PEMPHIGUS ERYTHEMATOSUS (SENEAR-USHER SYNDROME)

In Senear-Usher syndrome, the early lesions are circumscribed patches of erythema and crusting that clinically resemble lupus erythematosus and are immunopathologically positive for the lupus band in 80% of patients. The lesions are erythematous and thickly crusted, bullous, or even hyperkeratotic. These are usually localized on the nose, cheeks, and ears, sites frequently affected by lupus erythematosus. In addition, crusting and impetiginous lesions appear amid bullae on the scalp, chest, and extremities. In most patients, the disease runs an indolent course.

The histopathology is that of pemphigus foliaceus. DIF shows IgG and complement localized in both intercellular and basement membrane sites. At the dermoepidermal junction, the deposits are continuous and granular, as in lupus. In the epidermis, they resemble those of pemphigus. The antinuclear antibody is present in low titer in 30% of patients. Patients have demonstrated anti-Dsg1 but not anti-Dsg3 autoantibodies. Additional autoantibodies may be directed against bullous pemphigoid antigen 1 (BP230) and periplakin.

Patients often respond to low doses of prednisone, and may respond well to topical steroids and sunscreens. Immunosuppressants may be needed in severe cases.

PARANEOPLASTIC PEMPHIGUS

In 1990, Anhalt et al described five patients with underlying neoplasms who presented with painful mucosal ulcerations and polymorphous skin lesions, which progressed to blistering eruptions on their trunk and extremities. Most patients described since then have has associated neoplasms or Castleman's disease. The mucosal lesions pf paraneoplastic pemphigus (PNP) may appear lichenoid or more commonly Stevens-Johnson-like with crusting of the lips. The skin lesions may appear as erythematous macules, lichenoid lesions, erythema multiforme-like lesions, flaccid bullae, and erosions typical of pemphigus, or tense, more deep-set bullae.

Histologically, the lesions demonstrate epidermal acantholysis, suprabasal cleft formation, dyskeratotic keratinocytes, and vacuolar change of the basalar epidermis. Biopsies that demonstrate both acantholysis and lichenoid change or individual cell necrosis should raise the suspicion of PNP.

DIF reveals IgG and C3 deposition in the intercellular spaces of the epithelium, IIF shows a similar pattern in a wide range of stratified squamous epithelium and transitional epithelium (such as rat bladder). About 25% of cases will be negative and some erythema multiforme may be falsely positive. Immunoprecipitation is the definitive test. It reveals a complex immune response with autoantibodies directed against four high molecular weight keratinocyte proteins. Antibody targets include desmoplakin 1 (250 kD), envoplakin (210 kD), the major plaque protein of hemidesmosomes BPAg1 (230 kD), and periplakin (190 KD). Many cases also recognize an additional antigen at 170 kD. Finally, by ELISA testing, antibodies to Dsg3 and Dsg1 are frequently present. On DIF, some cases also demonstrate a linear or granular IgG and/or C3 at the basement membrane zone.

Whereas the dominant epitopes in PV reside in N-terminal regions of Dsg3, epitopes on Dsg3 in PNP are distributed more broadly through the extracellular domain. The Nterminal domains are still recognized more frequently than the C-terminal domains. IgG subclasses in PNP are IgG1 and IgG2 dominant, contrasting with the IgG4 dominance in PV. There is a significant association in PNP with HLA-DRB1*03 allele (61.5% of those studied). In one study, eight of nine fatal PNP cases had distinctive cell surface antibodies detected in a beaded pattern by complement indirect immunofluorescent (CIIF) tests on monkey esophagus. Three long-term survivors with PNP lacked this pattern, suggesting the test may have prognostic value.

A wide variety of both benign and malignant tumors are seen in these patients, and some have no identifiable neoplasm. The most common associations are non-Hodgkin lymphoma, chronic lymphocytic leukemia, Castleman tumor, sarcoma, and thymoma. Most reported patients die from their tumor. Others have died from bronchiolitis obliterans.

Therapy for the bullous dermatoses with prednisone and/ or immunosuppressive agents should be balanced with treatment of the tumor. Immunoablative high-dose cyclophosphamide without stem cell rescue, cyclosporin A, plasmapheresis, immunoapheresis, and rituximab have been successful in some cases.

INTRAEPIDERMAL NEUTROPHILIC IgA DERMATOSIS

In 1985, Huff et al reported the case of an elderly man with a chronic bullous dermatosis with unique histologic and immunopathologic findings. Clinically, there were generalized flaccid bullae, which rapidly ruptured and crusted. There was no scarring when the dermatosis healed. No mucosal lesions were present, and the distal extremities, face, and neck were spared. Neither grouping nor symmetry were present. Histologic findings consisted of neutrophilic exocytosis and in some areas neutrophils arranged in a linear fashion at the dermoepidermal junction. Later, intraepidermal abscesses were formed; no acantholysis was present. DIF repeatedly showed an intercellular deposition of IgA within the epidermis, with minimal staining of the basal layer. No circulating antibodies were found.

Since this report, many additional patients with intraepidermal IgA deposition have been described. They have been classified as belonging in two subsets, one closely mimicking pemphigus and the second simulating subcorneal pustular dermatosis (SPD). The former starts with vesicles that become pustular within a few days, enlarge peripherally, rupture in the center, then form a crust. Continued peripheral vesiculation may lead to a flower-like appearance. The head, neck, and trunk are frequent sites of involvement. In some patients, the condition is induced by ultraviolet (UV)A light. The second subset presents much like Sneddon-Wilkinson disease, with serpiginous and annular pustules. Some cases have been induced by granulocyte-macrophage colony-stimulating factor.

Histologically, intraepidermal bullae with neutrophils, some eosinophils, and acantholysis are seen. DIF shows intraepidermal IgA deposition, usually throughout the epidermis and IIF may reveal circulating autoantibody that binds to the same location. There is evidence that the IgA specificity in individual cases may be directed at either Dsg1 or Dsg3. Some patients have concurrent IgG intercellular antibodies directed at Dsg1, and some have a monoclonal IgA gammopathy. The antigen in SPD-type IgA pemphigus is

Fig. 21-6 Bullous pemphigoid.

Fig. 21-7 Urticarial pemphigoid.

desmocollin, a type of desmosomal cadherin. Some patients have a circulating IgA monoclonal gammopathy.

Therapy with topical corticosteroids may be effective in mild cases. Dapsone is often effective, and may be so even at doses as low as 25 mg/day. Oral corticosteroids may be necessary, and some resistant cases have required immunosuppressive agents and plasmapheresis. Colchicine, acitretin, adalimumab, mycophenolate mofetil, and isotretinoin have been effective in some patients.

BULLOUS PEMPHIGOID

Clinical Features

Bullous pemphigoid (BP) was described by Lever in 1953. Clinically, it is characterized by large, tense, subepidermal bullae with a predilection for the groin, axillae, trunk, thighs (Fig. 21-6) and flexor surfaces of the forearms. Key features

Fig. 21-8 Pemphigoid in psorlatic plaques (psoriasis pemphigoides).

distinguishing BP from other immunobullous diseases include subepidermal separation at the dermoepidermal junction, an inflammatory cell infiltrate that tends to be rich in eosinophils, and antibodies directed against two hemidesmosomal antigens, BP230 and BP180.

After the bullae rupture, large denuded areas are seen, but the bullae and denuded areas do not tend to increase in size as they do in PV. Instead, the denuded areas show a tendency to heal spontaneously. In addition to the bullae, there often are erythematous patches and urticarial plaques (Fig. 21-7), with a tendency to central clearing. These patches and plaques may be present without bullae early in the course of the disease. Later, bullae often occur on an urticarial base. Sometimes, targetoid lesions are present.

BP may begin at a localized site, frequently on the shins. The disease may also be limited to areas of radiation therapy, burns or plaques of psoriasis (Fig. 21-8). It may remain localized throughout the course of the disease or eventuate in generalized pemphigoid. Cases of the localized disease in which a vesicular eruption is limited to the palms or soles (dyshidrosiform pemphigoid) are occasionally observed. Young girls may present with localized vulvar erosions and ulcers that resemble the signs of child abuse (Fig. 21-9). These localized varieties have been shown to have circulating IgG antibody, which immunoprecipitates the 230-kD BP antigen.

Many other variants of BP have been described. A vesicular variant manifested by tense, small, occasionally grouped blisters is termed vesicular pemphigoid. Other patients, mostly women, have papules and nodules of the scalp and extremities, with sparing of the mucous membranes, in a pattern resembling prurigo nodularis (pemphigoid nodularis). Cases resembling pemphigus vegetans, but with IgG and C3 at the basement membrane zone, are occasionally observed (pemphigoid vegetans). Erythroderma may be present (erythrodermic pemphigoid) or there may be no bullae at all (nonbullous variant). The latter type may present as generalized pruritus, pruritic eczema or urticarial eruptions with peripheral eosinophilia. Overall, incidence of oral involvement is about 20%, but involvement of the pharynx, larynx, nasal mucosa, vulva, urethra, and eye is rare.

BP occurs most frequently in the elderly. The age of onset averages 65 to 75 years. It also occurs, however, in young children with clinical and pathologic findings similar to those in adults. Many of these cases begin with hand and foot bullae. Facial involvement may be somewhat more common in children. In children, the course of disease is usually under 1 year, with most cases lasting 5 months or less.

In patients with lichen planus, a bullous eruption similar to BP may develop. This condition, called lichen planus pemphigoides, is sometimes related to the 230-kD antigen, the 180-kD antigen, or a unique 200-kD subepidermal antigen. A nonscarring eruption with acute onset, widespread erosions and severe mucous membrane involvement resembling toxic epidermal necrolysis or PV has been referred to as anti-p105 pemphigoid. Linear IgG and C3 are noted at the basement membrane zone. The 105-kD antigen is found in the lower portion of the lamina lucida.

Etiologic Factors

Circulating basement membrane zone antibodies of the IgG class are present in approximately 70% of patients with BP. In most instances the antibodies fix complement in vitro,

Fig. 21-9 Vulvar pemphigoid.

in contrast to pemphigus antibodies, which fail to do so. Complement is activated by both the classic and alternate pathways. No close correlation exists between the titer of antibodies and clinical disease activity.

Passive transfer mouse models suggest that subepidermal blistering is initiated by anti-BP180 antibodies. Blister formation involves complement activation, mast cells, and neutrophils. Basement membrane zone damage is caused by proteinases and reactive oxygen species released by the infiltrating neutrophils.

The site of IgG binding has been localized to the lamina lucida, with accentuation near hemidesmosomes. BP antigen 1 (BPAg1) is synthesized by the keratinocyte and is an intracytoplasmic hemidesmosomal plaque protein of molecular weight 230 kD with disulfide-linked chains. The second BP antigen (the 180-kD BPAg2) is a transmembrane protein with a long C-terminal collagenous domain that projects into the extracellular region below the hemidesmosome. The antibody to BPAg2 is the primary pathogenic factor. The noncollagenous (NC) 16A domain harbors the major epitopes of autoantibodies in BP. A predominance of the IgG4 subclass has been observed in several studies. In addition to this humoral response, infiltrating T-helper lymphocytes with a mixed Th1/Th2 cytokine profile may play a role in blister formation. Peripheral blood eosinophilia is present in 50% of pemphigoid patients.

BP has occasionally been reported to be associated with other diseases, such as diabetes mellitus, rheumatoid arthritis, PF, dermatomyositis, ulcerative colitis, myasthenia gravis and thymoma. Drugs have been reported to induce BP; these include penicillamine, furosemide, captopril, penicillin, sulfasalazine, nalidixic acid, and enalapril.

Histopathology

The histologic changes are characterized by subepidermal bullae, by the absence of acantholysis, and by a superficial dermal infiltrate containing many eosinophils. The amount of inflammatory infiltrate varies, and individual bullae may be "infiltrate poor" or "infiltrate rich." Often the infiltrate contains many eosinophils, although neutrophil-predominant cases exist. Spongiosis with eosinophils occurs more frequently than in pemphigus. Urticarial lesions often demonstrate eosinophils lined up along the dermoepidermal junction.

Atypical presentations are fairly common. In one study of 23 new cases of BP, only 7 of 22 biopsy specimens showed subepidermal blister formation, and only 12 of these had a predominance of eosinophils in the blister cavity. In 23% of patients, the biopsy was not particularly suggestive of BP. DIF, IIF, immunoblot analysis and ELISA are critical in establishing the diagnosis in such cases.

DIF is a more sensitive test than IIF, just as in pemphigus. In a positive test, continuous linear (tubular or toothpaste pattern) IF is seen along the basement membrane zone. IgG and/or C3 are best found in perilesional skin. False-negative tests are somewhat more common on the lower extremities. A positive DIF test is found in nearly 100% of patients, with C3 most commonly present and IgG present in about 80% of cases. IgA and IgM are occasionally present.

About 20% of patients have negative staining for IgG on DIF, even though C3 is present. In some of these patients, IgG may be present at subthreshold levels which cannot

be detected. Also, the major subclass, IgG4, shows limited reactivity with most commercial antihuman IgG conjugates. Double sandwich antibody immunofluorescence methods have been developed that offer greater sensitivity for IgG4 antibodies.

All histologic features present in BP may also be seen in epidermolysis bullosa acquisita (EBA); therefore, immunofluorescence testing on salt-split skin is required to differentiate EBA from BP. C3 deposition is nearly always present in BP, whereas it may be absent in EBA. Type IV collagen mapping in BP localizes to the base of the blister. In EBA it stains the roof.

Bullous scabies can also mimic both the histology and DIF findings of BP.

Treatment

Relatively few controlled trials have been performed, and many recommendations are based on experience and consensus of opinion. A Cochrane Library search strategy identified seven randomized controlled trials through 2003. A total of 634 patients were enrolled in the trials. One comparing prednisolone, 0.75 mg/kg/day, with prednisolone, 1.25 mg/kg/ day, found no statistical difference between the two. The same was true of a trial comparing methylprednisolone with prednisolone. Higher doses of prednisolone were associated with more severe side effects in these studies. Two trials confirmed that adjuvant therapy with azathioprine or plasma exchange could reduce the required steroid dose. Another trial failed to confirm the superiority of combination treatment (with either azathioprine or plasma exchange) over steroid alone, and one trial found no statistically significant difference between prednisone and a combination of tetracycline and niacinamide. The steroid-treated group had more side effects.

Another study compared ultrapotent topical corticosteroid treatment (clobetasol propionate cream 40 g/day) with oral prednisone (0.5–1 mg/kg/day). In those with severe disease, the 1-year survival rate was better in the topical corticosteroid group (76% vs 58%). Disease control at 3 weeks was also better in the topical steroid group (99% vs 91%). Side effects were common in both groups, but more common in the prednisone group (29% vs 54%). Among those with moderate disease, there were no significant differences between the two groups.

Even is those with extensive disease, topical corticosteroid treatment should be attempted. Prednisone has long been the standard approach, but the complication rate must be weighed carefully, especially in those with severe disease. Oral therapy with tetracycline (500 mg four times a day) combined with niacinamide (500 mg three times a day) is effective in some cases. It should be noted that occasional patients with BP may respond to tetracycline alone or nicotinamide alone. Dapsone is also effective in some patients. Immunosuppressive therapy may still be necessary in resistant cases, either in combination with systemic or topical steroids, or as sole therapy. Azathioprine has been used most commonly, but mycophenolate mofetil is being used more commonly. Methotrexate, cyclophosphamide, chlorambucil, IVIG, and cyclosporin have also proved effective in some patients. In exceptionally severe cases, pulse therapy with methylprednisolone (15 mg/kg in 16 mL of bacteriostatic water over a period of 30-60 min/day for three doses) can be rapidly effective. Some patients may also respond to dapsone or sulfapyridine. These agents tend to be more effective in neutrophil-rich pemphigoid. Oral erythromycin and topical macrolactams have proved effective in some patients.

Double-filtration plasmapheresis (DFPP) may be more effective than conventional plasma exchange, possibly by removing pathogenic cytokines. DFPF reduces a variety of cytokines, including IL-8, MIP-1 α , TNF- α and IL-2. IVIG produces faster clearance of antibody titers, and may be helpful in inducing and maintaining remission.

Course and Prognosis

BP is usually self-limited over a 5- to 6-year period. This period is generally a year or less in children. Relapse occurs in 10% to 15% of patients once therapy is discontinued. The presence of circulating anti-BP180 antibodies, but not anti-BP230, is associated with a statistically increased chance of death in the first year after diagnosis. Other risk factors for death during the first year include greater age, higher daily steroid dosage at discharge, low serum albumin, and erythrocyte sedimentation rate greater than 30 mm/h.

PEMPHIGOID GESTATIONIS (HERPES GESTATIONIS)

Clinical Features

Pemphigoid gestationis (PG) is an autoimmune inflammatory, bullous disease with onset during pregnancy or during the postpartum period. It occurs in approximately 1 in 50,000 pregnancies. The onset is usually during the second trimester, with urticarial plaques and papules developing around the umbilicus and extremities. Targetoid lesions may be present (Fig. 21-10). As the disease progresses, lesions may spread over the abdomen, back, chest, and extremities, including the palms and soles. The face, scalp, and oral mucosa are usually spared. Within the infiltrated eryth-

Fig. 21-11 Bullous lesions of pemphigoid gestationis. (Courtesy of Martha McCollough, MD)

ematous plaques, tense vesicles and bullae erupt (Fig. 21-11), often in an annular or polycyclic configuration. Provitus is severe and may be paroxysmal. The disease will often flare shortly after delivery and then remit spontaneously, usually within 3 months. There is no scarring, except that caused by excoriations or secondary infections. Recurrences with subsequent pregnancies are common, and the disease may be provoked by subsequent menstrual periods or oral contraceptives. A number of cases of persistent disease have been reported.

Most studies data suggest that fetal loss is not statistically increased, although infants are often born prematurely and are small for gestational age. In fewer than 5% of cases, infants manifest the disease in the form of urticarial lesions or bullae. The lesions are usually limited and clear spontaneously without the need for therapy.

Etiologic Factors

PG is an autoimmune, antibody-mediated disease. A complement-fixing IgG antibody is present in the serum, and is deposited in the lamina lucida. The antigenic epitopes are usually restricted to the N-terminal portion of the extracellular domain of BP180 (BPAg2). The antigenic N-terminal portion of MCW-1 is located in the noncollagenous domain (NC16A) of BP180. Other antigens are located nearby, and four major PG epitopes are clustered within a 22 amino acid region of the BP180 ectodomain. Both IgG1 and IgG3 subtypes are noted.

Studies have documented an increased frequency of HLA-DR3, DR4, and C4 null alleles in patients with PG. A woman may have antibodies directed against her husband's HLA antigens. Black women rarely manifest PG, possibly related to the low incidence of HLA-DR4 in American black persons. There is an increased frequency of Graves' disease in PG patients.

Pathogenesis

Pathogenesis is similar to that of BP. However, hormonal factors influence the disease manifestation. In addition to being seen in pregnant patients, menstruating women, and those taking oral contraceptives, the disease may occur in association with hydatidiform mole and choriocarcinoma. The IgG antibodies bind to the lamina lucida and fix complement. Activated eosinophils, neutrophils, and T-cells with a predominant Th2 phenotype are involved in blister formation.

Patients with chronic PG tend to be older and multigravid, with a history of PG during previous pregnancies. They often have widespread cutaneous and mucosal involvement. The IgG1 subclass is commonly present. Antibodies to a C-terminal portion of BP180 have been noted in a patient with chronic PG. This same region is targeted in patients with cicatricial pemphigoid and some with BP.

Histopathology

A subepidermal bulla with eosinophils and some neutrophils is usually present. In the urticarial stage, eosinophils may line up along the dermoepidermal junction, as in urticarial BP. Civatte bodies may be present. On DIF, all patients have C3 deposited in a linear pattern at the dennoepidermal junction. Approximately 25% to 40% also have detectable IgG. By conventional IIF testing, approximately 25% of patients have a circulating IgG anti-basement zone antibody, but in nearly 75% the PG factor, a complement-fixing IgG antibody, can be demonstrated by complement-enhanced IF. Immunoelectron microscopy has demonstrated that the blister occurs at the level of the lamina lucida, with deposition of C3 and IgG at this site, exactly as in BP.

Differential Diagnosis

The main diagnosis to be considered is pruritic urticarial papules and plaques of pregnancy (PUPPP). The differential diagnosis also includes erythema multiforme, drug reactions, and bullous scabies. Acrodermatitis enteropathica has also been reported to flare as a bullous eruption with each pregnancy. Biopsy, immunofluorescence findings, and clinical course establish the diagnosis.

Treatment

The use of potent topical steroids may be adequate in some milder cases of PG. Prednisone in an oral dose of about 40 mg/day is usually effective in the remainder of cases. The dose is tapered to the lowest effective dose given on alternate days. Pyridoxine has been reported to be effective in some cases. Persistent PG after delivery has been treated with various tetracyclines, together with nicotinamide. A few severe cases have required treatment with cyclophosphamide, dapsone, methotrexate, IVIG, or plasmapheresis.

OTHER PREGNANCY-RELATED DERMATOSES

Intrahepatic Cholestasis of Pregnancy (Prurigo Gravidarum)

This pregnancy-related disease has no primary skin lesions, and is usually manifested only by severe generalized pruritus and jaundice. Secondary excoriations may be present. It is caused by cholestasis, occurs late in pregnancy, resolves after delivery, and recurs with subsequent pregnancies. There is an increased incidence of fetal complications. It has been estimated to occur in 0.5% of 3192 pregnancies. Both ursodeoxycholic acid and S-adenosyl-L-methionine improve pruritus, but the former is more effective in regard to improving liver function.

Polymorphic Eruption of Pregnancy

Some investigators have proposed grouping all the pruritic inflammatory dermatoses of pregnancy into the designation *polymorphic eruption of pregnancy*. This argument has some merit, as many of the pruritic eruptions of pregnancy are nonspecific or variable manifestations of pruritic urticarial papules and plaques of pregnancy, and there are no consistent hormonal or immunopathogenetic factors that reliably separate them. These eruptions occur in approximately 1 in 120 to 240 pregnancies.

Pruritic Urticarial Papules and Plaques of Pregnancy Lawley et al first reported seven patients under the name pruritic urticarial papules and plaques of pregnancy (PUPPP) in 1979. This eruption is characterized by erythematous papules and plaques that begin as 1- or 2-mm lesions within the abdominal striae. They then spread over the course of a few days to involve the abdomen, buttocks, thighs, and in some cases the arms and legs. The upper chest, face, and mucous membranes are generally spared. The lesions coalesce to form urticarial plaques, sometimes in figurate patterns, and occasionally spongiotic vesicles are

present. Intense proritus is characteristic. In contrast to PG, postpartum onset or exacerbation is uncommon. Fetal and maternal outcomes are not affected by this emption, and only rarely do newborns manifest transient lesions of PUPPP.

This eruption occurs in primigravidas 75% of the time, and rarely recurs with subsequent pregnancies. It begins late in the third trimester and resolves with delivery. Many studies have investigated the relationship of maternal weight gain to the development of this dermatosis. Patients with PUPPP average more weight gain and greater abdominal distension than those without the disease. It is more common in those carrying twins or triplets.

Histologic findings consist of a perivascular lymphohistiocytic infiltrate in the upper and mid-dermis, with a variable number of eosinophils and dermal edema. The epidermis is usually normal, although focal spongiosis, parakeratosis, or scales or crust may be present. The results of a direct immunofluorescence test are negative or nonspecific.

Usually, potent topical steroids are required to control the eruption. A few patients require prednisone. The disease remits after delivery.

Papular Dermatitis of Pregnancy Papular dermatitis of pregnancy is a controversial entity. It is defined as a pruritic, generalized eruption of 3- to 5-mm erythematous papules, each surmounted by a small, firm, central crust. The lesions may erupt at any time during pregnancy and usually resolve with delivery. Marked elevation of the 24-h urinary chorionic gonadotropin has been cited as a marker for the condition.

Administration of systemic corticosteroids is reportedly effective in controlling the eruption. The condition may recur in subsequent pregnancies. The high incidence of fetal deaths reported by Spangler is now felt to have been overstated. **Prurigo Gestationis (Besnier)** This eruption consists of pruritic, excoriated papules of the proximal limbs and upper trunk; these occur most often between the 20th and 34th week of gestation. It clears in the postpartum period and usually does not recur.

Therapy with potent topical steroidal agents is recommended. No adverse effects on maternal or fetal health are seen. This eruption may simply be an expression of atopic dermatitis in pregnancy.

Pruritic Folliculitis of Pregnancy Several authors have reported on pruritic folliculitis in gravid women, with small follicular pustules scattered widely over the trunk appearing during the second or third trimester and resolving by 2 or 3 weeks after delivery. Acute folliculitis and focal spongiosis with exocytosis of polymorphonuclear leukocytes are present on biopsy, and DIF results are negative. This condition may be a type of hormonally-induced acne.

Linear IgM Dermatosis of Pregnancy In 1988, Alcalay et al described a woman who developed small, red, follicular papules and pustules that on immunofluoresence testing showed linear deposits of IgM. This finding is common in a wide variety of dermatoses, and is nonspecific.

Impetigo Herpetiformis Impetigo herpetiformis is a form of severe pustular psoriasis occurring in pregnancy. It consists of an acute, usually febrile onset of grouped pustules on an erythematous base, which begins in the groin, axillae, and neck. There is a high peripheral white blood cell count, and hypocalcemia may be present. The histopathology is that of pustular psoriasis. The condition resolves with delivery, but recurrences with subsequent pregnancies may be expected. Fetal death is not uncommon, and results from placental insufficiency. Treatment is with systemic corticosteroids, in the range of 40 to 60 mg/day of oral prednisone. The condition is discussed in more detail in Chapter 10.

CICATRICIAL PEMPHIGOID (BENIGN MUCOSAL PEMPHIGOID)

In 1953, Lever suggested the designation benign mucosal pemphigoid for what had previously been called ocular pemphigus, cicatricial pemphigoid, or essential shrinkage of the conjunctiva. Because of its scarring nature, the designation cicatricial pemphigoid (CP) has gained predominance. The term encompasses a group of immunologically distinct immunobullous diseases with scarring.

Clinical Features

CP usually occurs in older women, with a female-to-male ratio of approximately 2:1. The condition is characterized by evanescent vesicles that rupture quickly, leaving behind erosions and ulcers. In most patients, they primarily occur on the mucous membranes, especially the conjunctiva (Fig. 21-12) and oral mucosa. Oral lesions occur in approximately 90% of cases and conjunctival lesions in 66%. The oral mucosa may be the only affected site for years.

Fig. 21-12 Cicatricial pemphigoid.

Desquamative gingivitis, diffuse erythema of the marginal and attached mucosa associated with mucosal desquamation and pain, is often the presenting sign. The mucosa readily peels away in response to pressure from a cotton-tipped applicator or stream of air from a dental air hose. The gingivae are almost always involved, and the lingual surfaces less regularly. The palate, tongue, and tonsillar pillars may be involved.

The disorder is chronic. In ocular cases, it leads to scarring and progressive shrinkage of the ocular mucous membranes. Blindness may result. It is usually bilateral and associated with redness and flaccid vesicles on the conjunctiva, xerosis, and fibrous adhesions (symblepharon). Entropion, trichiasis, and corneal opacities develop and ultimately, the adhesions attach both lids to the eyeball and narrow the palpebral fissure. Scarring may also develop in the pharynx, esophagus, larynx, and anogenital mucosa. Esophageal stricture may occur, and deafness has been reported.

Cutaneous lesions are seen in approximately 25% of patients. These begin as lense bullae, similar to those in BP. The bullae may occur on the face, scalp, neck, and the inguinal region or extremities. Generalized lesions may also occur. Some of these patients will have circulating antibodies targeted against the classic BP antigens, and should be classified as mucosal predominate BP. Some have secondary antibodies against other antigens. Some patients have EBA, as the IgG autoantibody was found to target type VII collagen. In Brunsting-Perry pemphigoid there are no mucosal lesions, but one or several circumscribed erythematous patches develop on which recurrent crops of blisters appear. Ultimately, atrophic scarring results. Generally, the areas of involvement are confined to the head and neck. The average age at onset is 58 with a 2:1 male-to-female ratio. In contrast to BP, cicatricial pemphigoid shows little tendency for remission. Although the disease is chronic, and produces significant morbidity, the patient's general health is usually not jeopardized.

Etiologic Factors

Circulating autoantibodies target the hemidesmosomal protein BP180, but the target epitopes differ from those usually targeted in BP. While most BP patients react with the noncollagenous domain (NC16a) on the extracellular N-terminal portion of BP180, most cicatricial pemphigoid antibodies target C-terminal domains. Fluorescence typically is found on the epidermal side of 1 M NaCl split skin.

Although patients share a similar phenotype, CP is a heterogeneous group of autoimmune subepidermal blistering diseases. Although most patients' autoantibodies target BP180, others target laminin 5 (antiepiligrin cicatricial pemphigoid), or the $\beta4$ subunit of $\alpha6\beta4$ integrin. Some patients with a CP phenotype have antibodies to multiple epitopes, including the $\beta4$ subunit of $\alpha6\beta4$ integrin, BP180 and BP230. Other subsets of patients targeting unique basement membrane zone antigens will likely be identified.

Among patients whose antibodies target laminin 5, most exhibit antibodies to the α subunit, especially the G domains of the α 3 subunit. Antibodies may also target the β 3 and γ 2 subunits. Other patients have been found to have autoantibodies that react with both laminin 6 as well as laminin 5, prompting the proposed designation of antilaminin cicatricial pemphigoid. In antilaminin cicatricial pemphigoid IgG anti-basement membrane zone autoantibodies bind to the dermal side of 1 M NaCl split skin. There is an increased relative risk for solid cancers (mostly adenocarcinomas) in these patients. Tumors are commonly found during the first year of the disease. Like other forms of CP, the disease rarely remits spontaneously.

Histopathology

The histologic findings are identical to those of bullous pemphigoid, with the exception that fibrosis and scarring may be present in the upper dermis. Basement membrane separation occurs in the lamina lucida or below the lamina densa, depending on the targeted antibody. The inflammatory infiltrate is variable.

DIF testing of perilesional skin or mucosa reveals C3 and IgG at the lamina lucida in 80% to 95% of patients. The basement membrane zone of mucosal glands stains as well. IgA may be found occasionally. A circulating antibody to the basement membrane zone is found by IIF in about 20% of cases. Immunoelectron microscopy shows that lamina lucida antibodies bind at a deeper level than with BP. Most IIFpositive cases show IgG binding to the epidermal side of saltsplit skin, although combined staining and dermal staining may be present in different subtypes, as noted above. Laser scanning confocal microscopy using fluorescein isothiocyanate-conjugated anti-human IgG antibody has been used to determine the localization of IgG at the basement membrane zone, and may be of value in patients with negative IIF. "Knockout" skin substrates and fluorescent overlay antigen mapping have also been used to differentiate between anti-epiligrin CP and EBA.

Treatment

A review of studies using the Cochrane criteria found two small randomized controlled trials, both in patients with severe eye involvement. In one, 6 months of cyclophosphamide was superior to prednisone. In the second trial, 20 of 20 patients responded well to 3 months of cyclophosphamide, while only 14 of 20 responded to dapsone. Based on these limited data, and other uncontrolled trials, the reviewers concluded that severe ocular CP responds best to cyclophosphamide combined with corticosteroids, and that mild-to-moderate disease may respond to dapsone.

In mild cases, oral hygiene, topical steroids, intralesional triamcinolone, or topical steroids occluded under vinyl inserts may be effective for desquamative gingivitis and other oral, genital or cutaneous disease. Cream and gel formulations may be used, or the steroid may be compounded in orabase. Topical sucralfate suspension may decrease the pain and healing time of the oral and genital ulcers. Cyclosporin washes have some efficacy but are too expensive for general use. Other topical calcineurin inhibitors have been used effectively. There have been reports of efficacy of thalidomide, tetracycline combined with niacinamide, dapsone, IVIG, systemic corticosterois, and immunosuppressive drugs.

EPIDERMOLYSIS BULLOSA ACQUISITA

Criteria for epidermolysis bullosa acquisita (EBA) were proposed in 1971 by Roenigk, and included 1) clinical lesions of dystrophic epidermoylsis bullosa, including increased skin fragility, trauma-induced blistering with erosions, atrophic scarring, milia over extensor surfaces, and nail dystrophy; 2) adult onset; 3) lack of a family history of epidermoylsis bullosa; and 4) exclusion of all other bullous diseases such as porphyria cutanea tarda, pemphigoid, pemphigus, dermatitis herpetiformis, and bullous drug eruption. In 1981, Roenigk et al extended these criteria to include 5) IgG at the basement membrane zone by DIF; 6) the demonstration of blister formation beneath the basal lamina; and (7) deposition of IgG beneath the basal lamina. Since then, the clinical spectrum of this disease has expanded, with evidence that some patients have histologic findings identical to BP, but show positive immunofluorescence on the floor of salt-split skin. The antibodies have been found to target type VII collagen, a major component of anchoring fibrils. The target is the same as that in bullous lupus erythematosus. In some patients, it has been shown that autoantibodies bind to the NC-1 domain of collagen VII within the lamina densa. ITF studies reveal circulating antibasement membrane zone antibodies in approximately half of cases. The antibodies are directed against multiple

epitopes on the N-terminal noncollagenous domain of type VII collagen.

The noninflammatory clinical presentation of EBA is the most commonly recognized type. The association of EBA with many systemic diseases, such as myeloma, granulomatous colitis, diabetes, lymphoma, leukemia, amyloidosis, and carcinoma is well established. In rare instances, cases of this noninflammatory subset may mimic either BP or CP. When the onset is in childhood, hereditary dystrophic epidermoylsis bullosa may be considered.

In 1982, Gammon described patients with generalized inflammatory bullous disease that resembled BP clinically, but with immunologic and ultrastructural features of EBA. Many of these patients have associated diabetes mellitus, are HLA-DR2 positive, and progress to the trauma-induced scarring type of EBA in the long-term. Approximately 5% to 10% of patients referred to medical centers as having BP may actually have EBA.

EBA patients usually have a predominance of neutrophils over eosinophils, although this is variable. On IIF, EBA patients are more likely to have linear IgG without concomitant C3 deposition than are patients with BP. Immunofluorescence on salt-split skin allows differentiation of the majority of cases without needing to resort to immunoblot techniques or immunoelectron microscopy. By DIF testing of the patient's salt-split skin biopsy, EBA will manifest IgG deposition only on the dermal side of the split, whereas the majority of BP patients will have IgG bound only to the epidermal side or to both sides. As demonstrated by IIF, the same results apply in the majority of cases. As noted above, some patients with BP have antibodies that target sub-lamina densa antigen. Absolute differentiation of these diseases is obtained by immunoelectron microscopy or immunoblot findings. In EBA, immunoblotting identifies 290-kD and 145-kD proteins, corresponding to type VII collagen.

Because bullous systemic lupus erythematosus (SLE) and EBA share antibasement membrane zone antibodies of identical specificity, and there is clinical and histologic overlap as well, this differential diagnosis may be difficult. The following features help to identify EBA: skin fragility, predilection for traumatized areas, and healing with scars and milia. In SLE, sun-exposed skin is involved by preference, the patient has a diagnosis of SLE established by ACR criteria, and in bullous SLE there is usually a dramatic response to dapsone. In addition to the cases of bullous SLE that show linear IgG staining below the lamina densa with circulating IgG autoantibodies to the 290-kD and 145-kD antigens, some patients will show granular staining of IgG at the basement membrane zone without circulating IgG. EBA-like eruptions are rarely seen as a result of penicillamine therapy.

Purely IgA-mediated EBA has been described. The patients resemble linear IgA dermatosis or inflammatory IgG-mediated EBA. Only a minority demonstrate milia or scarring.

Treatment

A review of the literature using Cochrane criteria failed to identify any randomized controlled trials. The disease is often resistant to therapy, but good responses have been reported in some patients treated with systemic steroids alone or in combination with azathioprine or dapsone. Other agents reported to be effective include mycophenolate mofetil, IVIG, cyclosporin, colchicine, plasmapheresis, and the humanized murine monoclonal anti-Tac antibody daclizumab. Extracorporeal photochemotherapy has been effective in a few patients with refractory disease. Supportive therapy, including control of infection, careful wound management, and maintenance of good nutrition should be emphasized.

DERMATITIS HERPETIFORMIS (DUHRING DISEASE)

Clinical Features

Dermatitis herpetiformis (DH) is a chronic, relapsing, severely pruritic disease characterized by grouped, symmetrical lesions on extensor surfaces, the scalp, nuchal area, and buttocks. As the lesions as severely pruritic, they generally present as excoriations. The emption usually occurs on an erythematous base and may be papular, papulovesicular, vesiculobullous (Fig. 21-13), bullous, or urticarial. Linear petechial lesions may be noted on the volar surfaces of the fingers as well as the palms (Fig. 21-14). Pigmented spots alone over the lumbosacral region should arouse suspicion of DH. The mucous membranes are involved in rare cases, mostly when bullae are numerous. Laryngeal lesions may manifest as hoarseness.

Itching and burning are usually intense, and their paroxysmal quality provokes scratching to the point of bleeding and, at times, scarring. Spontaneous remissions lasting as long as a week and terminating abruptly with a new crop of lesions are a characteristic feature of the disease. Perimenstrual flares may occur.

Seventy-seven to 90% of patients with DH and IgA deposits in the skin are HLA-B8 positive, a similar frequency to that observed in gluten-sensitive enteropathy (GSE). HLA antigens DR3 and DQw2 are also increased in frequency.

Fig. 21-13 Vesicle of dermatitis herpetiformis on the elbow.

Fig. 21-14 Characteristic linear petechial lesions on the digits in a patient with dermatitis herpetiformis.

Black and Asian patients are infrequent and some studies indicate this may be because of HLA differences. These HLA markers are associated with other autoimmune diseases and are a marker of patients who appear to have an overactive immune response to common antigens and may clear immune complexes slowly. DH is more common in those with affected family members.

DH in childhood is usually similar to the adult type, has identical histologic and immunofluorescent findings, and has a high incidence of HLA-B8 and -DR3 and abnormal jejunal biopsies. Palmer blisters and brown, hemorrhagic, purpuric macules may be more common than in adults. Treatment with sulfones results in prompt response, as in adults.

Gluten, a protein found in cereals except for rice and corn, provokes flares of the disease. Villous atrophy of the jejunum and inflammation of the small bowel occurs. IgA is bound to the skin, and this apparently activates complement, primarily via the alternate pathway. Oral iodides will cause a flare of the disease. Patch tests with 50% potassium iodide in petrolatum produce a bulla in uncontrolled DH, but only exceptionally in patients controlled by a gluten-free diet or by sulfone therapy.

Associated Disease

Thyroid disorders are increased in incidence in patients with DH. An increased incidence of malignancy, especially small bowel lymphoma has also been noted.

Enteropathy

Seventy to 100% of patients with DH have abnormalities in the jejunal mucosa, but most are asymptomatic. If given a high-gluten diet, virtually all patients with DH develop findings indistinguishable from celiac disease, and DH affects approximately 25% of patients presenting with celiac disease.

The dapsone requirement in DH is usually decreased after 3 to 6 months of a gluten-free diet. The majority of patients who adhere to a strict gluten-free diet can eventually stop their medication or significantly reduce the dosage. A glutenfree diet is not easy to follow.

Diagnosis

The distinction from linear IgA bullous dermatosis is often clinically impossible. Other conditions considered in the differential diagnosis at times are BP, bullous erythema multiforme, scabies, contact dermatitis, atopic dermatitis, nummular eczema, neurotic excoriations, insect bites, and chronic bullous disease of childhood. The finding of IgA in a granular pattern at the dermoepidemal junction with accentuation in the dermal papillae is specific for DH.

Autoantibodies Circulating IgA antibodies against the smooth muscle cell endomysium (anti-endomysial antibodies) are present in 70% of DH patients, in nearly all active celiac disease patients, and almost never in other conditions. Tissue transglutaminase (TTG) is the major autoantigen in GSE. Although anti-TTG antibodies are found in the majority of patients with DH, these patients have antibodies that bind more avidly to a related enzyme, epidermal (type 3) transglutaminase. IgA deposits in the papillary dermis contain epidermal transglutaminase, but not TTG. Dietary exposure to gliadin proteins in wheat and related proteins from barley and rye induce flares of the disease. These proteins are high-affinity substrates for TTG. The two are often tightly bound, which may explain why an antibody response is generated against both gliadin and TTG. Gliadins can also be found in rice, corn, and oats, but these proteins are poor substrates for TTG. Some data suggest that a diet with moderate quantities of oats can be tolerated in patients with controlled DH or GSE.

Epidemiology

This disease has an equal male-to-female incidence. The average age of onset is between 20 and 40 years. It does occur with some frequency in children. Black and Asian persons are rarely affected.

Histopathology

The initial changes are first noted at the tips of the dermal papillae, where edema, focal fibrin, and neutrophilic microabscesses are seen (Fig. 21-15). The cellular infiltrate contains many neutrophils, but may also include a few eosinophils. A

Fig. 21-15 Dermatitls herpetiformis, neutrophilic microabscesses within the dermal papillae.

subepidermal separation is noted histologically. Ultrastructurally the split may begin in the lamina lucida. In a study of 24 cases of confirmed DH, 37.5% had nonspecific findings on hematoxylin and eosin (H&E), including a lymphocytic infiltrate, ectatic capillaries, and fibrosis in the dermal papillae. Because of the potential for nonspecific biopsy findings, DIF studies are essential. Histologic differentiation of linear IgA bullous dermatosis from DH is extremely difficult unless DIF is performed.

DIF of noninvolved perilesional skin reveals deposits of IgA alone or together with C3 arranged in a granular pattern at the dermoepidermal junction. The granules may be vertically elongated, giving a "picket-fence" appearance. The deposits are typically accentuated in the dermal papillae. IgM and IgG deposits are occasionally observed in association with IgA. Deposits may be focal, so that multiple biopsies may be needed, and the deposits of antibody are more often seen in previously involved skin or normal-appearing skin adjacent to involved skin. By immunoelectron microscopy IgA is observed either alone or in conjunction with C3, IgG, or IgM as clumps in the upper dermis. A fibrillar staining pattern exists when the immune deposits are along dermal microfibrils. A few patients will have negative DIF despite typical clinical findings and evidence of anti-endomysial antibodies. IF is rarely positive.

Treatment

The drugs chiefly used are dapsone and sulfapyridine. The most effective sulfone is diaminodiphenylsulfone (dapsone). The dose varies between 50 and 300 mg/day, usually starting with 100 mg/day and increasing gradually to an effective level or until side effects occur. Once a favorable response is attained, the dosage is decreased to the minimum that does not permit recurrence of signs and symptoms. When dapsone is discontinued abruptly, large bullae similar to those seen in BP frequently occur. Hemolytic anemia, leukopenia, methemoglobinemia, agranulocytosis or peripheral neuropathy may occur with dapsone. Acute hemolytic anemia (which may be severe) occurs in patients with glucose-6-phosphate dehydrogenase (GDPD) deficiency, therefore a G6PD level should be done before therapy. In those whose ethnic background makes G6PD deficiency unlikely, some authorities begin dapsone at a low starting dose (25 mg/day) and watch the patient closely for dark urine. The patient should be warned to report by telephone any incident of red or brown urine or blue nailbeds or lips. A blood count should be done weekly for 4 weeks, bimonthly for the next 3 months, and every 2 to 6 months thereafter. Liver function tests should be monitored bimonthly for the first 4 months, then checked with the hematologic studies every 4 to 6 months.

Agranulocytosis is rare. It typically occurs 1 to 3 months after initiation of drug therapy, and presents with sore throat, aphthae or evidence of infection. The risk of agranulocytosis is higher in older individuals (>60 years) and non-white persons. The incidence varies with the disease. It is rarely seen in leprosy patients but patients with DH have a 25- to 33-fold increased risk.

Sulfapyridine can also be used to treat the disease. After a test dose of 0.5 g of sulfapyridine, one tablet (0.5 g) four times a day is given. The dose is then increased if necessary, or reduced if possible. Usually 1 to 4 g/day is required for good control. The drug is less water soluble than dapsone, and patients should remain hydrated. Sulfasalazine, 500 mg three times a day, increased to 1.5 g three times a day as tolerated, may also be used, since sulfapyridine is a metabolic product. Gastrointestinal intolerance may limit the dosage. In rare patients, it is necessary to find alternatives to the sulfone drugs. Tetracycline/nicotinamide and colchicine have controlled individual patients.

Gluten-Free Diet Patients must strictly avoid wheat, barley, and rye. Moderate amounts of oats may be tolerated. Corn and rice are generally well tolerated, corresponding to the poor binding of their gliadin proteins to TTG. If a glutenfree diet is followed strictly, the patient will almost certainly be able to take less medication or stop it altogether. Some evidence suggests this may decrease the incidence of associated malignancy; however, it is a very difficult diet to follow. The diet will help to achieve a remission. Once a prolonged remission has been obtained, some gluten may be tolerated in a subset of patients. In one study, 38 patients who had followed a gluten-free diet for a mean of 8 years reintroduced gluten to their diets. Thirty-one experienced recurrence within an average of 2 months, but seven remained in remission for a mean follow-up of 12 years. IgA deposits did not recur in their skin. This report suggests that clinical and histologic remission can be maintained in some patients with DH despite the reintroduction of dietary gluten. For most patients, however, a gluten-free diet remains an important aspect of disease management. Support may be obtained from the American Celiac Society/Dietary Support Coalition, Annette Bentley, President, 59 Crystal Avenue, West Orange, NJ 07052-3570, 973-325-8837 (Voice), 973-669-8808 (FAX). A list of celiac societies can be found at http://www.nowheat.com/grfx/nowheat/primer/celisoc.htm or http://www.enabling.org/ia/celiac/groups/groupsus.html. A commercial website with a search engine can be found at http://www.celiac.com, Another commercial source for products can be found at http://www.glutenfreemall.com. A Google search using the terms "celiac society" or "glutenfree diet" is a good starting point for patients with the disease who want more information about the diet and commercially available products.

LINEAR IGA BULLOUS DERMATOSIS

Linear IgA bullous dermatosis (LAD) is characterized by subepidermal blisters, a neutrophilic infiltrate, and a circulating IgA anti-basement membrane zone antibody with linear basement membrane zone deposits on DIF. Like CP, linear IgA disease is really a group of diseases with a similar immunofluorescent pattern.

Adult Linear IgA Disease

This acquired, autoimmune blistering disease may present with a clinical pattern of vesicles indistinguishable from DH, or with vesicles and bullae in a BP-like appearance. There may be urticarial lesions and bullae may occur on an urticarial base as in BP. Mucous membrane involvement may occur in up to 50% of cases. In some cases, oral and conjunctival lesions dominate the presentation, and scarring may occur as in CP. In the majority of patients, there is no association with enteropathy or with HLA-B8. The disease tends to remit after several years in approximately 60% of patients. IgA is commonly directed against a 97-kD antigen in the lamina lucida. Some patients demonstrate both IgA and IgG antibodies to BP180 and IgA to LAD285. IgA and IgG reactivity have been found to all three portions of the BP180 ectodomain. In some patients, the strongest reactivity is to the C-terminal portion of BP180 (the major antigenic

Bardella MT, et al: Long-term remission in patients with dermatitis herpetiformis on a normal diet. Br J Dermatol 2003; 149:968.

Fig. 21-16 Direct immunofluorescence of linear IgA disease.

area in CP). This may explain cases of clinical overlap with CP. Antigenic targets for LAD are expressed by both keratinocytes and fibroblasts.

Linear IgA dermatosis commonly occurs as a druginduced disease. In drug-induced disease, the eruption is self-limited, there is less mucosal involvement, and usually no detectable circulating autoantibody. The IgA may be deposited in the subbasal lamina area. Implicated drugs include vancomycin, lithium, amiodarone, carbamazipine, captopril, penicillin, PUVA, furosemide, oxaprozin, IL-2, interferon- γ , phenytoin, diclofenac, statins, tea tree oil, anigotension receptor antagonists, and glibenclamide. The antigen identified may be the 97-kD antigen, the 230-kD BP antigen, or the 180-kD BP antigen.

Some cases have been associated with internal malignancy or infection. Sporadic reports have linked single cases with dermatomyositis, rheumatoid arthritis, and multiple sclerosis, although these are probably fortuitous associations.

Biopsies commonly demonstrate papillary dernal microabscess with neutrophils. As in DH, eosinophils may be present. Subepidermal bullae commonly contain a mixture of neutrophils and eosinophils. On DIF, a homogeneous linear (tubular or toothpaste) pattern of IgA is present at the basement membrane zone (Fig. 21-16). Some cases will have both linear IgA and IgG in combination at the basement membrane zone. A lack of C3 may be a clue that both immunoglobulins recognize the 97-kD antigen.

By IIF, only a minority will have circulating IgA autoantibody with anti-basement membrane specificity, and this is usually present in low titer. On salt-split skin, deposition may occur on the roof, base, or a combination of the two. This correlates with the fact that on immunoelectron microscopy deposition of the autoantibody may be present in the lamina lucida, below the lamina densa, or both. Some patients with sublamina densa deposits have EBA.

In drug-induced disease, the drug must be stopped. Many cases resolve quickly, but some require drug therapy with a corticosteroid or dapsone. Idiopathic disease generally responds to dapsone in doses similar to that described for DH. Other cases require topical or systemic steroids in addition, or as sole treatment. A combination of tetracycline, 2 g/day, and nicotinamide, 1.5 g/day, may be effective. Other patients have responded to mycophenolate mofetil, IVIG, colchicine, or erythromycin. The rare patients with associated GSE may respond to a gluten-free diet.

Childhood Linear IgA Disease (Chronic Bullous Disease of Childhood)

Chronic bullous disease of childhood (CBDC) is an acquired, self-limited bullous disease that may begin by the time the patient is aged 2 or 3 and usually remits by age 13. The average age of onset is 5 years. Bullae develop on either erythematous or normal-appearing skin, preferentially involving the lower trunk, buttocks, genitalia, and thighs. Perioral and scalp lesions are common, and oral mucous membrane lesions may occur in up to 75% of patients. Bullae are often arranged in rosettes or an annular array, the so-called string of pearls configuration (Fig. 21-17). Tense individual bullae similar to those present in BP are also seen. Pruritus is often severe.

The prime histologic finding is the presence of a subepidermal bulla filled with neutrophils. Eosinophils may be present, and in some cases eosinophils predominate. DIF reveals a linear deposition of IgA at the basement membrane zone identical to that seen in the adult forms of the disease. IIF is positive for circulating IgA anti-basement membrane zone antibodies in approximately 50% of cases, usually in low titer. In contrast to adult LAD, children demonstrate an increased frequency of B8, DR3, and DQ2, and may be homozygous for these antigens. As in the adult disease, immunoelectron microscopy and immunomapping studies may demonstrate immune deposits within the lamina lucida, below the lamina densa, or both. As in adult disease, some children have both IgG and IgA deposits. GSE is rare.

Many patients' antibodies target the 97-kD peptide. Some children with subbasal lamina deposits target type VII collagen and have EBA. Patients with only IgA or with both IgG and IgA circulating autoantibodies may target BP230 or BP180. Individual patients may have a combination of JgA against the 97-kD peptide, and IgG against BP230 and BP180. Collagen XVII/BP180 is a transmembrane protein

Fig. 21-17 Chronic bullous disease of childhood.

with a soluble 120-kD ectodomain. In linear IgA dermatosis and CBCD, IgA targets the soluble ectodomain more efficiently than the full-length protein. Some sera target the Col15 domain.

The untreated disease runs a variable course, with eventual spontaneous resolution by adolescence being common. Treatment with either dapsone or sulfapyridine is usually successful. Occasional cases respond to topical steroids alone, and systemic steroids are sometimes necessary. Other patients have responded to mycophenolate mofetil, colchicine, or dicloxacillin.

TRANSIENT ACANTHOLYTIC DERMATOSIS (GROVER'S DISEASE)

In 1970, Grover described a new dermatosis that occurred predominantly in persons over 50 years of age consisting of a sparse eruption of limited duration. The lesions were fragile vesicles that rapidly turned into crusted and keratotic erosions. He termed the condition transient acantholytic dermatosis (TAD). Since then, the majority of cases have been found to persist or recur, and the term persistent and recurrent acantholytic dermatosis may be a more accurate description of the disorder. The distribution is predominantly limited to the chest or shoulder girdle area and upper abdomen, and there is a strong male predominance. The condition often appears or flares during periods of heat, sweating or hospitalization. Many patients are asymptomatic and the condition may be an incidental finding on examination. Other patients complain of pruritus. Asteatotic eczema occurs five times as often among patients with TAD as in controls. The disorder has been described in the setting of a variety of malignancies, but may be associated with the hospitalization rather than the malignancy itself. Patients at strict bedrest appear to have a higher incidence of the disease. The clinical differential diagnosis includes Galli-Galli disease, an acantholytic variant of Dowling-Degos disease that may resemble TAD clinically.

There are five histologic types resembling Darier's disease, PV, PF, benign familial pemphigus, or spongiotic dermatitis. The Darier type predominates. Often two or more types can be found in a single biopsy specimen. DIF studies yield negative or nonspecific results. Although heat and sweating are significant risk factors, only a minority of cases are associated with acrosyringia histologically.

About 50% of patients respond to topical steroids. Control of levers, hospital discharge, and avoidance of sun and sweating often result in improvement. Sustained remission has been described after a course of systemic corticosteroids. Isotretinoin and dapsone have been successful in some patients. PUVA has been reported to result in an initial flare followed by slow clearance.

CHAPTER

22 Nutritional Diseases

A nutritional disease is caused either by insufficiency or, less often, by excess of one or more dietary essentials. Nutritional diseases are particularly common in underdeveloped tropical countries. Infants and children are particularly at risk for deficiency states, especially malnutrition. Frequently, patients have features of several of these disorders if their diets have been generally restricted. An intertiginous or acral eruption, a seborrheic dermatitis-like facial eruption, atrophic glossitis, and alopecia are common features of many nutritional deficiencies. This occurs because these nutrients are essential to overlapping metabolic pathways of fatty acid metabolism, resulting in abnormal arachadonic acid metabolism and abnormal differentiation of the epidermis. The abnormal epidermal differentiation results in impaired epidermal lipid and intercellular junction production and defective barrier function. Impaired disposal of free radicals may also occur. The histologic findings in many types of nutritional dermatoses are also similar.

In developed countries, alcoholism is the main cause of nutritional diseases. Nutritional diseases should also be suspected in postoperative patients; psychiatric patients, including those with anorexia nervosa and bulimia; patients on unusual diets; patients with surgical or inflammatory bowel dysfunction, especially Crohn's disease; and patients with severe oral erosive disease (such as pemphigus) which prevents eating. Cystic fibrosis may be accompanied by nutritional deficiency dermatitis. In the pediatric setting, nutritional deficiency may also occur because of parental ignorance of the nutritional requirements of their infants. The diagnosis of nutritional deficiency is often missed since physicians fail to take adequate dietary histories. The edema of protein malnutrition may mask the problem. The dermatitis produced by elevated glucagon levels from islet cell tumors of the pancreas (necrolytic migratory erythema) and a similar dermatoses seen in hepatitis C infection and other forms of hepatic insufficiency (necrolytic acral erythema and pseudoglucagonoma) probably also represent nutritional deficiency dermatoses. Deficiency states caused by inborn errors of metabolism are discussed in Chapter 26.

VITAMIN A

Hypovitaminosis A (Phrynoderma)

Vitamin A is a fat-soluble vitamin found as retinyl esters in milk, fish oil, liver, and eggs, and as carotenoids in plants. Vitamin A deficiency is common in children in the developing world. It is rare in developed countries, where it is most commonly associated with diseases of fat malabsorption, such as bowel bypass surgery for obesity, pancreatic insufficiency, Crohn's disease, celiac disease, cystic fibrosis, and liver disease. Vitamin A is required for the normal keratinization of many mucosal surfaces. When deficient, the resultant abnormal keralinization leads to increased mortality from inflammatory disease of the gut and lung—diarrhea and pneumonia (especially in rubeola). Vitamin A supplementation of 200,000 IU/day for 2 days is recommended for children with rubeola.

The skin eruption, termed phrynoderma, or "toadskin," resembles keratosis pilaris. It consists of keratotic papules of various sizes, distributed over the extremities and shoulders, surrounding and arising from the pilosebaceous follicles. Individual lesions are firm, pigmented papules containing a central intrafollicular keratotic plug, which projects from the follicle as a horny spine and leaves a pit when expressed. Lesions are of two sizes: 1- to 2-mm papules closely resembling keratosis pilaris, and the more diagnostic large 2- to 6-mm crateriform papules filled with a central keratotic plug. These later lesions may simulate a perforating disorder. The eruption of small lesions usually begins on the anterolateral aspect of the thighs or the posterolateral aspect of the upper arms. It then spreads to the extensor surfaces of both the upper and lower extremities, shoulders, abdomen, back, and buttocks, and finally reaches the face and posterior aspect of the neck. The hands and feet are not involved and only occasionally are there lesions on the midline of the trunk or in the axillary and anogenital areas. On the face, the eruption resembles acne because of the presence of many large comedones, but it differs from acne in respect to dryness of the skin. The large dome-shaped nodules are on the elbows and knees. They have a surrounding red or brown rim. The whole skin displays dryness, fine scaling, and hyperpigmentation.

In vitamin A deficiency, eye findings are prominent and often pathognomonic. These include night blindness, an inability to see bright light, xerophthalmia, xerosis comeae, and keratomalacia. The earliest finding is delayed adaptation to the dark (nyctalopia). Sometimes there are circumscribed areas of xerosis of the conjunctiva lateral to the comea, occasionally forming well-defined white spots (Bitot spots). These are triangular, with the apex toward the canthus. Vitamin A deficiency is a major cause of blindness in children in the developing world. The histologic findings of vitamin A deficiency are hyperkeratosis, horny plugs in the upper portion of the hair follicle, coiled hairs in the upper part of the follicle, severe atrophy of the sebaceous glands, and squamous metaplasia of the secretory cells of the eccrine sweat glands. If the follicles rupture, perifollicular granulomatous inflammation is found.

The diagnosis of vitamin A toxicity is confirmed by determination of the serum retinol level. The treatment is oral vitamin A 100,000 JU/day for 2 to 3 days followed by the recommended dietary requirement. Serum retinol levels are monitored to determine adequacy of supplementation and to avoid vitamin A toxicity.

Hypervitaminosis A

Because the skin findings of hypervitaminosis A are similar to the side effects of synthetic retinoid therapy, they are well recognized by most dermatologists. Children are at greater risk for toxicity than adults. Excess megavitamin ingestion may be the cause. In adults, as little as 25,000 IU/day may lead to toxicity, especially in persons with hepatic compromise from alcoholic, viral, or medication-induced hepatitis. Dialysis patients also are at increased risk. If the patient is taking a synthetic retinoid, all vitamin A supplementation should be stopped.

Most cases of chronic hypervitaminosis A have been reported in children. There is loss of hair and coarseness of the remaining hair, loss of the eyebrows, exfoliative cheilitis, generalized exfoliation and pigmentation of the skin, and clubbing of the fingers. Moderate widespread itching may occur. Hepatomegaly, splenomegaly, hypochromic anemia, depressed serum proteins, and elevated liver function tests may be found. Bone growth may be retarded by premature closure of the epiphyses in children. Pseudotumor cerebri with papilledema may occur very early, before any other signs appear. In infants this may present as a bulging fontanelle.

In adults, the early signs are dryness of the lips and anorexia. These may be followed by joint and bone pains, follicular hyperkeratosis, branny desquamation of the skin, fissuring of the corners of the mouth and nostrils, dryness and loss of scalp hair and eyebrows, and dystrophy of the nails. Fatigue, myalgia, depression, anorexia, headache (from pseudotumor cerebri), strabismus, and weight loss commonly occur. Liver disease may be progressive and may lead to cirrhosis with chronic toxicity. Hypercalcemia commonly occurs in dialysis patients. Retinoids are teratogens, and birth defects may occur with excess vitamin A supplementation during pregnancy.

VITAMIN D

Although active vitamin D is produced in the skin, deficiency of vitamin D has no skin manifestations, except for alopecia. The elderly have decreased vitamin D cutaneous photosynthesis by reason of decreased sun exposure and poor intake of vitamin D, both of which predispose them to osteomalacia. Aggressive photoprotection may also reduce vitamin D levels. Other patients at risk include those who are debilitated with limited sun exposure, those taking anticonvulsants, and those with fat malabsorption. Supplementation for these patients should be considered. Rickets in malnourished children responds best to combination therapy with vitamin D and calcium supplementation.

- Welsh O, et al: Tropical dermatology. Part II. J Am Acad Dermatol 2002;46:748.

VITAMIN K DEFICIENCY

Dietary deficiency of vitamin K, a fat-soluble vitamin, does not occur in adults because it is synthesized by bacteria in the large intestine. However, deficiency may occur in adults because of malabsorption caused by biliary disease, malabsorption syndromes, cystic fibrosis, or anorexia nervosa. Liver disease of all causes produces deficiency. Drugs such as coumarin, salicylates, cholestyramine, and perhaps the cephalosporins may induce a deficiency state. Newborns of mothers taking coumarin or phenytoin, or premature infants with an uncolonized intestine, can be vitamin K-deficient. The result is a decrease in the vitamin K-dependent clotting factors II, VII, IX, and X. The cutaneous manifestations that result are purpura, hemorrhage, and ecchymosis. Treatment is 5 to 10 mg/day of intramuscular vitamin K for several days. In acute crises, fresh frozen plasma is used.

Soundararajan R, et al: Skin necrosis and protein C deficiency associated with vítamin K depletion in a patient with renal failure. Am J Med 1992;93:467.

VITAMIN B1 DEFICIENCY

Vitamin B_1 (thiamine) deficiency results in beribevi. The skin manifestations are limited to edema. Peripheral neuropathy is common.

Comabella M, et al: latrogenic fulminant beriberi. Lancet 1995; 346:182.

VITAMIN B2 DEFICIENCY

Vitamin B_2 (riboflavin) deficiency is seen most often in alcoholic patients; however, phototherapy for neonatal icterus, acute boric acid ingestion, hypothyroidism, and chlorpromazine use have been reported to cause it also. The classic findings are the oral-ocular-genital syndrome. The lips are prominently affected with angular cheilitis (perlèche) and cheilosis. The tongue is atrophic and magenta. A seborrheic-like dermatitis with follicular keratosis around the nares, primarily affects the face. Genital dermatitis is worse in men than it is in women who have riboflavin deficiency. There is a confluent dermatitis of the scrotum, sparing the midline, with extension onto the thighs. Photophobia and blepharitis angularis occur. The response to 5 mg/day of riboflavin is dramatic.

Roe DA: Riboflavin deficiency. Semin Dermatol 1991;10:293.

VITAMIN B₆

Pyridoxine Deficiency

Pyridoxine deficiency may occur in cases of uremia and cirrhosis, as well as with the use of certain pharmacologic agents. Skin changes include a seborrheic dermatitis-like eruption, atrophic glossitis with ulceration, angular cheilitis, conjunctivitis, and intertrigo. Occasionally, a pellagra-like eruption may occur. Neurologic symptoms include somnolence, confusion, and neuropathy.

Pyridoxine Excess

Friedman et al reported a patient who ingested large doses of pyridoxine (vitamin B_6) and developed a subepidernial vesicular dermatosis and sensory peripheral neuropathy. The bullous dermatosis resembled epidermolysis bullosa acquisita.

Friedman MA, et al: Subepidermal vesicular dermatosis and sensory peripheral neuropathy caused by pyridoxine abuse. J Am Acad Dermatol 1986;14:915.

VITAMIN B₁₂ DEFICIENCY

Vitamin B_{12} (cyanocobalamin) is absorbed through the distal ileum after binding to gastric intrinsic factor in an acid pH. Deficiency is caused mainly by gastrointestinal abnormalities, such as a deficiency of intrinsic factor, achlorhydria, ileal diseases, and malabsorption syndromes resulting from pancreatic disease or sprue. Congenital lack of transcobalamin II can also produce B_{12} deficiency. Because of the large body stores in adults, deficiency occurs 3 to 6 years after gastrointestinal abnormalities.

Glossitis, hyperpigmentation, and canities are the main dermatologic manifestations. The tongue is bright red, sore, and atrophic. The hyperpigmentation is generalized, but it is more commonly accentuated in exposed areas, such as the face and hands, and in the palmar creases and flexures, resembling Addison's disease. The nails may be pigmented. Premature gray hair may occur paradoxically. Megaloblastic anemia is present. Weakness, paresthesias, numbness, ataxia, and other neurologic findings occur.

Parenteral replacement with intramuscular injections, 1 mg/ week for 1 month, then 1 mg/month, leads to a reversal of the pigmentary changes in the skin, nails, mucous membranes, and hair. Neurologic defects may or may not improve.

FOLIC ACID DEFICIENCY

Diffuse hyperpigmentation, glossitis, cheilitis, and megaloblastic anemia, identical to vitamin B_{12} deficiency, occur in folic acid deficiency.

Downham TF, et al: Hyperpigmentation and folate deficiency. Arch Dermatol 1976;112:562.

SCURVY

Scurvy, or vitamin C deficiency, is the deficiency disease most commonly diagnosed by dermatologists, since cutaneous manifestations are early and prominent features. Elderly male alcoholics and psychiatric patients on restrictive diets are most commonly affected.

The four Hs are characteristic of scurvy: hemorrhagic signs, hyperkeratosis of the hair follicles, hypochondriasis, and hematologic abnormalities. Perifollicular petechiae are the characteristic finding (Fig. 22-1). In addition, ecchymoses of various sizes, especially on the lower extremities, are common (Fig. 22-2). These may be associated with tender nodules (subcutaneous and intramuscular hemorrhage) and subperiosteal hemorrhage, leading to pseudoparalysis in children. Woody edema may be present, simulating cellulitis. Subungual, subconjunctival, intramuscular, periosteal, and intra-articular hemorrhage may also occur. The referring diagnosis is often vasculitis.

Another characteristic finding is keratotic plugging of the hair follicles, chiefly on the anterior forearms, abdomen, and posterior thighs. The hair shafts are curled in follicles capped by keratotic plugs. This distinctive finding has been named "corkscrew hairs."

Hemorrhagic gingivitis occurs adjacent to teeth and presents as swelling and bleeding of the gums. The teeth are loose and the breath is foul (Fig. 22-3). Gingival disease may be absent. Edentulous areas do not develop gingivitis, and those with good oral hygiene have less prominent gingival involvement. Epistaxis, delayed wound-healing, and

Noppakun N, et al: Reversible hyperpigmentation of skin and nails with white hair due to vitamin B₁₂ deficiency. Arch Dermatol 1986;122:896.

depression also may occur. Frequently, anemia is present and may be the result of blood loss or associated deficiencies of other nutrients such as folate.

The diagnosis of scurvy is usually made on clinical grounds and confirmed by a positive response to vitamin C supplementation. A biopsy will exclude vasculitis and demonstrate follicular hyperkeratosis, coiled hairs, and perifollicular hemorrhage in the absence of inflammation. Serum ascorbic acid levels may be confirmatory in unusual cases. Treatment is with ascorbic acid, 1000 mg/day for a few days to 1 week, and a maintenance dose of 100 mg/day should be considered.

NIACIN DEFICIENCY (PELLAGRA)

Pellagra usually results from a deficiency of nicotinic acid (niacin, vitamin B_3) or its precursor amino acid, tryptophan. It is associated classically with a diet almost entirely composed of corn, millet, or sorghum. Other vitamin deficiencies (especially pyridoxine) or malnutrition, which interfere with the conversion of tryptophan to niacin, often coexist and are required for the signs and symptoms of pellagra to occur. In developed countries, most cases of pellagra occur in alcoholics. Other possible causes of pellagra are:

- Carcinoid tumors, which divert tryptophan to serotonin
- Hartnup disease (impaired absorption of tryptophan)
- Gastrointestinal disorders, e.g. Crohn and gastrointestinal surgery
- Prolonged intravenous supplementation
- Psychiatric disease, including anorexia nervosa

Pellagra can also be induced by medications, most commonly isoniazid, azathioprine (and its metabolite 6mercaptopurine), 5-fluorouracil, ethionamide, protionamide, and pyrazinamide. These medications may induce pellagra by interfering with the niacin biosynthesis. The anticonvulsants, including hydantoins, phenobarbital, and carbamazepine may rarely produce pellagra in a dose-dependent fashion.

Clinical Features

Pellagra is a chronic disease affecting the gastrointestinal tract, nervous system, and skin; hence, the mnemonic of the 3 Ds: diarrhea, dementia, and dermatitis.

The most characteristic cutaneous finding is the photosensitive eruption, which worsens in the spring and summer. It occurs symmetrically on the face, neck, and upper chest (Casal necklace); extensor arms; and backs of the hands (Fig. 22-4). Initially, there is erythema and swelling after sun exposure, accompanied by itching-and burning or pain. In

Fig. 22-4 Pellagra, erosive photosensitive eruption.

severe cases, the eruption may be vesicular or bullous (wet pellagra). When compared with normal sunburn, the pellagrous skin takes about four times longer to recover from the acute phototoxic injury. After several phototoxic events, thickening, scaling, and hyperpigmentation of the affected skin occurs. The skin has a copper or mahogany hue. In protracted cases, the skin ultimately becomes dry, smooth, paper-thin, and glassy with a parchment-like consistency. Scarring rarely occurs.

The nose is fairly characteristic. There is dull erythema of the bridge of the nose, with fine, yellow, powdery scales over the follicular orifices (sulfur flakes). The eruption resembles seborrheic dermatitis, except for its location. Plugs of inspissated seburn may project from dilated orifices on the nose, giving it a rough appearance.

At the onset, there is weakness, loss of appetite, abdominal pain, diarrhea, mental depression, and photosensitivity. Skin lesions may be the earliest sign, with phototoxicity being the presenting symptom in some cases. Neurologic and gastrointestinal symptoms can occur without skin changes. In the later stages of the disease, the neurologic symptoms may predominate. Apathy, depression, muscle weakness, paresthesias, headaches, and attacks of dizziness or falling are typical findings. Hallucinations, psychosis, seizures, dementia, neurologic degeneration, and coma may develop. The disease is progressive and can be fatal if untreated.

Pathology

Histologically, the findings in the skin vary according to the stage of the disease. There may be orthokeratosis or slight confluent parakeratosis; basilar pigmentation is increased. Papillary dermal vessels are dilated with papillary dermal edema. The most characteristic finding is pallor and vacuolar changes of the keratinocytes in a band in the upper layers of the stratum malpighii, just below the granular cell layer, which may be attenuated. If marked, a cleft may form in the upper epidermis, correlating with the blistering seen in wet pellagra.

Diagnosis and Treatment

If the characteristic skin findings are present, the diagnosis is not difficult clinically. Dietary treatment to correct the malnutrition is essential. Animal proteins, eggs, milk, and vegetables are beneficial. Supplementation with nicotinamide 100 mg three times a day for several weeks should be given. Fluid and electrolyte loss from diarrhea should be replaced, and in patients with gastrointestinal symptoms, possibly interfering with absorption, initial intravenous supplementation should be considered. Within 24 h after niacin therapy is begun, the skin lesions begin to resolve, confirming the diagnosis. Alcoholism must be treated if present, and the factors that may have led to pellagra must be corrected.

BIOTIN DEFICIENCY

Biotin is universally available and is produced by intestinal bacteria. Therefore, deficiency is rare but can occur in patients with a short gut or malabsorption. Sometimes it occurs in individuals taking antibiotics or receiving parenteral nutrition. Ingestion of avidin, found in raw egg white, may bind biotin, leading to deficiency. The three autosomalrecessive syndromes holocarboxylase synthetase deficiency (multiple carboxylase deficiency), biotinidase deficiency, and the very rare syndrome of inability to transport biotin into cells all have similar clinical features. Clinical presentation is variable, with some patients manifesting only certain features.

The skin and nervous system are primarily affected. A dermatitis similar to that found in cases of zinc deficiency and essential fatty acid deficiency is seen. It is periorificial and characterized by patchy, red, eroded lesions on the face and groin. Candida is regularly present on the lesions. Alopecia, sometimes total, including loss of the eyebrows and eyelashes can occur. Conjunctivitis may be present. Neurologic findings are prominent. In adults, these include depression, lethargy, hallucinations, and limb paresthesias. In infants, neurologic findings include hypotonia, lethargy, a withdrawn behavior, autism, ataxia, seizures, deafness, and developmental delay. Lactic acidosis may be present. The diagnosis of the inherited forms is made by detecting organic aminoaciduria of 3-hydroxyisovaleric acid. Measurement of serum biotinidase can distinguish biotinidase deficiency from holocarboxylase deficiency. Treatment consists of 10 mg of biotin/day, but depending on the severity of the enzyme mutation, higher doses may be required. Skin lesions resolve rapidly, but the neurologic damage may be permanent. One report suggested that valproic acid treatment in children, especially at doses of 40 mg/kg/day or higher, may lead to partial biotinidase deficiency, and that the skin lesions (seborrheic dermatitis-like rash and alopecia) improved with biotin supplementation at 10 mg/day.

ZINC DEFICIENCY

Zinc deficiency may be an inherited abnormality, acrodermatitis enteropathica, or it may be acquired. Premature infants are at particular risk because of inadequate body zinc stores, suboptimal absorption, and high zinc requirements. Normally, human breast milk has adequate zinc, and weaning classically precipitates clinical zinc deficiency in premature infants and in infants with acrodermatitis enteropathica. However, clinical zinc deficiency may occur in full-term and premature infants still breastfeeding. This is due to either low maternal breast milk zinc levels or a higher zinc requirement by the infant than the breast milk can provide (even though the zinc level in the breast milk is normal). A rare syndrome of congenital myopathy, recurrent diarrhea, microcephaly, and deafness has been associated with a neonatal bullous eruption characteristic of nutritional deficiency. These children have required very high doses of zinc supplementation.

Parenteral nutrition without adequate zinc content may lead to zinc deficiency. Acquired zinc deficiency also occurs in alcoholics as a result of poor nutritional intake and increased urinary excretion; as a complication of malabsorption, inflammatory bowel disease, or gastrointestinal surgery; and, occasionally, in cases of anorexia nervosa and acquired immunodeficiency syndrome (AIDS). Patients with severe erosive oral disease, such as pemphigus or graft-versus-host disease, may develop zinc deficiency due to malnourishment. Zinc requirements increase during metabolic stress, so symptomatic deficiency may present during infections, after trauma or surgery, with malignancy, during pregnancy, and with renal disease. Diets containing mainly cereal grains are high in phytate, which binds zinc, and have caused endemic zinc deficiency in certain areas of the Middle East and North Africa.

The dermatitis found in all forms of zinc deficiency is pustular and bullous, with an acral and periorifical distribution (Fig. 22-5). On the face, in the groin, and in other flexors there is a patchy, red, dry scaling with exudation and crusting angular cheilitis and stomatitis are present. The periungual areas are erythematous, scaling, and sometimes

Fig. 22-5 Zinc deficiency, acquired in a patient who had severe nausea following a gastric bypass procedure and was unable to eat.

have superficial, flaccid pustules. Nail dystrophy may result, with thinning of the nails and accentuated longitudinal ridges. Chronic lesions may be more psoriasiform. Generalized alopecia may occur.

Diarrhea is present in most cases. Growth retardation, ophthalmic findings, impaired wound healing, and central nervous system manifestations occur. Patients are particularly irritable and emotionally labile. Many abnormalities of the immune response occur in zinc deficiency.

The histopathologies of acquired and hereditary zinc deficiency are identical. There is vacuolation of the keratinocytes of the upper stratum malpighii. These areas of vacuolation may become confluent, forming a subcorneal bulla. In larger lesions, there may be total epidermal necrosis with subepidermal blister formation. Neutrophils are typically present.

The diagnosis of zinc deficiency should be suspected in at-risk individuals with acral or periorificial dermatitis. In particular, chronic diaper rash with diarrhea in an infant should lead to evaluation for zinc deficiency. The diagnosis can be confirmed by low serum zinc levels. A low serum alkaline phosphatase, a zinc-dependent enzyme, may be a valuable adjunctive test where the serum zinc level is normal or near normal. In some patients, even if the zinc level is in the normal range, if the skin lesions are characteristic, a trial of zinc supplementation should be considered. Replacement is with zinc sulfate 1 to 2 mg/kg/day (50 mg of elemental zinc per 220 mg zinc sulfate tablet). In acquired cases, transient treatment and addressing the underlying condition are adequate. In cases of acrodermatitis enteropathica, supplementation is 3 mg/ kg/day and should be lifelong. Overzealous zinc supplementation should be avoided as it may lead to low serum copper levels.

ESSENTIAL FATTY ACID DEFICIENCY

Essential fatty acid (EFA) deficiency may develop in multiple settings: low birth weight infants; cystic fibrosis; gastrointestinal abnormalities, including inflammatory bowel disease and intestinal surgery; and prolonged parenteral nutrition without EFA supplementation. The resulting dermatitis is similar to that seen in zinc and biotin deficiency, although characteristically more widespread, but with less periorifacial involvement and mucous membrane and nail changes. There is a generalized xerosis, since EFAs constitute up to one-quarter of the fatty acids of the stratum corneum and are required for normal epidermal barrier function. Widespread erythema and an intertriginous weeping eruption are seen. The hair becomes lighter in color, and diffuse alopecia is present. Poor wound healing, growth failure, and increased risk of infection may occur. This is especially important in patients with cystic fibrosis, who may have inherent abnormalities of essential fatty acid absorption/ metabolism independent of their pancreatic function and overall nutritional status. There is a decrease in linoleic acid and an increase in palmitoleic and oleic acids. A ratio of eicosatrienoic acid-to-arachidonic acid of more than 0.4 is diagnostic of EFA deficiency. Intravenous lipid therapy with Intralipid 10% reverses the process. Topical safflower oil emulsion or sunflower seed oil applications may not be able to prevent or treat EFA deficiency and may predispose patients to α -linolenic acid deficiency.

IRON DEFICIENCY

Iron deficiency is common, especially among actively menstruating women, and particularly if they have little red meat in their diets and have not made an effort to replace their losses with other foods. Mucocutaneous findings include koilonychia, glossitis, angular cheilitis, pruritus, and telogen effluvium diffuse hair loss. Plummer-Vinson syndrome is the combination of microcytic anemia, dysphagia, and glossitis, seen almost entirely in middle-aged women. The lips are thin and the opening of the mouth is small and inelastic, so that there is a rather characteristic appearance. Smooth atrophy of the tongue is pronounced. Koilonychia is present in 40% to 50% of patients, and alopecia may be present.

An esophageal web in the postcricoid area may occur, presenting as difficulty swallowing, or the feeling that food is stuck in the throat. The diagnosis is confirmed by measuring the serum iron level. Treatment consists of iron sulfate supplementation, 325 mg three times a day.

Sato S; Iron deficiency. Semin Dermatol 1991;10:313.

SELENIUM DEFICIENCY

Selenium deficiency occurs in patients on parenteral nutrition, in areas where soil selenium content is poor, and in low birth weight infants. Manifestations in children include hypopigmentation of the skin and hair (pseudoalbinism). Leukonychia and Terry-like nails have been reported. Cardiomyopathy, muscle pain, and weakness with elevated muscle enzymes are the major features. Treatment consists of $3 \mu g/kg/day$ of selenium.

Vinton NE, et al: Macrocytosis and pseudoalbinism: manifestations of selenium deficiency. J Pediatr 1987;111:711.

PROTEIN-ENERGY MALNUTRITION

Protein-energy malnutrition is a spectrum of related disease including marasmus, kwashiorkor, and marasmic kwashiorkor. These conditions are endemic in the developing world. Marasmus represents prolonged deficiency of protein and calories and is diagnosed in children who are below 60% of their ideal body weight without edema or hypoproteinemia. Kwashiorkor occurs with protein deficiency but a relatively adequate caloric intake. It is diagnosed in children between 60% and 80% of their ideal body weight with edema or hypoproteinemia. Marasmic kwashiorkor shows features of both conditions and is diagnosed in children who are less than 60% of their ideal body weight with features of edema or hypoproteinemia.

These conditions are rare in developed countries, but occasionally, kwashiorkor may occur as a result of cystic fibrosis or severe dietary restrictions instituted to improve infantile atopic dermatitis. In the US this may occur when rice beverage, which lacks protein, is substituted for cow's milk and soy in the diets of infants surviving largely on bottle feedings. Most cases, therefore, are in infants younger than 1 year of age.

Marasmus

In cases of marasmus, the skin is dry, wrinkled, and loose because of marked loss of subcutaneous fat. The "monkey

Fig. 22-6 Kwashlorkor, anasarca, hypopigmentation, and scaling skin, in a child who had milk allergy and was given rice milk instead.

facies," caused by loss of the buccal fat pad, is characteristic. In contrast to kwashiorkor, there is no edema or dermatosis.

Kwashiorkor

Kwashiorkor produces hair and skin changes, edema, impaired growth, and the characteristic potbelly (Fig. 22-6). In cases diagnosed in the US due to dietary restriction or social chaos, edema has masked growth failure, resulting in the diagnosis of malnutrition being delayed. The hair and skin changes are usually striking. Africans call the victims of kwashiorkor "red children." The hair is hypopigmented, varying in color from a reddish-yellow to gray or even white. The hair is dry and lusterless; curly hair becomes soft and straight; and marked scaling (crackled hair) is seen. Especially striking is the flag sign, affecting long, normally dark hair. The hair grown during periods of poor nutrition is pale, so that alternating bands of pale and dark hair can be seen along a single strand, indicating alternating periods of good and poor nutrition. The nails are soft and thin.

The skin lesions are hypopigmented on dark skin and erythematous or purple on fair skin. Lesions first appear in areas of friction or pressure: the flexures, grain, buttocks, and elbows. Hyperpigmented patches occur with slightly raised edges. As they progress, they resemble old, dark, deteriorating enamel paint with peeling or desquamation. This has been described variously as "crazy pavement," "crackled skin," "mosaic skin," "enamel paint," and "flaky paint." In severe cases, the peeling leaves pale, ulcerated hypopigmented areas with hyperpigmented borders.

CAROTENEMIA AND LYCOPENEMIA

Excessive ingestion of carrots, squash, spinach, green beans, rutabagas, pumpkins, yellow turnips, sweet potatoes, or papaya may lead to a yellowish discoloration of the skin, which is especially prominent on the palms, soles, and central face. The sclerae are spared. In lycopenemia, excess ingestion of red foods, such as tomatoes, beets, chili beans, and various fruits and berries, leads to a reddish discoloration of the skin. Carotenemia may also be seen in hypothyroidism.

derma in a child. Acta Dermatol Venereol 1995;75:70.

CHAPTER

23 Diseases of Subcutaneous Fat

An inflammatory disorder that is primarily localized in the subcutaneous fat is termed a panniculitis. This group of disorders may be challenging both for the clinician and the dermatopathologist. Clinically, in all forms of panniculitis, lesions present as subcutaneous nodules. Histopathologically, the subcutaneous fat is a rather homogenous tissue and inflammatory processes may show considerable overlap. One way of classifying panniculitis is to separate erythema nodosum (EN), as the prototypical septal panniculitis, from those processes that primarily involve the fat lobules-the lobular panniculitides. Some lobular panniculitides are due to vasculitedes (such as polyarteritis nodosa), which are discussed in other chapters. The remaining lobular panniculitides are categorized by their pathogenesis. Weber-Christian disease, Rothmann-Makai disease, lipomembranous or membranocystic panniculitis, and eosinophilic panniculitis are reaction patterns, and are not specific entities. Neutrophilic panniculitis appears to represent a variant of Sweet syndrome with primary involvement of the panniculus.

Given the depth of lesions in the panniculus, the choice of biopsy is critical in establishing the diagnosis. An incisional or excisional biopsy, narrow at the skin surface and wider in the panniculus, is the optimal procedure. An alternative double-punch method, using a 6- to 8-min punch first, followed by a 4- to 6-mm punch at the depth of the first punch, may be considered, but is less ideal. Panniculitis is one area of dermatopathology where the skill of the dermatopathologist is critical in establishing good clinicopathologic correlation. If the biopsy report from an adequate biopsy specimen does not match the clinical findings, repeat the biopsy, or ask for a second opinion on the original specimen.

SEPTAL PANNICULITIS (ACUTE AND CHRONIC ERYTHEMA NODOSUM)

EN is the most common inflammatory panniculitis. It occurs in two forms: acute, which is common, and chronic, which is

rare. Acute EN may occur at any age and in both sexes, but most cases occur in young adult women (female-to-male ratio, 3-6:1). The eruption consists of bilateral, symmetrical, deep, tender nodules and plaques 1 to 10 cm in diameter. Usually there are up to 10 lesions, but in severe cases many more may be found. Initially, the skin over the nodules is red, smooth, slightly elevated, and shiny (Fig. 23-1). The most common location is the pretibial area and lateral shins. In general, the lesions should be primarily on the anterior rather than posterior calf. Lesions may also be seen on the upper legs, extensor arms, neck, and rarely the face. The onset is acute, frequently associated with malaise, leg edema, and arthritis or arthralgia (usually of the ankles, knees, or wrists). Fever, headache, episclerifis, conjunctivitis, and various gastrointestinal complaints may also be present. Over a few days, the lesions flatten, leaving a purple or blue-green color resembling a deep bruise (erythema contusiforme). Ulceration does not occur, and the lesions resolve without atrophy or scarring. The natural history is for the nodules to last a few days or weeks, appearing in crops, and then slowly involute.

Fig. 23-1 Erythema nodosum, erythematous tender nodules on the anterior shins.

EN is much less common in children than adults, and affects boys and girls equally.

Acute EN is a reactive process. It is commonly associated with a streptococcal infection and in children this is by far the most common percipitant. Tuberculosis remains an important cause in areas where tuberculosis is endemic. Intestinal infection with Yersinia, Salmonella, or Shigella may precipitate EN. Other infectious causes include systemic fungal infections (coccidioidomycosis, histoplasmosis, sporotrichosis, and blastomycosis) and toxoplasmosis. EN-like lesions have been described in other infectious diseases such as *Helicobacter* septicemia, brucellosis, psittacosis, catscratch disease, and many others. Since these organisms are fastidious, it has not always been possible to exclude the possibility that the EN-like lesions seen in these diseases actually represent septic foci in the panniculus. Sarcoidosis may present with fever, cough, joint pains, hilar adenopathy, and EN. This symptom complex, known as Lofgren syndrome, is especially common in Scandinavian, Irish, and Puerto Rican women. It generally responds well to therapy and runs a self-limited course. EN is frequently seen in patients with inflammatory bowel disease, more commonly Crohn's than ulcerative colitis. EN has been rarely reported in association with various hematologic malignancies, but this is less common than Sweet syndrome or pyoderma gangrenosum.

Drugs may also induce EN. The bromides, iodides, and sulfonamides were once the most frequent causative agents. Currently, oral contraceptives and hormone replacement therapy are the most common medications inducing EN. This association, the predominance in young women, and the occurrence of EN in pregnancy suggest that estrogens may predispose to the development of EN. Echinacea herbal therapy can also induce EN.

EN-like lesions have been described in Behçet syndrome and Sweet syndrome, and probably represent these inflammatory processes occurring in the fat, rather than the coexistence of two disorders. Histologically, the subcutaneous lesions of Behçet syndrome show features different from EN—a lobular or mixed lobular and septal pattern, and most importantly, a vasculitis which may be lymphocytic, leukocytoclastic or involve a small arteriole. This vasculitis is proposed to be the primary event producing the subcutaneous lesions in Behçet syndrome.

A more chronic variant of EN, called chronic EN, EN migrans, or subacute migratory panniculitis of Vilanova and Piñol, is well described. This form of septal panniculitis is much less common than acute EN. It is distinguished from acute EN by the following features:

- 1. Lesions tend to occur in older women
- 2. Lesions are unilateral or asymmetrical if bilateral
- 3. Lesions are not associated with systemic symptoms except arthralgias
- Lesions are painless or less tender than acute EN lesions
- 5. Lesions are not associated with underlying diseases
- 6. Lesions begin as a single lesion that tends to resolve, but migrates centrifugally, forming annular plaques of subcutaneous nodules with central clearing
- 7. Lesions have a prolonged course of months to years

In the differential diagnosis of EN, other forms of panniculitis must be considered. Erythema induratum (EI) usually affects primarily the posterior calves alone and runs

a more chronic course, with the possibility of ulceration and scarring. Syphilitic gummas, as well as the nodules of sporotrichosis are, as a rule, unilateral. Subcutaneous fat necrosis associated with pancreatitis and nodular vasculitis may also occur on the shins, but associated clinical features and/or histologic features will allow the differentiation to be made. Subacute infectious processes, such as Helicobacter cellulits and atypical mycobacterial infection, may closely mimic EN. In most cases, the classic picture of the acute onset of symmetrical, red, tender nodules on the anterior shins of a young woman will allow the diagnosis of EN to be easily made without a biopsy. However, if the case is atypical or does not evolve typically, a biopsy should be performed. In cases where the diagnosis of EN has been made in error, either the clinical features were atypical and a biopsy was not performed or was inadequate (punch biopsy), or the biopsy was misinterpreted by the pathologist.

EN is a septal panniculitis: the inflammatory infiltrate principally involves the connective-tissue septa between fat lobules throughout the evolution of the lesion. The infiltrate may be composed of either neutrophils (early) or lymphocytes and other mononuclear cells (later), or a mixture, depending on the stage at which the lesion is biopsied. In older lesions bistiocytes and multinucleate giant cells may predominate. Fat lobules are only secondarily affected by the inflammation, but some foamy histiocytes may be seen in the evolution of the lesions. Meischer radial granulomas, aggregates of histiocytes around stellate clefts, are characteristic but not diagnostic of EN. Leukocytoclastic vasculitis is not a histologic feature of EN. In chronic EN septal fibrosis and septal granulomas of epithelioid macrophages are seen.

The management of EN involves three components: identifying the trigger, rest and elevation of the affected extremities; and specific anti-inflammatory medications. Since streptococcus is a common trigger, throat culture and ASO titer are indicated. A complete history of any preceding illness will often lead to clues. Preceding diarrhea might suggest Yersinia infection, for example. A travel and exposure history are especially important when considering endemic fungal infections. Four per cent of patients with histoplasmosis present with EN, so in endemic areas this cause should be excluded. Early treatment of the infectious cause does not appear to shorten the duration of the EN, although EN triggered by infections tends to last longer if the infection is more chronic-streptococcal-induced EN will tend to last a shorter period than tuberculosis-triggered EN. Bed rest is of great value and may be all that is required in mild cases. In children this is especially true. Gentle support hose are also helpful. Curtailing vigorous exercise during the acute attacks will shorten the course, and restriction of physical activities might prevent exacerbations and recurrences. Aspirin and nonsteroidal anti-inflammatory drugs (NSAIDs) such as indomethacin are often helpful. Potassium iodide is a sale and effective treatment. As a supersaturated solution, five drops three times a day, increased by one drop per dose per day up to 15 drops three times a day, is one easy-to-remember dose schedule. As a tablet, the dose is one 300-mg tablet three times a day. Induction of hypothyroidism by prolonged iodide therapy should be watched for. Once controlled, the therapy is gradually reduced over 2 to 3 weeks. Intralesional corticosteroid injections will control persistent lesions. Systemic steroids will result in rapid

resolution of lesions, if not contraindicated by the underlying precipitating cause. In acute lesions, colchicine is often rapidly effective at a dose of 0.6 mg twice a day. For chronic EN, SSKI is often effective. In refractory cases, antimalarials may be tried.

The prognosis in acute EN usually is good, the attack running its course in 3 to 6 weeks. Recurrences do occur, especially if the underlying condition or infection is still present, or if physical activity is resumed too quickly. Chronic or atypical lesions should suggest an alternative diagnosis and require a biopsy.

LOBULAR PANNICULITIS

VESSEL-BASED LOBULAR PANNICULITIS

Inflammation or thrombosis of blood vessels may lead to fat necrosis due to ischemia. This can occur in the primary vasculopathies, such as polyarteritis nodosa and Churg-Strauss, in metabolic disorders such as oxalosis and calciphylaxis, with atheromatous emboli, with heparin and Coumadin necrosis, and with various coagulopathies. These entities are discussed in other chapters.

Nodular Vasculitis

Clinically and histologically, nodular vasculitis is identical to EI. The two differ only by the presence of tuberculosis as a precipitating factor in EI. Nodular vasculitis presents as tender, subcutaneous nodules of the calves of middle-aged, thick-legged women. Venous insufficiency may be present. Lesions are bilateral and less red and tender than EN; they often ulcerate, drain oily liquid, and recur over years.

The early lesions may show a suppurative vasculopathy, proposed by various authors to be an arteritis, a venulitis, or both. In some cases, no vasculitis is found, and (despite the name) the presence of a vasculitis is not required to establish the diagnosis of nodular vasculitis. Nodular vasculitis results in substantial lobular necrosis of adipocytes with suppuration. Necrosis of the lobule results in loss of the lipocyte membrane and pooling of lipid into variably sized round aggregates. As lesions evolve, the fat becomes increasingly necrotic, forming microcysts, and suppuration progresses to the point where it may perforate through the epidermis, forming ulceration. Granulomatous inflammation appears adjacent to areas of fat necrosis, and eventually lesions resolve with fibrosis.

Nodular vasculitis must be distinguished from EI. Because clinical and pathologic features are identical, the differentiation is made by searching for tuberculous infection in the patient, by applying a tuberculin skin test. If this is positive, the appropriate diagnosis is El. Polymerase chain reaction (PCR) of the affected tissue may reveal the DNA of *Mycobacterium tuberculosis* in 50% to 70% of cases of El. As a tuberculid, El is a manifestation of cellular immunity to tuberculosis, and the PPD will always be positive. PCR of the tissue is *not* recommended in cases which are tuberculin skin test negative.

El requires antibiotic therapy for the underlying tuberculosis. Treatment of nodular vasculitis is usually SSKI, as outlined for EN. This is effective in about half of cases. In the others, trials of colchicine, antimalarials, NSAIDs, and systemic steroids may be attempted. Support stockings, elevation, and treatment of associated venous insufficiency may also improve nodular vasculitis.

Sclerosing Panniculitis (Hypodermitis Sclerodermiformis, Lipodermatosclerosis, Stasis Panniculitis)

Sclerosing panniculitis occurs primarily on the medial lower third of the lower legs of women older than 40, with an above average body mass index. It may be bilateral. If not bilateral, the left leg only is affected, or the process is more severe on the left leg. If the right leg is primarily affected, deep venous thrombosis currently or in the past or a venous injury to the right leg must be considered. Typically, there is marked woody induration in a stocking distribution resulting in calves that resemble inverted champagne bottles. This inducation results from fibrosis in the subcutaneous fat which may occur without the primary inflammatory panniculitis ever being clinically observed. It occurs multifocally and microscopically throughout the affected area. This pattern was called hypodermitis sclerodermiformis. When the areas of fat necrosis are larger, they present as erythematous, tender, subcutaneous nodules or plaques. This is designated sclerosing panniculitis.

It is now recognized that these are two aspects of the same disease with a common pathogenesis—venous insufficiency. These patients may have venous varicosities, superficial thrombophlebitis, deep venous thrombosis, or several of these conditions. Even when venous disease is not clinically evident, evaluation of the venous system of the lower leg will frequently reveal insufficiency. Laboratory evaluation may reveal a genetic mutation in the fibrinolytic system resulting in increased thrombosis in these patients. Venous insufficiency results in hypoxia, necrosis of fat, inflammation, and eventual fibrosis. If hypoxemia is present from other causes such as pulmonary disease, sclerosing panniculitis may be more severe.

The histologic features of sclerosing panniculitis are characteristic, but not all features may be seen on every biopsy, since the histologic features change over time within the lesion. The overlying dermis frequently shows changes of stasis with nodular proliferation of thick-walled vessels, hemosiderin deposition, fibrosis, and atrophy. In early lesions there is ischemic necrosis in the center of the fat lobules manifested as "ghost cells"—pale cell walls with no nuclei. There is a sparse lymphocytic infiltrate in the fat septa. As the lesions evolve, the septa are thickened and fibrosed, and there is a mixed inflammatory infiltrate of lymphocytes, plasma cells, and macrophages. Foamy histiocytes are present around the areas of fat necrosis. Fat microcysts are characteristic (but not diagnostic) and appear as small cysts with feathery eosinophilic remnants of adipocytes lining the cyst cavity and resembling frost on a window, so-called lipomembranous fat necrosis. In later lesions these microcysts collapse and are replaced by fibrosis. Despite these characteristic features, biopsy should be avoided in these patients. Biopsies heal poorly and may lead to chronic leg ulcers. If a biopsy must be performed, *it* should be from the most proximal edge of involvement.

This diagnosis can be clinically confirmed if a careful vascular evaluation is performed. The location on the lower medial calf is unusual for EN. Most other panniculitides favor the posterior mid-calf. The gradual progression from the ankles proximally is characteristic of sclerosing panniculitis and not other forms of lobular panniculitis.

The treatment of sclerosing panniculitis may be difficult. Fibrotic areas may be irreversible. Graded compression stockings and elevation, standard treatments for venous insufficiency, are most effective in this condition. Application of pressure dressings such as an Unna boot can produce dramatic, if temporary, improvement. Greater compression-Unna boot with Coban and a foam buttress (bolster material to apply extra pressure to the red inflamed area) or the Profore boot-can be beneficial. Unfortunately, some patients cannot tolerate compression because of the pain of the lesions. Pentoxyphylline in doses of 400 to 800 mg three times a day is useful, especially in cases not responding to compression and elevation alone, or in patients who are initially intolerant of compression dressings. Apparently by enhancing the fibrinolytic capacity of affected patients, stanozolol, 2 to 5 mg or oxandrolone 10 mg twice a day, may benefit some patients. It is rarely required if appropriate pressure dressings are applied and the patient is able to take full doses of pentoxyphylline. Stanazol and oxandrolone may be virilizing for women and should be avoided if possible in women of childbearing potential. Stanazol may induce hepatitis.

PHYSICAL PANNICULITIS

This category includes processes in the fat that occur from physical factors. Some are characterized by the presence of needle-like clefts—sclerema neonatorum, subcutaneous fat necrosis, and post-steroid panniculitis. Infants and children are most frequently affected, and in all these disorders metabolic differences in fat are apparently pathogenically important. Hypothermia or cold is frequently associated in some forms (cold panniculitis, sclerema, and subcutaneous fat necrosis). It may be difficult in some cases to clearly separate mild cases of sclerema neonatorum from subcutaneous fat necrosis, or differentiate cold panniculitis from subcutaneous fat necrosis of the newborn if the lesions are at sites of cold exposure. This is not surprising, since they may be pathogenically related. In general cold panniculitis refers to localized cases where there is a history of local cold exposure, sclerema to cases presenting in severely ill children soon after birth with a poor prognosis, and subcutaneous fat necrosis (the most common variant) to cases with more limited lesions occurring in the first 6 weeks of life, sometimes with associated hypercalcemia. Traumatic fat necrosis occurs from damage to the subcutaneous fat resulting from trauma. All these conditions are treated supportively, and in all except sclerema neonatorum, spontaneous and complete recovery is expected.

Sclerema Neonatorum

Sclerema neonatorum is the most severe and rarest disorder in this group. It affects premature neonates who are gravely ill for other reasons. Affected neonates usually die, unless the underlying diseases can be reversed. In the first few days of life, the skin begins to harden, usually initially on the buttocks or lower extremities, and rapidly spreads to involve the whole body. The skin on the palms, soles, and genitalia is spared. The skin becomes dry, livid, cold, rigid, and boardlike, so that the mobility of the parts is limited. The skin in the involved areas cannot be picked up. The skin of the entire body may appear half frozen and is yellowish white. Visceral fat may also be involved.

Histologically, adipocytes are enlarged and filled with needle-like clefts in a radial array. Affected fat cells undergo necrosis. There is sparse inflammation, and histiocytes containing needle-like clefts are rare, possibly because most children die before granulomas can form.

Subcutaneous Fat Necrosis of the Newborn

Subcutaneous fat necrosis of the newborn (SFN) occurs during the first 4 weeks of life (half in the first week) in term or post-term infants. A history of fetal distress, birth asphyxia, and meconium aspiration is common. Maternal cocaine use, severe neonatal anemia, thrombocytopenia, septicemia, and hypothermia have also been associated. SFN following delivery by emergency cesarian section and speaks against trauma as playing a role in SFN. Painful, firm to rubbery, erythematous nodules appear, usually on the upper back, buttocks, cheeks, or proximal extremities (Fig. 23-2). Lesions may fuse to form plaques and resolve spontaneously within 3 months with no scarring. In general, the infants remain well; however, hypercalcemia has occurred in more than 50% of recently reported cases, and in 4 of 11 consecutive cases seen at one institution. The hypercalcemia may appear weeks to months after the appearance and resolution of the skin lesions. Períodic serial serum calcium determinations for the first 3 to 4 months of life have been recommended. The pathogenesis of the hypercalcemia in SFN may be due to elevated prostaglandin E levels or inappropriately high levels of 1,25-hydroxyvitamin D. The mechanism of

Fig. 23-2 Subcutaneous fat necrosis.

hypercalcemia in SFN has been postulated to be similar to that seen in other granulomatous conditions, such as sarcoidosis. Hypercalcemia may result in failure to thrive, irritability, apathy, hypotonia, seizures, and renal failure. The hypercalcemia is treated with hyperhydration, calcium wasting diruretics (furosemide), and formulas low in calcium and vitamin D. Systemic steroids, calcitonin, and etidronate (bisphosphonate) may also be effective, when other methods fail to reduce the hypercalcemia.

Histologically, subcutaneous fat necrosis is a lobular panniculitis, with granular necrosis of adipocytes. Needleshaped clefts are arranged radially within histiocytes, and multinucleate foamy histiocytes are present. Lesions may resolve with calcification and fibrosis. Fine-needle aspiration has confirmed this diagnosis and characteristic magnetic resonance imaging (MRI) findings have been reported.

Cold Panniculitis

Infants and young children are particularly predisposed to cold panniculitis. It has been described in children who suck on ice or popsicles (popsicle panniculitis) (Fig. 23-3), in the scrotum of prepubertal males, and in infants treated for supraventricular tachycardia with the application of cold packs to the face. Most reported affected infants have been Black. Lesions occur within a few days of the cold application and appear as slightly erythematous, nontender, firm subcutaneous nodules. Equestrian panniculitis on the upper outer thighs of women riding horses in the cold appears to represent a form of perniosis rather than true panniculitis (see Chapter 3). The typical patient with fat necrosis of the scrotum is a prepubertal (9-14-year-old) boy, who is heavy-set or even obese, with scrotal swelling, usually bilateral, associated with mild-to-moderate pain. The gait is often guarded and broad based. There is a lack of systemic complaints and no symptoms related to voiding. The scrotal masses are bilateral and symmetrical in most cases. However, the lesions may be unilateral and there may be more than two. The masses are firm, tender, and do not transmit light. The overlying scrotal skin will be normal or red. Cryptorchidism is not unusual. The most common location of the lesions is near the perineum, consistent with the area of greatest concentration of scrotal fat in children. The adult scrotum lacks this fatty tissue. Without treatment lesions resolve over several days to weeks.

Histologically, there is necrosis of adipocytes within lobules of the upper subcutaneous fat adjacent to the lower dermis. A mixed inflammatory infiltrate of lymphocytes, neutrophils, and foam cells is present, and microcysts sometimes occur. This histology is not specific and the diagnosis relies largely on obtaining a history of cold exposure.

Ter Poorten JC, et al: Cold panniculitis in a neonate. J Am Acad Dermatol 1995;33:383.

Post-Steroid Panniculitis

This rare form of panniculitis occurs predominately in children treated acutely with high doses of systemic corticosteroids during rapid corticosteroid withdrawal. Substantial weight gain has usually occurred during the corticosteroid therapy. Firm subcutaneous nodules begin to appear within a month of tapering the corticosteroids. Areas of abundant subcutaneous fat are favored—the cheeks, trunk, and proximal extremities. Most cases resolve spontaneously within weeks, but if severe, the steroids must be reinstituted and tapered more slowly.

Histologically, the changes are identical to those seen in subcutaneous fat necrosis of the newborn. There is a lobular panniculitis with necrosis of adipocytes and needle-shaped clefts in both adipocytes and histiocytes. Foamy histiocytes are also present.

Silverman RA, et al: Poststeroid panniculitis. Pediatr Dermatol 1992;5:92.

Traumatic Panniculitis

Accidental trauma to the skin may induce necrosis of the fal. This is most common on the trunk and breasts of women. The prior history of trauma is frequently not recalled. Lesions present like a lipoina, as a firm, mobile subcutaneous mass (formerly reported as mobile encapsulated lipoma). Airbag injury may induce fat necrosis. The term myospherulosis (spherulocytosis) has been used to describe subcutaneous cystic lesions induced by trauma with hemorrhage into areas of high lipid content. Long-acting antibiotics formulated in oil bases were associated with myospherulosis. The structures resemble the sporangia of rhinosporidiosis, but represent degenerated red blood cells rather than true fungal organisms. Accidental trauma to the upper anteriolateral thigh from a desk or chair may result in semicircular bands of atrophy of fat called lipoatrophia semicircularis.

Histologically, there is a granulomatous lobular panniculitis with foamy histiocytes, membranous fat necrosis, and microcysts. Lesions heal with fibrosis of the septa. In myospherulosis, large round structures containing many smaller round eosinophilic bodies are noted. These represent degenerated erythrocytes.

Factitial Panniculitis

Self-induced panniculitis is rarely reported, but it is not uncommon. It may be induced by the injection of organic

materials, povidone, feces, saliva, vaginal fluid, and oils. In many cases, ulceration will occur. Factitial trauma may also induce a panniculitis. Medical personnel are at risk because they have ready access to syringes and needles. Pointed, detailed questioning of the patient may identify inconsistencies in the history, or the underlying cause for the behavior (e.g. attention seeking, revenge, malingering).

The clinician must have a high index of suspicion in cases in which the clinical pattern is not characteristic of a known form of panniculitis. Inspection of early lesions for tell-tale healing injection sites may help confirm the diagnosis. A biopsy is often required. Culture may demonstrate a consistent pattern of fecal, oral or vaginal flora. Careful evaluation of the biopsy material with polarization may identify foreign material. When the suspicion is high and no foreign material can be seen in the tissue, special evaluation by incineration and mass spectroscopy may identify the injected substance. Electron microscopy with x-ray emission spectrography can identify inorganic substances. Radiographs may demonstrate fractured needles or foreign bodies.

Kossard S, et al: Povidone panniculitis. Arch Dermatol 1980; 116:704.

Sclerosing Lipogranuloma

Sclerosing lipogranuloma describes the granulomatous and fibrotic reaction that occurs in the panniculus from the injection of silicone or mineral oils. Topical application of an antibacterial ointment to an open wound can rarely result in the formation of lipogranuloma. In most cases the injections are intentional and cosmetic. The time from injection to onset of symptoms may be months to more than 10 years.

Lesions are usually localized to the penis, scrotum, breasts, nose and buttocks, often after an attempt to augment the area by injection. The overlying skin is hyperpigmented and erythematous. Lesions are frequently diagnosed initially as cellulitis. On palpation, the skin is indurated and cannot be picked up between the fingers. The subcutaneous tissue is indurated, thickened, and lumpy. In some cases, there will be focal ulceration. The injected material will frequently migrate locally, extending beyond the sites of implantation. In some cases it is carried to other tissues, specifically the lymphoreticular system and lungs. Hepatosplenomegaly and pulmonary fibrosis may occur.

Histologically, the panniculus is replaced by the injected material, which is in various sized vacuoles, giving the affected tissue a "Swiss cheese" appearance. Because the material is usually washed out during the tissue processing, the material itself is not seen, only the spaces it occupied in the tissue in vivo. The vacuoles are surrounded by histiocytes, many of which have ingested the material, giving their cytoplasm a vacuolated appearance. Fibrosis may be prominent. Frozen section can be used to demonstrate the lipid.

ENZYME-RELATED PANNICULITIS

This category includes panniculitis induced by enzymes that damage fat (pancreatic panniculitis) and panniculitis caused by the absence of an enzyme critical in preventing tissue inflammation after injury (α_1 -antitrypsin).

PANCREATIC PANNICULITIS (SUBCUTANEOUS FAT NECROSIS)

Subcutaneous fat necrosis is most commonly associated with pancreatitis or pancreatic carcinoma, and more rarely with anatomic pancreatic abnormalities, pseudocysts, or druginduced pancreatitis. Men outnumber women 2:1 in cases of pancreatitis and 7:1 in cases of pancreatic carcinoma. In cases associated with pancreatic carcinoma, acinar cell carcinoma is most common. Even metastatic pancreatic carcinoma with no residual tumor in the pancreas may induce the syndrome. In 40% of cases, the skin lesions are the first symptom of the underlying pancreatic pathology and therefore represent an important clue to the diagnosis.

Skin lesions appear as tender or painless erythematous subcutaneous nodules from 1 to 5 cm in diameter (Fig. 23-4). The lower leg is the most common location, being affected in more than 90% of cases. Subcutaneous fat elsewhere may also be affected, except rarely on the head and neck. The number of lesions is usually fewer than 10 but may number in the hundreds. In most cases the lesions involute, leaving an atrophic scar. If the lat necrosis is severe, however, the lesion develops into a sterile abscess that may break down, draining a thick, brown, oily material.

Subcutaneous fat necrosis is frequently accompanied by a constellation of findings related to fat necrosis in other organs. Importantly, abdominal symptoms may be completely absent. Arthritis is found in 54% to 88% of cases, and may be monoarticular, oligoarticular, and rarely polyarticular. The arthritis may be intermittent, migratory, or persistent, and is usually in joints adjacent to the lesions of panniculitis. Examination of the joint fluid reveals the presence of free fatty acids, suggesting it is due to fat necrosis adjacent to the joint space. Other findings are medullary fat necrosis of bone, polyserositis, and pulmonary infiltrates or embolism.

Laboratory evaluation is useful in establishing the diagnosis. In most patients the amylase or lipase, or both, are elevated. In many cases, however, one of the tests may be normal and the other abnormal, so both tests must be performed. Sixty percent of patients with pancreatic carcinoma and subcutaneous fat necrosis will have a peripheral eosinophilia.

The histologic features of pancreatic panniculitis are diagnostic. They include focal areas of fat necrosis with anucleate "ghost cells;" finely stippled basophilic material, representing

calcium, within the residual rim of the necrotic cells and at the periphery of the affected foci; and a dense inflammatory polymorphous infiltrate at the periphery of the affected fat. The affected necrotic areas are relatively acellular. Several reports have suggested that the early features are those of a septal panniculitis, resembling EN. This may have represented sampling error but does indicate that if the initial sample is not diagnostic another, perhaps more adequate sample of a more advanced lesion, should be considered.

The necrosis of fat at all affected sites is at least in part due to the release of fat-digesting enzymes, lipases, from the affected pancreatic tissue. These lipases spread hematogenously to the affected sites.

EN represents the primary differential consideration, since pancreatic panniculitis may not have abdominal symptoms, also favors the lower legs, and may be accompanied by joint symptoms. The distinction can be made by skin biopsy, serum amylase, and lipase determinations, and especially if eosinophilia is present, a search for a pancreatic neoplasm.

Treatment revolves mainly around treating the cause of the pancreatitis. Obstruction or stenosis of ducts should be repaired, pseudocysts drained, and in the case of pancreatic carcinoma, octreotide administered, if necessary.

α1-ANTITRYPSIN DEFICIENCY PANNICULITIS

 α_1 -Antitrypsin is the most abundant antiprotease in circulation and a potent and irreversible inactivator of neutrophil elastase. Heterozygous deficiency of this enzyme occurs in 1 in 50 persons and homozygous deficiency in 1 in 2500 persons of European descent. Emphysema and liver disease are the most common manifestations of deficiency. A small percentage of patients with homozygous deficiency and the PiZZ or PiSZ phenotypes will develop panniculitis.

The panniculitis usually appears between the ages of 20 and 40 but can occur in childhood. Both sexes are equally affected. Lesions appear after relatively minor trauma and present as painful nodules on the extremities or trunk. They may spontaneously drain an oily, brown liquid. Multiple draining sinus tracts can occur, with lesions coalescing into large draining plaques.

The histologic findings in this form of panniculitis are dependent on the stage of the lesion. Early lesions show neutrophils splaying the collagen of the reticular dermis and subcutaneous septae. More fully evolved lesions show dissolution of the septae, with islands of normal fat "floating" in the spaces that represented the destroyed septae. This later finding is considered diagnostic by some. Elastic tissue stains may reveal decreased elastic tissue in the affected areas.

The clinical and histologic differential diagnosis is factitial panniculitis. This is not surprising since trauma produces both lesions and in the case of the enzyme deficiency, the inflammation-produced enzymes are simply not inactivated, leading to more pronounced lesions than would be expected from that degree of trauma.

Replacement of the deficient enzyme will lead to resolution of the skin lesions, but is costly. Dapsone and doxycycline can also be therapeutic apparently by their ability to reduce neutrophil chemotaxis. Colchicine can be attempted if dapsone is not tolerated. These agents can reduce the requirement for enzyme replacement and should be considered as maintenance treatment in previously affected patients. Systemic steroids may exacerbate the panniculitis. Liver transplantation leads to normal levels of the enzyme and resolution of the panniculitis.

CYTOPHAGIC HISTIOCYTIC PANNICULITIS

Cytophagic histiocytic panniculitis (CHP) is a multisystem disease characterized by widespread erythematous, painful subcutaneous nodules, which may occasionally become ecchymotic or break down and form crusted ulcerations. There is a progressive febrile illness, with hepatosplenomegaly, pancytopenia, hypertriglyceridemia, and liver dysfunction. These result from the proliferation of benign appearing histiocytes, which have a marked phagocytic capacity and extensively involve the reticuloendothelial system. Some patients progress to a terminal phase characterized by profound cytopenia, liver failure, and a terminal hemorrhagic diathesis.

Cytophagic histiocytic panniculitis represents a spectrum of disease that occurs in children and adults. Some cases are triggered by viral infections (Epstein-Barr virus [EBV] and human immunodeficiency virus [HIV]), and others represent subcutaneous B- or T-cell lymphomas. The benign cases are reportedly EBV negative and the lymphoma-associated cases are EBV positive.

Histologically, there is infiltration of the lobules of subcutaneous fat by histiocytes and inflammatory cells (primarily helper T-cells), with fat necrosis and hemorrhage. The characteristic cell is a "bean bag" cell: a histiocyte stuffed with phagocytized red blood cells, lymphocytes, neutrophils, platelets, or fragments of these cells. These "bean bag" cells are not diagnostic of CHP and can be seen uncommonly in other panniculitides, especially lupus profundus. The presence of atypical lymphocytes or the detection of a clonal B- or T-cell proliferation supports the diagnosis of subcutaneous lymphoma in cases of CHP.

The treatment of CHP is difficult. If malignancy cannot be detected, cyclosporin has been very effective in all reported cases treated with this agent, inducing a permanent remission. If malignancy is detected, aggressive chemotherapy and perhaps bone marrow transplantation may be considered.

MISCELLANEOUS FORMS OF PANNICULITIS

GOUTY PANNICULITIS

Uric acid crystals may deposit initially in the subcutaneous fat, leading to lesions resembling other forms of panniculitis. Histologically, there is a lobular panniculitis with necrosis of adipocytes and infiltration of polymorphonuclear leukocytes. Feathery needle-like crystals in sheaves are present.

LeBoit PE, et al: Gout presenting as lobular panniculitis. Am J Dermatopathol 1987;9:334.

LIPODYSTROPHY (LIPOATROPHY)

The lipodystrophies are conditions in which there is markedly reduced subcutaneous fat. They can be generalized (total), partial, or localized, and may be congenital, or acquired. In the congenital types, women are more commonly and severely affected. Hypertriglyceridemia and diabetes mellitus with insulin resistance occur in many of the congenital and acquired forms of lipodystrophy. These syndromes were quite rare until the 1990s. With the advent of combination antiviral therapy for HTV infection (highly active antiretroviral therapy [HAART]) acquired lipodystrophy has become very common in geographic regions where HIV infection is prevalent. In addition, localized fat loss can be a consequence of therapeutic injections into the fat.

Congenital Lipodystrophies

Congenital Generalized Lipodystrophy Congenital generalized liposystrophy, also known as Beradinelli-Seip syndrome, is a rare autosomal-recessive condition. From birth there is an extreme paucity of fat in the subcutaneous tissue and other adipose tissues, giving affected persons a generalized muscular appearance. The mechanical fat of the palms, soles, joints, orbits, and scalp are not affected in some types of this syndrome. The children have a voracious appetite. They have increased height and height velocity, advanced bone age, muscular hypertrophy, and a masculine habitus. This habitus plus enlargement of the genitalia in infancy (clitoromegaly) can lead to the misdiagnosis of precocious puberty. Scalp hair is abundant and curly, and there is generalized hypertrichosis and hyperbidrosis. The abdomen is protuberant and the liver and spleen are enlarged. The overall appearance is acromegalic due to enlargement of the mandible, hands, and feet. Acanthosis nigricans is invariably present and often generalized. Hyperinsulinemia, insulin resistance, and diabetes appear often around puberty. The diabetes mellitus resists insulin and oral hypoglycemic therapy, but ketoacidosis does not occur. Hypertriglyceridemia occurs and can produce eruptive xanthomas; pancreatitis; and fatty liver, which may eventuate in cirrhosis. Hypertrophic cardiomyopathy and mild mental retardation may occur. Lifespan is shortened, with patients frequently dying in young adulthood from complications of diabetes, liver or heart disease. Congenital generalized lipodystrophy is due to two genetic defects, classified as type 1 and type 2 respectively. Type 1 patients have homozygous or compound heterozygous mutation of the AGPAT2 gene encoding 1acylglycerol-3-phosphate O-acyl transferase 2. This enzyme is involved in the formation of triglycerides and phospholipids. Type 2 patients have mutations in the seipin gene. The role of seipin in causing this phenotype is unknown. Patients with seipin mutations are more likely to have mental retardation, hypertrophic cardiomyopathy, and also lack mechanical adipose tissue. Serum leptin and adiponectin levels are extremely low in both types. If leptin levels are low, leptin replacement decreases serum triglycerides and improves hyperglycemia. Twenty percent of patients with congenital generalized lipodystrophy do not have mutations in these two genes, suggesting there are other genetic causes.

Familial Partial Lipodystrophy Familial partial lipodystrophy is a heterogenous autosomal-dominant group of

disorders with distinct phenotypes. The most common variant is the Dunnigan type. Patients are normal at birth, but at around the time of puberty there is gradual loss of subcutaneous tissue from the arms and legs, and variably from the chest and anterior abdomen. Fat gain occurs in the face, neck, and intra-abdominally, resulting in a cushingoid appearance. Diabetes mellitus, hypertriglyceridemia, and atherosclerosis occur more frequently in female patients. The hypertriglyceridemia may result in pancreatitis and fatty liver, but cirrhosis has not been reported. The genetic defect in the Dunnigan variant of partial lipodystrophy is in the gene encoding lamins A and C (LMNA). Lamins are intermediate filaments integral to the nuclear envelope. The site of the mutation determines the phenotype expressed. Myopathy, musclar dystrophy, cardiomyopathy, and conducting system disturbances can occur in a minority of patients.

A second characterized form of familial partial lipodystrophy is related to mutations in the PPAR y gene. This rare syndrome is associated with marked loss of subcutaneous tissue of the forearms and calves and less prominently on the upper arms and thighs. The trunk is spared and there is no excess fat on the neck. Diabetes mellitus, hypertriglyceridemia, hypertension, and hisuitism also occur. Other forms of familial partial lipodystrophies not associated with the above two mutations have been described, suggesting additional genetic causes of this syndrome.

Mandibuloacral dysplasia is an extremely rare autosomalrecessive condition with hypoplasia of the mandible and clavicle, acro-osteolysis, joint contractures, mottled cutaneous pigmentation, skin atrophy, alopecia, a bird-like facies, and dental anomalies. Two distinct patterns of lipodystrophy occur. Type A is characterized by loss of subcutaneous fat from the arms and legs, but normal-to-excess fat of the face and neck. Type B has a more generalized lipodystrophy. Hyperinsulinemia, insulin resistance, diabetes mellitus, and hyperlipidemia occur in some patients. Mutations in the LMNA gene have been reported in type A patients. Mutations in the zinc metalloproteinase (ZMPSTE24), which is involved in the processing of prelamin A, have also been responsible for mandibuloacral dysplasia. Autosomalrecessive neonatal progeroid syndrome is characterized by near total absence of fat from birth, with sparing of the sacral and gluteal areas.

Acquired Lipodystrophy

There are several forms of acquired lipodystrophy. Although they appear later in life, are not inherited, and no genetic mutation has yet been described to be causal, they closely resemble the genetically determined diseases. Acquired lipodystrophy can be partial or generalized. In addition, hyperinsulinemia, hyperlipidemia, and diabetes mellitus may occur in patients with acquired lipodystrophy. Management involves controlling the hyperinsulinemia and its complications.

Acquired Partial Lipodystrophy (Barraquer-Simons Syndrome) Until HAART-associated lipodystrophy appeared, this was the most common form of lipodystrophy. Females outnumber males 4:1. It presents in the first and second decades. This progressive fat disorder is characterized by a diffuse and progressive loss of the subcutaneous fat that usually begins in the face and scalp and progresses down-

ward as far as the iliac crests, sparing the lower extremities. The upper half of the body looks emaciated and the cheeks sink in (Fig. 23-5A). There is an apparent, and sometimes real, adiposity of the buttocks, thighs, and legs, especially in affected women (Fig. 23-5B). The onset is insidious, with no discomfort or inflammation in the areas of fat loss. A few patients have developed other autoimmune diseases, including systemic lupus erythematosus and juvenile dermatomyositis. Histologically, the skin is normal except for the absence of fat. Most patients with this form of lipodystrophy have reduced levels of C3 resulting from the presence of a circulating polyclonal IgG called "C3 nephritic factor." Proteinuria caused by membranoproliferative glomerulonephritis occurs in about 20% of patients, appearing about 8 years after the onset of the lipodystrophy. C3 nephritic factor stabilizes C3b, Bb (C3 convertase), leading to unopposed activation of the alternative complement system and excessive consumption of C3.

Acquired Generalized Lipodystrophy This rare form of lipodystrophy appears during childhood or adolescence. Females outnumber males 3:1. The fat loss affects large areas of the body, particularly the face, arms, and legs. Mechanical fat of the palms and soles may be lost, but ocular and bone marrow fat are spared. Acanthosis nigricans is present. Hepatic steatosis and voracious appetite may be present. Cirrhosis occurs in about 20% of patients due to hepatitic steatosis or autoimmune hepatitis. Diabetes mellitus and hypertriglyceridemia may occur.

About 25% of patients will have a preceding inflammatory panniculitis at the onset of the syndrome. These patients tend to have less severe manifestations. Another 25% of patients with acquired generalized lipodystrophy have an associated connective tissue disease, especially juvenile dermatomyositis. Half of the patients give no history of panniculitis and have no connective tissue disease. One case has been associated with an abnormality of chromosome 10.

Centrifugal Abdominal Lipodystrophy

Most cases of "lipodystrophia centrifugalis abdominalis infantilis," as described by lmamura et al, have been reported from a single region of Japan. The cause is un-

Fig. 23-5 Partial lipodystrophy, acquired. A, Face and B. hypertrophy of subcutaneous fat on the lower half of the body.

497

known. It is almost invariably a disease of childhood; 90% of cases begin at age 3. Girls outnumber boys 2:1. It is characterized by depression of the skin caused by loss of fat in the groin (80% of cases) or axilla (20% of cases). The atrophic area enlarges slowly centrifugally for 3 to 8 years in most cases, often stopping with the onset of puberty. In 80% of cases the depressed area was surrounded by a discrete, erythematous border with scale. One-third of patients have multiple lesions and regional lymph nodes are enlarged in 65% of cases. The affected children are otherwise well. When the lesion stops expanding, the erythematous rim and lymphadenopathy disappear. After the progression stops, the skin returns to normal within a year or two.

Muller S, et al: Lipodystrophia centrifugalis abdominalis infantilis in a 4-year-old caucasian girl: association with partial IgA deficiency and autoantibodies. Br J Dermatol 1999;140:1161.

Lipoatrophia Annularis (Ferreira-Marques)

Lipoatrophia annularis affects primarily women and usually affects the upper extremity. The lipoatrophy may be preceded by erythema, a bracelet-shaped swelling, and tenderness of the entire extremity. This is followed by loss of subcutaneous fat so that the arm is divided into two parts by a depressed, atrophic, bracelet-like constriction. The depressed band is usually about 1 cm wide and up to 2 cm in depth. Arthralgias and pain of the affected extremity precede and accompany the process. The band persists for up to 20 years. The histology shows atrophy of the subcutaneous fat. The cause is unknown.

Rongioletti F, et al: Annular and semic/rcular llpoatrophies. J Am Acad Dermatol 1989;20:433.

Localized Lipodystrophy

Six months to 2 years after the initiation of insulin injections, localized atrophy of fat may develop at the sites, more frequently in children and women than in men. This dystrophic change may resolve if patients are switched to human insulin. Much less often, insulin injections may result in lipohypertrophy. Rarely, injections of other medications may result in lipoatrophy.

- Valenta LJ, et al: Insulin-induced lipodystrophy in diabetic patients resolved by treatment with human insulin. Ann Intern Med 1985;102:790.

HIV-Associated Lipodystrophy

In up to 80% of HIV-infected patients, most of whom are being treated with combination anti-HIV therapy (HAART). an unusual form of fat redistribution occurs. The fat of the face, especially the buccal fat pads, buttocks, and limbs is lost. There is increased fat deposition in other areas, especially the neck, upper back (buffalo hump), and intra-abdominally. It is related to non-nucleoside reverse transcriptase inhibitors which also inhibit the y DNA polymerase of mitochondria leading to adipocyte apoptosis. As with the other acquired and inherited forms of lipodystrophy, patients may suffer from hypertriglyceridemia, hypercholesterolemia, and insulin resistance, especially if a protease inhibitor is a part of their treatment. Metformin therapy at a dose of 500 to 850 mg twice a day combined with exercise reduces the body mass index and waist circumference, as well as insulin resistance. Various injectables may provide cosmetic improvement.

ACROMEGALY

Excess growth hormone in prepubertal children leads to gigantism, whereas once the epiphysial growth plates close, such excess leads to acromegaly. In acromegaly, changes in the soft tissues and bones form a characteristic syndrome. In association with the well-known changes in the facial features caused by gigantic hypertrophy of the chin, nose, and supraorbital ridges, there is thickening, reddening, and wrinkling of the forehead, and exaggeration of the nasolabial grooves (Fig. 24-1A). The lips and tongue are thick. Cutis verticis gyrata is present in approximately 30% of patients. The hands and feet enlarge (Fig. 24-1B), and there is gradual growth of the fingertips until they resemble drumsticks. There is diffuse hypertrophy of the skin. This is at least partly due to deposition of colloidal iron-positive material in the papillae and reticular dermis. This increased skin thickness can be demonstrated in lateral radiographs of the heel, with reversal toward normal after treatment. Skin thickness does not correlate well with growth hormone levels at the time of diagnosis. Hypertrichosis, hyperpigmentation, and hyperhidrosis occur in many patients. The clinical changes may suggest the leonine facies of leprosy, as well as Paget's disease, myxedema, and pachydermoperiostosis. Acromegaloid facial appearance syndrome is an inherited condition where only the facial changes are present, and no abnormality of growth hormone exist. Pseudoacromegaly is an acquired condition which may be seen in patients with severe insulin-resistant diabetes, which appears to be a fibroblast defect, or in patients on long-term minoxidil.

The cause of acromegaly is hypersecretion of growth hormone by the pituitary, usually because of a mixed chromophobe and eosinophilic adenoma of the gland. Rare cases of ectopic growth-hormone-releasing hormone producing tumors of the lung and pancreas have been reported. The peak age of diagnosis is in the 40s. Measurement of serum insulin-like growth factor (somatomedin C) and serum growth hormone after a glucose load and a magnetic resonance imaging (MRI) of the pituitary are diagnostic tests. It may occur as one of the manifestations of Carney complex or

Fig. 24-1 A and B, Acromegaly. B. Patient with acromegaly on the left compared to normal sized hand on the right.

multiple endocrine neoplasia-1.

The currently preferred treatment is a combination of transphenoidal microsurgical excision of the tumor followed by medical therapy for residual disease. Octreotide and lanreotide are potent, long-acting inhibitors of growth hormone (somatostatin analogs) that are given as once a month or biweekly intramuscular depot injections. Fatigue, paresthesias, and headaches improve rapidly. With continuous treatment, soft-tissue swelling and facial coarsening improve as growth hormone levels decline in almost all patients. After 18 to 24 months of therapy 50% of patients will completely normalize, with the exception of hyperhidrosis, which persists in most patients. The dopamine agonist bromocriptine suppresses growth hormone secretion and is used as an adjuvant medical therapy in some cases. Radiation is generally reserved for recalcitrant cases.

CUSHING SYNDROME

Chronic excess of glucocorticoids leads to a wide variety of signs and symptoms. Among the most prominent features of this syndrome is central obesity, affecting the face, neck, trunk, and markedly the abdomen, but sparing the limbs. There is classically deposition of fat over the upper back, referred to as a buffalo bump. This may be treated with liposuction. The face becomes moon-shaped, being wide and round. The peak age of onset is in the 20s and 30s.

The striking and distressing skin changes include hypertrichosis, dryness, fragility of the skin, facial acne, susceptibility to superficial dermatophyte and pityrosporon infections, a plethora over the cheeks, anterior neck, and V of the chest, and the characteristic purplish, atrophic striae on the abdomen (Fig. 24-2) and thighs. Women, who are affected four times more frequently than men in noniatrogenic cases, develop facial and body hypertrichosis, with thinning of the scalp hair. The thinning of the skin can be demonstrated and measured in lateral radiographs of the heels. There is reversal with treatment. Occasionally, there may be livedo reticularis, purpura, ecchymosis, or brownish pigmentation. Poikilodermalike changes have been observed. Opportunistic fungal infections occur, these may be with organisms that are not normally pathogenic or be uncommon presentations of common infections.

There is usually hypertension and marked generalized arteriosclerosis, with progressive weakness, prostration, and pains in the back, limbs, and abdomen; also kyphosis of the dorsal spine occurs, accentuating the buffalo appearance. Osteoporosis occurs and there is generally a loss of libido. In 20% of patients a disturbance in carbohydrate metabolism

Fig. 24-2 Cushing syndrome.

develops with hyperglycemia, glycosuria, and diabetes mellitus.

These varied symptoms indicate a marked and widespread disturbance caused by the hyperactive adrenal cortex. When microadenomas of the pituitary produce these clinical findings, it is referred to as Cushing's disease. This accounts for only 10% of patients; most adenomas are chromophobic. Forty to 60% of additional cases are due to increased adrenocorticotropic hormone (ACTH) production by the pituitary. but no adenoma is identified. Adrenal adenomas and carcinomas, and ectopic production of ACTH by other tumors, account for the remainder of cases of noniatrogenic Cushing syndrome. latrogenic Cushing syndrome is usually secondary to systemic administration of corticosteroids; however, absorption from topically applied steroids may occur, especially in children. Primary pigmented nodular adrenocortical disease leading to Cushing syndrome occurs in 30% of patients with Carney complex.

A rapid screening test for Cushing syndrome consists of oral administration of 1 mg of dexamethasone at 11 PM followed at 8 AM by a fluorometric determination of plasma cortisol. A cortisol level below 3 µg/dL essentially rules out Cushing syndrome, except for the latrogenic variety, in which there is adrenocortical hypoplasia, and the serum cortisol level is very low even without dexamethasone suppression. If this test is positive it must be confirmed by doing a 24-h urinary free cortisol test. A value of at least three times the upper limit of normal is 95% to 100% sensitive and specific. A serum ACTH is then obtained to determine if the source is the adrenals, pituitary or ectopic tumor (low, normal or high, and very high, respectively). Treatment is primarily surgical removal of the tumor, however, radiation, chemotherapy or medication that blocks steroid synthesis are occasionally employed.

ADDISON'S DISEASE

Adrenal insufficiency is manifested in the skin primarily by hyperpigmentation (Fig. 24-3). It is diffuse but most prominently observed in sun-exposed areas and sites exposed to recurrent trauma or pressure. The axillae, perineum, and nipples are also affected. Palmar crease darkening in patients of lighter skin type, scar hyperpigmentation, and darkening of nevi, mucous membranes, hair, and nails may all be seen. An eruptive onset of multiple new nevi may be an early sign of Addison's disease. Occasionally, pigmentation may not occur; this is referred to as white Addison's disease. Decreased axillary and pubic hair is seen in women as their androgen production primarily occurs in the adrenals. Fibrosis and calcification of the pinnae of the ears are rare complications.

Systemic signs such as weight loss, nausea, vomiting, diarrhea, weakness, fatigue, and hypotension add specificity to the cutaneous abnormalities. Addison's disease is usually the result of autoantibody destruction of adrenocortical tissue; however, infection, hemorrhage, or infiltration may be the cause of adrenal insufficiency. In young boys suspected of having Addison's disease, adrenoleukodystrophy must be considered. Hyperpigmentation may precede neurologic signs, so very-long-chain fatty acids should be determined. Addison's disease may be part of a polyglandular autoimmune disease in which various combinations of hypoparathyroidism, chronic candidiasis, and vitiligo or autoimmune thyroiditis and diabetes may occur.

Diagnosis is made by obtaining a serum cortisol followed by stimulation with cosyntropin. Failure to see an elevation above 20 μ g/dL in 1 h is diagnostic. Plasma ACTH is elevated in primary insufficiency but normal to low in patients with secondary adrenal insufficiency, where the damage is in the hypothalamic/pituitary axis. The adrenals should be imaged with CT to exclude infiltration or infection. Treatment is the replacement of the glucocorticoids and mineralocorticoids.

PANHYPOPITUITARISM AND GROWTH HORMONE DEFICIENCY

Pituitary failure results in many changes in the skin, hair, and nails as a result of the absence of pituitary hormone action on these sites. Pale, thin, dry skin is seen. Hypohidrosis is present. Diffuse loss of body hair, with axillary, pubic, and head hair being especially thin, is present. The nails are thin, fragile, and opaque, and grow slowly. Compromise of the pituitary is usually caused by a pituitary tumor, although infiltration, infection, trauma, hemorrhage or hypothalamic tumors, may be the etiology. Thyroid hormone, glucocorticoids, sex steroids, and growth hormones are low and require replacement. A pituitary MRI will screen for tumors or infiltrative processes.

Diseases of the pituitary that cause panhypopituitarism may also lead to growth hormone deficiency as an isolated finding. This condition may begin in childhood, in which case short stature is the most prominent problem, while in adults weight gain, decreased energy, decreased strength, and psychosocial disorders predominate. Children have sparse hair growth and frontal recession and pill torti et canaliculi and trichorrhexis nodsa are present in some patients. In children the most common finding is an idiopathic decrease in secretion of growth hormone from the pituitary, while in adults there is usually pituitary pathology demonstrable by MR1, as described above. An insulin tolerance test is the most common diagnostic test. Treatment is with growth hormone replacement.

ANDROGEN-DEPENDENT SYNDROMES

The androgen-dependent syndromes are caused by the excessive production of adrenal or gonadal androgens by adrenal adenomas, carcinoma or hyperplasia, Leydig cell tumors in men, and arrhenoblastomas and polycystic ovarian syndrome (PCOS) in women. The latter is defined as the association of biochemical or clinical androgenism with chronic anovulation without specific underlying disease of the adrenal or pituitary glands.

The cutaneous signs of excessive androgen in women include acne, hirsutism, temporal baldness, seborrhea, enlargement of the clitoris, and decreased breast size. Hyperpigmentation of the skin, areolae, genitalia, palmar creases, and buccal mucosa develops in some patients. Acanthosis nigricans is common in PCOS. A deepening voice, increased muscle mass, galactorrhea, and irregular or absent periods are other signs of androgen excess in women.

In the congenital adrenogenital syndrome, excess androgen is produced by an inherited defect in any of the five enzymatic steps required to convert cholesterol to cortisol. The formation of inadequate amounts of cortisol stimulates the pituitary to secrete excessive ACTH, which stimulates excess androgen production. In boys, precocious puberty results. In girls, masculinization occurs, with the prominent cutaneous signs of excess androgen production (Fig. 24-4). Among these may be childhood acne. It may begin before age 9 and manifest as primarily comedonal lesions in the central face associated with advanced bone age. Many children with this presentation of acne, however, reveal no abnormality. Accelerated bone growth with early closure of the epiphyseal plates results in short stature. Early appearance of pubic and axillary hair is also seen.

Testing includes serum total testosterone and dehydroepiandrosterone sulfate (DHEA-S). If the total testosterone is greater than 200 ng/dL, ovarian imaging is indicated to assess for an ovarian tumor. If DHEA-S is two to three times the upper limit, an adrenal mass should be suspected and a computed tomographic (CT) scan of the adrenals is needed. In congenital adrenal hyperplasia, testing should include levels of cortisol, aldosterone, and precursor hormones, and in some case cortrysin stimulation tests. Nonclassic adrenal hyperplasia is most commonly related to 21-hydroxylase deficiency, and may present as PCOS. It is best diagnosed by a corticotropin-stimulated 17-hydroxyprogesterone (17-HP) level greater than 10 ng/mL (30.3 nmol/L). The diagnosis can be confirmed by genotyping of the CYP21 gene. The baseline 17-HP level has been used as a screening test. Although the sensitivity and specificity of the test has been challenged, levels of 17-HP lower than 2 ng/mL (6.0 nmol/L) have a fairly good negative predictive value and those greater than 4 ng/mL (12.0 nmol/L) have a fairly good positive predictive value. The question remains whether treatment with corticosteroid replacement results in better outcomes than empiric antiandrogen therapy.

Fig. 24-4 Adrenogenital syndrome.

Treatment of the cutaneous signs of androgen excess is successful with the androgen-blocking agents cyproterone acetate, flutamide, and finasteride. Spironolactone, which competes for the androgen cytosol receptors, has proved useful as a systemic antiandrogen in the treatment of hirsutism and acne. Adrenal-androgenic female pattern alopecia may improve with topical minoxidil or spironolactone. Chorionic villous biopsy may identify homozygous adrenogenital female fetuses and allow for dexamethasone therapy to prevent intrauterine virilization of the external genitalia.

HYPOTHYROIDISM

Hypothyroidism is a deficiency of circulating thyroid hormone, or rarely peripheral resistance to hormonal action. Deficiency may be caused by iodine deficiency, late-stage Hashimoto autoimmune thyroiditis, pituitary or hypothalamic disease causing central hypothyroidism, or it may be iatrogenic secondary to surgery, radioactive iodine treatment or drug therapy with lithium, interferon or bexarotene. The condition produces various clinical manifestations, depending on when in life it occurs and on its severity. Middle-aged women are the most commonly affected adults. Patients with Turner and Down syndrome are predisposed to hypothyroidism and the production of thyroid autoantibodies. There is a wide array of immunologic conditions associated with Hashimoto thyroiditis such as autoimmune polyglandular syndrome type II/III, vitiligo, connective tissue disease, and autoimmune urticaria.

An autosomal-recessive variant of ectodermal dysplasia reported as ANOTHER (alopecia, nail dystrophy, ophthalmic complications, thyroid dysfunction, hypohidrosis, ephelides and enteropathy, and respiratory tract infections) syndrome has been described and thyroid tumors are a component of Carney complex and multiple endocrine neoplasia-2a and -2b.

Cretinism

Thyroid deficiency in fetal life produces the characteristic picture of cretinism at birth and in the next few months of life. Depending on the degree of thyroid deficiency, a wide variety of signs and symptoms may be evident. The main consequence of extreme thyroid deficiency is cretinism and its attendant mental retardation, but much more prevalent are lesser degrees of intellectual and neurologic deficits seen in areas where iodized salt is still not routinely available.

The person with cretinism has cool, dry, pasty white to yellowish skin. Disturbances in the amount, texture, and distribution of the hair with patchy alopecia are common. Pigmentation is less than normal after exposure to sunlight. Sweating is greatly diminished. The lips are pale, thick, and protuberant. The tongue is usually enlarged, and there is delayed dentition. Wide-set eyes, a broad, flat nose, and periorbital puffiness characterize the face. A protuberant abdomen with umbilical hernia; acral swelling; coarse, dry, brittle nails; a clavicular fat pad; and hypothermia with cutis marmorata are also seen.

Myxedema

When lack of secretion of thyroid hormone is severe, the systemic mucinosis called *myxedema* is produced. The skin becomes rough and dry, and in severe cases of primary myxedema, ichthyosis vulgaris may be simulated. The facial skin is puffy; the expression is often dull and flat; macroglossia, swollen lips, and a broad nose are present; and chronic periorbital infiltration secondary to deposits of mucopolysaccharides frequently develops (Fig. 24-5A). Such infiltrate can lead to a cutis verticis gyrata appearance of the scalp. Carotenemia may cause a yellow tint in the skin that is especially prominent on the palms and soles. Diffuse hair loss is common, and the outer third of the eyebrows is shed (Fig. 24-5B). The hair becomes coarse and brittle. The free edges of the nails break easily, and onycholysis may occur.

Mild Hypothyroidism

Lesser degrees of deficiency are common and far less easily diagnosed. Coldness of hands and feet in the absence of vascular disease, sensitivity to cool weather, lack of sweating, tendency to put on weight, need for extra sleep, drowsiness in the daytime, or constipation all suggest possible hypothyroidism and the need for appropriate tests. Palmoplantar keratoderma may be a sign of hypothyroidism and will resolve after thyroid replacement is given.

Diagnosis and Treatment

An increased thyroid-stimulating hormone (TSH) test is the best diagnostic test for primary hypothyroidism. T3 and T4 are low, and in Hashimoto thyroiditis, the most common cause of hypothyroidism in the US, thyroid peroxidase antibodies are present in 95% of patients. In those with positive antibodies but normal thyroid function, hypothyroidism will develop at a rate of 5% per year. Thyroid hormone replacement will reverse the skin findings of hypothyroidism.

HYPERTHYROIDISM

Excessive quantities of circulating thyroid hormone may be caused by a multinodular toxic goiter or a single toxic thyroid nodule, early Hashimoto autoimmune thyroiditis, a TSHsecreting pituitary adenoma, or Graves thyroiditis. The latter

Fig. 24-5 *A*, Periorbital infiltration with mucopolysaccharides and *B*, Loss of lateral eyebrow.

is mediated by thyroid stimulating antibodies that bind to the TSH receptor, mimic the effects of TSH, and induce hyperthyroidism. There are many skin changes common to all forms of hyperthyroidism. The cutaneous surface is warm, moist, and smooth textured. Palmar erythema or facial flushing may be seen. The hair is thin and has a downy texture, and nonscarring diffuse alopecia may be observed. The skin may darken to produce a bronzed appearance or melanoderma; sometimes melasma of the cheeks is seen. Nail changes are present in approximately 5% of patients with Plummer nails, a concave contour of the plate with distal onycholysis, being characteristic. Hyperhidrosis may be noted.

Graves' disease has a female-to-male ratio of 7:1, and the peak age at onset is 20 to 30 years. It is the most common cause of noniatrogenic hyperthyroidism. Ophthalmopathy, pretibial myxedema, and thyroid acropachy are findings nearly always limited to Graves patients (Fig. 24-6). Thyroid acropachy, seen in approximately 0.1% to 1% of Graves patients, is characterized by digital clubbing, soft-tissue swelling of the hands and feet, and diaphyseal proliferation of the periosteum in acral and distal long bones (tibia, fibula, ulna, and radius). It usually occurs after treatment of hyperthyroidism and is usually associated with exophthalmos and pretibial myxedema. It may, however, occasionally precede the thyrotoxicosis and has been recognized in euthyroid and hypothyroid patients. It can be confused clinically with acromegaly, pachydermoperiostosis, pulmonary osteoarthropathy, or osteoperiostitis, but the radiologic findings are pathognomonic.

Fig. 24-6 A, Thyroid acropachy and pretibial myxedema, and B, exophthalmos.

Pretibial myxedema, consisting of bilateral, localized, cutaneous accumulations of glycosaminoglycans, occurs in 4% of patients who have or have had Graves' disease (Fig. 24-7). The morphology may vary from a nonpitting infiltration to nodules, plaques, and even an elephantiasic form where the skin is thickened, firm, and hyperpigmented from just below the knees to the feet. It may uncommonly also occur during the course of Hashimoto thyroiditis and primary hypothyroidism. Patients with pretibial myxedema regularly have associated ophthalmopathy and occasionally have thyroid acropachy. While not usually clinically apparent, approximately half of patients with Graves' disease have mucopolysaccharide deposition in the preradial area of the extensor aspects of the forearms. Lesions of the shoulder, hands, thigh, and scalp have been reported.

Improvement in the plaques of pretibial myxedema has resulted from intralesional injections of triamcinolone acetonide, with high potency topical steroids under occlusion. Systemic steroids are usually not helpful. Compression stockings or complete decongestive physiotherapy, a combination of manual lymphatic drainage, bandaging, and exercise, are useful and safe. Improvement with intravenous immunoglobulin of the skin, eye, and immunologic parameters has been reported in small series of patients. Pentoxifylline, octreotide, plasmapheresis, and cytotoxic drugs have all been reported to help in small numbers of patients, but negative reports also exist.

Vitiligo is associated with hyperthyroidism in 7% of patients with Graves' disease and is seen with an increased frequency in Hashimoto thyroiditis. Urticaria may be seen in patients with thyroid autoantibodies and may clear with the administration of thyroid hormone, even in euthyroid patients. A wide range of other autoimmune disorders may be seen in patients with Graves or Hashimoto autoimmune thyroiditis.

The TSH level is low in all patients except those with a TSH-secreting pituitary adenoma. Free T3 and T4 are elevated. Anti-TSH antibodies are present in nearly all Graves patients but the presence of a diffuse goiter with classic signs

Fig. 24-7 Pretibial myxedema. (Courtesy of Lawrence Lieblich, MD)

precludes the need to order this test in most patients. A 24-h radioiodine scan will also help define the etiology. Treatment is with radioactive iodine or antithyroid drugs such as methimazole or propylthiouracil.

HYPOPARATHYROIDISM

Varied changes in the skin and its appendages may be evident. Most pronounced is faulty dentition when hypoparathyroidism is present during development of the permanent teeth. The skin is dry and scaly. A diffuse scantiness of the hair and complete absence of axillary and pubic hair may be found. The nails are brittle and malformed. Onycholysis with fungal infection may be present. Of patients with idiopathic hypoparathyroidism, 15% develop mucocutaneous candidíasis. Hypoparathyroidism is the most frequent endocrine abnormality present in patients with the APECED (autoimmune polyendocrinopathy, candidiasis, ectodermal dystrophy) syndrome. In autoimmune polyendocrinopathy syndrome type I, hypoparathyroidism is present in association with Addison's disease and chronic candidiasis. Hypoparathyroidism may additionally occur in DiGeorge syndrome, or with infiltration or inadvertent surgical removal during thyroid surgery. Hypoparathyroidism with resultant hypocalcemia has been reported to trigger bouts of impetigo herpetiformis or pustular psoriasis.

Pseudohypoparathyroidism (PH) is an autosomaldominant or X-linked inherited disorder characterized by end-organ unresponsiveness to parathyroid hormone. The parathyroid hormone and phosphorus levels are high, whereas the serum calcium is low. The typical clinical findings include short stature; obesity; round face; prominent forehead; low nasal bridge; attached earlobes; short neck; short, wide nails; delayed dentition; mental deficiency; amenorrhea; blue sclera; and cataracts. Brachycephaly, microcephaly, and shortened metacarpals or metatarsals, especially of the fourth and fifth digits, occur because of premature epiphyseal closure. The latter results in short, stubby fingers and toes, with dimpling over the metacarpophalangeal joints (Albright's sign) (Fig. 24-8). Subcutaneous calcification and ossification occur commonly in this disorder as it may in pseudopseudohypoparathyroidism (PPH), which has the same phenotype but patients have normal serum and calcium levels. PH and PPH are two types of Albright hereditary osteodystrophy. In PH type Ia there is a defect in a G protein that couples receptors for several hormones to adenylate cyclase. This causes a generalized resistance to agents acting through the cAMP pathway and explains the frequent association of hypothyroidism and hypogonadism.

HYPERPARATHYROIDISM

Whereas parathyroid hormone (PTH) regulates calcium levels, calcinosis cutis may develop from excess PTH. This can occur when the serum calcium/phosphorus product is greater than 65 mg/dL. This may manifest as large subcutaneous nodules or white, often linearly arranged, papules centered about joints. Additionally, calciphylaxis, while most common in the setting of secondary hyperparathyroidism and renal failure, may be seen occasionally in primary hyperparathyroidism.

Multiple endocrine neoplasia (MEN) type I is characterized by tumors of the parathyroids, endocrine pancreas, anterior pituitary, thyroid, and adrenal glands. The most commonly observed abnormality is hypercalcemia from hypersecreting tumors of the parathyroid glands. This autosomal-dominantly inherited disease usually presents in the fourth decade of life with clinical symptoms related to hypersecretion of hormone. They may also manifest multiple angiofibromas, collagenomas, café-au-lait macules, lipomas, confetti-like hypopigmentation, and gingival macules. The angiofibromas are smaller and less numerous than those present in tuberous sclerosis. The tumors in both MEN I and tuberous sclerosis apparently arise because of abnormalities within a tumor suppressor gene. The MEN I gene, which is present on chromosome 11, has a protein product termed menin whose function is yet to be delineated. Additionally, approximately 20% to 40% of cases of sporadic parathyroid adenomas have been linked to overexpression of cyclin D1. a key regulator of the cell cycle.

ACANTHOSIS NIGRICANS

Acanthosis nigricans is characterized by hyperpigmentation and velvet-textured plaques, which are symmetrically distributed. The regions affected may be the face, neck, axillae (Fig. 24-9), external genitals, groin, inner aspects of the thighs, flexor and extensor surface of the elbows and knees, dorsal joints of the hands, umbilicus, and anus. With extensive involvement, lesions can be found on the areolae, conjunctiva, lips, and buccal mucosa, and around the umbilicus. Rarely, the involvement may be almost universal. The color of the patches is grayish, brownish, or black. The palms or soles may show thickening of the palmar skin with exaggeration of the dermatoglyphs. In severe cases a rougose hypertrophy occurs and can be a sign of malignancy. Small,

Fig. 24-9 Acanthosis nigricans. papillomatous, nonpigmented lesions and pigmented macules may occasionally be found in the mucous membranes of the mouth, pharynx, and vagina. Acrochordons are a frequent accompaniment in the axillae and groin

Type I: Acanthosis Nigricans Associated with Malignancy

The "malignant" type of acanthosis nigricans may either precede (18%), accompany (60%), or follow (22%) the onset of the internal cancer. This rare type generally is the most striking clinically, both from the standpoint of extent of involvement and the pronounced nature of the lesions (Fig. 24-10). Most cases are associated with adenocarcinoma, especially of the gastrointestinal tract (60% stomach), lung, and breast; less often the gallbladder, pancreas, esophagus, liver, prostate, kidney, colon, rectum, uterus, and ovaries. Other types of cancer and lymphomas may be seen also. A few cases of this type of acanthosis nigricans have been observed in childhood, but most begin after puberty or in adulthood. This type should be highly suspected if widespread lesions develop in a nonobese male aged over 40.

Tripe palms (acanthosis palmaris) are characterized by thickened, velvety palms with pronounced dermatoglyphics; 95% occur in patients with cancer and 77% are seen in conjunction with acanthosis nigricans (Fig. 24-11). In 40% of these cases, tripe palms is the presenting sign of an undiagnosed malignancy. If only the palms are involved, lung cancer is most common, whereas in tripe palms associated with acanthosis nigricans gastric cancer is most frequent.

Type II: Familial Acanthosis Nigricans

This exceedingly rare type is present at birth or may develop during childhood. It is commonly accentuated at puberty. It is not associated with an internal cancer and is inherited in an autosomal-dominant manner.

Type III: Acanthosis Nigricans Associated with Obesity, Insulin-Resistant States, and Endocrinopathy

Type III is the most common variety of acanthosis nigricans. It presents as a grayish, velvety thickening of the skin of

Fig. 24-10 A and B, Extensive acanthosis nigricans in a patient with stomach cancer.

Fig. 24-11 Tripe palms. (Courtesy of James Fitzpatrick, MD)

the sides of the neck, axillae, and groins. It occurs in obese persons with or without endocrine disorders (Fig. 24-12). It also occurs in acromegaly and gigantism, pseudoacromegaly, Stein-Leventhal syndrome, Cushing syndrome, diabetes mellitus, hypothyroidism, Addison's disease, hyperandrogenic states, hypogonadal syndromes, and the various wellrecognized insulin-resistant states, including lipoatrophic diabetes, leprechaunism, pinealoma (Rabson-Mendenhall syndrome), acral hypertrophy syndrome; type A syndrome, where there is a defect in insulin-receptor, postreceptor pathways, or a lamin A mutation and type B syndrome, where autoantibodies to the insulin receptor are present. Whereas both types A and B syndrome occur most commonly in black females, type A predominates in young children with hyperandrogenic manifestations. Type B syndrome is seen in middle-aged patients with autoimmune disease (Fig. 24-13). Most, if not all, patients with this type of acanthosis nigricans may have either clinical or subclinical insulin resistance, and patients should have a glucose and insulin level drawn simultaneously. In adults a glucose-to-insulin ratio less than 4.5 is abnormal, while in prepubertal children less than 7 is abnormal. Many of the conditions associated with insulin resistance and acanthosis nigricans manifest as hyperandrogenism and have been dubbed the HAIR-AN syndrome. In one group of women with hirsutism, obesity, and hyperandrogenism, vulvar acanthosis nigricans was present in all patients, with other sites less frequently involved.

Acanthosis nigricans may occur in various syndromes such as Bloom syndrome, Alström syndrome, ataxia-telangiectasia, Costello syndrome, MORFAN syndrome (mental retardation, overgrowth, remarkable face, and AN), Capozucca syndrome, Prader-Willi syndrome, Beare-Stevenson cutis gyrata syndrome, Down syndrome, Crouzon syndrome, Hermansky-Pudlack syndrome, Rud syndrome, and Wilson's disease. Drugs known to induce acanthosis nigricans are nicotinic acid, niacinamide, somatotrophin, testosterone, triazinate, diethylstilbestrol, triazinate, oral contraceptives, and glucocorticoids. Approximately 10% of renal transplant patients have acanthosis nigricans.

The histopathology shows papillomatosis without thickening of the Malpighian layer. The term *acanthosis* was applied here to indicate the clinical, not the histologic, bristly thickening of the skin. Hyperkeratosis and slight hyperpigmentation of the basal layer is present in most cases; it appears,

Flg. 24-12 Obesity-related acanthosis nigricans.

Fig. 24-13 Diffuse acanthosis nigricans in type B syndrome.

however, that the clinically observed hyperpigmentation is due to hyperkeratosis and clinical thickening rather than to melanin.

The differential diagnosis includes intertriginous granular parakeratosis and several disorders of reticulated hyperpigmentation, including confluent and reticulated papillomatosis (Gougerot-Carteaud syndrome), Dowling-Degos' disease, Haber syndrome, and acropigmentatio reticularis of Kitamura. Granular parakeratosis presents as eryhthematous to brownish hyperkeratotic papules and plaques of the intertriginous regions. It is most often seen in middle-aged women in the axillae; however, the inguinal folds and submamamary areas may be involved. Histology reveals a thickened stratum corneum, severe compact parakeratosis with retention of keratohyalin granules, and vascular proliferation and ectasia. The cause is likely an irritant response to rubbing or to antiperspirants or deodorants. Dowling-Degos' disease is a familial nevoid anomaly with delayed onset in adult life. There is progressive, brown-black hyperpigmentation of flexures with associated soft fibromas and follicular hyperkeratoses. Pitted acneform scars occur periorally.

Treatment of the type associated with malignancy consists of finding and removing the causal tumor. Early recognition and treatment may be life-saving. The type occurring with obesity usually improves with weight loss. If there is associated endocrinopathy, it must be treated as well. One patient with lipodystrophic diabetes improved during dietary supplementation with fish oil. Etretinate, metformin, tretinoin, calcipotriol, urea, salicyclic acid, CO_2 laser ablation, and long-pulsed alexandrite laser therapy have been reported as successful treatments in individual cases.

CHAPTER

Abnormalities of Dermal Fibrous and Elastic Tissue

COLLAGEN

Many types of collagens have been identified in tissues of vertebrates (Table 25-1). There are four families of collagens. *Fibrillar collagens* (types I, II, III, V, and XI) form fibrils that are among the most abundant proteins in the body. Type I collagen accounts for 60% to 90% of the dry weight of skin, ligaments, and demineralized bone.

Type III collagen is abundant in fetal skin and blood vessels. It comprises 35% of the collagen in normal adult skin, but up to 40% in inflamed skin in the setting of contact dermatitis. Basement membrane-associated collagen is made up of types IV and VII. Fiber-associated collagens (types VIII, IX, and XIV) are found on the surface of type I and II collagens and are believed to serve as flexible spacers among fibrils. Fibril-associated collagens with interrupted triple helices (FACITs) do not form fibrils themselves but are found attached to the surfaces of preexisting fibrils of the fibril-forming collagens. FACITs are composed of types IX, XII, XIV, XVI, XIX, XX and XXI. Network-forming collagens are sheets formed from types VIII and X. Studies on types XV, XVII, and XIX demonstrate their widespread presence in basement membranes, particularly vascular endothelium, which may represent a new subgroup of collagens associated with angiogenic and pathologic processes. Type XVII collagen is also known as BP180, and contains the target antigens for several immunobullous diseases. Type VII collagen contains the target antigens for bullous lupus and epidermolysis bullosa aquisita. Type II collagen contains the target antigens for relapsing polychondritis.

The regulation of collagen synthesis and degradation is complex. Dermal fibrosis is largely related to increases in type l collagen mediated by prox1 and prox2 collagen genes. Transforming growth factor- β (TGF- β) results in increased type I procollagen synthesis. Angiotensin II type 1 receptor stimulation increases collagen production and inhibits collagen degradation, whereas type 2 receptor stimulation exerts the reverse effects.

Collagen type	Gene*	Chromosome	Tissue distribution
1	COL1A1-2	17q21.3-q22	Skin, bone, tendon
I-trimer		a second s	Tumors, cell cultures, skin, liver
II	COL2A1	7g21.3-g22	Cartilage, vitreous
III	COL3A1	12g13-g14	Fetal skin, blood vessels, intestines
IV	COL4A1-6	13q34, 2q35-q37, Xq22	Basement membranes
V	COL5A1-3	9934.2-934.3	Ubiguitous
VI	COL6A1-3	21q22.3, 2q37	Aortic Intima, placenta
VII	COL7A1	3p21	Amnion, anchoring fibrils
VIII	COL8A1-2	3q12-q13.1, 1p32.3-p34.3	Endothelial cell cultures
IX	COL9A1-3	6g12-g14, 1p32	Cartilage, type II collagen tissue
Х	COL10A1	6g12-g22	Cartilage
XI	COL11A1-2, COL2A1	1p21	Cartilage, skin
XII	COL12A1	6	Skin, cartilage, cornea, limbal
XIII	COL13A1	10q22	Ubiquitous
XIV	COL14A1	8g23	Ubigultous, fetal hair follicles, basement membranes
XV	COL15A1	9921-22	Skin hemidesmosomes, kidney, liver, spleen
XVI	COL16A1	1p34-35	Ubiquitous

ELASTOSIS PERFORANS SERPIGINOSA

In 1953, Lutz described a chronic papular keratotic eruption in an arciform shape located on the sides of the nape of the neck (Fig. 25-1). The papules range from 2 to 5 mm in diameter, and are grouped in a serpiginous or horseshoeshaped arrangement. Although the lesions typically occur on the neck, other sites may be involved, such as the upper arms, face, lower extremities, and rarely the trunk. Disseminated lesions may occur in Down syndrome. Elastosis perforans serpiginosa (EPS) is most common in young adults. Men outnumber women 4:1. The disease runs a variable course with spontaneous resolution often occurring from 6 months to 5 years after onset. Often, atrophic scarring remains.

Approximately one-third of cases occur in patients with associated diseases, the most frequent concomitant disorder being Down syndrome. Approximately 1% of patients with Down syndrome have EPS, and the lesions are likely to be more extensive and persistent than in other patients. Ehlers-Danlos syndrome, osteogenesis imperfecta, Marfan syndrome, Rothmund-Thomson syndrome, acrogeria, systemic sclerosis, morphea, XYY syndrome, and renal disease have also been associated with EPS. Reports of EPS associated with pseudoxanthoma elasticum are probably examples of perforating pseudoxanthoma elasticum. Several patients with Wilson's disease have developed EPS after prolonged treatment with penicillamine.

The distinctive histopathologic changes consist of elongated, tortuous channels in the epidermis into which eosinophilic elastic fibers perforate. The fibers are extruded from the dermis. There is degeneration and alteration of the elastic tissue in the adjacent papillary dermis with an accompanying inflammatory response. In penicillamine-associated disease, the fibers may have an irregular (bramble-bush) contour when examined with electron microscopy.

Treatment is difficult, but individual lesions may resolve following liquid nitrogen cryotherapy. Some cases have responded to CO_2 , Er:YAG, or pulsed dye laser therapy. Topical retinoids, such as tazarotene, have been reported to be of benefit in some patients.

REACTIVE PERFORATING COLLAGENOSIS

In 1967, Mehregan reported a rare, familial, nonpruritic skin disorder characterized by papules that grow to a diameter of 4 to 6 mm and develop a central area of umbilication in which keratinous material is lodged. The discrete papules may be numerous and involve sites of frequent trauma such as the backs of the hands, forearins, elbows, and knees. The lesion reaches a maximum size of about 6 mm in 4 weeks and then regresses spontaneously in 6 to 8 weeks. The lesions are broader than those of EPS and a broad crust containing collagen fibers is extruded centrally. Koebnerization is often observed. Young children are most frequently affected. Most reports support an autosomal-recessive mode of inheritance; however, a family in which it appeared to be inherited by autosomal dominance has been reported. Acquired reactive perforating collagenosis is discussed in Chapter 33 within the discussion of acquired perforating dermatosis.

No specific treatment is indicated, since the lesions involute spontaneously. Tretinoin 0.1% cream may be effective.

Kumar V, et al: Familial reactive perforating collagenosis. J Dermatol 1998;25:54.

PSEUDOXANTHOMA ELASTICUM

Pseudoxanthoma elasticum (PXE) is an inherited disorder involving the connective tissue of the skin, eye, and cardiovascular system. Many cases appear to be sporadic. In familial cases, both a recessive and a dominant inheritance pattern

Fig. 25-2 Pseudoxanthoma elasticum.

Fig. 25-3 Pseudoxanthoma elasticum.

have been reported, with the recessive form apparently more common. The skin changes generally present as small, circumscribed, yellow to cream-colored papules on the sides of the neck and flexures, giving the skin a "plucked chicken skin" appearance (Fig. 25-2). Lax, redundant folds of skin may be present (Fig. 25-3). Nuchal comedones and milia en plaque may also be seen. Characteristic exaggerated nasolabial folds and mental creases are common. Mental creases appearing in patients under the age of 30 years are highly suggestive of PXE. In addition, the inguinal, periumbilical, and periauricular skin, as well as the mucosa of the soft palate, inner lip, stomach, rectum, and vagina may be involved.

The characteristic retinal change is the angioid streak, which is the result of breaks in Bruch's elastic membrane. PXE can be demonstrated in more than half of patients with angioid streaks, and 85% of PXE patients will have retinal findings. The angioid streaks appear earlier than the skin changes, so that most cases are discovered by ophthalmologists. Angioid streaks may be the only sign of the disease for years. In such patients biopsies of the midportions of old scars may be diagnostic of PXE. The association of the skin lesions with angioid streaks is called *Grönblad-Strandberg syndrome*. Angioid streaks may also be seen in Ehlers-Danlos syndrome, Paget's disease of bone, diabetes, hemochromatosis, hemolytic anemia, hypercalcinosis, solar elastosis, neurofibromatosis, Sturge-Weber syndrome, tuberous sclerosis, myopia, sickle-cell anemia, trauma, lead poisoning, hyperphosphatemia, pituitary disorders, and intracranial disorders. PXE, Paget's disease of the bone, and sickle-cell disease account for the vast majority of patients with angioid streaks.

On funduscopic examination a reddish-brown band is evident around the optic disk, from which glistening streaks extend. With fluorescent photography early fluorescence of the angioid streaks and macular lesions are noted. In addition, there may be hemorrhages and exudates. Progressive loss of vision often starts after minor trauma to the eye. Drusen-like spots are commonly present, and show increased autofluorescence, unlike age-related drusen.

Vascular involvement commonly leads to hemorrhage. These vascular events are caused by the degeneration of the elastic fibers in the vascular media. Gastric hemorrhage occurs in 10% of patients, and viewed by gastroscopy diffuse rather than focal bleeding is common. Epistaxis occurs frequently, but hematuria is rare. PXE affects the elastic tissue of the cardiac valves, myocardium, and pericardium. In one study, initial valve prolapse was found in 71% of 14 patients examined. Hypertension occurs in many patients older than age 30. Any patient with hypertension at a young age should be examined for stigmata of PXE. Leg cramps and intermittent claudication occur prematurely, and peripheral pulses are diminished or absent. Calcification of peripheral arteries is seen in many patients over age 30 and may be detected by radiograph. Accelerated coronary artery disease can occur, especially in association with hypertension.

Mutations in the ABCC6 gene on the short arm of chromosome 16 have been implicated in the pathogenesis of pseudoxanthoma elasticum. ABCC6 encodes an ATP-binding cassette transporter and multidrug resistance protein. Although the most prominent manifestations of the disease are in the skin, eye, gut, and heart, mineralization of elastic fibers can be found in many organs.

Histologically, elastic fibers are fragmented and mineralized with calcium. They stain gray-blue with hematoxylin and eosin (H&E), and are twisted, curled, and broken, suggesting "raveled wool." Blind biopsies of scars or axillary skin in patients with a family history of PXE or with angioid streaks may sometimes show early changes of PXE. Calcium stains are helpful in identifying early disease.

The differential diagnosis includes PXE-like papillary dermal elastolysis, perforating calcific elastosis, and cutis laxa. Patients with PXE-like papillary dermal elastolysis may have cobble-stoned, yellow papules on the neck, similar to PXE, but lack any retinal or vascular alterations and the typical fragmentation of elastic fibers with calcium deposition on histology. Penicillamine may induce similar clinical and histologic features in patients with Wilson's disease or homocystinuria.

No definitive therapy is available. Some data suggest that patients benefit from limiting dietary calcium and phosphorus to the minimal daily requirement.

PERFORATING CALCIFIC ELASTOSIS

Also known as periumbilical perforating PXE and localized acquired cutaneous PXE, perforating calcific elastosis is an acquired, localized cutaneous disorder, most frequently found in obese, multiparous, middle-aged women. Lax, wellcircumscribed, reticulated or cobble-stoned plaques occur in the periumbilical region with keratotic surface papules. It is a distinct disorder that shares some features of PXE. Like PXE there may be calcific elastosis in the mid-dermis; however, hereditary PXE rarely causes perforating channels. None of the systemic features of PXE occurs in perforating calcific elastosis.

It is suggested that repeated trauma of pregnancy, obesity, and/or abdominal surgery promotes elastic fiber degeneration, resulting in localized disease. PXE can cause periumbilical lesions, and in the absence of documented perforation, evaluations to exclude PXE should be performed. There is no effective therapy.

EHLERS-DANLOS SYNDROMES

Ehlers-Danlos syndromes (EDSs), also known as cutis hyperelastica, India rubber skin, and elastic skin, are a group of genetically distinct connective tissue disorders characterized by excessive stretchability and fragility of the skin (Fig. 25-4) with hyperextensibility of the joints, and a tendency toward easy scar formation and formation of fibrous or calcified pseudotumors. Atrophic scarring on the distal fingers

Ehlers-Danlos type	Gene	Inheritance*	Molecular abnormality	Clinical features	
I	COL5A1-2 [†]	AD	Type V collagen	Gravis type: joint laxity, skin hyperextensibility	
1	COL5A1-2	AD	Type V collagen	Mitis type: same as EDS 1 but less severe	
III	TNXB haploid	AD	Unknown	Hypermobility	
١V	COL3A1	AD AR	Type III procollagen	Thin skin, bruising, ruptured blood vessels and viscera	
V			Unknown	Skin hyperextensibility, easy bruising	
V1	LH1, PLOD	AR	Lysyl hydroxylase deficiency	Severe eye defects and scoliosis	
VIIA, VIIB	COL1A1-2	AD	Type I procollagen	Arthrochałasis, subluxations, moderate skin stretchability	
VIIC		AR	Procollagen peptidase deficiency	Dermatosparaxis, severe stretchability, redundant skin	
VIII	Heterogenous, only some map to chromosome 12p13	AD	Unknown	Same as EDS types I and II, periodontitis	
Old-type IX, reclassified as a variant of Menkes' disease/occipital	АТР7А	X-linked	Lysyl oxidase	Abnormal facies, skeletal abnormalities including occipital horns, chronic diarrhea, and genitourinary abnormalities	
horn syndrome					
X (new-type IX)		AR	Fibronectin	Bruising	
Old-type XI (new-type X)				Familial joint hypermobility syndrome Relationship to EDS unclear	

Table 25-2 Features of Ehlers-Danlos syndromes

'AD, autosomal dominant; AR, autosomal recessive.

COL5A1-2 means COL5A1 and COL5A2 genes.

and wide atrophic "fish mouth" scars are typical. Patients demonstrate reduced thickness of the dermis as determined by high-resolution 20-MHz ultrasound. The reduction in thickness is most marked on the chest and distal lower leg. Classically, EDS has been divided into 10 numeric types, the salient features of which are listed in Table 25-2. Type IX EDS, an allelic variant of Menkes' disease, is now reclassified as the occipital horn syndrome and is identical to X-linked cutis laxa. It is related to mutations in an X-linked gene, ATP7A.

Types I, II, III, V, VII, and VIII EDS have hyperextensible skin. In these patients, the integument may be stretched out like a rubber band and snaps back with equal resilience. This rubbery skin is most pronounced on the elbows, neck, and sides of the abdomen. The skin is velvety in appearance and feels like wet chamois cloth. Minor trauma may produce a gaping "fish-mouth" wound with large hematomas underneath. The subcutaneous calcifications are 2- to 8-mm oval nodules. mostly on the legs. Two types of nodules occur in patients with EDS. Molluscoid pseudotumors are soft, fleshy nodules seen in easily traumatized areas such as the ulnar forearms and shins. Spheroids are hard subcutaneous nodules that become calcified. They are probably the result of fat necrosis. Trauma over the shins, knees, hands, and elbows produces cigarettepaper-thin scars. Approximately 50% of these patients can touch the tip of the nose with their tongue (Gorlin's sign), compared with 10% of persons without the disorder. Aortic root dilation is seen in up to 20% of patients with EDS. It is more common in types I and II than in type III.

Patients with type IV EDS have thin, translucent skin, characteristic facial features, and vascular fragility. They are prone to arterial rupture and often have extensive bruising. Perforations of the intestines and uterus may occur. Atlantoaxial subluxation has been noted. Protein analysis of collagen III in cultured fibroblasts usually shows a defect. Some type IV patients demonstrate no abnormalities of collagen III, although a mutation in the COL3A1 gene is identified. Type V patients have clinical features that are similar to the Gravis/Mitis form. Patients with type VI EDS may have microcornea, retinal detachment, and glaucoma, as well as scoliosis. In normal individuals, the ratio of hydroxylysylpyridinoline (HP) to lysylpyridinoline (LP) in urine is about 10:1. In patients with type VI EDS, the HP/LP ratio is reduced, ranging from 1:3 to 1:7.

In type VIIA and VIIB EDS there is marked joint hypermobility and moderate cutaneous elasticity. Joint dislocations of the large joints, such as the hips, are common. Type VIIC EDS, the autosomal-recessive form, is referred to as dermatosparaxis. Patients with this type have severe skin fragility and sagging, redundant skin. Type VIII EDS manifests as periodontitis as well as easy bruising. When type IX EDS was redefined as a variant of Menkes syndrome, old-type X EDS was reclassified by some authors as new type IX. It is characterized by hypermobile joints, easy bruising, fish-mouth scars, mitral valve prolapse, and platelets resistant to aggregation with collagen and adenosine diphosphate (ADP) reagents. A qualitative deficiency of fibronectin was the suggested cause, although never confirmed. Since the deletion of old-type IX, old-type XI has been reclassified by some as new-type X, or the familial joint hypermobility syndrome.

Because of the confusion concerning the numbered types, an alternate classification scheme has been proposed that groups

Box 25-1 New classification for Ehlers-Danlos syndrome (EDS)

- 1. Classic type (Gravis-EDS type I, and Mitis II)"
- 2. Hypermobility type (hypermobile-EDS III)
- Vascular types (arterial-ecchymotic EDS type IV, Qatarian EDS)[†]
- 4. Kyphoscoliosis type (ocular-scollotic EDS type VI)
- Arthrochalasia type (arthrochalasis multiplex congenita EDS type VIIA and VIIB)
- 6. Dermatosparaxis type (human dermatosparaxis—EDS type VIIC)
- Miscellaneous forms (X-linked—EDS type V, periodontitis; EDS type VIII, fibronectin-deficient EDS; EDS type X, familial hypermobility syndrome [formerly EDS type XI]; progeroid EDS; and unspecified forms). Some progeroid EDS is related to galactosyltransferase I deficiency.

'Mutations in the genes for collagen $\alpha 1$ (V) chain (COL5A1), collagen $\alpha 2$ (V) chain (COL5A2), tenascin-X (TNX), and collagen $\alpha 1$ (I) chain (COL1A1) have been characterized in patients with classical EDS. All are autosomal dominant, except the tenascin-X-related type, which is autosomal recessive.

[†]A distinct vascular type of EDS was described in an extended family in Qatar. Features of the syndrome include skin hyperextensibility, joint hypermobility, tortuous systemic arteries, epicanthic folds, flat saggy cheeks, elongated faces, micrognathia, hemias, an elongated aortic arch, aortic aneurysms, bifid pulmonary artery, pulmonic stenosis, hypotonia, and arterial rupture. Linkage to the major loci of other types of EDS was excluded.

EDS by associated signs and symptoms, as well as known genetic mutations. This new classification combines numeric types I and II because they share the same mutations (Box 25.1).

Histology

Collagen fibers may appear fine. Factor XIIIa-positive dermal dendrocytes may be markedly reduced in the adventitial dermis and almost absent in the reticular dermis.

Treatment

Patients must be counseled to avoid trauma. Intestinal perforations in EDS type IV have been managed with porcine small intestinal submucosa grafts. Matrix metalloproteinase inhibitors produce changes in connective tissue, and are being evaluated as possible therapeutic agents.

MARFAN SYNDROME

Marían syndrome is an autosomal-dominant disorder of connective tissue caused by mutations in the gene encoding fibrillin-1. It is one of the more common inherited diseases, with estimated incidence rates of 1 in 10,000 in the US. Among the important abnormalities are tall stature, loosejointedness, a dolichocephalic skull, high-arched palate, arachnodactyly, pigeon breast, pes planus, poor muscle tone, and large, deformed ears. The aorta, chordae tendineae, and aortic and mitral valves are often involved. Ascending aortic aneurysm and mitral valve prolapse are commonly seen. Ectopia lentis, extensive striae over the hips and shoulders, dental anomalies, and, rarely, elastosis perforans serpíginosa have been reported. Several cases document the occasional occurrence of spontaneous pneumothorax and congenital lung abnormalities.

Marfan syndrome is caused by a gene defect localized to chromosome 15 and producing abnormal elastic tissue in fibrillin 1 (aorta adventitia, the suspending ligaments of the lens, skin) and fibrillin 2 (elastin orientation in cartilage, aortic media, bronchi, and all tissues rich in elastin). Gene defects include substitutions, deletions, duplication missense, frameshift, splice site, and nonsense mutations. Ectopia lentis is more common in patients whose mutations involve a cysteine substitution in the gene for fibrillin 1, and less prevalent in those with premature termination mutations.

Death may result from aortic root aneurysm rupture or dissection. Echocardiography is helpful for early detection of cardiovascular involvement. Surgical intervention may be required for aneurysms of the aortic root or for aortic dissection. Long-term administration of propranolol may significantly reduce the rate of aortic dilatation. Antisense ribozymes are promising for gene therapy.

HOMOCYSTINURIA

Homocystinuria, an inborn error in the metabolism of methionine, is characterized by the presence of homocystine in the urine and deficiency of the enzyme cystathionine synthetase. Cystathionine β -synthase is a heme-containing enzyme that catalyses pyridoxal 5'-phosphate-dependent conversion of serine and homocysteine to cystathionine. Over 130 gene mutations have been described. The defect results in increased levels of homocysteine and methionine. and decreased levels of cysteine. The incidence of the disorder varies from 1 in 344,000 worldwide to 1 in 65,000 in Ireland where the disorder is more common. Among the signs of homocystinuria are ectopia lentis, genu valgum, kyphoscoliosis, pigeon breast deformity, and frequent fractures. Generalized osteoporosis, arterial and venous thrombosis, and mental retardation are features of homocystinuria not found in Marfan syndrome. Half of all patients will have a serious vascular event before the age of 30, and 25% experience a serious event before the age of 16.

The facial skin has a characteristic flush, especially on the malar areas, and the color has a tendency to become violaceous when the patient is reclining. Elsewhere the skin is blotchy red, suggestive of livedo reticularis. The hair is typically fine, sparse, and blond, and the teeth are irregularly aligned. Downward dislocation of the lens, as opposed to the upward displacement seen in Marfan syndrome, is a prominent feature. Treatment with pyridoxine, folic acid, and vitamín B₁₂ produces variable results. A methionine-restricted, cysteine-supplemented diet is generally recommended. Unfortunately, some methionine-free baby formulas contain significant amounts of homocysteine and should be reformulated. Betaine supplementation has been shown to be effective. Wheat flour is rich in betaine, but the amounts ingested are smaller than those needed to treat the disease. It has been recommended that methionine-free formulas be supplemented with 150 mg/dL of betaine. Alfalfa and bean sprouts contain ample homocysteine, and excessive amounts should be avoided. Other vegetables do not contain large amounts of homocysteine. Vitamin C ameliorates endothelial dysfunction, and the effect appears to be independent of homocysteine concentration. Some of the beneficial effects of folate are also independent of homocysteine lowering.

CUTIS LAXA (GENERALIZED ELASTOLYSIS)

Cutis laxa, also known as *dermatomegaly*, *dermatolysis*, *chalazoderma*, and *pachydermatocele*, is characterized by inelastic loose, redundant skin (Fig. 25-5). Around the eyelids, cheeks, and neck the drooping skin produces a bloodhound-like facies. Usually the entire integument is involved. The shoulder girdle skin may look like that of a St Bernard dog. The abdomen is frequently the site of large, pendulous folds.

There are two well-described genetic forms of cutis laxa, the autosomal-dominant and -recessive types. The dominant form is primarily a cutaneous, cosmetic form, with a good prognosis. The recessive form is more common, and is associated with significant internal involvement, including hernías, diverticula, pulmonary emphysema, cor pulmonale, aortic aneurysm, dental caries, large fontanelles, and osteoporosis. Pulmonary emphysema, cor pulmonale, and rightsided heart failure are often seen already in infancy. Frameshift mutations in the elastin gene have been reported in autosomal-dominant disease. Both homozygous and heterozygous missense mutations in the fibulin-5 gene have been reported in some patients with the disease, especially in families with the recessive form. X-linked recessive cutis laxa is now known as the *occipital horn syndrome* (formerly type IX EDS). It is caused by a mutation in the copperbinding ion transporting ATPase, ATP7A, and is allelic to another X-linked disorder, Menkes' disease. Nonfamilial cases (Fig. 25-6) have been associated with urticaria, lupus erythematosus, glomerulonephritis, plasma cell dyscrasias, and systemic amyloidosis. These acquired cases may have a preceding inflammatory phase with large numbers of interstitial neutrophils, eosinophils, or macrophages engulfing

Fig. 25-6 Acquired cutis laxa.

elastic fibers. Isolated acral disease has been associated with myeloma and rheumatoid arthritis.

The Costello syndrome is characterized by increased prenatal growth, postnatal growth retardation, coarse facies, loose skin that resembles cutis laxa, cardiomyopathy, and gregarious personality. Patients are predisposed to abdominal and pelvic rhabdomyosarcoma in childhood. The disorder appears to be inherited as an autosomal-dominant trait.

The de Barsy syndrome is associated with severe cutis laxa, mental and growth retardation, joint laxity, ocular abnormalities, and skeletal disease.

Mid-dermal elastolysis is an acquired, noninherited condition that usually affects young women. Wide areas of skin demonstrate atrophic wrinkling. Histologically, elastic tissue is absent from the mid-dermis. Many cases appear to be induced or aggravated by ultraviolet light exposure.

BLEPHAROCHALASIS

In blepharochalasis the eyelid skin becomes lax and falls in redundant folds over the lid margins. The condition may affect young adults, where a preceding inflammatory phase presents with episodes of lid swelling. Most cases are bilateral, but unilateral involvement may occur. Rarefy, elastolysis of the earlobes may accompany blepharochalasis. It is generally sporadic, but a dominantly inherited form has been described. Biopsy shows lack of elastic fibers, and abundant IgA deposits have been demonstrated in some cases, possibly binding to fibulin and fibronectin. Sequelae include excess thin skin, fat herniation, lacrimal gland prolapse, ptosis, blepharophimosis, pseudoepicanthic fold, proptosis, conjunctival injection and cysts, entropion, and ectropion.

Ascher syndrome consists of progressive enlargement of the upper lip and blepharochalasis. The minor salivary glands of the affected areas are inflamed, resulting in superfluous folds of mucosa, giving the appearance of a double lip. There is a superficial resemblance to angioedema. Treatment is by surgical correction.

Schaeppi H, et al: Unilateral blepharochalasis with IgA-deposits. Hautarzt 2002;53:613.

ANETODERMA (MACULAR ATROPHY)

Anetoderma is characterized by localized loss of elastic tissue resulting in herniation of subcutaneous tissue. The lesions protrude from the skin (Fig. 25-7), and on palpation have less resistance than the surrounding skin, producing the "button hole" sign identical to a neurofibroma. The surface skin may be slightly shiny, white, and crinkly. The usual locations are the trunk, especially on the shoulders, upper arms, and thighs. The intervening skin is normal.

Up to half of cases have an accompanying abnormality, such as lupus, antiphospholipid antibodies, Graves' disease, scleroderma, hypocomplementemia, hypergammaglobulinemia, autoimmune hemolysis, and infection with the human immunodeficiency virus (HIV). Screening for antiphospholipid antibodies is of particular importance, as they may produce a prothrombotic state, and some patients fulfill criteria for the antiphospholipid syndrome. The antibodies may be detected as anticardiolipin antibodies, anti-β2-glycoprotein-1

Fig. 25-7 Anetoderma. antibodies or a lupus anticoagulant. Patients may experience recurrent fetal loss, recurrent stokes, or recurrent deep vein thrombosis. Some cases of anetoderma may be related to borreliosis. Rare familial cases have been noted. Secondary anetoderma may be related to previous lesions of acne, *secondary* syphilis, measles, lupus erythematosus, leprosy, sarcoidosis, tuberous xanthoma, varicella, and lymphoreticular malignancy.

Anetoderma of prematurity (congenital anetoderma) occurs in premature infants and may be related to pressure, adhesives, or changes in flow of ions or water under monitor leads. Intrauterine borreliosis has also been implicated.

Histologically, a loss of elastic tissue is noted with special stains. In the late stage, the skin looks normal in H&E sections. In the acute stage, a neutrophilic, lymphoid or granulomatous response may be noted.

STRIAE DISTENSAE

Striae distensae are depressed lines or bands of thin, reddened skin, which later become white, smooth, shiny, and depressed. Elastotic striae have a yellow-gold iridescent appearance. Striae occur in response to changes in weight or muscle mass and skin tension, such as that induced by weight lifting. They are common on the abdomen during and after pregnancy (striae gravidarum) and on the breasts after lactation. They also occur on the buttocks and thighs, the inguinal areas, and over the knees and elbows in children during the growth spurt of puberty. Cushing syndrome, either endogenous or induced by systemic steroid treatment, is a frequent cause of striae, and they may occur after application of potent topical corticosteroid preparations, especially under occlusion or in folds. Striae are common in patients with Marfan syndrome.

The histologic findings are variable and depend on the stage of development. In some early lesions, perivascular and interstitial infiltration of lymphocytes and sometimes eosinophils is noted. In older lesions the primary changes are in the connective tissue. The collagen of the upper dermis is decreased, and thin collagen bundles lie parallel to the overlying epidermis as in a scar. Elastic tissue often appears increased, but this may be due to a loss of collagen in many cases. Dilated upper dermal vessels may be prominent.

Over time striae become less noticeable. Topical tretinoin and vascular lasers may produce some improvement in

Fig. 25-8 Linear focal elastosis on the lower back of an elderly man.

Fig. 25-9 Blue sclera of osteogenesis imperfecta in a patient with Grave's disease. (Courtesy Lawrence Lieblich)

appearance, although the benefits are more marked in the early erythematous phase. Lasers (585 nm) result in a moderate decrease in erythema in striae rubra. Although the total collagen per gram of dry weight increases in striae treated with pulsed dye laser, this change may not result in a clinically evidenced change in striae alba. Intense pulsed light has also demonstrated potential for improvement in the appearance of some striae, although darker skin types have greater risk and lower efficacy.

- Nouri K, et al: Comparison of the 585 nm pulse dye laser and the short pulsed CO2 laser in the treatment of striae distensae in skin types IV and VI. Dermatol Surg 1999;25:368.

LINEAR FOCAL ELASTOSIS (ELASTOTIC STRIAE)

This variant presents with asymptomatic, palpable or atrophic, yellow lines (Fig. 25-8) of the middle and lower back, thighs, arms and breasts. The condition is more common in males. Histologically, there are increased elastic fibers characterized by thin, wavy, elongated, as well as fragmented, elastic fiber bundles. Electron microscopy reveals elongated thin, irregular shaped, swollen elastic fibers with degenerative changes.

- Ramlogan D, et al: Linear focal elastosis. Br J Dermatol 2001; 145:188.

ACRODERMATITIS CHRONICA ATROPHICANS

Patients with acrodermatitis chronica atrophicans present with diffuse thinning of the skin on the extremities, sometimes associated with fibrous bands. It is reviewed in Chapter 14, since it results from infection with *Borrelia*.

OSTEOGENESIS IMPERFECTA

Osteogenesis imperfecta (OI), also known as Lobstein syndrome, affects the bones, joints, eyes, ears, and skin. It is estimated to affect approximately 10,000 persons in the US (4-5 in 100,000). There are seven recognized forms based on differences in clinical presentation and bone architecture. Types I and IV have only an autosomal-dominant inheritance, whereas types II and III have both autosomal-dominant and autosomal-recessive forms. Fifty percent of OI patients have the type I form. The type II form is lethal, and deaths usually occur within the first week of life.

The brittle bones result from a defect in the collagenous matrix. Fractures occur early in life, sometimes in utero. Loose-jointedness may be striking, and dislocation of joints can be a problem. Blue sclerae, when present, are a valuable diagnostic clue (Fig. 25-9). Scoliosis and defective teeth may be present. Deafness develops in many by the second decade of life and is audiologically indistinguishable from otosclerosis. The skin is thin and translucent, and healing wounds result in spreading atrophic scars. Elastosis perforans serpiginosa may occur. Some patients experience unusual bruisability, probably due to a structural defect in either the blood vessel wall or the supporting dermal connective tissue.

The basic defect is abnormal collagen synthesis, resulting in type I collagen of abnormal structure. Most forms of OI result from mutations in the genes for the proclor proc2 chains of type I collagen. Types V, VI, and VII are not associated with type I collagen gene defects. In type I (blue scleral dominant) there is diminished type I collagen with a mutation of COL1A1 gene; in type II (perinatal lethal) there is diminished type I collagen synthesis and decreased integrity of the helical domain of the α 1 (I) gene; in type III (progressive deforming) there is delayed secretion of type I collagen with altered mannosylation; and in type IV (white sclerae dominant) there is a defective proc1 (I) gene.

The major causes of death, attributed to OI, are respiratory failure secondary to severe kyphoscoliosis and head trauma, mostly observed in type III disease. Patients with type I and type IV disease have a normal lifespan. Brack

Arroyo MP, et al: Linear focal elastosis. Dermatol Online J 2001; 7:18.

syndrome is a combination of osteogenesis imperfecta and arthrogryposis multiplex.

Treatment includes surgical intervention, such as intramedullarly stabilization. Bisphosphonates and calcitriol are the most effective pharmacologic agents. Specifically, cyclical pamidronate therapy has been shown to suppress bone turnover, reduce bone pain and fracture incidence, and increase bone density and level of ambulation. Gene therapy is promising, but is complicated by the genetic heterogeneity of the disease. Most of the OI mutations result in a mutant allele product that interferes with the function of the normal allele. This sort of abnormality presents greater challenges for gene therapy than simple replacement of a missing enzyme.

CHAPTER

26 Errors in Metabolism

Amyloid is a material deposited in the skin and other organs that is eosinophilic, homogeneous, and hyaline in appearance. It represents beta-pleated sheet forms of various hostsynthesized molecules processed into this configuration by host cells.

Amyloidosis can be classified as primary (which often has skin manifestations), secondary (which has very rare skin manifestations), primary localized amyloidosis (also called *primary cutaneous amyloidosis* when the skin is affected), and secondary cutaneous or tumor-associated amyloidosis. Rare familial syndromes may be complicated by secondary amyloidosis or have genetic defects that lead to amyloid deposition (heredofamilial amyloidosis). Classification of cutaneous amyloidoses is shown below.

I. Systemic amyloidosis

- A. Primary (myeloma-associated) systemic amyloidosis
- B. Secondary systemic amyloidosis
- II. Cutaneous amyloidosis
 - A. Macular amyloidosis
 - B. Lichen amyloidosis
 - C. Nodular amyloidosis
 - D. Secondary (tumor-associated) cutaneous amyloidosis

III. Heredofamilial amyloidosis

All forms of amyloid have relatively identical histologic and electron microscopic findings. The amyloid in all forms is made up of three distinct components: protein-derived amyloid fibers, amyloid P component (about 15% of amyloid), and ground substance. It is the protein-derived amyloid fibers that differ among the various forms of amyloid.

Amyloid is weakly periodic acid-Schiff (PAS) positive and diastase resistant, Congo-red positive, purple with crystal violet, and positive with thioflavin T. Amyloid stained with Congo red exhibits apple-green birefringence under polarized light. Secondary systemic amyloid (AA amyloid) loses its birefringence after treatment with potassium permanganate, whereas primary and localized cutaneous forms do not.

Amyloid stains an intense, bright orange with cotton dyes such as Pagoda red, RIT Scarlet No. 5, or RIT Cardinal red No. 9. Ultrastructurally, amyloid has a characteristic fibrillar structure that consists of straight, nonbranching, nonanastomosing, often irregularly arranged filaments 60 to 100 nm in diameter. If the type of amyloid is known, specific antibodies against the protein component can be used. Only 50% of cases of primary systemic amyloidosis stain with antisera to κ or λ chains, because the amyloid protein frequently contains only the variable portion of the immunoglobulin light chain. Because amyloid substance P is present in all forms of amyloid, immunoperoxidase staining against this component will stain all forms of amyloid. In addition, since serum amyloid P (SAP) is avidly bound to amyloid, radiolabeled highly purified SAP can be used to localize amyloidosis, determine the extent of organ infiltration, study progression of disease, and see if therapy reduces the amount of amyloid in various organs.

SYSTEMIC AMYLOIDOSES

Primary Systemic Amyloidosis

Primary systemic amyloidosis involves mesenchymal tissue, the tongue, heart, gastrointestinal tract, and skin. Cutaneous manifestations occur in approximately 40% of cases of primary systemic amyloidosis. Myeloma-associated amyloidosis is included in this category. The amyloid fibril proteins in primary systemic (so-called immunocytic or plasma cell dyscrasia-associated) amyloidosis are composed of protein AL. This is derived from the immunoglobulin light chains, usually of the λ subtype, and is often only a fragment of the light chain, particularly from the amino terminal end or variable region. Ninety percent of patients will also have this immunoglobulin fragment in the serum or urine. This same type of amyloid, AL, is also found in nodular or tumefactive cutaneous amyloidosis, which is best considered a localized plasmacytoma-producing amyloid.

In primary systemic amyloidosis, the cutaneous eruption usually begins as shiny, smooth, firm, flat-topped, or spherical papules of waxy color, which, because of their tenseness, have the appearance of translucent vesicles. These lesions coalesce to form nodules and plaques of various sizes and, in some cases, bandlike lesions. The regions about the eyes, nose, mouth, and mucocutaneous junctions are commonly involved. Vulvar lesions (Fig. 26-1) may resemble giant condylomata.

Purpuric lesions and ecchymoses occur in about 15% of patients and are the most common cutaneous manifestation of primary systemic amyloidosis. They result from amyloid infiltration of blood vessels. Purpura chiefly affects the eyelids, limbs, and oral cavity. Purpura typically occurs after trauma (pinch purpura). Purpuric lesions also classically appear after actions or procedures that result in increased pressure in the vessels of the face, such as after vomiting, coughing, proctoscopic examination, or pulmonary function testing.

Glossitis, with macroglossia, occurs in at least 20% of cases, may be an early symptom, and can lead to dysphagia. The tongue becomes greatly enlarged, and furrows develop (Fig. 26-2). The lateral aspects show indentations from the teeth. Papules or nodules, sometimes with hemorrhage, occur on the tongue.

Bullous amyloidosis is a rare but important clinical manifestation of amyloidosis. Skin fragility and tense, hemorrhagic bullae appear at areas of trauma, usually the hands, forearms, and feet. Lesions heal with scarring and milia. Histolo-

gically, the lesions are subepidermal and pauci-inflammatory. Epidermolysis bullosa acquisita and porphyria cutanea tarda are the differential diagnoses. Amyloid staining may yield negative results, and direct immunofluorescence (DIF) may be falsely positive (because of AL protein deposition at the dermoepidermal junction). The diagnosis is confirmed by evaluation of the patient's serum and urine for immunoglobulin fragments and by electron microscopy of the skin biopsies, which will demonstrate the amyloid.

A diffuse or patchy alopecia, cutis verticis gyrata, a scleroderma-like, scleromyxedema-like, or a cutis laxa-like appearance have also rarely been described. Cutis laxa-like findings may be generalized or localized to the acral parts. The nail matrix may be infiltrated resulting in atrophy of the nail plate, presenting as longitudinal striae, partial anony-chia, splitting, and crumbling of the nail plate. Cordlike thickening along blood vessels can also occur.

Patients may present with or develop a plethora of systemic findings. Most characteristically they develop carpal tunnel syndrome, other peripheral neuropathies, a rheumatoid arthritis-like arthropathy of the small joints, orthostatic hypotension, gastrointestinal bleeding, nephrotic syndrome, and cardiac disease. These patients may appear to have prominent deltoid muscles as a result of deposition of amyloid in the muscles (shoulder pad sign). Cardiac arrhythmias and congestive heart failure are common causes of death.

The prognosis lor patients with primary systemic anyloidosis is poor. The median survival averages 43 months. Those presenting with neurologic findings survive longer than patients presenting with cardiac disease.

Treatment is improving but still relies heavily on systemic chemotherapy (usually melphalan). Secondary malignancies may complicate alkylating therapy. Hematopoetic stem cell transplantation after high-dose melphalan has led to remission in some patients.

Secondary Systemic Amyloidosis

Secondary systemic amyloidosis is amyloid involvement of the adrenals, liver, spleen, and kidney as a result of some

Fig. 26-2 Macroglossia and translucent papules of the tongue. (Courtesy of Lawrence Lieblich, MD)

chronic disease, such as tuberculosis, lepromatous leprosy, Hodgkin's disease, Behçet's disease, rheumatoid arthritis, ulcerative colitis, schistosomiasis, or syphilis. The parenchymatous organs are involved, but the skin is not. Certain dermatoses, such as hidradenitis suppurativa, stasis ulcers, psoriatic arthritis, and dystrophic epidermolysis bullosa may be complicated by systemic amyloidosis.

The amyloid fibrils in secondary systemic amyloidosis, and in the type associated with Muckle-Wells syndrome and with familial Mediterranean fever, are designated AA. The protein component is unrelated to immunoglobulin. Its precursor is serum amyloid A protein (SAA), which is an acute-phase reactant that is increased in various inflammatory states. Biopsy of normal skin in secondary systemic amyloidosis may be positive for perivascular amyloid in slightly more than half the cases. The treatment of secondary systemic amyloidosis is to treat the underlying condition optimally.

In patients undergoing hemodialysis, carpal tunnel syndrome is frequent; its prevalence is related to the duration of dialysis. This finding is now known to be associated with amyloid deposition in synovium, causing not only carpal tunnel syndrome but also trigger finger, bone cysts, and spondyloarthropathy. The protein component of dialysis-related amyloidosis is β 2-microglobulin, altered by uremia.

CUTANEOUS AMYLOIDOSIS

Primary Cutaneous Amyloidosis

The primary cutaneous amyloidoses have been divided into two forms—macular and lichen amyloid. Most patients have only one form, but rarely, patients may be seen with both patterns. Chronic rubbing of the skin resulting from pruritus or the use of nylon brushes during bathing (frictional amyloidosis) appears contributory. Individuals of Asian, Hispanic, or Middle Eastern ancestry seem to be predisposed. The deposited amyloid material contains keratin as its protein component, strongly suggesting that traumatic damage to basal keratinocytes results in the deposits. Why only certain individuals are affected is unknown. A rare form localized to the conchae has been described.

The histologic picture of both forms of primary cutaneous amyloidosis is similar, the only difference being the size of the amyloid deposits and the extent of the overlying epidermal changes. The overlying epidermis is frequently hyperkeratotic. Focal necrotic keratinocytes may be observed in the basal cell layer. Dermal papillae are expanded by

Fig. 26-3 Macular amyloid. (Courtesy of Lawrence Lieblich, MD)

amorphous deposits of amyloid that abut immediately below the epidermis. Melanin deposits are classically present in the amyloid. In all cases of postinflammatory hyperpigmentation with incontinence of pigment, the texture of the areas of dermal melanosis should be examined carefully to exclude amyloidosis. Systemic amyloidosis is excluded by the absence of amyloid deposits around blood vessels. Special stains may be used to confirm the diagnosis, but this is rarely required if the classic histology is found. In difficult cases, immunoperoxidase stains for keratin will stain the amyloid deposits and confirm the diagnosis of primary cutaneous amyloidosis. DIF may demonstrate immunoglobulin (usually IgM) in a globular pattern in the keratin-derived cutaneous amyloidoses, but this is caused by passive absorption rather than by specific deposition. This phenomenon is seen in all disorders with prominent apoptosis of keratinocytes.

Macular Amyloidosis Typical cases exhibit moderately pruritic, brown, rippled macules characteristically located in the interscapular region of the back (Fig. 26-3). Pigmentation is typically not uniform, giving the lesions a "salt and pepper" or rippled appearance. Notalgia paresthetica is localized to the same sites, and most cases of macular amyloid between the scapulae probably result from rubbing dysesthetic areas of notalgia paresthetica. Occasionally, the thighs, shins, arms, breasts, and buttocks may be involved, and these more diffuse cases are usually associated with diffuse pruritus. Macular amyloidosis is a chronic condition.

Lichen Amyloidosis Lichen amyloidosis is characterized by the appearance of paroxysmally itchy lichenoid papules, typically appearing bilaterally on the shins (Fig. 26-4). The primary lesions are small, brown, discrete, slightly scaly papules that group to form infiltrated large moniliform plaques. It may, less commonly, occur on the thighs, forearms, and even the upper back.

Treatment of the primary cutaneous amyloidoses is frequently unsatisfactory. Reducing friction to the skin is critical. Identifying the cause of the rubbing, whether it is habit, pruritus, or neuropathy (as in notalgia paresthetica), directs treatment. Occlusion plays a major role, because it both enhances topical treatments and provides a physical block to prevent trauma to the skin. Administration of topical high-potency corticosteroid agents can be beneficial, as can

Fig. 26-5 Nodular amyloidosis.

intralesional corticosteroid therapy when small areas are involved. Topical tacrolimus 0.1% ointment, PUVA, UVB, and calcipotriol benefit individual patients. Oral retinoids, cyclophosphamide, and dermabrasion have also been reported to be beneficial.

Nodular Amyloidosis Nodular amyloidosis is a rare form of primary localized cutaneous amyloidosis in which single, or rarely, multiple nodules or tumefactions preferentially involve the acral areas (Fig. 26-5); however, trunk, genital, or facial lesions may be seen. The overlying epidermis may appear atrophic, and lesions may resemble large bullae. The dermis and subcutis may be diffusely infiltrated with amyloid. The lesions may contain numerous plasma cells and are best considered isolated plasmacytomas. The amyloid in these patients is immunoglobulin-derived AL, as is seen in primary systemic amyloidosis, and is unrelated to keratinocyterelated amyloid or to AA amyloid. Progression to systemic amyloidosis may occur, but is rare. Treatment is physical removal or destruction of the lesion with shave removal and desiccation or CO₂ laser.

Secondary Cutaneous Amyloidosis

Following PUVA therapy and in benign and malignant cutaneous neoplasms, deposits of amyloid may be found. Most frequently, the associated neoplasms are nonmelanoma skin cancers or seborrheic keratoses. In all cases, this is keratin-derived amyloid.

FAMILIAL SYNDROMES ASSOCIATED WITH AMYLOIDOSIS (HEREDOFAMILIAL AMYLOIDOSIS)

Familial syndromes have been reported that have either systemic or localized amyloidosis. In familial Mediterranean fever and Muckle-Wells syndrome, the amyloid protein is AA; these are hereditary inflammatory diseases commonly complicated by secondary systemic amyloidosis. Multiple endocrine neoplasia 2A (MEN 2A) and familial medullary thyroid carcinoma are genetic diseases caused by activating mutations of the RET protooncogene. Affected patients can manifest keratin-derived amyloid. Most commonly this is lichen amyloidosis with pruritus being present since infancy. MEN 2A should be considered when a child or adolescent presents with nostalgia paresthetica or macular or lichen amyloidosis. Family history, calcitonin, calcium, parathyroid hormone levels, and urinary catecholamines and metanephrines will screen for the associated problems and RET mutations may be assessed. Poikiloderma-like cutaneous amyloidosis and other very rare hereditary variants of cutaneous amyloidosis exist.

Most forms of familial amyloidosis, however, present with neurologic disease and are designated familial amyloidotic polyneuropathy. Peripheral neuropathy, and, less commonly, autonomic neuropathy and cardiomyopathy occur. Several types of hereditary amyloidoses have been identified: two forms are caused by genetic defects in transthyretin. These are autosomal-dominant syndromes, and most affected patients are heterozygotes. Others are caused by a genetic defects in apolipoprotein A-I or A-II, by a defect in gelsolin, fibrinogen A α , Cystatin C or lysozome.

PORPHYRIAS

Porphyrinogens are the building blocks of all the hemoproteins, including hemoglobin and the cytochrome enzymes. They are produced primarily in the liver and bone marrow. In certain inherited and acquired disease states, called the *porphyrias*, these intermediate metabolites of hemoglobin synthesis are increased.

Each form of porphyria has now been associated with a deficiency in an enzyme in the metabolic pathway of heme synthesis. Cutaneous disease, characterized by photosensitivity, is observed in some forms of porphyria. The photosensitivity in porphyria is caused by the absorption of UV radiation in the Soret band (400-410 nm) by increased porphyrins. These activated porphyrins are unstable, and as they return to a ground state, they transfer energy to oxygen, creating reactive oxygen species. These unstable oxygen species interact with biologic systems, primarily plasma and lysosomal membranes, causing tissue damage. Mediators released from mast cells and polymorphonuclear leukocytes, acting through complement, eicosanoids, or factor XII pathways may augment tissue effects.

Understanding the biosynthetic pathway of heme has clarified the biochemical basis of the porphyrias. Deltaaminolevulinic acid (dALA) is synthesized in the mitochondria via dALA synthetase. From it are formed, successively, porphobilinogen, uroporphyrin III, coproporphyrin III, and protoporphyrin IX. This re-enters the mitochondrion, to be acted on by ferrochelatase to produce heme. Each step in this process is catalyzed by a specific enzyme. Heme, by negative feedback, represses the production, or activity, of dALA synthetase. If heme is inadequate, dALA synthetase activity may be increased, leading to the production of more porphyrins. Because this enzyme system is inducible, medications that increase the cytochrome drug metabolizing system in the liver can lead to exacerbation of the porphyrias by increasing the production of the porphyrin intermediates.

The current grouping of the porphyrias is based on the primary site of increased porphyrin production, either liver or bone marrow—the hepatic or erythropoietic porphyrias, respectively. Some include a hepatoerythropoietic category.

Fig. 26-6 Porphyria cutanea tarda.

Congenital erythropoietic porphyria, erythropoietic protoporphyria, and erythropoietic coproporphyria are the erythropoietic forms. Acute intermittent porphyria, ALA dehydratase deficiency, hereditary coproporphyria, variegate porphyria, and porphyria cutanea tarda are the hepatic forms. Hepatoerythrocytic porphyria has been classified as either a hepatic or hepatoerythropoietic type.

The porphyrias are diagnosed by identifying characteristic clinical and biochemical abnormalities, typically elevated levels of porphyrins in the urine, serum, red blood cell, or stool. Because there is some clinical overlap, biochemical testing should be performed to confirm any diagnosis of porphyria. The clinical syndromes may be chronic or have intermittent exacerbations with relative quiescent periods. The latter are called the *acute porphyrias*.

PORPHYRIA CUTANEA TARDA

Porphyria cutanea tarda (PCT) is the most common type of porphyria. It is characterized by photosensitivity resulting in bullae, especially on sun-exposed parts (Fig. 26-6). The dorsal hands and forearms, ears, and face are primarily affected. The bullae are not surrounded by erythema, and rupture easily to form erosions or shallow ulcers. These heal with scarring, milia, and dyspigmentation. Lesions on the legs, especially the shins and dorsal feet, occur primarily in women. In addition, patients frequently complain of skin fragility in affected areas. There is hyperpigmentation of the skin, especially of the face, neck, and hands. Hypertrichosis of the face, especially over the cheeks and temples, is seen. The face and neck, especially in the periorbital area, may show a pink to violaceous tint. Sclerodermatous thickenings may develop on the back of the neck, in the preauricular areas (Fig. 26-7), or on the thorax, fingers, and scalp. In the latter instance, there is associated alopecia. A direct relationship between the levels of uroporphyrins in the urine and sclerodermatous changes has been reported.

Liver disease is frequently present in patients with PCT. A history of alcoholism is common. Hepatitis C virus (HCV) infection has been found in 17% (Northern Europe), 20% (Australia/New Zealand), 65% (Southern Europe), and 94% (US) of patients with PCT. All PCT patients should be screened for HCV infection. Iron overload in the liver is frequently found in patients with PCT. This may be as a consequence of chemical or viral liver damage, or because 20% of patients with PCT are homozygous for the C282Y

Fig. 26-8 Porphyria cutanea tarda with hemochromatosis. (Courtesy of Curt Samlaska, MD)

mutation (and a few with the H63D mutation) causing hemochromatosis (Fig. 26-8). This leads to increases in serum iron, ferratin, and hepatic iron overload. Hepatocellular carcinoma may rarely produce PCT.

PCT has been frequently associated with other diseases. It is estimated that diabetes mellitus occurs in 15% to 20% of patients with PCT. Numerous cases of lupus erythematosus concomitant with PCT have been reported. Patients may have systemic and/or purely cutaneous lupus, and either disease may present initially. The pathogenesis of this association is unclear.

PCT occurs not infrequently in patients infected with the human immunodeficiency virus (HIV). This is not solely related to coexistent HCV infection, which is increased in some risk groups of HIV-infected persons. Subtle porphyrin abnormalities are found in HIV disease, but the porphyrin levels are well below those capable of inducing clinical disease. Other risk factors, such as alcoholism, should be evaluated and the existence of PCT should not be attributed to the HIV disease alone. However, effective anti-HIV therapy has led to improvement of PCT in one HIV/HCV-infected patient.

Fig. 26-7 Porphyria cutanea tarda with sclerosis. Estrogen treatment is associated with the appearance of PCT by an unknown mechanism. Before oral contraceptives were introduced, PCT cases occurred predominantly among men, but in most recent series, 60% of cases occurred in men and 40% in women. Men treated with estrogens for prostate cancer may develop PCT.

PCT is caused by a deficiency in the enzyme uroporphyrinogen decarboxylase. Several types have been described. The most common is the sporadic, nonfamilial form, which represents about 80% or more of cases. Enzymatic activity of uroporphyrinogen decarboxylase is abnormal in the liver but normal in other tissues. With remission, the enzyme activity in the liver may return to normal. Patients present most commonly in midlife, averaging 45 years at disease onset.

The second, or familial type, is an autosomal-dominantly inherited deficiency of uroporphyrinogen decarboxylase in the liver and red blood cells of patients, and also of clinically unaffected family members. There is an approximate 50% decrease in both the activity and concentration of the enzyme. Multiple genetic defects have been reported producing the same phenotype. Familial PCT tends to present at an earlier age, and development of PCT before age 20 strongly suggests familial PCT. A third form, acquired toxic PCT, is associated with acute or chronic exposure to hepatotoxins, specifically polyhalogenated hydrocarbons, such as hexachlorobenzene and dioxin. These patients have biochemical and clinical features identical to those of patients with sporadic and familial PCT.

A diagnosis of PCT can be strongly suspected on clinical grounds. A useful confirmatory test that can be performed in the office is the characteristic pink or coral-red fluorescence of a random urine specimen under a Wood's light. A 24-h collected urine specimen usually contains less than 100 μ g of porphyrins in a normal individual; in PCT it may range from 300 to several 1000 μ g. The ratio of uroporphyrins-to-coproporphyrins in PCT is typically 3:1 to 5:1, distinguishing PCT from variegate porphyria.

Biopsy of a blister reveals a noninflammatory subepidermal bulla with an undulating, festooned base. PAS-positive thickening of blood vessel walls in the upper and mid-dermis is present. A useful and highly characteristic—but not diagnostic —feature is the presence of the so-called caterpillar bodies. These eosinophilic, elongated, wavy structures are present in the lower and mid-epidermis and lie parallel to the basement membrane zone. They stain positively with PAS and are positive for type IV collagen and laminin, suggesting they represent basement membrane material present in the epidermis. DIF of involved skin shows IgG and C3 at the dermoepidermal junction and in the vessel walls in a linear pattern.

Initial treatment of PCT involves removal of all precipitating environmental agents such as alcohol and medications. This may lead to sufficient improvement that further therapy is not required. Chemical sunscreens are of little value since they do not typically absorb radiation in the near-visible UVA range. Barrier sunscreens such as titanium dioxide and zinc oxide may be more beneficial, but physical barriers such as hats and gloves may be encouraged while therapy is initiated.

Phlebotomy is the treatment of choice for PCT. Uroporphyrinogen decarboxylase is inhibited by iron, and removal of hepatic iron may therefore lead to recovery of enzyme activity. Typically, phlebotomy of 500 mL at 2-week intervals is performed until the hemoglobin reaches 10 g/dL or the serum iron 50 to 60 µg/dL. Ideally, serum ferratin will become normal also. Urinary porphyrin excretion initially increases, but gradually, 24-h uroporphyrin levels are markedly reduced, with most patients able to achieve normal levels. This process takes several months, usually requiring a total of 6 to 10 phlebotomies. As the porphyrins fall, the skin lesions also involute. Initially, blistering improves, then skin fragility decreases, and finally the cutaneous sclerosis and hypertrichosis can eventually reverse. A common error in management is coadministration of oral iron supplementation during the phlebotomies to treat the anemia.

Antimalarials are an alternative to phlebotomy and may be combined with phlebotomy in difficult cases. Full doses of antimalarials may produce a severe hepatotoxic reaction. The initial dose is 125 mg of chloroquine twice a week. Improvement is gradual, but can be more rapid than phlebotomy.

After both phlebotomy and antimalarial therapy, a remission is induced that may last many years. If the patient relapses, these treatments can be repeated. Alternative treatments, which are rarely required, include desferrioxamine (iron chelation) and erythropoietin treatment. Erythropoietin may be combined with phlebotomy. PCT in renal failure may respond to erythropoietin and low volume phlebotomy or to renal transplantation. If HCV infection coexists, interferon- α treatment of the HCV infection may lead to improvement of the PCT.

PSEUDOPORPHYRIA

In certain settings patients develop blistering and skin fragility identical to PCT with the histologic features of PCT but with normal urine and serum porphyrins. Hypertrichosis, dyspigmentation, and cutaneous sclerosis do not occur. This condition is called *pseudoporporphyria*. Most commonly this is caused by medications, typically a nonsteroidal antiinflammatory drug (NSAID), usually naproxen. Other NSAIDs, such as nebumetone and rofecoxib, tetracycline (Fig. 26-9), and multiple other medications can cause a similar picture. Sunbed use can also cause pseudo-PCT. Some patients on hemodialysis develop a similar PCT-like picture.

Fig. 26-9 Pseudoporphyria cutanea tarda from tetracycline in a young woman.

Less commonly, dialysis patients develop true PCT. In the anuric dialysis patient, true PCT and pseudo-PCT are distinguished by analysis of serum porphyrins in a laboratory knowledgeable in the normal porphyrin levels in patients undergoing hemodialysis. The treatment of pseudoporphyria is physical sun protection and discontinuance of any inciting medication. Ibuprofen is a safer alternative NSAID which usually does not cause pseudoporphyria. Those cases induced by medications usually resolve over several months; the management of those associated with hemodialysis is much more difficult; however, remission by the administration of *N*-acetylcysteine, 400 mg of powder dissolved in orange juice twice a day, has been reported.

HEPATOERYTHROPOIETIC PORPHYRIA

Hepatoerythropoietic porphyria (HEP) is a very rare form of porphyria that is inherited as an autosomal-recessive trait, HEP is the homozygous form of PCT. It is caused by a homozygous or compound heterozygous deficiency of uroporphyrinogen decarboxylase, which is about 10% of normal in both the liver and erythrocytes. The biochemical abnormalities are similar, but more marked, than those in PCT, but the clinical features are similar to congenital erythropoietic porphyria. Dark urine is usually present from birth, but may be noted later. In infancy vesicles occur in sun-exposed skin, followed by sclerodermoid scarring, hypertrichosis, pigmentation, red fluorescence of the teeth under Wood's light examination, and nail damage. Neurologic disease has been reported in one patient. The diagnosis is confirmed by abnormal urinary uroporphyrins, as seen in PCT, elevated erythrocyte protoporphyrins, and increased coproporphyrins in the feces. In congenital erythropoietic porphyria, uroporphyrins are elevated in the erythrocytes, allowing differentiation from HEP. Sun protection is necessary.

ACUTE INTERMITTENT PORPHYRIA

Acute intermittent porphyria (AJP), the second most common form of porphyria, is characterized by periodic attacks of abdominal colic, gastrointestinal disturbances, paralyses, and psychiatric disorders. Skin lesions do not occur, since the elevated porphyrin precursors are not photosensitizers. It is inherited as an autosomal-dominant trait and is caused by a deficiency in porphobilinogen deaminase, which has 50% activity in affected persons. Only 10% of those with the genetic defect develop disease, but all may be at risk for primary liver cancer. AIP is particularly common in Scandinavia, especially Lapland. AIP usually presents after puberty in young adulthood, and women outnumber men 1.5 to 2:1.

Severe abdominal colic is most often the initial symptom of AIP. Usually there is no abdominal wall rigidity, although tenderness and distension are present. Nausea, voiniting, and diarrhea or constipation accompany the abdominal pain. Peripheral neuropathy, mostly motor, is present. Severe pain in the legs occurs. Optic atrophy, diaphragmatic weakness, respiratory paralysis, flaccid quadriplegia, facial palsy, and dysphagia are but a few of the many neurologic signs. Psychiatric disturbances are varied and frequently apparent. Attacks may be induced by numerous medications.

A diagnosis of AIP is established by finding elevated levels of urinary porphobilinogen (PBG) and increased dALA in the plasma and urine. Erythrocyte and fecal porphyrin levels are normal. No specific treatment is available for AIP. It is important for the patient to avoid such precipitating factors as a wide variety of medications, including sex steroid hormones, and to maintain adequate nutrition. Glucose loading has been used extensively and appears to be beneficial in many cases. Hematin infusions, in the form of heme arginate, results in clinical improvement and a marked decrease in ALA and PBG excretion. Early treatment may ameliorate attacks. The phenothiazines (chlorpromazine) may be helpful for pain; opiates and propoxyphene are also useful for analgesia.

VARIEGATE PORPHYRIA

Variegate porphyria (VP) is also known as mixed porphyria, South African genetic porphyria, and mixed hepatic porphyria. VP has an autosomal-dominant inheritance, with a high penetrance. It results from a decrease in activity of protoporphyrinogen oxidase. The majority of affected relatives have silent VP, in which there is reduced enzyme activity but no clinical lesions. Such persons should be identified and counseled to avoid known precipitating medications.

VP is characterized by the combination of the skin lesions of PCT and the gastrointestinal and neurologic disease of AIP. Seventy percent of patients develop skin lesions; in 50%, this is the presenting finding. Vesicles and bullae with erosions, especially on sun-exposed areas, are the chief manifestations. In addition, hypertrichosis is seen in the temporal area, especially in women. Hyperpigmentation of sun-exposed areas is also a feature. Facial scarring and thickening of the skin may give the patient a prematurely aged appearance.

The presence of VP should be suspected in a patient when findings indicate both PCT and AIP, especially if he/she is of South African ancestry. Fecal coproporphyrins and protoporphyrins are always elevated, and during attacks urine porphobilinogen and ALA are elevated. Urinary coproporphyrins are increased over uroporphyrins, distinguishing VP from PCT. A finding in the plasma of a unique fluorescence at 626 nun is characteristic of VP and distinguishes it from all other forms of porphyria. Treatment is symptomatic and as outlined for PCT and AIP.

HEREDITARY COPROPORPHYRIA

Hereditary coproporphyria (HCP) is a rare, autosomaldominant porphyria resulting from a deficiency of coproporphyrinogen oxidase (CPO). About one-third of patients are photosensitive, with blistering similar to but less severe than in VP. Affected persons are prone to attacks with gastrointestinal and neurologic symptoms similar to those seen in AIP and VP. Fecal coproporphyrin is always increased; urinary coproporphyrin, ALA, and PBG are increased only during attacks.

Harderoporphyria is caused by a homozygous defect of CPO with patients having 10% of normal activity. Children present with photosensitivity, hypertrichosis, and hemolytic anemia. Harderoporphyrin is the natural intermediate between coproporphyrinogen and protoporphyrinogen.

ERYTHROPOIETIC PROTOPORPHYRIA

Erythropoietic protoporphyria (EPP) is an inherited disorder with both autosomal-dominant and -recessive forms. The ferrochelatase activity is 10% to 25% of normal in affected persons. EPP typically presents early in childhood (2-5 years old), but presentation late in adulthood can occur.

Unique among the more common forms of porphyria is an immediate burning of the skin on sun exposure. Because the elevated protoporphyrin IX absorbs both in the Soret band and at 500 to 600 nm, visible light through window glass or in the operating room may precipitate symptoms. Infants cry when exposed to sunlight. Erythema, plaque-like edema, and wheals such as those seen in hydroa aestivale or solar urticaria can be seen. These lesions appear solely on sun-exposed areas. In severe cases, purpura is seen in the sun-exposed areas.

With repeated exposure, the skin develops a weatherbeaten appearance. Shallow linear or elliptical scars, waxy thickening and pebbling of the skin on the nose, cheeks, and over metacarpophalangeal joints, and atrophy of the rims of the ears have been described.

Many EPP patients have mildly elevated liver function tests. Severe liver disease develops in 10% of patients, and 1% of EPP patients die of liver failure. Excessive porphyrins are deposited in the liver, porphyrin gallstones are frequently found, and affected livers are cirrhotic. Autosomal-recessive inheritance of EPP may be a risk factor for the development of liver failure. Liver failure requires liver transplantation. A mild microcytic anemia is present in 25% of patients with EPP, but therapy with iron should be used only if iron deficiency is detected, since it may exacerbate symptoms.

Histologically, there is prominent ground-glass, PASpositive material in the upper dermis, mostly perivascularly. This material is type IV collagen. On DIF, IgG and C3 may be found perivascularly.

A diagnosis of EPP can usually be suspected on clinical grounds, especially if both the acute symptoms and chronic skin changes are found. Because protoporphyrin IX is not water soluble, urine porphyrin levels are normal. Erythrocyte protoporphyrin is elevated, and can be detected by red blood cell (RBC) fluorescence. Erythrocyte, plasma, and fecal protoporphyrin can also be assayed to confirm the diagnosis. Erythrocyte protoporphyrin levels in affected persons may range from several 100 to several 1000 µg/ 100 mL of packed RBC (normal values, <35 µg/100 mL of packed RBCs).

The differential diagnosis of EPP includes hydroa vacciniforme, xeroderma pigmentosa, and solar urticaria. In infancy, before the appearance of the chronic skin changes, erythrocyte porphyrins may need to be screened to confirm the diagnosis. Once chronic changes are present, a skin biopsy will confirm the diagnosis.

The treatment consists of protection from exposure to sunlight with clothing and barrier sunscreens with titanium dioxide or zinc oxide. Beta-carotene, 60 to 180 mg/day in adults and 30 to 90 mg/day for children, to maintain a serum level of $600 \mu g/100 \text{ mL}$, provides some protection for most cases. As the child grows, the dose must be increased to maintain adequate tissue levels. Cysteine at a dose of 500 mg twice a day can reduce symptoms. Transfusions of washed packed RBCs may be used to treat anemia, if the patient is symptomatic.

Cholestyramine, oral bile acids, hematin, and a highcarbohydrate diet have all been proposed to prevent or slow the progression of liver disease, but no definitive therapy has been developed.

CONGENITAL ERYTHROPOLETIC PORPHYRIA

Congenital erythropoietic porphyria (CEP) is a rare form of porphyria, also known as *erythropoietic porphyria* or *Gunther's disease*. It is inherited as an autosomal-recessive trait and is caused by a homozygous defect of the enzyme uroporphyrinogen III synthase.

CEP presents soon after birth with the appearance of red urine (noticeable on diapers). Severe photosensitivity occurs, and may result in immediate pain and burning so that the affected child screams when exposed to the sun. Redness, swelling, and blistering occur and result in scarring of the face, dorsal hands, and scalp (with subsequent alopecia). Ectropion can occur with subsequent corneal damage and loss of vision. Erythrodontia of both deciduous and permanent teeth is also characteristic. This phenomenon is demonstrated by the coral-red fluorescence of the teeth when exposed to a Wood's light. Mutilating scars, especially on the face, and the hypertrichosis of the cheeks with profuse eyebrows, and long eyelashes occurs. Other features seen in CEP include growth retardation, hemolytic anemia, thrombocytopenia, porphyrin gallstones, osteopenia, and increased fracturing of bones.

A diagnosis of CEP can be easily suspected when an infant has dark urine and is severely photosensitive. Milder forms of the disease resemble adult PCT and may present in adult life. Abnormally high amounts of uroporphyrin I and coproporphyrin I are found in urine, stool, and red cells. There is stable red fluorescence of erythrocytes. On biopsy there is a subepidermal bulla identical to that seen in PCT.

Treatment is strict avoidance of sunlight, and sometimes splenectomy for the hemolytic anemia. Oral activated charcoal is efficacious; presumably it retards the absorption of endogenous porphyrins. Repeated transfusions of packed red cells, enough to maintain the hematocrit level at 33%, turns off the demand for heme and reduces porphyrin production. Bone marrow transplantation can be an effective treatment.

TRANSIENT ERYTHROPORPHYRIA OF INFANCY (PURPURIC PHOTOTHERAPY-INDUCED ERUPTION)

Paller et al reported seven infants exposed to 380 to 700 nm blue lights for the treatment of indirect hyperbilirubinemia who developed marked purpura in skin exposed to UV light. Extensive blistering and erosions occurred in one case. Biopsies of the skin show hemorrhage without epidermal changes in the cases associated with purpura, and a pauci-inflammatory, subepidermal bulla in the case with blistering. The infants had all received transfusions. Elevated plasma coproporphyrins and protoporphyrins were found in the four infants examined. The pathogenesis is unknown.

CALCINOSIS CUTIS

Cutaneous calcification results from deposits of calcium and phosphorous in the skin. Calcinosis cutis is divided into four forms. *Dystrophic calcinosis* includes conditions in which calcification occurs in damaged tissue (usually collagen or elastic tissue). Serum calcium and phosphorus levels are normal. Dermatomyositis is a classic example. *Metastatic calcification* refers to deposition of calcium resulting from elevated serum levels of calcium or phosphorus. Hyperparathyroidism is an example of this form of calcification. *Iatrogenic and traumatic calcinosis* is associated with medical procedures or occupational exposures that may involve both tissue damage and local elevated calcium concentrations. *Idiopathic calcinosis cutis* refers to those forms of cutaneous calcification of unknown cause with normal serum calcium. In osteoma cutis, true bone is formed in the skin.

DYSTROPHIC CALCINOSIS CUTIS

This type occurs in a preexisting lesion or inflammatory process. Systemic calcium metabolism is normal, and lesions affect the skin only. This may be divided into localized (calcinosis circumscripta) and widespread (calcinosis universalis) types. Localized calcinosis cutis may present as small deposits of chalky granular material around the fingers and on the elbows. This may spontaneously extrude from the skin. It occurs most commonly in limited scleroderma (the CREST syndrome: calcinosis cutis, Raynaud's phenomenon, esophageal disorders, sclerodactyly, and telangiectasia) (Fig. 26-10), but may be seen in progressive systemic sclerosis and systemic lupus erythematosus. Pancreatic and lupus panniculitis typically demonstrate dystrophic calcification, but the process tends to remain microscopic. Patients with Werner syndrome and PCT may also develop calcifications within the scleroderma-like lesions. Various benign and malignant neoplasms may develop calcification or ossification. Pilomatrixomas, pilar cysts, nevi, mixed tumors, melanomas, and atypical fibroxanthomas are the most commonly reported of these. In the above cases, calcification is in the dermis or subcutaneous tissue; however, in one patient with welldefined infiltrated white plaques of the labia majora and

Fig. 25-10 Calcinosis cutis in CREST syndrome. genital mucosa who had chronic irritation from urinary incontinence and a vesicovaginal fistula, calcification occurred in the epithelium.

Calcinosis universalis is usually seen in children with dermatomyositis. It affects the skin, muscles, and tendons, as well as more diffusely. This calcification can persist for many years after the dermatomyositis is inactive. Calcinosis cutis in dermatomyositis may occur in adults, particularly those with a delay in diagnosis, or who receive inconsistent treatment, or who have the tumor necrosis factor- α -308A allele. Idiopathic cases of calcinosis universalis have been reported. Dystrophic calcification is treated with limited surgical removal as needed to control discomfort. Bisphosponates, calcium-channel blockers, warfarin, colchicines, probenecid, and a low calcium, low phosphate diet combined with aluminum hydroxide have been reported to be of benefit in the treatment of calcinosis cutis in individual patients.

METASTATIC CALCINOSIS CUTIS

This rare entity is characterized by calcifications in the skin, elevated serum calcium, and sometimes hyperphosphatemia. Metastatic calcinosis is often associated with bone loss or destruction, the bone providing the source of the elevated serum calcium. Conditions associated with metastatic calcinosis include parathyroid neoplasms, primary hyperparathyroidism, chronic renal failure, hypervitaminosis D, sarcoidosis, and excessive intake of milk and alkali. Destruction of bone by osteomyelitis, leukemia, Paget's disease of the bone, myeloma, and metastatic calcification. In calcinosis cutis with hyperparathyroidism, the skin manifestations are numerous, small, firm, white papules, about 1 to 4 mm in diameter, occurring symmetrically in the popliteal fossae, over the iliac crests, and in the posterior axillary lines.

The most common metabolic condition associated with metastatic calcification is renal failure. Usually there is an elevated phosphorus level and secondary hyperparathyroidism, resulting in high calcium and phosphorous production and deposition of calcium phosphate in tissues. Less commonly, cutaneous calcification in renal disease can occur with normal serum calcium and phosphorus levels. Three forms of cutaneous calcification in renal disease have been described: tumoral calcinosis, calcifying panniculitis, and calciphylaxis. Tumoral calcinosis is a very rare complication of renal disease. Managing the metabolic abnormalities may lead to resolution of the large deposits of calcium.

Often calcifying panniculitis and calciphylaxis occur in the same patient at the same time, suggesting that they may be of a common pathogenesis. Isolated, firm, indurated nodules, usually on the legs or thighs, in the subcutaneous fat have been called *calcifying panniculitis*. Usually they are seen with the most severe complication of the abnormal calcium and phosphorus metabolism of renal disease, calciphylaxis. This life-threatening condition, which leads to livedo reticularis and ischemic tissue necrosis, is discussed in Chapter 35.

IATROGENIC AND TRAUMATIC CALCINOSIS CUTIS

Medical procedures that may inadvertently introduce calcium into tissue in association with tissue trauma may lead to cutaneous calcification. This has been reported after extra-

Fig. 26-11 Scrotal calcinosis.

vasation of calcium chloride or calcium gluconate infusion, and after electroencephalography or electromyography. The electrode paste is high in calcium, and the skin is traumatized during the procedure, leading to calcifications at the sites of electrode insertion. The most common setting is on the scalp of children. Lesions spontaneously resolve over months. Performing frequent heel sticks in neonates has led to similar lesions. Injections of low molecular weight calciumcontaining heparins in patients suffering from renal failure may develop calcification at the sites of injection.

Traumatic calcinosis may occur as a result of occupational exposure to calcium-containing materials, as in the cases reported in oil-field workers and coal miners. Exposure of the skin to cloth sacks of calcium chloride, limewater compresses, and refrigerant calcium chloride can all cause calcinosis cutis.

IDIOPATHIC CALCINOSIS CUTIS

Idiopathic Scrotal Calcinosis

Idiopathic scrotal calcinosis is the most common form of idiopathic calcinosis cutis. Lesions present in young to middle-aged adult men as multiple, asymptomatic, firm, round, yellow papules from several millimeters up to 1 cm in diameter (Fig. 26-11). The papules resemble infundibular follicular cysts. Similar lesions may be seen less commonly in girls or women on the labia majora or areola. Histologically, there are localized deposits of calcium surrounded by foreign body reaction. At least some are calcified scrotal infundibular cysts. Why they have such a high proclivity to calcification at this anatomic location is unclear. Treatment is not required, but surgical removal cures individual lesions.

Subepidermal Calcified Nodule

Subepidermal calcified nodule is an uncommon but distinct type of idiopathic calcinosis; it occurs most frequently as one or a few lesions on the scalp or face of children (Fig. 26-12). Males outnumber females by nearly 2:1, and the average age at onset is 7 years. Lesions present as fixed, uninflamed papules that look very much like those of molluscum contagiosum with a central umbilication. A similar condition, milia-like idiopathic calcinosis cutis, has a wider distribution (hands,

Fig. 26-12 Subepidermal calcified nodules.

feet, elbows, knees are common sites). Two-thirds of patients have Down syndrome. Treatment is not required, but surgical removal will cure any individual lesion.

Tumoral Calcinosis

Tumoral calcinosis is a rare disease of unknown cause that can be divided into two forms. The idiopathic, primary, or normophosphatemic form is seen in young adults, primarily in African natives. It is not familial, lesions are usually solitary, and antecedent trauma is frequently present. Primary hyperphosphatemic tumoral calcinosis is a familial disease, primarily of black males. Most cases present before the second decade of life. Three-quarters of these individuals have affected siblings, but the exact mode of inheritance is unknown. Multiple lesions predominate, and there is no preceding history of trauma. The serum calcium level is normal, but serum phosphorus and calcitriol levels are elevated.

Lesions in both types present as large subcutaneous masses of calcium overlying pressure areas and large joints, usually the hips, elbows, shoulders, or knees. Skin involvement, apart from the tumoral masses, is extremely rare but may occur as localized calcinosis cutis. The internal organs are not involved, and serum calcium levels are generally normal. Surgical excision has been the mainstay of therapy; however, recurrences are frequent after incomplete removal. Various dietary restrictions to lower calcium and phosphorus intake have shown some success.

OSTEOMA CUTIS

Bone formation within the skin may be primary in cases where there was no preceding lesion; metastatic (associated with abnormalities of parathyroid metabolism); or dystrophic, where ossification occurs in a preexisting lesion or inflammatory process.

Primary osteoma cutis includes four genetic disorders, fibrodysplasia ossificans progressiva, progressive osseous heteroplasia, widespread or single, platelike osteoma cutis, and Albright hereditary osteodystrophy. Additionally, single osteomas may occur as an idiopathic event in later life, or multiple miliary osteomas of the face can be seen, usually in women (Fig. 26-13). Some feel the latter are dystrophic because they occur in patients with acne and are associated with scars. If tetracycline or minocycline is ingested for treatment of the acne, the cutaneous osteomas may be pigmented. Improvement with topical tretinoin, erbium:YAG laser or with incision, curettage, and primary closure has been reported in theses miliary osteomas.

Patients with fibrodysplasia ossificans progressiva develop osteoma cutis as endochondral bone formation associated with deep connective tissue and skeletal muscle involvement. They have dystrophic great toes, baldness, mental retardation, and deafness. The prognosis is poor due to the progressive and deep nature of the lesions, leading to extreme morbidity and early death due to restricted movement of the chest. Mutations in the noggin gene in the 17q 21-22 region have been documented in several families.

Progressive osseous heteroplasia is a rare form of cutaneous ossification initially seen between birth and 6 months of age, often in the first month of life. Females are preferentially affected. Lesions begin as small papules that can coalesce to large plaques. Sometimes these plaques will have small firm calcified papules overlying them. Lesions are randomly distributed and may be unilateral or only involve one anatomic area. There is no preceding trauma or inflammatory phase. Serum calcium, phosphorus, parathyroid hormone and calcitriol are normal, but alkaline phosphatase, lactate dehydrogenase (LDH), and creatine phosphokinase (CPK) may be elevated, indicating increased bone formation (alkaline phosphatase) or muscle destruction (CPK and LDH). Histologically, the lesions reveal intramembranous bone formation and can affect the soft tissues as well as skin. Only calcification without ossification may be found in superficial dermal biopsies, so a deep biopsy, including subcutaneous fat, may be required to confirm the diagnosis. The condition is progressive and can lead to serious sequelae, including ulceration, infection, and severe pain. Platelike osteoma cutis also occurs in newborns or young children, is unassociated with dysmorphic features or abnormalities of calcium or phosphorus metabolism, has intramembranous bone formation histologically, but is nonprogressive. These disorders are most likely polar ends of a spectrum of disease, as one family

Fig. 26-13 Osteoma cutis. (Courtesy of Curt Samlaska, MD)
has been described with members having either condition, and they both have been associated with mutations in the α -subunit of the stimulatory G protein that interacts with adenyl cyclase.

Albright hereditary osteodystrophy is described in Chapter 24. It is characterized by childhood development of intramembranous bone formation in the dermis and subcutaneous tissue. The cutaneous ossifications may be noted soon after birth and are usually multiple, small, superficial plaques. They favor the scalp, hands, feet, periarticular regions, abdomen, and chest wall. Small lesions are of little consequence, but large subcutaneous masses may disrupt underlying structures. There may be characteristic dysmorphic features and the presence of pseudo- or pseudopseudohpyoparathyroidism. It also is associated with mutations of the GNAS1 gene.

Dystrophic osteoma cutis occurs most frequently in pilomatricomas; however, other lesions in which bone formation may occur are basal cell epithelioma, intradermal nevi, mixed tumor of the skin, scars, scleroderma, and dermatomyositis.

LIPID DISTURBANCES

XANTHOMATOSIS

Xanthomatosis is a cutaneous manifestation of lipidosis in which the plasma lipoproteins and free fatty acids are changed quantitatively. There is accumulation of lipids in large foam cells in the tissues. Cholesterol or triglycerides are usually found, but when cholesterol levels are normal, β -sitosterol, campesterol, stigmasterol (plant sterols), or cholestanol may rarely be at fault.

The names for cutaneous manifestations of xanthomatosis are based on clinical morphology. Several different genetic diseases may present with similar cutaneous xanthoma patterns. The morphologies are relatively specific for the associated elevated lipid, however, with eruptive xanthomas seen with hypertriglyceridemia and other forms of xanthomas seen with elevations in cholesterol.

Xanthoma Tuberosum

Tuberous xanthomata are variously found as flat or elevated and rounded, grouped, yellowish or orange nodules located over the joints, particularly on the elbows and knees (Fig. 26-14). The lesions are indurated and tend to coalesce. They may also occur over the face, knuckles, toe joints, axillary and inguinal folds, and buttocks. Solitary lesions may occur. Early lesions are usually bright yellow or erythe-

Fig. 26-14 A and B, Tuberous xanthomas.

Fig. 26-15 Tendonous xanthomas.

xanthomas.

Fig. 26-17 A and B, Eruptive xanthomas.

matous; older lesions tend to become fibrotic and lose their color. Pedunculated, fissured, and suppurative nodules may also be seen.

Xanthoma tuberosum is associated with primary hyperlipoproteinemias with elevated cholesterol levels, such as familial hypercholesterolemia and familial dysbetalipoproteinemia. It also occurs in biliary cirrhosis, myxedema, phytosterolemia, and normocholesterolemic dysbetalipoproteinemia.

Xanthoma Tendinosum

Papules or nodules 5 to 25 mm in diameter are found in the tendons, more especially in extensor tendons on the backs of the hands (Fig. 26-15) and dorsa of the feet and in the Achilles tendons (Fig. 26-16). These predominate in conditions with elevated cholesterol, such as the primary hyperlipoproteinemias of familial hypercholesterolemia, familial defective apolipoprotein B-100, and familial dysbetalipoproteinemia. They are usually seen in association with tuberous xanthomas and xanthelasma. They also occur in obstructive liver disease, diabetes, myxedema, cerebrotendinous xanthomatosis, and phytosterolemia.

Eruptive Xanthoma

Xanthoma eruptivum consists of small, yellowish-orange to reddish-brown papules that appear in crops over the entire body (Fig. 26-17). These occur in association with markedly elevated triglycerides. Causes for such elevations are genetic deficiency of lipoprotein lipase, familial deficiency of apoprotein CII, familial inhibitor of lipoprotein lipase, and endogenous familial hypertriglyceridemia. Certain diseases or drugs raise the triglyceride level either by increased production, decreased catabolism, or decreased excretion. These include diabetes mellitus, obesity, pancreatitis, chronic renal failure, hypothyroidism, and treatment with estrogens, corticosteroids, or systemic retinoids.

The papules may be surrounded by an erythematous halo and may be grouped in various favored locations such as the buttocks, flexor surfaces of the arms and thighs, knees, inguinal and axillary folds, and oral mucosa. Koebnerization may occur. Pruritus is variable.

Xanthoma Planum (Plane Xanthoma)

These xanthomas appear as flat macules or slightly elevated plaques with a yellowish-tan or orange coloration of the skin that is spread diffusely over large areas. They are frequently associated with biliary cirrhosis and myeloma but have been described in patients with high-density lipoprotein (HDL) deficiency (isolated A-1 apolipoprotein deficiency type), monoclonal gammopathy, lymphoma, leukemia, and in xanthomas following erythroderma. Characteristically, plane xanthomas may occur about the eyelids, neck, trunk, shoulders, or axillae (Fig. 26-18). These well-defined macular patches may be situated on the inner surface of the thighs and antecubital and popliteal spaces. Xanthelasma palpebrarum may be associated with xanthoma planum elsewhere.

Palmar Xanthomas

These consist of nodules and irregular yellowish plaques involving the palms and flexural surfaces of the fingers (Fig. 26-19). Striated xanthomas appear as yellowish streaks that follow the distribution of creases of the palms and soles. These lesions are seen in familial dysbetalipoproteinemia, multiple myeloma, and biliary cirrhosis.

Fig. 26-19 Xanthomas of the palmar striae. (Courtesy of James Fitzpatrick, MD)

Xanthelasma Palpebrarum (Xanthelasma)

Xanthelasma is the most common type of xanthoma. It occurs on the eyelids and is characterized by soft, chamoiscolored or yellowish orange oblong plaques, usually near the inner canthi (Fig. 26-20). The xanthelasmata vary from 2 to 30 mm in length. Frequent symmetry, with a tendency to be permanent, progressive, multiple, and coalescent, is also characteristic. Frequently xanthelasmata are associated with other types of xanthomas, but they are usually present without any other disease.

The disorder is encountered chiefly in patients of middle age. It is common among women who have hepatic or biliary disorders. Xanthelasma may be seen in familial hyper-

Fig. 26-20 Xanthelasma.

cholesterolemia, familial defective apolipoprotein B-100, and familial dysbetalipoproteinemia; however, half or more of the patients are normolipemic. It is a common finding in generalized xanthoma planum, in obstructive liver disease, myxedema, diabetes, and phytosterolemia.

Several studies have found abnormalities in apolipoprotein E phenotypes or other lipoproteins more frequently than in controls. New patients with xanthelasma should be evaluated with a full lipoprotein profile, as well as a careful history and physical examination. Patients with a young age at onset and a family history of hyperlipidemias are at higher risk of having lipid abnormalities.

Treatment of xanthelasma is discussed here because of its uniqueness among the xanthomas, in that surgical therapy is often successful. The best method is surgical excision. The anesthetized lesion is grasped with mouse-tooth forceps and clipped off with scissors, and the skin edges undermined and sutured with fine silk. Excellent cosmetic results are obtained, even if the wound is not closed. Fulguration, trichloracetic acid cauterization, and CO_2 and erbium: YAG laser treatments are other methods. Complete removal of the lesions does not preclude the possibility that other new lesions will develop.

Tuberoeruptive Xanthomas

These xanthomas are red papules and nodules that appear inflamed and tend to coalesce. They are associated with familial dysbetalipoproteinemia.

Nodular Xanthomas

These are multiple, yellowish, dome-shaped lesions, 4 to 5 mm or larger in diameter; they may be discrete or confluent and may occur on the earlobes, neck, elbows, and knees. They are usually associated with biliary cirrhosis and atresia of the bile ducts.

The histologic features in all varieties of xanthoma are similar, characterized by the presence of numerous large xanthoma or foam cells, which are phagocytes (fat-laden histiocytes). They may be multinucleated. In addition to the foam cells, giant cells of the Touton type occur. Clefts representing cholesterol and fatty acids dissolved by embedding agents may be noted. There is generally a connective tissue reaction about the nests of foam cells, and in old lesions most of the foam cells are replaced with fibrosis. To demonstrate lipids in the histologic sections, frozen sections should be stained with lipid stains (scarlet red).

PRIMARY HYPERLIPOPROTEINEMIAS

Cutaneous xanthomas are usually manifestations of a disorder of lipid metabolism. The blood lipids, with the exception of free fatty acids, are bound to circulating plasma proteins and are mainly cholesterol, phospholipid, and triglyceride. The total serum lipids have a range of 400 to 1000 mg%. Of this, serum cholesterol values vary according to age. Generally, a serum cholesterol below 200 mg/dL is normal, while a level of more than 240 mg/dL requires further evaluation. A triglyceride level of more than 250 mg/dL is considered abnormal.

Lipoprotein fractions may be demonstrated by paper electrophoresis. Four lipoprotein bands may be evident: the α -lipoprotein band (HDL), β -lipoprotein (low-density lipoprotein, LDL), pre β -lipoprotein (very-low-density lipoprotein, VLDL), and the chylomicron band. When the lipoproteins are subjected to ultracentrifugation it is found that the HDLs are composed mostly of phospholipid and esterified cholesterol. The LDLs are composed mostly of cholesterols. The VLDL fraction is the main carriers of endogenous triglycerides. The lowest density chylomicrons are the exogenous triglycerides.

Frederickson classified hyperlipoproteinemias into six types on the basis of electrophoretic patterns, as follows:

- Type I: Excess chylomicrons
- Type IIa: Excess β -lipoprotein
- Type IIb: Excess β -lipoprotein with slightly elevated VLDLs
- Type III: Increased intermediate-density (remnant) lipoprotein
- Type IV: Increased preβ-lipoprotein

Type V: Increased preß-lipoproteins and chylomicrons

Although this phenotypic classification has been useful for many years, advances in the understanding of lipoprotein metabolism and transport, coupled with new knowledge of molecular defects which result in these phenotypes, has led to the use of a genetic classification of lipoproteinemias.

Lipoprotein metabolism may be viewed based on the lipid source: an exogenous and an endogenous category. Exogenous lipids in the diet are absorbed and incorporated into triglyceride-rich chylomicrons. These are hydrolyzed by the action of lipoprotein lipase and certain cofactors, among them apoprotein CII. The resulting remnants are taken up by the liver. Endogenously produced VLDLs are synthesized in the liver and (again through the action of lipoprotein lipase) are connected to cholesterol-rich intermediate-density lipoproteins (IDLs) and eventually into LDLs.

These are then available for uptake by peripheral tissues, as well as by the liver. The uptake of LDL, IDL, and chylomicron remnants is dependent on specific receptors. Abnormalities of lipoprotein lipase, the apolipoproteins, cofactors, receptors, or stimulators or retarders of endogenous production or catabolism, whether on a genetic or sporadic basis, may accelerate or block the pathway in different areas. If blockade occurs early and results in elevation of triglyceriderich particles, eruptive xanthoma may result. If a defect occurs later in the pathway, and cholesterol-rich particles accumulate, xanthelasma, tuberous xanthomas, and tendinous xanthomas are to be expected, along with premature atherosclerotic cardiovascular disease.

Lipoprotein Lipase Deficiency

Lipoprotein lipase deficiency causes type I disease (chylomicronemia) early in life. It is rare, results from a homo-

Fig. 26-21 Eruptive xanthomas in lipoprotein lipase deficiency.

zygous defect, and is associated with highly elevated triglycerides. With levels above 2000 mg/dL, a high risk of pancreatitis and eruptive xanthomas (Fig. 26-21) exists. As patients grow older, their VLDLs (type V) become elevated. Dietary modification is the only effective treatment.

Familial Apoprotein CII Deficiency

Patients with the rare familial apoprotein CII deficiency lack lipoprotein lipase activator; very high triglyceride levels, up to 10,000 mg/dL, result. They are at risk for pancreatitis and eruptive xanthomas; management again is through dietary reduction of fats.

Familial Hypertriglyceridemia

In familial hypertriglyceridemia, increased hepatic production of VLDLs occurs first (type IV), but overloaded removal mechanisms result in accumulation of dietary lipids, and chylomicrons accumulate, so a type V pattern results. Eruptive xanthomas are common, and atherosclerotic heart disease may occur. Cholelithiasis, polyarthritis, and arthralgia frequently occur.

Familial Hypercholesterolemia

Familial hypercholesterolemia is Frederickson type II disease: LDLs are found in high levels in the plasma; there may be a moderate increase in VLDLs and in the triglycerides that they carry. There is overproduction of LDL cholesterol (caused by loss of normal feedback inhibition) and impaired removal of it (because of impaired formation of LDL receptors). There is elevated plasma β -lipoprotein from birth in heterozygotes, and symptoms begin in the third to sixth decade, when tendinous or less commonly tuberous xanthomas appear. Atherosclerotic coronary heart disease begins in the 30s and 40s in men and a decade later in women. Statins are the treatment of choice.

Homozygotes generally develop coronary atherosclerosis before the age of 15, as their cholesterol levels are in the 800 to 1000 mg/dL range. Tendinous xanthomas, tuberous xanthomas, and xanthelasma appear in childhood. Characteristic xanthomatous plaques occur, which may be generalized (Fig. 26-22), but typically involve intertriginous areas such as the interdigital spaces (Fig. 26-23) or the intergluteal cleft. Cultured amniotic fluid cells permit prenatal diagnosis in homozygotes. LDL-apheresis or liver transplantation are treatments employed for this homozygous type. Autosomal-

Fig. 26-22 Xanthomas In homozygous familial hypercholesterolemia. gout, and obesity. Familial apolipoprotein E deficiency is a rare disease that is associated with marked atherosclerosis and xanthomatosis.

Familial Combined Hyperlipidemia or Multiple-Type Hyperlipoproteinemia

This, the most common of the genetic lipoproteinemias, has a high risk of myocardial infarction and diabetes, and a low incidence of tuberous or tendinous xanthomas.

Fig. 26-23 Interdigital xanthomas in homozygous familial hypercholesterolemía.

recessive hypercholesterolemia is a rare condition in which the internalization of the LDL receptor on cells is defective. This leads to clinical disease which is similar, but generally less severe than, homozygous familial hypercholesterolemia.

Familial Defective Apolipoprotein B-100

In this condition, a structural defect in apolipoprotein B-100 means it binds poorly to LDL receptors, allowing for accumulation of LDL. In the more common heterozygous form, hypercholesterolemia occurs, tendinous xanthomas and xanthelasma may be seen, and premature coronary heart disease develops. In the rare homozygous form there are higher levels of cholesterol present but not to the heights seen in homozygous familial hypercholesterolemia. Statins are an effective intervention.

Familial Dysbetalipoproteinemia (Broad Beta Disease)

In this disorder, remnant lipoproteins increase, LDLs and HDLs are teduced, and triglyceride and cholesterol levels are increased. The cholesterol-rich IDLs form a broad band on electrophoresis, extending from pre β -lipoproteins to β -lipoproteins: hence broad beta disease. The presence of an abnormal form of apolipoprotein E, apolipoprotein E2, allows for the definitive diagnosis to be made. Xanthomas (tuberous, eruptive, palmar, or tendinous) are common; xanthelasmas are infrequent. Atherosclerosis is common, as are diabetes,

SECONDARY HYPERLIPOPROTEINEMIA

Obstructive Liver Disease (Xanthomatous Biliary Cirrhosis)

This type of hyperlipoproteinemia shows an increase of the serum phospholipid and cholesterol, giving a type II lipoprotein pattern. This is caused by the presence of lipoprotein X, which is secreted by the liver in cholestasis. It has the ability to carry large quantities of free cholesterol and phospholipids. The triglycerides are not elevated and the plasma is clear, showing no chylomicrons.

The xanthomatous lesions are plane xanthomas, with lesions on the face, flexor surfaces of the extremities, and trunk. Striate palmar and plantar lesions, and xanthelasmas are also seen. Tuberous xanthomas may also occur. Pruritus is extremely severe. Hepatomegaly and jaundice are present. Cholestyramine is of help in allaying pruritus.

Alagille syndrome is a congenital disorder characterized by intrahepatic bile ductular atresia, patent extrahepatic bile ducts, a characteristic facies (prominent forehead; deeply set eyes; straight nose; small, pointed chin), cardiac murmur, vertebral and ocular abnormalities, low intelligence, and hypogonadism. It is an autosomal-dominantly inherited condition. There is persistent cholestasis early in life with pruritus and hyperbilirubinemia. Lipid levels elevate by the age of 2 and planar or papular xanthomas may occur. This is a treatable condition with cholestyramine and fat-soluble vitamins leading to prolonged improvement.

Hematopoietic Diseases

Xanthomas may occur secondarily in myelomas; Waldenström macroglobulinemia; cryoglobulinemia, and occasionally, lymphoma; and hemochromatosis. These xanthomas are usually generalized plane xanthomas of the eyelids, periorbital areas, sides of the neck, shoulders, and upper back. The lipoproteinemia may be of type I, V, or Ua pattern. In some patients no lipoprotein abnormality is present. These patients may have paraproteins that bind to the lipoproteins, preventing their metabolism.

Xanthoma Diabeticorum

Eruptive xanthomas may occur secondarily, especially in young persons unresponsive to insulin. Cardiovascular disease and hepatomegaly are common. Insulin is necessary for the normal plasma triglyceride clearing action of lipoprotein lipase. Therefore, in insulin deficiency, an acquired lipoprotein lipase deficiency exists, which leads to impaired clearance of chylomicrons or VLDLs, or both. This results in a type I, IV, or V lipoprotein pattern and hypertriglyceridemia. When the diabetes is brought under control, the triglyceride levels are lowered and prompt involution of the lesions is seen. Weight reduction and carbohydrate intake restriction are also helpful. Identical phenomena may occur in von Gierke's disease, a form of glycogen storage disease in which there is a lack of hepatic glucose-6-phosphatase.

Chronic Renal Failure

If plasma protein levels are reduced by urinary loss in the nephrotic syndrome (or by plasmapheresis or repeated bleeding), a compensatory increase of lipoproteins may occur, with hyperlipidemia and various kinds of xanthoma.

Renal failure with or without dialysis may cause hypertriglyceridemia. In long-term dialysis there is increased cardiovascular disease because of increased levels of VLDL, as well as lowered HDLs. Type IV and V profiles are most commonly seen.

Myxedema

Lipoprotein lipase needs thyroid hormone to work, and its failure may lead to type I, IV or V disease; also thyroid hormone deficiency may lead to hypercholesterolemia, because thyroid hormone is needed in the oxidation of hepatic cholesterol to bile salts. Xanthelasma and xanthomas are common in myxedema.

Pancreatitis

Hyperlipidemia in the hyperchylomicronemic syndromes (types I and V) may cause pancreatitis; it may be recurrent, and pancreatic necrosis and death may occur. Alternatively, pancreatitis (perhaps initiated by ethanol) may cause type I or V hyperlipoproteinemia by inducing insulin deficiency and a relative lack of lipoprotein lipase activity.

Medication-Induced Hyperlipoproteinemia

Estrogens, by decreasing lipoprotein lipase activity and increasing VLDL synthesis, may cause type I or type IV patterns. Eruptive xanthomas may occur. Oral prednisone may induce insulin deficiency and cause type IV or V patterns to develop. Oral retinoids, indomethacin, highly active antiretroviral therapy (HAART) and olanzapine may also cause eruptive xanthomas.

Normolipoproteinemic Xanthomatoses

The normolipoproteinemic xanthomatoses are conditions in which serum cholesterol and lipoproteins are normal, yet secondary lipid deposition in the skin occurs. Hematopoietic conditions, particularly monoclonal gammopathies and myeloma, may be associated with normolipoproteinemic planar xanthomas.

Cerebrotendinous Xanthomatosis Cerebrotendinous xanthomatosis is an autosomal-recessive disease caused by an accumulation of cholestanol in plasma lipoproteins and xanthomatous tissue. The underlying abnormality is a mutation in the sterol 27-hydroxylase gene (CYP27A) leading to incomplete oxidation of cholesterol to bile acids. Cholestanol, an intermediate, accumulates as a result. It accumulates in tendons, brain, heart, lungs, and ocular lenses. There may be tendinous xanthomas, especially of the Achilles tendons; progressive neurologic dysfunction; cerebellar ataxia; dementia; spinal cord paresis; cataracts; atherosclerotic coronary disease; and endocrine abnormalities. Urinary gas chromatography is a specific test for this disease. The condition is treated with chenodeoxycholic acid and cholic acid.

Fig. 26-24 Verruciform xanthoma.

Phytosterolemia In phytosterolemia, a rare disorder, plant sterols such as β -sitosterol, stigmasterol, and campesterol are absorbed from the gastrointestinal tract in excessive amounts. This autosomal-recessive disorder is caused by mutations in the genes encoding the ABCG5 and ABCG8 transporters, which are needed to pump sterols out to intestinal cells in the lumen of the gut. The plant sterols accumulate in the body as xanthelasmas, tendinous xanthomas, and tuberous xanthomas. In most patients there is also type IIa hyperlipoproteinemia. There is a risk of hemolysis, arthritis, and premature atherosclerosis.

Verruciform Xanthoma Verruciform xanthoma (VX) is an uncommon lesion that occurs as a reddish-orange or paler hyperkeratotic plaque or papillomatous growth with a pebbly or verrucous surface. The most common site is the oral mucosa. It has also been reported on other mucosal surfaces, genitalia, lower extremities (Fig. 26-24), and elsewhere. The type of epidermal nevus that is present in CHILD syndrome may have characteristics of VX. Additionally, VX has been reported in psoriatic lesions undergoing PUVA therapy and in psoriasiform skin lesions in an HIV-positive patient. Histologically, there is acanthosis without atypia, parakeratosis, and xanthoma cells in the papillary dermis. The etiology is unknown.

Familial α -Lipoprotein Deficiency (Tangier Disease) Tangier disease is caused by mutations in the cell-membrane protein ABCA1, which mediates the secretion of excess cholesterol from cells into the HDL metabolic pathway. This results in a profound deficiency of HDL, an accumulation of cholesterol in tissue macrophages, and prevention of atherosclerosis. The characteristic clinical finding is yellow, enlarged tonsils from accumulation of lipid in this localized area. Xanthomas do not occur, however, there is diffuse accumulation of cholesterol esters in the skin, as well as the intestines, thymus, bone marrow, lymph nodes, and spleen. ABC (ATP-binding cassette) transporters generally have transmembrane domains that move substrates across cell membranes. Defects in 14 of the over 50 known ABC transporters cause 13 genetic diseases, including cystic fibrosis, age-related macular degeneration, phytosterolemia, and adrenoleukodystrophy.

NIEMANN-PICK DISEASE

This rare autosomal-recessive condition has six recognized subtypes. The originally described severely affected infants of Ashkenazi Jewish background have type A disease. Type B disease, which also results from mutations in the gene on chromosome 11 encoding for acid sphingomyelinase, is a non-neuropathic form that is the so-called adult type. Sphingomyelin (which is a ceramide phospholipid) and other lipids accumulate in the monocyte-macrophage system leading to shared systemic findings, such as hepatosplenomegaly, lymphadenopathy, pancytopenia, and pulmonary disease. There are two subtypes of C and type D (Nova Scotia), which result from defects in cholesterol metabolism.

Cutaneous changes in those patients with acid sphingomyelinase gene mutations are seen in type A patients. They are uncommon and consist of distinctive yellowish coloration of the skin and, in rare patients, skin-colored to tan papules. These latter lesions involve the head and upper extremities, and histologically contain foamy histiocytes, scattered multinucleateted cells, and a few lymphocytes. Inclusions may be observed in sweat gland epithelium. Black macular patches may occur on the mucous membranes.

GAUCHER'S DISEASE

Gaucher's disease is a rare autosomal-recessive disorder of the reticuloendothelial system. Acid- β -glucosidase is lacking, with a resulting accumulation of glucocerebrosides in the brain and in the reticuloendothelial cells of the liver, spleen, and marrow. In rare cases, Gaucher's disease is caused by mutations in the prosaposin gene which encodes the saposin C activator protein, which is necessary for optimal activity of β -glucosidase. The disease occurs at any age, but three forms are recognized: type 1 (adult type), without neurologic involvement; type 2 disease, the infantile form, with acute early neurologic manifestations; and type 3, the juvenile chronic neuropathic type.

Some type 2 patients have congenital ichthyosis that precedes neurologic manifestations, and some are born with a collodian membrane. Epidermal ultrastructural and biochemical abnormalities occur in all type 2 patients. Hepatosplenomegaly, rarefaction of the long bones, pingueculae of the sclera, and a distinctive bronze coloration of the skin from melanin characterize the adult type. A deeper pigmentation may extend from the knees to the feet (Fig. 26-25). This is often caused by hemosiderin and may be accompanied by thrombocytopenia and splenomegaly.

Fig. 26-25 Gaucher pigmentation of the lower leg.

Lipoid Proteinosis 537

Fig. 26-26 Papules of the eyelid in lipoid proteinosis. (Courtesy of Eric Krause, MD)

The disease occurs most frequently among Ashkenazi Jews. Approximately 1 in 20 carry the defective gene, the lack of which leads to the accumulation of glucocerebroside in histiocytes in the bone marrow and spleen, and Kupffer cells in the liver, forming Gaucher cells. These are large, 20 to 100 μ m in diameter, with one nucleus or a few small nuclei and pale cytoplasm that stains faintly for fat but is PAS positive. Elevated plasma acid phosphatase occurs and is a useful clue to the diagnosis. There is thinning of the cortex of the long bones.

Bone marrow transplantation performed before neurologic deficits occur has a high mortality rate (20-50%), but when successful has halted neurologic progression. Enzyme therapy is successful in treating some of the manifestations of the adult form, but it is limited by cost. Substrate-reduction therapy using the glycolipid synthesis inhibitor N-butyldeoxynojirimycin is also available. Symptomatic treatment includes radiation therapy to the long bones to relieve bone pain and splenectomy for hypersplenism (anemia and thrombocytopenia, with petechiae and bruising). With the identification of the gene defect, carrier screening and prenatal diagnosis are possible.

LIPOID PROTEINOSIS

Also known as Urbach-Wiethe disease and hyalinosis cutis et mucosae, this rare autosomal-recessive disturbance is characterized by yellowish-white infiltrative deposits on the inner surfaces of the lips, undersurface of the tongue, fauces, and uvula. Other parts of the upper respiratory tract are also affected. In the early stage, crops of bullae and pustules occur; these heal, leaving acne-like scars (Fig. 26-26). Changes in the larynx lead to a marked degree of hoarseness, which usually appears within the first few weeks of life. Failure to cry and a hoarse, gravelly voice are suggestive signs.

The patient's tongue is "like wood" and moves only with difficulty. The patient is unable to protrude the tongue.

Marked changes occur in the epiglottis. The vocal cords are thickened by an infiltration of grayish-yellow material, giving rise to the hoarseness observed so early. In some patients, similar yellowish and cream-colored deposits are sometimes observed on the labia majora, urethral orifice, scrotum, gluteal folds, and axillae. Severe xerostomia and poor salivation may result from infiltration of the salivary glands. Patchy alopecia is common.

Hyperkeratotic wartlike or nodular lesions are found on the dorsal aspects of the hands, fingers, elbows, and knees. The eyelid margins contain small, yellowish, transparent, pearly papules in about two-thirds of patients (Fig. 26-27). Drusen of Bruch's membrane are seen in the fundi in half the patients. Sickle-shaped calcifications dorsal and lateral to the sella turcica in skull x-ray films are pathognomonic.

Distinctive histologic features include extreme dilation of the blood vessels, thickening of their walls, progressive hyalinization of sweat glands, and infiltration of the dermis and subcutaneous tissue with extracellular hyaline deposits, which are also demonstrable in the vessel walls. Normal skin and mucous membranes also show changes of endothelial proliferation of the subpapillary vessels and a homogeneous thickening of the walls of the deeper vessels. Type IV collagen and laminin are increased around vessels.

The disease is caused by mutations in the extracellular matrix protein 1. Differentiation from erythropoietic protoporphyria may be difficult, especially histologically. Topical steroids, surgical removal of selected deposits, and occasional reports of improvement with systemic retinoids are treatments of limited benefit. One patient improved after 2 years of D-penicillamine treatment. While occasional patients die of respiratory obstruction in infancy, the disease is otherwise compatible with a normal lifespan.

ANGIOKERATOMA CORPORIS DIFFUSUM (FABRY DISEASE)

Also known as Anderson-Fabry disease, in angiokeratoma corporis diffusum (ACD), a storage disease, glycosphingolipids accumulates in the skin and viscera. The skin lesions are widespread punctate telangiectatic vascular papules that on first inspection suggest purpura. Some show hyperkeratotic tops, but this is less prominent than in other forms of angiokeratoma. Myriad tiny telangiectatic papules are seen, especially on the lower extremities, scrotum and penis, lower trunk, axillae, ears, oral mucous membranes (Fig. 26-28), and lips, where the small, sometimes linear, angiokeratomas are most numerous on the midline of the lower lip. Hair growth is scanty.

The deposits of glycolipids (ceramide trihexoside) occur in the endothelial cells, fibroblasts, and pericytes of the dermis, and in the heart, kidneys, and autonomic nervous system. Cardiac disease (cardiomyopathy) and renal insufficiency bring death, usually in the fifth decade. The disease may be limited to one organ, such as the heart or kidney. Edema of the ankles, paralyses, paresthesias manifested by a burning sensation of the hands and feet, and hypohidrosis are often present. Abnormal vascular structures are noted in the conjunctiva and eye-grounds. Distinctive whorl-like opacities of the cornea occur in 90%, and 50% develop characteristic spokelike cataracts in the posterior capsular location. The urine, in addition to albuminuria, may show "Maltese cross" material on polaroscopy, and glycolipids may be seen in the form of "mulberry cells" in the sediment.

The cause of the disease is a deficiency of α -galactosidase A. Inheritance is by an X-linked recessive route. Female

heterozygotes may show evidence of the disease in varying degrees; approximately 30% have angiokeratomas. The diagnosis can be confirmed by finding diminished levels of α -galactosidase A in leukocytes, serum, tears, skin fibroblasts, or amniotic fluid cells.

Histologically, there is dilation of capillaries in the papillary dermis, resulting in endothelium-lined lacunae filled with blood and surrounded by acanthotic and hyperkeratotic epidermis. Electron microscopy reveals characteristic electrondense bodies in endothelial cells, pericytes, and fibroblasts (Fig. 26-29). They are also present in normal skin of affected adults and children.

Laser treatment of the angiokeratomas is cosmetically helpful. Phenytoin, neurontin, and carbamazepine afford significant relief of pain. Enzyme replacement therapy is safe and can reverse substrate storage in the lysozyme.

FUCOSIDOSIS

Angiokeratomas identical to those of Fabry disease occur in this rare disorder. It can be distinguished clinically by the frequent presence of coarse thickening of the skin of the face, severe mental retardation, weakness, spasticity, and seizures.

Histologically, there are granule-filled vacuoles in endothelial and other cells. The defect, a lack of α -L-fucosidase, is transmitted as an autosomal-recessive trait. Progressive mental and motor deterioration begins in infancy and progresses, with death by age 18 to 20 as a rule.

SIALIDOSIS

Another disease manifesting Fabry-like angiokeratomas is caused by mutations in the sialidase gene NEU1, resulting in intracellular accumulation of sialiated oligosaccharides. Mental retardation, myoclonus, cerebellar ataxia, skeletal abnormalities, and coarse facies occur.

B-MANNOSIDASE DEFICIENCY

This is a rare autosomal-recessive disorder of glycoprotein metabolism. In addition to the Fabry-like angiokeratomas, mental retardation, hearing loss, aggressive behavior, peripheral neuropathy, recurrent infections, epilepsy, coarse facies, and skeletal abnormalities are often present.

Several patients with other rare autosomal-recessive lysosomal enzyme disorders, such as galactosialidosis, aspartylglycosaminuria, GM₁ gangliosidosis (β -galactosidase deficiency which may also manifest extensive dermal melanocytosis), and α -N-acetylgalactosaminidase deficiency (Kanzaki disease) have been reported to have Fabry-like angiokeratomas. Finally, several patients without any detectable enzyme deficiency have been reported. Among them was a family with autosomal-dominantly inherited Fabry-like angiokeratomas associated with arteriovenous malformations. It should be emphasized that there are many normal patients who have widespread small petechia-like lesions that erupt in adulthood. This is a variant of cherry angiomas.

NECROBIOSIS LIPOIDICA (NECROBIOSIS LIPOIDICA DIABETICORUM)

Necrobiosis lipoidica is characterized by well-circumscribed, firm, depressed, waxy, yellow-brown, lesions on the skin of persons who may also have diabetes mellitus. Women are three times more commonly affected than men.

The earliest changes are sharply bordered, elevated, small red papules; these may be capped by a slight scale and do not disappear under diascopic pressure. Later, the lesions develop into irregularly round or oval scleroderma-like lesions with well-defined borders and a smooth, glistening (glazed) surface. The center becomes depressed and sulfuryellow, so that a firm yellowish lesion forms, surrounded by a broad violet-red or pink border. In the yellow portion numerous telangiectases are evident. Ulceration is not unusual. Rarely, squamous cell carcinoma may occur in chronic ulcers.

The most common location of the lesions is the shins (Fig. 26-30); about 85% occur on the legs. A much less common site is the forearms, and they have been reported on the trunk, face, scalp, palms, and soles. Only rarely are sites exclusive of the legs present.

Sixty percent of patients with necrobiosis lipoidica have diabetes mellitus; another 20% will have glucose intolerance or a family history of diabetes. In 15%, necrobiosis lipoidica precedes the onset of frank diabetes by an average of 2 years. Control of the diabetes does not influence the course of the disease. Its incidence is 3 to 7 in 1000 diabetic patients.

The average age of onset is 34 years—22 years, on average, in insulin-dependent patients and 49 years in non-insulin-dependent patients.

Histologically, well-developed lesions of necrobiosis lipoidica demonstrate a superficial, deep, and interstitial inflammatory process that involves the whole reticular dermis and often the panniculus. Because the dermis is firm, punch biopsy specimens appear rectangular rather than tapered. The inflammatory cells include lymphocytes, histiocytes, multinucleate giant cells, and plasma cells. At low magnification there are layered palisaded granulomas with pale pink degenerated collagen alternating with ampophilic staining histiocytes. In contradistinction to granuloma annulare, mucin is not increased in the centers of the granulomas. The overlying epidermis tends to be thinned, with loss of the normal rete ridge pattern.

Treatment, after control of the diabetes is achieved, is not completely satisfactory. The best results have occurred after intralesional injections of triamcinolone suspension into the inflammatory papules and active advancing edges. Injection into the yellow center is of little benefit and may result in ulceration. Concerns about atrophy limit topical steroid use; however, in the actively inflamed early stage potent topical steroids with occlusion have produced resolution. Some cases have benefited from excision and skin grafts, but others have had recurrences in or at the edges of the grafts.

One series of six cases reported that systemic corticosteroids given over a 5-week period were effective in all patients treated and there was no recurrence after a mean follow-up of 7 months. Control of the diabetes was achieved by oral hypoglycemics or insulin. The atrophy did not improve. Pentoxifylline, chloroquine, nicotinamide, ticlopidine, topical PUVA, topical tacrolimus, cyclosporin, and tretinoin have been reported to be helpful in individual cases. Other case reports document that hyperbaric oxygen, topically applied bovine collagen, and cyclosporin are helpful in healing chronic ulcers. Spontaneous resolution may occur in 13% to 19% of patients after 6 to 12 years.

OTHER DIABETIC DERMADROMES

In addition to necrobiosis lipoidica, there are many cutaneous signs in this common endocrinopathy.

Diabetic Dermopathy (Shin Spots)

Dull-red papules that progress to well-circumscribed, small, round, atrophic, hyperpigmented lesions on the shins are the most common cutaneous sign of diabetes. Although they occur individually in people who do not have diabetes, if four or more are present the specificity is high for microvascular disease in other tissues. They are present in 50% of people with diabetes, most commonly men.

Diabetic Bullae

Noninflammatory, spontaneous, painless blistering, most often in acral locations, is characteristic (Fig. 26-31). Lesions heal spontaneously in 4 to 5 weeks, usually without scarring.

Both sub- and intra-epidermal locations have been reported as the site of blister formation, but in the authors' experience lesions are subepidermal. Electron microscopic studies show separation at the lamina lucida level. DIF is negative. UV light, trauma, neuropathy, and cation imbalance have all been hypothesized to be inciting factors to the blistering. There is a reduced threshold to suction-induced blistering in insulin-dependent diabetics.

Carotenosis

Carotenosis is a yellowish discoloration of the skin, especially of the palms and soles (Fig. 26-32), that is sometimes seen in diabetic patients. Of the 50% of diabetic persons who have carotenemia, about 10% have carotenosis. The sclerae remain white. There may be night blindness (delayed dark adaptation) as a result of reduced conversion of carotene to vitamin A in the liver.

Limited Joint Mobility and Waxy Skin

Limited joint mobility and waxy skin are important not only because of the 30% to 50% prevalence of these conditions in diabetic patients with long-standing disease, but also because they are associated with microvascular complications, such as nephropathy and retinopathy. Joint symptoms begin with limitation of joint mobility in the fifth finger at the metacarpophalangeal and proximal joints and progress radially to the other fingers. It is bilateral, symmetrical, and painless. Involvement of the feet also occurs and is thought to contribute to the development of chronic ulcerations. Such open sores on the neuropathic, microvascularly compromised, infection-prone diabetic foot pose a constant threat to life and limb.

Other Associated Conditions in Patients with Diabetes

Various abnormalities associated with diabetes are erysipelaslike erythema of the legs or feet; sweating disturbances; paresthesias of the legs; mal perforans ulcerations; a predisposition to certain infections such as mucormycosis, group B streptococcal infections, nonclostridial gas gangrene, and malignant external otitis resulting from *Pseudomonas*; disseminated granuloma annulare; eruptive xanthomas; clear cell syringomas; eruptive xanthomas; rubeosis of the face; lipodystrophy; acquired perforating disorders; acanthosis nigricans; skin tags; Dupuytren contracture; and fingerpebbling.

OTHER METABOLIC DISORDERS

CITRULLINEMIA

Citrullinemia occurs in two forms. Type I is caused by a deficiency of the enzyme argininosuccinic acid synthetase. This enzyme converts citrulline and aspartic acid to argininosuccinic acid, as a part of the urea cycle. Low plasma arginine levels result, and the hypothesis is that since keratin is 16% arginine, dermatitis may occur. Neonates who present with severe deficiencies and hyperammonemic crises may develop erosive, erythematous, scaling patches, and plaques prominent in the perioral, lower abdominal, diaper, and buttock regions. This eruption clears with arginine supplementation. Short, sparse hair may also be present. Cirtullinemia type II is due to a defect in the SCL25A13 gene and is seen nearly exclusively in adult Japanese patients.

In carbamoyl phosphate synthetase deficiency, low plasma arginine levels may also occur, and similar cutaneous findings have been reported in this second metabolic defect of the urea cycle.

Diets high in arginine will heal the skin lesions.

HARTNUP DISEASE

Hartnup disease is an inbom error of tryptophan excretion; it was named after the Hartnup family, in which it was first noted. The outstanding findings are a pellagra-like dermatitis following exposure to sunlight, intermittent cerebellar ataxia, psychiatric manifestations, and constant aninoaciduria.

The dermatitis occurs on exposed parts of the skin, chiefly the face, neck, hands, and legs. The erythematous scaly patches flare up into a hot, red, exudative state after exposure to sunlight, followed after subsidence by hyperpigmentation. Stomatitis and vulvitis also occur. The disease becomes milder with increasing age. Hartnup disease is an autosomalrecessive trait. Large amounts of indole-3-acetic acid and indican are secreted in the urine. Hartnup disease is caused by mutations in the SLC6A19 gene on chromosome 5. SLC6A19 transports neutral amino acids across the apical membrane of epithelial cells. The skin lesions respond to niacinamide, 200 mg/day.

PROLIDASE DEFICIENCY

Prolidase deficiency is an autosomal-recessive inherited inborn error of metabolism. Prolidase, or peptidase D, cleaves dipeptides containing C-terminal proline or hydroxyproline. When this enzyme is deficient, the normal recycling of proline residues obtained from collagen degradation is impaired. A build-up of iminodipeptides results, with disturbances in connective tissue metabolism and excretion of large amounts of iminodipeptides in the urine. Also, the absence of prolidase activity causes the activation of a necrosis-like cellular death, which may be responsible for the skin lesions.

Clinically, 85% of patients have some dermatologic manifestations. The most important cutaneous signs, which almost always appear before the affected person is 12 years old, are skin fragility, ulceration, and scarring of the lower extremities; photosensitivity and telangiectasia; poliosis; scaly, erythematous, maculopapular, and purpuric lesions; and thickening of the skin with lymphedema. Systemic signs and symptoms include mental deficiency, splenomegaly, and recurrent infections. An unusual facial appearance is noted at times, with low hairline, frontal bossing, and saddle nose. Prolidase measurement may be determined in erythrocytes, leukocytes, or fibroblasts. Many therapeutic options have been described, such as oral supplements of manganese and ascorbic acid, both modulators of prolidase activity; however, results of treatment are highly variable. Apheresis exchange repeated monthly may improve the leg ulcers. In longstanding ulcerations squamous cell carcinomas may occur.

PHENYLKETONURIA

Phenylketonuria, an autosomal-recessive disorder of phenylalanine metabolism, is characterized by mental deficiency; epileptic seizures; the presence of phenylpyruvic acid in the urine; pigmentary dilution of skin, hair, and eyes; pseudoscleroderma; and dermatitis (Fig. 26-33). It is most common in white persons. Phenylalanine hydroxylase is lacking in the liver and also in peripheral lymphocytes. Phenylalanine is therefore not oxidized to tyrosine.

Fig. 26-33 Light skinned, light haired PKU patient with dermatitis. (Courtesy of Jeff Miller, MD)

Fig. 26-34 Ochronotic pigmentation of ear cartilage.

Affected children are blue eyed, with blond hair and fair skin. They are usually extremely sensitive to light, and about 50% have an eczematous dermatitis. It is clinically similar to atopic dermatitis, with a predilection for the flexures. It is worst in the youngest patients, may improve with dietary treatment, and has been exacerbated by phenylalanine challenge in a carrier of the recessive gene. Skin lesions may be sclerodermatous in nature. Indurations of the thighs and buttocks are present early in infancy and increase with time. After many years the lesions soften and become atrophic.

Blood levels of phenylalanine are high. The presence of phenylpyruvic acid in the urine is demonstrated by a characteristic deep-green color when a few drops of ferric chloride solution are added to it. Green diapers occur in histidinemia as well as in phenylketonuria.

In developed countries universal screening is practiced so dietary therapy with phenylalanine restriction combined with supplementation of tyrosine and other amino acids may be instituted. This prevents the manifestations of the disease. If compliance is poor, the manifestations, including eczema, may develop at any age, followed by improvement of the skin with reinstitution of the diet.

Nova MP, et al: Scleroderma-like skin indurations in a child with phenylketonuria. J Am Acad Dermatol 1992;26:329.

ALKAPTONURIA AND OCHRONOSIS

Alkaptonuria, inherited as an autosomal-recessive trait, is caused by the lack of renal and hepatic homogentisic acid oxidase, the enzyme necessary for the catabolism of homogentisic acid to acetoacetic and fumaric acids. It is characterized by the excretion of homogentisic acid in the urine to produce a black-staining urine, the deposition of a grossly brown-black pigment in the connective tissue, and ochronotic arthropathy.

In patients with alkaptonuria the voided urine is dark and on standing turns black from the homogentisic acid. For many years the dark urine may be the only indication of the presence of alkaptonuria. In the meantime, large amounts of homogentisic acid are accumulated in the body tissues. By the third decade of life the deposition of pigment becomes apparent. Cartilage is preferentially affected. The early sign is the pigmentation of the sclera (Osler's sign) and the cartilage of the ears (Fig. 26-34). Later the cartilage of the nose and tendons, especially those on the hands, become discolored.

Blue or mottled brown macules appear on the skin. The bluish macules have a predilection for the fingers, ears, nose, genital regions, apices of the axillae, and buccal and vaginal mucosa. Palmoplantar pigmentation may occur. The sweat glands are rich in ochronotic pigment granules, and the intradermal injection of epinephrine into the skin of the axillary vault will yield brown-black sweat droplets in the follicular orifices. The cerumen is often black. Internally, the larynx, great vessels, and valves of the heart, kidneys, esophagus, tonsils, and dura mater may be involved.

Histologically, there are large, irregular ochre bodies within the reticular dermis. They represent degenerated elastic fibers with deposition of ochronotic pigment and stain black with crystal violet or methylene blue.

Ochronotic arthropathy involves the spinal joints first, resembling osteoarthritis. Next affected are the knees, shoulders, and hips. Radiographic films show a characteristic appearance of early calcification of the intervertebral disk and later narrowing of the intervertebral spaces with eventual disk collapse.

There is no effective treatment. Nitisinone, used in treating tyrosinemai type I, inhibits the enzyme that produces homogentisic acid. Its safety and efficacy in alkaptonuria is being investigated.

Exogenous Ochronosis

Topically applied phenolic intermediates such as hydroquinone, carbolic acid (phenol), picric acid, and resorcinol may produce exogenous ochronosis (Fig. 26-35). Hydroquinone specifically inhibits the enzyme homogentisic acid oxidase locally, resulting in accumulation of this substance on the collagen fibers in tissues where it is applied. Histologically, exogenous ochronosis and alkaptonuria have identical changes on skin biopsy (Fig. 26-36). Treatment with dermabrasion and the CO₂ and Q-switched alexandrite lasers.

WILSON'S DISEASE (HEPATOLENTICULAR DEGENERATION)

Wilson's disease is an autosomal-recessive derangement of copper transport. Affected persons develop hepatomegaly, splenomegaly, and neuropsychiatric changes. Slurred speech, a squeaky voice, salivation, dysphagia, tremors, incoordination, and spasticity may all occur. There is progressive, fatal hepatic and central nervous system degeneration. The body retains an excessive amount of copper, leading to damage to the liver and brain. As a result, azure lunulae (sky-blue moons) of the nails occur in 10% of patients, and the smoky, greenish-brown Kayser-Fleischer rings develop at the edges of the corneas. Hyperpigmentation develops on the lower extremities in most patients. A vague greenish discoloration of the skin on the face, neck, and genitalia may also be present. An idiopathic blistering eruption that ceased with treatment of Wilson's disease has been reported. Skin changes of cirrhosis (vascular spiders and palmar erythema) may occur. Low ceruloplasmin level in the serum is diagnostic.

The disease is caused by the synthesis of a defective coppertransporting enzyme, P-type ATPase (ATP7B), leading to accumulation of copper in the brain, liver, and kidney. The treatment is o-penicillamine, which removes copper by chelating it. The dose is 1 or 2 g/day orally. Potential side effects include pemphigus, cutis laxa, and elastosis perforans serpiginosa, which has been reported repeatedly in Wilson patients on penicillamine. Treatment must be continued for life.

TYROSINEMIA II (RICHNER-HANHART SYNDROME)

Tyrosinemia is an autosomal-recessive syndrome resulting from a deficiency of hepatic tyrosine aminotransferase. Serum tyrosine ranges from 200 to 300 μ mol/100 mL (norma), \leq 10). Clinical features are mild-to-severe keratitis, and hyperkeratotic and erosive lesions of palms and soles, often with mental retardation. Photophobia and tearing commonly occur as the keratitis begins, and ultimately neovascularization is seen. Painful palmar and plantar erosions and hyperkeratoses usually appear within the first year of life, weeks to months after the eye lesions. Thigh skin, grafted to the heel, is spared. A low tyrosine, low phenylalanine diet may improve or prevent the eye and skin lesions but may or may not benefit the mental retardation.

HURLER SYNDROME (MUCOPOLYSACCHARIDOSIS I)

Hurler syndrome, or gargoylism, is an autosomal-recessive disorder of mucopolysaccharide metabolism. A deficiency of α -L-iduronidase is the causative defect. It is characterized by mental retardation, hepatosplenomegaly, umbilical and inguinal hernia, genital infantilism, corneal opacities, and skin abnormalities. Patients with Hurler syndrome have gargoylelike features, with a broad saddle nose, thick lips, and a large tongue. The skin is thickened, with ridges and grooves, especially on the upper half of the body. Fine lanugo hair is profusely distributed all over the body. Large, coarse hair is prominent, especially on the extremities. Dermal melanocytosis characterized by extensive, blue pigmentation with both a dorsal and ventral distribution, indistinct borders, and a persistent and/or progressive course occurs in some patients with lysosomal storage disease, including patients with Hurler syndrome, Hunter syndrome, and GM1gangliosidosis type 1. The skeletal system is deformed, with hydrocephalus, kyphosis, and gibbus (cat-back shape). The hands are broad and have clawlike fingers. The joints are distorted.

The two acid mucopolysaccharides, dermatan sulfate and heparan sulfate, are produced excessively in gargoylism, so that in many tissues there is an accumulation, and they are excreted in the urine in large amounts. Dried urine on filter paper will show a purple color when acetic acid followed by toluidine blue reagent is added.

Prenatal diagnosis is possible. Bone marrow transplantation is the most effective treatment of Husler syndrome. It can prevent dementia if performed early enough. Enzyme replacement therapy with recombinant human α -L-idronidase is also effective in treating the attenuated forms of Husler syndrome (those without neuronal involvement).

- Hanson M, et al: Association of dermal melanocytosis with lysosomal storage disease. Arch Dermatol 2003;139:916.

HUNTER SYNDROME

Hunter syndrome is X-linked mucopolysaccharidosis (MPS) II. The clinical features are similar to those of Hurler syndrome and are characterized by an excessive storage and excretion of mucopolysaccharides. The relative mildness and mode of inheritance distinguish it from Hurler syndrome. The pebbly lesions of MPS II in the skin over the inferior angles of the scapulas represent the only diagnostic skin changes of the MPSs. These are firm, flesh-colored to white papules and nodules, which coalesce (Fig. 26-37). They are most common on the back, but may be seen on the pectoral areas, nape of the neck, and lateral aspects of the arms and thighs. They generally occur at about age 10. Additionally, the dermal melanocytosis described above with Hurler syndrome may occur in Hunter syndrome.

The deficient enzyme is iduronate-2-sulfatase. Dermatan sulfate and heparin sulfate are excreted in the urine in large amounts. Hematopoietic stem cell transplantation has limited efficacy but does result in the disappearance of the pebbly lesions within a month of the procedure.

MORQUIO'S DISEASE (MUCOPOLYSACCHARIDOSIS IV)

This autosomal-recessive disorder is characterized by dwarfism, prognathism, corneal opacities, deafness, progressive kyphoscoliosis, flat feet, and knock-knees. The standing position is a crouch. There is increased excretion of keratan sulfate. The enzyme deficiencies are galactosamine-6-sulfate sulfatase in Morquio A and β -galactosidase in Morquio B.

- Chudley AE, et al: Genetic landmarks through philately. Clin Genet 2002;62:438.
- Urban Z, et al: Elastic-fiber pathologies. Am J Hum Genet 2000;67:4.

HYALURONIDASE DEFICIENCY (MUCOPOLYSACCHARIDOSIS IX)

A deficiency of hyaluronidase, caused by mutations in HYAL1, leads to short stature, erosions of the acetabula, and multiple periauricular soft-tissue masses. There is no neurologic or visceral involvement. Hyaluronan is an extracellular matrix component important for cell migration, cellular proliferation and differentiation, and is a structural component of connective tissue. Turnover of this glycosaminoglycan is dependent upon hyaluronidases, each of which has different tissue expression patterns, likely explaining the mild phenotype of this newly described condition.

Trigs-Raine B, et al: Mutations in HYAL1, a member of a tandemly distributed multigene family encoding disparate hyaluonidase activities, cause a newly described lysosomal disorder, mucopolysaccharidosis IX. Proc Natl Acad Sci USA 1999;96:6296.

LAFORA'S DISEASE

Lafora's disease is an autosomal-recessive form of progressive epilepsy beginning at puberty. It is characterized by myoclonic jerks followed by progressive ataxia, dysphagia, dysarthria, dementia, and death in early adulthood. Diagnosis is established in the proper clinical setting by demonstration of characteristic PAS-positive cytoplasmic inclusion bodies in the eccrine ducts, axillary apocrine myoepithelial cells (Fig. 26-38), and peripheral nerves. The best site to biopsy is the axilla. Other conditions in which similar polyglucosan inclusions can be seen include normal aging (amyloid bodies), double athetosis syndrome, amyotrophic lateral sclerosis, and glycogen storage disease, type IV.

Cutaneous manifestations are rare. Papulonodular lesions on the ears and indurated, thickened plaques on the arms have been reported. Large amounts of acid mucopolysaccharides were demonstrated histologically in these lesions. In 80% of patients the disease is caused by a mutation in the EPM2A gene, which encodes lafin protein tyrosine phosphatase Abnormalities in an additional locus, EPM2B, which encodes the laforin binding partner protein malin, suggests an alteration in microtubular axonal and dendritic transport to be causative. There is no treatment.

Karimipour D, et al: Lafora's disease. J Am Acad Dermatol 1999; 41:790.

CADASIL SYNDROME

Cerebral autosomal-dominant arteriopathy with subcortical infarcts and leukoencephalopathy is a neurovascular disease of young and middle-aged people. Children have cognitive impairment, young adults depression and migrane headaches, and those in their 40s and 50s experience multi-infarct dementia. One patient developed generalized hemorrhagic macules and papules. There is deposition of a granular

Fig. 26-38 PASstained inclusions in Lafora disease. eosinophilc material, NOTCH 3, in the media of arterial walls due to mutations in the NOTCH intercellular signaling pathways. This may be demonstrated on skin biopsy by electron microscopy or by a specific immunostain.

Walsh JS, et al: CADASIL. J Am Acad Dermatol 2000;43:1125.

FARBER DISEASE

Also known as fibrocytic dysmucopolysaccharidosis and lipogranulomatosis, Farber disease is characterized by periarticular swellings; a weak, hoarse cry; pulmonary failure; painful joint deformities; and motor and mental retardation. The onset is during the first months of life; death can be expected before the age of 2.

The rubbery subcutaneous nodules have a distinct yellowish hue and are 1 to 2 cm in diameter. They are usually located over the joints, lumbar spine, scalp, and weightbearing areas. Histologically, they are granulomas. Diagnosis can be aided by finding Farber bodies (curvilinear bodies) within the cytoplasm or phagosomes of fibroblasts, histiocytes, or endothelial cells, banana-shaped bodies within Schwann cells, and zebra bodies within endothelial cells and neurons. There is an accumulation of ceramide and its degradation products in foam cells due to a specific deficiency of lysosomal ceramidase.

- Levade T, et al: Neurodegenerative course in ceramidase deficiency (Farber disease) correlates with the residual lysosomal ceramide turnover in cultured living patient cells. J Neurol Sci 1995;134:108.
- Rauch HJ, et al: Banana bodies in disseminated lipogranulomatosis (Farber disease). Am J Dermatopathol 1983;5:263.

ADRENOLEUKODYSTROPHY (SCHILDER'S DISEASE)

Adrenoleukodystrophy (ALD) is an X-linked disorder in which cerebral white matter becomes progressively demyelinated and serious adrenocortical insufficiency usually occurs. Skin hyperpigmentation often calls attention to the adrenal disease, and mental deterioration indicates the even graver diagnosis of ALD. A mild ichthyotic appearance to the skin of the trunk and legs and sparse hair with trichorrhexis nodosa-like features may occur. Skin biopsies may show characteristic vacuolization of eccrine secretory coils (duct cells being spared), and biopsies of the skin and conjunctiva may show diagnostic clefts in Schwann cells surrounding myelinated axons. Mutations are in the ABCD1 gene, leading to abnormalities in a peroxisomal ABC half-transporter, involved in the import of very long-chain fatty acids into the peroxisome. Bone marrow transplantation may prevent dementia and result in a better quality of life.

GOUT

Classic gout presents as an acute monoarthritis, usually of the great toe or knee, in a middle-aged to elderly man with hyperuricemia. In such patients with chronic disease, usually present for more than 10 years, monosodium urate monohydrate may be deposited in the subcutaneous tissues, forming nodules called tophi. These vary from pinhead- to pea-sized or, rarely, even baseball-sized. They are commonly found on the rims of the ears and over the distal interphalangeal articulations (Fig. 26-39). Tophi are of a yellow or cream color. In the course of time they tend to break down and discharge sodium urate crystals, afterward healing and perhaps breaking down again. The diagnosis is verified histologically by finding the characteristic long, needle-shaped crystals of monosodium urate. Because routine processing dissolves these deposits, fixation in absolute ethanol or freezing is optimal for their demonstration. Atypical gout occurs as a polyarticular chronic arthritis, often of the hands. It occurs equally in women as in men, and there may be tophi, frequently overlying Hebreden nodes, at presentation. Another risk group is organ transplant patients of whom 10% develop gout. Acute arthritis is treated with NSAIDs, prednisone or colchicines, while long-term management is with uricosuric agents or xanthine oxidase inhibitors.

LESCH-NYHAN SYNDROME

Also known as *juvenile gout*, Lesch-Nyhan syndrome is a rare, X-linked, recessively-inherited disorder characterized by childhood hyperuricemía, gout, tophi (Fig. 26-40), choreo-athetosis, progressive mental retardation, and self-mutilation.

The cutaneous lesions are distinctive. Massive selfmutilation of lips with the teeth occurs. The fingers are also badly chewed. The ears and nose are occasionally mutilated. An early diagnostic clue is orange crystals in the diaper. The blood uric acid is increased and allopurinol, 200 to 400 mg/ day, is given. There is a marked deficiency in an enzyme of purine metabolism, hypoxanthine guanine phosphoribosyltransferase (HGPRT).

CHAPTER

27 Genodermatoses and Congenital Anomalies

Genetic disorders are often grouped into three categories: chromosomal, single gene, and polygenetic. Chromosomal disorders can be numerical, such as trisomy and monosomy, or structural, resulting from translocations or deletions. Most genodermatoses show single-gene or mendelian inheritance (autosomal-dominant, autosomal-recessive, or X-linked recessive genes). Polygenetic syndromes often involve complex interactions of genes.

Autosomal-dominant conditions require only a single gene to produce a given phenotype. Usually the patient has one affected parent or is affected by a new mutation. The disease is transmitted from generation to generation. Autosomalrecessive traits require a homozygous state to produce the abnormality. The pedigree will often reveal parental consanguinity. Parents will be clinically unaffected but often have affected relatives. X-linked conditions occur when the mutant gene is carried on the X chromosome. If a disease is X-linked recessive, the loss is evident in males (XY) who do not have a second X chromosome to express the normal allele. Therefore, X-linked recessive traits occur almost exclusively in males. They cannot transmit the disease to sons (who inherit their Y chromosome), but all their daughters will be carriers. Carrier females who are heterozygous (having one normal and one abnormal X chromosome) occasionally show some subtle evidence of the disease. This occurs as a result of Lyonization (the physiologic segmental inactivation of one of the X-chromosomes). X-linked dominant disease states are commonly lethal in males. Survival is possible in females who retain a normal allele. As the mutation is commonly lethal in many affected cell lines, females commonly demonstrate loss of normal tissue in the affected segments (loss of digits, microphthalmia, loss of teeth). X-linked dominant traits result in pedigrees in which more than one female is affected but no males express the disease. Rarely, males may survive, especially if they have Kleinfelter syndrome (XXY).

Mosaicism is the presence of two or more genetically distinct cell lines in a single individual. It may occur as a result of physiologic inactivation of one X-chromosome (Lyonization) or as the result of post-zygotic somatic mutation. Mosaicism often presents in a linear and whorled pattern along the lines of Blaschko. In mosaic states, genes that are detrimental to a cell population during fetal development often result in thin segments that are overgrown by the adjacent normal tissue. Genes that confer a growth advantage during fetal development (e.g. mutated tumor suppressor genes) may result in broader plaque-type lesions that have grown beyond the boundaries of a typical Blaschko segment. In autosomal-dominant conditions, a normal allele remains, but is not enough to prevent disease. Loss of heterozygosity (LOH) is the segmental loss of this remaining normal allele. LOH may give rise to segments of the body with an exaggerated presentation of the syndrome. The affected area corresponds to a Blaschko segment or plaque. The forehead plaque of tuberous sclerosis is related to a mutation in a tumor suppressor gene. The loss of the tumor suppressor gene imparts a growth advantage and loss of heterozygosity leaves no suppressor gene product in the segment. As a result, the affected segment grows beyond its Blaschko boundaries forming a broad plaque.

When a patient presents with segmental distribution of a disorder, it is critical to determine if the disorder is a result of mosaicism or LOH. In the latter case, the abnormal allele is present throughout the body, with loss of the normal remaining allele in the affected segment. In a patient who presents with segmental neurofibromatosis, but has Lisch nodules or axillary freckling, LOH rather than mosaicism is likely to account for the segmental presentation. The risk of passing the gene to a child is roughly 50:50. A geneticist should be involved during discussions of risk of transmission, as the mechanisms may be complex. Patients with mosaicism based on post-zygotic somatic gene mutation may have gonadal mosaicism and be capable of passing on the gene. Gonadal mosaicism is more likely when more than one segment is present on different regions of the body. During embryonic development, cells are dedicated to produce segments of the body at about the time of gastrulation (when a cavity forms in the embryo). Prior to gastrulation, every cell is pleuripotent and can give rise to an entire organism, or contribute to multiple sites of the body. Blaschko segments in different regions suggest a mutation that occurred prior to gastrulation when the involved cell lines could contribute to different parts of the body, including the gonads.

X-LINKED, MOSAIC, AND RELATED DISORDERS

INCONTINENTIA PIGMENTI

Also known as Bloch-Sulzberger disease, incontinentia pigmenti is an X-linked dominant condition characterized by spattered pigmentation on the trunk preceded by vesicular and verrucous changes. It appears in girls during the first weeks after birth. Most lesions are evident by the time the infant is 4 to 6 weeks old. A vesicular phase is present in 87% of cases. This first stage begins in most individuals before 6 weeks of age and is replaced by vertucous lesions after several weeks to months in two-thirds of patients. Although these usually resolve by 1 year of age, lesions may persist for many years. In the third, or pigmentary, phase, pigmented macules in streaks, sprays, splatters, and whorls follow the lines of Blaschko. The pigmentary stage may last for many years and then fade away, leaving no sequelae. A fourth stage may be seen in some adult women, manifesting subtle, faint, hypochromic or atrophic linear lesions, most commonly on the extremities.

Histologically, the vesicular stage is characterized by spongiosis with eosinophils. As the lesions mature, clusters of dyskeratotic cells appear within the epidermis. Dyskeratotic cells predominate in the vertucous stage, and pigmented incontinence (dermal melanophages) predominates in hyperpigmented lesions.

Other cutaneous changes include patchy alopecia at the vertex of the scalp, atrophic changes simulating acrodermatitis chronica atrophicans on the hands, onychodystrophy, subungual tumors with underlying lytic bone lesions, and palmoplantar hyperhidrosis. Extracutaneous manifestations occur in 70% to 90% of patients. Most commonly involved are the teeth (up to 90%), bones (40%), central nervous system (CNS) (33%), and eyes (35%). Immune dysfunction with defective neutrophil chemotaxis and elevated IgE has been reported. Eosinophilia is common.

Dental abnormalities usually manifest by the time the individual is 2 years old. Dental defects include delayed eruption, partial anodontia (43%), microdontia, and cone- or peg-shaped teeth (30%). The most common CNS findings are seizures (13%), mental retardation (12%), spastic paralysis (11%), microcephaly, destructive encephalopathy, and motor retardation. The eye changes include strabismus, cataracts, retinal detachments, optic atrophy, blue sclerae, and exudative chorioretinitis. Skeletal abnormalities include syndactyly, skull deformities, dwarfism, spina bifida, club foot, supernumerary ribs, hemiatrophy, and shortening of the legs and arms.

Incontinentia pigmenti is caused by a mutation in the NEMO gene on the X chromosome, localized to Xq28. The gene is generally lethal in male fetuses, although males with Klinefelter syndrome (47,XXY) may survive. Mosaicism may also account for some cases in males.

Incontinentia pigmenti achromians differs in that it is a negative image, with hypopigmentation (see below). It has autosomal-dominant in inheritance, no vesicular or verrucous stages, and a higher incidence of CNS abnormalities. Patients with linear and whorled nevoid hypermelanosis lack the vesicular and verrucous phases.

There is no treatment for incontinentia pigmenti. Use of ruby lasers to treat pigmented lesions in infants and young children is not necessary and may worsen the condition. Usually the end stage of streaks of incontinentia pigmenti start to fade at age 2, and by adulthood there may be little residual pigmentation.

NAEGELI-FRANCESCHETTI-JADASSOHN SYNDROME

Also known as the chromatophore nevus of Naegeli, Naegeli-Franceschetti-Jadassohn syndrome differs from incontinentia pigmenti in that the pigmentation is reticular and there are no preceding inflammatory changes, vesiculation, or verrucous lesions. Vasomotor changes and hypohidrosis are present. There is reticulate pigmentation involving the neck, flexural skin, and perioral and periorbital areas. Diffuse keratoderma and punctiform accentuation of the palms and soles may occur. Dermatoglyphics are abnormal, producing atrophic or absent ridges on fingerprints.

Congenital malalignment of the great toenails may be found. Dental abnormalities are common, and many patients are edentulous. Both sexes are equally affected, and the syndrome appears to be transmitted as an autosomaldominant trait, with linkage to chromosome 17q.

INCONTINENTIA PIGMENTI ACHROMIANS (HYPOMELANOSIS OF ITO)

Incontinentia pigmenti achromians (IPA) is characterized by various patterns of bilateral or unilateral hypopigmentation following the lines of Blaschko. The lesions suggest the "negative image" of incontinentia pigmenti and usually develop by the first year of life. The female-to-male ratio is about 2.5:1. Three-quarters of affected individuals have associated anomalies of the CNS, eyes, hair, teeth, skin, nails, musculoskeletal system, or internal organs. Patients may manifest psychomotor or mental retardation, autism, microcephaly, coarse facies, and dysmorphic ears. Some patients have had associated Sturge-Weber syndrome-like leptomeningeal angiomatosis.

More than half of these patients have chromosomal abnormalities, with most demonstrating mosaicism for an euploidy or unbalanced translocations. Several patients have demonstrated trisomy 13 mosaicism. No inflammatory changes or vesiculation are found before the development of the hypopigmentation. There is no treatment, but eventual repigmentation is the rule.

Failla P, et al: Hypomelanosis of Ito: a syndrome requiring a multisystem approach. Australas J Dermatol 1997;38:65. Garcia Muret MP, et al: Hypomelanosis of Ito with Sturge-Weber syndrome-like leptomeningeal angiomatosis. Pediatr Dermatol 2002;19:536.

LINEAR AND WHORLED NEVOID HYPERMELANOSIS

This disorder of pigmentation develops within a few weeks of birth and progresses for 1 to 2 years before stabilizing. There is linear and whorled hyperpigmentation following the lines of Blaschko without preceding bullae or verrucous lesions. Sparing of mucous membranes, eyes, palms, and soles is noted. Congenital anomalies, such as mental retardation, cerebral palsy, atrial septal defects, dextrocardia, auricular atresia, and patent ductus arteriosus may be present. Bilateral giant cerebral aneurysms have been reported. There is no sexual predilection. Biopsy of pigmented areas demonstrates increased pigmentation of the basal layer and prominence of melanocytes without incontinence of pigment.

Most cases appear to be sporadic although familial cases have been reported. Sporadic forms have been attributed to mosaicism. Because of confusion with other pigmented disorders, such as incontinentia pigmenti, early linear epidermal nevi, hypomelanosis of Ito, and nevus depigmentosus, it is likely that linear and whorled nevoid hypermelanosis may be more common than previously appreciated.

- Mendiratta V, et al: Linear and whorled nevoid hypermelanosis. J Dermatol 2001;28:58.

CHONDRODYSPLASIA PUNCTATA

A variant of the original *Conradi-Hünermann syndrome* or *chondrodystrophia calcificans congenita*, chondrodysplasia punctata is characterized by ichthyosis of the skin similar to that of the collodion baby, followed by hyperkeratotic "whirł and swirl" patterns on erythematous skin. In addition to reddening, the waxy, shiny skin has hyperkeratotic scales of a peculiar crushed-eggshell configuration. As the child grows, follicular atrophoderma and pseudopelade develop. Usually the ichthyosis clears within the first year of life but may leave behind hyperpigmentation similar to that seen in incontinentia pigmenti. An additional feature is minor nail defects, such as platonychia and onychoschizia.

There are four forms of chondrodysplasia punctata, which are classified by their inheritance patterns. The Conradi-Hünermann type is associated with autosomal-dominant inheritance, facial dysmorphia with a low nasal bridge, short stature, mild disease, cataracts, and few skin lesions. The rhizomelic form has autosomal-recessive inheritance, marked shortening of the extremities, cataracts, ichthyosis, and nasal hypoplasia; the patient dies in infancy. The X-linked recessive type has been described as part of contiguous gene deletion syndromes, with short stature, telebrachydactyly, and nasal hypoplasia. The X-linked dominant form (Happle syndrome, Conradi-Hünermann-Happle syndrome, or CDPX2) is lethal in males. Happle syndrome (X-linked dominant chondrodysplasia punctata) has ichthyosiform erythroderma along the lines of Blaschko, cataracts, asymmetrical limb shortening, and calcified stippling of the epiphyses of long bones. Follicular atrophoderma replaces the erythroderma after the first year.

The skeletal defects revealed on radiographic evaluation show irregular calcified stippling of the cartilaginous epiphyses in the long bones, costal cartilages, and vertebral diaphysis. The stippling occurs in the fetus and persists until age 3 or 4. The humeri and femurs may be shortened, and there may be joint dysplasia. Histologic evaluation of the ichthyotic lesions reveals a thinned, granular cell layer, calcification of keratotic follicular plugs, and focal hyperpigmentation of basal keratinocytes. The keratotic follicular plugs and calcium deposits are characteristic of this disease and very helpful in establishing the diagnosis in newborns. The syndrome is caused by mutations in an emopamil-binding protein, important in the cholesterol biosynthesis pathway.

KLINEFELTER SYNDROME

Klinefelter syndrome, the most common sex chromosome disorder, consists of hypogonadism, gynecomastia, eunuchoidism, small or absent testicles, and elevated gonadotropins. There may be a low frontal hairline, sparse body hair with only a (ew hairs in the axillary and pubic areas, scanty or absent (acial hair in men, and shortening of the fifth digit of both hands.

Thrombophlebitis and recurrent or chronic leg ulcerations may be a presenting manifestation; these may be more common than previously reported. The cause of the hypercoagulable state is believed to be an increase in plasminogen activator inhibitor-1 levels. Patients are at an increased risk of a variety of cancers, especially male breast cancer, hematologic malignancies, and sarcomas (retinoblastoma and rhabdomyosarcoma).

Many of these patients are tall; some are obese. Dull mentality or misbehavior is frequent, and psychiatric disorders occur in about one-third of these patients. Klinefelter syndrome is most frequently associated with an XXY sex chromosome pattern, although other variations occur as the number of X chromosomes increases. Marked improvement in appearance has been achieved by the injection of testosterone.

XXYY GENOTYPE

The XXYY genotype is considered to be a variant of Klinefelter syndrome. In addition to the changes seen in Klinefelter, there are vascular changes, such as cutaneous angiomas, acrocyanosis, and peripheral vascular disease leading to stasis dermatitis.

- Swerdlow AJ, et al: Cancer incidence and morality in men with Klinefelter syndrome: a cohort study. J Natl Cancer Inst 2005;97:1204.

TURNER SYNDROME

Turner syndrome, also known as gonadal dysgenesis, is characterized by a webbed neck, low posterior hairline margin, increased carrying angle at the elbow (cubitus valgus), congenital lymphedema, and a triangular mouth. Patients may demonstrate alopecia of the frontal area on the scalp, koilonychia, cutis laxa, cutis hyperelastica, mental retardation, short stature, infantilism, retarded sexual development, primary amenorrhea, numerous melanocytic nevi, and an increased risk of melanoma and thyroid disease. Coarctation of the aorta is frequently found. There may be an increased incidence of alopecia areata and halo nevi in these patients.

These patients have only 45 chromosomes rather than the normal 46. An X chromosome is missing, resulting in an XO genotype. Mosaicism, structural abnormalities of the X chromosome, or a partial deficiency of one sex chromosome may account for a number of the variations in gonadal dysgenesis. Several genetic loci have been implicated, including the short stature homeobox gene. Loss of long-arm material (Xq) can result in short stature and ovarian failure, but deletions distal to Xq21 do not appear to affect stature. Loss of the short arm (Xp) produces the full phenotype. Very distal Xp deletions usually have normal ovarian function. No specific treatment is available. Growth hormone (hGH) has been shown to be effective in treating the short stature. A review of the Cochrane Central Register of Controlled Trials determined that hGH increases short-term growth, but there are few data regarding its effects on final height.

Sybert VP, et al: Turner's syndrome. N Engl J Med 2004; 351:1227.

NOONAN SYNDROME

Noonan syndrome is an autosomal-dominant disease with a webbed neck that mimics Turner syndrome. Males and females are equally affected, and the chromosome number is normal. The major features are a characteristic facies with hypertelorism, prominent ears, webbed neck, short stature, undescended testicles, low posterior neck hairline, cardiovascular abnormalities (pulmonary stenosis and hypertrophic cardiomyopathy), and cubitus valgus. Some 25% to 40% of patients have dermatologic findings: lymphedema; short, curly hair; dystrophic nails; a tendency toward keloid formation; soft, elastic skin; keratosis pilaris atrophicans (ulerythema of the eyebrows); and abnormal dermatoglyphics. The Noonan syndrome gene, PTPN11, encodes the nonreceptor protein tyrosine phosphatase SHP-2.

MULTIPLE-LENTIGINES (LEOPARD) SYNDROME

The LEOPARD (multiple lentigines, electrocardiographicconduction abnormalities, ocular hypertelorism, pulmonary stenosis, abnormal genitalia, retardation of growth, and sensorineural deafness) syndrome is also known as the multiple lentigines syndrome, Gorlin syndrome II, cardiocutaneous syndrome, lentiginosis profusa syndrome, or progressive cardiomyopathic lentiginosis. The lentigines are small, dark brown, polygonal, and irregularly shaped macules, usually measuring 2 to 5 mm in diameter. Individual lesions may be larger, even up to 1 to 1.5 cm. LEOPARD syndrome shares many clinical features with Noonan syndrome. They are allelic disorders, as patients with both syndromes demonstrate mutations in the Noonan syndrome gene. PTPN11. Although the "R" in LEOPARD stands for growth retardation, some individuals with the syndrome also exhibit mild mental retardation or speech difficulties. Many cases appear sporadically; however, inheritance as an autosomaldominant genetic trait has also been reported.

CARDIO-FACIO-CUTANEOUS SYNDROME

Cardio-facio-cutaneous syndrome is a congenital condition manifested by numerous anomalies. Typical features include a characteristic craniofacial appearance, psychomotor and growth retardation, congenital cardiac defects, and skin and hair abnormalities. The most frequent dermatologic finding is hair that is sparse, curly, fine or thick, woolly or brittle. In more than half of the reported cases, the patient has dry, scaly, or "hyperkeratotic," ichthyotic skin.

Other cutaneous findings include sparse or absent eyebrows and eyelashes, low posterior hairline, patchy alopecia, scant body hair, follicular hyperkeratosis, keratosis pilaris, keratosis pilaris atrophicans faciei, palmoplantar keratoderma, seborrheic dermatitis, eczema, lymphedema, hemangiomas, café-au-lait spots, pigmented nevi, hyperpigmented macules or stripes, cutis marmorata, and sacral dimples. Nail dystrophy, koilonychia, and dysplastic teeth have also been reported.

The differential diagnosis includes Noonan syndrome, Turner syndrome, Pallister-Killian mosaic aneuploid syndrome (mosaic tetrasomy 12p/trisomy 12p), and Costello syndrome. The difficulty often arises in assessing the facial features, which are similar in all of these syndromes. Exclusion of PTPN11 mutations in cardio-facio-cutaneous syndrome and Costello syndrome confirms distinct genetic etiologies. Deletion of the long arm of chromosome 12, del(12)(q21.2q22), has been associated with cardio-facio-cutaneous syndrome.

- Tartaglia M, et al: Exclusion of PTPN11 mutations in Costello syndrome: further evidence for distinct genetic etiologies for Noonan, cardio-facio-cutaneous and Costello syndromes. Clin Genet 2003;63:423.

PHAKOMATOSES

The phakomatoses are the various inherited disorders of the CNS that have congenital retinal tumors and cutaneous involvement. They include tuberous sclerosis, von Recklinghausen's disease (neurofibromatosis), von Hippel-Lindau disease (angiomatosis retinae), ataxia-telangiectasia, nevoid basal cell carcinoma syndrome, nevus sebaceus, and Sturge-Weber syndrome.

TUBEROUS SCLEROSIS (EPILOIA, BOURNEVILLE DISEASE)

Tuberous sclerosis, described by Desiree-Magloire Bourneville in 1880, is also called *epiloia* (*epi* = epilepsy, *loi* = low intel-

Fig. 27-1 Angiofibromas (adenoma sebaceum).

Fig. 27-2 Periungual fibromas (Koenen tumors). (Courtesy of Brooke Army Medical Center Teaching File)

ligence, a = adenoma sebaceum). This classic triad of adenoma sebaceum (Fig. 27-1), mental deficiency, and epilepsy, however, is present in only a minority of patients. Other associated features include periungual fibromas (Fig. 27-2), shagreen plaques (collagenoma), oral papillomatosis, ash-leaf hypomelanotic macules (Fig. 27-3), skin fibromas, and café-au-lait spots.

Adenoma sebaceum (angiofibromas) are 1- to 3-mm, yellowish-red, translucent, discrete, waxy papules that are distributed symmetrically, principally over the cheeks, nose, and forehead. They have also been reported in patients with multiple endocrine neoplasia (MEN 1). These lesions are present in 90% of patients older than 4 years of age, persist indefinitely, and may increase in number.

Shagreen plaque is named after a type of leather tanned to produce knobs on the surface, resembling shark skin. Patches of this type of "knobby" skin, varying from 1 to 8 cm in diameter, are found on the trunk, most commonly on the lumbosacral area. They are connective tissue nevi composed almost exclusively of collagen. They occur in 40% of patients and develop in the first decade of life.

Koenen tumors (periungual angiofibromas) (Fig. 27-4) occur in 50% of patients. The tumors are small, digitate, protruding, asymptomatic, and periungual and/or subungual. They have their onset at puberty. Similar lesions may occur on the gingiva.

Fig. 27-3 Ash-leaf macules.

Fig. 27-4 Periungual fibromas.

Congenital white leaf-shaped macules, called *hypomelanotic macules*, are found in 85% of patients with tuberous sclerosis, their number ranging from 1 to 100. Occasional patients may not develop them until they are 6 to 8 years of age. They may be shaped like an ash leaf, but linear and confetti-type white macules may also be present. Wood's light examination should be performed when evaluating a patient for tuberous sclerosis. Focal poliosis (localized tufts of white hair) may be present at birth. Solitary ash-leaf macules are not uncommon in the general population and may be confused with other hypopigmented macules, such as nevus depigmentosus.

Mental deficiency, usually appreciated early in life, is present in 40% to 60% of patients, varying widely in its manifestations. Epilepsy also occurs, is variable in its severity, and usually also presents early in life. Eighty to 90% of patients have seizures or nonspecific electroencephalographic abnormalities. Hamartomatous proliferations of glial and neuronal tissue produce potato-like nodules in the cortex. X-ray evaluation will reveal these once they are calcified, but computed tomographic (CT) scans, cranial ultrasonography, and magnetic resonance imaging (MRI) may define these lesions as early as 6 weeks of age, and thus are useful in making an early diagnosis. These brain tumors may progress to gliomas. Subependymal nodules (candle drippings) are similar lesions in the ventricular walls. Astrocytomas may also occur.

Retinal tumors (phakomas) occur, which are optic nerve or retinal nerve hamartomas. Various ophthalmologic findings, such as pigmentary changes, nystagmus, and angioid streaks, occur in 50% of patients.

Renal hamartomas (angiomyolipomas [45%], cystic disease [18%], fibroadenomas, or mixed tumors) and cardiac tumors (rhabdomyomas [43%]) may also occur. In the familial variety of tuberous sclerosis, 80% of patients have angiomyolipomas, which are often bilateral and frequently cause renal failure. Women of childbearing age may present with pulmonary lymphangioleiomyomatosis with progressive respiratory failure or spontaneous pneumothorax. The condition is characterized by diffuse proliferation of smooth muscle cells and cystic degeneration of the pulmonary parenchyma. Nearly half of patients with epiloia have bony abnormalities such as bone cysts and sclerosis, which can be seen on x-ray evaluation. Five or more pits in the enamel of permanent teeth are a marker for this disease.

Tuberous sclerosis is a common inherited autosomaldominant disease with highly variable penetrance. Prevalence estimates range from 1 in 5800 to 1 in 15,000. Up to 50% of cases may occur as a result of spontaneous mutations.

There are two genes, the mutations of which produce indistinguishable phenotypes—9q34 (TSC1) and 16p13.3 (TSC2). TSC1 and TSC2 are tumor suppressor genes. TSC2 encodes for tuberin, a putative GTPase-activating protein for rap1 and rab5. TSC1 encodes for hamartin, a novel protein with no significant homology to tuberin or any other vertebrate protein. Hamartin and tuberin associate physically in vivo, suggesting that they function in the same complex rather than in separate pathways. This interaction of tuberin and hamartin explains the indistinguishable phenotypes caused by mutations in either gene. Hamartomas frequently demonstrate loss of the remaining normal allele (loss of heretozygosity).

Diagnosis

The ash-leaf macules are usually present at birth and most easily seen with a Wood's light. If X-ray examination fails to show calcified intracranial nodules, ultrasonography, a CT scan or MRI should be performed. Funduscopic examination, hand and foot x-ray evaluation, and renal ultrasonography are often rewarding in a patient with few clinical findings, as up to 31% of asymptomatic parents have been identified using these tests.

Multiple periungual fibromas are highly correlated with the syndrome, but solitary fibromas may occur in unaffected individuals. Molecular analysis for TSC1 and TSC2 may be the only way to ultimately identify "mildly affected" individuals.

Treatment

Adenoma sebaceum can be treated by shaving, dermabrasion, or laser therapy. Lesions are likely to recur, requiring repeat treatment. Cranial irradiation of astrocytomas should be avoided because this may result in the subsequent development of glioblastomas.

NEUROFIBROMATOSIS (VON RECKLINGHAUSEN'S DISEASE)

Neurofibromatosis is an autosomal-dominantly inherited syndrome manifested by developmental changes in the nervous system, bones, and skin. In type 1 neurofibromatosis (NF-1, von Recklinghausen's disease), which includes more than 85% of cases, patients have many neurofibromas, caféau-lait spots, axillary freckles (Fig. 27-5), giant pigmented hairy nevi, sacral hypertrichosis, cutis verticis gyrata, and macroglossia. Neurofibromas of the areolae occur in more than 90% of women with this disease. Lisch nodules (Fig. 27-6) are found in the irides of about one-quarter of patients under 6 years of age and in 94% of adult patients. Type 2 neurofibromatosis, central or acoustic neurofibromatosis, is distinguished by bilateral acoustic neuromas, usually in the absence of cutaneous lesions, although neurofibromas and schwannomas may occur. Type 3 (mixed) and 4 (variant) forms resemble type 2 but have cotaneous neurofibromas.

Fig. 27-5 Axillary freckling,

Neurofibromas are soft tumors that can be pushed down into the panniculus by light pressure with the finger ("buttonholing") and spring back when released. Histologically, they are well circumscribed, but rarely encapsulated, spindle cell proliferations with a mucinous background and many mast cells. The spindle cells have a wavy appearance. Neurofibromas occur as a result of proliferation of all supporting elements of the nerve fibers. The proliferation is composed of Schwann cells, perineurial cells, endoneurial cells, mast cells, and blood vessels. Axon stains demonstrate individual axons spread randomly throughout the tumor.

Subcutaneous plexiform neurofibromas are virtually pathognomonic of NF-1 and may be a manifestation of LOH. They occur as large nodules containing multiple encapsulated neurofibromas. The overlying skin is usually hyperpigmented. On palpation, they resemble a "bag of worms." Histologically, they demonstrate numerous elongated encapsulated neurofibromas, often embedded in diffuse neurofibroma that involves the dermis and subcutaneous fat.

The café-au-lait macule is a uniformly pigmented, smooth edged, light brown macule. Most often, they are present at birth and almost always present by the time the patient is 1 year of age. The finding of six or more of these lesions at least 1.5 cm in diameter is diagnostic, usually indicating NF-1. In children, the minimum diameter for a significant lesion is 0.5 cm. Histologically, basilar hyperpigmentation is noted, and giant melanosomes may be seen. Axillary freckling (Crowe's sign) may occur, extending to the neck and involving the inguinal, genital, and perineal areas.

Many organ systems may be involved. Acromegaly, cretinism, hyperparathyroidism, myxedema, pheochromocytoma (<1%), or precocious puberty may be present. Bone changes (usually erosive) may produce lordosis, kyphosis, and pseudoarthrosis, as well as spina bifida, dislocations, and atraumatic fractures. Neuromas of spinal nerves may cause various paralyses. Patients with NF-1 are four times more likely to develop malignancies than the general population. Cutaneous neurofibromas rarely develop into neurofibrosarcomas (malignant schwannomas), but a growing or hardening lesion is an indication for biopsy. Wilms tumor, rhabdomyosarcomas, gastrointestinal malignancies, and chronic myelogenous leukemia have also been reported. Xanthogranulomas are associated with a higher incidence of chronic myelogenous leukemia. Children with NF-1 are 200 to 500 times more likely to develop malignant myeloid disorders than agematched controls.

Mental retardation, dementia, epilepsy, and a variety of intracranial malignancies may occur. Hypertelorism heralds a severe expression of neurofibromatosis with brain involvement. Diffuse interstitial lung disease occurs in 7% of patients.

Approximately 50% of cases of NF-1 represent new mutations. The gene for NF-1 is in the pericentric region of chromosome 17q11.2 and codes for neurofibromin, a protein that negatively regulates signals transduced by Ras proteins. The gene for NF-2 is on the long arm of chromosome 22q11-q13 and encodes for merlin (schwannomin), a protein that links the actin cytoskeleton to cell-surface glycoproteins and functions as a negative growth regulator.

Diagnosis

The diagnosis of NF-1 requires two or more of the following criteria: 1) six or more café-au-lait macules of more than

Fig. 27-6 Lisch nodules. (Courtesy of Brooke Army Medical Center Teaching File)

Fig. 27-7 Segmental neurofibromatosis.

Patients with these types are at greater risk for developing optic gliomas, neurilemomas, and meningiomas. These forms are inherited as autosomal-dominant traits. Segmental neurofibromatosis (Fig. 27-7) may arise from postzygotic somatic mutation or loss of heterozygosity (LOH). 5 mm in greatest diameter in prepubertal individuals, and more than 15 mm in greatest diameter in postpubertal individuals; 2) two or more neurofibromas of any type or one plexiform neurofibroma; 3) freckling in the axillary or inguinal regions; 4) optic glioma; 5) two or more Lisch nodules; 6) a distinctive osseous lesion, such as a sphenoid dysplasia or thinning of the long bone cortex with or without pseudarthrosis; and 7) a first-degree relative (parent, sibling, or offspring) with the disease.

A diagnosis of NF-2 requires either of the following: 1) bilateral eighth nerve masses as demonstrated on CT or MRI; or 2) having a first-degree relative with NF-2 and either unilateral eighth nerve mass or two of the following: a neuro-fibroma, meningioma, glioma, schwannoma, and juvenile posterior subcapsular lenticular opacity.

Screening and Monitoring for Complications

In one study of 93 asymptomatic patients with NF-1 who underwent cerebral imaging, 12 optic gliomas were detected, suggesting that screening MRI or CT scans may be of value. However, this is a single study, and the results have not been validated by other authors. The National Institutes of Health (NIH) consensus panel concluded that studies should be dictated by findings on clinical evaluation. It concluded that laboratory tests in asymptomatic patients are unlikely to be of value. In the majority of patients with NF-1, imaging studies should only be performed as indicated by signs or symptoms. NF-2 patients, in contrast, often require imaging studies. Screening studies should include an audiogram and brainstem auditory evoked responses. MRI is the best imaging procedure for patients with evidence of hearing impairments or abnormal evoked responses. Tests of vestibular function may be useful, as eighth nerve tumors develop on the vestibular division. A screening MRI should be performed by puberty. Other tests should be performed as dictated by signs and symptoms. Pediatric patients with NF-2 have a worse prognosis, with 75% demonstrating hearing loss, 83% visual impairment, and 25% abnormal ambulation.

PROTEUS SYNDROME

Although not a phakomatosis, Proteus syndrome may be confused with neurofibromatosis. This rare sporadic disease is named after the Greek god Proteus who could change shape. The syndrome has protean manifestations that include partial gigantism of the hands and feet, cerebriform plantar hyperplasia (Fig. 27-8), hemangiomas, lipomas, lipohypoplasia, linear verrucous epidermal nevi, patchy dermal hypoplasia, macrocephaly, hyperostosis, muscular hypoplasia, and hypertrophy of the long bones. Many investigators believe that Joseph Merrick, who was known as "the Elephant Man," had Proteus syndrome rather than neurofibromatosis. It is believed to be caused by a somatic mutation, lethal in the nonmosaic state. Those patients with a greater number of cutaneous lesions also have the most extracutaneous abnormalities. The findings of both overgrowth (pleioproteus component) and hypoplasia (elattoproteus component) in the same patient may be a manifestation of genetic twin spotting (didymosis), overexpression, and deficiency of a gene product. Although mutations in PTEN have been reported in up to 20% of patients with Proteus syndromelike findings, no patients have been found in other studies of patients with the syndrome. Those patients with PTEN mutations are best classified as having the PTEN hamartomatumor syndrome. Somatic PTEN mutations also occur in sporadic primary tumors, including endometrial carcinomas and glioblastoma multiforme.

VON HIPPEL-LINDAU SYNDROME

von Hippel-Lindau syndrome is an autosomal-dominant disorder consisting of retinal angiomas, cerebellar medullary angioblastic tumors, pancreatic cysts, and renal tumors and cysts. Usually the skin is not involved, although occasionally angiomas may occur in the occipitocervical region. The syndrome is associated with a germline mutation of a tumor suppressor gene on the short arm of chromosome 3.

Ten to 20% of cerebellar hemangioblastomas produce erythropoietin and are accompanied by a secondary polycythemia. Ocular lesions may lead to retinal detachment. Ten percent of hypernephromas and less than 8% of renal cysts also produce erythropoietin. Pheochromocytoma has been associated in several kindreds with von Hippel-Lindau disease.

Lonser RR, et al: von Hippel-Lindau disease. Lancet 2003; 361:2059.

ATAXIA-TELANGIECTASIA

Also known as Louis-Bar syndrome, ataxia-telangiectasia consists of cerebellar ataxia, oculocutaneous telangiectasia, and sinopulmonary infection. It is familial and is usually first noted when the child begins to walk. There is awkwardness and a swaying gait, which by about 10 years of age results in the child needing to use a wheelchair. Choreic and athetoid movements and pseudopalsy of the eyes are other features. Fine telangiectases appear on the exposed surfaces of the conjunctiva at about age 3. Nystagmus is present. Telangiectases also appear later on the butterfly area of the face, inside the helix, and over the backs of the ears (Fig. 27-9), in the roof of the mouth, the necklace area, the flexures, and over the dorsa of the hands and feet. Other stigmata are café-au-lait patches, hypopigmented macules, seborrheic dermatitis, premature graving and sparsity of the hair, and progeroid features. The skin tends to be dry and coarse, and in time becomes tight and inelastic, as in

Fig. 27-9 Ataxiatelanglectasia.

scleroderma. Atrophic, granulomatous, scarring plaques may occur. Early death from bronchiectasis occurs in more than half of these patients, most of whom suffer from recurrent sinus and lung infections that begin when the patient is between 3 and 8 years of age.

Patients may have a marked IgA deficiency, with decreased lymphocytes and a small to absent thymus. The most common types of malignancies are lymphomas, usually of the B-cell type, and leukemias. It has been shown that homozygous patients also have a higher risk of breast cancer—100 times higher than age-matched controls. Heterozygous carriers share the defective repair of radiation-induced damage, and there is a three- to five-fold higher risk for development of neoplasms, especially breast cancer, in heterozygotes under the age of 45. The ovaries and testicles do not develop normally. There is deficient thymus development, with absence of Hassall's corpuscles, and a lack of T-helper cells. Suppressor T-cells are normal. In 80% of cases, IgA is absent or deficient, in 75% absent or deficient IgE is seen, and in 50% IgG is very low.

Ataxia-telangiectasia is transmitted as an autosomalrecessive trait, and heterozygotes, although they lack clinical findings, are cancer prone. The gene has been designated ATM (ataxia-telangiectasia mutated gene) and is a member of a family of phosphatidylinositol-3-kinase-like enzymes that are involved in cell-cycle control, meiotic recombination, telomere length monitoring, and DNA-damage response. Affected cells are hypersensitive to ionizing radiation and are defective at the G1/S check-point after radiation damage. They are abnormally resistant to inhibition of DNA synthesis by ionizing radiation. The ATM gene is located on chromosome 11q22.3. Translocations are common in these patients, particularly for chromosomes 7 and 14. A high prevalence of ATM gene mutations has also been found in a diverse array of sporadic lymphoproliferative disorders.

Early diagnosis can be difficult and the most frequent misdiagnosis is cerebral palsy. Persistently elevated levels of α -fetoprotein and carcinoembryonic antigen occur. These may be useful in early diagnosis. In culture, ataxia-telangiectasia fibroblasts are three times more sensitive to killing by ionizing radiation, but not ultraviolet light. Evaluations for elevated α -fetoprotein and radiosensitivity of fibroblasts used to be the standard for diagnosis of this disorder, but immunoblotting the ATM protein expression is now possible.

EPIDERMOLYSIS BULLOSA

Epidermolysis bullosa (EB) is a group of rare genetic disorders that have in common the formation of blisters in

Fig. 27-10 Epidermolyis bullosa simplex.

Fig. 27-11 Epidermolyis bullosa simplex.

be at the roof; and in junctional types bullous pemphigoid antigen will be on the roof, while type IV collagen and LDA-1 will be at the base. KF-1 has been found to be absent or diminished in dystrophic EB. The specific keratin abnormalities along with the abnormal genes have been identified for many of these disorders. Many types of EB simplex are caused by defects in genes encoding for keratins 5 and 14. In junctional EB there are defective genes encoding for kallidin/laminin 5. Dystrophic forms result from mutations in type VII collagen gene COL7A1.

Intraepidermal Forms

Epidermolysis Bullosa Simplex (Koebner) The generalized type of EB simplex (EBS), dominantly inherited, with complete penetrance, occurs in 1 in 500,000 births. It is characterized by the development of vesicles, bullae, and milia over the joints of the hands (Fig. 27-10), elbows, knees, and feet (Fig. 27-11), and other sites subject to repeated trauma. The child is affected at birth or shortly thereafter, with improvement within the first few months, only to recur when the child begins crawling or later. in childhood. The blistering is worse during the summer and improves during the winter. The lesions are sparse and do not lead to severe atrophy. The Nikolsky sign is negative. Usually the mucous membranes and nails are not involved. EBS is usually milder than other forms of EB.

Box 27-1 Inherited types of epidermolysis bullosa (EB)

Intraepidermal

- EB simplex, generalized (Koebner)
- EB simplex, localized (Weber-Cockayne)
- EB herpetiformis (Dowling-Meara)
- EB simplex (Ogna)
- EB simplex with mottled pigmentation
- EB with muscular dystrophy

Junctional (intralamina lucida)

- Junction EB (JEB) atrophicans generalisata gravis (Herlitz, EB letalis)
- JEB atrophicans generalisata mitis
- JEB atrophicans localisata
- JEB atrophicans inversa
- JEB progressiva
- JEB with pyloric atresia
- Generalized atrophic benign EB (GABEB)
- Cicatricial junctional EB

Dermolytic or dystrophic (sublamina densa)

- Dystrophic EB, albopapuloid variant (Pasini)
- Bart syndrome
- Transient bullous dermolysis of the newborn
- Acrokeratotic poikiloderma (Weary-Kindler)
- 2. Recessive forms
 - Generalized (gravis or mitis)
 - Localized
 - Inverse

response to minor physical injury. Treatment consists of prevention of trauma, decompression of large blisters, and treatment of infection. EB acquisita is an autoimmune disease, discussed in Chapter 21.

The inherited types of EB are classified as in Box 27-1.

Internal involvement may occur in several of these subtypes of EB. Esophageal and laryngeal complications are seen primarily in recessive dystrophic EB, but may be present in junctional EB (Herlitz). Pyloric atresia is reported to occur in junctional EB. Ocular lesions may be severe in dystrophic EB, and mild lesions have been reported in simplex and junctional disease.

Clinical findings and routine histologic features overlap, and accurate diagnosis depends on genetic mutation mapping, electron microscopic studies or immunofluorescent mapping. The latter two can identify the level of the epidermal separation, and in addition may define other defects, such as absence of anchoring fibrils or hypoplasia of hemidesmosomes. In recessive dystrophic EB, electron microscopy reveals the cleavage is below the basal lamina and that anchoring fibrils are diminished or absent.

Immunofluorescent mapping may define the level of the split without resorting to electron microscopy. By staining biopsy specimens for normal components of the basement membrane zone, such as bullous pemphigoid antigen, laminin, type IV collagen, or LDA-1 antigen, the level of the split may be determined by whether the antigen localizes at the roof or base of the blister. In simplex types, all of these components will be at the base; in dystrophic types, all will Inherited as an autosomal-dominant trait, EBS is a disease in which keratin gene mutations cause the production of defective intermediate filaments, which lead to epidermal basal cell fragility and subsequent blistering. Gene mutations produce abnormalities in keratins 5 and 14, keratins expressed in the basal cell layer. Patients heterozygous for abnormal keratin 14 have blistering limited to the hands and leet, but homozygotes have more severe and widespread blistering of the skin and mucous membranes.

Separation occurs through the basal cell layer. Rubbing skin with an eraser may lead to a subclinical lesion that demonstrates the split histologically.

Localized Epidermolysis Bullosa Simplex Recurrent bullous eruption of the hands and feet (Weber-Cockayne) is autosomal-dominantly determined and appears in a chronic form in infancy or at times later in life. The lesions exacerbate during hot weather and when the patient is subjected to prolonged walking or marching, as is experienced in military service. Hyperhidrosis may be an associated finding. In localized EBS, the bullae are intraepidermal and suprabasal, and healing occurs without scarring.

Application of aluminum chloride hexahydrate in anhydrous ethanol (Drysol) on the normal skin of hands and feet twice a day has been shown to reduce blistering in this form of EB. After 2 weeks of daily therapy the patient can be switched to once or twice weekly applications.

Epidermolysis Bullosa Herpetiformis (Dowling-Meara) In this autosomal-dominant variant of EBS, active blisters with circinate configuration occur in infancy. Milia may develop, but there is no scarring. The oral mucosa is involved. Nails are shed but may regrow, sometimes with dystrophy. Blistering lessens with age. Hyperkeratosis of the palms and soles may occur. Histologically, the split is through the basal layer, and tonofilaments are clumped on electron microscopy. Point mutations have been shown in keratin 5 and 14 genes.

Epidermolysis Bullosa Simplex (Ogna) Generalized bruising and hemorrhagic blisters occur. It is transmitted as an autosomal-dominant trait. At birth there are small, acral, traumatic sanguinous blisters. The basal keratinocytes in this syndrome do not stain with antiplectin antibodies.

Epidermolysis Bullosa Simplex with Mottled Pigmentation One Swedish family has been reported with autosomal-dominant EBS with congenital scattered hyper- and hypo-pigmented macules which fade slowly after birth. The remaining features are similar to those of generalized EBS. Ultrastructural studies show vacuolization of the basal cell layer.

Epidermolysis Bullosa Simplex with Muscular Dystrophy There is a form of EBS associated with lateonset neuromuscular disease. It is inherited as an autosomalrecessive trait. There is widespread blistering at birth associated with scarring, milia, atrophy, nail dystrophy, dental anomalies, laryngeal webs, and urethral strictures. Progressive muscular dystrophy with weakness and wasting begins in childhood or later. This disease is caused by a mutation in the plectin gene, with affected patients having absent plectin in their skin and muscles.

Junctional Forms

Junctional Epidermolysis Bullosa (Epidermolysis Bullosa Letalis, Epidermolysis Bullosa Herlitz) In junctional EB, a rare type, which has autosomal-recessive transmission, severe generalized blistering may be present at birth, and extensive denudation may prove fatal within a few months. There is generalized blistering with relative sparing of the hands, and characteristic perioral and perinasal hypertrophic granulation tissue. Eventually the lesions heal without scarring or milia formation, but erosions may persist for years. Dysplastic teeth are common. Laryngeal and bronchial lesions may cause respiratory distress and even death. Additional systemic complications include gastrointestinal tract, gallbladder, corneal, and vaginal disease. In patients who survive infancy, there is growth retardation, and moderateto-severe refractory anemia is frequent. Separation occurs in the lamina lucida, as shown by electron microscopy.

Herlitz junctional EB is caused by mutations in three genes: LAMA3, LAMB3, or LAMC2, which code for polypeptide subunits of laminin 5.

In addition to good wound care and control of infection, epidermal autographs of cultured keratinocytes, isolated from clinically uninvolved skin and grown on collagen sponges, may be useful for chronic facial erosions. Complete re-epithelialization is achieved over 7 to 10 months.

Junctional Epidermolysis Bullosa with Pyloric Atresia This rare autosomal-recessively inherited form of junctional EB presents at birth with severe mucocutaneous fragility and gastric outlet obstruction. Even if the pyloric atresia is repaired, the neonates may die because of the severity of their skin disease. If they survive the neonatal period, the blistering diminishes. Persistent scarring of the urinary tract may occur, however, with stenosis of the ureteral-vesicular junction, requiring numerous urologic procedures. This syndrome is caused by a genetic mutation in either the $\alpha 6$ or $\beta 4$ integrin genes (ITGA6 and ITGB4). This $\alpha 6-\beta 4$ integrin complex is uniquely expressed on epithelial surfaces.

Generalized Atrophic Benign Epidermolysis Bullosa Most cases of generalized atrophic benign EB are characterized by onset at birth, generalized blisters and atrophy, mucosal involvement, and thickened, dystrophic, or absent nails. Enamel defects in deciduous and permanent teeth and atrophic alopecia are prominent features. Multiple cutaneous squamous cell carcinomas have been reported. Cleavage is within the lamina lucida, and hemidesmosomes are reduced or absent. The basal lamina, anchoring fibrils, collagen fibers, and denmal microfibril bundles are unaltered. Inheritance is autosomal recessive. In contrast to EB Herlitz, patients often survive to adulthood. Studies have shown mutations in the COL17A1 gene encoding for type XVII collagen (BPAg2), a transmembrane component of hemidesmosomes.

Cicatricial Junctional Epidermolysis Bullosa In 1985, Haber et al described another type of junctional EB, which they named cicatricial junctional epidermolysis bullosa, because the blisters heal with scarring, which may produce syndactyly and contractures, and there is stenosis of the anterior nares. Electron microscopy reveals junctional

bullae with rudimentary hemidesmosomes. The bases of the bullae are covered by an intact basal lamina with normal anchoring fibrils.

Dermolytic or Dystrophic Forms

The cause of dystrophic EB in both autosomal-dominantly and -recessively inherited forms is mutations in the COL7A1 gene encoding for type VII collagen. The anchoring fibrils in these patients are defective or deficient.

Dominant Dystrophic Epidermolysis Bullosa On the extensor surfaces of the extremities, vesicles and bullae appear; these are most pronounced over the joints, especially over the toes (Fig. 27-12), fingers, knuckles, ankles, and elbows. Spontaneous, flesh-colored, scarlike (albopapuloid) lesions may appear on the trunk, often in adolescence, with no previous trauma. The nails may be thickened. Usually the Nikolsky sign is present, and frequently the accumulated fluid in a bulla can be moved under the skin several centimeters away from the original site. Healing usually occurs with scarring and atrophy. Milia are often present on the rims of the ears, dorsal surfaces of the hands, and extensor surfaces of the aims and legs.

The mucous membranes are frequently involved. Bullae, vesicles, and erosions are encountered on the buccal mucosa, tongue, palate, esophagus, pharynx, and larynx. The latter involvement is manifested by persistent hoarseness in some of these patients. There may be angular contractures at the gingivolabial sulcus and dysphagia from pharyngeal scarring. Scarring on the tip of the tongue is typical. The teeth are normal. Usually the conjunctiva is not involved.

Other changes include nail dystrophy, partial alopecia of the scalp, absence of body hair, dwarfism, and the formation of contractures and clawlike hands, with atrophy of the phalangeal bones and pseudosyndactylism. The albopapuloid type (Pasini) is the more severe expression of dominant dystrophic EB. The Cockayne-Touraine type is more limited in extent and severity, and no albopapuloid lesions are seen.

Histologically, a noninflammatory subepidermal bulla is generally present. On electron microscopy, cleavage occurs beneath the basal lamina, and anchoring fibrils are rudimen-

Fig. 27-12 Epidermolvsis bullosa, dominant dystrophic.

tary and reduced in number. In blistered areas they are not demonstrable.

Autologous meshed split-thickness skin grafts and allogeneic cultured keratinocytes may be used in treating nonhealing skin defects. In many patients with dominant dystrophic EB, blistering reduces with time and only nail dystrophy may be present in adulthood.

Bart Syndrome Bart described congenital localized defects of the skin, mechanoblisters, and nail deformities with autosomal-dominant inheritance. Although the clinical and histologic picture of this syndrome is one of a mildly scarring mechanobullous dermatosis with a favorable prognosis, associations with mandibulolacial dysostosis, renal aplasia, and congenital abnormalities of the lower extremities have been reported. Bart syndrome is a clinical variant of dominant dystrophic EB, based on identification of a defect in the COL7A1 gene (chromosome 3p) encoding for type VII collagen.

Transient Bullous Dermolysis of the Newborn In 1985. Hashimoto et al reported a newborn who developed blisters from every minor trauma. Separation was below the basal lamina, with degeneration of collagen and anchoring fibrils. There was rapid healing by 4 months of age. Nails were not damaged, and there was no scarring.

They considered as criteria for this entity: 1) vesiculobullous lesions present at birth or induced by friction; 2) spontaneous recovery at a few months of age; 3) no dystrophic scars; 4) subepidermal blisters beginning in the dermal papillae; 5) ultrastructurally observed collagenolysis and damaged anchoring fibrils, and 6) enormous dilation of rough endoplasmic reticulum, with stellate bodies of keratinocytes in their vacuoles.

The cause has been shown in one family to be a transversion mutation in the COL7A1 gene encoding for type VII collagen, and it is therefore allelic with other variants of dominant dystrophic EB. The mechanism for the transient nature of reduced amounts of type VII collagen along the dermoepidermal junction remains to be defined.

Acrokeratotic Poikiloderma (Kindler, Weary-Kindler) In 1954, Kindler reported a combination of poikiloderma congenitale and traumatic blistering of the feet from minor trauma. It shares some clinical features with dominant dystrophic EB, but in the largest reported familial cluster, inheritance followed an autosomal-recessive pattern. Characteristic features include skin fragility with blistering, congenital acral bullae, generalized poikiloderma with prominent atrophy, photosensitivity, acral keratoses, severe periodontal disease, and phimosis. Pseudoainhum and sclerotic bands were reported in one case. The principal histologic change is absence of elastic fibers in the papillary dermis and fragmented ones in the mid-dermis. Ultrastructural studies have shown replication of the lamina densa.

Recessive Dystrophic Epidermolysis Bullosa (Hallopeau-Siemens) There are three variants of recessive dystrophic EB-generalized, localized, and inverse. The generalized type has two variants: a mild or mitis form and the severe (Hallopeau-Siemens) variety. All forms result from mutations in the gene encoding type VII collagen,

Fig. 27-13 Epidermolyis bullosa, recessive dystrophic type.

COL7A1. Generalized recessive dystrophic EB in its mild (mitis) form has blisters limited primarily to the hands, feet, elbows, and knees, and limited complications. The more severe variety characteristically begins at birth with generalized cutaneous and mucosal blistering. Digital fusion with encasement of the fingers and toes in scar tissues, forming a "mitten-like" deformity (Fig. 27-13), is characteristic of the severe form of recessive dystrophic EB, occurring in up to 90% of patients by age 25. Dental complications may be severe, such as rampant dental caries and microstomia. Esophageal stricture may be present. Anemia and growth retardation are frequently seen in the most severe cases, and progressive nutritional deficiency can result in fatal cardiomyopathy. Fatal systemic amyloidosis (AA type) has also been reported. There is a high risk of developing cutaneous squamous cell carcinomas (SCCs), with up to 50% of patients affected by age 35. These SCCs may be multiple and can metastasize and cause death.

Treatment remains primarily palliative. Debilitating oral lesions produce pain, scarring, and microstomia. Aggressive dental intervention is recommended. Nutritional support is of critical importance. Autologous meshed split-thickness skin grafts and allogeneic cultured keratinocytes have been shown to be useful in treating nonhealing cutaneous defects, or they may be used for closure after removal of large cutaneous malignancies. Family education and referral to DEBRA (Dystrophic Epidermolysis Bullosa Research Association of America, 5 West 36 th Street, Room 404, New York, NY 10018, www.debra.org) is strongly recommended.

FAMILIAL BENIGN CHRONIC PEMPHIGUS (HAILEY-HAILEY DISEASE)

In 1939, Hailey and Hailey described a familial disease characterized by persistently recurrent bullous and vesicular dermatitis of the sides of the neck, axillae, and flexures (Fig. 27-14). The eruption may remain localized or may become widespread. Usually, intact blisters are not evident. Instead, the lesions appear as macerated plaques with a reticulated pattern of fissuring. Lesions may become thickly crusted and may resemble impetigo. Sometimes the center becomes dry and crusted and there is an actively inflammatory border that spreads peripherally, producing circinate and figurate patterns. The onset is usually in the late teens or early 20s.

The condition is typically worse during the summer. Lesions tend to recur at sites of prior involvement. A papular variant in the genital area has been described, simulating condylomata. There may be tenderness and enlargement of the regional lymph glands caused by secondary bacterial infection. Involvement of the esophagus, mouth, and labia majora is rare. Hailey-Hailey's disease is inherited in an autosomal-dominant manner. Thirty percent of patients express new mutations. The disease is due to a genetic defect in a calcium ATPase (ATP2C1) on chromosome 3q21.

In predisposed persons with Hailey-Hailey's disease, skin trauma, bacterial or fungal infection, and dermatoses may trigger lesions. Sunburn may also exacerbate the disease. Widespread bullous lesions may occur in response to drug eruptions, and be misdiagnosed as toxic epidermal necrolysis. The histopathologic picture is unique. There is acanthosis and full-thickness acantholysis resembling a "dilapidated brick wall." The basal cell layer remains attached to the dermis.

The treatment of Hailey-Hailey is difficult. Many cases improve with the use of systemic antibiotics effective against Staphylococcus aureus, topical clindamycin, antifungal agents, or mupirocin. Corticosteroids, administered topically, systemically, or both, have shown response. Cyclosporin, oral retinoids, topical calcineurin inhibitors, topical calcitriof, botulinum toxin, photodynamic therapy, and dapsone have been used in severe cases. Dermabrasion and CO_2 laser vaporization have been shown to be effective, as the epidermis heals from uninvolved adnexal structures. Grafting has been helpful in the most severe forms of the disease.

DISORDERS OF CORNIFICATION (ICHTHYOSES AND ICHTHYOSIFORM SYNDROMES)

The term *ichthyosis* is derived from the Greek word *ichthys*, meaning "fish." Ichthyosis is not one disease but a group of diseases in which the homeostatic mechanism of epidermal cell kinetics or differentiation is altered, resulting in the clinical appearance of scale. Because these disorders manifest as abnormal differentiation of the epidermis, the term *disorders of cornification* is preferred to ichthyosis.

Treatment

Symptomatic treatment with alphahydroxy acids, such as lactic acid or 12% ammonium lactate lotion, is helpful. Patients with atopic dermatitis and ichthyosis vulgaris may find that these products sting. Other compounds with hydrating and keratolytic properties are also beneficial. Creams containing 10% urea are effective humectants. Widespread use of topical salicylic acid in children may lead to salicylism, and salicylic acid products are best reserved for localized thicker areas, when 40% urea has failed. Baths may help by hydrating the horny layer, but the water must be sealed in with an evaporation barrier such as white petrolatum. Topical calcipotriene ointment has proved effective in a variety of ichthyoses. Application of a 40% to 60% solution of propylene glycol in water under an occlusive suit removes the scales. Proplyene glycol can produce renal failure and cardiac toxicity when given systemically, but few reports of

adverse effects have been noted with topical use. Many patients benefit from the use of a sauna suit even without the use of propylene glycol.

Ichthyosis Vulgaris

Ichthyosis vulgaris is autosomal-dominantly inherited and is characterized by onset in early childhood, usually between 3 and 12 months of age, with fine scales that appear "pastedon" over the entire body. Varying degrees of dryness of the skin may be evident. The scales are coarser on the lower extremities than they are on the trunk. The extensor surfaces of the extremities are most prominently involved. The axillary and gluteal folds are usually not involved. Although the antecubital and popliteal fossae are usually spared by ichthyosis vulgaris, atopic changes may be present, as these disorders are frequently associated. Accentuated skin markings and hyperkeratosis of the palms are common features. Keratosis pilaris is frequently associated. The scalp is involved, with only slight scaling. Keratotic lesions may be found on the palmar creases (keratosis punctata). Atopy manifested as hay fever, eczema, asthma, or urticaria is frequently present. The course is favorable, with limited findings by the time the patient is an adult.

Histologically, there is a moderate degree of compact eosinophilic orthokeratosis. The granular layer is reduced or absent, and keratohyalin granules may appear spongy or fragmented on electron microscopy. The spinous layer is of normal thickness. Filaggrin is reduced in involved epidermis, and profilaggrin mRNA is unstable in keratinocytes. This is a retention hyperkeratosis, with a normal rate of epidermal turnover.

The differential diagnosis includes severe xerosis, X-linked ichthyosis, and acquired ichthyosis.

X-Linked Ichthyosis

X-linked ichthyosis is transmitted only to males by heterozygous mothers as an X-linked recessive trait. This condition results from a deficiency of steroid sulfatase (aryl sulfatase C), and occurs once in every 2000 to 5000 male births. Onset is usually before 3 months of age. The children are commonly born via cesarian section, with failure of progression of labor owing to a placental sulfatase deficiency. Scales are dark, large, and prominent on the anterior neck, extensor surfaces of the extremities (Figs 27-15 and 27-16), and the trunk. The sides of the neck are invariably involved, giving the child an unwashed look. The elbow and knee flexures are relatively spared, as are the face and scalp; the palms and soles are nearly always spared.

Flg. 27-15 X-linked ichthyosis.

baby.

Fig. 27-17 Collodion

Biochemical and genetic studies have helped to define the specific subtypes. Clinical features often overlap, and in the past, the severity of the disease determined the classification. Identification of specific defects, such as transglutaminase 1, and profilaggrin/filaggrin are important to define each disorder, and are the basis for classification of ichthyotic disorders.

Lamellar lchthyosis Lamellar ichthyosis is present at birth or becomes apparent soon after, and almost always involves the entire cutaneous surface. Usually a collodionlike membrane encases the baby at birth, then desquamates over the first 2 to 3 weeks of life. The ensuing ichthyosis is characterized by large (5–15 mm), grayish-brown scales, which are strikingly quadrilateral, free at the edges and adherent in the center. In severe cases, the scales may be so thick that they are like armor plate. Moderate hyperkeratosis of the palms and soles is frequently present. The follicles in most instances have a crateriform appearance. Ectropion is almost always present and is a helpful diagnostic sign.

Lamellar ichthyosis is inherited as an autosomal-recessive trait. About half the patients have decreased or absent transglutaminase 1 (TGM1) activity. ALOXE3 and ALOX12B mutations can produce a similar appearance. Lamellar ichthyosis type 2 has been associated with mutations in the ABCA12 gene.

In addition to the topical agents recommended for the treatment of other ichthyoses, tazarotene (Tazorac) and orally administered retinoids can improve symptoms. The adverse effects of prolonged oral retinoid therapy make their use for long-term maintenance therapy difficult.

Nonbullous Congenital Ichthyosiform Erythroderma Most infants with nonbullous congenital ichthyosiform erythroderma are born enclosed in a constricting parchment- or collodion-like membrane (Fig. 27-17). They also have ectropion of the eyelids, which has led to confusion with lamellar ichthyosis, and at one time the term lamellar ichthyosis was used for almost all patients with nonbullous autosomal-recessive ichthyoses. As mutations in TGM1, ALOXE3 or ALOX12B can lead to either congenital ichthyosiform erythroderma or lamellar ichthyoses, the separation of the entities is largely on the basis of the clinical phenotype.

The condition may be confused with ichthyosis vulgaris, but typically has darker scales and demonstrates dramatic clearing during the summer months. A diagnosis of X-linked ichthyosis is likely if the abdomen is more involved than the back and if the ichthyosis extends down the entire dorsum of the leg. Keratosis pilaris is not present, and the incidence of atopy is not increased. Corneal opacities (which do not affect vision) are seen by slit-lamp examination on the posterior capsule or Descemet's membrane in about 50% of affected males and female carriers. Another extracutaneous feature is a 12% to 15% incidence of cryptorchidism and an independently increased risk of testicular cancer. Unlike ichthyosis vulgaris, X-linked ichthyosis does not improve with age, but gradually worsens in both extent and severity.

There is usually a deletion at Xp22.3, and steroid sulfatase is lacking in fibroblasts, leukocytes, and keratinocytes. The diagnosis can be confirmed by lipoprotein electrophoresis, because the increase in cholesterol sulfate makes the low-density lipoproteins (LDLs) migrate much more rapidly, and cholesterol sulfate is elevated in serum, erythrocyte membranes, and keratin. The reduced enzyme activity can be assessed in fibroblasts, keratinocytes, leukocytes, and prenatally in amniocytes.

Multiple Sulfatase Deficiency

Patients with multiple sulfatase deficiency display an overlap of steroid sulfatase deficiency, mucopolysaccharidosis, and metachromatic leukodystrophy. The scaling is sometimes milder than X-linked recessive ichthyosis. There may be developmental delay, spastic quadriparesis, and coarse facial features. Histologic examination shows hyperkeratosis with a normal granular cell layer. This autosomal-recessive disorder is caused by a lack of or deficiency in all known sulfatases. Within 24 h after birth, fissuring and peeling begin, and large keratinous lamellae are cast off in 10 to 14 days, coincident with rapid improvement. As the membrane is shed, underlying redness and scaling are apparent. Generalized involvement is the rule, including the face, palms, soles, and flexures. Cicatricial alopecia, nail dystrophy, and some ectropion are common. Scales may be large and platelike on the legs but are likely to be fine on the trunk, face, and scalp. The condition has been found in association with neutral lipid storage disease.

Histologically, parakeratosis and inflammation are seen more frequently in congenital ichthyosiform erythroderma than in lamellar ichthyoses. The stratum corneum is usually thicker in lamellar ichthyoses, and is usually not parakeratotic.

Harlequin Fetus Harlequin fetus is a severe disorder that affects the skin in utero, causing thick, horny, armor-like plates covering the entire surface (Fig. 27-18). The ears are rudimentary or absent, and eclabium and ectropion are severe. The child is often stillborn or dies soon after delivery; however, with aggressive management, there have been long-term survivors. These survivors develop features of congenital ichthyosiform erythroderma or lamellar ichthyosis. Absent or abnormal lamellar granules, a lack of extracellular lipid lamellae, and lipid droplets in the stratum corneum have been reported. Abnormalities of profilaggrin, and K6 and K16 expression have been reported. Recessive inheritance has been favored, and is supported by reports of consanguinity. Some reports suggest a dominant mutation with parental mosaicism.

Epidermolytic Hyperkeratosis (Bullous Ichthyosiform Erythroderma)

An autosomal-dominantly inherited disorder, epidermolytic hyperkeratosis (EHK), or bullous congenital ichthyosiform erythroderma, is usually manifested by blisters at or shortly after birth. Later, thickened, horny, warty or spine-like, ridged scales predominate (Fig. 27-19). They are particularly prominent at the flexures. There is remarkable heterogeneity, particularly in regard to the degree of hyperkeratosis, the extent of body surface involvement, presence or absence of erythroderma, and palm and sole involvement. Epidermal nevi of the epidermolytic type are mosaic expressions of epidermolytic hyperkeratosis.

Epidermolytic hyperkeratosis is caused by mutations in the genes for keratins K1 and K10. Keratin distribution patterns in keratinocytes are abnormal, suggesting that there is an altered assembly process of cornified cell envelopes in epidermolytic hyperkeratosis.

Histologically, the lesional skin demonstrates compact hyperkeratosis. The granular layer is markedly thickened and contains coarse keratohyaline granules. Epidermal cells detach in the granular cell layer and may appear disrupted. Electron microscopy reveals the formation of perinuclear haloes. These findings allow prenatal diagnosis by fetal skin biopsy. Epidermolytic hyperkeratosis has been described as an incidental finding in normal skin, skin adjacent to benign and malignant epidermal tumors, and normal oral mucosa. It may be more commonly seen in association with dysplastic nevi than with banal nevi.

Short intensive therapy with high-dose vitamin A (750,000 U of Aquasol A daily) for 2 weeks produces modest

Fig. 27-19 Epidermolytic hyperkeratosis. (Courtesy of Dr Shyam Verma)

clinical improvement. Others have tried administering systemic retinoids, with similar results; however, the patient's blistering may worsen, despite clinical improvement of the scales. Decisions regarding systemic retinoid therapy must therefore be made on a case-by-case basis. Application of 0.1% retinoic acid (Retin-A cream) has been used successfully. Pyogenic infection is a common problem, and appropriate antibiotics should be administered. A water solution of 10% glycerin and 3% lactic acid applied to wet skin can result in clinical improvement. The disease tends to become less severe with age.

Ichthyosis Bullosa of Siemens

Once classified as a subtype of epidermolytic hyperkeratosis, this condition is characterized by a lack of erythema, relatively mild hyperkeratosis usually limited to the flexures, and superficial molting or peeling of the skin (the "mauserung" phenomenon). Ichthyosis bullosa of Siemens is caused by mutations in the gene for keratin 2e.

Suga Y, et al: Hot spot mutations in keratin 2e suggest a correlation between genotype and phenotype in patients with ichthyosis bullosa of Siemens. Exp Dermatol 2000;9:11.

Restrictive Dermopathy

Restrictive dermopathy is a rare, lethal, autosomalrecessively inherited disease characterized by abnormal facies, tight skin, sparse or absent eyelashes, and secondary joint changes. Virtually all cases are associated with polyhydramnios, reduced fetal movements, and premature delivery. Infants exhibit a fixed facial expression, with blurring of groove between nose and cheek, sometimes described as an "Asiatic porcelain doll" appearance. Patients also exhibit micrognathia, mouth in the "O" position, rigid and tense skin with erosions and denudations, and multiple joint contractures. Some patients have wide cranial sutures, small pinched nose, low-set ears, microstomia, rocker-bottom feet, scaly skin, and respiratory insufficiency. Pulmonary hypoplasia, microcolon, vessel transposition, natal teeth, ectropion, submucous cleft palate, hypospadias, urethral duplication, dysplasia of clavicles, adrenal hypoplasia, and an enlarged placenta with short umbilical cord may be noted. Histopathologic features include hyperkeratosis, parakeratosis, abnormal keratohyaline granules, and effacement of the rete ridge pattern. The dermis is attenuated with collagen fibers parallel to the epidermis, resembling a scar or tendon. Elastic fibers are absent. The subcutis demonstrates hypoplastic eccrine and sebaceous glands.

critical review of all hypotheses of its origin. Pediatr Dermatol 2002;19:67.

Ichthyosis Linearis Circumflexa

Ichthyosis linearis circumflexa is an inherited autosomalrecessive disorder of cornification in which migratory annular and polycyclic patches occur (Fig. 27-20). It may first appear as severe congenital generalized exfoliative erythroderma. Later, lesions predominate on the trunk and extremities, and appear as a polycyclic serpiginous eruption characterized by constantly changing patterns. In about a week the lesions attain their maximum diameter and involute, leaving no atrophy, scarring, or pigmentation. The lesions may clear almost completely during the summer. Most patients are found to have bamboo hair (trichorrhexis invaginata). The association of ichthyosiform dermatitis, hair abnormality, and atopic diathesis is called Netherton syndrome. Because of coexistent atopic dermatitis, the scalp, face, and eyebrow regions are erythematous and scaly. Hairs may fracture below the surface of the scalp, so that the patient appears bald. Mutations in SPINK5, which encodes the serine protease inhibitor Kazal-type 5 protein, have been identified in Netherton syndrome.

Histologic examination shows hyperkeratosis, parakeratosis, and acanthosis. The granular layer is typically absent.

Acitretin has been effective in some patients, but should be avoided in erythrodermic neonates and long-term use is limited by toxicity. Topical tacrolimus has also been reported as effective, but in one report, three patients treated twice with 0.1% tacrolimus ointment were found to have significant tacrolimus blood levels. Although none of these patients developed signs or symptoms of toxic effects, monitoring of blood levels is advised if tacrolimus is used in this setting.

Neutral Lipid Storage Disease

Dorfman-Chanarin syndrome is a rare autosomal-recessive disorder characterized by an ichthyosiform eruption, myopathy, and vacuolated leukocytes. Lipid vacuoles are present in all circulating granulocytes and monocytes, as well as dermal fibroblasts, Schwann cells, smooth muscle cells, and sweat gland cells. Other organ systems, such as the CNS, liver, muscles, ears, and eyes, may also have deposits. Associated cutaneous disorders include poikiloderma atrophicans vasculare and bullous congenital ichthyosiform erythroderma. The disorder is caused by a regulatory defect that alters the rates of synthesis and degradation of the major cellular phospholipids, particularly triacylglycerolderived diacylglycerol. Electron microscopic findings show electron-lucent globular inclusions in lamellar structures. Dietary intervention, with modulation of dietary fats, has been shown to aid in controlling the disease.

Pena-Penabad C, et al: Dorfman-Chanarin syndrome (neutral lipid storage disease): new clinical features. Br J Dermatol 2001;144:430.

Ichthyosis Follicularis

Ichthyosis follicularis is characterized by noncicatricial universal alopecia, severe photophobia, and generalized cutaneous follicular projections that are flesh-colored and spiny. There is xerosis of nonspiny skin, and absence of sebaceous glands has been noted histologically. Hepatosplenomegaly, undescended testicles, nail dystrophy, inguinal hemia, short stature, seizures, psychomotor developmental delay, digital anomalies, and ptosis have been reported. It has also been called *ichthyosis follicularis, alopecia, and photophobia (IFAP) syndrome*. Males outnumber females 5:1. The main considerations in differential diagnosis are the keratitis-ichthyosis-deafness (KID) syndrome and keratosis follicularis spinulosa decalvans (KFSD). The disorder may be transmitted by an X-linked recessive gene, although an autosomal-dominant form has also been reported.

Alfadley A, et al: Ichthyosis follicularis: a case report and review of the literature. Pediatr Dermatol 2003;20:48.

Megarbane H, et al: Ichthyosis follicularis, alopecia, and photophobia (IFAP) syndrome: report of a new family with additional features and review. Am J Med Genet 2004;124A:323.

Sjögren-Larsson Syndrome

Sjögren-Larsson syndrome is characterized by ichthyosis, spastic paralysis, oligophrenia, mental retardation, and a degenerative retinitis. The ichthyosis is usually generalized, with little or no involvement of the scalp, hair, or nails. There is a flexural and lower abdominal accentuation. The central face is spared, ectropion is unusual, and palms and soles are involved. Beginning by the age of 2 or 3, there is spastic paralysis consisting of a stiff, awkward movement of the extremities. Electron microscopy reveals prominent Golgi apparatus and increased numbers of mitochondria in keratinocytes. Usually, a severe mental deficiency is present. The epilepsy is of the grand mal type. This syndrome is of autosomal recessive inheritance, localized to chromosome 17p11.2. These patients have a fibroblast and leukocyte deficiency in fatty aldehyde dehydrogenase.

- Huag S, et al: Adeno-associated virus vectors are able to restore fatty aldehyde dehydrogenase-deficiency. Implications for gene therapy in Sjorgren-Larsson syndrome. Arch Dermatol Res 2005;296:568.
- Willemson MA, et al: Clinical, biochemical and molecular genetic characteristics of 19 patients with the Sjögren-Larsson syndrome. Brain 2001;124:1426.

Refsum Syndrome

Refsum syndrome (heredopathia atactica polyneuritiformis) is an autosomal-recessively inherited ichthyosis with atypical retinitis pigmentosa, hypertrophic peripheral neuropathy, cerebellar ataxia, nerve deafness, and various electrocardiographic changes. The ichthyosis resembles ichthyosis vulgaris. It may be generalized or localized to the palms and soles. It is of delayed onset and shows lipid vacuoles in the basal layer. The epidermal cell turnover rate is increased. Biochemically the disease is a peroxisomal disorder characterized by excessive accumulation of phytanic acid, pristanic acid, and picolenic acid in fatty tissues, invelin sheaths, heart, kidneys and retinal tissues. The disease is caused by a deficiency of phytanolyl/pristanoyl-CoA-hydroxilase. In most patients, mutations in the PHYH gene have been identified, and a second locus has been found on chromosome 6q22-24 with mutations in PEX7 (a gene also associated with rhizomelic chondrodysplasia punctata type 1). Dietary restriction of phytanic acid-containing vegetables can lead to an improvement of neurologic symptoms, but does not affect retinal changes. Unfortunately, in many patients, dietary restriction is not sufficient to prevent acute attacks or stabilize the progressive course. The acids are localized within very low-density lipoprotein (VLDL), LDL, and high-density lipoprotein (HDL) particles, and may be removed by extracorporal LDL-apheresis.

- Straube R, et al: Membrane differential filtration is safe and effective for the long-term treatment of Refsum syndrome an update of treatment modalities and pathophysiological cognition. Transfus Apheresis Sci 2003;29:85.
- van den Brink DM, et al: Identification of PEX7 as the second gene involved in Refsum disease. Am J Hum Genet 2003;72:471.

Rud Syndrome

Rud syndrome is characterized by ichthyosis, hypogonadism, small stature, mental retardation, acanthosis nigricans, epilepsy, macrocytic anemia, and, rarely, retinitis pigmentosa. Most kindreds have shown autosomal-recessive inheritance and may be atypical variants of well-described disorders, such as Sjögren-Larsson syndrome or Refsum syndrome, rather than representing a distinct inherited disorder. Some patients have X-linked steroid sulfatase deficiency.

Stoll C, et al: A syndrome of congenital ichthyosis, hypogonadism, small stature, facial dysmorphism, scoliosis and myogenic dystrophy. Ann Genet 1999;42:45.

Keratitis-Ichthyosis-Deafness Syndrome

The KID syndrome (Senter syndrome) is characterized by vascularization of the cornea, an extensive congenital ichthyosiform eruption, neurosensory deafness, reticulated hyperkeratosis of the palms and soles, hypotrichosis, partial anhidrosis, nail dystrophy, and tight heel cords. Distinctive leathery, verrucoid plaques involve the central portion of the face and ears. These changes, with absent eyebrows and eyelashes, and furrows about the mouth and chin, give the children a unique facies. The disorder is related to missense mutations in the GJB2 gene that encodes connexin-26 (Cx26). Most cases are sporadic.

Isotretinoin treatment may exacerbate and promote corneal vascularization. Treatment with acitretin has been reported to clear the hyperkeratotic ichthyotic lesions with little effect on the cornea or hearing. Cyclosporin A eye drops have been used to treat corneal neovascularization.

- Sahoo B, et al: KID syndrome: response to acitratin. J Dermatol 2002;29:499.

Congenital Hemidysplasia with Ichthyosiform Erythroderma and Limb Defects Syndrome

Present at birth, congenital hemidysplasia with ichthyosiform erythroderma and limb defects (CHILD) syndrome is characterized by unilateral inflammatory epidermal nevi and ipsilateral limb hypoplasia or limb defect. Features may vary widely, from complete absence of an extremity to defects of internal organs involving the musculoskeletal, cardiovascular, or central nervous systems. It is believed to be Xlinked dominant and lethal in hemizygous males. Survival in males has been reported as a result of mosaicism. In females, Lyonization may produce cutaneous patterns following the lines of Blaschko, similar to incontinentia pigmenti or Xlinked dominant chondrodysplasia. The pathogenesis is related to mutations in the gene NSDHL that is localized at Xq28 and involved in cholesterol metabolism. When unilateral epidermal nevi show features of verruciform xanthoma, CHILD syndrome should be suspected. The CHILD nevus is distinguished by ptychotropism (flexural involvement), waxy yellowish scaling, lateralization showing both diffuse and linear involvement, and the presence of foamy macrophages in the dermal papillae.

- Hashimoto K, et al: CHILD syndrome with linear eruptions, hypopigmented bands, and verruciform xanthoma. Pediatr Dermatol 1998;15:360.

Erythrokeratodermia Variabilis

Erythrokeratodermia variabilis, also called erythrokeratodermia figurata variabilis, erythrokeratodermia variabilis, and Mendes da Costa type erythrokeratodermia, is a rare autosomal-dominant disorder characterized by erythematous patches and hyperkeratotic plaques of sparse but generalized distribution. The erythematous patches may assume bizarre geographic configurations that are sharply demarcated. Over time, they change their shape or size or involute completely. The keratotic plaques are reddish-brown, often polycyclic, and fixed in location. The extensor surfaces of the limbs, buttocks, axillae, groins, and face are most often involved. Approximately 50% of patients display a palmoplantar keratoderma associated with peeling. Hair, nails, and mucous membranes are spared.

The onset of the condition is shortly after birth or, rarely, at birth, or in early adult life. There may be some improvement with age, particularly after menopause. Exacerbations have been seen during pregnancy. The figurate erythematous component may be accentuated by exposure to heat, cold, or wind. Emotional upsets may also be a factor.

The gene has been mapped to 1p34-p35, the gene GJB3 coding for a gap junction protein α -4 (connexin 31). Histologically, there is hyperkeratosis and parakeratosis, and a diminished granular layer. Acanthosis may occur. Ultrastructurally, epidermal keratinosomes are diminished.

Systemic retinoids such as acitretin or isotretinoin can restore the deficient keratinosomes and partially clear the hyperkeratotic plaques. The disease often relapses when therapy is discontinued. Urea, salicylic acid, and lactic acid have proved useful for the hyperkeratotic plaques

Morley SM, et al: A new, recurrent mutation of GJB3 (Cx31) in

erythrokeratodermia variabilis. Br J Dermatol 2005;152:1143. Strober BE: Erythrokeratodermia variabilis. Dermatol Online J 2003;9:5.

Progressive Symmetric Erythrokeratodermia

Progressive symmetric erythrokeratodermia (erythrokeratodermia progressiva symmetrica) is a rare, autosomaldominantly inherited disorder that manifests soon after birth with erythematous, hyperkeratotic plaques that are symmetrically distributed on the extremities, buttocks, and face, sparing the trunk. Palmoplantar keratoderma may be present. The lesions may regress at puberty. The cause in one kindred was related to an insertion mutation in the loricrin gene. Topical treatments, including keratolytics, corticosteroids, and retinoids, have had variable success.

Khoo BP, et al; Generalized erythematous plaques. Progressive symmetric erythrokeratodermia PSEK) (erythrokeratodermia progressiva symmetrica). Arch Dermatol 2000;136:665, 668.

Acquired Ichthyosis

Ichthyosis clinically similar to ichthyosis vulgaris may develop in patients with several systemic diseases. Acquired ichthyosis has been reported with Hodgkin's disease, and may be a presenting symptom. It has also occurred in non-Hodgkin lymphoma, mycosis fungoides, multiple myeloma, and carcinomatosis. In hypothyroidism, patients may develop fine scaling of the trunk and extremities, as well as carotenemia and diffuse alopecia. Characteristic ichthyosiform lesions may develop in patients with sarcoidosis, particularly over the lower extremities. Biopsy of the lesion will often show granulomas. Ichthyosiform changes have also been reported

Gray LC, et al: Progressive symmetric erythrokeratodermia. J Am Acad Dermatol 1996;34:858.
in patients with leprosy, nutritional deficiency, acquired immune deficiency syndrome (AIDS), human T-cell lymphotropic virus infection, lupus erythematosus, and dermatomyositis. Drug-induced ichthyosis may occur with nicotinic acid, triparanol, and butyrophenones.

Okulicz JF, et al: Hereditary and acquired ichthyosis vulgaris. Int J Dermatol 2003;42:95.

PITYRIASIS ROTUNDA

Pityriasis rotunda (pityriasis circinata) manifests as perfectly circular scaly patches on the torso and proximal portions of the extremities. The scale is adherent and resembles that of icthyosis vulgaris. There is a strong ethnic predisposition, with a preponderance of reports in black persons, Japanese, Koreans, and Italians. Some cases are associated with systemic illnesses, especially in darker skinned patients. Associated illnesses include tuberculosis, other pulmonary disorders, liver disease, malnutrition, leukemia, lymphoma, and carcinoma of the esophagus or stomach. Familial cases with autosomal-dominant transmission have also been described.

Two forms of the disease occur. Type I is found in black or Asian persons, usually has fewer than 30 hyperpigmented lesions, is nonfamilial, and may be associated with systemic disease. Type II disease occurs in white persons, has larger numbers of hypopigmented lesions, is often familial, and usually is not associated with internal disease.

The differential diagnosis includes tinea versicolor, tinea corporis, erythrasma, leprosy, fixed drug eruptions, and pityriasis alba. Some patients note a seasonal improvement during the summer, and some respond to emollients during the winter months. Topical and systemic retinoids have been used successfully, but often the condition is unresponsive unless there is an underlying systemic illness that can be treated.

Mafong EA: Pityriasis rotunda. Dermatol Online J 2002;8:15. Pinto GM, et al: Pityriasis rotunda. Cutis 1996;58:406.

POROKERATOSIS

Porokeratosis is a heterogeneous group of disorders that are inherited in an autosomal-dominant fashion. Except for the punctate type, they are characterized by distinct clinical findings of a keratotic ridge with a central groove that corresponds to the cornoid lamella on histology. The groove may be accentuated by the application of gentian violet followed by removal with alcohol. The dye remains in the groove. Povidone iodine has been used in a similar fashion. Immunosuppression, ultraviolet exposure, and radiation therapy may exacerbate porokeratosis and promote the development of skin cancers within the lesions. The linear type has the greatest risk of malignant transformation.

Topical 5-fluorouracil (5-FU) is generally effective in destroying individual lesions. It may have to be applied under occlusion but may result in scarring. In disseminated superficial actinic porokeratosis (DSAP), where the risk of malignant transformation is very low, the risks of trealment with 5-FU must be weighed against the generally indolent course of the lesions. Sun protection, emollients, and observation for signs of malignant degeneration may be the most

suitable course of action for many patients with DSAP. Other agents that have been shown to be effective for some patients with DSAP include topical vitamin D3 analogs and topical retinoids, including tazarotene. Salicylic acid and α hydroxyl acids may make the lesions less noticeable. Topical imiquimod has been used for porokeratosis, including porokeratosis of Mibelli. Oral retinoids have shown efficacy. but the lesions commonly recur after treatment, and longterm treatment with these agents is impractical. Combinations of oral retinoids and topical 5-FU have been effective for refractory DSAP and porokeratosis plantaris, palmaris, et disseminata, but the side effects of treatment may be considerable. Destructive modalities must extend into the dermis and produce scarring. More superficial treatment is commonly [ollowed by recurrence. Other effective modalities include cryotherapy, electrodesiccation and curettage, CO₂ laser ablation, flashlamp-pumped pulsed dye laser, frequencydoubled Nd:YAG laser, dermabrasion and Grenz ray.

Plaque-Type Porokeratosis (Mibelli)

Plaque-type porokeratosis is a chronic, progressive disease characterized by the formation of slightly atrophic patches surrounded by an elevated, warty border. The lesion begins as a small keratotic papule, which spreads peripherally and becomes depressed centrally. Eventually, it becomes a circinate or serpiginous, well-defined plaque surrounded by a keratotic wall or collar. This wall is gravish or brownish and frequently is surmounted by a tiny groove or linear ridge running along its summit. The enclosed central portion of the plaque consists of dry, smooth, atrophic skin, the lanugo hairs generally being absent when the patches occur in hairy areas. Linear or zosteriform distribution of the lesions may also occur. If the nail matrix is involved, nail dystrophy may develop. Lesions may appear during chemotherapy for malignancy, after renal transplantation, while on PUVA treatment, and in areas of chronic sun damage, or chemical exposure, such as benzylhydrochlorothiazide.

Sites of predilection are the surfaces of the hands and fingers, and the feet and ankles. The disease also occurs on the face and scalp (where it produces bald patches), on the buccal mucosa (where the ridge becomes macerated by moisture and appears as a milky white, raised cord), and on the glans penis (where it causes erosive balanitis).

Histologically, the principal diagnostic changes are in the area of the cornoid lamella. This area demonstrates a column of parakeratotic keratin extending at about a 45° angle from a focus of dyskeratotic cells in the malpighian layer. The column trails behind the focus of dyskeratosis as the focus expands peripherally. The granular cell layer is absent beneath the parakeratotic column. The central portion of the lesion may demonstrate atrophy with loss of the rete ridge pattern, lichenoid dermatitis, or psoriasiform hyperplasia.

Disseminated Superficial Actinic Porokeratosis

DSAP is characterized by numerous superficial, annular, keratotic, brownish-red macules found on sun-exposed areas. It is more common in women. The keratotic ridge is thin and thread-fike, but may be accentuated by application of gentian violet followed by removal with alcohol. A surgical skin marking pen or cotton tipped applicator work equally well for dye application. The distribution of the lesions on the sun-exposed areas indicates that actinic radiation is an important factor in its pathogenesis, and new lesions have been induced by exposure to commercial tanning salons. Exacerbations occur in up to two-thirds of patients during summer. Immunosuppression is also well documented to exacerbate the disease. It has been seen in patients with AJDS, cirrhosis, and Crohn's disease. Organ transplant patients may develop DSAP. Improvement of the immunosuppression may lead to resolution of the lesions. Gene loci for DSAP have been localized to chromosomes 12q23.2-24.1 and 15q25.1-26.1, suggesting that DSAP is a genetically heterogeneous disorder.

Linear Porokeratosis

Linear porokeratosis may be segmental or generalized. It may be identified during the newborn period, and when found in the segmental pattern, may follow the lines of Blaschko. Ulcerations and erosions involving the face or extremities may delay the correct diagnosis, and linear porokeratosis should be included in the differential diagnosis of ulcerative lesions in the neonatal period. This form of porokeratosis has the highest risk of developing cutaneous malignancies, including squamous cell carcinoma, Bowen's disease, and basal cell carcinoma.

Porokeratosis Palmaris, Plantaris, et Disseminata

In this distinctive form of porokeratosis, lesions first appear on the palms or soles, or more often both. Onset is frequently noted when patients are in their 20s. Slowly, the lesions may extend over the entire body. In porokeratotic eccrine ostial and dermal duct nevus, the presentation clinically appears like a nevus comedonicus of the palm or sole, but histologic analysis reveals multiple comedoid lamella-like parakeratotic columns. In porokeratosis punctata, palmaris et plantaris or punctate porokeratosis, lesions are limited to the hands and feet.

DARIER'S DISEASE (KERATOSIS FOLLICULARIS, DARIER-WHITE DISEASE)

Darier's disease is an autosomal-dominantly inherited skin disorder characterized by brown keratotic papules that tend to coalesce into patches in a seborrheic distribution. Early lesions are small, firm papules, almost the color of normal skin. Each papule becomes covered with a greasy, graybrown crust that fits into a small concavity in the summit of

Fig. 27-21 Darier's disease. (Courtesy of Larry Lieblich, MD)

the papule. As the lesions grow older, their color darkens (Fig. 27-21). In the course of years, the papules grow and may fuse to form malodorous, papillomatous and vegetating growths.

The neck and shoulders, face, extremities, front of the chest, and midline of the back are sites of predilection for the disease. A frequent site for the earliest lesions is behind the ears. As the eruption spreads, the entire trunk, buttocks, genitals, and other parts of the skin may be involved. Usually the eruption is symmetrical and widespread, but striking unilateral or segmental involvement may also occur. Cases with segmental distribution probably represent post-zygotic mutations.

Vegetations appear chiefly in the axillae, gluteal crease, groin, and behind the ears. The scalp is generally covered with greasy crusts. Lesions on the face are often prominent about the nose. The lips may be crusted, fissured, swollen, and superficially ulcerated, and there may be a patchy keratosis with superficial erosions on the dorsum of the tongue. Small white papules or pebbling may be present on the gingiva and palate. Involvement of the oropharynx, esophagus, hypopharynx, larynx, and anorectal mucosa has been reported. Punctate keratoses are frequently noted on the palms and soles. A general horny thickening of the palms and soles may be present because of innumerable closely set small papules. On the dorsa of the hands and on the shins

the flat vertucous papules may resemble vertucae planae. The nails show subungual hyperkeratosis, fragility, and splintering, with longitudinal alternating white and red streaks, and triangular nicking of the free edges (Fig. 27-22).

Darier's disease is usually worse in the summer. It may begin after severe sunburn, and in some patients the lesions may be reproduced with suberythema doses of UVB. Lithium carbonate has been shown to induce Darier's disease in some individuals. Disseminated cutaneous herpes simplex may be a complication of the disease.

Abnormal dissolution of desmosomal plaque proteins is seen, specifically desmoplakin I and II, plakoglobin, and desmoglein. Acantholysis occurs as a result of deficiency in the tonofilament/desmosonic attachment. Ca^{2+} -dependent cell-cell adhesion molecules (epithelial cadherins) are markedly reduced on the acantholytic cells of patients with Darier's disease. The Darier gene (ATP2A2) has been localized to 12q23-24.1 and codes for the second isoform of a calcium ATPase of the sarco/endoplasmic reticulum (SERCA2) pump, which transports Ca^{2+} from the cytosol into the endoplasmic reticulum. Inhibition of SERCA impairs trafficking of desmoplakin to the cell surface, contributing to acantholysis.

Histology

Darier's disease is characterized by acantholytic dyskeratosis with overlying hyperkeratosis. Abnormally keratinizing cells appear as round eosinophilic or basophilic cells (corps ronds), which often demonstrate a pale halo surrounding the nucleus. Grains are flat, deeply basophilic, dyskeratotic cells, seen most frequently in the stratum granulosum and stratum corneum. Both grains and corps ronds are separated from the surrounding cells as a result of acantholysis. Formation of a suprabasal cleft (lacuna) is noted, and may involve hair follicles as well as the surface epidermis. Dermal papillae covered by a single layer of basal cells project as villi into the acantholytic space.

Fig. 27-22 Darier

Treatment

During flares, topical antibacterial agents, oral antibiotics and short-term application of a corticosteroid may be of benefit. For localized disease, topical retinoids may be effective, but papules often occur at the periphery of the treated region. Oral retinoids are the drugs of choice for most severe cases. Cyclosporin may control severe flares, and topical sunscreens and ascorbic acid can prevent disease flares in some patients. For hypertrophic lesions, dermabrasion, laser vaporization, or excision and grafting can be considered. Photodynamic therapy using topical 5-aminolaevulinic acid produces an initial inflammatory response that lasts 2 to 3 weeks. In some patients, this is followed by sustained improvement. Because of the initial inflammatory response, it is only appropriate for patients who have failed most other options.

ACROKERATOSIS VERRUCIFORMIS

This rare autosomal-dominant genodermatosis is characterized by numerous flat vertucous papules occurring on the backs of the hands, insteps, knees, and elbows. The papules are closely grouped and resemble warts except that they are flatter and more localized. The vertucous lesions are identical to those in Darier's disease, and acrokeratosis vertuciformis of Hopf is allelic to Darier's disease (caused by mutations in the same gene).

Histologically, hyperkeratosis, thickening of the granular layer, acanthosis and church spire papillomatosis characterize the disease. Available treatments are liquid nitrogen therapy, shave excision, and CO_2 laser ablation. Recurrence is common.

Dhitavat J, et al: Acrokeratosis veruciformis of Hopf is caused by mutation in ATP2A2: evidence that it is allelic to Darier's disease. J Invest Dermatol 2003;120:229.

PACHYONYCHIA CONGENITA

In 1906, Jadassohn and Lewandowsky described a rare, often (amilial, anomaly of the nails to which they gave the name pachyonychia congenita. It is characterized by thickened nailbeds of all fingers and toes, palmar and plantar hyperkeratosis, blistering under the callosities, palmar and plantar hyperhidrosis, spiny follicular keratoses, and benign leukokeratosis of the mucous membranes. The nail plates are extremely hard and are firmly attached to the nailbeds. The nailbed is filled with yellow, horny, keratotic debris, which may cause the nail to project upward at the free edge (Fig. 27-23). Paronychial inflammation is frequently present.

Fig. 27-23 Pachyonychia congenita.

Fig. 27-25 Pachyonychia congenita.

Fig. 27-26 Pachyonychia congenita.

Branauer syndrome) is like type 1 with the addition of leukokeratosis of the corneas. *Pachyonychia congenita tarda* was suggested as the name for late-onset disease (type IV). Type IV disease has been described with hyperpigmentation around the neck, waist, axillae, thighs, flexures of the knees, buttocks, and abdomen. Pigmentary incontinence and amyloid deposition are seen in biopsy specimens.

Pachyonychia congenita is usually inherited as an autosomal-dominant trait, although recessive forms have been reported. There is a genetic mutation of keratin 6a or 16 in type J and keratin 6b or 17 in type II disease.

Avulsion of the nails brings about only temporary relief. Vigorous curettage of the matrix and nailbed is the simplest and most effective therapy. Destruction of the nail matrix with phenol may be partially effective, but recurrence of nailbed hyperkeratosis is common. The keratoderma is difficult to treat, but topical lactic acid, ammonium lactate, salicylic acid, or urea may be of some benefit. Isotretinoin has been reported to clear the keratotic papules and the oral leukokeratosis but not the palms or soles. Acitretin has been shown to be effective in treating the late-onset form.

Elston DM: Pachyonychia congenita. Cutis 2003;72:104, 143. Strober BE: Pachyonychia congenita. Dermatol Online J 2003; 9:12.

Garcia-Rio I, et al: A severe case of pachyonychia congenita type 1 due to a novel proline mutation in keratin 6a. Br J Dermatol 2005;152:800.

Fig. 27-24 Pachyonychia congenita.

Delayed onset of pachyonychia in young adulthood has been described.

On the extensor surfaces of the extremities (Fig. 27-24), buttocks (Fig. 27-25), and lumbar regions are spine-like follicular keratotic papules. Removal of these central cores leaves a slightly bleeding cavity. The eruption on the outer aspects of the upper and lower extremities is also follicular, resembling keratosis pilaris. This latter condition is not constant and disappears at times.

Painful friction blisters may develop on the plantar aspects of the toes or heels or along the edges of the feet, and cases have been misdiagnosed as epidermolysis bullosa. Leukokeratosis of the tongue (Fig. 27-26) and oral mucosa, as well as occasional laryngeal involvement with hoarseness, may occur. This oral leukokeratosis resembles an oral white sponge nevus histologically and is not predisposed to the development of malignancy.

Pachyonychia congenita is divided into four types. Type I (Jadassohn-Lewandowsky syndrome) is the most common and is described above. Type II (Jackson-Sertoli syndrome) has the same features as type I, with the additional features of natal teeth and steatocystoma multiplex. Patients with type II syndrome typically have less severe palmoplantar keratoderma and ora) lesions may be absent. Type III (SchafterWard KM, et al: Identification of a recurrent mutation in keratin 6a in a patient with overlapping clinical features of pachyonychia congenita types 1 and 2. Clin Exp Dermatol 2003;28:434.

DYSKERATOSIS CONGENITA (ZINSSER-COLE-ENGMAN SYNDROME)

Dyskeratosis congenita is a rare congenital syndrome characterized by cutaneous poikiloderma, nail dystrophy, and premalignant leukoplakia. Atrophy and telangiectasia are accompanied by tan-gray mottled hyper- and hypopigmented macules or reticulated patches. These lesions are located typically on the upper torso, neck, and face, although the extremities may also be involved.

The nails may be thin and dystrophic, although only ridging and longitudinal fissuring may be seen in mild cases. This is the first component of the syndrome to appear, becoming apparent between the ages of 5 and 15. The other cutaneous lesions generally follow within 3 to 5 years. Leukoplakia occurs mostly on the buccal mucosa, where extensive involvement with verrucous thickening may be present. The anus, vagina, conjunctiva, and urethral meatus can be involved. Malignant neoplasms of the skin, mouth, nasopharynx, esophagus, rectum, and cervix may occur in sites of leukoplakia.

Other manifestations of dyskeratosis congenita include hyperhidrosis of the palms and soles, bullous conjunctivitis, gingival disorders, dysphagia resulting from esophageal strictures and diverticula, skeletal abnormalities, aplastic anemia, mental deficiency, and hypersplenism. In many cases, a Fanconi type of anemia develops, beginning with leukopenia and thrombocytopenia, and progressing to severe pancytopenia. Pulmonary complications include interstitial fibrosis and *Pneumocystis carinii* pneumonia.

The genetic defect for the X-linked form is located on Xq28 and associated with the DKC1 gene for *dyskerin*, a protein implicated in both telomerase function and ribosomal RNA processing. Autosomal-dominant inheritance is associated with mutations in hTR (hTERC), involved in the RNA component of telomerase. Some autosomal-dominant cases have anemia and reticulated pigmentation following the lines of Blaschko. Of interest, some patients with idiopathic aplastic anemia or myelodysplastic syndrome without skin findings demonstrate hTERC mutations. Autosomalrecessive inheritance of dyskeratosis congenita has also been reported.

Granulocyte colony-stimulating factor and erythropoietin may provide short-term benefits in treating bone marrow failure. Bone marrow transplantation or hematopoietic stem cell transplantation with nonmyeloablative conditioning affords the best outcomes.

Hoyeraal-Hreidarsson syndrome is characterized by intrauterine growth retardation, cerebellar hypoplasia, mental retardation, microcephaly, progressive combined immune deficiency, and aplastic anemia. The syndrome is genetically heterogeneous. Some patients demonstrate DIKC1 gene mutations and are therefore allelic to dyskeratosis congenita.

FANCONI SYNDROME

Also known as familial pancytopenia or familial panmyelophthisis, Fanconi syndrome may be associated with diffuse pigmentation of the skin (hypopigmentation, hyperpigmentation, and café-au-lait macules), absence of the thumbs, aplasia of the radius, severe hypoplastic anemia, thrombocytopenia, retinal hemorrhage, strabismus, generalized hyperreflexia, and testicular hypoplasia. The syndrome is associated with increased risk of myelomonocytic leukemia, squamous cell carcinoma, and hepatic tumors. No hypersensitivity to UV light, x-rays, or chemical agents is present. Human papillomavirus DNA is often found in the squamous cell carcinomas. Some patients manifest short stature, failure to thrive, absent thumbs, short palpebral fissures, and typical skin abnormalities, but no hematologic abnormalities.

The syndrome is inherited in an autosomal-recessive fashion. Complementation analysis has shown five complementation groups (FA-A, -B, -C, -D, and -E) and therefore five associated genes. The genes play an important role in hematopoiesis, and abnormal gene expression has been shown to increase apoptosis. FA-A has been localized to 16q24.3, and FA-D to 3p22.26. Chromosome patterns are frequently abnormal.

ECTODERMAL DYSPLASIA

The ectodermal dysplasias are a clinically and genetically heterogenous group of genodermatoses in which the cardinal features are the abnormal, absent, incomplete, or delayed development during embryogenesis of one or more of the epidermal or mucosal appendages (hair, sebaceous glands, nails, teeth, or mucosal glands).

Hypohidrotic Ectodermal Dysplasia (Anhidrotic Ectodermal Dysplasia, Christ-Siemens-Touraine Syndrome)

The classic triad of this disorder consists of hypotrichosis, anodontia, and hypohidrosis or anhidrosis. Febrile seizures may occur in childhood. Biopsy confirms that eccrine glands are absent or rudimentary. Prenatal skin biopsy may be diagnostic.

Patients with the disorder have facies suggestive of congenital syphilis. The cheekbones are high and wide, whereas the lower half of the face is narrow. The supraorbital ridges are prominent and the nasal bridge is depressed, forming a saddle nose. The tip of the nose is small and upturned, and the nostrils are large and conspicuous. The eyebrows are scanty, and the eyes slant upward. The lips are thickened, with the upper lip particularly protrusive. At the buccal commissures there may be radiating furrows (pseudorhagades), and on the cheeks there may be telangiectases. Sebaceous gland hyperplasia may be noted on the cheeks and forehead. Absence of mammary glands and nipples has been reported.

Generalized hypotrichosis is present with thin, sparse hair on the scalp. The skin is soft, thin, dry, and smooth. There is partial or total anodontia, and nails may be thinned, brittle,

Sznajer Y, et al: Further delineation of the congenital form of X-linked dyskeratosis congenita (Hoyeraal-Hreidarsson syndrome). Eur J Pediatr 2003;162:863.

Fig. 27-27 Hypohidrotic ectodermal dysplasia. (Courtesy of James Fitzpatrick, MD)

and ridged. The teeth may be conical in shape (Fig. 27-27). Mental retardation has been reported but may be a consequence of hyperthermic episodes in childhood.

The inheritance pattern is almost always X-linked recessive. Three genes, ectodysplasin (EDA1), EDA-receptor (EDAR), and EDAR-associated death domain (EDARADD) have been described. They are all involved in nuclear factor (NF)- κ B activation. Female carriers may have segmental expression that can be demonstrated with a starch iodide test for sweating. Both autosomal-recessive and -dominant modes of inheritance have been described. The gene for autosomal-dominant hypohidrotic ectodermal dysplasia has been mapped to 2q11-q13.

X-linked anhidrotic ectodermal dysplasia with immunodeficiency is caused by mutations in the gene encoding encoding NF- κ B modulator, NEMO, or inhibitor of κ B kinase (IKK- γ). Stop codon mutations are associated with a severe phenotype with associated osteopetrosis and lymphoedema.

Hidrotic Ectodermal Dysplasia

The hidrotic type of congenital ectodermal dysplasia is often referred to as *Clouston syndrome*. Inheritance is autosomal dominant, eccrine sweat glands function normally, and facial features are normal. Alopecia, nail dystrophy, palmoplantar hyperkeratosis, and eye changes, such as cataracts and strabismus, are seen. Some patients have features resembling pachyonychia congenita. Widespread poromas and palmoplantar syringofibroadenomas have been described. The defective gene has been identified as GJB6, encoding the gap junction protein connexin 30 on the pericentromeric region of chromosome 13q (13q11-q12.1).

AEC Syndrome (Hay-Wells Syndrome)

Ankyloblepharon, ectodermal defects, and cleft lip and/or palate constitute the AEC syndrome. It has an autosomaldominant pattern of inheritance. Fusion or partial fusion of the lids (ankyloblepharon) may be present at birth. Sparse hair, dental defects, cleft palate and lip, dystrophic nails, hypospadias, syndactyly, short stature, absent lacrimal puncta, stenotic auditory canals, and short stature may be present. An erosive scalp dermatitis is more likely to be observed in AEC than in other ectodermal disorders and occurs at an early age. The scalp dermatitis is often extensive, difficult to treat, and persists or recurs. The syndrome is associated with mutations in the p63 gene.

EEC Syndrome

Ectodermal dysplasia, ectrodactyly, and cleft lip/palate are defining features of EEC syndrome. EEC lacks scalp dermatitis, has mild hypohidrosis, and ectrodactyly (congenital absence of all or part of a digit) is a prominent feature. Folliculitis with scarring may be noted during puberty. Like the AEC syndrome, EEC syndrome is associated with mutations in the p63 gene.

Rapp-Hodgkin Ectodermal Dysplasia Syndrome

Characteristic features of Rapp-Hodgkin ectodermal dysplasia syndrome include anomalies of hair (pili torti, pili canaliculi, alopecia, erosive folliculitis, thinning of eyebrows/lashes), cleft lip/palate, onychodysplasia, dental caries, hypodontia, craniofacial abnormality, hypohidrosis, otitis media (hearing deficits), and hypospadias. It is usually inherited in an autosomal-dominant manner. The syndrome is allelic to AEC and EEC, with mutations in the p63 gene have been demonstrated in all three.

Ectodermal Dysplasia with Corkscrew Hairs

Abramovits-Ackerman et al described this disorder in 27 patients from seven families who live on Margarita Island, northeast of Venezuela. Salient features include corkscrew hairs (exaggerated pili torti), scalp keloids, follicular plugging, keratosis pilaris, xerosis, eczema, palmoplantar keratodermia, syndactyly, onchodysplasia, and conjunctival neovascularization. Typical facies, anteverted pinnae, malar hypoplasia, cleft lip and palate, and dental abnormalities may also be found. Inheritance is autosomal recessive. Anhidrosis or hypohidrosis are not features.

Odonto-Tricho-Ungual-Digital-Palmar Syndrome

First described by Mendoza et al, the salient clinical features are natal teeth, trichodystrophy, prominent interdigital folds, simian-like hands with transverse palmar creases, and ungual digital dystrophy, inherited as an autosomal-dominant trait. Hypoplasia of the first metacarpal and metatarsal bones and distal phalanges of the toes may also occur.

Costello Syndrome

Costello syndrome is characterized by growth retardation, failure to thrive in infancy, coarse facies, redundant skin on the neck, palms, soles, and fingers, acanthosis nigricans, and nasal papillomata. Ventricular dilatation is observed in more than 40% of cases. Hydrocephalus, brain atrophy, Chiari malformation, and syringomyelia may occur. Mild-tomoderate mental deficiency is frequently discovered, and most patients exhibit a characteristic sociable and friendly personality.

Lenz-Majewski Syndrome

Lenz-Majewski syndrome is characterized by hyperostosis, craniodiaphyseal dysplasia, dwarfism, cutis laxa, proximal symphalangism, syndactyly, brachydactyly, mental retardation, enamel hypoplasia, and hypertelorism.

CHIME Syndrome

The CHIME syndrome, a rare neuroectodermal disorder, comprises colobomas of the eye, heart defects, ichthyosiform dermatosis, mental retardation, and ear defects. Other features may include facial anomalies, epidermal nevi, developmental delay, infantile macrostomia, recurrent infections, acute lymphoblastic leukemia, and duplicated renal collecting system. The inheritance is believed to be autosomal recessive.

Lelis syndrome

The Lelis syndrome is a form of ectodermal dysplasia with acanthosis nigricans, palmoplantar hyperkeratosis, hypotrichosis, hypohidrosis, nail dystrophy, early loss of adult teeth, and mental retardation.

PACHYDERMOPERIOSTOSIS (IDIOPATHIC HYPERTROPHIC OSTEOARTHORPATHY, TOURAINE-SOLENTE-GOLE SYNDROME)

Pachydermoperiostosis is characterized by thickening of the skin in folds and accentuation of creases on the face and scalp, clubbing of the fingers, and periostosis of the long bones. The changes are especially prominent on the forehead, where the horizontal lines are deepened and the skin becomes shiny. The eyelids, particularly the upper ones, are thickened. Likewise, there is thickening of the ears and lips, and the tongue is enlarged. The scalp may be thickened and show cutis verticis gyrata (pachydermie vorticelle). The extremities, especially the elbows, knees, and hands, are enlarged and spade shaped. The fingers become club shaped. The palms are rough, and the thenar and hypothenar eminences are enlarged. Hyperhidrosis is common. Hyperkeratotic linear lesions of the palms and soles may be present. These lines are rippled, resembling sand of the "wind-blown desert." Movements of the muscles may be painful.

There are inherited and acquired forms. The acquired form may occur with chronic pulmonary, mediastinal, and cardiac diseases that are associated with chronic hypoxia in peripheral tissues. Some cases have been associated with bronchogenic carcinoma. When such an association occurs, enlargement of the forehead, hands, and fingers may antedate the recognition of the tumor or may develop after the tumor is known to be present. Bronchogenic carcinomaassociated pachydermoperiostosis occurs almost exclusively in men over the age of 40, whereas inherited Touraine-Solente-Gole syndrome usually occurs as an autosomaldominant disorder with onset in late adolescence. It is not associated with malignant disease. More prominent signs are seen in males. Autosomal-recessive inheritance with cleft palate and congenital heart defects has been described.

CUTIS VERTICIS GYRATA

Cutis verticis gyrata is characterized by folds and furrows on the scalp, usually in an anteroposterior direction. Most frequently the vertex is involved, but other areas may have the distinctive furrowing. There may be 2 to 20 folds. The hair itself is normal.

Cutis verticis gyrata has been reported primarily in males, with a male-to-female ratio of 6:1. Onset is usually at puberty, with more than 90% of patients developing it before age 30. The condition may be familial when it occurs as a component of pachydermoperiostosis. It has been reported to be the result of developmental anomalies, inflammation, trauma, tumors, nevi, amyloidosis, syphilis, myxedema, Ehlers-Danlos syndrome, Turner syndrome, Klinefelter syndrome, fragile X syndrome, and the insulin-resistance syndrome. Biopsy findings can be normal or show thick collagen bundles and hypertrophy of adnexal structures.

Cutis verticis gyrata is frequently found in patients with mental retardation, seizures, and schizophrenia. Rarely, a cerebriform intradermal nevus may be mistaken for this disorder. In severely involved cases, excision with grafting or scalp reduction may be indicated.

Nguyen NQ: Cutis verticis gyrata. Dermatol Online J 2003;9:32.

APLASIA CUTIS CONGENITA

Aplasia cutis congenita has a predilection for the midline of the vertex of the scalp. It presents with localized absence of skin and is rarely associated with full-thickness defects of the cranium. An association with thyroid disease and thyroid medications has been noted. Rarely, multiple symmetrical defects may occur in the skin of the lower extremities. Distal radial epiphyseal dysplasia has been associated with localized aplasia cutis congenita.

The "hair collar sign" refers to a ring of dark, long hair encircling the lesion. It is commonly seen with membranous aplasia cutis, which may represent a form fruste of a neural tube defect. Bullous aplasia cutis congenita demonstrates a fibrovascular or edematous stroma similar to that seen in encephaloceles and meningoceles, suggesting is may also be related to a neural tube defect.

FOCAL DERMAL HYPOPLASIA (GOLTZ SYNDROME)

Goltz syndrome is characterized by multiple abnormalities of mesodermal and ectodermal tissues. Reddish-tan, atrophic, often linear or cribriform patches are commonly present on the buttocks, axillae, and thighs (Fig. 27-28). Later, lipocytes acculumate in the lesions in a nevoid fashion, resulting in yellowish-brown nodules. The lesions are strikingly linear and often serpiginous, following lines of Blaschko. They are often narrower than typical Blaschko segments, suggesting that the genetic defect is lethal in many of the affected cells during development. Telangiectases are commonly present. Papillomas may occur around the orifices of the mouth, anus, and vulva (Fig. 27-29). They may be misdiagnosed as condyloma acuminata. Eighty percent of patients have skeletal defects. Bone changes most commonly involve the extremities, where there may be syndactyly, oligodactyly, and adactyly (Fig. 27-30). Scoliosis, spina bifida, and hypoplasia of the clavicle have also been reported. Forty to 50% of patients have ocular or dental abnormalities, with coloboma being the most common ocular defect. Van Allen-Myhre syndrome appears to represent a severe form of Goltz syndrome with split foot and split hand anomalies.

Fig. 27-30 Goltz syndrome.

The large majority of patients with Goltz syndrome have been female. X-linked dominant inheritance, with lethality in males, is likely. Females are protected by X-chromosome mosaicism, identical to the situation in incontinentia pigmenti. Treatment of atrophic erythematous patches has been successful using a flashlamp-pumped pulsed dye laser.

Hancock S, et al: Probable identity of Goltz syndrome and Van Allen-Myhre syndrome: evidence from phenotypic evolution. Am J Med Genet 2002;110:370.

WERNER SYNDROME (ADULT PROGERIA)

Werner syndrome is a premature-aging syndrome characterized by many metabolic and structural abnormalities involving the skin, hair, eyes, muscles, fatty tissues, bones, blood vessels, and carbohydrate metabolism. Cells demonstrate genomic instability. Because most of these signs are not fully manifested before the age of 30, the diagnosis is usually made in middle age. These patients usually die before the age of 50 from malignant disease or vascular accidents.

The most characteristic findings are premature aging and arrest of growth at puberty, senile cataracts developing in the late 20s and 30s, premature balding and graying, and scleroderma-like lesions of the skin. A characteristic change is the loss of subcutaneous tissue and wasting of muscles, especially the extremities, so that the legs become spindly and the trunk becomes stocky. Osteoporosis and aseptic necrosis are frequent in the small bones of the hands. The skin changes include poikiloderma, scleroderma, atrophy, hyperkeratoses, and leg ulcers. The skin has a dark gray or blackish diffuse pigmentation. A high-pitched voice and hypogonadism in both sexes are distinctive in this syndrome.

Painful callosities with ulcerations may occur around the malleoli, Achilles tendons, heels, and toes. The hair thins on the eyebrows, axillae, and pubis. The skin over the cheek bones becomes taut to produce proptosis and beaking of the nose. Cataracts develop early, and the vocal cords become thickened so that a weak, high-pitched voice ensues. Premature arteriosclerosis and sexual impotence are frequently observed. Diabetes is frequent, and areas of calcinosis circumscripta occur. Gene expression mimics normal aging.

A high rate of malignancy is associated with Werner syndrome. Uterine sarcoma, hepatoma, carcinoma of the breast, fibrosarcoma, and thyroid adenocarcinoma have occurred. Histologic changes in the skin may include atrophy of the epidermis and fibrosis of the dermis.

Consanguinity and familial incidence are encountered, suggesting a mendelian recessive mode of transmission. Werner syndrome is molecularly heterogeneous. The Werner protein confers adhesive properties to macromolecular proteins and is required for genomic stability. It belongs to the RecQ family of DNA helicases. Mutant LMNA encoding nuclear lamin A/C is associated with atypical Werner syndrome with a more severe phenotype. Mutations in LMNA also cause Hutchinson-Gilford progeria, Emery-Dreifuss muscular dystrophy, and dilated cardiomyopathy.

PROGERIA (HUTCHINSON-GILFORD SYNDROME)

Progeria, or Hutchinson-Gilford syndrome, is characterized by accelerated aging, dwarfism, alopecia, generalized atrophy of the skin and muscles, enlarged head with prominent scalp veins, and a high incidence of generalized atherosclerosis, usually fatal by the second decade. The large bald head and lack of eyebrows and eyelashes are distinctive. The skin is wrinkled, pigmented, and atrophic. The nails are thin and atrophic. Most patients lack subcutaneous fat, which produces the appearance of premature senility. There are usually sclerodermatous plaques on the extremities. The intelligence remains intact. Arteriosclerosis, anginal attacks, and hemiplegia may occur, followed by death from coronary heart disease at an early age. Mutations in LMNA and mosaicism have been identified. Treatment is symptomatic: chiefly, control of diabetes mellitus and treatment of leg ulcerations.

Flg. 27-31 Xeroderma pigmentosum. (Courtesy of Keri Kraemer, MD)

XERODERMA PIGMENTOSUM

Xeroderma pigmentosum is an autosomal-recessive disorder characterized by defective DNA thymidine dimer excision repair, extreme sun sensitivity, freckling, and skin cancer. Sun sensitivity and lentigines (Fig. 27-31) are early skin findings with the median onset before the age of 2. Skin cancers often appear before 10 years of age, and an increase in internal cancer has been noted as well. In a study of 830 patients, 45% had basal cell carcinoma or squamous cell carcinoma and melanoma was noted in 5%. Most of the tumors occur on the head and neck. Ocular abnormalities were found in 40% and included ectropion, corneal opacity, and neoplasms. Progressive neurologic degeneration is seen in about 20% of patients. Xeroderma pigmentosum patients in complementation group C remain free of neurologic problems. Complementation groups are defined by correction of excision repair when fibroblasts from patients in different groups are fused. A variant type with normal excision repair has also been described. Retinoids can prevent the appearance of new cancers, but side effects are significant, and a rebound in the number of cancers occurs when the drug is stopped, suggesting that the tumors are merely suppressed. Photoprotection remains essential for management. Topical application of recombinant liposomal encapsulated T4 endonuclease V repairs UV-induced cyclobutan-pyrimidine dimers and is a promising form of therapy. Gene therapy is also being pursued. Guidelines for evaluation and management from the XP Society can be found at www.xps.org. A publication from the NIH can be found at www.cc.nih.gov/ccc/ patient_education/pepubs/xeroderma.pdf.

Xeroderma pigmentosum, Cockayne syndrome, and trichothiodystrophy are all associated with defects in nucleotide excision repair. Skin tumors in xeroderma pigmentosum patients have sunlight-induced mutations in ras, p53, and ptch genes. Mutations in the XPG gene give rise to the complementation group G form of xeroderma pigmentosum, as well as early-onset Cockayne syndrome.

The De Sanctis-Cacchione syndrome consists of xeroderma pigmentosum with mental deficiency, dwarfism, and gonadal hypoplasia. It occurs most often in patients in complementation group D. Mutations in the ERCC6 gene which also cause Cockayne syndrome type B, have also been demonstrated

COCKAYNE SYNDROME

Cockayne syndrome is an autosomal-recessive syndrome with sun sensitivity and neurologic degeneration. It differs from xeroderma pigmentosum by the lack of freckling and skin cancer, and by the presence of dwarfism, beaked nose, loss of subcutaneous tissue, deafness, basal ganglia calcification, and retinopathy.

Cockayne described the syndrome as *dwarfism with* retinal atrophy and deafness. Dermatologic features include photodermatitis with telangiectasia, atrophy, and scarring. The hands and feet are large and cyanotic. Microcephaly, sunken eyes, severe flexion contractures, dorsal kyphosis, cryptorchidism, cataracts, growth retardation, mental retardation, hypothalamic and cerebellar dysfunction, and retinitis pigmentosa with optic atrophy may be seen. There is progressive neurologic disturbance with a shortened lifespan. Dermal fibroblasts and lymphoblastoid cell lines, as well as cultured anniotic fluid cells from an affected fetus, demonstrate impaired colony-forming ability, and decreased DNA and RNA synthesis after UV light exposure (254 nm).

DNA helicases unwind DNA and are important in DNA replication, DNA repair, and RNA transcription. Mutations in XPB or XPD DNA helicase can result in xeroderma pigmentosum, Cockayne syndrome, or trichothiodystrophy. The CSA and CSB genes responsible for Cockayne syndrome are associated with RNA polymerase. Cockayne syndrome has also been associated with mutations in XPG.

XERODERMA PIGMENTOSUM/COCKAYNE SYNDROME COMPLEX

Some patients have skin features of xeroderma pigmentosum and neurologic features of Cockayne syndrome. Patients in complementation groups B, D, and G have presented with the complex. Mutations in the associated genes may give rise to clinical manifestations of xeroderma pigmentosum, Cockayne syndrome, or the xeroderma pigmentosum/ Cockayne syndrome complex.

TRICHOTHIODYSTROPHY

Trichothiodystrophy is an autosomal-recessive disorder characterized by photosensitivity, ichthyosis, brittle hair, intellectual impairment, decreased fertility, and short stature (PIBIDS). Tay syndrome is similar but lacks photosensitivity. Abnormalities in nucleotide excision repair of UV-damaged DNA are present in about 50% of those with the disorder. The UV sensitivity and defective excision repair are similar to that of xeroderma pigmentosum patients, but these patients do not experience an increased incidence of skin cancer. Two of the three described complementation groups match xeroderma pigmentosum groups B and D, with the XPD gene accounting for most photosensitive trichothiodystrophy. A combined xeroderma pigmentosum/trichothiodystrophy complex has been described. Patients with trichothiodystrophy without xeroderma pigmentosum do not have an increase in skin cancer formation.

The hair, with sulfur reduced to 50% of the normal value, has distinctive features under polarizing, light, and scanning electron microscopy. With polarizing microscopy, the hair shows alternating bright and dark regions that give a striking striped, or tiger tail, appearance, but the pattern may not be evident at birth. With light microscopy, trichoschisis (clean fractures), and trichorrhexis nodosa-like fractures may be seen. In addition, the hair is markedly flattened and folds over itself like a thick ribbon. The hair shaft outline is irregular and slightly undulating, and the melanin granules are distributed in a wavy pattern. With scanning electron microscopy, the surface shows marked ridging and fluting, and the cuticle scales may be absent or greatly reduced.

BLOOM SYNDROME (BLOOM-TORRE-MACHACEK SYNDROME)

Bloom syndrome is transmitted as an autosomal-recessive trait, chiefly among Jewish persons of eastern European origin. It is characterized by photosensitive telangiectatic erythema in the butterfly area of the face and dwarfism. Telangiectatic erythematous patches resembling lupus erythematosus develop in the first 2 years of life. Bullous, crusted lesions may be present on the lips. Exacerbation of skin lesions occurs during the summer. Other changes that may be noted are café-au-lait spots, ichthyosis, acanthosis nigricans, syndactyly, irregular dentition, prominent ears, hypospadias, and cryptorchidism. The stunted growth is characterized by normal body proportions, no endocrine abnormalities (except diabetes mellitus), and low birth weight at full term. Dolichocephaly and narrow, delicate facies are present. Immune functions are abnormal, and gastrointestinal and respiratory infections occur frequently. Cancer of all cell types and sites are increased in frequency. Leukemia, lymphoma, adenocarcinoma of the sigmoid colon, and oral and esophageal squamous cell carcinoma, as well as other malignancies, have been associated with Bloom syndrome. About one-quarter of patients under the age of 20 develop a neoplasm. Regular use of a broad-spectrum sunscreen as well as photoprotection is recommended.

The gene mutated in Bloom syndrome, BLM, codes for a RecQ DNA-helicase. BLM is localized to the nuclear bodies and the nucleolus and is critical for genomic stability. BLM interacts with WRN, the DNA helicase mutated in Werner syndrome, and is part of a large BRCA-1-containing complex containing DNA repair factors. BLM expression is highest during the S and G2 phases of the cell cycle. BLM associates with telomeres and ribosomal DNA. BLM interacts directly with ATM (the protein product of the gene mutated in ataxia-telangiectasia) and together they recognize abnormal DNA structures.

ROTHMUND-THOMSON SYNDROME (POIKILODERMA CONGENITALE)

Rothmund-Thomson syndrome is a rare autosomal-recessive disorder. Poikiloderma begins at 3 to 6 months of age, with tense, pink, edematous patches on the cheeks, hands, feet, and buttocks, sparing the chest, back and abdomen (acute phase). Sensitivity to sunlight may be manifested by the development of bullae or intense erythema after brief sun exposure. There follows fine reticulated or punctate atrophy associated with telangiectasia and reticulated pigmentation (chronic phase) (Fig. 27-32). Characteristically, the arms and legs are affected with sparing of the antecubital and popliteal fossae.

The skin lesions are characteristic. Otherwise, patients with Rothman-Thomson syndrome may have a broad range of noncutaneous lesions. Short stature (two-thirds of patients), small hands with radial ray defects, saddle nose, absence or sparseness of eyebrows and eyelashes (73%), alopecia of the scalp (50%), and numerous bone defects (75%) are frequently observed. Hypogonadism, dystrophic nails, and defective dentition are seen in a significant proportion of patients (25-60%). Cataracts occur in a small percentage of patients in childhood or young adult life. Squamous and basal cell carcinoma of the skin occasionally occur, but it is the risk for osteosarcoma of bone that is

Fig. 27-32 Rothmund-Thomson syndrome. particularly high (>30%). Several patients with compound heterozygous mutations in RECQL4, a human helicase gene, have been reported. Thus, at least a subset of patients with Rothmund-Thomson syndrome has abnormal DNA helicase activity, as do patients with Werner and Bloom syndromes.

HEREDITARY SCLEROSING POIKILODERMA AND MANDIBULOACRAL DYSPLASIA

Hereditary sclerosing poikiloderma is an autosomaldominant condition The skin changes consist of generalized poikiloderma appearing in childhood (but not at birth), with hyperkeratotic and sclerotic cutaneous bands extending across the antecubital spaces, axillary vaults, and popliteal fossae. In addition, the palms and soles may show sclerosis resembling shiny scotch-grain leather. Aortic stenosis, clubbing of the fingers, and localized calcinosis of the skin have also been noted. There is no treatment.

The cases reported by Weary were subsequently reported later in life as mandibuloacral dysplasia, a rare autosomalrecessive syndrome characterized by mandibular hypoplasia; delayed cranial suture closure; dysplastic clavicles; abbreviated, club-shaped terminal phalanges; acroosteolysis; atrophy of the skin of the hands and feet; and typical facial changes. Mandibuloacral dysplasia must be distinguished from progeria and Werner syndrome.

- Fryburg JS, et al: Long-term follow-up of cutaneous changes in siblings with mandibuloacral dysplasia who were originally considered to have hereditary sclerosing poikiloderma. J Am Acad Dermatol 1995;33:900.
- Salvat G, et al: Hereditary sclerosing polkiloderma of Weary: report of a new case. Br J Dermatol 1999;140:366.

SCLEROATROPHIC SYNDROME OF HURIEZ

Huriez syndrome, a very rare autosomal-dominant disorder, is characterized by: 1) scleroatrophy of the hands, with sclerodacyly; 2) ridging, clubbing, or hypoplasia of the nails; and 3) lamellar keratoderma of the hands and, to a lesser extent, the soles. Patients with Huriez syndrome may also have multiple telangiectasias of the lips and face, and flexion contractures of the little finger. Aggressive squamous cell carcinomas occur in the scleroatrophic skin, including that of the palms and soles (13% lifetime risk, 5% mortality in affected persons). Affected patients have reduced Langerhans cells in affected skin, but normal dermal dendritic cells.

Guerriero C, et al: Huriez syndrome: case report with a detailed analysis of skin dendritic cells. Br J Dermatol 2000;143:1091.

FRANCESCHETTI-KLEIN SYNDROME (MANDIBULOFACIAL DYSOSTOSIS)

This syndrome includes palpebral antimongoloid fissures, hypoplasia of the facial bones, macrostomia, vaulted palate, nulformations of both the external and internal ear, buccal-auricular fistula, abnormal development of the neck with stretching of the cheeks, accessory facial fissures, and skeletal deformities. Patients who have the complete syndrome usually die in infancy, but patients with the abortive type may live to an old age. The syndrome is allelic to the Treacher Collins syndrome and caused by the Treacher Collins Franceschetti (TCOF1) gene.

TREACHER COLLINS SYNDROME

This syndrome includes midface hypoplasia with micrognathia, microtia, conductive hearing loss, and cleft palate. It is inherited as an autosomal-dominant trait and caused by mutations in the TCOF1 gene which encodes a protein called treacle.

POPLITEAL PTERYGIUM SYNDROME

Pterygia or skinfolds may extend from the thigh down to the heel and thus prevent extension or rotation of the legs. Crural pterygia, cryptorchism, bifid scrotum, agenesis of the labia majora, cleft lip and palate, adhesions between the eyelids, syndactyly, and talipes equinovarus may be present. Autosomal-dominant inheritance has been described, and the syndrome is allelic to the van der Woude syndrome.

VAN DER WOUDE SYNDROME

The syndrome is an autosomal-dominant craniofacial disorder characterized by hypodontia, pits of the lower lip, and cleft palate. It is associated with mutations in the IRF6 gene. Other reported associations include natal teeth, ankyloglossia, syndactyly, equinovarus foot deformity, and congenital heart disease. Lower lip pits may be found in other congenital disorders, such as popliteal pterygium syndrome, and occasionally in orofaciodigital syndrome type I (oral frenula and clefts, hypoplasia of alae nasi, and digital asymmetry). Surgical excision is the treatment of choice.

APERT SYNDROME (ACROCEPHALOSYNDACTYLY)

Apert syndrome is autosomal-dominantly inherited and characterized by craniosynostosis and fusion of the digits (syndactyly). Patients present with synostosis of the feet, hands, carpi, tarsi, cervical vertebrae, and skull. The facial features are distorted and the second, third, and fourth fingers are fused into a bony mass with a single nail. Neurologic defects may be due in part to brain compression by the abnormal skull. Oculocutaneous albinism and severe acne vulgaris have been reported with Apert syndrome, although some of the acneiform lesions actually represent follicular hamartomas. Mutations in the fibroblast growth factor receptor (FGFR2) gene are responsible for Apert syndrome, Crouzon syndrome, and Pfeiffer syndrome.

PFEIFFER SYNDROME

The syndrome is autosomal-dominantly inherited and consists of osteochondrodysplasia and craniosynostosis. Type 1 has normal intelligence and generally good outcome. Types 2 and 3 have severe neurologic compromise, a poor prognosis, and sporadic occurrence.

CROUZON SYNDROME

The syndrome includes craniosynostosis and acanthosis nigricans. It is associated with mutations in the FGFR2 gene. The Crouzonodermoskeletal syndrome with choanal atresia and hydrocephalus is caused by mutations in the FGFR3 gene, a gene associated with achondroplastic dwarfism.

WHISTLING FACE SYNDROME

In this rare disorder, also known as *cranio-carpo-tarsal* syndrome, Freeman-Sheldon syndrome, Windmill-Vane-Hand syndrome, and distal arthrogryposis type 2, the child appears to be whistling all the time. This configuration is the result of microstomia, deep-set eyes, flattened mid-face, coloboma, contracted joint muscles of the fingers and hands, and alterations of the nostrils. Ulnar deviation of the fingers, lcyphoscoliosis, and talipes equinovarus may be present. Brain anomalies have also been reported. Autosomal-dominant, -recessive, and sporadic variants have been reported. Prenatal diagnosis can be made on ultrasound. Surgical intervention may be required for some patients.

SYNDROMES THAT INCLUDE ABNORMALITIES OF THE HAIR

Hallerman-Streiff Syndrome

This syndrome includes characteristic "bird facies," congenital cataracts, microphthalmia, mandibular hypoplasia, hypotrichosis, and dental abnormalities. The nose is thin, sharp, and hooked, and the chin is absent. The hair is diffusely sparse and brittle. Baldness may occur frontally or at the scalp margins, but sutural alopecia—hair loss following the lines of the cranial sutures—is characteristic of this syndrome. The small face is in sharp contrast with a disproportionately large-appearing head. The lips are thin; some of the teeth may be absent while others are dystrophic, resulting in malocclusion. Nystagmus, strabismus, and other ocular abnormalities are present. Cleft palate and syndactyly may be present, representing overlap with oculodentodigital dysplasia associated with GJA1 gene mutation.

Polyostotic Fibrous Dysplasia (Albright's Disease)

This may present as slowly progressive lifelong unilateral hair loss: scalp, pubic, axillary, and palpebral. Sickle-cell disease is often characterized by scantiness of body and facial hair.

Cronkhite-Canada Syndrome

The Cronkhite-Canada syndrome is characterized by alopecia, skin pigmentation, onychodystrophy, malabsorption, and generalized gastrointestinal polyposis.

Marinesco-Sjögren Syndrome

This syndrome consists of cerebellar ataxia, mental retardation, congenital cataracts, inability to chew food, thin brittle fingernails, and sparse hair. The dystrophic hairs do not have the normal layers (cortex, cuticle, and medulla), and 30% of the hair shafts show narrow bands of abnormal incomplete keratinization. There is an autosomal-recessive type of inheritance in this syndrome and the gene has been mapped to chromosome 5q31.

Trichothiodystrophy

This is discussed above with xeroderma pigmentosum.

Generalized Trichoepitheliomas

Generalized trichoepitheliomas, alopecia, and myasthenia gravis may be a variant of the generalized hair follicle hamartoma syndrome. There is a report of a localized variant of this syndrome. Histologically, there is replacement of the hair follicles by trichoepithelioma-like epithelial proliferations associated with hyperplastic sebaceous glands.

Crow-Fukase (POEMS) syndrome

This syndrome is characterized by polyneuropathy, organomegaly, endocrinopathy, M-protein, and skin changes such as diffuse hyperpigmentation, dependent edema, skin thickening, hyperhidrosis, and hypertrichosis.

Cartilage–Hair Hypoplasia (McKusick Type Metaphyseal Chondrodysplasia)

This encompasses short-limbed dwarfism and abnormally fine and sparse hair in children. These children are especially susceptible to viral infections and recurrent respiratory infections. A functional defect of small lymphocytes, with impaired cell-mediated immunity, may occur. Most patients are anergic to skin-test panels and have increased numbers of natural killer (NK) cells. The major mutation involves the RMRP gene, which encodes a component of mitochondrial RNA-processing endoribonuclease.

Tricho-Rhino-Phalangeal Syndrome

This is a genetic disorder consisting of fine and sparse scalp hair, thin nails, pear-shaped broad nose, and cone-shaped epiphyses of the middle phalanges of some fingers and toes. There is an autosomal-dominant and also a recessive inheritance type. The syndrome can result from either single base pair mutations or deletion of the TRPS1 gene, which encodes a zinc-finger transcription factor located on chromosomal band 8q24.1.

Papillon-Lefèvre Syndrome

This is characterized by hyperkeratosis palmaris et plantaris, periodontosis, and sparsity of the hair. Hyperhidrosis and other signs and symptoms begin early in life. Inheritance of this disease is of an autosomal-recessive type.

Klippel-Feil Syndrome

This syndrome consists of a low posterior scalp hairline extending onto the shoulders, with a short neck, limiting movement of the neck and suggestive of webbing. The cervical vertebrae are fused. This syndrome is caused by faulty segmentation of the mesodermal somites between the third and seventh weeks in utero. Strabismus, nystagmus, cleft palate, bifid uvula, and high palate are other features. This syndrome occurs mostly in girls.

McCusick Syndrome

Features of this syndrome include short-limbed dwarfism and fine, sparse, hypoplastic, and dysmorphic hair.

Atrichia with Papules

This is a rare disorder characterized by loss of hair beginning shortly after birth and the development of cutaneous cystic papules. Mutations in the hairless gene have been identified in both humans and mice, but a similar phenotype has also been reported with a normal hairless gene but with vitamin D-resistant rickets type IIA and mutations in the vitamin D receptor gene. The cyst epithelium demonstrates keratin-15 and -17, suggesting derivation from the follicular bulge and the presence of stem cells. Both the hairless gene and the vitamin D receptor gene produce zinc finger proteins and may have overlapping functions.

KERATOSIS PILARIS

Keratosis pilaris may be limited in mild cases to the posterior upper arms, and manifests as a horny plug in each hair follicle. The thighs are the next most common site, but lesions may occur on the face, forearms, buttocks, trunk, and legs. Facial involvement may be mistaken for acne vulgaris and may leave small pitted scars, even when the condition does not scar elsewhere. Variants of keratosis pilaris with more prominent scarring are included under the heading of keratosis pilaris atrophicans.

The individual lesions are small, acuminate, follicular papules. They may or may not be erythematous. Sometimes the keratotic plugs are the most prominent feature of the eruption, whereas at other times most of the lesions are punctate erythematous papules. Occasionally, inflammatory acneiform pustules and papules may appear.

Forcible removal of one of the plugs leaves a minute cupshaped depression at the apex of the papule, which is soon filled by new keratotic material. The lesions tend to be arranged in poorly defined groups, dotting the otherwise normal skin in a fairly regular pattern. They are prone to appear in xerotic or atopic subjects. Autosomal-dominant inheritance has been described.

Other conditions associated with keratosis pilaris are iclithyosis follicularis, atrichia with papular lesions, mucoepidermal dysplasia, cardiofacio-cutaneous syndrome, ectodermal dysplasia with corkscrew hairs, and KID syndrome.

Treatment is difficult, but some patients respond to topical retinoids. Twelve percent ammonium lactate can produce some smoothing of the lesions but seldom results in improvement of the erythema. Topical calcipotriene is effective in some patients.

Gerbig AW: Treating keratosis pilaris. J Am Acad Dermatol 2002;47:457.

Lateef A, et al: Keratosis pilaris. Cutis 1999;63:205.

FOLLICULAR ATROPHODERMA

Follicular atrophoderma consists of follicular indentations without hairs, notably occurring on extensor surfaces of the hands, legs, and arms. Scrotal (fissured) tongue may also be found. It has been described repeatedly in association with other genetically-determined abnormalities, including X-linked dominant chondrodysplasia punctata, Bazex syndrome (follicular atrophoderma type), and keratosis palmoplantaris disseminata.

KERATOSIS PILARIS ATROPHICANS

Keratosis pilaris atrophicans is seen in three syndromes: 1) keratosis pilaris atrophicans faciei; 2) atrophodermia vermiculata; and 3) keratosis pilaris follicularis spinulosa decalvans. Keratosis pilaris atrophicans has been reported associated with woolly hair and Noonan syndrome. Overlap between the three entities may occur.

Response to therapy is often limited, but some response has been noted with keratolytics and retinoids. Pulsed dye laser has led to improvement in erythema, but not skin roughness.

Keratosis Pilaris Atrophicans Faciei and Ulerythema Ophryogenes

Keratosis pilaris atrophicans faciei is characterized by persistent erythema and small horny follicular papules with onset during childhood. On involution these leave pitted scars and atrophy with resulting alopecia. It involves the eyebrows, from which it may rarely spread to the neighboring skin and even to the scalp. The term *ulerythema ophryo*genes is used to describe cases with involvement limited to the lateral third of the eyebrows.

Lesions may also begin on the cheeks or temples, rather than the eyebrows. The follicles become reddened, then develop papules, and finally, follicular atrophy. In keratosis pilaris atrophicans faciei the follicular involvement extends to the cheeks and forehead.

Histologically, follicular hyperkeratosis of the upper third of the hair follicle is seen. A small depressed scar forms when the lesion heals. It may occur with atopy, and may be seen in Noonan syndrome and the cardio-facio-cutaneous syndrome. Transmission is autosomal dominant.

Atrophodermia Vermiculata

Atrophodermia vermiculata is also known as atrophoderma vermiculata, atrophodermia ulerythematosa, folliculitis ulerythematosa reticulata, and honeycomb atrophy. It is characterized by symmetrical involvement of the face by numerous closely crowded small areas of atrophy separated by narrow ridges, producing a cribriform or honeycomb surface. This worm-eaten (vermiculate) appearance results from atrophy of the follicles and surrounding skin. Each atrophic area is an abrupt, pitlike depression 1 to 3 mm in diameter. Among the ridges a few milia may be seen.

The skin covering the ridges is even with the normal skin and is contrasted with it by being somewhat waxy, firmer, and apparently stretched. The cause of the disease is undetermined but familial occurrence has been noted, and it may be associated with other diseases, such as congenital heart block, other cardiac anomalies, neurofibromatosis, oligophrenia, or Down syndrome.

Histologically, the epidermis is slightly atrophic with diminution in size of the interpapillary projections. In the dermis the capillaries are dilated and the vessels have a moderate lymphocytic perivascular infiltration. Follicles may be enlarged, tortuous, dilated, and hyperkeratotic.

Rombo Syndrome

Rombo syndrome is a rare disorder characterized by atrophodermia vermiculata, cyanosis of the hands and feet, milia, telangiectases, hypotrichosis, multiple basal cell carcinomas, and trichoepitheliomas. The associated vermicular atrophoderma produces a coarse, grainy skin texture. The syndrome is inherited in an autosomal-dominant fashion. It must be distinguished from Bazex syndrome, Rasmussen syndrome (milia, trichoepithelioma, and cylindroma), and multiple trichoepitheliomas.

Keratosis Follicularis Spinulosa Decalvans (Siemens-1 syndrome)

In keratosis follicularis spinulosa decalvans, keratosis pilaris begins on the face and progresses to involve the scalp, limbs, and trunk. There is hyperkeratosis of the palms and soles. Cicatricial alopecia of the scalp and eyebrows is characteristic. Atopy, photophobia, and corneal abnormalities are commonly associated. Deafness, physical and mental retardation, recurrent infections, nail abnormalities, and aminoaciduria have also been purported associations. The disorder is genetically heterogeneous. Although inheritance in large kindreds has been X-linked recessive, X-linked dominant and autosomal-dominant inheritance have also been suggested. In one X-linked form, the defective genetic site is on Xp22.13-p22.2 in the region of the gene for spermidine/ spermine N(1)-acetyltransferase.

CHAPTER

28 Dermal and Subcutaneous Tumors

The dermis and subcutaneous tissue contain many cellular elements, all capable of both reactive and neoplastic proliferation. In this chapter, proliferations derived from vascular endothelial cells, fibroblasts, myofibroblasts, smooth muscle cells, Schwann cells, and lipocytes are reviewed. Also discussed are several neoplasms of cells invading or aberrantly present in the dermis, such as metastatic cancer, endometriosis, and meningioma.

CUTANEOUS VASCULAR ANOMALIES

Clear differentiation between infantile hemangiomas and vascular malformations is helpful when planning therapy, as infantile hemangiomas involute spontaneously while vascular malformations are persistent. The biology of vascular lesions remains a fertile area for research. Blie et al reported six kindreds in which infantile hemangiomas and/or vascular malformations occurred in various family members in an autosomal-dominant fashion. This unexpected finding clinically links malformations and hemangiomas. The nature of underlying angiogenic etiologic factors awaits elucidation. PHACE syndrome is another instance where hemangiomas and vascular malformations segregate together. Pediatric patients with vascular abnormalities benefit from multidisciplinary evaluation by experts, as the diagnosis and management may be difficult.

Hamartomas

Hamartomas are characterized by an abnormal arrangement of tissues normally present in a given site.

Phakomatosis Pigmentovascularis Patients with a combination of vascular malformations and melanocytic or epidermal nevi are grouped into this disorder, and are manifestations of genetic twin spotting. In the traditional classification, types 1 to IV have nevus flammeus. Those with a coexisting epidermal nevus have type I; if aberrant Mongolian spots are present, it is classified as type II; if a nevus spilus is seen, it is classified as type III; and when both ectopic Mongolian spots and nevus spilus are present, it is

classified as type IV. The last three categories may have associated nevus anemicus. The association of extensive cutis marmorata telangiectatica congenita and aberrant Mongolian spots has been classified as type V. If cutaneous disease only is present, the patient's condition is designated subtype a; if there is associated systemic disease, subtype b is appended. A revised classification includes only 3 types: phacomatosis cesioflammea (blue spots and nevus flammeus), phacomatosis spilorosa (nevus spilus and a pale pink spot), and phacomatosis cesiomarmorata (blue spots and cutis marmorata telangiectatica congenita). Associated systemic findings may include intracranial and visceral vascular anomalies, ocular abnormalities, choroidal melanoma and hemihypertrophy of the limbs. Type II is the most common (85%). Half of patients with this type have serious manifestations, such as Klippel-Trenaunay-Parkes-Weber syndrome or Sturge-Weber syndrome. Type III has been associated with multiple granular cell tumors. Most patients are Asian.

Eccrine Angiomatous Hamartoma Eccrine angiomatous hamartoma usually appears as a solitary nodular lesion on the acral areas of the extremities, particularly the palms and soles. This lesion appears at birth or in early childhood and is often associated with pain and hyperhidrosis. The lesion is a dome-shaped, tender, bluish nodule. When stroked or pinched, drops or beaded rings of perspiration may be seen.

Histologically, there is a combination of lobules of mature eccrine glands and ducts with thin-walled blood vessels. Excision may be necessary because of pain.

Pelle MT, et al. Eccrine angiomatous hamartoma. J Am Acad Dermatol 2002;47:429.

Malformations

These are abnormal structures that result from an aberration in embryonic development or trauma. The abnormality may result from an anatomic malformation, or from functional alteration (as in nevus anemicus). The former are subdivided according to the type of vessel involved: capillary, venous, arterial, lymphatic, or combined.

Nevus Anemicus Nevus anemicus is a congenital disorder characterized by macules of varying size and shape that are paler than the surrounding skin and cannot be made red by trauma, cold, or heat. The nevus resembles vitiligo, but there is a normal amount of melanin. Wood's light does not accentuate it, and diascopy causes it to merge into the surrounding blanched skin. The patches are usually well defined with irregular edges. Rarely, it may occur in neuro-fibromatosis, tuberous sclerosis, or as one component of phakomatosis pigmentovascularis. In nevus anemicus the triple response of Lewis lacks a flare, but outside the nevus a flare does develop after rubbing the skin. The underlying defect is an increased sensitivity of the blood vessels to catecholamines.

Ahkami RN, et al: Nevus anemicus. Dermatology 1999;198:327.

Nevus Oligemicus Nevus oligemicus presents as a patch of livid skin that is cooler than the normal skin, as a result of decreased blood flow. Vasoconstriction of deep vessels is thought to be the underlying defect.

- Plantin P, et al: Nevus oligemicus. J Am Acad Dermatol 1992; 26:268.

Cutis Marmorata Telangiectatica Congenita (Congenital Phlebectasia, Van Lohuizen Syndrome) Cutis marmorata telangiectatica congenita is characterized by the presence of a purplish, reticulated vascular network with a segmental distribution, usually involving the extremities (Fig. 28-1). The mottling is pronounced and is made more distinct by crying, vigorous activity, and cold. Lesions usually improve by 2 years of age, but may remain stable. The condition occurs sporadically, and there is a female preponderance. The segmental distribution suggests mosaicism, and occasional familial occurrence could be explained by paradominant inheritance, where heterozygous individuals are phenotypically normal, the mutation is transmitted unperceived, and only becomes manifest when a post-zygotic mutation gives rise to loss of heterozygosity.

Associated anomalies occur in more than half of patients. Common anomalies include varicosities, nevus flammeus, ulceration, macrocephaly, and hypoplasia and hypertrophy of soft tissue and bone. Unusual associations include generalized congenital fibromatosis, premature ovarian failure, Chiari I malformation, and rectal and genital anomalies. These lesions are associated with Mongolian spots as type 5 phacomatosis pignentovascularis. They have also been reported in association with features of the Adams-Oliver syndrome (limb abnormalities, scalp defects, skull ossification defects).

The differential diagnosis includes residual vascular lesions from neonatal lupus and Bockenheimer syndrome. Bockenheimer syndrome appears in childhood and shows

progressive development of large venous ectasias involving one limb. No treatment is required. Many will become less noticeable with time.

Nevus Flammeus (Capillary Malformation, Port-Wine Stain) Nevus flammeus nuchae (stork bite) is a congenital capillary malformation present in 25% of newborns. It may persist in at least 5% of the population. It usually is a pink-red macule situated on the posterior midline between the occipital protuberance and the tip of the spine of the fifth cervical vertebra. The long axis is usually up and down. A similar appearing midline nevus flammeus (salmon patch or angel's kiss) on the glabellar region or on one upper eyelid is present in approximately 15% of newborns. They tend to fade during childhood.

Other port-wine stains occur in an estimated 3 in 1000 children. They are present at birth, and vary in color from pink to dark or bluish red. The lesions are usually unilateral

Fig. 28-1 Cutis marmorata telangiectatica congenital. (Courtesy of Brooke Army Medical Center Teaching File)

Fig. 28-2 Port-wine stain.

Fig. 28-3 Port-wine stain

and located on the face and neck, although they may be widespread and involve as much as half the body. The most common site is a unilateral distribution on the face (Fig. 28-2). The mucous membrane of the mouth may be involved (Fig. 28-3). Although the surface of a nevus flammeus is usually smooth, small vascular nodular outgrowths or warty excressences may develop over time. These lesions often become more bluish or purple with age. Several reports document multiple basal cell carcinomas occurring in adult life over sites of long-standing nevus flammeus. Rarely, nevus flammeus may appear as an acquired condition, usually with onset after trauma.

Nevus flammeus in the area supplied by the ophthalmic division of the trigeminal cranial nerve is a component of the Sturge-Weber syndrome (encephalotrigeminal angiomatosis), but the leptomeningeal component is present in only 10% of patients with all or most of the V1 branch of the trigeminal nerve involved. Leptomeningeal angiomatosis may clinically manifest as epilepsy, mental retardation, hemiplegia, hemisensory defects, and homonymous hemianopsia. Characteristic calcifications are present in the outer layers of the cerebral cortex; these consist of double-contoured "tram tracks" that follow the brain convolutions. Ocular abnormalities, such as glaucoma, buphthalmos (infantile glaucoma, related to abnormal development of the angle formed by cornea and iris), retinal detachment, and blindness affect approximately 50% of patients. These may be present without leptomeningeal involvement. The syndrome results from the persistence of the primitive embryonal vascular plexus that develops during the sixth fetal week around the cephalic neural tube and in the region destined to become facial skin. Normally, the plexus regresses during the ninth week, but in the Sturge-Weber syndrome it persists. Fibronectin gene expression is increased in lesional fibroblasts.

Overgrowth of soft tissue and underlying bone may occur in an affected extremity, giving rise to the Klippel-Trenaunay-Parkes-Weber syndrome. The Klippel-Trenaunay syndrome is characterized by port-wine malformations and the Parkes-Weber syndrome by deep arteriovenous malformations.

Port-wine stains are components of many rare congenital disorders. Occasionally, nevus flammeus may be associated with nevus anemicus, nevus spilus, atypical Mongolian spots, or epidermal nevi. Such patients have a condition called phakomatosis pigmentovascularis. The Beckwith-Wiedemann syndrome may comprise facial port-wine stain, macroglossia, omphalocele, visceral hyperplasia, occasionally hemihypertrophy, and hypoglycemia. Cobb syndrome (cutaneous meningospinal angiomatosis) is a nonfamilial disorder characterized by a port-wine hemangioma or other vascular malformation in a dermatome supplied by a segment of the spinal cord containing a venous or arteriovenous malformation. Kyphoscoliosis is common and multiple neurologic, gastrointestinal, urologic, and skeletal abnormalities may also be present. Proteus syndrome is characterized by vascular malformations including nevus flammeus, hemihypertrophy, macrodactyly, vertucous epidermal nevus, soft-tissue subcutaneous masses, and cerebritorm overgrowth of the plantar surface. Roberts syndrome consists of a facial portwine stain and hypomelia, hypotrichosis, growth retardation, and cleft lip. The Wyburn-Mason syndrome consists of unilateral retinal arteriovenous malformation associated with ipsilateral port-wine stain near the affected eye. This may be present in association with Sturge-Weber syndrome. The TAR syndrome is defined by congenital thrombocytopenia, bilateral absence or hypoplasia of the radius, and port-wine stain. Coats' disease manifests retinal telangiectasia and ipsilateral facial port-wine stain.

Occasional familial segregation of port-wine stains has been noted, and a large associated gene locus, CMC1, has been identified on chromosome 5q. RASA1, a gene encoding p120-RasGAP, is found within this region and heterozygous inactivating RASA1 mutations have been found in affected families.

Histologically, port-wine stains demonstrate dilation of capillaries in the subpapillary network. Laser therapy has been used with satisfactory results, but a number of treatments are required and recurrence is common. The flashlamp pulsed dye laser has the best record of safety and efficacy. Commonly, a pulse duration of 0.45 ms is used. A study of cryogen-spray cooled laser treatment at wavelengths of 585 versus 595 nm, both with 7-mm spot size in a range of 7 to 10 J/cm², demonstrated better blanching at 585 nm. In another study, purple lesions responded best to 585 nm at

0.5 ms, while red and pink lesions showed similar results with either 585 nm at 0.5 ms or 595 nm for 20 ms. In this study, 595 nm at 0.5 ms was less effective than the other settings. Optical-thermal models predict that for vessel diameters of 40, 80, and 120 μ m, effective pulse durations should be approximately 1.5, 6, and 20 ms, respectively. Cryospray cooling and fluence can be varied to produce optimal results. For darker skinned patients, multiple pulse stacking with multiple cryogen spurts provides better epidermal protection. Intense pulsed light has been effective in some patients resistant to multiple pulsed dye laser treatments.

Verrucous Vascular Malformation (Angiokeratoma Circumscriptum Naeviforme) This is a malformation of dermal and subcutaneous capillaries and veins. The vascular malformation is congenital. Over time, a verrucous component appears. The lesions are bluish-red, well-defined, and occur on the lower extremities mostly, but also on the chest or forearm. Linear segmental lesions have been described. Associated spinal lesions (Cobb syndrome) have been reported. Klippel-Trenaunay syndrome has also been reported in association with verrucous vascular malformation. Superficial ablative therapy is typically followed by recurrence, regardless of whether ablation is performed by excision, laser, cryotherapy, or electrocautery. Full-thickness excision is generally effective, and may be used in combination with laser therapy.

- Yang CH, et al: Successful surgical treatment of vertucous hemangioma: a combined approach. Dermatol Surg 2002;28:913.

Deep Venous Malformations Including Cavernous

Venous Malformation Cavernous venous malformations present as rounded, bright red or deep purple, spongy nodules. They occur chiefly on the head and neck and may involve both the skin and the mucous membranes. There is usually a deep component with a connection to the venous circulation. Calcified phleboliths and localized hyperhidrosis may occasionally be present, but the lesions are generally asymptomatic. The deep components are not amenable to laser therapy. Results of surgical resection are generally poor. Compression may be helpful. Customized, snug-fitting garments are preferable to elastic bandages.

Several syndromes are associated with venous malformations. The Bannayan-Riley-Ruvalcaba syndrome is described in Chapter 30. Maffucci syndrome, also known as dyschondroplasia with hemangiomata, is characterized by multiple vascular malformations with dyschondroplasia. The dyschondroplasia is manifested by uneven bone growth as a result of the defects of ossification, with enchondromatosis that results in multiple and frequent fractures in the period of bone growth. During the prepubertal years, 1- to 2-cm nodules appear on the small bones of the hand or foot. Later, larger nodules, the enchondromas, appear on the long bones. Much later, similar lesions appear on the trunk. Sarcomatous degeneration occurs in 50% of patients. The distribution of the lesions is mostly unilateral. Multiple venous malformations of the skin and mucous membranes are present in this nonhereditary mesodermal dysplasia disorder. Lymphangiomas may also occur. Pigmentary changes, such as vitiligo and café-au-lait macules, have been noted. In Ollier disease, the enchondromatosis is present without the cutaneous abnormalities. Human enchondromatosis has been associated with abnormalities in parathyroid hormone-related protein (PTHrP), its receptor, and the Indian hedgehog (IHH) gene. PTHrP delays differentiation of proliferating chondrocytes, whereas IHH promotes proliferation.

The blue rubber bleb nevus syndrome is characterized by cutaneous and gastrointestinal venous malformations. The skin lesions have a cyanotic, bluish appearance with a soft, elevated, nipple-like center, but deeper lesions may also occur. They can be emptied by firm pressure, leaving them flaccid. They are located predominantly on the trunk and arms. Nocturnal pain may occur and is a characteristic symptom. Gastrointestinal hemangiomas are found throughout the gastrointestinal tract, but are numerous in the small intestines. Rupture of a lesion may produce melena. Occasionally, other organs may express venous malformations and symptomatic central nervous system (CNS) lesions have been described. This syndrome generally occurs as a sporadic condition. It may be present as an autosomal-dominant familial trait. Treatment of bleeding or painful lesions is destruction or excision. Minimally invasive surgical techniques are well suited to the treatment of numerous lesions. For patients who continue to have bleeding episodes that require blood transfusions, octreotide, a somatostatin analog known to decrease splanchnic blood flow, may be effective. Epsilonaminocaproic acid has also been used.

Gorham's disease (Gorham's sign) is characterized by cutaneous and osseus venous and lymphatic malformations associated with massive osteolysis or "disappearing bones." Although multiple areas of the skeletal system may be involved, usually only a single bone is destroyed. There is complete or partial replacement of the bone with fibrous tissue. The cutaneous malformation may be the initial sign of the disease, which appears commonly in young children, usually in areas adjacent to involved bones.

Sinusoidal hemangioma is a vascular malformation that usually presents in adults as a bluish-purple nodule, less than 4 cm in diameter, on the trunk or breasts. Multiple lesions may occur and a facial location has also been reported. Histologically, it appears as a lobular, circumscribed mass with dilated interconnected vascular channels filled with blood.

A familial condition of multiple cutaneous and mucosal venous malformations that show abnormal venous channels with decreased or absent smooth muscle has been shown to be the result of an activating mutation in the receptor tyrosine kinase TIE-2 endothelial gene. It is located on chromosome 9p and is the result of a single amino acid substitution in the kinase domain of the TIE-2 receptor.

Cerebral cavernomas are vascular malformations that may be inherited in an autosomal-dominant fashion. The gene, CCM1, has been mapped to chromosome 7. Cutaneous malformations are sometimes present, including hyperkeratotic cutaneous capillary venous malformations.

Venous malformations (VM) should be distinguished from glomuvenous malformations (GM, gomangioma). VM are usually sporadic, while GM are frequently inherited. VM is linked to chromosome 9p21, while GM is linked to 1p21 and loss of function mutations in glomulin. GM can be pink at initial presentation, but evolves to blue-black with a cobblestone appearance with minimal hyperkeratosis. Involvement of an extremity is typical and the lesions are often painful if compressed. VM is an isolated mucosal or subcutaneous blue lesion that may involve muscle. The lesion often shrinks with external pressure and is typically painful in the morning due to congestion. Increased pain may be noted at puberty, during menstruation, with pregnancy or with oral contraceptives. VM may be associated with intravascular coagulopathy. Sclerotherapy is more effective in VM than in GM.

Klippel-Trenaunay Syndrome (Hemangiectatic Hypertrophy, Angioosteohypertrophy Syndrome) Klippel-Trenaunay syndrome (KTS) is characterized as a triad of nevus flammeus, venous and lymphatic malformations, and soft-tissue hypertrophy of the affected extremity. The lower limb is affected in approximately 95% of patients. When there is an associated arteriovenous fistula, Parkes-Weber is appended to the diagnosis.

The earliest and most common presenting sign is a nevus flammeus that is confined to the skin of an extremity. The port-wine stain often stops abruptly at the midline with a sharp, linear border, but it may be patchy and extend over the buttocks and trunk, and may occasionally be seen with a bilateral or generalized distribution. Varicose veins may be present. The deeper venous malformation in this sporadic syndrome may be confined to the skin; however, it is common for the malformation to extend to muscle and bone. Venous thromboembolism has been reported with an incidence as high as 22%. In other patients, the deep venous system is hypoplastic.

The involved limb is usually larger and longer than normal. Other less frequent features include intermittent claudication, venous ulcers, increased skin temperature, diffuse hair loss, hypertrichosis, lymphedema, altered sweating, lacrimation, or salivation. Gait abnormalities are common. Hemihypertrophy of the face; cutaneous lymphangioma; varicose pulmonary, bladder, and colonic veins; and recurrent pulmonary emboli have been reported. Intradural spinal cord arteriovenous malformations, epidural hemangioma, and epidural angiomyolipoma have been reported to occur at the same segmental level as cutaneous lesions of KTS syndrome. Clinical evaluation consists of color duplex ultrasonography to evaluate the patency of the deep venous system, magnetic resonance imaging (MRI) for visualization of hypertrophic muscle and bone, arteriography when an arteriovenous fistula is suspected, and conventional radiography of both extremities. Early venography may be performed, if the deep venous system is not hypoplastic, to determine whether there are defects that might be amenable to surgical correction. Thick-slice dynamic magnetic resonance projection angiography (MRPA) and intra-arterial digital subtraction angiography can be used to detect arteriovenous shunting in Parkes-Weber syndrome.

Mutations associated with the angiogenic factor, VG5Q, have been described in KTS. A balanced translocation involving chromosomes 8q22.3 and 14q13 has also been reported.

Flashlamp pumped pulsed dye laser treatments may be used for the nevus flammeus component. The varicosities and

Bertucci V, et al: What syndrome is this? Ollier disease + vascular lesions: Maffucci syndrome. Pediatr Dermatol 1995;12:55.

edema may be managed with elevation, graded compression pumps, fitted garments, and diuretics. Surgery may be performed to correct the inequality in limb length, to relieve deep venous obstruction, or to correct an associated arteriovenous fistula. Arteriovenous Fistulas The arteriovenous (AV) fistula is a route from artery to vein, bypassing the capillary bed. AV fistulas may be congenital or acquired. Congenital AV fistulas occur mostly on the extremities and may be recognized, or at least suspected, in the presence of varicose veins, ulcerations, hemangiomas, and nevus flammeus. They may occur internally as a component of Osler-Weber-Rendu disease (hereditary hemorrhagic telangiectasia). Acquired fistulas are usually the result of trauma, but may be created intentionally for hemodialysis access.

The skin over these fistulas is warmer, hair may grow faster, and the affected limb may be larger than the other, thrills and bruits may be discerned in some cases. There may be changes resulting from stasis, edema, a vascular mass, increased sweating, or paresthesias. At times, reddish-purple nodules or a plaque may be present that clinically resembles Kaposi sarcoma; this has been called pseudo-Kaposi surcoma (Stewart-Bluefarb syndrome). It may occur because of congenital malformations, in which case a unilateral purplish discoloration of the skin over or distal to the AV anomaly begins to appear in the second or third decade of life. This type accounts for 80% of cases; the remainder are secondary to fistulas caused by trauma. Jatrogenic AV fistulas, such as those produced to facilitate hemodialysis, may also bring about skin changes, including reactive angioendotheliomatosis. Histologically, there is an increase in thick-walled vessels lined by plump endothelial cells, extravasated erythrocytes, and deposits of hemosiderin. Proliferating endothelial cells may occlude the lumen.

Cirsoid aneurysms (angioma arteriale racemosum) are uncommon congenital AV fistulas of the scalp or face. They may appear on the skin as a pulsating mass that may extend over the neck and scalp, and may penetrate into the cranium, or they may simply manifest as a solitary blue or red papule in the mid-adult period.

Diagnosis of an AV fistula is established by plethysmography, thermography, determination of oxygen saturation of venous blood, or arteriography. Treatment of traumatically-induced AV fistulas by excision is curative. Because the congenital malformation variety consists of multiple small distal lesions, surgical intervention is not feasible in most cases. Color echo-Doppler ultrasonography-guided sclerotherapy with polidocanol microfoam has been used successfully in this setting. Pressure and elevation as supportive measures may limit ulceration, infection, and other secondary complications. Cirsoid aneurysms of the scalp have been treated by embolization and injection of sodium tetradecyl sulfate.

Prominent Inferior Labial Artery The arteries supplying the lips are normally tortuous to accommodate the movements of the mouth. Howell and Freeman reported a potentially troublesome arterial anomaly of the lower lip characterized by the appearance of a pulsating papule in the lower vermilion, a centimeter or two from the oral commissure, formed by an especially tortuous segment of the inferior labial artery. A similar anomaly may involve the upper lip. Caliber-persistent labial artery may be misdiagnosed as squamous cell carcinoma, and the biopsy may produce significant bleeding. On the lip, it is best to "palpate for pulsation prior to puncture."

Acral Arteriolar Ectasia Paslin and Heaton reported a man with purple serpiginous ectatic arterioles on the backs of his fingers, which appeared in the fifth decade of life.

Paslin DA, Heaton CL: Acral arteriolar ectasia. Arch Dermatol 1972;106:906.

Superficial Lymphatic Malformation (lymphangioma circumscriptum) The old term for superficial lymphatic malformation was lymphangioma circumscriptum; however, this is not a tumor but rather a congenital malformation of the superficial lymphatics. A superficial lymphatic malformation presents as groups of deep-seated, vesicle-like papules, resembling frog spawn, at birth or shortly thereafter. The lesions are usually yellowish but may be pink, red, or dark. When the papules are punctured, they exude clear, colorless lymph. The papules are arranged irregularly in groups that may be interconnected by sparsely scattered lymph cysts. The entire process, however, is as a rule localized to one region. The sites of predilection are the abdomen, axillae, genitalia, and mouth, particularly the tongue. The scrotum is subject to multifocal lymphatic malformations presenting as clear, thick-walled, vesicle-like lesions. At times the surface is verrucous, in which instance the color may be brownish,

and the lesions may be mistaken for warts. Lesions resembling molluscum contagiosum have also been described.

Frequently, the lesions consist of a combination of blood and lymph element so that purple areas are sometimes seen scattered within the vesicle-like papules. The lesions are also frequently associated with a deep component that occupies the subcutaneous tissues and muscles. In the course of time, these lymphatic malformations show only slight changes.

Excision and grafting, fulguration, or coagulation are frequently unsatisfactory because of recurrences resulting from vascular connections between the surface lesions and deep-seated lymphatic cisterns. The deeper component should be evaluated by MRI or other suitable radiologic imaging procedure to delineate the extent of deep involvement before planned procedures. Vaporization with the CO_2 laser may be successful if deeper components are not present. Pulsed dye laser has also been reported as effective. Keloid formation has been described after laser vaporization of genital lymphangiomas. Sclerotherapy may be successful.

Cystic Lymphatic Malformation Cystic lymphatic malformations are deep-seated, typically multilocular, illdefined soft-tissue masses that are painless and covered by normal skin. They are most common in the oral cavity and on the extremities, and have been described in Maffucci syndrome. Cystic hygromas are clinically better circumscribed, occurring usually in the neck, axilla, or groin. The posterior neck lesions may be associated with Turner syndrome, other chromosomal aneuploidy conditions, hydrops fetalis, or other congenital abnormalities. Cytogenic analysis of children born with cystic hygromas is indicated as aneuploidy may recur in subsequent pregnancies, Transabdominal or transvaginal sonography can visualize these lesions in utero. Usually these lesions will recur after surgical treatments because of their depth, but injection sclerotherapy with agents such as OK-432 may result in regression.

Lymphangiomatosis Diffuse or multifocal dilated lymphatic channels involving the skin, soft tissues, bone, and parenchymal organs are a rare congenital condition. If an extremity is affected, the prognosis is good; however, when vital internal organs are involved, the prognosis is poor. Skin lesions are a presenting sign in 7% of patients with thoracic lymphangiomatosis. These patients have a high incidence of complications, including chylothorax (49%), pulmonary infiltrates (45%), bone lesions (39%), splenic lesions (19%), cervical involvement (15%), and disseminated intravascular coagulation (9%).

Dilation of Preexisting Vessels

Spider Angioma (Vascular Spider, Spider Nevus, Nevus Araneus) The lesion of spider angioma is suggestive of a red spider; hence its name. The ascending central arteriole represents the "body" of the spider, and the radiating fine vessels are suggestive of the multiple legs. These small telangiectases occur singly or severally, most frequently on the face and neck, with decreasing frequency on the upper trunk and upper extremities. In young children, the sites of predilection are the backs of the hands and forearms, and the face.

Young children and pregnant women show these lesions most frequently. In pregnant women palmar erythema is usually present with the vascular spiders. The presence of vascular spiders in otherwise healthy children is common.

The vascular spiders of childhood usually involute without treatment; however, several years may elapse before that happens. In pregnant women, most lesions will involute soon after delivery.

Vascular spiders also occur in patients with cirrhosis, hepatitis C, malignant disease of the liver, and other hepatic dysfunctions. The common denominator has been shown to be an elevated blood estrogen level. Elevations in vascular endothelial growth factor and basic fibroblastic growth factor are also significant predictors for spider angiomas in cirrhotic patients. When vascular spiders occur with palmar erythema and pallid nails with distal hyperemic bands, cirrhosis of the liver should be considered. Arteriovenous hemangioma has also been reported to be associated with chronic liver disease.

If active therapy is to be performed, either obliteration by electrodesiccation of the central punctum or laser treatment produces excellent results.

Venous Lakes Venous lakes (phlebectases) are small, dark blue, slightly elevated blebs (Fig. 28-4). These are easily compressed (Fig. 28-5), and are located on the face, ears, lips, neck, forearms, and backs of the hands. These manifestations of chronic sun damage are markedly dilated, blood-filled spaces that are lined with thin, elongated endothelial cells, and are usually surrounded by prominent solar elastosis.

Venous lakes may be treated by light electrocautery, laser ablation, fulguration, infrared coagulation, intralesional injection of 1% polidocanol, and cryotherapy. Sometimes they must be treated because of traumatic bleeding.

Capillary Aneurysms These flesh-colored solitary lesions, resembling an intradermal nevus, may suddenly grow larger and darker and become blue-black or black as a result of thrombosis. They are surrounded by a zone of erythema. The lesions may be clinically indistinguishable from malignant melanoma. Histologically, these are thrombotic, dilated capillaries lying just below the epidermis. Shave excision in stages will expose the clot and eliminate the uncertainty.

Telangiectasia A telangiectasis is a dilated cutaneous blood vessel—venule, capillary, or arteriole. Telangiectases are fine, linear vessels coursing on the surface of the skin; the name given to them collectively is *telangiectasia*. Telangiectasia may occur in normal skin at any age, in both sexes, and anywhere on the skin and mucous membranes. Fine telangiectases may be seen on the alae nasi of most adults.

They are prominent in areas of chronic actinic damage seen in fair-skinned persons. Persons long exposed to wind, cold, or heat are also subject to telangiectasia.

Telangiectases can be found in such conditions as radiodermatitis, xeroderma pigmentosum, lupus erythematosus, dermatomyositis, scleroderma and the CREST syndrome, rosacea, cirrhosis of the liver, acquired immunodeficiency syndrome (AIDS), poikiloderma, basal cell carcinoma, necrobiosis lipoidica diabeticorum, sarcoid, lupus vulgaris, adenoma sebaceum, keloid, angioma serpiginosum, angiokeratoma corporis diffusum, ataxia-telangiectasia, pregnancy, Osler-Weber-Rendu disease, and Bloom syndrome. These entities are discussed in other sections with the disease states in which they occur.

Altered capillary patterns on the fingernail folds (cuticular telangiectases) are indicative of collagen vascular disease, such as lupus erythematosus, scleroderma, or dermatomyositis. Tortuous glomeruloid loops are characteristic of lupus erythematosus, whereas dilated loops and avascular areas are typical for scleroderma and dermatomyositis. Reticular telangiectatic erythema may occur overlying implantable cardioverter defibrillators.

Electrodessication and laser ablation can be effective. Pulsed dye laser and other vascular lasers, such as the 532nm Nd:YAG laser, are usually well tolerated and associated with a low risk of scarring. Larger vessels require a longer pulse duration. Contact or cryospray cooling can reduce the incidence of complications. Pulse stacking (multiple pulses of low fluencies) has been used to reduce the incidence of side effects, such as purpura, hyperpigmentation, hypopigmentation, and scar formation.

Generalized Essential Telangiectasia Generalized essential telangiectasia (GET) is characterized by the dilation of veins and capillaries over a large segment of the body without preceding or coexisting skin lesions. The telangiectases may be distributed over the entire body or be localized to some large area such as the legs, arms, and trunk. They may be discrete or confluent. Distribution along the course of the cutaneous nerves may occur. This type of telangiectasia is not associated with systemic disease, although patients with a similar appearance may have autoimmune disease. One report documented gastrointestinal bleeding from a watermelon stomach in a woman with GET.

GET develops most frequently in women in their 40s and 50s. The initial onset is on the lower legs and then spreads to the upper legs, abdomen, and arms. The dilations persist indefinitely. Generally, this is a sporadic condition, although it has been described in families as an autosomal-dominant condition. In the latter case it has been termed hereditary benign telangiectasia.

It has been reported that GET may be differentiated from telangiectasia associated with systemic disease by the presence of alkaline phosphatase activity. Telangiectatic vessels in GET do not have alkaline phosphatase activity in the endothelium of the terminal arteriole and the arterial portion of the capillary loops.

Individual areas may be treated with laser ablation. Highenergy, high-frequency, long-pulse Nd:YAG laser and the 585-nm flashlamp-pumped pulsed dye laser have been reported to produce good results. Tetracycline, ketoconazole, and the treatment of a chronic sinus infection have led to involution in individual reports.

Universal Angiomatosis Universal angiomatosis, called generalized telangiectasia by Bean, is a bleeding disease that affects the blood vessels of the skin and mucous membranes as well as other parts of the body. Bean and Rather reported a 13-year-old boy who had frequent nose bleeds, and ear and upper respiratory infections. He had

mottled skin with redness that blanched on pressure. Finely dilated blood vessels were universal, suggesting the term "pink man." Some irregular white patches were also present. Continual bleeding into the skin was evident despite normal coagulation of the blood. This type of angiomatosis differs from generalized telangiectasia because of its hemorrhagic tendency, especially epistaxis.

Bean WB, Rathe J: Universal angiomatosis. Arch Intern Med 1963;112:869.

Unilateral Nevoid Telangiectasia In unilateral nevoid telangiectasia, fine, threadlike telangiectases develop in a unilateral, sometimes dermatomal, distribution. The areas most often involved are the trigeminal and C3 and C4 or adjacent areas, with the right side involved slightly more often than the left. In some cases the condition is congenital, but more often it is acquired. Increased estrogen appears to play a role in the onset of acquired cases, e.g. pregnancy, puberty in women, adrenarche in men, and hepatitis/alcohol related cases have all been reported.

Sardana K, et al: Unilateral nevoid telangiectasia syndrome. J Dermatol 2001;28:453.

Hynes LR, et al: Unilateral nevoid telangiectasia. J Am Acad Dermatol 1997;36:819.

Angiokeratomas Angiokeratomas are essentially telangiectases that have an overlying hyperkeratotic surface (Fig. 28-6). These are dilations of preexisting papillary dermal vessels. Angiokeratoma circumscriptum is discussed in the malformations section above. Angiokeratoma corporis diffusum is discussed in Chapter 26.

Angiokeratoma of Mibelli The lesions of angiokeratoma of Mibelli consist of 1- to 5-mm red vascular papules, the surfaces of which become hyperkeratotic in the course of time. The papules are dull red or purplish-black, vertucous, and rounded, and are usually situated on the dorsum of the fingers and toes, the elbows, and knees. Frequently, these are called *telangiectatic warts*. The patient often has cold, cyanotic hands and feet.

This is a rare genodermatosis with an autosomal-dominant trait for vascular lesions located over bony prominences

Fig. 28-6 Angiokeratoma.

and a family history of chilblains. The condition is most frequently discovered in prepubertal children.

Histologically, hyperkeratosis, increased thickness of the granular layer, and dilation of the subpapillary vessels to form lacunae are the chief features.

In the differential diagnosis of angiokeratomas of the dorsal hands in children is acral pseudolymphomatous angiokeratoma in children (APACHE). However, APACHE is unilateral, sporadic in nature, has no associated cold sensitivity, and on histologic examination there is a dense, nodular, lymphohistiocytic infiltrate with occasional plasma cells, eosinophils, and multinucleated giant cells. It is a variant of pseudolymphoma and not primarily a vascular lesion. Similar lesions may occur in adolescents and adults, and the term acral angiokeratoma-like pseudolymphoma has been proposed for these lesions in all age groups.

Angiokeratoma may be treated with electrocautery, fulguration, CO_2 laser ablation, long-pulse vascular laser therapy, or cryotherapy with fairly good results.

Angiokeratoma of the Scrotum (Fordyce) The angiomas are multiple small vascular papules that stud the scrotum (Fig. 28-7) and sometimes the vulva in middle-aged and elderly individuals. There is often a diffuse redness of the involved area that may be a source of concern to the patient. Urethral or clitoral lesions may be seen also. Infrequently, the keratotic part may be involuntarily scratched off to produce considerable bleeding. Rarely, they may bleed spontaneously.

Histologically, the many communicating lacunae in the subpapillary layer are lined with endothelium and connected underneath by dilated veins.

Treatment is best accomplished by shave excision, cautery, laser ablation, or fulguration of troublesome lesions. The primary therapy is reassurance.

Solitary Angiokeratoma Described by Imperial and Helwig in 1967, solitary angiokeratoma is a single small, bluish-black, warty papule that occurs predominantly on the lower extremities. It is not a hereditary lesion and probably follows trauma, with subsequent telangiectasia before the formation of the angiokeratoma. The mode of acquiring this lesion, and its small size, solitary nature, and location distinguish it from other forms of angiokeratoma.

Fig. 28-7 Fordyce angiokeratomas.

Solitary angiokeratoma is to be considered in the differential diagnosis of seborrheic keratosis, melanoma, pigmented basal cell carcinoma, and ordinary hemangioma. Treatment is by electrosurgery, laser ablation, or excision.

Lymphangiectasis (Lymphangioma) Lymphangiectases are acquired dilations of lymph vessels. Some forms are discussed under malformations (above). Solitary lymphangiomas have an appearance resembling frog's eggs. Like angiokeratomas, they may be seen adjacent to café-au-lait macules (Fig. 28-8). This may represent a twin spotting phenomenon. Acquired lesions occur on the arms, axillae, chest, and back of women after lymph node dissection and irradiation for breast cancer, and on the scrotum, penis, thighs, and pubic region of men treated aggressively for prostate cancer. Other cancers treated similarly, such as cervical carcinoma, may result in similar lesions. If cancers obstruct outflow from an extremity, lymphangiectases may occur and may be the presenting sign of disease. At times, benign disease, such as scrofuloderma or recurrent erysipelas, which leads to progressive scarring of the lymphatic

Fig. 28-8 Lymphangioma adjacent 10 café-aulait macule.

vessels, may induce lymphangiectasia. Rarely, degenerative changes to the supporting connective tissue may allow lymphangiectasia to develop. A peculiar penicillamine-induced dermopathy may result from damage to the underlying supporting structures of the dermis and allow dilation of lymph vessels within areas of trauma, such as the dorsal hands and knees. Central facial involvement may be seen in variegate porphyria, and sites of chronic high potency steroid application may develop lymphangiectasia.

The lesions are thick-walled, translucent, 2- to 5-mm white vesicles. They are multiple and when present on the penis may mimic condylomata. Spontaneous drainage of a strawcolored to milky white fluid may occur. Such chylous discharge may induce surface irritation and erythema of the site. At times, recurrent erysipelas may complicate the moist, superficially eroded flexural skin. In penicillamine-induced dermopathy there is a hemorrhagic macular stain that is often surmounted by milia.

The method of treatment depends on the cause. If lymphangiectasis results from cancer infiltration and pressure, treatment of the primary process may reopen the lymphatic drainage and lead to resolution. If the condition results from penicillamine or topical steroid application, decreasing the dose or discontinuance may result in improvement. If the underlying process is fibrosis and scarring, and the involved part is amenable to pressure dressings or a pump, the chylous discharge may be improved. If recurrent erysipelas is a recurrent complication, long-term oral antibiotic prophylaxis may prevent this.

Hyperplasias

Angiolymphoid Hyperplasia with Eosinophilia Patients with angiolymphoid hyperplasia with eosinophilia (AHLE) usually present with pink to red-brown, domeshaped, dermal papules or nodules of the head or neck, especially about the ears and on the scalp (Fig. 28-9). AHLE may also occur in the mouth, trunk and extremities, penis, and vulva. Grouped lesions merge to form plaques or grapelike clusters. There is a female preponderance, and the average age of onset is 32 years. Symptoms can be pain or pruritus; these may occur after trauma. An underlying arteriovenous shunt is present as a result of damage to and repair of an artery or vein.

Histologically, central thick-walled vessels with hobmail endothelium are noted. Surrounding hyperplasia of smaller vessels and nodular lymphoid aggregates with eosinophils are present.

Lesions do not spontaneously regress. Treatment with surgical excision is successful in 65% of cases. The lesions may recur if the underlying arteriovenous shunt is not excised. Intralesional corticosteroids, pulsed dye laser therapy, cryotherapy, pentoxifylline, indomethacin, and electrodesiccation have been successful in some cases. Difficult cases have been controlled with interferon (IFN)- α 2b or vinblastine, and partial responses to intralesional cytotoxic agents have been reported.

Fig. 28-9 Angiolymphoid hyperplasia with eosinophilia. (Courtesy of Brooke Army Medical Center Teaching File)

Fig. 28-10 Kimura's disease. (Courtesy of Department of Dermatology, Keio University School of Medicine)

Much confusion in the literature has centered on distinguishing AHLE from Kimura's disease (Fig. 28-10). The latter is an inflammatory disorder that presents as massive subcutaneous swelling in the periauricular and submandibular region in young Asian men. Histologically, prominent germinal centers with eosinophils are present in the subcutaneous tissue. Although blood vessels are abundant, changes are less prominent than in AHLE. Additionally, Kimura's disease is associated with allergic conditions such as asthma, rhinitis, and eczema, and is frequently accompanied by lymphadenopathy, peripheral blood eosinophilia, and an elevated IgE level. Although clonal T-cell gene reamangement has been reported in both ALHE and Kimura's disease, heteroduplex-PCR has disproved clonality in some cases positive by conventional polymerase chain reaction (PCR).

Pyogenic Granuloma A pyogenic granuloma is a small, eruptive, usually solitary, sessile or pedunculated, friable papule (Fig. 28-11). The lesion is common in children, but may occur at any age. It occurs most often on an exposed surface: on the hands, forearms, or face, or at sites of trauma. The lesion also occurs in the mouth, especially on the gingiva, most often in pregnant women (granuloma gravidarum). On the sole of the foot or nailbed, it may be mistaken for a melanoma. Pyogenic granulomas bleed easily on the slightest trauma and, if cut off superficially, promptly recur. Recurring lesions may have one or many satellite lesions.

Pyogenic granulomas may be seen in patients treated with isotretinoin, capecitabine, or indinavir. Isotretinoin treatment of acne vulgaris can be complicated by numerous exuberant pyogenic granuloma-like lesions of the trunk, or periungual lesions. Some data suggest that patients with pyogenic gra-

Fig. 28-11 Pyogenic granuloma.

nuloma have a statistically higher prevalence of Bartonella seropositivity compared with controls, but a definite etiologic role has not been established.

Histologically, pyogenic granuloma is a lobular capillary hemangioma, with lobules separated by connective tissue septae. With time, the epidermis becomes thinned, then eroded. Heavy secondary staphylococcal colonization is common. Intravascular pyogenic granuloma appears as a lobular capillary proliferation within a vein.

Treatment is by curettage or shave excision, followed by destruction of the base by fulguration or silver nitrate. Silver nitrate alone may be sufficient to treat smaller lesions. Sclerotherapy with monoethanolamine oleate has also been used successfully. At times, a recalcitrant lesion may require excision or laser ablation. The drug-induced variety will regress after lowering of the dose or discontinuation of the medication. Systemic steroids have been used to treat recurrent giant pyogenic granulomas.

Intravascular Papillary Endothelial Hyperplasia Masson described this intravascular papillary proliferation that may mimic angiosarcoma. The lesions appear as red or purplish 5-mm to 5-cm papules or deep nodules on the head, neck, or upper extremities. The condition represents recanalization of a thrombosed vessel. Histologic examination reveals intravascular papillary projections lined by endothelial cells. Thrombi may still be present, and the papillary projections may have a fibrinous or hyaline core. Excision is curative.

Angioma Serpiginosum Angioma serpiginosum, first described by Hutchinson in 1889, is characterized by minute, copper-colored to bright red angiomatous puncta that have a tendency to become papular. These puncta occur in groups, which enlarge through the constant formulation of new points at the periphery, whereas those at the center fade. In this manner small rings or serpiginous patterns are formed. No purpura is present, but a netlike or diffuse erythema forms the background. In the areas undergoing involution, a delicate tracery of rings and lines, a fine desquamation, and, at times, a semblance of atrophy are seen. Slight lichenification and scaling may be evident in the papular lesions. The eruption predominates on the lower extremities. Although it affects both sexes at all ages, 90% of cases occur in girls under 16. It is usually slowly progressive and chronic, and although involution may occur it is probably never complete. Treatment with a pulsed dye laser will improve or eliminate such lesions.

Angioma serpiginosum must be differentiated from the progressive pigmentary disease of Schamberg. In the latter, pinpoint areas of purpura, the so-called cayenne pepper spots, form macules that tend to coalesce and form diffusely pigmented patches. The pigment is hemosiderin. Purpura annularis telangiectodes (Majocchi) is often bilateral and is characterized by acute outbreaks of telangiectatic points that spread peripherally and form small rings. In lichenoid purpuric and pigmentary dermatosis of Gougerot and Blum, the primary lesion is a minute, lichenoid, reddish-brown papule that is sometimes hemorrhagic. It has a tendency toward central involution and residual pigmentation.

In angioma serpiginosum, the most important histologic finding is dilated and tortuous capillaries in the dermal papillae and the upper dermis. No inflammatory infiltrate or extravasation of red cells is observed. The dilated capillaries show no alkaline phosphatase activity, in contrast to normal capillaries.

Benign Neoplasms

Infantile Hemangioma (Strawberry Hemangioma) Strawberry (capillary) hemangiomas, the most common benign tumor of childhood, is present at birth in one-third of cases. The remainder appear shortly thereafter. Sixty percent are on the head and neck, but they may occur anywhere. The dome-shaped lesion is dull to bright red, and when involution begins, streaks or islands of white appear in the lesion as it flattens. The lesions have sharp borders; they are soft and easily compressed (Fig. 28-12).

Generally, they tend to grow over the first year or so, remain stable for a period of months, and then slowly involute spontaneously. Approximately 30% resolve by the third year, 50% by age 5, and 70% by the time the patient is 7 years of age. The skin may appear normal after involution, but more commonly, atrophy, telangiectasia, or anetodermatype redundancy is present.

The majority of these lesions occur sporadically, but kindreds with autosomal-dominant inheritance of infantile hemangiomas and/or vascular malformations have been described. Approximately 7% of hemangiomas may occur in association with structural malformations. One grouping of associated abnormalities is the PHACE syndrome. This acronym, proposed by Frieden et al in 1996, denotes the

association of posterior fossa brain malformations (primarily the Dandy-Walker malformation), hemangiomas, arterial anomalies, coarctation of the aorta and cardiac defects, and eye abnormalities. When sternal clefting and abdominal raphae are present, the designation PHACES is used. The hemangiomas tend to be large, plaquelike, and facial in location, frequently involving more than one dermatome. They recommended that brain imaging studies be performed in all infants with such hemangiomas. Solitary segmental hemangiomas of the skin are also associated with visceral hemangiomatosis involving the liver, gastrointestinal tract, lung, brain, and mediastinum: 40% have PHACE(S) syndrome.

Multiple hemangiomas, usually 1 to 10 mm in size, may appear in the first few weeks to months of life and can be large in number. If they are purely cutaneous, generally they involute without sequelae, and the term *benign neonatal hemangiomatosis* is applied. However, visceral lesions may be present in the CNS, lungs, liver, or other organs. When internal lesions are present, complications may occur, such as gastrointestinal or CNS bleeding, high-output cardiac failure, obstructive jaundice, or respiratory failure; this results in a high mortality rate among untreated patients. This more ominous variant is called *diffuse neonatal hemangiomatosis*. Flat lumbar hemangiomas are often associated with occult spinal dysraphism.

Rapidly involuting congenital hemangioma (RICH) and noninvoluting congenital hemangioma (NICH) are rare vascular tumors that present fully grown at birth and either involute rapidly or fail to involute. Whereas smooth muscle actin (α SMA)-positive cells are common in the walls of infantile hemangiomas, they are rare in RICH. Children with RICH or NICH coexisting with infantile hemangioma have been described, as have children with RICH showing rapid but incomplete regression. In these cases, the residuum was NICH. Gorham's Sign (Gorham Stout Syndrome) is massive osteolysis (disappearing bone) associated with a proliferation of hemangioma-like tissue. Response to bishopsphonates has been noted.

Histologically, strawberry marks are composed of primitive endothelial cells similar to those found before

the embryonic development of true venous channels. Ultrastructurally, they lack typical Weibel-Palade bodies but do have crystalloid inclusions typical of embryonic endothelium and stain for GLUT-1 (a glucose transporter normally restricted to endothelial cells with blood-tissue barrier function, such as in brain and placenta). They also stain for FcyRII, Lewis Y antigen (LeY), and merosin. Some subgroups, such as rapidly involuting hemangiomas and noninvoluting hemangiomas lack GLUT-1 staining. Young hemangiomas show evidence of endothelial progenitor cells that stain with CD133 and CD34. In late stages the endothelium flattens and the lumina are more apparent because of increased blood flow. In time, fibrosis becomes pronounced as involution progresses.

In most cases, intervention produces a cosmetic result no better or worse than that achieved with simple observation. Proponents of early treatment point out that many of these hemangiomas remain significant body image factors to children when they enter school. Cryotherapy or laser ablation of early lesions has generally not been successful. The pulsed dye laser can improve the appearance of residual involuted lesions with prominent telangiectasia; however, the depth of the hemangiomas does not allow the lasers to be effective in growing or stable childhood hemangiomas. Vascular lasers have been used to treat ulcerated hemangiomas, but have also caused ulceration.

The so-called Cyrano defect, a hemangioma that causes the end of the nose to become bulbous, may be successfully approached surgically in many cases before beginning school. Additionally, surgical intervention in small pedunculated hemangiomas and eyelid tumors may also be excellent options. Finally, compressive wraps may improve extremity hemangiomas.

Specific circumstances necessitate treatment. Indications for intervention include severe hemorrhage, thrombocytopenia, threatened cardiovascular compromise from highoutput cardiac failure, nasal or auditory canal obstruction, hepatic hemangiomatosis, skin ulceration, or threatened interference with vital functions, such as feeding, respiration, passage of urine or stool, limb function, tissue destruction, or vision. There is a risk of occlusion amblyopia, astigmatism, and myopia from periorbital hemangiomas. Additionally, strong consideration should be given to treatment of those hemangiomas that may lead to permanent disfigurement or long-term psychological consequences, such as large hemangiomas of the ear, nose, glabellar area, or lips.

Oral prednisone or intralesional steroids have been employed, but intralesional treatment carries some risk of embolization and occlusion of ocular vessels. Injection regularly produces pressures exceeding the systemic arterial pressure, leading to the possibility of embolization. SubTenon steroid infusion with a blunt cannula may be useful for the treatment of orbital hemangiomas in children and may be safer than direct intralesional injection.

Oral treatment with prednisone requires a dose of 2 to 4 mg/kg/day. In the 30% of patients who respond well to treatment, the enlarging hemangioma stops growing in 3 to 21 days. Ulcerations will heal within 2 weeks. The lesion will usually shrink if treatment is continued for 30 to 90 days. Laryngeal involvement and stridor, if present, are usually dramatically relieved by treatment. Repeated courses of treatment may be undertaken if rebound of growth occurs

on discontinuation of the steroidal agent. Some experts recommend prolonged low-dose oral steroids over a 12-month period to prevent this rebound phenomenon. In another 40%, the clinical situation will stabilize with this treatment; however, the remaining 30% do not respond to treatment with prednisone. Treatment with recombinant IFN- α 2a or 2b may result in a good response in 80% of patients. The dose is usually 1 to 3 MU/m²/day. Many patients require prolonged therapy for 6 to 10 months or more. Thyroid dysfunction and neurotoxicity in the form of spastic diplegia may occur. In a meta-analysis, 11 of 441 children treated for vascular lesions developed spastic diplegia and 16 developed a motor developmental disturbance. Of interest, all of these children were under 1 year of age when the therapy was started. Topical imiquimod and selective arterial embolization have also been used. Both Nd: YAG and KTP lasers have been used to deliver intralesional laser therapy.

Cherry Angiomas (Senile Angiomas, De Morgan Spots) These round, slightly elevated, 0.5 to 6 mm in diameter, ruby-red papules are the most common vascular anomalies. It is a rare 30-year-old person who does not have a few, and the number increases with age. Probably every 70-year-old person has some. Most are on the trunk; they are rarely seen on the hands, feet, or face. Early lesions may mimic petechiae. When lesions are surrounded by a purpuric halo, amyloidosis should be suspected.

They are easily obliterated without scarring by light electrodesiccation or laser ablation. Shave excision can also be performed, but most patients accept reassurance and do not request their removal.

Targetoid Hemosiderotic Hemangioma In 1988, Santa Cruz and Aronberg described a lesion characterized by a central brown or violaceous papule that is surrounded by an ecchymotic halo (Fig. 28-13). The term hobnail hemangioma has been proposed, as many lesions are not targetoid. These acquired hemangiomas occur in the young to middle aged and are present on the trunk or extremities. They likely represent trauma to a preexisting hemangioma with thrombosis and subsequent recanalization. Histologically, a biphasic growth pattern is seen, with central superficial dilated vascular structures lined by prominent hobnail endothelial cells, and collagen-dissecting, narrow vessels in deeper parts of the lesion. The endothelial cells commonly

Fig. 28-13 Targetoid hemosiderotic hemangioma.

stain for CD31, but not CD34. Carlson et al studied 33 cases and concluded that targetoid hemosiderotic hamangiomas are variants of solitary angiokeratomas. They found episodic changes of swelling, darkening, and/or involution in three patients.

Glomeruloid Hemangioma This distinctive benign vascular neoplasm was described in 1990 and has been reported in patients with POEMS (polyneuropathy, organomegaly, endocrinopathy, monoclonal gammopathy, and skin changes) syndrome (Crow-Fukase syndrome) and Castleman's disease.

POEMS syndrome consists of polyneuropathy (severe sensorimotor), organomegaly (heart, spleen, kidneys), endocrinopathy, M protein, and skin changes (hyperpigmentation, hypertrichosis, thickening, sweating, clubbed nails, leukonychia, and angiomas). Small, firm, red to violaceous papules appear on the trunk and proximal extremities in approximately one-third of patients. Histologically, they may be microvenular hemangiomas, cherry angiomas, multinucleated cell angiohistiocytomas or glomeruloid hemangiomas. The latter consist of ectatic vascular structures containing aggregates of capillary loops within a dilated lumin, simulating the appearance of a renal glomerulus. Sequestered degenerating red blood cells are a characteristic finding. Two types of endothelial cells have been noted within the lesions, a capillary-type endothelium with large vesicular nuclei, open chromatin pattern, and large amount of cytoplasm, and sinusoidal endothelium with small basal nuclei with dense chromatin and scant cytoplasm.

Kishimoto S, et al: Glomeruloid hemangioma in POEMS syndrome shows two different immunophenotypic endothelial cells. J Gutan Pathol 2000;27:87.

Yang SG, et al: A case of glomeruloid hemangioma associated with multicentric Castleman's disease. Am J Dermatopathol 1998;20:266.

Microvenular Hemangioma This recently described acquired benign vascular neoplasm presents as an asymptomatic, slowly growing, 0.5- to 2.0-cm reddish lesion on the forearms or other sites of young to middle-aged adults. Monomorphous, elongated blood vessels with small lumina involve the entire reticular dermis. In many areas, the endothelial cells are surrounded by pericytes. The main differential diagnosis is that of Kaposi sarcoma. Along with glomeruloid hemangioma, they may sometimes be present in POEMS syndrome.

- Stefanaki C, et al: Microvenular hemangioma: a rare vascular lesions. J Dermatol 2005;32:402.

Tufted Angioma (Angioblastoma) This lesion usually develops in infancy or early childhood on the neck and upper trunk. These angiomas are ill-defined, dull red macules with a mottled appearance; they vary from 2 to 5 cm in diameter. Some show clusters of smaller angiomatous papules superimposed on the main macular area, and associated hypertrichosis has been noted. The lesions are usually sporadic, although familial cases have been reported. Histologic examination reveals small, circumscribed angiomatous tufts and lobules scattered in the dermis in a so-called cannonball pattern. Tumors with features of both tufted angioma and kaposiform hemangioendothelioma (KHE) have been described, and transformation between the tumors has also been noted. Immunostaining can be helpful in distinguishing these tumors. Tufted angioma is characterized by a proliferation CD34+ endothelial cells with few actin-positive cells. KHE shows CD34 staining only in the luminal endothelial cells. In infantile hemangiomas, actin-positive cells outnumber CD34+ cells.

Most lesions slowly extend with time, being progressive but benign in nature. Occasional spontaneous regression is documented; however, treatment with pulsed dye laser, excision, high-dose steroids, and IFN- α has been successful in individual cases.

The term angioblastoma has also been used for a rare pediatric tumor often associated with destruction of regional structures including bone. Basic fibroblast growth factor has been reported to be elevated, and some patients have responded to treatment with IFN- α 2b.

Kaposiform Hemangioendothelioma KHE is an uncommon vascular tumor that affects infants and young children. Rare cases have been reported in adults. It was first designated KHE in 1993. Although it frequently occurs in

the retroperitoneum, they may present as multinodular soft-tissue masses, purpuric macules, plaques, and multiple telangiectatic papules. The lesions extend locally and usually involve the skin, soft tissues, and even bone. The cutaneous variant may be associated with lymphangiomatosis. KHE is locally aggressive and may be complicated by platelet trapping and consumptive coagulopathy (Kasabach-Merritt syndrome), but distant metastases have not yet been reported. It has also been reported in association with Milroy-Nonne disease (primary hereditary lymphedema).

Histologically, there are combined features of cellular infantile hemangioma and Kaposi sarcoma. Additionally, in some tumors, lymphangiomatosis is seen sharply separated from the vascular lesion. There is a multilobular appearance that closely resembles that of tufted angioma, but in KHE they are larger, less circumscribed, and involve the deep soft tissue and even bone. Transition between these tumors has been described.

The prognosis depends on the depth and location of the lesion. Significant morbidity and mortality may occur as a result of the compression and invasion of surrounding structures. If localized to the skin, they may be successfully excised. However, because of their tendency for deep and infiltrative growth this is usually not possible. Prednisone may shrink the tumor or limit tumor expansion. If Kasabach-Merritt phenomenon occurs, prognosis is linked to this complication.

Multifocal Lymphangioendotheliomatosis Patients with multifocal lymphangioendotheliomatosis present at birth with hundreds of red-brown plaques as large as several centimeters. Similar lesions may occur in the gastrointestinal tract and are associated with severe bleeding. Severe thrombocytopenic coagulopathy (Kasabach-Merritt syndrome) occurs in affected children. Corticosteroids and/or IFN- α results in little to no improvement. The histology is distinctive with delicate thin-walled vessels lined by hobnailed endothelium with papillary tufting. The endothelial cells demonstrate a high proliferative fraction with Ki-67 staining, and are reactive with LYVE-1, suggesting lymphatic differentiation.

North PE, et al: Multifocal lymphangioendotheliomatosis with thrombocytopenia. Arch Dermatol 2004;140:599.

Kasabach-Merritt Syndrome (Hemangioma with Thrombocytopenia) This syndrome is seen in infants at an average age of 7 weeks. Before the onset of the acute event, the infant will often have a reddish or bluish plaque or tumor on the limb or trunk, or in rare instances no visible lesion at all. The lesions usually have an associated lymphatic component and most are KHEs. Kasabach-Merrit syndrome (KMS) also occurs in tufted angiomas and multifocal lymphangioendotheliomatosis, lesions that both demonstrate lymphatic differentiation. It is rarely reported in association with capillary hemangiomas. Some patients with venous malformations will have a chronic low-grade consumptive coagulopathy that occurs throughout life, and this is not to be confused with KMS.

Infants with KMS suddenly develop a painful violaceous mass in association with purpura and thrombocytopenia. The most striking sign is the bleeding tendency, especially in the hemangioma itself or into the chest or abdominal cavities. The spleen may be enlarged. Hemoglobin, platelets, fibrinogen, and factors II, V, and VIII are all reduced. Prothrombin time and partial thromboplastin time are prolonged, and fibrin split products may be elevated. Cases of microangiopathic hemolytic anemia have also been described. Repeated episodes of bleeding may occur, and although these may be spontaneous, it is not uncommon for bleeding to be precipitated by surgery, directed either at the hemangioma or elsewhere. The mortality may be as high as 30%, with most deaths being secondary to bleeding complications.

As KMS may be a self-limited disorder, expectant observation may be the best approach initially. Systemic steroids, IFN- α 2a, vincristine, vinblastine, cyclophosphamide, actinomycin D, embolization, ε -aminocaproic acid, antiplatelet agents, irradiation, excision, and compression therapy have been utilized alone or in combination, but treatment is often difficult and some patients responds poorly to all attempted treatment.

Acquired Progressive Lymphangioma (Benign Lymphangioendothelioma) The term acquired pro-

gressive lymphangioma was introduced by Wilson-Jones in 1976 to designate a group of lymphangiomas that occur anywhere in young individuals, grow slowly, and present as bruise-like lesions or erythematous macules. Rarely, the lesion is yellow or alopecic. The histologic appearance is that of delicate endothelium-lined spaces dissecting between collagen bundles. A similarity to the plaque stage of Kaposi sarcoma may be striking. Simple excision is curative. Prednisolone has caused some extensive lesions to regress.

Glomus Tumor (Glomangioma) The solitary glomus or neuromyoarterial tumor is most frequently a skin-colored or slightly dusky blue firm nodule 1 to 20 mm in diameter. Subungual tumors show a bluish tinge through the translucent nail plate. The tumor is usually extremely tender and paroxysmal pain occurs frequently. Sensitivity is likely to be present constantly, and when touched the tumor responds with severe radiating pain. However, nontender glomus tumors are encountered. The characteristic location is subungual, but it may occur on the fingers and arms, or elsewhere. Digital lesions are more common in women, and there is a male predominance of nondigital lesions. High-resolution MRI, high-resolution ultrasonography (5-9 MHz) and color duplex sonography may be used to define the limits of the tumor before surgery is undertaken. Progressive growth may lead to ulceration.

Multiple glomangiomas are usually nontender and are generally widely distributed over the body. These may be inherited as an autosomal-dominant trait and can be congenital. Clinically, they may resemble lesions of blue rubber bleb nevus. When grouped in one area they may appear as a confluent mass. Hereditary multiple glomus tumors may represent an autosomal-dominant mosaic trait and may be congenital. The glomus coccygeum is a normal structure that may be seen in pilonidal sinus excision specimens.

Histologically, glomus tumors contain numerous vascular lumina lined by a single layer of flattened endothelial cells. Peripheral to the endothelial cells are layers of glomus cells. Generally these are round and arranged in distinct rows resembling strings of black pearls. Rarely, the cells have a somewhat spindled morphology. Multiple glomangiomas tend to have only one or two layers of glomus cells. Glomangiomyomas have a prominent muscularis media in addition to one or two layers of glomus cells. Both solitary and multiple glomus tumors are related to the arterial segment of the cutaneous glomus, the Sucquet-Hoyer canal. . The glomus cells are modified vascular smooth muscle cells and stain with vimentin rather than desmin. Smooth muscle actin is often positive.

Treatment of solitary glomus tumors is best carried out by complete excision, which immediately produces relief from pain. The subungual tumors are most difficult to locate and eradicate since they are usually small, seldom more than a few millimeters in diameter. Rare reports of glomangiosarcomas describe large, deeply located extremity lesions that consist of sarcomatous areas intermingled with areas of benign glomus tumor.

Hemangiopericytoma A hemangiopericytoma is a nontender, bluish red tumor that occurs on the skin or in the subcutaneous tissues on any part of the body. The firm, usually solitary nodule may be up to 10 cm in diameter.

Histologically, the tumor is composed of endotheliumlined vessels that are filled with blood and surrounded by cells with oval or spindle-shaped nuclei (pericytes). The pericytes often form a concentric perivascular pattern. Staghorn-like ecstatic spaces are often encountered. Wide local excision is the treatment of choice, but radiation therapy may produce excellent palliation.

It is difficult to distinguish between benign and malignant forms of hemangiopericytoma, although large lesions and those with numerous mitoses are more likely to metastasize. Nearly half of the malignant hemangiopericytomas of deep soft tissues metastasize. The rate of metastases from lesions of the skin is closer to 20%. The most common cause of death is pulmonary metastasis. Infantile tumors are almost always cutaneous or subcutaneous, and do not metastasize.

Espat NJ, et al: Conventional hemangiopericytoma: modern analysis of outcome. Cancer 2002;95:1746.

Proliferating Angioendotheliomatosis Diseases designated angioendotheliomatosis have historically been divided into two groups: a reactive, involuting type and a malignant, rapidly (atal type. "Malignant angioendotheliomatosis" has been shown to be *intravascular* (angiotropic) *lymphoma*, rather than a true vascular lesion.

The reactive type of angioendotheliomatosis is uncommon. It occurs in patients who have subacute bacterial endocarditis, Chagas' disease, pulmonary tuberculosis, cryoproteinemia, severe atherosclerotic disease, and antiphospholipid antibodies, as well as in patients with no identifiable underlying process. They present with red-purple patches, plaques, nodules, petechiae, and ecchymoses, usually of the lower extremities. Some patients may present with a livedoid pattern or lesions resembling atrophie blanche. Diffuse dermal angiomatosis is a variant associated with atherosclerosis. The lesion occurs most often on the thigh in areas of vascular insufficiency and clears with revascularization. It has also been described in association with an arteriovenous fistula and with anticardiolipin antibodies.

Histologically, the vessels in benign reactive angioendotheliomatosis are dilated and are filled with proliferating endothelial cells, usually without atypia. Some cases demonstrate a proliferation of capillaries in the dermis, with diffuse, lobular, or mixed patterns. Fibrin microthrombi are common, and some cases show amyloid deposits or positive immunohistochemical staining for human herpesvirus (HHV)-8 in lesional endothelial cell nuclei. The course in this type is characterized by involution over 1 to 2 years. Therapy for the underlying condition has been considered to hasten involution.

The malignant type of "angioendotheliomatosis" is actually a large-cell intravascular lymphoma. It is a rapidly progressive disease: usually death ensues within 10 months of diagnosis. The mean age at onset is 55 years. Reddishpurple plaques, nodules, or patches develop in the skin. Multisystem involvement is characteristic, with the CNS often involved. There may be progressive dementia or focal signs that reflect ischemic infarcts. Kidney, heart, lung, and gastrointestinal lesions may occur. Biopsy will show a proliferation of atypical cells that fill the lumen of cutaneous vessels. Immunochemical stains for leukocyte/common antigen have confirmed the lymphomatous nature of these cells. Angioendotheliomatosis is usually B-cell in phenotype, but cases of T-cell lineage have been reported. Some organs may show diffuse large-cell lymphoma.

Doxorubicin alone, as well as in combination with vincristine, prednisone, and cyclophosphamide, has been effective in isolated cases. Rituximab has also been useful in CD20+ B-cell intravascular lymphoma.

Fig. 28-15 Kaposi sarcoma.

Malignant Neoplasms

Kaposi Sarcoma Moritz Kaposi described this vascular neoplasm in 1872 and called it multiple benign pigmented idiopathic hemorrhagic sarcoma. Since his description, the disease has been reported in five separate clinical settings, with different presentations, epidemiology, and prognoses. The five subtypes are: 1) classic Karposi sarcoma (KS), an indolent disease seen chiefly in middle-aged men of Southern and Eastern European origin; 2) African cutaneous KS, a locally aggressive process affecting middle-aged Africans in tropical Africa; 3) African lymphadenopathic KS, an aggressive disease of young patients, chiefly children under age 10; 4) KS in patients immunosuppressed by AIDS; or by 5) lymphoma or immunosuppressive therapy.

Clinical Features

Classic Kaposi Sarcoma. The early lesions appear most commonly on the toes or soles as reddish, violaceous, or bluish-black macules and patches that spread and coalesce to form nodules or plaques (Fig. 28-15). These have a rubbery consistency. There may be brawny edema of the affected leg. Macules or nodules may appear, usually much later, on the arms and hands, and rarely may extend to the face, ears, trunk, genitalia, or buccal cavity, especially the soft palate. The course is slowly progressive and may lead to great enlargement of the lower extremities as a result of lymphedema.

However, there may be periods of remission, particularly in the early stages of the disease, when nodules may undergo spontaneous involution. After involution there may be an atrophic and hyperpigmented scar.

African Cutaneous Kaposi Sarcoma. Nodular, infiltrating, vascular masses occur on the extremities, mostly of men between the ages of 20 and 50. This form of KS is endemic in tropical Africa, and has a locally aggressive but systemically indolent course.

African Lymphadenopathic Kaposi Sarcoma. Lymph node involvement, with or without skin lesions, may occur in children under 10 years of age. The course is aggressive, often terminating fatally within 2 years of onset.

AIDS-Associated Kaposi Sarcoma. Cutaneous lesions begin as one or several red to purple-red macules, rapidly

Spindle-Cell Hemangioendothelioma Spindle-cell hemangioendothelioma is a vascular tumor that was first described in 1986. The condition commonly presents in a child or young adult who develops blue nodules of firm consistency on a distal extremity (Fig. 28-14). Usually, multifocal lesions occur within an anatomic region. Histologically, a well-circumscribed dermal nodule will contain dilated vascular spaces with fascicles of spindle cells between them. Areas of the tumor will have an open alveolar pattern resembling hemorrhagic lung tissue. Phleboliths are common. A thrombosed large adjacent vessel with recanalization may be identified. The lesions appear to represent benign vascular proliferations in response to trauma to a larger vessel. They may repeatedly recur focally after excision.

progressing to papules, nodules, and plaques. There is a predilection for the head, neck, trunk, and mucous membranes. A fulminant, progressive course with nodal and systemic involvement is expected. This may be the presenting manifestation of human immunodeficiency virus (HIV) infection.

Immunosuppression-Associated Kaposí Sarcoma. The lesion's morphology resembles that of classic KS; however, the site of presentation is more variable.

Internal Involvement

The gastrointestinal tract is the most frequent site of internal involvement in classic KS. The small intestine is probably the most commonly involved viscus. In addition, the lungs, heart, liver, conjunctiva, adrenal glands, and lymph nodes of the abdomen may be involved. Skeletal changes are characteristic and diagnostic. Bone involvement is always an indication of widespread disease. Changes noted are rarefaction, cysts, and cortical erosion.

African cutaneous KS is frequently accompanied by massive edema of the legs and frequent bone involvement.

African lymphadenopathic KS has been reported among Bantu children, who develop massive involvement of the lymph nodes, especially the cervical nodes, preceding the appearance of skin lesions. The children also develop lesions on the eyelids and conjunctiva from which masses of hemorrhagic tissue hang down. Eye involvement is often associated with swelling of the lacrimal, parotid, and submandibular glands with a picture similar to Mikulicz syndrome.

In AIDS-associated KS, 25% of patients have cutaneous involvement alone, whereas 29% have visceral lesions only. The most frequent sites of visceral involvement are the lungs (37%), gastrointestinal tract (50%), and lymph nodes (50%). Visceral involvement ultimately occurs in more than 70% of patients with AIDS-associated KS.

Other immunosuppressed patients with KS may have visceral involvement in a variable percentage of cases.

Epidemiology

KS is worldwide in distribution. In Europe there are foci of classic KS in Galicia, near the Polish-Russian border, and extending southward to Austria and Italy. In New York City, KS has occurred mostly in elderly male Galician Jewish and southern Italian persons. In Africa, KS occurs largely south of the Sahara. Northeast Congo and Rwanda-Burundi areas have the highest prevalence, and to a lesser extent, West and South Africa.

The prevalence of AIDS-related KS has decreased since the 1980s. Most cases are in male homosexuals. Very few reports have documented the exceptional occurrence of KS in patients with AIDS who acquired their infection from intravenous drug use, or in Haitians, children, or people with hemophilia.

Patients at risk for developing KS associated with other causes of immunosuppression include those with iatrogenic suppression from oral prednisone or other chronic immunosuppressive therapies, as may be given to transplant patients.

KS is associated with an increased risk of developing second malignancies, such as malignant lymphomas (Hodgkin's disease, T-cell lymphoma, non-Hodgkin lymphoma), leukemia, and myeloma. The risk of lymphoreticular malignancy is about 20 times greater in KS patients than in the normal population.

Etiopathogenesis

KS is formed by proliferation of abnormal vascular endothelial cells. HHV-8 was first found in tissue of a patient with KS and was reported in 1994. Now it has been found in KS lesional tissue irrespective of clinical type. Detection of HHV-8 in HIV-infected individuals who do not have KS is predictive of the development of KS, usually within 2 to 4 years. It is considered at this time that sexual or fecal-oral transmission is the most likely means of acquiring this infection. The HHV-8 genome has many open reading frames that encode products that produce growth dysregulation or evasion of immune surveillance. How these orchestrate the formation and proliferation of spindle cells is under active investigation. Primary effusion lymphoma, solid lymphoma, and Castleman's disease are other confirmed associations with HHV-8 infection.

Histology

There is considerable variation in the histopathology according to the stage of the disease. Early lesions demonstrate irregularly shaped ecstatic vessels with scattered lymphocytes and plasma cells. The endothelial cells of the capillaries are large and protrude into the lumen, like buds. Later lesions show proliferation of vessels around preexisiting vessels and adnexal structures. The preexisting structure may jut into the vascular space forming a promontory sign. Dull pink globules, extravasated erythrocytes, and hemosiderin are present. Nodular lesions are composed of spindle cells with erythrocytes that appear to line up between spindle cells with no apparent vascular space.

Treatment

All types of KS are radiosensitive. Radiation therapy has been used with considerable success, either by small fractionated doses, larger single doses to limited or extended fields, or by electron beam radiation. Local excision, cryotherapy, alitretinoin gel (Panretin), locally injected chemotherapy or IFN, and laser ablation have been used for troublesome, localized lesions.

Vincristine solution 0.1 mg/mL injected intralesionally, not more than 3 mL at one time and at intervals of 2 weeks, produces involution of tumors, some for as long as 8 months. These studies indicate that adequate control of the lesions may be had, at least for periods of 6 to 12 months. The development of resistance to medication seems to be inevitable.

Many other agents have been found to be effective; among the best are IFN, vinblastine, and actinomycin D. The response rate initially is high, but recurrent lesions, which are common, are generally less responsive. Systemic therapy is usually needed if more than 10 new KS lesions develop in 1 month, or if there is symptomatic lymphedema, symptomatic pulmonary disease, or symptomatic visceral involvement.

In the setting of HIV, protease inhibitors have been shown to have antiangiogenic effects; however, the results of nonnucleoside reverse transcriptase inhibitor-based regimens are not inferior to protease inhibitor-based therapy in the prevention of KS. This suggests regression of KS is mediated by an overall improvement in immune function and not by the effects of specific antiretrovirals. Liposomal anthracyclines and paclitaxel have been approved by the US Food and Drug Administration (FDA) as first- and second-line monotherapy, respectively, for advanced KS.

Course

Classic KS progresses slowly, with rare lymph node or visceral involvement. Death usually occurs years later from unrelated causes. African cutaneous KS is aggressive, with early nodal involvement, and death from KS is expected within 1 to 2 years. AIDS-related KS, although widespread, is almost never fatal; nearly all patients die of intercurrent infection. The course of the disease is variable in patients who develop immunosuppression-related KS from causes other than AIDS. Removal of the immunosuppression may result in resolution of the KS without therapy.

Epithelioid Hemangioendothelioma In 1982, Weiss et al described this rare tumor that both clinically and histologically is intermediate between angiosarcoma and hemangioma. It is usually a solitary, slowly growing papule or nodule on a distal area of an extremity. There is a male preponderance, and onset is frequently before the individual is 25 years of age. Histologically, there are two components: dilated vascular channels and solid epithelioid and spindle cell elements with intracytoplasmic lumens. Some may have cellular pleomorphism and mitotic activity. Wide excision is recommended with evaluation of regional lymph nodes. This is the usual site of metastases, and if they occur here, further surgery may be curative. In the minority of cases in which distant metastatic lesions develop, chemotherapy, radiation, or both may be employed. Of the 31 patients from the original series who had follow-up at an average of 18 months, 20 were alive and well.

Epithelioid sarcoma-like hemangioendothelioma demonstrates round to slightly spindled cells in sheets and nests. The cells demonstrate immunohistochemical evidence of endothelial differentiation. Local recurrence and regional soft-tissue metastases may occur.

Fernandez-Flores A, et al: Cutaneous epithelioid angiomatous nodule of the external ear. Am J Dermatopathol 2005;27:175. Forschner A, et al: Ulcerated epithelioid hemangioendothelioma of the foot in childhood. J Am Acad Dermatol 2003;49:113.

Retiform Hemangioendothelioma Retiform hemangioendothelioma is a low-grade angiosarcoma, first described in 1994. It presents as a slow-growing exophytic mass, dermal plaque, or subcutaneous nodule. It most commonly occurs on the upper or lower extremities of young adults. Histologically, there are arborizing blood vessels reminiscent of normal rete testis architecture. HHV-8 DNA sequences have been reported in this tumor. Wide excision is recommended, although local recurrences are common. To date, no widespread metastases have occurred, although regional lymph nodes may develop tumor infiltrates.

Schommer M, et al: Retiform hemangioendothelioma: another tumor associated with human herpesvirus type 8? J Am Acad Dermatol 2000;42(2 Pt 1):290.

Composite Hemangioendothelioma This low-grade angiosarcoma typically occurs in adults, although it has been described in infancy. The tumor exhibits a mix of retiform hemangioendothelioma-like, spindle cell hemangioma-like, cavernous hemangioma-like, epithelioid hemangioendothelioma -like, and angiosarcoma-like patterns. Local recurrences and regional lymph node metastasis have been noted.

Reis-Filho JS, et al: Congenital composite hemangioendothelioma: case report and reappraisal of the hemangioendothelioma spectrum, J Cutan Pathol 2002;29:226.

Endovascular Papillary Angioendothelioma (Dabska *Tumor* Endovascular papillary angioendothelioma, a rare low-grade angiosarcoma, presents as a slow-growing tumor on the head, neck, or extremity of infants or young children. It shows multiple vascular channels with papillary plugs of endothelial cells surrounding central hyalinized cores that project into the lumina, sometimes forming a glomeruloid pattern. The entity is controversial, as similar histologic features have been observed in other vascular tumors, such as angiosarcoma, retiform hemangioendothelioma, and glomeruloid hemangioma. The tumor may be a distinct entity, or a histologic pattern seen in other vascular tumors. One patient with this histologic pattern developed KMS, and others have developed regional metastasis. Wide excision and, in cases where they are involved, regional lymph node excision is usually curative.

Fukunaga M: Endovascular papillary angioendothelioma (Dabska tumor). Pathol Int 1998;48:840.

Schwartz RA, et al: The Dabska tumor: a thirty-year retrospect. Dematology 2000;201:1.

Angiosarcoma Angiosarcomas of the skin occur in four clinical settings. First and most common are those that occur in the head and neck of elderly people. The male-to-female ratio is 2:1. The lesion often begins as an ill-defined bluish macule that may be mistaken for a bruise. Distinguishing features are the frequent occurrence of a peripheral erythematous ring, satellite nodules, the presence of intratumoral hemorrhage, and the tendency for the lesion to bleed spon-

Quecedo E, et al: Dabska tumor developing within a preexisting vascular malformation. Am J Dermatopathol 1996;18:302.
taneously, or after minimal trauma. The tumor progressively enlarges asymmetrically, often becomes multicentric, and develops indurated bluish nodules and plaques. The sudden development of thrombocytopenía may herald metastatic disease or an enlarging primary tumor.

Histologically, anaplastic pleomorphic endothelial cells are present, with new vascular channels among them. Solid sheets of epithelioid cells may be present, but more commonly, the pattern is that of subtle infiltration in the dermis, producing the appearance of cracks between collagen bundles. The spaces are lined by hyperchromatic nuclei. Immunoperoxidase staining for endothelial markers such as CD31, CD34, and Ulex europeus lectin aids in the diagnosis.

Early diagnosis and complete surgical excision followed by moderate dose, very wide field radiotherapy offer the best prognosis for limited disease. Chemotherapy and radiation therapy for extensive disease are often only palliative, especially when dealing with scalp lesions. Doxorubicinifosfamide chemotherapy produces a modest response rate. Paclitaxel and interferon have shown some response for scalp and facial angiosarcomas. Because of the multicentricity of lesions, the frequent occurrence on the face or scalp, and the rapid growth with early metastasis, death occurs in most patients within 2 years. Spieth et al reported a dramatic response in a 77-year-old man with recurrent angiosarcoma of the face and scalp after combination treatment with IFN- α 2a and 13-*cis*-retinoic acid.

The second classic clinical situation in which angiosarcoma develops is in chronic lymphedematous areas, such as that which occurs in the upper arm after mastectomy, the so-called Stewart-Treves syndrome (Fig. 28-16). This tumor appears approximately 11 to 12 years after surgery in an estimated 0.45% of patients. The prognosis is poor for these patients, with a mean survival of 19 to 31 months, and a 5-year survival rate of 6% to 14%. Metastases to the lungs are the most frequent cause of death. Early amputation offers the best hope.

Fig. 28-16 Stewart-Treves syndrome. A third setting includes tumors that develop in previously irradiated sites. If the condition for which radiation therapy was given was a benign one, the average interval between radiation and development of angiosarcoma is 23 years. If the preceding illness was a malignant condition, the interval is shortened to 12 years. Again, the prognosis is poor, with survival time generally between 6 months and 2 years after diagnosis. Many patients with the Stewart-Treves syndrome received radiation, and radiation may play a pathogenic role.

Angiosarcomas develop in settings other than those previously described, and this small miscellaneous subset comprises the fourth category. An angiosarcoma producing granulocyte colony-stimulating factor was associated with prominent peripheral leukocytosis.

FIBROUS TISSUE ABNORMALITIES

Keloid

A keloid is a firm, irregularly shaped, fibrous, hyperpigmented, pink or red excrescence. The growth usually arises as the result of a cut, laceration, or burn—or, less often, an acne pustule on the chest or upper back—and spreads beyond the limits of the original injury, often sending out clawlike (cheloid) prolongations. The overlying epidermis is smooth, glossy, and thinned from pressure. The early, growing lesion is red and tender, and has the consistency of rubber. It is often surrounded by an erythematous halo, and the keloid may be telangiectatic. Lesions may be tender, painful, pruritic, and may rarely ulcerate or develop draining sinus tracts.

Keloids are often multiple. They may be as tiny as pinheads or as large as an orange. Those that follow burns and scalds are large. Lesions are often linear, often with bulbous expansions at each end. The surface may be larger than the base, so that the edges are overhanging. The most common location is the sternal region, but keloids also occur frequently on the neck, ears (Fig. 28-17), extremities, or trunk, and rarely on the face, palms, or soles. The earlobes are frequently involved as a result of ear piercing, but involvement of the central face is rare. They are much more common, and grow to larger dimensions, in black persons than in other races.

Why certain individuals develop keloids still remains unsolved. Trauma is usually the immediate causative factor, but

Fig. 28-17 Keloid.

Flg. 28-18 Keloid.

this induces keloids only in those with a predisposition for their development. There is also a regional predisposition.

Histologically, a keloid is a dense and sharply defined nodular growth of myofibroblasts and collagen with a whorllike arrangement resembling hypertrophic scar. Centrally, thick hyalinized bundles of collagen are present, and distinguish keloids from hypertrophic scars. There is a paucity of elastic tissue, just as in a scar. By pressure, the tumor causes thinning of the normal papillary dermis and atrophy of adjacent appendages, which it pushes aside. Mucopolysaccharides are increased, and often there are numerous mast cells.

Keloids are usually distinctive. They may be distinguished from hypertrophic scars by their clawlike projections (Fig. 28-18), which are absent in the hypertrophic scar, the extension of the lesion beyond the confines of the original injury, and the presence of thick hyalinized collagen bundles histologically. Frequently there is a spontaneous improvement of the hypertrophic scar over a period of months, whereas in the keloid this does not occur. Atypical lesions should be biopsied, as carcinoma en cuirasse may mimic keloid.

Initial treatment is usually by means of intralesional injection of triamcinolone suspension. Using a 30-gauge needle on a 1-mL tuberculin Luer syringe, triamcinolone

suspension is injected into various parts of the lesion; 40 mg/ mL is generally used for initial treatment and, as the lesion softens, 10 to 20 mg/mL may be sufficient to produce involution with less risk of surrounding hypopigmentation and atrophy related to lymphatic spread of the corticosteroid. Injections are repeated at intervals of 6 to 8 weeks, as required. Flattening and cessation of itching are reliably achieved by this approach, and may sometimes even be achieved with topical corticosteroids. The lesions are never made narrower, however, and hyperpigmentation generally persists. Transforming growth factor (TGF)- β is known to be involved in keloid formation, and triamcinolone acetonideinduced decreases in cellular proliferation and collagen production are associated with a statistically significant decrease in the level of TGF-B1 in both normal and keloid fibroblast cell lines.

Other approaches to treatment include flashlamp pulsed dye laser treatment, which is also associated with reduced expression of TGF- β 1. Cryosurgery (including contact, intralesional needle cryoprobe, and spray cryosurgery), intralesional 5-fluorouracil, and calcium-channel blockers have some demonstrated efficacy in the treatment of keloids. Fibroblasts derived from the central part of keloids grow faster than peripheral keloid and nonkeloid fibroblasts. Verapamil has been shown to decrease interleukin (IL)-6 and vascular endothelial growth factor in these cultured cells, and to inhibit cell growth.

If surgical removal by excision is feasible, and if narrowing of the keloid is a vitally important goal, the keloid may be excised. After the excision, intralesional injection of triamcinolone or IFN- α 2b may be combined with postoperative xray irradiation or topical application of imiquimod. Silicone sheeting and pressure are other adjunctive methods used to limit recurrences. Results with these modalities have been mixed. Silicone gel-sheet treatment has been shown to reduce lesional mast cell numbers and decrease itching.

Pierced-ear keloids occur with considerable frequency. When the keloid is young, intralesional injection of triamcinolone is frequently sufficient to control the problem. In old keloids, excision of the lesion using lidocaine with triamcinolone, followed by injections at 2-week intervals, produces good results. CO_2 laser excision has also been successful in old mature keloids in this site.

Dupuytren Contracture

Dupuytren contracture is a fibromatosis of the palmar aponeurosis. The lesion arises most commonly in men between the ages of 30 and 50 as multiple firm nodules in the palm. Usually three to five nodules about 1 cm in diameter develop, proximal to the fourth finger. Later the fibromatosis produces contractures, which may be disabling. It occurs at times with alcoholic cirrhosis, diabetes mellitus, and chronic epilepsy. It is also associated with Peyronie's disease, plantar fibromatosis, and knuckle pads. In some cases there is a familial predisposition. The fibrous nodules are composed of myofibroblasts that express androgen receptors. 5-a-Díhydrotestosterone induces an increase in Dupuytren fibroblast proliferation. In contrast to deep fibromatoses which behave more aggressively, superficial fibromatoses lack B-catenin and adenomatous polyposis coli (APC) gene mutations.

Early intralesional triamcinolone may help, but surgical excision of the involved palmar fascia may be the only way to liberate severely contracted fingers. Androgen blockade represents a potential avenue of pharmacologic therapy.

Plantar Fibromatosis

The plantar analog of Dupuytren contracture, plantar fibromatosis (Ledderhose's disease) occurs as slowly enlarging nodules on the soles that ultimately cause difficulty in walking or even weight-bearing. The diagnosis is usually made clinically, but both biopsy and MRI can be used to confirm the diagnosis. The usual treatment, as for Dupuytren contracture, is wide excision of the plantar fascia. Subtotal excision is associated with a high rate of recurrence. Although adjuvant radiotherapy is effective in decreasing the recurrence rate, it has a significant complication rate with functional impairment. Improvement by the intralesional injection of triamcinolone acetonide, 30 mg/mL monthly for 5 months, has been reported. The triamcinolone can be diluted with lidocaine solution.

Knuckle Pads

Knuckle pads (heloderma) are well-defined, round, plaquelike, fibrous thickenings that develop on the extensor aspects of the proximal interphalangeal joints (Fig. 28-19) of the toes and fingers, including the thumbs. They develop at any age and grow to be some 10 to 15 mm in diameter in the course of a few weeks or months, then persist permanently. They are flesh colored or somewhat brown, with normal or slightly hyperkeratotic epidermis overlying and adherent to them. They are a part of the skin and are freely movable over underlying structures.

Knuckle pads are sometimes associated with Dupuytren contracture and camptodactylia (irreducible flexion contracture of one or more fingers). Some cases are familial and some are related to trauma or frequent knuckle cracking. An autosomal-dominant association of knuckle pads, mixed

Fig. 28-19 Knuckle pads. hearing loss (sensorineural and conductive), and total leukonychia has been reported. Knuckle pads have also be associated with autosomal-dominant epidermolytic palmoplantar keratoderma with a mutation in keratin 9.

Histologically, the lesions are fibromas. They are to be differentiated clinically from the nodular type of neurodermatitis and from the small hemispherical pitted papules that may develop over the knuckles after frostbite or in acrocyanosis, and from rheumatic nodules. Treatment with intralesional injection of corticosteroids may be beneficial.

Pachydermodactyly

Pachydermodactyly represents a benign fibromatosis of the fingers. There is a fullness of the medial and lateral digit just proximal to the proximal interphalangeal joint. This asymptomatic process is most often first noted in adolescence and usually involves multiple fingers. Five types have been described: classic pachydermodactyly localized pachydermodactyly, transgrediens pachydermodactyly in which the abnormality extends to the metacarpophalangeal areas, familial pachydermodactyly, and pachydermodactyly associated with tuberous sclerosis. Increased collagen or mucin account for the swelling. No treatment is required.

Bardazzi F, et al: Pachydermodactyly: seven new cases. Ann Dermatol Venereol 1998;125:247.

Yebenes M, et al: Acquired fusiform swelling of the fingers. Arch Dermatol 2005;141:1035.

Peyronie's Disease

Plastic induration of the penis is a fibrous infiltration of the intercavernous septum of the penis. This fibrosis results in the formation of nodules or plaques. As a result of these plaques, a fibrous chordee is produced, and curvature of the penis occurs on erection, sometimes so severe as to make intromission difficult or impossible. Sometimes pain may be severe. The association of this disease with Dupuytren contracture has been recognized. Intralesional triancinolone suspension injected or iontophoresed into the plaques and nodules may be curative. Injection of IFN has also been used.

Surgical correction tailored to the degree of deformity is often successful. Extracorporeal shock wave therapy may reduce penile pain and improve sexual function, although objective changes in plaque size and curvature have not been demonstrated.

Desmoid Tumor

Desmoid tumors occur as large, deep-seated, wellcircumscribed masses arising from the muscular aponeurosis. They most commonly occurs on the abdominal wall, especially in women during or soon after pregnancy. Desmoid tumors have been divided into five types: abdominal wall, extra-abdominal, intra-abdominal, multiple, and those occurring in Gardner syndrome/familial adenomatous polyposis. They recur locally and can kill if they invade, surround, or compress vital structures. The most dangerous, then, are those at the root of the neck and the intra-abdominal type. MRI will aid in the evaluation of soft-tissue extension and recurrence following treatment.

Treatment may be with wide local excision, radiotherapy, or hormonal manipulation. High-dose tamoxifen in combination with sulindac has been effective. Mesenteric desmoid tumors have been treated with antiangiogenic therapy with toremifene and IFN- α 2b.

Collagenous Fibroma (Desmoplastic Fibroblastoma)

This slow-growing, deep-set, benign fibrous tumor is usually located in the deep subcutis, fascia, aponeurosis, or skeletal muscle of the extremities, limb girdles, or head and neck regions. It is characterized by hypocellularity and dense bands of hyalinized collagen that may infiltrate into skeletal muscle. Despite this, no tumors have been reported to metastasize or recur after excision. Chromosomal translocation (2;11)(q31;q12) has been reported.

Bernal K, et al: Translocation (2;11)(q31;q12) is recurrent in collagenous fibroma (desmoplastic fibroblastoma). Cancer Genet Cytogenet 2004;149:161.

Aponeurotic Fibroma

Aponeurotic fibroma has also been called *juvenile* aponeurotic fibroma (calcifying fibroma). It is a tumor-like proliferation characterized by the appearance of slowgrowing, cystlike masses that occur on the limbs, especially the hands and feet.

Histologically, the distinctive lesions are sharply demarcated and composed of collagenous stroma showing acid mucopolysaccharides infiltrated by plump mesenchymal cells with oval nuclei. Hyalinized areas are also present, suggesting chondroid or osteoid metaplasia.

An aid to the diagnosis is stippled calcification, readily seen on roentgenograms. Surgical excision is the treatment.

Infantile Myofibromatosis

Infantile myofibromatosis is the most common fibrous tumor of infancy. Eighty percent of patients have solitary lesions with half of these occurring on the head and neck. About 60% are present at or soon after birth.

Congenital generalized fibromatosis is an uncommon condition that presents at birth or soon after. It is characterized by multiple firm dermal and subcutaneous nodules. Skeletal lesions, primarily of the metaphyseal regions of the long bones, occur in 50% of patients. If only the skin and bones develop fibromas, the prognosis is excellent, with spontaneous resolution of the lesions without complications expected within the first 1 to 2 years of life. Some refer to this limited disease as congenital multiple fibromatosis. Females more commonly get the generalized disease.

The fibromas may involve the viscera, including the gastrointestinal tract, breast, lungs, liver, pancreas, tongue, serosal surfaces, lymph nodes, or kidney. Autosomal-dominant inheritance has been reported. Histologically, fascicles of spindle cells occur in a whorled pattern. These nodules are composed of myofibroblasts.

Mortality in this more widespread subset is high. Eighty percent of alfected individuals die from obstruction or compression of vital organs. Those who survive past 4 months have spontaneous regression of their disease. Some life-threatening cases have responded to low-dose chemotherapy.

Juvenile Hyaline Fibromatosis and Infantile Systemic Hyalinosis

Juvenile hyaline fibromatosis and infantile systemic hyalinosis are allelic autosomal-recessive conditions characterized by multiple subcutaneous skin nodules, hyaline deposition, gingival hypertrophy, osteolytic bone lesions, and joint contractures. Nodular tumors of the scalp, face, and extremities usually appear in early childhood. Pink confluent papules may occur on the paranasal folds, and periauricular and perianal regions. The gene has been mapped to chromosome 4q21 with at least 15 different mutations in the gene encoding capillary morphogenesis protein 2, a transmembrane protein that is induced during capillary morphogenesis and that binds laminin and collagen IV.

Histologically, there are fibroblasts with fine intracytoplasmic eosinophilic granules, embedded in a homogeneous eosinophilic dermal ground substance. Ultrastructurally, the fibroblasts demonstrate defective synthesis of collagen, deposited as fibrillogranular material. Hanks S, et al: Mutations in the gene encoding capillary morphogenesis protein 2 cause juvenile hyaline fibromatosis and infantile systemic hyalinosis. Am J Hum Genet 2003;73:791.

Larralde M, et al: Juvenile hyaline fibromatosis. Pediatr Dermatol 2001;18:400.

Infantile Digital Fibromatosis (Infantile Digital Myofibroblastoma, Inclusion Body Fibroma)

Infantile digital fibromatosis is a rare neoplasm of infancy and childhood that usually occurs on the dorsal or lateral aspects of the distal phalanges of the toes and fingers. The thumb and great toe are usually spared. These asymptomatic, firm, red, smooth nodules occur during the first year of life, 47% in the first month. Rare congenital lesions have been noted. The lesions do not metastasize, but may infiltrate deeply.

Histologically, the epidermis is normal, but the dermis is infiltrated with proliferating myofibroblasts and collagen bundles. Eosinophilic cytoplasmic inclusions in many of the fibroblasts are characteristic. Treatment by surgical excision has a high risk of recurrence, and conservative, nonsurgical management is often appropriate. Spontaneous regression is generally noted, but the lesion may cause functional impairment and may infiltrate deeply before regression occurs. Mohs micrographic surgery has been performed successfully using both trichrome staining and smooth muscle actin staining to demonstrate the inclusion bodies within tumor cells.

Albertini JG, et al: Infantile digital fibroma treated with Mohs micrographic surgery. Dermatol Surg 2002;28:959.

Kanwar AJ, et al: Congenital infantile digital fibromatosis. Pediatr Dermatol 2002;19:370.

Fibrous Hamatoma of Infancy

Fibrous hamartoma of infancy is a single dermal or subcutaneous firm nodule of the upper trunk that is present at birth or shortly thereafter. Overlying skin changes are uncommon, but may include increased hair, alteration in pigmentation, and eccrine gland hyperplasia. Most cases are solitary, but multiple tumors have been reported. Ninety-one percent are noted within the first year of life and 23% are congenital. The male-to-female ratio is 2.4:1. Most lesions occur in the axillary region, upper arm, upper trunk, inguinal region, and external genital area. Biopsy shows an organoid pattern with different types of tissue organized in whorls or bands. In early lesions, lobules of mature fat are interspersed between myxoid and fibrous areas. Myxoid zones have primitive mesenchymal cells with stellate nuclei. Fibrosing areas demonstrate delicate collagen bundles and many elongated fibroblast nuclei. Over time, both the myxoid and fibrosing areas develop into cell-poor fibrous areas with thick collagen bundles. There is no recurrence after excision.

Dickey GE, et al: Fibrous hamartoma of infancy: current review. Pediatr Dev Pathol 1999;2:236.

Scott DM, et al: Fibrous hamartoma of infancy. J Am Acad Dermatol 1999;41(5 Pt 2):857.

Fibromatosis Colli

In fibromatosis colli there is a fibrous tissue proliferation infiltrating the lower third of the sternocleidomastoid muscle at birth. Fine needle aspiration is useful to confirm the diag-

Haleem A, et al: Juvenile hyaline fibromatosis: morphologic, immunohistochemical, and ultrastructural study of three siblings. Am J Dermatopathol 2002;24:218.

nosis. Spontaneous remission occurs within a few months. Occasionally, some patients are left with a wryneck deformity; however, this complication is amenable to surgery.

Kurtycz DF, et al: Diagnosis of fibromatosis colli by fine-needle aspiration. Diagn Cytopathol 2000;23:338.

Diffuse Infantile Fibromatosis

This process occurs within the first 3 years of life and is usually confined to the muscles of the arms, neck, and shoulder area. There is a multicentric infiltration of muscle fibers with fibroblasts resembling those seen in aponeurotic fibromas. Calcification does not occur. Recurrence after excision occurs in about a third of cases.

Ahn JM, et al: Infantile fibromatosis in childhood: findings on MR imaging and pathologic correlation. Clin Radiol 2000 Jan; 55:19.

Allen PW: The fibromatoses. Am J Surg Pathol 1977;1:255, 305.

Aggressive Infantile Fibromatosis

The clinical presentation of this locally recurring, nonmetastasizing lesion involves single or multiple fast-growing masses that are present at birth or occur within the first year of life. Infantile fibromatosis may be seen in any location, although the arms, legs, and trunk are the usual sites. Histologically, it is hypercellular and mimics malignancy.

Amoric JC, et al: Infantile aggressive fibromatosis. Ann Dermatol Venereol 1993;120:762.

Giant Cell Tumor of the Tendon Sheath

This tumor, which is most commonly attached to the tendons of the fingers, hands, and wrists, has a predilection for the flexor surfaces. It is firm, measures from 1 to 3 cm in diameter, and does not spontaneously involute. It recurs after excision in approximately 25% of cases. Another tumor of the tendon sheath, fibroma of the tendon sheath, may represent a variant of the giant cell tumor. It also affects the flexural tendons of the fingers and hands, and morphologically, it and the giant cell tumor are identical. The condition tends to occur in younger men (the average age at onset is 30) than the giant cell variety. When a proliferation similar to giant cell tumor of the tendon sheath occurs in deeper tissues, it is referred to as pigmented villo-nodular tenosynovitis. The pigment is hemosiderin.

Histologically, the giant cell tumor consists of lobules of densely hyalinized collagen. The characteristic osteoclast-like giant cells have deeply eosinophilic cytoplasm that moulds to adjacent cells. A variable number of randomly distributed nuclei are present. Lipophages and siderophages may be numerous, and hemosiderin deposition may impart a brown color to the lesions on gross examination. The fibroma of the tendon sheath generally lacks lipophages, siderophages, and giant cells, with the lobules being composed of dense fibrocollagenous tissue.

The rate of recurrence depends on the presence or absence of a pseudocapsule, lobulation of the tumor, extra-articular location, and the presence of satellite lesions. Local recurrence has been treated with more extensive surgery. Radiation therapy has been reported anecdotally. Al-Qattan MM: Giant cell tumours of tendon sheath: classification and recurrence rate. J Hand Surg [Br] 2001;26:72.

Scott SJ, et al: Giant-cell tumour of the tendon sheath. J Bone Joint Surg Br 2000;82:1206.

Ainhum

Ainhum is also known as *dactylolysis spontanea*, *bankokerend*, and *sukhapakla*. Ainhum is a disease affecting the toes, especially the fifth toe, characterized by a linear constriction around the affected digit, which leads ultimately to the spontaneous amputation of the distal part. It occurs chiefly among black men in Africa. Usually it is unilateral, but it may be bilateral.

The disease begins with a transverse groove in the skin on the flexor surface of the toe, usually beneath the first interphalangeal articulation. The furrow is produced by a ringlike fibrosis and an induration of the dermis. It deepens and extends laterally around the toe until the two ends meet, so that the digit becomes constricted as if in a ligature. The constricted part becomes swollen and soft and after a time greatly distended. Ulceration may result in a malodorous discharge, with pain and gangrene. The course of the disease is slow, but in 5 to 10 years spontaneous amputation occurs, generally at a joint.

The cause is unknown. The condition may result from chronic trauma and exposure to the elements by walking barefoot in the tropics. Fissuring followed by chronic inflammation and fibrosis may then result.

Treatment in early cases by cutting the constricting band is unsuccessful; in advanced cases amputation of the affected member is advisable. Surgical correction by Z-plasty has produced good results. Intralesional injection of betamethasone (total, 15 injections) has also been successful.

Pseudo-Ainhum

Pseudo-ainhum has been a term used in connection with certain hereditary and nonhereditary diseases in which annular constriction of digits occurs. Hereditary disorders include hereditary palmoplantar keratodermas, especially Vohwinkel syndrome and mal de Meleda, pachyonychia congenita, Ehlers-Danlos syndrome, erythropoietic protoporphyria, and congenital ectodermal defect. Nonhereditary disorders associated with constriction of digits are ainhum, leprosy, cholera, ancyclostomiasis, scleroderma, Raynaud syndrome, pityriasis rubra pilaris, psoriasis, Olmstead syndrome, Reynold syndrome (scleroderma and primary biliary cirrhosis with antimitochondrial antibodies), syringomyelia, ergot poisoning, and turnors of the spinal cord. Factitial pseudo-ainhum may be produced by self-application of a rubber band, string, or other ligature.

Congenital cases have been reported that may affect digits or limbs. It may occur as a familial condition or may result secondary to amniotic bands.

Treatment may be with surgery or intralesional injection of corticosteroids, as in ainhum. Retinoids may be used in diseases responsive to them.

Connective Tissue Nevi

These uncommon lesions may present as acquired isolated plaques, as multiple lesions either acquired or congenital, or as one finding in a more generalized disease. Biopsy findings in many cases do not appear very different from normal skin, although in some cases altered amounts of collagen or elastin may be identified.

These lesions characteristically occur on the trunk, most often in the lumbosacral area. They may be solitary, but are often multiple, in which case they may show a zosteriform arrangement. Individual lesions are slightly elevated plaques 1 to 15 cm in diameter, varying in color from light yellow to orange, with a surface texture resembling shagreen leather. In Proteus syndrome, the connective tissue nevi are present as plantar, or occasionally, palmar masses with a cerebriform surface.

Connective tissue nevi of the acquired type have been classified as eruptive collagenomas, isolated collagenomas, or isolated elastomas, depending on the number of lesions and the predominant dermal fibers present. They cannot be differentiated clinically.

Hereditary types of connective tissue nevi include dermatofibrosis lenticularis disseminata in the Buschke-Ollendorff syndrome, familial cutaneous collagenoma, and the shagreen patches seen in tuberous sclerosis.

Buschke-Ollendorff syndrome is an autosomaldominantly inherited disorder in which widespread dermal papules and plaques develop asymmetrically over the trunk and limbs. Elastic fiber thickening, highly variable fiber diameter, and desmosine increases three- to seven-fold above normal have been described in these patients. The associated feature of osteopoikilosis is asymptomatic, but it is diagnostic in x-ray evaluation. Focal sclerotic densities are seen, primarily in the long bones, pelvis, and hands. The syndrome is highly variable, and familial inheritance of elastic tissue naevi without evidence of osteopoikilosis has been reported.

Papular elastorrhexis is characterized by multiple white evenly scattered papules usually occurring on the trunk. There is a decrease of elastic fibers, which may appear thin and fragmented. Most reported cases are sporadic but familial occurrence has been described.

Patients with familial cutaneous collagenomas may present with numerous symmetric asymptomatic dermal nodules on the back. The age of onset is usually in the mid to late teens. In patients with the inherited disease, multiple endocrine neoplasia type I multiple collagenomas were reported in 23 of 32 patients. These were less than 3 mm in diameter and were on the upper torso, neck, and shoulders. They occurred in association with numerous other cutaneous findings such as angiofibromas, café-au-lait macules, and lipomas.

The collagenomas of tuberous sclerosis are associated with adenoma sebaceum, periungual fibromas, and ash-leaf macules. Because at least half the cases of tuberous sclerosis result from new mutations, all patients with connective tissue nevi should be carefully studied for evidence of tuberous sclerosis, even in the absence of a family history of the disease. Isolated plantar collagenoma may exhibit a cerebriform appearance and resemble plantar fibromas of Proteus syndrome.

Eruptive collagenomas may be widespread or localized. They have rarely been associated with infectious diseases such as syphilis.

Mucinous nevus is a form of connective tissue nevus characterized by increased ground substance without increases in collagen or elastin. Histologically, collagen bundles are widely separated by mucin and may be attenuated. Overlying follicular induction similar to that seen in dermatofibromas may be present.

Elastofibroma Dorsi

Elastofibroma dorsi is a rare benign tumor usually located in the deep soft tissues in the subscapular region, but sometimes at other sites. The tumor is firm, unencapsulated, and measures up to several centimeters in diameter. It is believed to represent an unusual response to repeated trauma. Histologically, the tumor consists of abundant compact sclerotic collagen mixed with large, swollen, irregular elastic fibers, often appearing as globules of elastic tissue. Computed tomography (CT) and MRI can define the extent of the lesion, and excision is curative.

Kudo S: Elastofibroma dorsi: CT and MR imaging findings. Semin Musculoskelet Radiol 2001;5:103.

Abe S, et al. Elastofibroma dorsi: CT, MRI, and pathologic findings. Plast Reconstr Surg 1999;104:2121.

Angiofibromas

These skin-colored to reddish papules, which show fibroplasia and varying degrees of vascular proliferation in the upper dermis, may occur as a solitary nonhereditary form, the fibrous papule of the nose, as multiple nonhereditary lesions, pearly penile papules, or as multiple hereditary forms as in tuberous sclerosis, Birt-Hogg-Dube Syndrome (in combination with the specific lesion, the fibrofilliculoma) and multiple endocrine neoplasia type I. There have been reports of agminated or segmental angiofibromas that may represent a segmental form of tuberous sclerosis. The multiple hereditary types are discussed in other chapters.

Cellular angiofibroma of the vulva is a well circumscribed but not truly encapsulated lesion that occurs in older women. It is composed of small spindle cells arranged in short fascicles and relatively abundant small rounded vessels. They may express estrogen and progesterone receptors, and also CD34.

- Dargent JL, et al: Cellular angiofibroma of the vulva. J Cutan Pathol 2003;30:405.
- Schaffer JV, et al: Multiple facial angiofibromas. J Am Acad Dermatol 2005;53:S108.
- Trauner MA, et al: Segmental tuberous sclerosis presenting as unilateral facial angiofibromas. J Am Acad Dermatol 2003; 49(2 Suppl):S164.

Fibrous Papule of the Nose (Fibrous Papule of the Face, Benign Solitary Fibrous Papule) These lesions occur in adults as dome-shaped, sessile, skin-colored, white, or reddish papules 3 to 6 mm in diameter on or near the nose (Fig. 28-20). Fibrous papule is usually solitary, but it is not uncommon for a few lesions to occur. It may be confused with a nevocytic nevus, neurofibroma, granuloma pyogenicum, or a basal cell carcinoma. Like other angiofibromas, fibrous papules demonstrate concentric fibrosis surrounding vessels and adnexal structures. Stellate dermal dendrocytes are often prominent. They stain for factor XIIIa. Large pyramidal junctional melanocytes are often noted overlying the lesion, and a superficial shave biopsy may be mistaken for a melanocytic lesion. Conservative excision is curative; recurrence is rare. Multiple lesions should prompt a search for other stigmata of tuberous sclerosis.

Cerio R, et al: An immunohistochemical study of fibrous papule of the nose: 25 cases. J Cutari Pathol 1989;16:194.

Pearly Penile Papules This is the term given to pearly white, dome-shaped papules occurring circumferentially on the coronal margin and sulcus of the glans penis. The lesions may be firm or soft and filliform. Occasionally, lesions are also present on the penile shaft. Pearly penile papules are not uncommon. Patients usually present around the age of 20 to 30 years concerned these are condylomata or are referred as treatment-resistant venereal warts.

These lesions should be distinguished from papillomas, hypertrophic sebaceous glands, and condyloma acuminatum.

No treatment is necessary, only reassurance. If treatment is desired, laser ablation or shave excision is effective.

Acral Fibrokeratoma

Acral fibrokeratoma, often called *acquired digital fibrokeratoma*, is characterized by a pinkish, hyperkeratotic, homlike projection occurring on a finger, toe, or palm. The projection usually emerges from a collarette of elevated skin. The average age of the patient is 40. The lesion resembles a rudimentary supernumerary digit, cutaneous horn, or a neuroma.

Histologic sections show a central core of thick collagen bundles interwoven closely in a vertical position. This is surrounded by capillaries and a fine network of reticulum fibers. Stellate dermal dendrocytes may be present, as in fibrous papule.

Simple surgical excision or laser ablation at the level of the skin surface is effective.

Kakurai M, et al: Giant acquired digital fibrokeratoma. J Am Acad Dermatol 2003;48(5 Suppl):S67.

Familial Myxovascular Fibromas

Multiple vertucous papules on the palms and fingers, which on biopsy show focal neovascularization and mucin-like changes in the papillary dermis, have been described. Clinically, these lesions closely resemble warts. They have been reported from several family members, with a probable autosomal-dominant inheritance.

Subungual Exostosis

Subungual exostosis is a solitary osteochondroma protruding from beneath the distal edge of the nail, most commonly of the great toe. Rarely, the terminal phalanges of other toes, particularly the little toe or even the fingers, may be involved. The exostosis is seen chiefly in women between the ages of 12 and 30. The first appearance is a small pinkish growth projecting slightly beyond the inner free edge of the nail. The overlying nail becomes brittle and either breaks or is removed, after which the tumor, being released, mushrooms upward and distally above the level of the nail. It grows slowly to a maximum diameter of about 8 mm. Pressure of the shoe on the lesion causes great pain.

Subungual exostosis must be differentiated from pyogenic granuloma, vertuca vulgaris, pterygium inverum unguis, ingrowing nail, and glomus tumor. If subungual exostosis is suspected, the diagnosis can be confirmed by radiographic examination. Complete excision or curettage is the proper method of treatment.

Ilyas W, et al: Subungual exostosis of the third toe. J Am Acad Dermatol 2001;45(6 Suppl):S200.

Chondrodermatitis Nodularis Chronica Helicis

This is a small, nodular, tender, chronic inflammatory lesion occurring on the helix of the ear. Most patients are men. The lesions are not uncommon and sometimes as many as 12 nodules may arrange themselves along the edge of the upper helix. The lesions are 2 to 4 mm in diameter, well defined, slightly reddish, and extremely tender. At times the surface is covered by an adherent scale or a shallow ulcer. After the masses have reached a certain size, growth ceases, but the lesions persist unchanged for years. There is no tendency to malignant change. Similar lesions may occur on the anthelix, predominantly in women.

The lesion is produced by ischemic necrosis of the dermis, and generally occurs on the side the patient favors during sleep. There may be a history of frostbite, chronic trauma, or chronic actinic exposure with concomitant actinically induced lesions of the face and dorsal hands.

Histologically, a zone of eosinophilic necrosis of collagen is flanked by granulation tissue. Overlying acanthosis and hyperkeratosis and central ulceration may be present. The histologic changes resemble those of a decubitus ulcer, but on a smaller scale. Occasionally, bizarre reactive fibroblasts are noted, as in atypical decubital fibroplasia.

The lesions may be excised. The underlying cartilage may be excised or fenestrated to reduce pressure on the overlying skin during sleep. The patient may be encouraged to change sleeping positions, but many find this difficult. Pillows with an ear slot are also available.

Oral Submucous Fibrosis

A distinctive fibrosis of the oral mucosa occurs in the western Pacific basin and south Asia among persons whose diet is heavily seasoned with chili or who chew betel, a compound of the nut of the areca palm, the leaf of the betel pepper, and lime. The irritation produced causes first a thickening of the palate, tonsillar pillars, and fauces secondary to dermal and muscular fibrosis. As the disease progresses, opening of the mouth and protrusion of the tongue develops such that eating, swallowing, and speech are impaired. Later ulceration and leukoplakic areas occur and finally, in approximately 7% of patients, malignant transformation to squamous cell carcinoma develops. Treatment consists of the intralesional injection of dexamethasone and hyaluronidase, and in advanced cases surgical excision and grafting. Discontinuance of the offending substance and physical therapy are also needed.

Fascial Hernia

Evanescent herniations in the form of nodules appear in the skin where the deep and superficial veins meet going through the fascia. These herniated nodules, seen most frequently on the lower extremities, become prominent when the underlying muscles contract, and pain may occur with prolonged exertion. Treatment is not indicated unless the area is chronically painful. Light compression may be effective.

Harrington AC, et al: Hernias of the anterior tibialis muscle. J Am Acad Dermatol 1990;22:123.

Acrochordon (Cutaneous Tag, Papilloma Colli, Fibroma Pendulum, Cutaneous Papilloma, Fibroma Molluscum, Templeton Skin Tags, Skin Tags)

Small, flesh-colored to dark brown, pinhead-sized and larger, sessile and pedunculated papillomas commonly occur on the neck, often in association with small seborrheic keratoses. These tags are also seen frequently in the axillae and on the eyelids, less often on the trunk and groins, where the soft, pedunculated growths often hang on thin stalks. These flesh-colored, teardrop-shaped tags feel like small bags. Occasionally, as a result of twisting of the pedicle, one will become inflamed, tender, and even gangrenous. Both sexes have the same incidence, with nearly 60% of individuals acquiring them by the age of 69. They often increase in number when the patient is gaining weight or during pregnancy and may be related to the growth hormone-like activity of insulin. They may be associated with diabetes mellitus. In patients preselected for gastrointestinal complaints, skin tags appear to be more prevalent in those with colonic polyps. This association has not been proved for the general population.

Histologically, acrochordons are characterized by epidermis enclosing a dermal fibrovascular stalk. The baglike papillomas generally show a flattened epidermis. Smaller lesions often demonstrate seborrheic keratosis-like acanthosis and horn cysts.

Small lesions can be clipped off at the base with little or no anesthesia. Aluminum chloride may be applied for hemostasis if needed. Light electrodesiccation can also be effective. For larger lesions, anesthesia and snip excision are preferred.

An entity that is frequently reported as perianal acrochordons or skinfolds has now been named infantile perianal pyramidal protrusions. This occurs in young children, usually girls, in the midline anterior to the anus. This reduces with time and no treatment is necessary. Child abuse, genital warts, hemorrhoids, granulomatous lesions of inflammatory bowel disease, or rectal prolapse must be considered in the differential diagnosis of these lesions.

Tag-like basal cell carcinomas in childhood should suggest a diagnosis of nevoid basal cell carcinoma syndrome (NBCCS). Biopsy should be performed on acrochordons in children because the lesions are uncommon in this age group, and they may be the presenting sign of NBCCS.

Dermatofibroma (Fibrous Histiocytoma)

This common skin lesion's appearance is usually sufficiently characteristic to permit clinical diagnosis. It is generally a single round or ovoid papule or nodule about 0.5 to 1 cm in diameter that is reddish-brown, sometimes with a yellowish hue (Fig. 28-21A). The sharply circumscribed nodule is more evident on palpation than expected from inspection. The larger lesions may present an abrupt elevation at the border to form an exteriorized tumor resting on a sessile base.

It may be elevated or slightly depressed. The hard lesion is adherent to the overlying epidermis, which may be thinner from pressure or even indented, so that there is a dell-like depression over the nodule (Fig. 28-21B). In such cases only the depression is seen, but on palpation the true nature of the lesion is found. Fitzpatrick proposed the term *dimple sign* for the depression created over a dermatofibroma when it is grasped gently between thumb and forefinger.

Dermatofibromas seldom occur in children; they are encountered mostly in middle-aged adults. Their size generally varies from 4 to 20 mm, although giant lesions greater than 5 cm occur. After reaching this size, growth ceases and the harmless lump remains stationary. The principal locations are on the lower extremities, above the elbows, or on the sides of the trunk. Systemic lupus erythematosus, treatment with prednisone or immunosuppressive drugs, chronic myelogenous leukemia and HIV infection have been associated with the development of multiple dermatofibromas.

It is suspected that many dermatofibromas are initiated by injuries to the skin, such as insect bites or blunt trauma.

On histologic examination there is a dermal mass composed of close whorls of fibrous tissue in which are numerous spindle or histiocytic cells. The cells have features of fibroblasts and myofibroblasts, but are probably of primitive mesenchymal origin. Immunohistochemical studies show most cells are positive for factor XIIIa, and negative for MAC387, S-100, and CD34. The tumor is not well circumscribed and may extend into adjacent structures and surround individual collagen bundles at the periphery (collagen trapping). Overlying acanthosis is typical, and induction of primitive epithelial germs or mature follicular structures may be noted. Basal cell carcinoma-like changes commonly overlie dermatofibromas, but true basal cell carcinoma is quite rare.

At times, large histiocytic cells within the lesion are strikingly atypical (monster cells). Occasionally, granular cytoplasm may predominate.

Hemosiderin, may be present, and foam cells and lipid deposits may be seen. The presence of Touton giant cells containing hemosiderin is pathognomonic of dermatofibroma. There is a great variation in the vascular components. Rarely, the vascularization is pronounced and suggests a kind of hemangioma (sclerosing hemangioma). Deep penetrating dermatofibromas may grow into the subcutaneous tissue via the fibrous septa or with a pushing front of tumor. They lack the extensive lacy and lamellar infiltrative growth pattern of dermatofibrosarcoma protuberans. Deep fascial fibrous histiocytomas may involve the fat or muscle at times.

The clinical appearance of the lesion and its location, chiefly on the lower extremities, are distinctive. Clinically, granular cell tumor, dermatofibrosis lenticularis disseminata, clear-cell acanthoma, and melanoma are some of the lesions to be considered. At times only a biopsy can differentiate these.

Progressive enlargement beyond 2 or 3 cm in diameter suggests a malignant fibrous histiocytoma or dermatofibrosarcoma protuberans, and excisional biopsy is indicated.

These lesions usually are asymptomatic and do not require treatment. Involution may occur after many years if the lesion is left alone. Simple reassurance is suggested.

Dermatofibrosarcoma Protuberans

Dermatofibrosarcoma protuberans (DFSP) is characterized by bullcy, protuberant, neoplastic masses. Fifty to 60% occur on the trunk, with less common involvement of the proximal extremities and the head and neck. The disease begins with one or multiple elevated, erythematous, firm, nodules or plaques associated often with a purulent exudate or with ulceration. Patients, usually middle-aged, complain of a firm, painless lump in the skin that has been slowly increasing in size for several years.

The course is slowly progressive, with pain becoming prominent as the lesion grows, and frequent recurrence after initial conservative surgical intervention (Fig. 28-22). In untreated patients, severe pain and contractures may result. There is little tendency to metastasize, although wide dissemination has been reported.

Histologically, the tumor shows a subepidermal fibrotic plaque with uniform spindle cells and variable vascular spaces. In many instances there is a pronounced matlike woven pattern of spindle cells. Giant cells may be present in small numbers. Pigmented DFSP, in which the cells contain melanin, predominantly affect persons of color, and are called Bednar tumors. CD34 and stromelysin 3 positivity are characteristic and serve as markers to discern DFSP from dermatofibroma. S-100 is negative and may be used to separate spindle cell melanoma from a Bednar tumor. Recurrent DFSP can be myxoid and resembles the diffuse type of neurofibroma histologically. A juvenile variant, called giant cell fibroblastoma, is characterized by a loose arrangement of spindle cells, and by multinucleated giant cells adjacent to dilated spaces that resemble dilated lymphatic vessels.

The differential diagnosis, especially in the early stage, is that of keloid and a large dermatofibroma.

Mohs surgical excision technique is the treatment of choice. In a series of 50 patients the recurrence rate was 2%, with wide local excision recurrence is 11% to 50%. A preoperative MRI may assist in planning successful clearance.

Nodular Fasciitis (Nodular Pseudosarcomatous Fasciitis)

Also known as subcutaneous pseudosarcomatous fibromatosis, this benign mesenchymal neoplasm occurs most often on the arms. Clinically, a firm, solitary, sometimes tender nodule develops in the deep fascia, and often extends into the subcutaneous tissue. It measures usually 1 to 4 cm in diameter. The lesion appears suddenly over a period of a few weeks, without apparent cause, in normal, healthy persons. Sex distribution is equal, and the average age at onset is 40.

Microscopic findings consist of well-defined, loose nodules of stellate and spindled cells that may have a myxoid appearance. Capillary proliferation is typical, and erythrocyte extravasation between spindle cells is common. Nodular lymphoid infiltrates are often noted within the lesion. On electron microscopic examination, the component cells in the neoplasm have proved to be myofibroblasts.

Dermal, intravascular, and proliferating variants (proliferative fasciitis) have been described. These are designated when the nodular masses arise in the dermis, in intimate association with blood vessels, or show ganglion-like giant cells and infiltration of collagen. The proper treatment is complete excision. Recurrence is rare and the prognosis is excellent. A rapid response to intralesional corticosteroids has been reported in one case.

Cranial fasciitis of childhood is an uncommon variant of nodular fasciitis, manifesting as a rapidly enlarging mass in the subcutaneous tissue of the scalp, which may invade the cranium. It occurs in infants and children, resembles nodular fasciitis histologically, and usually does not recur after surgical excision.

Plexiform Fibrohistiocytic Tumor

This rare tumor arises primarily on the upper extremities of children and young adults. There is a strong female predisposition. It presents as a slowly growing painless growth in the subcutaneous tissue. There is usually extension into the dermis or the underlying skeletal muscle. Histologically, it is a distinctly biphasic tumor, with a fibroblastic component mixed with aggregates of mononuclear histiocyte-like cells and multinucleated osteoclast-like cells. The multinucleated cells react to CD68, while the spindle cells express smooth muscle actin but not factor XIIIa. While most patients are cured with excisional surgery, some tumors will recur locally, and uncommonly regional and systemic metastases will occur.

Morio O, et al: Plexiform fibrohistiocytic tumor. Eur J Dermatol 2004;14:118.

Atypical Fibroxanthoma

Atypical fibroxanthoma (AFX) of the skin is a low-grade malignancy related to malignant fibrous histiocytoma, which it resembles histologically. Its smaller size and more superficial location account largely for its more favorable prognosis. The lesion occurs chiefly on the sun-exposed parts of the head or neck in white persons over age 50. The tumor begins as a small, firm nodule often with an eroded or crusted surface without characteristic morphologic features (Fig. 28-23). A clinical variant presents as a slowly enlarging tumor on a covered area, in patients with an average age of 39. This variant accounts for 25% of cases.

The lesion develops in the dermis and is separated from the epidermis by a thin band of collagen. The tumor consists of bizarre spindle cells mingled with atypical histiocytes. Some spindle cells have a vesicular nucleus. The cytoplasm may be vacuolated and resembles the xanthoma cell. Mitotic figures, prominent eosinophilic nucleoli, and the presence of a biphasic tumor cell population are characteristic findings. S-100 staining is sparse when compared with melanoma, and prekeratin staining is negative: this helps to distinguish AFX from squamous cell carcinoma. Variants with clear cells, granular cells and osteoclast-type cells have been described.

The treatment of choice is complete surgical excision. Mohs microsurgery results in fewer recurrences and smaller defects than in wide excision. Although the prognosis is excellent, local recurrence after inadequate excision is usual, and cases of metastasizing AFX have been reported.

Malignant Fibrous Histiocytoma

Malignant fibrous histiocytoma (MFH) is the most common soft-tissue sarcoma of middle and late adulthood. It arises deeply and is more likely to appear in deep fascial planes than in subcutaneous tissue. One-third occur on the thigh or buttock. Peak incidence is in the seventh decade. They sometimes arise in an area of radiodermatitis or in a chronic ulceration.

Several histologic variants of MFH have been described, including myxoid, inflammatory, and giant cell types. Cell staining is positive for vimentin. Pleomorphic cellular elements and bizarre mitotic figures are characteristic. AFXs are smaller and more superficial tumors of the dermis, compared with the deeper location of MFH. Epithelioid sarcoma lacks the large, bizarre, multinucleated cells often seen in MFH.

The prognosis in MFH is related to the site; deeper and more proximally located tumors have a poorer prognosis. The myxoid variant is less likely to metastasize. An especially poor prognosis attends tumors arising in sites of radiodermatitis. Local recurrence after excision occurs in 25%, 35% metastasize, and the overall survival rate is 50%. Mohs surgical removal may result in fewer recurrences.

A tumor that presents on the extremities of children as a slowly growing dermal or subcutaneous mass may be the angiomatoid type. It has been separated from the term malignant as it has a relatively good prognosis.

Dermal Dendrocyte Hamartoma

Three female patients who were born with a rounded, medallion-like lesion on the upper trunk were found to have a proliferation of fusiform CD34, factor XIIIa-positive cells in the mid and reticular dermis. The lesions were asymptomatic, brown or erythematous in color, and had a slightly atrophic, wrinkled surface (Fig. 28-24).

Rodriguez-Jurado R, et al: Medallion-like dermal dendrocyte hamartoma: a new clinically and histopathologically distinct lesion. J Am Acad Dermatol 2004;51:359.

Epithelioid Sarcoma

Epithelioid sarcoma occurs chiefly in young adults, with onset usually being from 20 to 40 years of age. Two-thirds of

Fig. 28-24 Dermal dendrocyte hamartoma.

Fig. 28-25 Epithelial sarcoma.

cases are in men. Nearly all lesions are on the extremities, half of them on the hands or wrists (Fig. 28-25). It has, however, been reported from a wide variety of locations, including the genital region, the "proximal type".

The tumor grows slowly among fascial structures and tendons, often with central necrosis of the tumor nodules and ulceration of the overlying skin. Initial clinical diagnoses may include granuloma annulare, rheumatoid nodule, or ganglion cyst. Histologically, irregular nodular masses of large, deeply acidophilic polygonal cells merge with spindle cells in a biphasic pattern. Central necrosis within masses of epithelioid cells may give the impression of a palisaded granuloma. Absence of staining for CD68 (KP-1) and coexpression of keratins and vimentin confirm the diagnosis.

Wide local excision of small, early lesions may achieve a cure. Recurrence after attempted excision occurs in three of four cases, and late metastasis in 45% of patients. There is a propensity for lymph node and lung metastases and in one series of eight patients, 25% 5- and 10-year survival rates were reported. Women have a more favorable prognosis; the proximal lesions have a worse prognosis.

Myxomas

Cutaneous myxomas may be solitary, and appear as fleshcolored nodules on the face, trunk, or extremities. They may also occur as part of Carney complex. This has also been reported under the eponyms NAME (nevi, atrial myxoma, myxoid neurofibromas, and ephelides) and LAMB (lentignes, atrial myxoma, mucocutaneous myxomas, blue nevi), and simply as cutaneous lentiginosis with atrial myxoma.

The Carney complex consists of patients who have two or more of the following: 1) cardiac myxomas (79%); 2) cutaneous myxomas (not myxoid neurofibromas) (45%); 3) mammary myxoid fibromas (30%); 4) spotty mucocutaneous pigmentation, including lentiginoses (not ephelides) and blue nevi often of a distinctive epithelioid variety (65%); 5) primary pigmented nodular adrenocortical disease (45%), which results in Cushing syndrome; 6) testicular tumors (56% of male patients); and 7) pituitary growth hormonesecreting tumors (10%). A peculiar type of schwannoma featuring melanin and psammoma bodies may also be present.

The cutaneous myxomas occur as small (<1 cm), multiple, skin-colored papules having a predilection for development by a mean age of 18 years, and a tendency to occur on the ears, eyelids, and nipples. The lentigines are prominent on the face, lips, conjunctival mucosa, rectal mucosa, and genital mucosa. Cardiac myxomas may occur in any of the four chamber of the heart and are recurrent in 20%. They may embolize to the skin, producing acral necrotic lesions.

Recognition of this syndrome, with diagnosis and removal of the atrial myxomas, can be lifesaving. The first-degree family members should be examined as this is an autosomaldominantly inherited condition. The disease has been mapped to two loci and a third is likely. Mutations in the gene coding for the protein kinase A type I-a regulatory subunit (PPKAR1A) on chromosome 17 have been documented in about half of the families.

A malignant counterpart, the myxosarcoma, is a tumor that arises in the subcutaneous fat and underlying soft tissues. There is a tendency for local recurrence after wide and deep excision. Metastases are rare.

MASTOCYTOSIS

Mastocytosis is a general term applied to local and systemic accumulations of mast cells. Mast cells are bone-marrowderived CD34+ cells. These cells carry preformed mediators, such as histamine, heparin, and various cytokines, which, when released, may cause symptoms such as flushing, urticaria, diarrhea, abdominal pain, headache, dyspnea, syncope, and palpitations.

Mastocytosis is divided into childhood- and adult-onset disease. The condition varies in these two age groups, in clinical presentation, prognosis, and pathogenic factors. Studies have revealed mutations in the c-KIT protooncogene in many adult-onset cases. Its protein product is the transmembrane tyrosine kinase KIT receptor (CD117) whose ligand is stem cell factor (also known as mast cell growth factor). Both clonality studies and mutational analysis indicate that many adult cases of mastocytosis result from a neoplastic proliferation of mast cells, with a mutation at codon 816 in the c-kit gene This mutation is activating, resulting in the proliferation of mast cells. A second mutation, a chromosomal deletion on 4q12 results in the juxtaposition of platelet-derived growth factor receptor- α and FIP1L1. This fusion gene activates hematopoetic cells and is pathogenic in a subset of patients with systemic mastocytosis and eosinophilia. This subset of patients has also been considered a type of "hypereosinophilic syndrome." Thus, the vast majority of adults with mastocytosis have systemic disease which may be viewed as a fundamentally myelodysplastic disorder.

Children often do not express any c-KIT mutation, nor do the uncommon familial cases. The latter is usually transmitted by autosomal-dominant inheritance with reduced expressivity, although other patterns may occur. The mutations leading to familial disease have not been defined. It appears spontaneous childhood disease may occur from either cytokine-derived hyperplasias, from mutations other than the activating 816 type, or from mutations yet to be described. Some pediatric cases, however, are known to have inactivating mutations of c-KIT and a few have the adult-type activating mutations. Childhood disease is defined as occurring before age 15. The majority of children develop their disease before the age of 2, and in most of them the condition spontaneously involutes.

Clinical Classification

Mast cell disease is divided into two broad categories cutaneous and systemic. Cutaneous mastocytosis describes those cases with involvement of the skin only, and includes most cases of childhood mastocytosis and infrequent adult cases. Childhood cases usually fall into one of three categories of cutaneous mastocytosis: the most common (60-80%of patients) have urticaria pigmentosa or so-called maculopapular cutaneous mastocytosis; fewer (10-35%) patients present with solitary mastocytosis; the remainder have the rare forms of diffuse cutaneous mastocytosis or the telangiectastic type.

A classification has been proposed by Akin and Metcalfe which incorporates the World Health Organization (WHO) criteria (Box 28-1).

The vast majority of adult patients with mastocytosis are classified as systemic mastocytosis, since they typically have clonal proliferation of the bone-marrow derived mast cells.

Box 28-1 Classification of mastocytosis

Cutaneous Mastocytosis Systemic Mastocytosis

- 1. Indolent systemic mastocytosis (ISM)
 - Isolated bone marrow mastocytosis
 - Smouldering systemic mastocytosis (SSM)
- Systemic mastocytosis with associated hematopoetic disease (SM-AHD, AHNMD [associated hematologic disorder mast cell disease]): systemic mastocytosis with leukaemia, myelodysplastic syndrome/disease, or non-Hodgkin lymphoma.
- 3. Aggressive systemic mastocytosis (ASM)
- 4. Mast cell leukemia
- 5. Mast cell sarcoma
- 6. Extracutaneous mastocytoma

Of adult patients with systemic mastocytosis not associated with hematopoetic disease, 60% have indolent mastocytosis and 40% have aggressive mastocytosis. Patients with aggressive systemic mastocytosis usually lack skin lesions. Mast cell leukemia and sarcoma are very rare. Many patients who present to the dermatologist with only skin lesions will have the indolent variety. Symptoms and signs of systemic disease are classified as those related to organ infiltration by mast cells, and those due to mediator release from mast cells. Direct organ involvement is most frequently bone pain from lytic bone lesions, hepatosplenomegaly, lymphadenopathy, or cytopenia from bone marrow involvement. For the dermatologists, the most important symptoms are those related to mediator release, usually acting on the gastrointestinal tract, respiratory tree, or blood vessels. These include pruritus, flushing, urtícaría, angioedema, headache, nausea, vomitíng, abdominal cramps, diarrhea, gastric and/or duodenal ulcer, malabsorption, asthma-like symptoms, presyncope, syncope, and anaphylaxis. These may occur spontaneously or be the result of massive histamine release after ingestion of known mast cell degranlators such as alcohol, morphine, codeine or extended rubbing of the skin. Hymenoptera stings may induce anaphylaxis. Mast cells also produce heparin, which may result in hematemesis, epistaxis, melena, and ecchymoses. Osteoporosis may also occur from chronic heparin release, resulting in fractures.

Cutaneous Mastocytosis

Cutaneous mastocytosis is relatively common, representing about 1 in 500 initial consultations to pediatric dermatologists.

Solitary Mastocytoma About 10% to 40% of childhood mastocytosis presents in this way. The solitary lesion may be present at birth or may develop during the first weeks of life. It originates as a brown macule that urticates on stroking. It may develop into a papule, a raised round or oval plaque, or a tumor. The size is usually less than 1 cm, but occasionally may reach two or three times this diameter. The surface is usually smooth, but may have a peau d'orange appearance. Although the mastocytoma may occur anywhere on the body, its favorite location is on the dorsum of the hand near the wrist. Edema, urtication, vesiculation, and even bulla formation may be observed in the lesion. Even a solitary lesion may produce systemic symptoms, usually flushing.

Although the generalized form may begin with a single lesion, dissemination usually occurs within 3 months of its appearance. Most solitary mastocytomas involute spontaneously by the age of 10 or earlier. They also respond favorably to excision, or the application of a hydrocolloid dressing to prevent the rubbing which triggers mediator release and symptomatology. Progression to malignant disease does not occur.

Generalized Eruption, Childhood Type (Urticaria Pigmentosa) This form of cutaneous mastocytosis represents 60% to 90% of childhood cases. In this type, the eruption usually begins during the first weeks of life, presenting with rose-colored, pruritic, urticarial, slightly pigmented macules, papules, or nodules. The lesions are oval or round, and vary in diameter between 5 and 15 mm and may coalesce. The color varies from yellowish-brown to yellowish-red. Occasionally the lesions are a pale yellow color and this has been called xanthelasmoidea. Vesicle and bulla formation is a frequent prominent feature early in the disease (Fig. 28-26). Indeed, vesicles and bullae may be the initial presenting signs, but they usually persist no longer than 3 years. In the older age groups vesiculation rarely occurs.

At their onset, lesions are similar to urticaria except that they are not evanescent. The lesions persist and gradually become chamois- or slate-colored (Fig. 28-27). When they

Fig. 28-26 Bullous mastocytosis.

Fig. 28-27 Urticaria pigmentosa.

are firmly stroked or vigorously nibbed, urticaria with a surrounding erythematous flare (Darier's sign) usually develops. Dermographism of clinically uninvolved skin is present in a third to a half of patients. For many years the brown, waxy skin lesions may persist before they begin to involute. Pigmentation and all evidence of the disease commonly disappear within a few years, generally before puberty. The eruption, however, may uncommonly persist into adult life. Although systemic involvement is possible, malignant systemic disease is extremely rare.

Diffuse Cutaneous Mastocytosis In this rare form, with diffuse involvement, the entire integument may be thickened and infiltrated with mast cells to produce a peculiar orange color, giving rise to the term *homme orange*. There is an infiltrated doughy or boggy consistency to the skin, and lichenification may be present. In the neonatal period diffuse cutaneous blistering may occur, leading to the diagnosis of epidermolysis bullosa or some other primary bullous disorder. This is termed "bullous mastocytosis."

Systemic Mastocytosis

Systemic mastocytosis is diagnosed by fulfilling the one major criterion and one minor criteria, or three minor criteria. The major criterion is the finding of dense infiltrates of mast cells (aggregates of 15 or more) in bone marrow or other extracutaneous tissues. The four minor criteria are: 1) atypical mast cell morphology; 2) aberrant mast cell surface phenotype (CD25 or CD2); 3) serum/plasma tryptase greater than 20 ng/mL; and 4) a codon 816 c-KIT mutation in peripheral blood, bone marrow or lesional tissue.

The most common type of systemic mastocytosis in adults is indolent systemic mastocytosis. These patients lack evidence of an associated nonmast cell hematologic disorder; lack end-organ dysfunction such as ascites, malabsorption, cytopenias, and pathologic fractures; and lack mast cell leukemia. The disorder is then diagnosed through physical and histopathologic examination of skin lesions. Several different patterns of cutaneous involvement have been described.

Generalized Eruption, Adult Type This is the most common pattern of mastocytosis presenting to the dermatologist. The most common lesions are macules, papules or nodules disseminated over most of the body but especially on the upper arms, legs, and trunk (Fig. 28-28). The upper arms and upper inner thighs may be the only areas involved on presentation. These may be reddish-purple (Fig. 28-29), rust colored, or brown. In the latter case they may closely resemble common nevi. They may urticate upon rubbing, as is seen in children with urticaria pigmentosa.

Erythrodermic Mastocytosis There is generalized erythroderma and the skin has a leather-grain appearance. Urtication can be produced over the entire surface.

Telangiectasia Macularis Eruptiva Perstans This is a persistent, pigmented, asymptomatic eruption of macules usually less than 0.5 cm in diameter with a slightly reddish-brown tinge. Despite the name, little or no telangiectasia may evident. Darier's sign may not be demonstrable, as the number of mast cells in the skin may not be greatly increased.

Fig. 28-28 Adult generalized mastocytosis.

Fig. 28-29 Adult generalized mastocytosis.

Classification and Prognosis in Adult Systemic Mastocytosis

Patients with systemic mastocytosis and associated hematologic disorder (AHDMD/SM-AHD) are typically older adults with signs and symptoms of systemic disease. A variety of associated nonmast cell hematologic conditions, including polycythemia vera, hypereosinophilic syndrome, chronic myelogenous or monocytic leukemia, lymphocytic leukemia, primary myelofibrosis, and Hodgkin's disease may be seen. Typically this type does not have skin lesions. The prognosis in these patients is that of their underlying hematologic condition. Smouldering systemic mastocytosis is characterized by a slow progression and lack of end-organ dysfunction due to mast cell infiltration. It describes patients with 30% or more infiltration of the bone marrow cavity by mast cells, a serum typtase of greater than 200 ng/mL and hepatosplenomegaly. Adult systemic mastocytosis has a more fulminant course and describes those patients with endorgan dysfunction due to mast cell infiltration (bone marrow failure, liver dysfunction, splenomegaly with hypersplenism, pathologic fractures, and gastro-intestinal involvement with malabsorption and weight loss). This group of patients has a poor prognosis. Mast cell leukemia occurs when the atypical mast cells (multilobular or multiple nuclei) represent 10% of circulating cells or 20% of bone marrow cells. The prognosis is poor.

Mast Cell Sarcoma and Extracutaneous Mastocytoma

These are rare findings of isolated tumors of either atypical mast cells in mast cell sarcoma, or benign appearing mast cells in extracutaneous mastocytoma. They occur in sites other than the skin or bone marrow. Mast cell sarcomas are aggressive locally destructive lesions as opposed to the benign mastocyomas which carry a good prognosis.

Biochemical Studies

Mast cells produce tryptase. It has become the preferred laboratory test to demonstrate evidence of increased mast cell burden, replacing urinary histamine and urinary histamine metabolites. It is of prognostic significance in some cases. Tryptase is measured as a total serum tryptase level. This should be obtained when the patient is in his/her normal state of health as anaphylaxis will increase it transiently. Mastocytosis patients may have a persistently and significantly elevated level. Results above 20 ng/mL are a minor criterion for the diagnosis of systemic mastocytosis.

Histopathology

The typical skin lesion shows a dense dermal aggregate of mononuclear cells with abundant basophilic cytoplasm. When these large mononuclear cells are stained with Giemsa or toluidine blue, the metachromatic granules are observed. When blisters are present, the roof of the vesicle or bulla is subepidermal. The mast cells collect in a band below the vesicle. Infiltration of local anesthetic adjacent to the lesion rather than directly into it and the use of anesthetic without epinephrine may help to avoid mast cell degranulation. Monoclonal antibodies against tryptase and CD117 (KIT) are available and sensitive when done well. They are rarely required, however.

Diagnosis

The typical case of cutaneous mastocytosis is easily diagnosed by the presence of solitary or multiple pigmented macules, papules or nodules that urticate when irritated by stroking or scratching. The diagnosis is confirmed by biopsy of the lesion with the demonstration of increased numbers of mast cells. The bullous and vesicular lesions may be more difficult to diagnose clinically; however, scrapings from the base of the bulla when stained with Giemsa or Wright stain will show mast cells in profusion.

Once the diagnosis of skin lesions of mastocytosis is made, the decision to assess for bone marrow involvement is key. While therapy to reduce the disease burden of proliferating clonal mast cells is not effective, bone marrow examination will provide information about the extent of the disease and the presence or absence of a nonmast-cell hematologic

disorder, and will assist in the counseling concerning prognosis. All adult patients and children with the unexplained presence of an abnormal complete blood count (CBC), hepatomegaly, splenomegaly, lymphadenopathy or a serum baseline tryptase of greater than 20 ng/mL should be offered a bone marrow examination. In asymptomatic adults with their only sign or symptom of mastocytosis being skin lesions, and who do not desire a bone marrow examination, serum tryptase and CBC should be repeated at least yearly during a complete history and physical examination. Elevation of the tryptase level, a drop in the platelet count or hemoglobin or a rise in the monocytes, or the onset of organomegaly should trigger a bone marrow examination. In children with early-onset disease, the prognosis is good; usually tryptase evaluations or mutational analysis is reserved for those with the above findings, or with persistent localized bone pain, severe gastrointestinal symptoms or biochemical evidence of hepatic insufficiency.

Differential Diagnosis

Clinically, a small solitary mastocytoma most frequently resembles a pigmented nevus or juvenile xanthogranuloma. Urtication establishes the diagnosis. The disseminated lesions are also distinctive enough to give little or no difficulty in the diagnosis. The nodular form may resemble xanthomas; however, the presence of urtication is distinctive. The vesicular and bullous lesions are to be distinguished from various hereditary and nonhereditary bullous diseases. The main histologic similarity is to Langerhans cell histiocytosis.

Prognosis

Most cases of early-onset, skin-limited disease in children clear completely. The solitary mastocytoma involutes spontaneously, usually within 3 years of onset. In those children and adults with indolent systemic mastocytosis the prognosis is also good. This is the most common category of patients presenting for diagnosis in the dermatology clinic. Patients with AHNMD have the prognosis of the associated disease. In the newly described patients with smouldering systemic mastocytosis, the prognosis is intermediate and not yet well defined. Aggressive systemic mastocytosis, mast cell leukemia, and mast cell sarcoma patients have a poor prognosis.

Treatment

Symptomatic relief of histamine-mediated symptoms may be achieved in many cases by the use of antihistamines. Both H1 and H2 blockers and antiserotonin drugs, such as cyproheptadine may alleviate urtication, pruritus, and flushing. Nifedipine, 10 mg three times a day, may also be effective in isolated cases, Psoralen with ultraviolet A (PUVA) or mediumdose UVA1 alone produce excellent clearing of the skin in most cases. Most patients will have sustained benefit for at least 6 months following treatment. Approximately 25% will have a remission lasting longer than 5 years and in others the frequency of phototherapy may be tapered to once or twice a month and still remain clear. Intralesional triamcinolone or potent topical steroids under occlusion may also clear cutaneous lesions; however, the lesions do recur after discontinuance. Also, concern about local atrophy, striae, and systemic absorption limit the utility of this treatment.

It cannot be overemphasized that avoidance of physical stimuli, such as extremes of temperature, pressure/friction, and chemical degranulators of mast cells, is important. The application of a hydrocolloid dressing over an isolated mastocytoma in an infant may reduce the flushing it produces. The chemicals patients with mastocytosis must avoid include opiates, aspirin, alcohol, quinine, scopolamine, gallamine decamethonium, reserpine, amphotericin B, polymyxin B, and D-tubocurarine. *Hymenoptera* stings may induce anaphylaxis; the patient (and parents, if the affected individual is a child) should be taught to recognize the signs of anaphylactic shock, given a premeasured dose of epinephrine (Epipen) for emergency use, and taught about its use. After such an event it is prudent to treat for several days with 20 to 40 mg of prednisone to avoid recurrent attacks.

Control of diarrhea in systemic mastocytosis may be achieved by orally administered disodium cromoglycate. Gastrointestinal ulcers may be treated with proton-pump inhibitors and H₂ antagonists. The treatment of the systemic mast cells disease is of limited efficacy. For patients with indolent systemic mastocytosis and severe osteoporosis, IFNa may be considered. In patients with smoldering systemic mastocytosis, watchful waiting is recommended, although IFN- α with or without glucocorticoids may be considered for progressive "B" findings. In aggressive systemic mastocytosis, IFN- α may also be used with or without glucocorticoids. 2-Chlorodeoxyadenosine (as used in Langerhans cell histiocytosis) can also be effective in aggressive systemic mastocytosis. Patients with systemic mastocytosis with or without eosinophilia who have the FIP1L1-PDGFRA translocation or lack the 816 c-KIT mutation may respond to imatinib mesylate. Patients with the 816 c-KIT mutation do not respond to this treatment. Bone marrow transplantation for the most severely affected patients with systemic mastocytosis is being investigated.

ABNORMALITIES OF NEURAL TISSUE

Solitary Neurofibroma

The ordinary solitary cutaneous neurofibroma may be 2 to 20 mm in diameter. It is soft, flaccid, and pinkish-white. Frequently the soft small tumor can be invaginated, as if through a ring in the skin, by pressure with the finger (this is called "button-holing").

Neurofibroma is either solitary or multiple. When only one or two lesions are present, they are typically spontaneous tumors without any internal manifestations. When three or more are present, a diagnosis of neurofibromatosis should be considered. Uncommonly, large pendulous masses occur in which numerous, tortuous, thickened nerves can be felt; this has been likened to a "bag of worms." These plexiform neurofibromas, which often have overlying pigmentation, usually occur in neurofibromatosis. Neurofibromatosis is discussed in Chapter 27.

Histologically, the lesion demonstrates wavy spindled nuclei and fine collagen fibers. The stroma is often myxoid and contains many mast cells. Cholinesterase activity is markedly positive in the neurofibromas. Immunochemical staining shows positivity for S-100, vimentin, and myelin basic protein, markers for schwannian tissue.

Treatment of those lesions that are particularly objectionable is by surgical excision. Lin V, et al: Is a plexiform neurofibroma pathognomonic of neurofibromatosis type I? Laryngoscope 2004;114:1410.

Sugiura K, et al: Solitary neurofibroma. Int J Dermatol 2004;43:451.

Granular Cell Tumor

About one-third of reported cases occur on the tongue (Fig. 28-30), one-third involve the skin (Fig. 28-31), and onethird occur in the internal organs. The tumor is usually a well-circumscribed, solitary, firm nodule ranging from 5 to 30 mm with a brownish-red or flesh tint, depending on nearness to the surface. Its surface may be smooth, rough or verrucous. Rarely, the lesions may ulcerate. They are multiple in 10% to 15% of cases.

The solitary lesion may be located anywhere on the body, but nearly half of all tumors appear on the head or neck. Usually the patients are in their third to fifth decade. About two-thirds of patients are black, and two-thirds are women. In most cases it grows very slowly, and when completely removed does not usually recur. However, local or multicentric recurrence may at times cause confusion in determining if a granular cell tumor is malignant.

The histologic picture is distinctive. The cells are large, pale, and irregularly polygonal, with a poorly defined cellular

Fig. 28-30 Granular cell tumor of the tongue.

Fig. 28-31 Granular cell tumor.

membrane, and contain coarsely granular cytoplasm. Some of the cells are multinucleated or contain vacuoles or small pyknotic or eosinophilic inclusions. At times the arrangement is in cords or sheets, in irregular alveolar masses, or even organoid. Pseudo-epitheliomatous hyperplasia is a regular feature. The cells stain positively with vimentin, neuron-specific enolase, S-100, and myelin protein.

Malignant granular cell tumor is uncommon. Most are much larger than the benign granular cell tumors, with an average diameter of 9 cm; benign lesions average less than 2 cm. Most malignant granular cell tumors demonstrate cytologic atypia, but some are quite bland cytologically. Other factors that correlate with malignant behavior are an infiltrative growth pattern, history of local recurrence, older patient age, presence of necrosis, increased mitotic activity, spindling of tumor cells, and nuclear staining with the proliferation marker Ki67 (MIB 1) in greater than 10% of tumor nuclei. Mutant p53 protein has been identified in more thana half of malignant granular cell tumors studied. About onethird are aneuploid, one-third hyperdiploid, and one-third diploid. In contrast, almost all benign tumors are diploid.

Because of the difficulties in distinguishing benign from some malignant granular cell tumors, complete excision is advisable whenever possible. Malignant granular cell tumors often have an infiltrative growth pattern and perineural extension. Mohs micrographic surgery may be helpful in ensuring complete excision.

Neuroma Cutis

Cutaneous neuromas are uncommon. Three true neuromas exist in the skin and mucous membranes: traumatic neuromas, multiple mucosal neuromas, and solitary palisaded encapsulated neuromas.

Traumatic neuromas (Fig. 28-32) result from the overgrowth of nerve fibers in the severed ends of peripheral nerves. The lesion may be tender or painful, and when scarring has occurred or the distal stump has been removed, a phantom limb syndrome may result. These often occur on the fingers, at sites of amputation of supernumerary digits, or on the sole, usually at the third metatarsal space.

Multiple mucosal neuromas (Fig. 28-33) occur as part of the autosomal-dominantly inherited multiple mucosal neuroma syndrome (multiple endocrine neoplasia, type 2b). These patients have a marfanoid habitus, thickened protruding lips, and multiple neuromas of the oral mucosa (lips, tongue, and gingiva), conjunctiva, and sometimes sclera. A few have multiple cutaneous neuromas, usually limited to the face. There is a strong association with medullary carcinoma of the thyroid, bilateral pheochromocytomas, and diffuse gastrointestinal tract ganglioneuromatosis. It is caused by a mutation in the RET proto-oncogene. Infants at risk should be screened for this mutation, and total thyroidectomy performed if positive.

The palisaded, encapsulated neuroma of the skin is a solitary, large, encapsulated tumor, usually of the face. It is a slow-growing, flesh-colored, dome-shaped, firm lesion usually appearing around the mouth or nose. It closely resembles a basal cell carcinoma or an intradermal nevus.

Neurothekeoma (Nerve Sheath Myxoma)

Neurothekeoma, meaning a tumor of the nerve sheath, is composed of cords and nests of large cells packed among collagen bundles in close proximity to small nerves. Mitotic figures and nuclear atypia are sometimes seen, but the tumor is benign. These benign intradermal or subcutaneous tumors histologically are divided into two distinct subtypes, the classic or myxoid variant and the cellular type. An intermediate or mixed variety is also recognized. The myxoid variant (nerve sheath myxoma) is characterized by large islands of stellate and spindled cells in a mucinous matrix. The cells stain strongly for S-100 protein. Myxoid neuro-

Fig. 28-32 Traumatic neuroma.

Fig. 28-33 Multiple mucosal neuromas.

thekeoma occurs in middle-aged adults, primarily on the head, neck, and upper extremities. It is twice as common in women. The cellular type occurs in childhood, with a high female preponderance, and has a predilection for the head, neck, or shoulders. The cellular type does not stain for S-100 protein, but does stain for S-100A6, PGP9.5, and NK1C3.

- Watanabe K, et al: Subcutaneous cellular neurothekeoma. Br J Dermatol 2001;144:1273.

Schwannoma (Neurilemmoma)

Peripheral schwannomas are usually solitary nerve sheath tumors, most often seen in women. They occur almost exclusively in deep tissues, along the main nerve trunks of the extremities, especially the flexor surface of the arms, wrists, and knees. They are also seen on the scalp, sides of the neck, and tongue. The solitary tumor is a nodule of 3 to 30 mm in diameter (Fig. 28-34). It is soft or firm, pale pink or yellowish; it may or may not be painful. Schwannomas occur in many other organs, and brain tumors such as meningiomas, gliomas, and astrocytomas may occur.

Sometimes the tumors are multiple. When this occurs, they may be seen with neurofibromatosis type 1 (NF-1) or, more commonly type 2, or as an entity independent of neurofibromatosis. The independent type may be congenital or have a delayed onset. It may be sporadic or familial. Three clinical patterns are described: elevated dome-shaped nodules; pale brown indurated macules; and multiple papules coalescing into plaques from 2 to 100 mm in diameter,

Flg. 28-34 Neurilemmoma. with a predilection for the trunk. Cases have occurred that appeared to be unassociated with NF-2, but on further investigation of the individual or family revealed other signs of NF-2 and the gene abnormality on chromosome 22.

Plexiform schwannomas may occur as single or multiple lesions, localized to a single anatomic site or more generalized, and arise in the dermis or subcutaneous tissue. They may occur as a solitary lesion, or be associated with NF-1, NF-2, or multiple schwannomas. Another subtype of schwannoma is the melanotic psammomatous type that is seen in association with Carney syndrome of spotty pigmentation, myxomas, and endocrine overactivity.

Histologically, the classic types are well encapsulated and composed of two types of tissue, referred to as Antoni types A and B. Hard schwannomas are firm on gross examination, and are composed of Antoni A tissue-palisades of basophilic Schwann cell nuclei separated by brightly eosinophilic zones (Verocay bodies). Soft schwannomas are edematous. They are composed mostly or entirely of Antoni B tissue, a degenerative change characterized by loose, edematous connective tissue and ectatic blood vessels. S-100, vimentin, and myelin basic protein stains are positive in hard schwannomas. Staining is variable in soft schwannomas. A Bodian or neurofilament stain reveals very few or no nerve fibers within the bulk of the tumor, although a compressed nerve may be present at one edge of the mass in a subcapsular location. Ancient schwannomas may demonstrate remarkable nuclear atypia, which represents a benign degenerative change. Mitoses are absent. Ancient schwannomas should not be confused with malignant schwannoma (neurofibrosarcoma), a tumor that generally arises in long-standing neurofibromas in the setting of NF-1. Excision is almost invariably curative, except in the malignant variety where combined wide resection and radiotherapy is needed.

Infantile Neuroblastoma

Neuroblastoma is the most common malignant tumor of early childhood. Cutaneous nodules are most often seen in younger patients, being present in 32% of infants with the disease. These occur as multiple 2- to 20-mm, firm, blue nodules that, when rubbed, blanch and form a halo of erythema. The blanching persists for 1 to 2 h and is followed by a refractory period of several hours. Biopsy shows clusters of basophilic cells with a high nuclear-to-cyfoplasmic ratio, surrounded by eosinophilic fine fibrillar material. Two other findings that may be present are periorbital ecchymoses (the so-called raccoon eyes) and heterochromia of the irises.

For infants with skin involvement the prognosis is good, with either spontaneous remission or spontaneous transformation into benign ganglioneuromas expected. Prognostic factors other than age, based upon molecular genetic characteristics such as the status of the oncogene MYCN and chromosome 1p deletion, are helping to stratify prognosis and therapeutic recommendations.

Maher-Wiese VL, et al: Metastatic cutaneous lesions in children and adolescents with a case report of metastatic neuroblastoma, J Am Acad Dermatol 1992;26:620.

Ganglioneuroma

Ganglioneuroma has only rarely been described in the skin as an isolated entity. These tumors are composed of mature ganglion cells comingled with fascicles of spindle cells. They arise most often in von Recklinghausen neurofibromatosis or with neuroblastomas, and usually occur in childhood. The tissue stains positively for both argyrophilic and argentaffin granules.

Gambini C, et al: Primary congenital cutaneous ganglioneuroma. J Am Acad Dermatol 1996;35:353.

Parkham DM: Neuroectodermal and neuroendocrine tumors principally seen in children Am J Clin Pathol 2001;115(Suppl): S113.

Nasal Glioma (Cephalic Brainlike Heterotopias) Nasal gliomas are rare, benign, congenital tumors. When

they occur extranasally, they are easily confused with hemangiomas. The tumor is usually a firm, incompressible (unlike a hemangioma and encephalocele), reddish-blue to purple lesion occurring on the nasal bridge or midline near the root. It does not transilluminate or enlarge with crying, unlike some encephaloceles. They may also occur intranasally.

Nasal gliomas differ from encephaloceles in that the latter are connected to the subarachnoid space by a sinus tract, while the former usually lose this connection before birth. Clinically, these cannot be absolutely differentiated, so a biopsy should not be performed. Skull radiographs, MRI, ultrasound, and Doppler flow studies may be performed; these will help define the lesion and detect possible skull involvement. Neurosurgical consultation is advisable.

Histologically, the nodule consists of glial tissue associated with glial giant cells, fibrous tissue, and numerous blood vessels. It is unencapsulated. The lesion does not involute spontaneously.

Cutaneous Meningioma

Primary cutaneous meningioma, also known as rudimentary meningocele, is a developmental defect. It results from the

presence of meningocytes outside the calvarium. If actual brain remnants are present, the lesion is called a *rudimentary cephalocele*. Small, hard, fibrous, calcified nodules occur along the spine, in the scalp, on the forehead, or rarely in the external ear canal. Most occur over the scalp, some have an underlying connection to the CNS or an underlying bony abnormality, and usually come to medical attention in the first year of life. On the scalp they may present with a dark tuft of hair or an alopecic area surrounded by a dark collar of hair (hair collar sign).

Cutaneous meningiomas may develop in the scalp secondary to an intracranial meningioma, either by means of erosion of the skull, or by extension through an operative defect of the skull. Finally, they may also arise from cranial or spinal nerves. Clinically, these lesions have no distinctive appearance. They are firm subcutaneous nodules adherent to the skin.

Diagnosis is made by histologic examination. The tumors consist of strands of cells with large oval vesicular nuclei and granular cytoplasm. Lamellar, calcified psammoma bodies are commonly present. Psammoma bodies are not specific for meningiomas, and may also be found in intradermal nevi, juvenile xanthogranuloma, the pituitary of the fetus and newborn, schwannomas associated with Carney syndrome, meninges, choroid plexus, pineal gland, papillary carcinoma of the thyroid, ovarian neoplasms, and mammary intraductal papilloma.

- Stone MS, et al: Rudimentary meningocele presenting with a scalp hair tuft. Arch Dermatol 1994;130:775.

Encephalocele and Meningocele

Primary defects in the neural tube may lead to encephaloceles, meningoceles, or meningomyeloceles. They present in infancy along the midline of the face, scalp, neck, or back as soft, compressible masses that may transilluminate or enlarge with crying. Tufts of long, dark hair, or alopecia with a surrounding collar of dark hair may overlie them.

Many cutaneous lesions of the midline of the back, most commonly at the base of the spine, suggest malformations of the spinal cord and associated structures are present. Cutaneous manifestations of spinal dysraphism include depressed or polypoid lesions; dyschromic or hairy lesions; deimal or subcutaneous lesions; vascular malformations; or neoplasms of many types. Midline masses require intensive radiologic and neurosurgical evaluation before biopsy because of the possible connection to the CNS. The MRI is the imaging modality of choice. Approximately 10% of patients with one lesion will have occult spinal dysraphism, whereas the majority with two or more different lesions are affected.

Drolet BA, et al: Cutaneous signs of neural tube dysraphism. Pediatr Clin North Am 2000;47:813. Drolet BA, et al: When good is not good enough. Arch Dermatol 2004;140:1153.

Chordomas

These slow-growing, locally invasive neoplasms present as firm, smooth nodules in the sacrococcygeal region or at the base of the skull in middle-aged patients. They arise from notochord remnants. The pathologic appearance is that of incompletely encapsulated sheets, nests, and cords of large epithelioid cells with fibrous trabeculae present. They may metastasize late in their course to various sites, including the skin.

Wide excision with postoperative radiation therapy is the treatment of choice.

Su WP, et al: Chordoma cutis, J Am Acad Dermatol 1993;29:63.

ABNORMALITIES OF FAT TISSUE

Lipomas

Lipomas, subcutaneous tumors composed of fat tissue, may occur as a solitary sporadic lesion or as multiple lesions with or without a familial component. There are multiple histologic subtypes, and these frequently have an associated clinical correlation. Most have specific chromosomal alterations that help in their identification in difficult cases. Protease inhibitors given for HIV disease may induce lipomas, angiolipomas, or benign symmetric lipomatosis, as well as lipodystrophy.

Lipomas are most commonly found on the trunk. They also occur frequently on the neck, forearms, and axillae.

They are soft, single or multiple, small or large, lobulated, compressible growths, over which the skin on traction often becomes dimpled, although otherwise unchanged. They usually stop growing after attaining a certain size, then remain stationary indefinitely. Frontalis-associated lipomas of the forehead are relatively large lesions arising either within or deep to the frontalis muscle (Fig. 28-35).

A lipoma located in the midline of the sacral region may be a marker for spinal dysraphism or other embryologic malformation. Other midline lesions, such as tufts of hair ("fawn's tail"), hemangiomas (Cobb syndrome), skin tags, sinuses, or pigmented lesions should also raise suspicion for occult embryologic malformations. An MRI is the most sensitive imaging modality. If spinal dysraphism is diagnosed, early treatment may be possible before irreversible damage has occurred. Do not attempt to biopsy a sacrococcygeal lipoma; call a neurosurgeon into consultation. It may be a lipomeningocele with communicating sinuses to the dura.

Histologically, the lipoma is an encapsulated, lobulated tumor containing normal fat cells held together by strands of connective tissue. Occasionally, eccrine sweat glands may be associated and then they are called *adenolipomas*. Alterations in chromosomes 12q13–15 and chromosome 13q12–22 may be detected in benign lipomas.

In the differential diagnosis, the epidermoid cyst should always be considered. At times it is difficult to distinguish the two. Many soft, deep, single, nongrowing lesions of the skin do not require biopsy. The appearance of multiple lesions or progressive growth indicates the need for biopsy. Large solitary lesions should be investigated for malignancy, especially when they occur on the upper thigh.

Lipomas may be left untreated unless they are large enough to be objectionable. They may be excised, removed with liposuction, extruded through a 3-mm incision after being freed with a cutting curette, or segmentally extracted through a stab incision. More advanced surgical technique is necessary to remove the deep lesions on the forehead, which may lie below the fascial plane.

Multiple lipomas may occur in groups of two to hundreds of confluent painless tumors of various sizes over any part of the body (Fig. 28-36). These lesions are sometimes painful when growing rapidly. When present in certain patterns, special designations are applied. Madelung's disease (benign symmetric lipomatosis or multiple symmetric lipomatosis)

Fig. 28-36 Multiple Ilpomas.

Miller SD, et al: Multiple smooth skin nodules. Arch Dermatol 1997;133;1579.

occurs most commonly in middle-aged men, who may develop multiple, large, painless, coalescent lipomas around the neck, shoulders, and upper arms. Familial multiple lipomatosis is a dominantly-inherited syndrome in which multiple asymptomatic lipomas of the forearms and thighs appear in the third decade of life. The shoulders and neck are spared, and the lipomas are encapsulated and movable. Diffuse lipomatosis is characterized by an early age of onset, usually before the age of 2; diffuse infiltration of muscle by an unencapsulated mass of histologically mature lipocytes: and progressive enlargement and extension of the tumor mass. It usually involves a large portion of the trunk or an extremity. Some cases are associated with distant lipomas or hemangiomas or with hypertrophy of underlying bone.

Dercum's disease (adiposis dolorosa) is seen most often in obese or corpulent menopausal women who develop symmetrical, tender, circumscribed fatty lesions. They are often accompanied by weakness and psychiatric disturbances. Relief of pain lasting for weeks after intravenous infusions of lidocaine, 1.3 g/day for 4 days, has been reported.

Several other conditions are characterized by multiple abnormalities including lipomas. Encephalocraniocutaneous lipomatosis is a rare neurocutaneous syndrome characterized by unilateral porencephalic cysts with cortical atrophy, ipsilateral facial and scalp lesions, ocular abnormalities, cranial asymmetry, and neurologic complications. The skin changes consist of unilateral lipomatous scalp tumors with overlying alopecia and connective tissue nevi. Ipsilateral lipodermoids, choristomas, and calcifications are the eye findings. CNS abnormalities are unilateral cerebral atrophy, dilated ventricles, porencephaly, cerebral calcifications, and lipomas of the leptomeninges. Seizures and mental retardation may occur. Some cases may have overlapping features of Proteus syndrome-multiple lipomas, epidermal nevi, cerebriform lesions of the plantar surfaces, vascular malformations, macrodactyly, hemilypertrophy, exostoses, and scoliosis.

Bannayan-Riley-Ruvalcaba syndrome is characterized by multiple subcutaneous lipomas and vascular malformations, lentigines of the penis and vulva, vertucae, and acanthosis nigricans. There is overlap in some of these cases with Cowden syndrome. Both have been found to have allelic mutations of the PTEN gene.

Multiple endocrine neoplasia type 1 has been found to have skin lesions consisting of multiple facial angiofibromas, collagenomas, café-au-lait spots, lipomas, confetti-like hypopigmented macules, and multiple gingival papules in addition to the tumors of the parathyroid glands, endocrine pancreas, and anterior pituitary.

Fröhlich syndrome consists of multiple lipomas, obesity, and sexual infantilism.

Gardner syndrome consists of multiple osteomas, fibromas, desmoid tumors, lipomas, fibrosarcomas, epidermal inclusion cysts, and leiomyomas, associated with intestinal polyposis exclusively in the colon and rectum. The coexistence of cutaneous cysts, leiomyomas, and osteomas (mostly on the skull) with intestinal polyposis is frequently not recognized until malignant degeneration of one of the polyps occurs and operative removal brings the syndrome to notice. Half of such patients develop carcinoma of the colon before the age of 30, and practically all these patients die before the age of 50 unless they have surgical treatment. In general, total colectomy is advised. Bony exostoses occur in 50% of patients and usually involve the membranous bones of the face and head. Cysts occur in 63% of patients, and again occur most commonly on the face and in the scalp. These are epidermal inclusion cysts; two-thirds have within them loci of pilomatrical differentiation. Pigmented lesions of the ocular fundus occurred in 90% of 41 patients with Gardner syndrome and 46% of 43 first-degree relatives. They are usually multiple and bilateral, and, having been seen in a 3-month-old infant, are probably congenital. Gardner syndrome is transmitted as an autosomal-dominant disease. The defect is a mutation in the APC gene located at chromosome 5q21. In some families polyposis and carcinoma may occur without the skin and bone tumors.

Subtypes

The angiolipoma is a painful subcutaneous nodule, having all the other features of a typical lipoma. It is seen in young adults who have multiple painful lumps in the skin. Multiple subcutaneous angiolipomas have no invasive or metastatic potential. They may be induced by protease inhibitor therapy of HIV disease.

The angiolipoleiomyoma affects the acral skin of middleaged men. No signs of tuberous scleosis or renal angiomyolipoma are present. Mature adipocytes, thick-walled blood vessels, and smooth muscle cells in facicles around blood vessels are present. Neural fibrolipoma is an overgrowth of fibro-fatty tissue along a nerve trunk that often leads to nerve compression. Patients are usually aged 30 or younger and note a slowly enlarging subcutaneous mass with associated tenderness, decreased sensation, or parasthesia. The median nerve is most commonly involved. At times macrodactyly appears, with elongation and splaying of the phalanges. MRI will provide the diagnosis, but unfortunately there is no effective treatment.

Chondroid lipomas are deep-seated, firm, yellow tumors that characteristically occur on the legs of women. Histologically there is a thin capsule around mature lipocytes that have a single large vacuole and multivacuolated S-100, vimentin-positive cells within a chondromyxoid matrix.

The spindle-cell lipoma is an asymptomatic, slow-growing subcutaneous tumor that has a predilection for the posterior back, neck and shoulders of older men. It is usually solitary, although multiple lesions may occur. Some patients have been described who have a familial background of these. The neoplasm consists of lobulated masses of mature adipose tissue with areas of spindle-cell proliferation. The spindle-cells stain positively for CD34. Abnormalities of chromosome 16 and 13 have been reported. The spindled component of young spindle-cell lipomas may be myxoid or cellular. The nuclei may be wavy and accompanied by mast cells, as in a neurofibroma. In old spindle-cell lipomas (fibrolipomas), the spindle cell component has matured into dense collagen bundles.

Pleomorphic lipomas, like spindle-cell lipomas, occur for the most part on the backs or necks of elderly men. There are floret giant cells with overlapping nuclei. Occasional lipoblast-like cells and atypical nuclei may be present and require differentiation from a liposarcoma. There is loss of chromosome 16q material. Despite this alarming appearance, the lesions behave in a perfectly benign manner. Pleomorphic lipomas lack the size, depth, infiltrative growth, and arborizing vascular pattern of liposarcoma.

The intradermal spindle cell/pleomorphic lipoma is distinct in that it most commonly affects women, and has a wide distribution, occurring with relatively equal frequency on the head and neck, trunk, and the upper and lower extremities. Histologically they are unencapsulated and have infiltrative margins. Again the spindle cells stain positively with CD34

Hibernoma (lipoma of brown fat) is a form of lipoma composed of finely vacuolated fat cells of embryonic type. Hibernomas have a distinctive brownish color and a firm consistency, and usually occur singly. These tumors are benign. They occur chiefly in the mediastinum and the interscapular region of the back, but they also occur on the scalp, sternal region, and legs. They are usually about 3 to 12 cm in breadth and the onset is most often in adult life. Abnormalities of chromosomes 10 and 11 have been reported in the lesions. Epidural lipomatosis, collections of fat in the epidural space, may cause acute chord compression in the course of systemic corticosteroid treatment. A case of this distinctive, uncommon side effect proved to be the result of deposits of brown fat.

Nevus Lipomatosus Superficialis

Soft, yellowish papules or cerebriform plaques, usually of the buttock or thigh, less often of the ear or scalp, with a wrinkled rather than warty surface, characterize this tumor. The distribution may be either zonal (as in the multiple lesions reported by Hoffmann and Zurhelle) or solitary. Solitary lesions appear as a fatty acrochordon. Onset before the age of 20 is the rule.

Benign Lipoblastomatosis

This tumor, frequently confused with a liposarcoma, affects exclusively infants and young children, with approximately 90% occurring before 3 years of age. It involves most commonly the soft tissues of the upper and lower extremities. A circumscribed and a diffuse form can be distinguished. The circumscribed form is superficially located and clinically comparable to a lipoma. The diffuse form is more deeply situated and is analogous to diffuse lipomatosis. Microscopically, both forms consist of lobulated immature adipose tissue composed of lipoblasts, a plexiform capillary pattern, and a richly myxoid stroma. Rearrangements of chromosome 8q11-q13 are present and help to distinguish this tumor from liposarcoma, a distinction that can be difficult histologically. Complete local excision is the treatment of choice; however, recurrences may occur in as many as one-quarter of patients.

Pediatr Surg 2001;11:342.

Liposarcoma

Liposarcomas are the most common soft-tissue sarcoma. They usually arise from the intermuscular fascia, and only rarely from the subcutaneous fat. They do not arise from preexisting lipomas. The usual course is an inconspicuous swelling of the soft tissue that undergoes an imperceptibly gradual enlargement. When a fatty tumor becomes larger than 10 cm in diameter liposarcoma should be seriously considered. The upper thigh is the most common site. Other frequent sites are the buttocks, groin, and upper extremities. Adult males are affected mostly.

Liposarcomas may be well-differentiated; subtypes include the adipocytic, sclerosing, inflammatory, spindle cell, and dedifferentiate variants. In this category there are aberrations of chromosome 12. Myxoid and round-cell variant liposarcoma often shows poorly differentiated histology. In most cases there is a reciprocal translocation t(12;16) (q13;q11). The third major class is pleomorphic liposarcoma.

Treatment is adequate radical excision of the lesion. In well-differentiated superficial lesions the prognosis is good; for deeper, high-grade lesions, the extension between fascial planes and presence of small satellite nodules require carefully planned surgery, which may be assisted by MRI guidance. For metastatic liposarcomas, radiation therapy may be effective. Dei Tos AP: Liposarcoma. Ann Diagn Pathol 2000;4:252. Bal-Bernal JF, et al: Primary purely intradermal pleomorphic

liposacrooma. J Cutan Pathol 2003;30:516.

ABNORMALITIES OF SMOOTH MUSCLE

Leiomyoma

Cutaneous leiomyomas are smooth muscle tumors characterized by painful nodules that occur singly or multiply. They may be separated conveniently into solitary and multiple cutaneous leiomyomas arising from arrectores pilorum muscles (piloleiomyomas); solitary genital leiomyomas arising from the dartoic, vulvar, or mammillary muscle; and solitary angioleiomyomas arising from the muscles of veins.

Solitary Cutaneous Leiomyoma The typical lesion is a deeply circumscribed, rounded nodule ranging from 2 to 15 mm in diameter. It is freely movable. The overlying skin may have a reddish or violaceous tint. Although the lesion is insensitive at first, painful paroxysms may occur. Once pain commences, the tendency is for it to intensify.

Multiple Cutaneous Leiomyomas These brownish, grouped, papular lesions vary from 2 to 23 mm in diameter and are the most common variety of leiomyomas (Fig. 28-38). Two or more sites of the skin surface may be involved. The firm, smooth, superficial, sometimes translucent, and freely movable nodules are located most frequently on the trunk and extremities. They often form linear or dermatomal patterns, either alone or with scattered isolated nonsegmental lesions elsewhere. These leiomyomas may occur on the tongue or, less often, elsewhere in the mouth as well. The usual age at onset is in the teens to the fourth decade. Eruptive lesions have been described in chronic lymphocytic leukemia.

Multiple leiomyomas are inherited in an autosomaldominance fashion. Women with this inherited type often have uterine leiomyomas as well. This is part of an inherited syndrome where some patients also have a predisposition to type II papillary renal carcinomas or renal collecting duct cancer. Mutations in the fumaratae hydratase gene are present in 75% of patients with this syndrome. Fumarate hydratase gene mutations may also be inherited in an autosomalrecessive manner. Fully affected children have severe neurologic impairment. The adult carriers may develop leiomyomas. Sporadic leiomyoma, leiomyosarcomas, renal cancers, and

Fig. 28-38 Multiple leiomyomas.

uterine leiomyomas have a very low frequency of fumarate hydratase mutations.

Genital Leiomyomas These lesions are located on the scrotum, on the labia majora, or rarely, on the nipples. They may be intra- or sub-cutaneous in location. Most genital leioniyomas are painless and solitary. Alport syndrome is an X-linked dominant syndrome consisting of hematuric nephropathy, deafness, and maculopathy due to mutations in type IV collagen. Some of these patients will have diffuse leiomyomatosis, which may affect the esophagus, tracheobronchial tree, perirectal area, and genital tract and vulva.

Angioleiomyoma (Vascular Leiomyoma) This variety of leiomyoma arises from the muscle of veins. Pain, either spontaneous or provoked by pressure or cold, occurs in roughly half the cases. It is found mostly on the lower leg in middle-aged women. Solid tumors occur three times more frequently in women, and cavernous tumors occur four times more frequently in men. Solid lesions on the extremities are commonly painful; tumors of the head are rarely painful. In AIDS, multiple skin and visceral antioleiomyomas may occur. These tumors cells possess the Epstein-Barr virus genome.

Histologically, the leiomyoma is made up of bundles and masses of smooth muscle fibers. Varying amounts of collagen are intermingled. The smooth muscle cells are finely fibrillated and contain a glycogen vacuole adjacent to the nucleus. The nuclei are typically long, thin, and cigar shaped.

Angiolipoleiomyoma Fitzpatrick et al reported eight patients with acquired, solitary, asymptomatic acral nodules. Seven were men and all were adults. Histologically, they were well-circumscribed subcutaneous tumors composed of smooth muscle cells, blood vessels, connective tissue, and fat.

Treatment

Leiomyomas are benign. Solitary painful lesions may be excised. When multiple and familial, monitoring for renal cell or collecting duct carcinoma is important. When multiple lesions are present and painful, as they may be especially in the winter, relief of pain may be achieved by giving doxazosin, an oral α -1 adrenoceptor antagonist. This is better tolerated than phenoxybenzamine, an α -adrenergic blocker, which also has been reported to provide pain relief. Nifedipine, 10 mg three times a day, gabapentin, oral nitroglycerin, and β -blockers have also had variable success. An ice cube applied over the lesions often induces pain, and the effectiveness of therapy may be assessed by the length of time it takes the ice cube to cause pain.

Congenital Smooth Muscle Hamartoma

Congenital smooth muscle hamartoma is typically a skincolored or lightly pigmented patch or plaque with hypertrichosis (Fig. 28-39). It is often present at birth, usually on the trunk, with the lumbosacral area involved in two-thirds of patients. Older patients may have perifollicular papules. They vary in size from 2×3 to 10×10 cm. The Michelin tire baby syndrome may result from a diffuse smooth muscle hamartoma. One patient presented with a linear reddishpurple plaque. The incidence is approximately 1 in 2600 newborns. Transient elevation on rubbing may be seen (pseudo-Darier's sign) in 80%.

Fig. 28-39 Smooth muscle hamartomas.

Histologically, numerous thick, long, well-defined bundles of smooth muscle are seen in the dermis at various angles of orientation. There may be an increase in hair follicles.

In some cases there is clinical and histologic overlap with Becker nevus. Classically, Becker nevus is a unilateral (rarely bilateral) acquired hyperpigmentation, usually beginning as a tan macule on the shoulder or pectoral area of a teenage male. Over time hypertrichosis develops within it. Biopsy of such lesions shows acanthosis, papillomatosis, and increased basal cell pigmentation. Occasional congenital lesions manifesting hyperpigmentation and hypertrichosis have shown biopsy findings consistent with those of a Becker nevus (no smooth muscle proliferation), and lesions with a typical late-onset history compatible with Becker nevus have occasionally shown smooth muscle-bamartoma-like changes in the dermis. Other cases of late-onset smooth muscle hamartomas are occasionally reported that are not hyperpigmented or hypertrichotic.

No treatment is necessary.

Leiomyosarcoma

Superficial leiomyosarcomas (those originating in the dermis or subcutaneous tissue) comprise approximately 2% of all soft-tissue sarcomas. Occasionally, a lesion may present in the skin that is a metastasis from an internal source. The cutaneous leiomyosarcoma appears in the dermis as a solitary nodule. It may originate from the arrector pili or genital dartoic muscle. This has a good prognosis. Recurrence rates with Mohs surgery are approximately 15%, with metastases a rare event. Subcutaneous leiomyosarcomas, on the contrary, have a guarded prognosis, since hematogenous metastases occur in approximately 35% of patients. These prove fatal in about one-third of cases. Lung metastases are frequent so chest imaging is an important part of monitoring these patients.

The clinical appearance of these lesions is not distinctive, so that the diagnosis is established by the histopathologic findings. These differ from the leiomyoma by dense cellularity, nuclear pleomorphism, numerous mitotic figures, and disarray of the smooth muscle bundles. Collagen is found only in the septa. Desmin, smooth muscle actin, and h-Caldesmon are helpful in differentiating leiomyosarcoma from other spindle cell or pleomorphic tumors.

The preferred method of treatment is wide local excision. The Mohs surgical approach is useful in limiting recurrences and sparing tissue. Radiation therapy and chemotherapy are generally not effective.

MISCELLANEOUS TUMORS AND TUMOR-ASSOCIATED CONDITIONS

Cutaneous Endometriosis

Endometriosis of the skin is characterized by the appearance of brownish papules at the umbilicus or in lower abdominal scars after gynecologic surgery in middle-aged women. The usually solitary tumor ranges from a few to 60 mm (average, 5 mm) in diameter. The tender or painful lesion is bluish-black from the bleeding that occurs cyclically in many patients.

Histopathologic findings are glandular structures with a decidualized stroma typically containing extravasated red blood cells and hemosiderin. Treatment of choice is surgical excision. Preoperative treatment with danazol or leuprolide may reduce its size.

- Munoz H, et al: An ulcerated umbilical nodule. Arch Dermatol 1999;135:1113.

Teratoma

Teratomas may develop in the skin but are most common in the ovaries or testes. They have no characteristic clinical features, but on microscopic examination many types of tissue, representative of all three germ layers, are present. Hair, teeth, and functioning thyroid tissue are examples of fully differentiated tissues that may develop. Occasionally, malignancy may occur.

- Tsai TF, et al: A cystic teratoma of the skin. Histopathology 1996;29:384.

Metastatic Carcinoma

Malignant tumors are able to grow at sites distant from the primary site of origin; thus, dissemination to the skin may occur with any malignant neoplasm. These infiltrates may result from direct invasion of the skin from underlying tumors, may extend by lymphatic or hematogenous spread, or may be introduced by therapeutic procedures.

Bellezza G, et al: Primary cutaneous leiomyosarcoma. Int J Surg Pathol 2004;12:39.

Five to 10% of patients with cancer develop skin metastases. The reported incidence figures vary widely according to the type of study undertaken and the site of primary lumor studied. The frequency of involvement of the skin is low when other sites are considered, such as the lung, liver, lymph nodes, and brain.

Usually, metastases occur as numerous firm, hard, or rubbery masses, with a predilection for the chest, abdomen, or scalp, in an adult over the age of 40 who has had a previously diagnosed carcinoma. Many variations in morphology, number of lesions, site of growth, age at onset, and timing of metastases exist, however. They are most commonly intradermal papules, nodules, or tumors that are firm, skincolored to reddish, purplish, black or brown; may be fixed to underlying tissues; and marely ulcerate.

Several unusual morphologic patterns occur. Carcinoma en cuirasse is a diffuse infiltration of the skin that imparts an indurated and hidebound leathery quality to it. This sclerodermoid change, also referred to as scirrhous carcinoma, is produced by fibrosis and single rows of tumor cells. This type primarily occurs with breast carcinoma. Carcinoma telangiectaticum is another unusual type of cutaneous metastasis from breast carcinoma that presents as small pink to purplish papules, pseudovesicles, and telangiectases.

Inflammatory carcinoma (carcinoma erysipelatoides) is characterized by erythema, edema, warmth, and a welldefined leading edge, similar to erysipelas in appearance (Fig. 28-40). This is usually caused by breast carcinoma, but has been reported with many other primary tumors. Histologically, there is little to no inflammation, but rather neoplastic cells within dilated superficial dermal vessels.

Alopecia neoplastica (Fig. 28-41) may present as a cicatricial localized area of hair loss, which on biopsy is usually caused by breast metastases in women, and lung or kidney carcinoma in men. Metastatic breast cancer may be darkly pigmented, as may Paget's disease of the breast.

The so-called Sister Mary Joseph nodule is formed by localization of metastatic tumors to the umbilicus (Fig. 28-42). The most common primary sites are the stomach, large bowel,

Fig. 28-40 Metastatic rectal cancer presenting as inflammatory carcinoma. ovary, and pancreas. Zosteriform, linear, or chancroidal ulcerations of the genitalia, and vertucous nodules of the legs, are other rarely reported clinical presentations.

The primary tumor is usually diagnosed before the appearance of metastases, and dissemination to the skin is often a late finding. Metastases to other more commonly involved organs such as the lung and liver have usually occurred. A poor prognosis is thus the rule. Skin infiltrates may, however, be the first harbinger of a malignant visceral neoplasm and is often the first clinically apparent metastatic site.

The principal anatomic sites to which metastases localize are the chest, abdomen, and scalp, with the back and extremities being relatively uncommon areas. Involvement of the skin is likely to be near the area of the primary tumor. Thus, chest lesions are usually caused by breast carcinoma in women and lung carcinoma in men, abdominal or perineal lesions to colonic carcinoma, and the face to squamous cell carcinoma of the oral cavity. Extremity lesions, when they occur, are most commonly caused by melanoma.

Because of its overall high prevalence, breast cancer is the type most commonly metastatic to the skin in women, and melanoma, followed by lung cancer, are the types seen most commonly in men. Colon carcinoma is also common because of its high incidence in both sexes. Renal cell carcinoma, while less common, has a predilection for scalp metastases. Metastatic lesions are uncommon in children, but when they do occur, neuroblastoma and leukemia are the most frequent causes.

Fig. 28-41 Alopecia neoplastica secondary to breast carcinoma.

Fig. 28-42 Sister Mary Joseph nodule.

Fig. 28-43 Stewart-Treves tumor.

Lymphangiosarcoma (Stewart-Treves syndrome) develops in a site of chronic lymphedema, such as in breast cancer patients who have had lymph node resection (Fig. 28-43). Antikeratin antibodies are useful in identifying metastatic breast carcinoma, while CD34, CD31 and *Ulex europeus* lectin are positive in Stewart-Treves angiosarcoma.

Paraneoplastic Syndromes

Some cancers produce findings in the skin that indicate that an underlying internal malignancy may be present. These may range from a specific eruption characteristic of a particular type of cancer, such as necrolytic migratory erythema, to a nonspecific cutaneous reaction pattern, among the causes of which may be an internal malignancy. Although many of these syndromes are discussed in other sections of the book, a few are mentioned here as illustrative examples of this phenomenon.

Bazex syndrome, or acrokeratosis paraneoplastica, is characterized by violaceous erythema and scaling of the fingers, toes, nose, and aural helices. Nail dystrophy and palmoplantar keratoderma may be seen. These cases are secondary to primary malignant neoplasms of the upper aerodigestive tract or metastatic cancer to lymph nodes, often in the cervical region.

The glucagonoma syndrome is characterized by weight loss, glucose intolerance, anemia, glossitis, and necrolytic migratory erythema. Erythematous patches with bullae and light brown papules with scales involving the face, groin, and abdomen characterize the skin eruption. This is seen with glucagon-secreting tumors of the pancreas.

Fig. 28-45 Superficial migratory thrombophlebitis secondary to breast cancer.

Erythema gyratum repens is a gyrate serpiginous erythema with characteristic wood-grain-pattern scales; it is nearly always associated with an underlying malignancy (Fig. 28-44). Hypertrichosis lanuginosa acquisita, or malignant down, is the sudden growth of profuse, soft, nonmedullated, nonpigmented, downy hair in an adult. The most common sites of associated carcinoma were the lung and colon.

The sign of Leser-Trelat is the sudden appearance of multiple pruritic seborrheic keratoses, associated with an internal malignancy. Trousseau's sign, or migratory thrombophlebitis, is usually associated with pancreatic carcinoma (Fig. 28-45). A form of pemphigus, paraneoplastic pemphigus, is most commonly associated with lymphoma, chronic lymphocytic leukemia, and Castleman's disease.

Several cutaneous diseases that are not associated with internal malignancy with the frequency of the above conditions, but that may be a sign of internal malignancy in some cases, are exfoliative erythroderma (lymphoproliferative

Fig. 28-46 A and B. Acanthosis nigricans from gastrointestinal carcinoma.

disease), acanthosis nigricans (adenocarcinoma) (Fig. 28-46), multicentric reticulohistiocytosis, Sweet syndrome (acute myelogenous leukemia), nodular fat necrosis (pancreatic carcinoma), Paget's disease (underlying adnexal or breast carcinoma, or adenocarcinoma of the genitourinary tract or colon), dermatomyositis in patients over the age of 40, palmar fasciitis and polyarthritis syndrome, and acquired ichthyosis (lymphoproliferative).

A variant of acquired ichthyosis, pityriasis rotunda, manifests circular, brown, scaly patches from 1 to 28 cm in diameter and varying in number from 1 to 20. They may occur on the trunk or extremities. These symptomless patches may be a clue to the diagnosis of hepatocellular carcinoma in South African black patients. Tripe palms, considered by some to be acanthosis nigricans of the palms, are associated with carcinoma in more than 90% of cases. Filiform hyperkeratosis of the palms may present in patients who develop cancer.

Carcinoid

Carcinoid involves the lungs, heart, gastrointestinal tract, as well as the skin. The outstanding feature of the skin is flushing, usually lasting 5 to 10 min. It involves most prominently the head and neck, but also produces a diffuse, scarlet color, with mottled red patches on the thorax and abdomen. Striking color changes may occur, with salmon red, bluish-white, and other colors appearing simultaneously on various portions of the skin. Cyanosis may also be present. As the episodic flushing continues over months to years, telangiectases and plethora appear, as though the patient has polycythemia vera. Gyrate and serpiginous patches of erythema and cyanosis flare up and subside, not only on the face but on all parts of the body and extremities.

Pellagroid changes may appear as a result of shunting of dietary tryptophan away from the kynurenine-niacin pathway and into the 5-hydroxyindole pathway. Periorbital swelling, edema of the face, neck, and feet, and sclerodermatous changes may occur. Disseminated deep dermal and subcutaneous metastatic nodules from a primary bronchial carcinoid tumor have been documented.

The clinical features of the carcinoid syndrome become evident only after hepatic metastases have occurred, or when the primary tumor is a bronchial carcinoid, or if the carcinoid arises in an ovarian teratoma, where the venous drainage bypasses the hepatic circulation.

The release of excessive amounts of serotonin and bradykinin into the circulation produces attacks of flushing of the skin, weakness, abdominal pain, nausea, vomiting, sweating, bronhoconstiction, palpitation, diarrhea, and collapse. These attacks may last a few hours. Right-sided cardiac valvular fibrosis occurs in 60% of chronically affected patients. Symptoms may be induced in these patients by the injection of epinephrine, at which time kinin peptide is released. Alcohol, hot beverages, exercise, and certain foods, among others, may induce flushing. The patient will provide the relevant triggers by history.

Etiologic Factors

Carcinoid, also called *argentaffinoma*, is a tumor that arises from the argentaffin Kulchitsky chroma(fin cells in the appendix or terminal ileum, but also in other parts of the gastrointestinal tract, from the lungs as bronchial adenomas, and rarely from ovarian or testicular teratomas. Some of these produce large amounts of serotonin (5-hydroxytryptamine), a derivative of tryptophan, and others do not. The primary lesion is more active in the production of serotonin than are the metastases. The tumor frequently metastasizes to the draining lymph glands or to neighboring organs, especially the liver, rarely to more distal sites.

Laboratory Findings

The diagnosis may be established by finding a high level of 5-hydroxyindolacetic acid (5-HJAA) in the urine. The normal urinary excretion of 5-HIAA is 3 to 8 mg/day, but in the presence of carcinoid it may reach 300 mg. Urinary values greater than 25 mg/day are diagnostic of carcinoid. Any value above the normal output is considered suspicious. The ingestion of bananas may cause significant elevations of 5-HIAA in the urine within a few hours, because banana pulp contains serotonin (4 mg/banana) and catecholarmines. Tomatoes, red plums, pineapples, avocados, and eggplants also contain serotonin, but in much smaller amounts.

A screening test for 5-HIAA is the addition of nitrosonaphthol to the urine. A purple color is produced when there 40 mg/day of 5-HIAA is excreted. Other serotonin metabolites besides 5-HIAA are found in the urine. The blood also contains serotonin in amounts of 0.2 to 0.4 mg%. In the presence of carcinoid the amount may be 10 times normal.

Treatment

In the rare cases where there is only a primary tumor without metastases, this should be removed. Excision of metastatic lesions in the liver may also be considered. If this is impossible, long-acting somatostatin analogs provide good long-term symptomatic control of the flushing and diarrhea. Injections are given monthly. Vitamin supplementation with niacin and avoidance of known trigger factors to flushing is recommended. Restriction of tryptophan-containing foods for short periods may limit serotonin production.

CHAPTER

29 Epidermal Nevi, Neoplasms, and Cysts

EPIDERMAL NEVI

Keratinizing epidermal nevi are described by a great variety of terms, such as hard nevus of Unna, soft epidermal nevus, nevus verrucosus (verrucous nevus), nevus unius lateris, linear epidermal nevus, and ichthyosis hystrix. Hyperkeratosis without cellular atypia characterizes them all: melanocytic nevus cells do not occur. In some cases the primary constituent is hyperplasia of an adnexal component (nevus comedonicus, nevus sebaceous). These lesions are all considered to represent somatic mosaicism in the affected region. The histologic features are apparently a consequence of the genetic mutation affecting that region. These lesions follow the lines of Blascko rather than dermatomes, suggesting they represent mutations that occurred at some postzygotic time during fetal development. Epidermal nevi are relatively common, with a prevalence of about 1 in 1000.

Linear Verrucous Epidermal Nevus

The individual lesions are vertucous skin-colored, dirty-gray or brown papules, which coalesce to form a serpiginous plaque (Figs 29-1 and 29-2). Interspersed in the localized patch may be horny excrescences and, rarely, comedones. The age of onset of epidermal nevi is generally at birth, but they may also develop within the first 10 years of life. They

Fig. 29-1 Verrucous linear epidermal nevus, note the superficial resemblance to seborrheic keratosis. follow the lines of Blaschko. The term *ichthyosis hystrix* had been used to describe cases with extensive bilateral involvement.

The histologic changes in the epidermis are hyperplastic and affect chiefly the stratum corneum and stratum malpighii. There is variable hyperkeratosis, acanthosis, and papillomatosis. Up to 62% of biopsies of epidermal nevi have this pattern. About 16% show epidermolytic hyperkeratosis. At times, other histologic patterns may be found, including a psoriatic type, an acrokeratosis verruciformis-like type, and a Darier's disease-like type.

Rarely keratinocytic and adnexal malignancies occur in epidermal nevi. Any newly appearing lesion within a stable epidermal nevus should be biopsied to exclude this possibility. Management of epidermal nevi is difficult, since unless the treatment also affects the dermis (and hence may cause scarring), the lesion recurs. The combination of 5% 5-fluorouracil (5-FU) plus 0.1% tretinoin creams once a day may

Fig. 29-2 Linear epidermal nevus, histologically this lesion showed epidermolytic hyperkeratosis. be beneficial and the response may be enhanced by occlusion. CO_2 and Er: YAG laser treatment may also be effective.

- Stosiek N, et al: Chromosomal mosaicism in two patients with epidermal vertucous nevus. J Am Acad Dermatol 1994;30:622.

Nevus Comedonicus

Nevus comedonicus is characterized by closely arranged, grouped, often linear, slightly elevated papules that have at their center keratinous plugs resembling comedones (Fig. 29-3). Cysts, abscesses, fistulas, and scars develop in about half the cases, which have been described as "inflammatory" nevus comedonicus. As with other epidermal nevi, lesions may be localized to a small area or have an extensive nevoid type of distribution. They are most commonly unilateral; however, bilateral cases are also seen. Lesions occur mostly on the trunk and follow the lines of Blascko. The lesions may develop any time from birth to age 15, but are usually present by the age of 10. Associated abnormalities of bone, the central nervous system (CNS), skin, and eyes, which may accompany epidermal nevi, may also be seen in extensive nevus comedonicus.

Fig. 29-3 Nevus comedonicus.

The pilosebaceous follicles are dilated and filled with keratinous plugs. On the palms, pseudocomedones are present. Histologic examination reveals large dilated follicles filled with orthokeratotic horny material and lined by atrophic squamous epithelium. The interfollicular epidermis is papillomatous, as is seen in typical epidermal nevi. Hair follicle differentiation, well-formed follicular structures, and normal sebaceous glands are not common in well-formed lesions. Occasionally, epidermolytic hyperkeratosis may be present, supporting the contention that nevus comedonicus is a form of "epidermal" nevus.

Treatment of lesions not complicated by inflammatory cysts and nodules is primarily cosmetic. Pore-removing cosmetic strips and comedone expression may improve the cosmetic appearance. Topical tretinoin may be beneficial. Patients with inflammatory lesions are much more difficult to manage. If the area affected is limited, surgical excision may be considered. Oral isotretinoin, chronically at the minimum effective dose (0.5 mg/kg/day or less if possible) may partially suppress the formation of cysts and inflammatory nodules; however, as in hidradenitis suppurativa, many cases of nevus comedonicus fail to respond. The comedonal lesions are not improved by the oral isotretinoin.

Epidermal Nevus Syndrome

In 1968, Solomon et al described the epidermal nevus syndrome (ENS), consisting of extensive epidermal nevi with abnormalities of the CNS, skeleton, skin, cardiovascular system, genitourinary system, and eyes. About 8% of patients with epidermal nevi have systemic involvement, and 10% to 18% have systemic developmental disorders (as compared to 1.7% of children without epidermal nevi). The more extensive the epidermal nevus, the more likely there is to be systemic disease. Bladder cancer at an early age (<21 years) has been reported in patients with epidermal nevi and pigmentary abnormalities.

Cutaneous lesions other than epidermal nevi in ENS that may occur are café-au-lait spots, speckled lentiginous nevi, multiple melanocytic nevi, and vascular malformations (phakomatosis pigmentovascularis). The combination of an organoid sebaceous nevus and a speckled lentiginous nevus is termed *phakomatosis pigmentokeratotica*. In virtually all cases, the cutaneous lesions and abnormalities are congenital. Since the original description of systemic involvement with keratotic epidermal nevi, similar cases have been reported in association with sebaceous nevi and nevus comedonicus. This has led Happle to suggest a broader concept for the "epidermal nevus" syndrome. At least six types exist:

- Schimmelpenning syndrome (sebaceous nevus associated with cerebral anomalies, coloboma, and lipodermoid of the conjuctiva) (Fig. 29-4)
- 2. Nevus comedonicus syndrome (associated with cataracts, scoliosis, and neurologic abnormalities)
- 3. Pigmented hairy epidermal nevus syndrome (Becker nevus, ipsilateral hypoplasia of the breast, and skeletal defects such as scoliosis)
- 4. *Proteus syndrome* (the epidermal nevus is of the vernucous/keratinocytic type)
- 5. CHILD syndrome
- 6. *Phakomatosis pigmentokeratotica* (hypophosphatemic rickets)

Many cases, especially those reported from pediatric dermatology referral centers, do not fit one of these categories. Final classification will await the finding of the genetic basis for each of these syndromes.

Inflammatory Linear Verrucous Epidermal Nevus

The term ILVEN may encompass as many as four separate conditions. The most common form is the classic ILVEN or "dermatitic" epidermal nevus. At least three-quarters of these cases appear before age 5 years, most before age 6 months. Later onset in adulthood has been reported. ILVEN is characteristically pruritic and pursues a chronic course. Lesions follow the lines of Blascko. The individual lesions comprising the affected region are enythematous papules and plaques with fine scale (Fig. 29-5). The lesions are morphologically nondescript and, if the distribution is not recognized, could be easily overlooked as an area of dermatitis. Multiple widely separated areas may be affected, usually on only one side of the body; it may be bilateral, analogous to other epidermal nevi. Familial cases have been reported. Rarely, systemic involvement with musculoskeletal and neurologic sequelae (developmental delay, epilepsy) have been reported.

Histologically, classic ILVEN demonstrates abruptly alternating areas of hyperganulosis with orthokeratosis, and parakeratosis with agranulosis. The epidermis is acanthotic and the stratum corneum is hyperkeratotic throughout the lesion. An inflammatory infiltrate of lymphocytes is present in the upper dermis. At times the histology may simply be that of a subacute dermatitis. While the histologic diagnosis of psoriasis can be considered, the correct diagnosis can be established if the dermatopathologist is made aware of ILVEN as a consideration. If there is a question, the presence of involucrin expression in the parakeratotic areas can distinguish ILVEN from psoriasis.

Fig. 29-4 Nevus sebaceous syndrome with lipodermoid of the conjunctiva.

Fig. 29-5 Inflammatory linear verrucous epidermal nevus.

Three other types of inflammatory nevi have been included in this group. Some cases of "linear" lichen planus have been considered as "epidermal nevi," as they commonly follow lines of Blascko. CHILD syndrome, also considered a type of "inflammatory" epidermal nevus, is usually clinically distinct, demonstrating its characteristic hemidysplasia. The most confusing entity has been the so-called "nevoid" or "linear" psoriasis. These cases are of two types. The first type is a child with a family history of psoriasis who has a nevoid lesion at or near birth. The child later develops psoriasis which "koebnerizes" into the ILVEN lesion, suggesting it is a "locus minoris resistensiae" for psoriasis. Treatment of the psoriasis clears the psoriasis overlying the ILVEN, but not the ILVEN. Arthritis developed in one such case. The second type is one in which psoriasis initially presents in one band or area. Histologically, it resembles psoriasis. Most of these cases later develop typical psoriasis later in life, suggesting a mosaicism which allowed expression of the psoriasis earlier in the initially affected area.

ILVEN is differentiated from other epidermal nevi by the presence of erythema and pruritus clinically and by histologic features. Lichen striatus can be distinguished by its histology and natural history. Topical steroids and topical retinoids appear to have limited benefit in ILVEN. Topical Vitamin D (calcipotriol and calcitriol) and topical anthralin have been beneficial, however. Surgical modalities include excision, cryotherapy, and pulsed dye laser. In cases of "nevoid" psoriasis, eximer laser could be considered if topical treatments fail.

HYPERKERATOSIS OF THE NIPPLE AND AREOLA

Hyperkeratosis of the nipple and areola (HNA) is an uncommon benign, asymptomatic, acquired condition of

unknown pathogenesis. Women represent 80% of cases and it presents in their second or third decade. In men the time of presentation is variable. Most cases are bilateral, although unilateral cases can occur. In about half the cases, both the areola and nipple are involved. Isolated involvement of the areola is more common than isolated involvement of the nipple. Breastfeeding is usually not affected. Clinically, there is verrucous thickening and brownish discoloration of the nipple and/or areola. Histologically, there is orthokeratotic hyperkeratosis with occasional keratinous cysts in the filiform acanthotic epidermis. The course is chronic. Treatment with calcipotriol has benefited some patients. It must be distinguished from epidermal nevi, ichthyosis, acanthosis nigricans, Darier's disease, and lichen simplex chronicus. Isolated papules or small plaques in this location probably represent seborrheic keratoses affecting the nipple or areola.

CLEAR CELL ACANTHOMA (PALE CELL ACANTHOMA)

Clear cell acanthoma is also known as *Degos acanthoma* and *acanthome cellules claires of Degos and Civatte*. The typical lesion is a circumscribed, reddish, moist nodule with some crusting and peripheral scales; it is usually about 1 to 2 cm in diameter. A collarette is commonly observed and there may be pigmented variants. The favorite site is on the shin, calf, or occasionally the thigh, although other sites have been reported, such as the abdomen and scrotum. The lesion is asymptomatic, slow-growing, and can occur in either sex, usually after the age of 40. Solitary lesions are most common, but multiple ones have been described. Rarely, an eruptive form of the disease occurs, producing up to 400 lesions. Squamous cell carcinoma (SCC) arising from clear cell acanthoma has also been reported. Lesions occurring in plaques of psoriasis on the buttocks have been described.

The acanthotic epidermis consists of pale, edematous cells and is sharply demarcated. The basal cell layer is normal. Neutrophils are scattered within the acanthoma and in groups below and within the stratum corneum, a finding similar to the micropustules of psoriasis. The dermal blood vessels are dilated and tortuous, as seen in psoriasis. The clear keratinocytes abound in glycogen, staining positive with periodic acid-Schiff (PAS).

Clear cell acanthoma must be differentiated from eccrine poroma, which appears most frequently on the hair-free part of the foot, and from clear cell hidradenoma, which occurs most frequently on the head, especially on the face and eyelids. Treatment is surgical, either with cryotherapy or excision.

WAXY KERATOSES OF CHILDHOOD (KERINOKERATOSIS PAPULOSA)

Waxy keratosis of childhood is a genodermatosis that is either sporadic or familial. It may be generalized or segmental. Clinically, the lesions are keratotic, flesh-colored papules which affect the trunk and extremities. They appear before the age of 3 years. Histologically, there is papillomatosis with focal "church-spire" tenting of the epidermis and marked hyperkeratosis. The natural history of this rare disorder is unknown. Clinically and histologically the lesions must be distinguished from warts.

Happle R, et al: Kerinokeratosis papulosa with a type 2 segmental manifestation. J Am Acad Dermatol 2004;50:S84.
Mehrabi D, et al: Waxy keratoses of childhood in a segmental distribution. Pediatr Dermatol 2001;18:415.

MULTIPLE MINUTE DIGITATE HYPERKERATOSIS

Multiple minute digitate hyperkeratosis (MMDH) is a rare disorder. About half of cases are familial, inherited in an autosomal-dominant fashion, and the other half are sporadic. This condition has also been called *digitate keratoses*, *disseminated spiked hyperkeratosis*, *minute aggregate keratosis*, and *familial disseminated piliform hyperkeratosis*. Clinically, hundreds of asymptomatic tiny digitate keratotic papules appear on the trunk and proximal extremities. Histologically, each lesion represents a spiked, digitate or tented area of acanthotic epidermis with overlying orthohyperkeratosis. Similar lesions can be seen after inflammation and radiation therapy. The relationship of the familial/sporadic cases and the postinflammtory condition is unclear.

Takagawa S, et al: Multiple minute digitate hyperkeratoses. Br J Dermatol 2000;142:1044.

SEBORRHEIC KERATOSIS

Seborrheic keratoses are incredibly common and usually multiple. They present as oval, slightly raised, tan/light brown to black, sharply demarcated papules or plaques,

Fig. 29-6 Seborrheic keratosis.

Fig. 29-7 Seborrheic keratosis.

rarely more than 3 cm in diameter. They appear "stuck-on" the skin, as if they could be removed with the flick of a fingernail (Fig. 29-6). They are located mostly on the chest and back, but also commonly involve the scalp, face, neck, and extremities (Fig. 29-7). An inframammary accumulation is common. Occasionally, genital lesions are seen. The palms and soles are spared; "seborrheic keratoses" in these areas are usually eccrine poromas. The surface of the warty lesions often becomes crumbly, like a crust that is loosely attached. When this is removed, a raw, moist base is revealed. Seborrheic keratoses may be associated with itching. Some patients have hundreds of these lesions on the trunk. While it had been thought that the age of onset is generally in the fourth to fifth decade, in Australia the prevalence of seborrheic keratoses was 20% in males and 25% in females aged 15 to 25 years. Typical lesions of the trunk are much more common in white persons; however, the "dermatosis papulosa nigra" variant of the central face is common in African Americans and Asians.

The pathogenesis of seborrheic keratoses is unknown. Clinically they usually originate de novo or appear initially
as a lentigo. A sudden eruption of many seborrheic keratoses may follow an exfoliative erythroderma, erythrodermic psoriasis, or an erythrodermic drug eruption. These lesions may be transient.

Histologically, most seborrheic keratoses demonstrate acanthosis, varying degrees of papillomatosis, hyperkeratosis, and at times keratin accumulations within the acanthotic epidermis (pseudo-horn cysts). The epidermal cells lack cytologic atypia, except at times in the irritated variant where typical normal mitoses may occur. Six histologic typeshyperkeratotic, acanthotic, adenoid or reticulated, clonal, irritated, and melanoacanthoma-are distinguished. There is a poor correlation between the clinical appearance and the observed histology, unlike for inverted follicular keratosis, dermatosis papulosa nigra, and stucco keratosis, where the histologic features are characteristic and match the clinical lesion. Melanoacanthoma differs from regular seborrheic keratosis by the presence of numerous dendritic melanocytes within the acanthotic epidermis. Oral melanoacanthoma, which has also been called *melanoacanthosis*, is clinically a reactive pigmented lesion seen primarily in young black patients (see Chapter 34). Many cases of inverted follicular keratosis represent irritated seborrheic keratoses.

The differential diagnosis usually poses no problems in most cases, but clinically atypical lesions can be a challenge. The most difficult, especially for the nondermatologist, is to differentiate the solitary black seborrheic keratosis from melanoma. The regularly shaped verrucous lesion is often different from the smooth-surfaced and slightly infiltrating pattern of melanoma. Dermoscopy can at times be of great value; however, at times seborrheic keratoses may demonstrate dermatoscopic features typical of melanocytic lesions, and the presence of horn cysts does not exclude a melanocytic lesions. Actinic keratoses are usually erythematous, more sharply rough, and slightly scaly. The edges are not sharply demarcated, and they occur most often on sunexposed surfaces, especially the face, bald scalp, and backs of the hands. Nevi may be closely simulated. Clonal seborrheic keratoses demonstrate intraepidermal nests suggestive of intraepidermal epithelioma of Jadassohn. Rarely, Bowen's disease, SCC, basal cell carcinoma (BCC), or melanoma arise within typical-appearing seborrheic kemtosis. It is prudent to biopsy any lesion that appears atypical, since even the most seasoned dermatologist has been humbled by the occasional diagnosis of melanoma in low-suspect lesions.

Seborrheic keratoses are easily removed with liquid nitrogen, curettage, or the combination of the two to avoid the need for local anesthesia to perform the curettage. The spray freezes the lesion to make it brittle enough for easy removal with the curette. Scarring is not produced by this method. Light freezing with liquid nitrogen alone is also effective, as is simple curettage with local anesthesia. Light fulguration, shave removal, and CO_2 laser vaporization are other acceptable methods.

Sign of Leser-Trélat

The sudden appearance of numerous seborrheic keratoses in an adult may be the cutaneous finding of internal malignancy. Sixty percent of the neoplasms have been adenocarcinomas, primarily of the stomach. Other common malignancies are lymphoma, breast cancer, and SCC of the lung, but many other types have been reported. To be considered a case of Leser-Trélat, the keratoses should begin at approximately the same time as the development of the cancet and run a parallel course in regard to growth and remission. The lesions are often pruritic and acanthosis nigricans, and tripe palms may accompany the appearance of the seborrheic keratoses of Leser-Trélat.

DERMATOSIS PAPULOSA NIGRA

Dermatosis papulosa nígra occurs in about 35% of black persons and is also relatively common in Asians. It usually begins in adolescence, appearing first as minute, round, skincolored or hyperpigmented macules or papules that develop singly or in sparse numbers on the malar regions or on the cheeks below the eyes. It has been described as early as the age of 3. The lesions increase in number and size over time, so that in the course of years the patient may have hundreds of lesions. They are distributed over the periorbital regions initially, but may occur on the rest of the face, neck, and upper chest. Lesions do not spontaneously resolve. These lesions closely simulate seborrheic keratoses. They are asymptomatic and do not develop scaling, crusting, or ulceration.

Microscopically, the chief alterations are in the epidermis. Irregular acanthosis, papillomatosis, and deposits of uncommonly large amounts of pigment throughout the rete, and particularly in the basal layer, are characteristic. Many believe it to be a form of seborrheic keratosis.

Treatment is made difficult by the tendency for the development of dyspigmentation. Light curettage with or without anesthesia; light, superficial liquid nitrogen application; and light electrodesiccation are effective, but may result in hyper- or hypo-pigmentation. Aggressive treatment should be avoided to minimize dyspigmentation and scarring.

Babapour R, et al: Dermatosis papulosa nigra in a young child. Pediatr Dermatol 1993;10:356.

STUCCO KERATOSIS

Stucco keratoses or keratoelastoidosis verrucosa of the extremities have been described as "stuck-on" lesions occurring on the lower legs, especially in the vicinity of the Achilles tendon. They are also seen on the instep, dorsa of the feet, forearms, and dorsal hands. The palms, soles, trunk, and head are never affected. Varying in diameter from 1 to 5 mm, they are loosely attached, so that they can easily be scratched off. They vary in number from a few to more than 50. Stucco keratoses are common in the US and Australia. They occur mostly in men over 40 years old. Histologically, the picture is that of a hyperkeratotic type of seborrheic keratosis, with no hypergranulosis and no wart particles seen by electron microscopy. The treatment, if any is required, consists of emollients, which soften the skin and cause the scaly lesions to fall off. Ammonium lactate lotion, 12%, may be effective in improving the appearance of the lesions. Imiquimod improved one widespread case, which may have represented widespread human papillomaviruses infection. Stucco keratoses must be distinguished from Flegel's disease.

- Stockfleth E, et al: Detection of human papillomavirus and response to topical 5% imiquimod in a case of stucco keratosis. Br J Dermatol 2000;143:846.

HYPERKERATOSIS LENTICULARIS PERSTANS (FLEGEL'S DISEASE)

Rough, yellow-brown keratotic, flat-topped papules, 2 to 5 mm in diameter, and primarily on the calves are characteristic. The palms, soles, and oral mucosa may rarely be involved. Familial cases have been reported.

The histologic findings are distinctive, with hyperkeratosis and parakeratosis overlying a thinned epidermis, and irregular acanthosis at the periphery. A bandlike inflammatory infiltrate occurs in the papillary dermis. Topical emollients, topical 5-FU, and PUVA have been reported as useful. Oral retinoids may cause improvement, but are hard to justify in this chronic asymptomatic condition. The lesions do not recur after shallow shave excision. Cooper SM, George S: Flegel's disease treated with psoralen ultraviolet A. Br J Dermatol 2000;142:340.

- Jang KA, et al: Hyperkeratosis lenticularis perstans (Flegel's disease): histologic, immunohistochemical, and ultrastructural features in a case. Am J Dermatopathol 1999;21:395.
- Miranda-Romero A, et al: Unilateral hyperkeratosis lenticularis perstans (Flegel's disease). J Am Acad Dermatol 1998;39:655.

WARTY DYSKERATOMA

Warty dyskeratomas are most commonly solitary and found on the head and neck (70%), trunk (20%), or extremities. Rare oral lesions occur. The lesion is a brownish-red papule or nodule with a soft, yellowish, central keratotic plug. Histologically, a cup-like depression filled with a keratotic plug is most common. The epithelium lining the invagination shows the features of Darier's disease with intraepidermal clefts, acantholytic cells, and pseudovilli. Keratin pearls, corps ronds, and grains may be seen. Cystic lesions with prominent keratinous cysts can occur. Cutaneous lesions appear to originate from a hair follicle. Warty dyskeratoma must be distinguished histologically from keratoacanthoma and acantholytic SCC. Treatment is surgical.

Kaddu, et al: Warty dyskeratoma—"follicular dyskeratoma": Analysis of clinicopathologic features of a distinctive follicular adnexal neoplasm. J Am Acad Dermatol 2002;47:423.

BENIGN LICHENOID KERATOSES (LICHEN PLANUS-LIKE KERATOSIS)

Benign lichenoid keratoses are usually solitary dusky-red to violaceous papular lesions up to 1 cm in diameter, but are at times larger (Fig. 29-8). They occur most often on the distal forearms, hands, or chests of middle-aged white women. The lesions are commonly biopsied since the clinical features are identical to a superficial BCC. A slight violaceous hue or the presence of an adjacent solar lentigo can raise the suspicion of lichen planus-like keratosis. Multiple lesions may simulate a photodermatitis, such as lupus erythematosus. Evolution from preexisting solar lentigines is often noted histologically or by history.

Histologically, the lesion may be indistinguishable form idiopathic lichen planus. While idiopathic lichen planus

Fig. 29-8 Lichen planus-líke keratosis.

rarely demonstrates parakeratosis, plasma cells or eosinophils, these may be present in lichen planus-like keratosis. The remnants of a solar lentigo may be seen at the periphery. These features, plus the clinical information that it represents a solitary lesion, suggest the correct diagnosis. Clinical correlation is essential, as similar histologic findings may be seen in lichenoid drug eruptions, acral lupus erythematosus, and lichenoid regression of melanoma. Direct immunofluorescence is positive, with clumped deposits of IgM in a lichen planus-like pattern at the dermoepidermal junction. This differs from the continuous granular immunoglobulin deposition of acral lupus erythematosus. Cryotherapy with liquid nitrogen is effective.

Ramesh V, et al: Benign lichenoid keratosis due to constant pressure. Australas J Dermatol 1998;39:177.

ARSENICAL KERATOSES

Arsenical keratoses are keratotic, pointed, 2- to 4-mm wartlike lesions on the palms, soles, and sometimes ears of persons who have a history of drinking contaminated well water or taking medications containing arsenic trioxide, usually for asthma (Fowler's solution, Bell's Asthma Mixture), atopic dermatitis, or psoriasis, often years previously (Fig. 29-9). These lesions resemble palmar pits, but may have

Fig. 29-9 Arsenical keratosis in a patient who had been exposed to arsenic in drinking water. a central hyperkeratosis. When the keratosis is picked off with the fingernails, a small dell-like depression is seen.

Bowen's disease and invasive arsenical SCC may be present, with the latent period being 10 and 20 years, respectively. The profound increase in Bowen's disease and SCC appears to be characteristic of patients with arsenic exposure from well water. In patients exposed to arsenic via elixirs, BCCs are more characteristically seen. The latency period for development of BCC is also 20 years. Lesions are most common on the scalp and trunk. Internal carcinoma also occurs with increased frequency, after an average latent period of 30 years, with pulmonary and genitourinary carcinoma being most common. Arsenic has also been implicated in causing Merkel cell carcinoma.

NONMELANOMA SKIN CANCERS AND THEIR PRECURSORS

Nonmelanoma skin cancers (NMSCs) are the most common form of cancer diagnosed in the US, with 1.3 million cases diagnosed annually. One in two men and one in three women in the US will develop NMSC in their lifetime, usually after the age of 55. While these result in only about 2000 to 2500 deaths annually, due to their sheer numbers NMSCs represent about 5% of all Medicare cancer expenditures. Those at risk for skin cancer are fair-skinned individuals who tan poorly and who have had significant chronic or intermittent sun exposure. Red hair phenotype with loss-of-function mutations in the melanocortin-1 receptor may be a risk factor as well. Additional risk factors include a prior history of skin cancer, prior radiation therapy, PUVA treatment, arsenic exposure, and systemic immunosuppression (Fig. 29-10). Once an individual has developed a NMSC, his/her risk for a second is increased 10-fold. Over the 3-year period following the initial NMSC diagnosis, more than 40% of BCC and SCC patients develop a BCC, and 18% of SCC patients develop another SCC. By 5 years as many as 50% of women and 70% of men will develop a second NMSC. The rate of developing NMSCs is not different 3 years or 10 years after the initial NMSC diagnosis. Patients with a history of NMSC should be examined for NMSCs on a regular basis.

Ultraviolet radiation (UVR) is the major cause of nongenital NMSCs and actinic keratoses. The effect of UVR appears to be mediated through mutation of the p53 gene, which is found mutated in a substantial percentage of NMSCs

and actinic keratoses. Most skin cancers are highly immunogenic, but the immune response is suppressed by continued actinic exposure. Both chronic sun exposure and intermittent intense exposure are risk factors for the development of NMSCs. It is believed that avoiding sun exposure reduces the risk for NMSC. The use of sunscreens in the prevention of NMSCs has been controversial, as they may inadvertently lead to prolonged intentional sun exposure, negating their possible beneficial effect. Nonetheless, dermatologists and their societies recommend a program of sunscreen use together with sun avoidance to patients at risk for skin cancer. This includes avoiding midday sun, seeking shade, wearing protective clothing, and regularly applying a sunblock of sun protection factor (SPF) 15 to 30 with both UVB and UVA coverage. This program, which was pioneered in Australia, has led to improvements in some skin cancer rates in that country. Lack of standards for label claims of UVA blockade remains a problem, but superior UVA-blocking sunscreen ingredients, such as avobenzone zinc oxide and titanium dioxide, are gaining consumer recognition.

ACTINIC KERATOSIS (SOLAR KERATOSIS)

Actinic keratoses represent in situ dysplasias resulting from sun exposure. They are found chiefly on the chronically sun-exposed surfaces of the face, ears, balding scalp, dorsal hands, and forearms. They are usually multiple, discrete, flat or elevated, vertucous or keratotic, red, pigmented, or skin colored. Usually the surface is covered by an adherent scale, but sometimes it is smooth and shiny. On palpation the surface is rough, like sandpaper, and at times lesions are more easily felt than seen. The patient may complain of tenderness when the lesion is rubbed or shaved over with a razor. The lesions are usually relatively small, measuring 3 mm to 1 cm in diameter, most being less than 6 mm. Rarely, lesions may reach 2 cm in size, but a lesion larger than 6 mm should only be considered an actinic keratosis if confirmed by biopsy or if it completely resolves with therapy. The hypertrophic type, which may lead to cutaneous horn formation, is most frequently present on the dorsal forearms and hands.

Actinic keratoses are the most common epithelial precancerous lesions. While lesions typically appear in persons over 50 years of age, actinic keratoses may occur in the 20s or 30s in patients who live in areas of high solar irradiation and are fair-skinned. Patients with actinic keratoses have a propensity for the development of nonmelanoma cutaneous malignancies. Actinic keratoses can be prevented by the regular application of sunscreen and by a diet low in fats. Beta-carotene is of no benefit in preventing actinic keratoses.

Six types of actinic keratoses can be recognized histologically: hypertrophic, atrophic, bowenoid, acantholytic, pigmented, and lichenoid. The epidermis may be acanthotic or atrophic. Keratinocyte maturation may be disordered with overlying parakeratosis sometimes present. The basal cells are most frequently dysplastic, although in more advanced lesions dysplasia may be seen throughout the epidermis, simulating Bowen's disease (bowenoid actinic keratosis).

The clinical diagnosis of actinic keratosis is usually straightforward. Early lesions of chronic cutaneous lupus erythematosus and pemphigus foliaceus are sometimes confused for actinic keratoses. Seborrheic keratoses, even when they lack pigmentation, are usually more "stuck on" in appearance and more sharply marginated than actinic keratoses. Magnification may aid in this distinction. It is difficult to distinguish hypertrophic actinic keratoses from early SCC and a low threshold for biopsy is recommended. Similarly, actinic keratoses, which present as red patches, can not easily be distinguished from Bowen's disease or superficial BCC. If there is a palpable dermal component, or if on stretching the lesion there is a pearly quality, a biopsy should be considered. Any lesion larger than 6 mm, and any lesion which has failed to resolve with appropriate therapy for actinic keratosis should also be carefully evaluated for biopsy.

Since some percentage of actinic keratoses will progress to NMSC, their treatment is indicated. There are many effective therapeutic modalities. Cryotherapy with liquid nitrogen is most effective and practical when there are a limited number of lesions. A bulky cotton applicator dipped into liquid nitrogen or a handheld nitrogen spray device can be used. If the cotton-tip applicator method is used, the liquid nitrogen into which the applicator is dipped should be used for only one patient, as there is theoretical risk of cross-contamination from one patient to another. Infectious agents are not killed by freezing. For this reason, many dematologists now use the spray devices. We recommend using a small opening tip with continuous bursts of nitrogen spray in a circular motion, depending on the size of the lesion, attempting an even frosting. Only the lesion should be frosted and the duration of cryotherapy must be carefully controlled. A long freeze that results in significant epidermal-dermal injury produces white scars, which are easily seen on the fair skin of those at risk for actinic keratoses. When correctly performed, healing usually occurs within a week on the face, but may require up to 4 weeks on the arms and legs. Caution should be exercised when treating below the knee, since wound healing in these regions is particularly poor and a chronic ulcer can result. Also, use caution in persons at risk for having a cryoprotein (hepatitis C virus-infected patients, and patients with connective tissue disease or lymphoid neoplasia). They may have an excessive reaction to cryotherapy. It is better on the first visit to "under-treat" until the tolerance of a patient's skin to cryotherapy is known. Application of 0.5% 5-FU for 1 week prior to cryotherapy improves the response to cryotherapy.

For extensive, broad, or numerous lesions, topical chemotherapy is recommended. Any lesion which potentially might represent a NMSC should be biopsied prior to beginning topical chemotherapy for AK's. Foul self-treatment of AK's by patients should be discouraged. In both settings the diagnosis of NMSC may be delayed by ineffective topical chemotherapy. The two agents most commonly used are 5-FU cream, 0.5% to 5%, or imiquimod 5% cream. Topical tretinoin and adapalene do not have the efficacy of these two agents, but can be used for prolonged periods and represent an option for patients with a few early lesions. Three percent diclofenac in 2.5% hyaluronan gel when used for 60 days can also be effective for actinic keratoses.

The frequency and duration of treatment are determined by the individual's reaction and the anatomic site of

application. 5-FU is applied once a day in most cases. For the face, 0.5% 5-FU tends to give a predictable response, which is a bit less severe than that produced by the 1% to 5% concentrations. Some patients prefer the stronger concentration for a briefer period, while others favor a slower onset of the reaction and a more prolonged course. For the 5% cream, treatment duration rarely needs to exceed 2 to 3 weeks. For the 0.5% cream, the treatment course is usually 3 to 6 weeks. Usually the central face will respond more briskly than the temples and forehead, which may require a longer duration of treatment. If the reaction is brisk, the treatment can be stopped and restarted at a lower concentration. Depending on the individual's sensitivity, an erythematous burning reaction will occur within several days. Treatment is stopped when a peak response occurs characterized by a change in color from bright to dusky-red, by reepithelialization, and by crust formation. Healing usually occurs within another 2 weeks after treatment has been stopped, depending on the treatment site. Certain areas of the face are prone to intense irritant dermatitis when exposed to 5-FU and tolerance can be improved if the patient avoids application to the glabella, melolabial folds, and chin. For the scalp, the 0.5% concentration may be adequate, but often prolonged or multiple treatment courses are required if this low concentration is used. The 5% cream produces a more predictable, albeit brisk, reaction. A thick cutaneous horn can prevent penetration of 5-FU and hypertrophic actinic keratoses on the scalp, dorsal hand, and forearm may respond poorly unless the area is pretreated with an agent to remove excessive keratin overlying the lesions. Pretreatment with tretinoin for 2 to 3 weeks can improve efficacy and shorten the duration of subsequent 5-FU treatment. It has been observed that 5-FU "seeks out" lesions that may not be clinically apparent. Clinically inapparent BCCs may be detected during or on completion of the treatment. Rarely, patients who have had multiple courses of 5-FU topical chemotherapy will develop a true allergic contact dermatitis to the 5-FU. This is manifested by the redness, edema or vesculation extending beyond the area of application and by the patient developing pruritus rather than tenderness on the treated areas. Patch testing can be confirmatory.

Imiquimod is an interferon inducer and apparently eradicates actinic keratoses by producing a local immunologic reaction against the lesion. The ideal protocol for application of imiquimod may not yet be determined. About 80% of patients respond to imiquimod and 20% may not respond at all, perhaps due to the fact that they lack some genetic component required to induce an inflammatory cascade when imiquimod is applied. If applied three times a week, patients develop an inflammatory reaction similar to that seen with daily application of 5-FU. It is somewhat unpredictable how severe the reaction will be, with a small subset of patients (especially fair-skinned women) developing a severe burning and crusting reaction after only one or a few applications. In others, no reaction at all occurs. With twice a week application, the treatment course is prolonged, up to 16 weeks. Severe erythema occurs in 17.7% and scabbing/crusting in 8.4% of patients so treated. The median percent reduction in actinic keratoses is 83.3% with this treatment protocol. Overall, while the reaction is less predictable from imiquimod, it is also typically less severe than with high concentrations of 5-FU. The adverse event

rates are similar to those with low concentration (0.5%) 5-FU. Another regimen is to apply imiquimod for long periods at a reduced frequency (once or twice a week). Applications can be in alternating 1-month cycles or continuous for many months. This may allow some patients who require treatment but cannot tolerate any significant changes in appearance to be managed. In the end, the choice between topical 5-FU and imiquimod will be based on patient preference, prior physician and patient experience with the modalities, and the cost of the medication. Imiquimod is significantly more expensive per gram than any form of 5-FU. A paired comparative trial would be of great value in determining the optimal and most cost-effective strategy for the treatment of extensive actinic keratoses. Surgical management of actinic keratoses with chemical peels, laser resurfacing, and photodynamic therapy is discussed in Chapters 37 and 38.

CUTANEOUS HORN (CORNU CUTANEUM)

Cutaneous horns are encountered most frequently on the face and scalp. Lesions may also occur on the hands, penis, and eyelids. They are skin-colored, horny excrescences, 2 to 60 mm long, sometimes divided into several antler-like projections.

These lesions are most often benign, with the hyperkeratosis being superimposed on an underlying seborrheic keratosis, verruca vulgaris, angiokeratoma, molluscum contagiosum or trichilemmoma about 60% of the time. However, 20% to 30% may overlie premalignant keratoses and 20% may overlie SCCs or BCCs. The risk for a cutaneous horn overlying a malignancy is much higher in elderly fair-complexioned persons. Hyperkeratotic actinic plaques less than 1 cm in diameter on the dorsum of the hand, wrist, or forearms in white patients have been shown to have a malignancy rate of 50%. One-third of penile horns are associated with underlying malignancies. Excisional biopsy with histologic examination of the base is necessary to determine the best therapy, which would be dictated by the diagnosis of the underlying lesion and by the apparent adequacy of removal.

KERATOACANTHOMA

Clinical Features

There are four types of keratoacanthomas: solitary, multiple, eruptive, and keratoacanthoma centrifugum marginatum. The exact biologic behavior of keratoacanthoma remains controversial. In the past it had been considered a reactive condition or pseudomalignancy which could be treated expectantly. Now the favored view is that keratoacanthomas are malignant tumors, which in many cases will regress. The regression may be partially mediated by immunity, but takes the form of terminal differentiation. The course of these tumors is unpredictable. Even those that ultimately involute can cause considerable destruction before they regress. Any lesions with the histologic features of keratoacanthoma and which appear in an immunosuppressed host should be managed as an SCC, with complete eradication.

Sunlight appears to play an important role in the etiology, especially in the solitary types. In addition, light-skinned persons are more apt to develop keratoacanthoma than darkskinned persons. Instances of keratoacanthomas following trauma and surgical excisions suggest an isomorphic phenomenon may occur. Lesions histologically identical to keratoacanthomas can be seen rarely in patients with hypertrophic lichen planus and discoid lupus erythematosus. The biologic behavior of these lesions is unknown, but they have added to the controversy of keratoacanthoma as a reactive versus a malignant process. In Muir-Torre syndrome, sebaceous tumors and keratoacanthomas occur in association with multiple internal malignancies. A second, less common cancer syndrome is the keratoacanthoma visceral carcinoma syndrome (KAVCS). Only a handful of cases have been reported. Patients have multiple or large keratoacanthomas which appear at the same time as an internal malignancy, always of the genitourinary tract. The relation-

Fig. 29-11 Keratoacanthoma.

ship of Muir-Torre to KAVCS awaits identification of the genetic basis of both syndromes.

Solitary Keratoacanthoma

This type of keratoacanthoma is a rapidly growing papule that enlarges from a 1-mm macule or papule to as large as 25 mm in 3 to 8 weeks. When fully developed it is a hemispheric, dome-shaped, skin-colored nodule in which there is a smooth crater filled with a central keratin plug (Fig. 29-11). The smooth shiny lesion is sharply demarcated from its surroundings. Telangiectases may run through the lesion. Subungual keratoacanthomas are tender subungual tumors which usually cause significant nail dystrophy. Subungual lesions often do not regress spontaneously and induce early underlying bony destruction, characterized on radiograph as a crescent-shaped lytic defect without accompanying sclerosis or periosteal reaction.

The solitary keratoacanthoma occurs mostly on sunexposed skin, with the central portion of the face, backs of the hands, and arms being the most commonly involved sites. Less frequently, other sites are involved, such as the buttocks, thighs, penis, ears, and scalp. Elderly fair-skinned individuals most commonly develop keratoacanthomas. Lesions of the dorsal hands are more common in men and keratoacanthomas of the lower legs are more common in women. The most interesting feature of this disease is the rapid growth for some 2 to 6 weeks, followed by a stationary period for another 2 to 6 weeks, and finally a spontaneous involution over another 2 to 6 weeks to leave a slightly depressed scar. The stationary period and involuting phase are variable; some lesions may take 6 months to a year to completely resolve. It has been estimated that some 5% of treated lesions recur. Invasion along nerve trunks has been documented and may result in recurrence after a seemingly adequate excision.

Histopathology

The histologic findings of keratoacanthoma and a low-grade SCC are so similar that it is frequently difficult to make a definite diagnosis on the histologic findings alone. When a properly sectioned specimen is examined under low magnification, the center of the lesion shows a crater filled with eosinophilic keratin. Over the sides of the crater, which seems to have been formed by invagination of the epidermis, a "lip" or "marginal buttress" of epithelium extends over the keratin-filled crater. At the base and sides of the crater, the epithelium is acanthotic and composed of keratinocytes which are highly keratinized and have an eosinophilic, glassy cytoplasm. Surrounding the keratinocyte proliferation, a dense inflammatory infiltrate is frequently seen. Neutrophilic microabscesses are common within the tumor and trapping of elastic fibers is commonly identified at the periphery of the tumor. These features favor a diagnosis of keroacanthoma. The most definitive histologic feature is evidence of terminal differentiation, where the scalloped outer border of the tumor has lost its infiltrative character and is reduced to a thin rim of keratinizing cells lining a large keratin-filled crater. The presence of acantholysis within the tumor is incompatible with a diagnosis of keroacanthoma. It is also important to distinguish keratoacanthoma from marked pseudoepitheliomatous hyperplasia as seen in prurigo nodularis.

Treatment

Although keratoacanthomas spontaneously involute, it is impossible to predict how long this will take. The patient may be faced with destructive growth of a tumor for as long as a year. More importantly, clinically SCC cannot always be excluded. Therefore, excisional biopsy of the typical keratoacanthoma of less than 2 cm in diameter should be considered in most cases. If the history is characteristic or multiple lesions have appeared simultaneously, less aggressive interventions may be considered. Nonsurgical therapy may also be considered in certain sites to preserve function or improve cosmetic outcome.

Intralesional injections of 5-FU solution, 50 mg/mL (undiluted from the ampule) at weekly intervals; bleomycin 0.5 mg/mL; or methotrexate 25 mg/mL can be effective. For a typical lesion, four injections along the base at each pole are recommended. Low-dose systemic methotrexate can be considered if multiple lesions are present and there is no contraindication. For clinically typical lesions these modalities may be tried before resorting to surgical removal, especially if the latter presents any problem. Excision is recommended if there is not at least 50% involution of the lesion after 3 weeks. Radiation therapy may also be used on giant keratoacanthomas when surgical excision or electrosurgical methods are not feasible.

Multiple Keratoacanthomas (Ferguson Smith Type)

This type of keratoacanthoma is frequently referred to as the *Ferguson Smith type of multiple self-healing keratoacanthomas.* These lesions are identical clinically and histologically to the solitary type. There is frequently a family history of similar lesions. This condition has been traced to two large *Scottish kindreds.* Affected families from other countries have also been reported. Beginning on average at about the age of 25, but as early as the second decade, patients develop crops of keratoacanthomas that begin as small red macules and rapidly become papules which evolve to typical keratoacanthomas. Lesions may number from a few to hundreds but generally only 3 to 10 lesions are noted at any one time. Sun-exposed sites are favored, especially the ears and nose, and in most cases scalp lesions occur. In addition, these patients typically develop keratoácanthomas at sites of trauma. Lesions grow over 2 to 4 weeks reaching a size of 2 to 3 cm, then remain stable for 1 to 2 months before slowly involuting. They leave a prominent crateriform scar. If the early lesions are aggressively treated with cryotherapy, shave removal, or curettage, the scar may be less marked than that induced by spontaneous involution. Treatment with etretinate can be effective in stopping the appearance of new lesions and causing involution of existing ones.

Generalized Eruptive Keratoacanthomas (Grzybowski Variant)

This type of keratoacanthoma is very rare and sporadic, with most patients having no affected family members. The usual age of onset is between 40 and 60. The patients are usually in good health and are not immunosuppressed. The cause of this condition is unknown. Human papilloma viruses have not been detected in most cases in which it was sought. The clinical features are characteristic and unique. Grzybowski type of multiple keratoacanthomas is characterized by a generalized eruption of numerous dome-shaped, skincolored papules from 2 to 7 mm in diameter. Multiple larger typical keratoacanthomas may also appear. Thousands of lesions may develop. The eruption is usually generalized, but spares the palms and soles. The oral mucous membranes can be involved. Severe pruritus may be a feature. Clinically, pityriasis rubra pilaris or widespread lichen planopilaris are often considered. Bilateral ectropion, narrowing of the oral aperture, and severe facial disfigurement can result. Linear arrangement of some lesions, especially over the shoulders and arms, has also been noted. Despite the multiplicity of lesions, no case of "metastasis" from a skin lesion or increased risk of internal malignancy has been reported in the Grzybowski variant of keratoacanthoma. Dr Grzybowski's original patient died 16 years after diagnosis of a myocardial infarction. Treatment with oral retinoids may improve the larger keratoacanthomas but they are at best partially beneficial for the widespread lesions.

There are reports of multiple keratoacanthomas appearing after surgical procedures in the setting of immunosuppression and after treatment with infliximab. These cases of "eruptive" keratoacanthomas are considered multiple "solitary" keratoacanthomas, rather than the Grzybowski variant of keratoacanthoma.

Keratoacanthoma Centrifugum Marginatum

This uncommon variant of keratoacanthoma is most commonly solitary, but multiple lesions can occur. Keratoacanthoma centrifugum marginatum is characterized by progressive peripheral expansion and concomitant central healing leaving atrophy. Spontaneous involution, as may be seen in other variants of keratoacanthoma, does not occur. Lesions range from 5 to 30 cm in diameter (Fig. 29-12). The dorsum of the hands and pretibial regions are favored sites. Treatment with oral etretinate and oral methotrexate with prednisone have been effective in isolated cases.

BASAL CELL CARCINOMA

BCC is the most common cancer in the US, Australia, New Zealand, and many other countries with a largely white, fairskinned population with the opportunity to expose their skin to sunlight. Intermittent intense sun exposure, as identified by prior sunburns; radiation therapy; a positive family history of BCC; immunosuppression; a fair complexion, especially red hair; and easy sunburning (skin types I or II); and blistering sunburns in childhood are risk factors for the development of BCC. Of interest, actinic elastosis and wrinkling are not risk factors for the development of BCC. In fact, BCCs are relatively rare on the dorsal hand, where sun exposure is high, and actinic keratoses and SCCs abound. SCC is three times more common than BCC on the dorsum of the hand. These findings suggest that the mechanism by which UVR induces BCC is not related solely to the total amount of UVR received.

Fig. 29-14 Basal cell carcinoma, nodular type.

Many clinical morphologies of BCC exist. Clinical diagnosis is dependent on the clinician being aware of the many forms BCC may take. Since these clinical types may also have different biologic behavior, histologic classification of the type of BCC may also influence the form of therapy chosen.

Nodular Basal Cell Carcinoma (Classic Basal Cell Carcinoma)

The classic or nodular BCC comprises 50% to 80% of all BCCs. Nodular BCC is composed of one or a few small, waxy, semitranslucent nodules forming around a central depression that may or may not be ulcerated, crusted, and bleeding (Fig. 29-13). The edge of larger lesions has a characteristic rolled border. Telangiectases course through the lesion. Bleeding on slight injury is a common sign.

As growth progresses, crusting appears over a central erosion or ulcer, and when the crust is knocked or picked off, bleeding occurs and the ulcer becomes apparent. This ulcer is characterized by chronicity and gradual enlargement over time. The lesions are asymptomatic and bleeding is the only difficulty encountered. The lesions are most frequently found on the face (85–90% are found on the head and neck) and especially on the nose (25–30%). The forehead, ears (Fig. 29-14), periocular areas, and cheeks are also favored sites. Any part of the body may be involved, however.

Fig. 29-15 Basal cell carcinoma, cystic.

Fig. 29-16 Basal cell carcinoma.

Cystic Basal Cell Carcinoma

These dome-shaped, blue-gray cystic nodules are clinically similar to eccrine and apocrine hidrocystomas (Fig. 29-15).

Morphoeic, Morpheaform, or Cicatricial Basal Cell Carcinoma

This type of BCC presents as a white sclerotic plaque. Ninety-five percent of these BCCs occur on the head and neck. Ulceration, a pearly rolled border, and crusting are usually absent. Telangiectasia is variably present. For this reason, the lesion is often missed or misdiagnosed for some time. The differential diagnosis includes desmoplastic trichoepithelioma, a scar, microcystic adnexal carcinoma, and desmoplastic melanoma. The unique histologic feature is the strands of basal cells interspersed amid densely packed, hypocellular connective tissue. Morpheic BCCs constitute 2% to 6% of all BCCs.

Infiltrative Basal Cell Carcinoma

Infiltrative BCC is an aggressive subtype characterized by deep infiltration of spiky islands of basaloid epithelium in a fibroblast rich stroma. Clinically, it lacks the scarlike appearance of morphoeic BCC. Histologically, the stroma is hypercellular, the islands are jagged in outline and squamous differentiation is common.

Micronodular Basal Cell Carcinoma

These tumors are not clinically distinctive, but the micronodular growth pattern makes them less amenable to curettage.

Superficial Basal Cell Carcinoma

Superficial BCC is also termed superficial multicentric BCC. This is a very common form of BCC, comprising at least 15% of BCCs. This form favors the trunk (45%) or distal extremities (14%). Only 40% occur on the head and neck. The multicentricity is merely a histologic illusion created by the passing of the plane of section through the branches of a single, multiply branching lesion.

This type of BCC most frequently presents as a dry, psoriasiform, scaly lesion. They are usually superficial flat growths, that in many cases exhibit little tendency to invade or ulcerate. They enlarge very slowly and may be misdiagnosed as patches of eczema or psoriasis. These lesions may grow to be 10 to 15 cm in diameter. Close examination of the edges of the lesion will show a thread-like raised border

Fig. 29-17 Basal cell carcinoma, superficial.

(Figs 29-16 and 29-17). These erythematous plaques with telangiectasia may show atrophy or scarring occasionally. Some lesions may develop an infiltrative component in their deeper aspect and grow into the deeper dermis. When this occurs they may induce dermal fibrosis and multifocal ulceration, forming a "field of fire" type of large BCC. Sometimes the lesion will heal at one place with a white atrophic scar and then spread actively to the neighboring skin. It is not uncommon for a patient to have several of these lesions simultaneously or with time. This form of BCC is the most common pattern seen in patients with human immunodeficiency virus (HIV) infection and BCC.

Pigmented Basal Cell Carcinoma

This variety has all the features of nodular BCC, but in addition, brown or black pigmentation is present (Fig. 29-18). When dark-complexioned persons such as Latin Americans, Hispanics, or Asians develop BCC, this is the type they tend to develop. Pigmented BCCs comprise 6% of all BCCs. In the management of these lesions it should be known that if ionizing radiation therapy is chosen as the therapeutic modality, the pigmentation remains at the site of the lesion.

Rodent Ulcer

Also known as *Jacobi ulcer*, rodent ulcer is a neglected BCC which has formed an ulceration (Fig. 29-19). The pearly

Fig. 29-18 Basal cell carcinoma, pigmented.

Fig. 29-19 Basal cell carcinoma, rodent ulcer.

border of the lesion may not be recognized. If it occurs on the lower extremity it may be misdiagnosed as a vascular ulceration.

Fibroepithelioma of Pinkus

First described by Pinkus as premalignant fibroepithelial tumor, the tumor is usually an elevated, skin-colored, sessile lesion on the lower trunk, the lumbosacral area, groin, or thigh and may be as large as 7 cm. The lesion is superficial and resembles a fibroma or papilloma.

Histologically, there are interlacing basocellular sheets that extend downward from the surface to form an epithelial meshwork enclosing a hyperplastic mesodermal stroma. Like infundibulocystic BCC, fibroepithelioma is composed of pink epithelial strands with blue basaloid buds. Fibroepitheliomas has a more prominent fibromucinous stroma and lacks the horn cysts characteristic of infundibulocystic BCC. Fibroepithelioma often demonstrates sweat ducts within the pink epithelial strands. A slight inflammatory infiltrate may also be present. Simple removal by excision or electrosurgery is the treatment of choice.

Polypoid Basal Cell Carcinoma

These tumors present as exophytic nodules of the head and neck.

Pore-Like Basal Cell Carcinoma

Patients with thick sebaceous skin of the central face may develop a BCC that resembles an enlarged pore or stellate pit. The lesions virtually always occur on the nose, melolabial fold, or lower forehead. Affected patients are generally men and the majority are smokers. Many years pass from the appearance of the lesion until a diagnostic biopsy is taken because the lesion is considered inconsequential.

Aberrant Basal Cell Carcinoma

Even in the absence of any apparent carcinogenic factor, such as arsenic, radiation, or chronic ulceration, BCC may occur in odd sites, such as the scrotum, vulva, perineum, nipple, and axilla.

Solitary Basal Cell Carcinoma in Young Persons

These curious lesions are typically located in the region of embryonal clefts in the face and are often deeply invasive. Complete surgical excision is much safer than curettage for their removal. Cases in children and teenagers, unassociated with the basal cell nevus syndrome or nevus sebaceus, are well-documented.

Natural History

BCCs run a chronic course as the lesion slowly enlarges and tends to become more ulcerative. As a rule, there is a tendency for the lesions to bleed without pain or other symptoms. Some of the lesions tend to heal spontaneously and to form scar tissue as they extend. Peripheral spreading may produce configurate, somewhat serpiginous, patches. The ulceration may burrow deep into the subcutaneous tissues or even into cartilage and bone, causing extensive destruction and mutilation. At least half of the deaths that occur from BCC result from direct extension into a vital structure rather than metastases.

Metastasis

Metastasis is extremely rare, occurring in 0.0028% to 0.55% of BCCs. This low rate is believed to be due to the fact that the tumor cells require supporting stroma to survive. The following criteria are now widely accepted (or the diagnosis of metastatic BCC:

- 1. The primary tumor must arise in the skin
- 2. Metastases must be demonstrated at a site distant from the primary tumor and must not be related to simple extension
- 3. Histologic similarity between the primary tumor and the metastases must exist
- 4. The metastases must not be mixed with SCC

Metastatic BCC is twice as common in men as in women. Immunosuppression does not appear to increase the risk of metastasis of BCC. Most BCCs which metastasize arise on the head and neck, and tend to be large tumors that have recurred despite multiple surgical procedures or radiation therapy. The histologic finding of perineural or intravascular BCC increases the risk for metastasis. The regional lymph nodes are the most frequent site of metastasis, followed by the lung, bone, skin, liver, and pleura. Spread is equally distributed between hematogenous and lymphatic. An average of 9 years elapses between the diagnosis of the primary tumor and metastatic disease, but the interval for metastasis ranges from under 1 year to 45 years. Although the primary tumor may be present for many years before it metastasizes, once metastases occur the course is rapidly downhill. Fewer than 20% of patients survive 1 year and less than 10% will live past 5 years after metastasis.

Association with Internal Malignancies

Frisch et al reported a series of 37,674 patients with BCCs followed over 14 years. Comparison of cancer rates for the general population was remarkable with 3663 new cancers compared with 3245 in the control population. Malignant melanoma and lip cancers were the most frequently found; however, internal malignancies were also noted to be excessive, involving the salivary glands, larynx, lung, breast, kidney, and lymphatics (non-Hodgkin lymphoma). The rate of non-Hodgkin lymphoma was particularly high. Patients receiving the diagnosis of BCC before the age of 60 were found to have a higher rate of breast cancer, testicular cancer, and non-Hodgkin lymphoma.

Immunosuppression

Immunosuppression for organ transplantation increases the risk for the development of BCC by about 10-fold. Some increased risk for BCC is considered also to occur in HIV infection and in persons on immunosuppressive medications for other reasons. Patients with chronic lymphocytic leukemia are also at increased risk for BCC. In the immunosuppressed population, a history of blistering sunburns in childhood is a strong risk factor for the development of BCC following immunosuppression.

Etiology and Pathogenesis

It appears that BCCs arise from immature pluripotential cells associated with the hair follicle. Mutations that activate the hedgehog signaling pathway, which controls cell growth, are found in most BCCs. The affected genes are sonic hedgehog, Patched 1, and Smothened genes. Inactivation of the Patched 1 gene is most common.

Histopathology

There is a general belief that there is a correlation between histologic subtype of BCC and biologic behavior. BCCs are considered low or high risk, depending on their probability of causing problems in the future: subclinical extension, incomplete removal, aggressive local invasive behavior, and local recurrence. Therefore, the dermatopathology report of a BCC should include a subtype descriptor when possible. Unfortunately, many shave biopsy specimens do not allow for accurate typing and the presence of an indolent growth pattern superficially does not exclude the possibility of a more aggressive deeper growth pattern. The common histologic patterns are nodular, superficial, infiltrative, morphoeic, micronodular, and mixed. The nodular type is a low-risk type. High-risk types include the infiltrative, morphoeic, and micronodular types, due to aggressive local invasive behavior and a tendency to recurrence. Superficial BCC is prone to increased recurrence due to inadequate removal. When evaluating the histologic margin of superficial BCC,

tumor stroma involving the margin should be considered a positive margin.

The early lesion shows small, dark staining, polyhedral cells resembling those of the basal cell layer of the epidermis, with large nuclei and small nucleoli. These occur within the epidermis as thickenings or immediately beneath the epidermis as downgrowths connected with it. After the growth has progressed, regular compact columns of these cells fill the tissue spaces of the dermis and a connection with the epidermis may be difficult to demonstrate. At the periphery of the masses of cells, the columnar cells may be characteristically arranged like fence posts (palisading). This may be absent when the tumor cells are in cord arrangement or in small nests. Cysts may form. The interlacing strands of tumor cells may present a lattice-like pattern. The dermal stroma is an integral and important part of the BCC. The stroma is loose and fibromyxoid with a sparse lymphoid infiltrate commonly present. The stroma can be highlighted by metachromatic toluidine blue staining, which can be useful during Mohs surgery.

Differential Diagnosis

Distinguishing between small BCCs and small SCCs is largely an intellectual exercise. Both are caused chiefly by sunlight; neither is likely to metastasize; and both will have to be removed, usually by simple surgical excision or curettage. A biopsy is always indicated, but may be performed at the time of the definitive procedure when the likelihood of the diagnosis of NMSC is high and the patient is fully informed and gives consent.

A waxy, nodular, rolled edge is fairly characteristic of BCC (Fig. 29-20). The SCC is a dome-shaped, elevated, hard, and infiltrated lesion. The early BCC may easily be confused with sebaceous hyperplasia, which has a depressed center with yellowish small nodules surrounding the lesion. These lesions never bleed and do not become crusted.

Bowen's disease, Paget's disease, amelanotic melanoma, and actinic and seborrheic keratoses may also simulate BCC. Ulcerated BCC on the shins is frequently misdiagnosed as a stasis ulcer and a biopsy may be the only way to differentiate the two. Pigmented basal cell epithelioma is frequently misdiagnosed as melanoma or as a pigmented nevus. The superficial BCC is easily mistaken for psoriasis or eczema. The careful search for the rolled edge of the peripheral nodules is important in differentiating BCC from all other lesions.

Fig. 29-20 Basal cell carcinoma, accentuation of the pearly border when the skin is stretched.

Treatment

Each lesion of BCC must be thoroughly evaluated individually. Age and sex of the patient as well as the size, site, and type of lesion are important factors to be considered when choosing the proper method of treatment. No single treatment method is ideal for all lesions or all patients. The choice of treatment will also be influenced by the experience and ability of the treating physician in the various treatment modalities. A biopsy should be performed in all cases of suspected BCC, to determine the histologic subtype and to confirm the diagnosis.

The aim of treatment is for a permanent cure with the best cosmetic results. This is important because the most common location of BCC is the face. Recurrences result from inadequate treatment and are usually seen during the first 4 to 12 months after treatment. A minimum 5-year follow-up is indicated, however, to continue a search for new lesions, since the development of a second BCC is common.

Treatment of BCC is usually surgical (see Chapter 37), but some forms of BCC are amenable to medical treatment.

Topical Therapy

Topical treatment appears to be most effective in the treatment of superficial BCC. For nodular BCCs the cure rates are only 65% which is unacceptable given the other options available. On the other hand, superficial BCCs may be cured 80% of the time with topical treatment. Topical 5-FU is not extraordinarily effective and recurrence rates are high. Imiquimod applied three times a week with occlusion or five times a week without occlusion is the favored form of topical, patient-applied treatment for superficial BCC. Duration of treatment is for 6 weeks, but may be extended if the lesion does not appear to have been eradicated. Cosmetic results are excellent, especially for lesions of the anterior chest and upper back where significant scarring usually results from surgical procedures. Photodynamic therapy has also emerged as a treatment option for BCC.

NEVOID BASAL CELL CARCINOMA SYNDROME (GORLIN SYNDROME)

Clinical Features

The nevoid BCC syndrome or basal cell nevus syndrome (BCNS) is an autosomal-dominantly inherited disorder characterized by the development of multiple BCCs (Fig. 29-21); odontogenic cysts of the jaws; pitted depressions on the hands and feet; osseous anomalies of the ribs, spine, and skull; and multiple other disorders. Keratin cysts are frequently seen and calcium deposits in skin, especially in the scalp, may be present. A characteristic facies is present with frontal bossing, a hypoplastic maxilla, a broad nasal root, and true ocular hypertelorism being features.

Of 105 patients reported in one series, 80% were white. The first tumor developed by the mean age of 23 years for white patients. Palmar pits were seen in 87%. Jaw cysts were found in 74%, with 80% manifested by the age of 20. The total number of cysts ranged from 1 to 28. Medulloblastomas developed in four patients and three had cleft lip or palate.

Fig. 29-21 Multiple basal cell carcinomas in BCNS.

Physical findings in this series included "coarse face" (54%), macrocephaly (50%), hypertelorism (42%), frontal bossing (27%), pectus deformity (13%), and Sprengel deformity (11%). Previously described features not found in this series include short fourth metacarpal, scoliosis, cervical ribs, and spina bifida occulta.

Skin Tumors

The BCCs occur at an early age or any time thereafter as multiple lesions, usually numerous. The usual age of appearance is between 17 and 35 years. Although any area of the body may be affected, there is a marked tendency toward involvement of the central facial area, especially the eyelids, periorbital area, nose, upper lip, and cheeks. Any variety of BCC may be present. In children there may be pigmented papules resembling skin tags.

Jaw Cysts

Jaw cysts occur in 70% of patients. Both the mandible and the maxilla may show cystic defects by x-ray, with mandibular involvement occurring twice as often. The patient may complain of jaw pain and tenderness, fever, difficulty in closing the mouth, and swelling of the jaw. The cysts are uni- or multi-locular and may occur anytime during life, with the first decade being the most common time of appearance. They may have a keratinized lining and some are ameloblastomas.

Pits of Palms and Soles

An unusual pitting of palms and soles is a distinguishing feature of the disease. They usually become apparent in the second decade of life. Up to 87% of patients with nevoid BCC syndrome will have pits. Histologically, they show basaloid proliferation, but the lesions do not progress or behave like a BCC.

Skeletal Defects

Numerous skeletal defects are easily detected by roentgenograms. Such defects may be spina bifida; bifid, fused missing or splayed ribs; scoliosis; and kyphosis. An interesting finding is shortened fourth metacarpal and metatarsal bones. The shortened fourth metacarpal results clinically in a dimple over the fourth metacarpophalangeal joint (Albright's sign). Radiographic evidence of multiple lesions is highly suggestive of this syndrome and since most are present congenitally, roentgenograms may be useful in diagnosing this syndrome in patients too young to manifest other abnormalities. Seventy to 75% of patients manifest skeletal abnormalities. Flame-shaped lucencies of the phalanges, metacarpal, and carpal bones of the hands were found in 30% of 105 patients. Other radiographic findings in this series include bifid ribs (26%), hemivertebra (15%), and fusion of the vertebral bodies (10%).

Disorders of the Central Nervous System

Important radiographic signs include calcification of the falx cerebri (65%), of the tentorium cerebelli (20%), and of the bridged sella (68%). On computed tomography (CT) the calcification of the falx is distinctly lamellar. Varying mental problems may be encountered in patients.

Other Defects

Ophthalmologic abnormalities and mesenteric, ovarian, and mammary cysts, as well as uterine fibromas, lipomas, epithelial cysts, milia, and renal calculi are known to occur at times in these patients. Calcified multinodular ovarian fibromas are characteristic.

Etiology

This is a genetic disorder with an autosomal-dominant inheritance. Penetrance may be as high as 95%. Mutations in the Patched 1 (PTCH1) tumor suppressor gene and less commonly in the sonic hedgehog (SHH) or Smoothened (SMOH) genes are responsible for this syndrome.

Histopathology

The histology of BCCs arising in syndrome patients is identical to those arising in non-syndrome patients, with the solid and superficial types being most common.

Differential Diagnosis

Several other unique types of presentation of BCCs should not be confused with BCNS. One is the linear unilateral BCC syndrome, in which a linear arrangement of close-set papules, sometimes interspersed with comedones, is present at birth. Biopsy reveals basal cell epitheliomas; however, they do not increase in size with the age of the patient. The second type, referred to as Bazex syndrome, is an X-linked dominantly inherited disease comprising follicular atrophoderma of the extremities, localized or generalized hypohidrosis, hypotrichosis, and multiple BCCs of the face, which often arise at an early age. The third is the syndrome of multiple hereditary infundibulocytic BCCs, which is also an autosomal-dominant syndrome. It is distinguished from BCNS by the absence of palmar pits and jaw cysts in most cases. Clinically, patients appear to have multiple trichoepitheliomas. Numerous skin-colored pearly papules affect the center face, accentuated in the nasolabial folds. The generalized basaloid follicular hamartoma syndrome differs from BCNS by having basaloid follicular hamartomas instead of BCCs. It is reported from a large kindred in the southeastern US (see below). Tiny palmar pits are present. Histologically, infundibulocystic BCC and basaloid follicular hamartoma may be indistinguishable, so the two familial syndromes may be difficult to separate. Rombo syndrome, reported in one large Swedish family, has multiple BCCs and vermiculate atrophoderma and hypotrichosis. A patient with multiple BCCs and myotonic dystrophy has been reported,

suggesting yet another genodermatosis associated with multiple BCCs.

Treatment

Genetic counseling is essential. Strict sun avoidance and maximum sun protection, as recommended for xeroderma pigmentosa patients, is recommended. Treatment involves very regular monitoring and biopsying of suspicious lesions. Topical therapy with tazarotene and imiquimod may find some use in preventing and treating the superficial tumors. Surgical treatments are used for most lesions. One case with intractable lesions responded to systemic chemotherapy with paclitaxel. Oral retinoid therapy may reduce the frequency of new BCCs.

SQUAMOUS CELL CARCINOMA

SCC is the second most common form of skin cancer. Most cases of SCC of the skin are induced by UVR. Chronic, longterm sun exposure is the major risk factor and areas which have had such exposure (the face, scalp, neck, and dorsal hands) are favored locations. SCC is relatively more common as the annual amount of UVR increases, so SCC is more common in Texas than in Minnesota, for example. Immunosuppression greatly enhances the risk for the development of SCC. Etanercept treatment has been associated with the appearance of cutaneous SCC in patients with rheumatoid arthritis also being treated with methotrexate. Human papilloma viruses (HPV-16, -18, -31, and -35 primarily) play a role in SCCs that develop on the genitalia and periungually. A chronic ulcer, hidradenitis suppurativa, prior X-radiation exposure, PUVA treatment, recessive dystrophic epidermolysis bullosa, lesions of discoid lupus, and erosive lichen planus are all risk factors for the development of SCC. Metastasis, with a mortality rate of 18%, is very uncommon for SCCs arising in sites of chronic sun damage, whereas it is relatively high (20-30%) in SCCs occurring in the various scarring processes. Patients with epidermodysplasia vertuciformis (EDV) also develop SCCs on sun-exposed sites, associated with unique HPV types. These unique EDV HPV types (HPV-5, -8, and others) may also play a role in SCCs which develop in immunosuppressed persons. SCC of the oral mucosa is discussed in Chapter 34. Because the vast majority of cutaneous SCCs are induced by UVR, sun protection with avoidance of the midday sun, protective clothing, and the regular application of a sunblock of SPF 15 to 30 is recommended. Some researchers have suggested that smoking is also a risk factor for cutaneous SCC, but this is controversial.

Clinical Features

Frequently, SCC begins at the site of actinic keratosis on sun-exposed areas such as the face and backs of the hands. BCCs far outnumber SCCs on the facial skin, but SCCs on the hand occur three times more commonly than BCCs. The lesion may be superficial, discrete, and hard, and arises from an indurated, rounded, elevated base (Figs 29-22 and 29-23). It is dull-red and contains telangiectases. In the course of a few months the lesion becomes larger, deeply nodular, and

Fig. 29-22 Squamous cell carcinoma, ulcerating tumor in an area of chronic sun exposure.

Fig. 29-23 Squamous cell carcinoma, preauricular ulceration in a patient with AIDS.

ulcerated. The ulcer is at first superficial and is hidden by a crust. When this is removed, a well-defined, papillary base is seen and on palpation a discrete hard disk is felt. In the early phases this tumor is localized, elevated, and freely movable on the underlying structures; later it gradually becomes diffuse, more or less depressed, and fixed. The growth eventually invades the underlying tissues. The tumor above the level of the skin may be dome-shaped, with a core-like center that later ulcerates. The surface in advanced lesions may be cauliflower-like, composed of densely packed, filamentous projections, between which are clefts filled with a viscid, purulent, malodorous exudate.

In black patients SCCs are 20% more common than BCCs. The most common sites are the face and lower extremities, with involvement of non-sun-exposed areas more common. Elderly women (mean age, 77) are primarily affected in cases involving the lower legs. Prior direct heat exposure from open fireplaces may be the predisposing factor. In contrast, in white patients the frequent predisposing conditions are scarring processes, such as burns, leg ulcers, and hidradenitis suppurativa.

On the lower lip, SCC often develops on actinic cheilitis. From repeated sunburn the vermilion surface becomes dry, scaly, fissured, and actinic cheilitis develops. Cancer usually arises on fissure or keratosis. At the beginning only a local thickening is noticeable. This then becomes a firm nodule. It may grow outward as a sizable tumor or inward with destructive ulceration. A history of smoking is also frequent and a significant predisposing factor. Lower lip lesions far outnumber upper lip lesions, men far outnumber women (12:1), and the median age is the late 60s. SCCs occurring on the lower lip metastasize approximately 10% to 15% of the time. SCC of the lip may also occur in areas of discoid lupus (DLE) in black patients. Neoplastic transformation into SCC may develop in 0.3% to 3% of patients with DLE of the lip.

Periungual SCC frequently presents with signs of swelling, erythema, and localized pain. It commonly arises in the nailfolds of the hands and initially resembles a periungual wart. Fifty percent of those x-rayed show changes in the terminal phalanx. There is a low rate of metastases (3%), but local excision with Mohs microsurgery is recommended as it reduces the risk of recurrence. Periungual SCC is strongly associated with genital HPV types, primarily 16, 18, 31, and 35.

Given the numerous presentations of SCC on the skin, there should be a low threshold for biopsy of any suspicious lesions, especially in the background of chronic sun exposure.

Histopathology

SCC is characterized by irregular nests of epidermal cells invading the dermis to varying degrees. The degree of cell differentiation has been used to grade SCC. Although interpretations vary, it is believed that the greater the differentiation, the less the invasive tendency, and therefore the better the prognosis. In grade I SCC, most of the cells are welldifferentiated, whereas in grade IV most are undifferentiated or anaplastic. The anaplastic type of tumors may be difficult to differentiate from other tumors such as melanoma, lymphoma, and mesenchymal tumors. This is true also when the tumor is of the spindle cell type. Immunoperoxidase staining for keratins is very useful in this setting. Desmoplastic SCCs by light microscopy have prominent trabecular growth patterns, narrow columns of atypical epithelial cells, and marked desmoplastic stromal reaction. Acantholytic SCC is a recognized histologic subtype, but its behavior parallels that of cutaneous SCC. The finding of perineural and vascular invasion are bad prognostic features for recurrence and metastasis in any form of cutaneous SCC.

Differential Diagnosis

The differentiation of SCC from keratoacanthoma is of academic interest in most cases as simple surgical excision is performed on most of these lesions. However, if nonsurgical modalities are contemplated, a biopsy confirming the diagnosis of keratoacanthoma is recommended. In the setting of immunosuppression, keratoacanthoma-like lesions should be managed as SCCs. The rapid growth and presence of a rolled border with a keratotic central plug suggest the diagnosis of keratoacanthoma, as does explosive growth. An early SCC may be confused with a hypertrophic actinic keratosis and indeed the two may be indistinguishable clinically. Biopsy to include the base of the lesion is necessary to make the diagnosis.

Pseudoepitheliomatous hyperplasia must be distinguished histologically from true SCC. Marked pseudoepitheliomatous hyperplasia may be seen in granular cell tumor, bromoderma, blastomycosis, granuloma inguinale, and chronic pyodermas. It is frequently mistaken for SCC in chronic stasis ulcers, ulcerations occurring in thermal burns, lupus vulgaris, leishmaniasis, and even in sporotrichosis. Pseudoepitheliomatous hyperplasia (PEH) arises from adnexal structures as well as the surface epidermis. Hyperkeratosis and hypergranulosis of adjacent hair follicles is often present. Strands of epidermal cells may extend into the reticular dermis and commonly trap elastic fibers, a finding also seen in keratoacanthoma, but rarely in conventional SCCs. A potential diagnostic pitfall is the presence of benign PEH adjacent to and overlying invasive SCC. This is particularly common in lesions that have been picked or scratched.

Metastases

The rate of SCC metastasis from all skin sites ranges from 0.5% to 5.2%. Careful attention should be paid to regional lymph nodes draining the site of the SCC. These should be examined at the time of the initial evaluation when the suspicious lesion is identified and at the regular visits which follow the treatment of the SCC. Risk factors for local recurrence and metastasis include: 1) treatment with a modality that does not check the margins of the specimen (such as curettage and desiccation, cryotherapy or radiation); 2) recurrence after prior treatment; 3) location (temples, scalp, ear, lip); 4) size; 5) depth; 6) histologic differentiation; 7) histologic evidence of perineural invasion; 8) histologic evidence of desmoplastic features; 9) precipitating factors other than UV light; and 10) host immunosuppression. In reference to metastatic disease, the highest rates occur from scars (37.9%), the lip (13.7%), and the external ear (8.8%). Risk of metastasis rises for lesions larger than 2 cm in diameter, skin lesions deeper than 4 mm, and lip lesions deeper than 8 mm. Patients with perineural spread have a local recurrence rate of 47.2% and a metastatic rate of 34.8%. Desmoplastic SCCs are six times more likely to metastasize than other histologic patterns, excluding neurotropic forms.

Patients with SCC are at increased risk of developing other malignancies, such as cancers of the respiratory organs,

buccal cavity, pharynx, small intestines (in men), non-Hodgkin lymphoma, and leukemía.

Treatment

The primary treatment of SCC of the skin is surgical (see Chapter 37). Oral retinoids may be useful as a preventive strategy in patients with immunosuppression who develop frequent cancers.

VERRUCOUS CARCINOMA (CARCINOMA CUNICULATUM)

Verrucous carcinoma is a distinct, well-differentiated variety of SCC. It affects mostly elderly men. The primary characteristic of these lesions is their close resemblance, clinically and histologically, to a wart. The lesions present as a bulbous mass with a soft consistency and often multiple sinuses opening to the surface, resembling "rabbit burrows." Lesions of this type are most common on the sole, but also occur in the genital area (giant condyloma of Buschke and Lowenstein), on the sacrum, and in the oral mucosa. In some cases, as in the Buschke-Lowenstein tumor, verrucous carcinomas are induced by HPV. These HPV may be of the "low-risk" types, such as HPV-6 or -11, or the high-risk types, such as HPV-16. In other cases no HPV can be found and pressure or other factors (but not UV light) are felt to play a role. The natural history is of a slow-growing and invading mass that over years may invade the bony structure beneath the tumor.

Histologically, the lesion shows a characteristic picture of bulbous rete ridges that are topped by an undulating keratinized mass. The squamous epithelium is welldifferentiated and cytologic atypia is minimal. The cytoplasm is often apple pink and may have a glassy appearance. The tumor border is smooth and bulldozing, rather than spiky and infiltrative.

Excision is the best treatment and Mohs microsurgery may be a helpful technique. Radiotherapy may induce anaplastic transformation and is best avoided if other treatment options exist. Lymph node metastasis is rare and the prognosis is favorable when complete excision is accomplished. In SCC of the penis derived from vertucous forms, the prognosis is much better than other causes of penile SCC.

BOWEN'S DISEASE (SQUAMOUS CELL CARCINOMA IN SITU)

Bowen's disease is an intraepidermal SCC that probably arises from adnexal epithelium and invades the adjacent epidermis. It may ultimately become invasive. When it does, it tends to behave like an anaplastic adnexal carcinoma.

Clinical Features

Bowen's disease may be found on any part of the body as an erythematous, slightly scaly and crusted, noninfiltrated patch from a few millimeters to many centimeters in diameter (Figs 29-24 to 29-26). The lesion is sharply defined. The scale may be pronounced enough for the lesions to be mistaken for psoriasis or the plaque may have a stuck-on appearance and may be mistaken for a broad sessile seborrheic keratosis.

As the lesion slowly enlarges, spontaneous cicatrization may develop in portions of the lesion. When the intraepithelial growth becomes invasive, the lesion may appear ulcerated and fungating. The squamous carcinoma that evolves from Bowen's disease tends to be more aggressive than SCC arising in actinic keratosis. When SCC in situ occurs as a velvety plaque on the glans penis it is referred to as *erythroplasia of Queyrat*.

Etiology

Bowen's disease affects mostly older white men in whom the lesions occur primarily on sun-exposed surfaces. Most patients with Bowen's disease have chronic sun damage. Chronic arsenism produces Bowen's disease in non-sun-exposed sites and a history of exposure to arsenic should be sought when Bowen's disease is found on the palms, soles, and covered nongenital sites. High-risk HPV types (HPV-16, -18, -31, and -35) have been implicated in lesions involving the periungual and genital regions.

Histopathology

The atypical keratinocytes may invade the adjacent epidermis in a buckshot or clonal nested pattern. With time, they may replace the entire epidermis, often with deep fullthickness involvement of adnexal structures. The epidermis shows hyperkeratosis, parakeratosis, and broad acanthosis or

Fig. 29-24 Bowen's disease.

Fig. 29-25 Bowen's disease.

Fig. 29-26 Bowen's disease.

anastamosis of adjacent rete ridges. Epidermal maturation is absent, so the epidermis appears disorganized, and individually keratinizing cells and atypical cells are seen at all levels of the epidermis. There is, however, a sharp delineation between dermis and epidermis, and the basement membrane is intact. The upper dermis usually shows a chronic inflammatory infiltrate. Although the cells tend to be anaplastic with a high nuclear-to-cytoplasmic ratio, variants with smaller nuclei and abundant cytoplasm exist and transitional areas between the patterns may be seen.

656 EPIDERMAL NEVI, NEOPLASMS, AND CYSTS

Differential Diagnosis

Bowen's disease is frequently misdiagnosed as psoriasis, superficial multicentric BCC, tinea corporis, nummular eczema, seborrheic keratosis, and actinic keratosis. Paget's disease, especially the extramammary type, not only clinically but also histologically may mimic Bowen's disease. There is no dyskeratosis in Paget's disease and the intervening nonvacuolated epidermal cells are not atypical in Paget's disease. Stains for mucin and carcinoembryonic antigen are positive in Paget's disease and negative in pagetoid Bowen's disease. Bowen's disease may be heavily pigmented, especially when occurring in the anogenital region. Lesions of bowenoid papulosis show a histologic spectrum from genital warts with buckshot atypia to fullthickness atypia indistinguishable from Bowen's disease. If the lesions are multicentric and behave like genital warts, the term bowenoid papulosis may be applied. Treatment is guided completely by the clinical pattern. Since genital SCC is induced by high-risk HPV, bowenoid papulosis represents the initial clinical lesion in the progression from HPV infection to carcinoma. There is no clear boundary where bowenoid papulosis stops and SCC in situ begins.

Treatment

Topical treatment of SCC in situ with cryotherapy and topical 5-FU has been disappointing due to a high rate of recurrence. Iontophoresis will enhance the response to 5-FU, but is not commonly performed by dermatologists. Imiquimod 5% cream applied once a day for up to 16 weeks seems to be effective enough to recommend it as a therapeutic option. Response rates have been as high as 90% in limited series. It may allow treatment of large lesions which might be difficult to approach surgically. The combination treatment with imiquimod 5% cream three times a week and 5% 5-FU twice a day (except at the times of the imiquimod application) has also been reported as effective.

Simple excision of small lesions is a reasonable treatment option. Large, ill-defined lesions, or lesions in which preservation of normal tissue is critical, are indications for Mohs microsurgery. Other surgical techniques to treat SCC in situ are described in Chapter 37. Curettage and desiccation may also be performed, but recurrence may occur if the extension down the follicles is not eradicated. Lesions of the lower legs are particularly problematic, as they are often multiple, and in the elderly are often found in conjunction with significant venous insufficiency. Any form of therapy may result in chronic leg ulceration in this setting. Consideration should be given to using a compression bandage after surgery identical to one applied to a chronic leg ulcer. This may prevent ulceration.

ERYTHROPLASIA OF QUEYRAT

Erythroplasia of Queyrat is SCC in situ of the glans penis or prepuce. SCC in situ on the penile shaft also occurs and is probably similar. Both conditions are caused by high-risk HPV types (16, 18, 31, 35). Clinically, erythroplasia of Queyrat is characterized by single or multiple fixed, well-circumscribed, erythematous, moist, velvety or smooth, red-surfaced plaques on the glans penis (Fig. 29-27). Uncircumcised men, usually over age 40 are most commonly affected, and when Bowen's disease affects the penile shaft it is usually distally under the foreskin. The differential diagnosis includes Zoon balanitis, candidiasis, penile psoriasis, irritant balanitis, and Paget's disease. A biopsy is usually indicated to confirm the diagnosis. Since red lesions on the glans of elderly uncircumsized men are common, the following factors suggest a biopsy is indicated: 1) the lesion is fixed (does not move or resolve); 2) the patient lacks other stigmata of psoriasis or another skin disease that could affect the glans penis; 3) the patient's sexual partner has cervical dysplasia; and 4) the

Fig. 29-27 Erythroplasia of Queyrat.

lesion does not resolve with effective topical therapy for irritant balanitis, candidiasis, and psoriasis. Once the diagnosis of SCC in situ of the penis is made, the patient's sex partner(s) should be referred for evaluation. Sexual partners of men with SCC of the penis are more likely to develop preinvasive and invasive cancer of the cervix or anus.

Progression to invasive SCC is more common in erythroplasia of Queyrat than in Bowen's disease of the nongenital skin, and the resulting SCCs are more aggressive and tend to metastasize earlier than those that develop in Bowen's disease of the nongenital skin. There is no evidence of an increase in internal malignancy in patients with erythroplasia.

Topical therapy can be effective in the treatment of erythroplasia of Queyrat and has the advantage that it can identify and treat areas not visible clinically. Topical 5% 5-FU cream applied once a day under occlusion (with the foreskin or a condom) can be effective. It will induce a brisk reaction and superficial erosion, which can be uncomfortable. Treatment is continued for 3 to 12 weeks, depending on the response. Imiquimod cream 5% applied between once a day and three times a week will similarly induce a significant reaction, but after 3 to 12 weeks may clear the lesion. Careful follow-up is required, especially for the first few years. Surgical modalities such as excision, laser treatments, and photodynamic therapy are reserved for cases failing topical treatments. Radiation therapy can also be effective.

BALANITIS PLASMACELLULARIS (ZOON)

Balanitis plasmacellularis is also known as *balanoposthitis chronica circumscripta plasmacellularis*. It is a benign inflammatory lesion characteristically with a plasma cell infiltrate. The plasma cell infiltrate, while characteristic, may not be present in all lesions of this type, and in fact, some researchers feel there is a spectrum of histology in idiopathic, benign, nonscarring balanitis, from lesions containing few plasma cells to lesions containing many plasma cells. Clinically, Zoon balanitis is characterized by a red patch, which is usually sharply demarcated and usually on the inner surface of the prepuce and the glans penis (Fig. 29-28). The lesion is erythematous, moist, and shiny. It occurs as a single lesion, but it may consist of several confluent macules. It is asymptomatic and does not produce inguinal adenopathy. Uncircumcised men from ages 24 to 85 are most often affected.

Vulvitis chronica plasmacellularis is the counterpart of balanitis in women. The vulva shows a striking lacquer-like luster. Erosions, punctate hemorrhage, synechiae, and a slate-to-ochre pigmentation may supervene.

Plasmacytosis circumorificialis is the same disease on the oral mucosa, lips, cheeks, and tongue, clinically suggestive of SCC.

Fig. 29-28 Zoon balanitis, fixed red papule on the glans penis indistinguishable from erythroplasia of Queyrat.

Histologically, the epidermis is atrophic with flattened diamond-shaped keratinocytes and mild spongiosis. In the papillary dermis a band of infiltrate consisting almost exclusively of plasma cells is present. Dilated vessels are also seen. This picture is strikingly different from that of the main clinical differential diagnosis, erythroplasia of Queyrat, in which the epidermis is principally involved, with atypia of keratinocytes throughout the entire epithelium. HPV has not been detected. Topical steroids, alone or in combination with anticandidal treatment, are helpful. Circumcision may be curative. Laser ablation can also be effective.

PSEUDOEPITHELIOMATOUS KERATOTIC AND MICACEOUS BALANITIS

Pseudoepitheliomatous keratotic and micaceous balanitis was described by Lortat-Jacob and Civatte in 1966. The lesions occurring on the glans penis are vernucous excrescences with scaling. Ulcerations, cracking, and fissuring on the surface of the glans frequently are present. The keratotic scale is usually micaceous and resembles psoriasis. Most patients are over the age of 50 and frequently have been circumcised for phimosis in adult life.

Histologically, there is marked hyperkeratosis and parakeratosis, as well as pseudoepitheliomatous hyperplasia. Acanthotic masses give rise to a crater-like configuration. HPV has not been detected. This is probably best considered

Fig. 29-29 Paget's disease of the breast.

as a form of vertucous carcinoma. The treatment is usually surgical and might include Mohs microsurgery. Topical 5-FU has been effective, but the hyperkeratotic scale may make penetration suboptimal. If topical chemotherapy is utilized, post-treatment biopsies are recommended.

PAGET'S DISEASE OF THE BREAST

Clinical Features

Paget's disease of the nipple is characterized by a unilateral, sharply marginated, erythematous, and at times a crusted patch or plaque affecting the nipple and occasionally the areola (Figs 29-29 and 29-30). In the course of months or years it may become infiltrated and ulcerated. The nipple may or may not be retracted. A subjacent mass and ipsilateral axillary adenopathy may be palpable. There is virtually always an invasive or in-situ ductal adenocarcinoma of the affected breast.

Histopathology

Paget's disease is characterized by the presence of Paget cells: large, round, pale-staining cells with large nuclei. Intercellular bridges are absent. The cells appear singly or in small nests between the squamous cells. Usually, acanthosis is present, the granular layer is preserved, and there is no parakeratosis, but atypical cells may be "spat out" into the stratum corneum. Frequently a layer of basal cells separates the Paget cells from the basement membrane and is seen crushed beneath the nests of Paget cells. This histologic feature helps to distinguish Paget's disease from pagetoid melanoma and Bowen's disease. In the dermis an inflammatory reaction is often present.

The Paget cell is PAS positive, diastase resistant, CEA positive, almost always HER-2/neu positive, EMA positive,

and stains with CAM 5.2 and CK 7. This staining profile and negativity for S-100 and cytokeratins 5/6 allow clear distinction from pagetoid melanoma and pagetoid Bowen's disease. The Toker cell, a normal clear cell of the breast, stains similarly and is proposed as the precursor cell of Paget's disease. Clear cell papulosis is an intraepidermal proliferation of benign Toker cells. Lack of atypia distinguishes it from Paget's disease.

Diagnosis

The presence of unilateral eczema of the nipple recalcitrant to simple treatment is suspicious for Paget's disease and the lesion should be biopsied. The presence of bilateral lesions suggests a benign process, usually atopic dermatitis. Papillary adenoma of the nipple clinically resembles Paget's disease, but on biopsy shows a papillary and adenomatous growth in the dermis with connection to the surface. There is a lining of apocrine-type secretory epithelium. Hyperkeratosis of the nipple and areola may occasionally be unilateral, but histologically reveals only hyperkeratosis, acanthosis, and papillomatosis. Clear cell papulosis of the skin presents with scattered, white, flat-topped lesions distributed on the lower abdomen and along the milk line in otherwise healthy children (adult cases are very rare). Histologic examination reveals benign pagetoid clear cells in the basal layer. The clear cells are AE1 positive and CAM5.2 positive, suggesting they derive from glandular secretory cells.

Treatment

Patients with Paget's disease of the breast should be referred to a center with expertise in the management of breast cancer.

EXTRAMAMMARY PAGET'S DISEASE

Extramammary Paget's disease (EMPD) presents most commonly as a unifocal process, but multifocal lesions may occur. Lesions typically affect apocrine sites, including the groin (vulva, scrotum, perianal, penis, inguinal folds) (Fig. 29-31) and axilla, but rare cases can affect other anatomic locations. EMPD typically affects persons older than 50. The lesions of extramammary Paget's disease are clinically similar to those of Paget's disease, but often go undiagnosed longer as they are initially misdiagnosed as pruritus ani, a fungal infection, or intertrigo. A nonhealing banal eczematous patch persisting in the anogenital or axillary region should raise concern for EMPD. Intense pruritus is common. Bleeding is a late sign. Lesions may simulate lichen simplex chronicus or leukoplakia.

Extramammary Paget's disease can be divided into four forms: 1) primary EMPD (arising intraepidermally); 2) EMPD associated with an underlying apocrine carcinoma; 3) EMPD associated with an underlying gastrointestinal malignancy; and 4) EMPD associated with an underlying carcinoma of the genitourinary tract. The majority of patients with EMPD do not have underlying carcinoma and the process apparently begins as an intraepidermal neoplasm, which can then invade (invasive EMPD). The clinical appearance of all types of EMPD is identical.

Histologically, the findings are similar to those found in mammary Paget's disease: hyperkeratosis, parakeratosis, acanthosis, and the pale, vacuolated Paget cells in suprabasilar levels of the epithelium. Histologic staining cannot distinguish Paget's disease of the breast and EMPD due to intraepidermal or underlying apocrine carcinoma. Cytokeratin staining is unable to clearly distinguish forms of EMPD, except that CK 20 stains cases of EMPD with underlying transitional carcinoma (but not cases of primary EMPD), and PSA (prostate specific antigen) may stain cases of EMPD due to underlying prostate cancer. The mucin core proteins may be used to distinguish other forms of EMPD. Mammary Paget's disease stains positively for MUC1 (mammary type apomucin), but negative for MUC2 (intestinal type mucin) and MUC5AC (gastric surface mucin). Vulvar EMPD with underlying apocrine carcinoma stains in a pattern similar to mammary Paget's disease (some of these cases may represent "extramammary breast cancer"). Lesions of perianal EMPD and underlying gastrointestinal adenocarcinomas stain with MUC2, but only variably with MUC1 or MUC5AC. EMPD with no underlying carcinoma (primary EMPD) are MUC1+, MUC2-, and MUC5AC+.

EMPD can remain within the epithelium or "invade" the dermis. "Invasive" EMPD has a high rate of metastases and a very poor prognosis. Sentinal node examination of patients with "invasive" EMPD should be considered as it predicts the risk for metastases.

Surgical removal is the treatment of choice, which may require Mohs microsurgery. Despite what appears to be adequate margins, recurrence rates are high because of the multifocal nature of extramammary Paget's disease. The recurrence rate following micrographic surgery exceeds 25%. One case of scrotal EMPD responded to imiquimod 5% cream applied daily. Radiation therapy, photodynamic therapy, and laser treatments have also been used.

Merkel Cell Carcinoma (Trabecular Carcinoma)

Merkel cell carcinoma (MCC) was first described by Toker in 1972. The cell of origin is felt to be the Merkel cell, a slowacting mechanoreceptor in the basal layer of the epidermis. MCC is a rare tumor with an incidence of about 2 in a million per year in the white population. Ninety-five percent of cases occur in persons over the age of 50 years (mean age 69 years). Men outnumber women by more than 2:1. MCC are felt to be induced by sun exposure since 90% of cases occur on sun-exposed sites, 50% on the head and neck, and 40% on the extremities. PUVA therapy and arsenic exposure may also be potential causes. Immunosuppression by organ transplantation, chronic lymphatic leukemia, and HIV infection all substantially increase the risk for developing MCC.

Clinically, it presents as a rapidly growing, red-toviolaceous nodule with a shiny surface and overlying telangiectasia. Most lesions are diagnosed when they are less than 2 cm in size, but the diagnosis is rarely suspected at the time of biopsy. MCC is an aggressive tumor with a propensity for dermal and nodal spread. At presentation about one-third of cases have regional node involvement and hematogenous spread will eventuate in 50% of cases. Spontaneous remissions occur, and between 10% and 20% of cases present with no primary tumor evident.

Patients should be staged for therapy and prognosis. Physical examination and CT scanning of the relevant nodal region, chest, and liver should be performed. Stage I, or localized disease, represents 70% to 80% of patients at presentation. Five-year survival is 64%. Stage 11 patients have locoregional disease and are 10% to 30% of patients at diagnosis. Five-year survival is 47%. Stage III disease is distant metastases, and accounts for 1% to 4% of patients at presentation. Median survival is 9 months. Lymph node involvement at presentation is the major predictor of survival. Lesions on the legs are particularly difficult to control because wide excisions and complete courses of radiation therapy are hard to perform on the lower extremity in elderly patients. Undertreatment of lower leg lesions is common, resulting in a poor outcome.

The treatment of MCC should be directed by persons with expertise in managing this rare tumor. Therapy may need to be individualized, depending on various risk factors present. The goal of treatment for patients with stage I and II disease is cure and local control. This involves the combined use of surgery and radiation therapy in most cases. For stage I patients, local removal (by standard surgery with 2-3-cm margins on the trunk or Molis micrographic surgery on the head and neck) is recommended. Comparative trials are not available to demonstrate the benefit of radiation therapy following excision. However, since radiation therapy alone has induced sustained remissions. MCC is radiosensitive. Radiation therapy added to surgery may provide additional benefit. Both the local area with 3- to 5-cm margins and the draining lymph nodes should be treated. Untreated lymph nodes experience recurrence from 46% to 76% of the time. Even after Mohs surgery, radiation therapy seems to provide additional benefit. Prophylactic lymph node dissection enhances local control, but does not improve survival. Stage II patients are treated with the same principals as stage I patients. The affected nodal masses are either removed surgically then the area radiated, or treated with radiation alone. It is unclear if surgery improves outcome. Adjunctive chemotherapy may provide some benefit in patients with high-risk disease, using synchronous chemoradiotherapy and adjuvant chemotherapy. Treatment of patients with stage III disease is palliative.

Histologically, MCC is a dermal tumor that may extend into the subcutaneous tissue. The cells are about 15 μ m in diameter and have very scanty cytoplasm and hyperchromatic nuclei with a distinctive smudged chromatin pattern. Mitoses and apoptotic cells are numerous. The cells are arranged in sheets and cords. MCC must be distinguished from small cell lung cancer, lymphoma, neuroblastoma, small cell endocrine carcinoma, Ewing sarcoma, melanoma, and even BCC. While electron microscopy may detect the dense core granules, this is varely used diagnostically. Instead, immunoperoxidase markers with characteristic staining for both keratins such as CK 20, CK 7, CAM 5.2 (in a perinuclear "dot" pattern) and neuroendocrine markers (neuron-specific enolase, neurofilament protein, neuropeptides, chromogranin, synaptosyn) are the primary method used to confirm the diagnosis of MCC. MCC is S-100 and leukocyte common antigen (LCA) negative.

SEBACEOUS NEVI AND TUMORS

Nevus Sebaceus (Organoid Nevus)

Nevus sebaceus of Jadassohn occurs in approximately 3 in 1000 neonates. It presents as a sharply circumscribed, yellow-orange, hamartoma varying from a few millimeters to several centimeters in size. These lesions are usually solitary, congenital, and linear in configuration. The scalp is the most common location (50%), but other areas of the head and neck (45%) are also common. The trunk is involved in 5% or less of cases. The lesions persist throughout life and are usually alopecic. In childhood they are slightly papillated or velvety, but in adulthood, with hyperplasia of the sebaceous elements, the lesions become more elevated and cerebriform (Figs 29-32 and 29-33). Numerous neoplasms, most of them adnexal, have been described arising in nevus sebaceus. The most common tumors are trichoblastoma and syringocystadenoma papilliferum, each occurring in about 5% of nevus sebaceus. Both of these tumors present as new, often pigmented, papules or nodules arising in the nevus sebaceus. BCC is uncommon, occurring in less than 1% of lesions. Many cases previously diagnosed as BCC are actually trichoblastomas. Many of the tumors are difficult to classify precisely as a well-described entity. Development of benign tumors occurs in less than 5% of nevus sebaceus before the age of 16 and malignant tumors are rare in childhood or adolescence. The risk for tumor development increases with age. Rarely, aggressive malignant adnexal neoplasms may arise. Familial cases have been described and a paradominant pattern of transmission has been suggested.

Nevus sebaceus may be associated with multiple internal abnormalities, making it one of the cutaneous abnormalities to be included within the epidermal nevus syndrome (see above). In cases of nevus sebaceus syndrome, the nevus sebaceus is usually on the scalp, linear, and of larger size (several centimeters).

Histologically, in prepubertal lesions, the epithelium is acanthotic and papillomatous. Pilosebaceous structures are immature and resemble the fetal pilar germ. After puberty, the epidermis is more hyperplastic and at times papillomatous. It may resemble a seborrheic keratosis, acanthosis nigricans, or have features of an epidermal nevus. Sebaceous glands are usually abundant, placed high in the dermis, and connect directly to the epidermal surface, but may be partially lipidized near puberty. Follicular structures, if present are usually vellus or partially formed. Apocrine glands are present in about half of the lesions. The dermis is thickened with increased vascularity and fibrous connective tissue. Mature lesions have been described as broad, bald, bumpy (papillomatous), and bubbly (sebaceous).

Although the risk of development of malignancy exists, it is small, and virtually always occurs after adolescence. For

Flg. 29-32 Nevus sebaceus.

Fig. 29-33 Nevus sebaceus in a prepubescent child. this reason, surgical removal can be delayed until adulthood, when the patient can make an informed decision regarding removal. If the lesion leads to disfigurement, stigmatization, or symptomatology, it may be removed at any age.

Sebaceous Hyperplasia

This condition is especially common in persons with significant chronic sun exposure. The age of onset is usually past 40. The areas of predilection are the forehead, infraorbital regions, and temples. The lesions are small, creamcolored or yellowish umbilicated papules 2 to 6 mm in diameter. Unusual sites may be affected, such as the areolas, nipples, penis, neck, and chest, where they occur as solitary lesions, clustered papules or beaded lines. Prominent sebaceous hyperplasia occurs in 10% to 15% of patients taking cyclosporin and may involve ectopic sites such as the oral mucosa. It often appears many years after the cyclosporin is begun. Histologically, the sebaceous glands are hypertrophied, with normal-appearing acini. The glands are multilobulated, each dividing into other lobules to produce a cluster resembling a bunch of grapes. Clinically, they may mimic an early BCC.

Premature sebaceous hyperplasia, also known as *familial* presentile sebaceous hyperplasia, presents with extensive sebaceous hyperplasia with onset at puberty and worsening with age. Familial patterns have been reported, inherited in an autosomal-dominant fashion. It involves the face, neck, and upper thorax but spares the periorificial regions.

Treatment is solely for cosmetic purposes and employs electrosurgery, laser treatment, photodynamic therapy, or even shallow shave biopsy. Isotretinoin will reduce lesions, but they immediately recur when it is stopped, so it is probably not indicated for this condition.

Sebaceous Adenoma

This slow-growing tumor usually presents as a pink, fleshcolored, or yellow papule or nodule. It occurs primarily on the head and neck in the elderly. Histologically, the tumor is composed of multiple sharply marginated sebaceous lobules. Each lobule has a basal layer of darker germinative cells, but the maturation is not as well-developed as in a normal sebaceous gland. Multiple openings directly to the overlying epidermis may be found. Sebaceous adenoma may be a cutaneous marker of the Muir-Torre syndrome and immunohistochemical staining for MLH-1 and MSH-2 may be used to demonstrate microsatellite instability.

Sebaceoma (Sebaceous EpFithelioma)

Clinically, sebaceomas have the same morphologic characteristics as BCCs. They appear as yellow or orange papules, nodules, or plaques, usually on the scalp, face, and neck. They may be associated with Muir-Torre syndrome. Histologically, the tumor consists of oval nests of irregularly shaped basaloid cells with differentiation toward sebaceous cells. Also, there may be cystic spaces containing vacuolated amorphous material.

Sebaceous Carcinoma

This rare carcinoma most frequently arises on the eyelids from the meibomian or Zeis glands. It usually appears in the tarsal region of the upper eyelids (75%) and represents 1% or more of eyelid malignancies. It frequently is misdiagnosed as a chalazion, delaying appropriate treatment. The scalp, other areas of the face, and the trunk are the next most common areas involved. Rarely, it has been reported to involve the feet, external genitalia, and the oral mucosa. Fatal metastatic disease occurs in up to 30% of eyelid cases and the 5-year survival for this tumor is 80%. Sebaceous carcinomas arising in nonocular locations can also metastasize, usually to regional lymph nodes. Sebaceous carcinoma may be seen in Muin-Torre syndrome (Fig. 29-34).

Histologically, the tumor is composed of lobules or sheets of cells which extend deeply into the dermis, subcutaneous fat, or muscle. The tumor cells are pleomorphic and show various degrees of sebaceous differentiation, manifested by a vacuolated rather than clear cytoplasm. Undifferentiated

Fig. 29-34 Sebaceous carcinoma in a patient with Muir-Torre syndrome.

cells with mitotic figures can be found. The cells vary greatly in size and shape. A characteristic feature in ocular tumors is pagetoid or bowenoid spread of the tumor onto the overlying conjunctiva or skin. Sebaceous differentiation may be minimal in this in situ component, leading to the misdiagnosis of SCC in situ. Treatment is surgical with Mohs' microsurgery having had good results in some cases. Given their extent, oculoplastic reconstruction is usually required. In extraocular cases, complete excision, as for an adnexal carcinoma, and careful follow-up is recommended.

Muir-Torre Syndrome

Sebaceous tumors of the skin were first reported by Muir in 1967 and Torre in 1968 to be associated with the development of internal malignancy, a combination that has been called the Muir-Torre syndrome. The internal tumors often occur a decade or two before the cutaneous lesions, but may occur before or simultaneously with the internal malignancies. The age of presentation of the internal tumors is variable, even within the same kindred. Exacerbation of the syndrome occurs with immunosuppression.

The most common malignancy is colonic adenocarcinoma, but neoplasms of the genitourinary tract may also occur. The visceral tumors are malignant or premalignant, but may not behave as aggressively as predicted. Muir-Torre syndrome is allelic to hereditary nonpolyposis colorectal cancer syndrome. The cutaneous lesions may be sebaceous adenomas, sebaceomas, sebaceous carcinomas, or keratoacanthomas. Cystic sebaceous neoplasms are seen only in patients with Muir-Torre syndrome. Since sebaceous neoplasms are very uncommon, even the presence of one of these lesions should trigger an evaluation for Muir-Torre syndrome. In one study, 60% of patients with a sebaceous neoplasm were found to have Muir-Torre syndrome.

The genetic basis of Muir-Torre syndrome is an inactivating germline mutation of the DNA mismatch repair genes, very commonly MSH-2 and at times MLH-1, resulting in microsatellite instability. Loss of expression of MSH-2 or MLH-1 can be demonstrated in associated neoplasms by means of immunohistochemical staining. Since the genetic defects and the presence of microsatellite instability can be detected in routinely processed pathology specimens, the diagnosis can be confirmed from both skin biopsies and any visceral tumors removed from the patient. Once the diagnosis is confirmed, the patient and his/her genetically-related family members should be appropriately screened for the presence of the mutation and for underlying malignancies. Genetic counseling should be provided.

Surgical excision of cutaneous lesions is recommended. Grossly involved lymph nodes should also be excised. Patients have responded well to 40 mg/day of isotretinoin and may continue to experience good results with doses as low as 10 mg/day. Patients with this syndrome should have regular examinations for gastrointestinal and genitourinary cancer, including annual colonoscopy beginning at age 25 and first morning urine for cytology. Asymptomatic relatives should also be counseled and evaluated.

SWEAT GLAND TUMORS

Syringoma

Syringoma are very common neoplasms demonstrating sweat duct differentiation. They present as small papules 1 to 3 mm in diameter. The may be yellow, brown, or pink. They are virtually always multiple and most frequently occur on the eyelids and upper cheeks (Fig. 29-35). They are disproportionately common in these sites in Japanese women. Other sites of involvement include the axillae, abdomen, forehead, penis, and vulva. Genital syringomas may cause genital pruritus and be mistaken for genital warts. Rarely they may be unilateral or linear. Symmetrical distal extremity involve-

Fig. 29-35 Syringomas.

Fig. 29-36 Syringomas.

ment has also been reported. Eruptive syringonias are histologically identical to syringomas of the eyelid, but appear suddenly as numerous lesions on the neck, chest, axillae, upper arms, and periumbilically, usually in young persons (Fig. 29-36). Many individual case reports document unusual clinical variants of syringomas. These include types limited to the scalp, associated with alopecia; a unilateral linear or nevoid distribution; those limited to the vulva or penis; those limited to the distal extremities; and the lichen planusand milia-like types.

Familial cases of syringomas occur. In general, except in eruptive cases, syringomas develop slowly and persist indefinitely without symptoms. Syringomas occur in 18% of adults with Down syndrome, particularly females. This is approximately 30 times the frequency seen in patients with other mental disabilities.

Histologically, syringomas are characterized by dilated cystic spaces lined by two layers of cuboidal cells and epithelial strands of similar cells. Some of the cysts have small comma-like tails to produce a distinctive picture, resembling tadpoles or the pattern of a paisley tie. There is a dense fibrous stroma. At times the cells of the syringoma have abundant clear cytoplasm which represents accumulated glycogen. This has been called "clear cell syringoma" and is often associated with diabetes mellitus. Syringomas stain positive for EKH-6 and CEA, a pattern similar to normal eccrine ducts, but are negative for EKH-5 and SKH1, which label the ductal portions of the eccrine glands. The microscopic differential diagnosis of "paisley tie" epithelial islands embedded in a sclerotic stroma includes microcystic adnexal carcinoma (sclerosing sweat duct carcinoma), desmoplastic trichoepithelioma, and morphoeiform BCC.

Treatment is difficult, but many lesions respond to very light electrodessication or shave removal. For larger lesions, surgical removal may be considered.

Hidrocystomas

Hidrocystomas are 1 to 3 mm translucent papules that occasionally have a bluish tint (Fig. 29-37). They usually are

Fig. 29-37 Hidrocystoma.

Fig. 29-38 Hidrocystomas.

solitary, occur on the face or scalp, and are more common in women. In some patients, multiple lesions may be present (Fig. 29-38) and they may be pigmented. They may become more prominent during hot weather. Multiple hidrocystomas of the eyelids may be found in Schopf-Schulz-Passarge syndrome, an adult-onset form of focal dennal hypoplasia. Microscopically, a single cystic cavity lined by two layers of small cuboidal epithelial cells is present. Apocrine differentiation in the form of decapitation secretion is common. Lesions with papillary proliferations of the lining are classified as cystadenomas. Treatment, if desired, is by excision for solitary lesions. Laser treatment may be effective. Topical atropine ointment 1% or scopolamine cream 0.01% (1.2 mL of 0.25% scopolamine eyedrops in 30 g of Eucerin) once daily, have been used with variable success in patients with multiple lesions. Pupil size may increase with these agents. Botulinum toxin may also be effective.

Acrospiromas (Poroma, Hidroacanthoma Simplex, Dermal Duct Tumor, Nodular Hidradenoma, Clear Cell hidradenoma)

Acrospiromas are benign tumors with acrosyringial differentiation. A poroma presents as a slow-growing, 2- to 12-mm, slightly protruding, sessile, soft, reddish tumor that occurs most often on the sole (Fig. 29-39) or side of the foot. Palmar lesions may also occur and more rarely lesions appear wherever sweat glands are found. The lesion will bleed on slight trauma. A distinctive finding is the cup-shaped shallow depression from which the tumor grows and protrudes. Poromas tend to occur singly, but multiple lesions may also occur. A rare variant is called eccrine poromatosis, in which more than 100 lesions may involve the palms and soles and may be associated with hidrotic ectodermal dysplasia. These may represent acrosyringeal nevi. Dermal duct tumors present deep nodules that may involve any part of the body. Nodular and clear cell hidradenomas are larger nodules that often involve the head or neck, but may occur anywhere. Hybrid combinations of different patterns of acrospiroma are very common.

Histologically, poromas demonstrate solid masses of uniform, cuboidal epithelial cells with ample cytoplasm and focal duct differentiation. The cells are smaller than those in the contiguous epidermis and tend to arrange themselves in cords and broad columns extending downward from the normal epidermis. Areas of clear cell and cystic degeneration may be present, and an underlying dermal duct tumor or hidradenoma may be present. The surrounding stroma is highly vascular with telangiectatic vessels. Hidroacanthoma simplex represents an intraepidermal eccrine poroma. They resemble clonal seborrheic keratoses except for the presence of focal duct differentiation. Dermal duct tumors are composed of the same small acrosyringeal cells as other acrospiromas. The cells form small dermal islands with ductal differentiation. When the cells form a large nodule, the tumor is referred to as a nodular hidradenoma. When clear cells and cystic degeneration are prominent, the tumor is referred to as a clear cell hidradenoma. A distinctive feature of the latter two tumors is the presence of areas of eosinophilic hyalized stroma. These areas represent a degenerative change of vascular walls, and always contain small endothelial-lined lumens. The appearance of these areas has been likened to that of osteoid stroma. Much of this unique stroma appears to represent massive reduplication of the vascular basement membrane.

The clinical differential diagnosis includes porocarcinoma, granuloma pyogenicum, melanoma (amelanotic and melanotic), Kaposi sarcoma, BCC, and seborrheic keratosis. The lesions are benign, but often recur following inadequate excision. Malignant degeneration may occur, and atypia is sometimes minimal within tumors that have metastasized. For these reasons, simple complete excision is recommended when feasible.

Malignant Acrospiroma (Malignant Poroma, Porocarcinoma)

This represents the most common form of sweat duct carcinoma. Most malignant acrospiromas appear clinically similar to poromas, but may also manifest as a blue or black nodule, plaque, or ulcerated tumor. Porocarcinoma affects men and women equally at an average age of 70 years. The most frequent sites of involvement are the legs (30%), feet (20%), face (12%), thighs (8%), and arms (7%). Of interest is the rare involvement of the palms and soles, despite these having the greatest concentration of sweat glands. The average age from onset to treatment is 8 years. These tumors are of intermediate aggressiveness, with metastases usually occurring to regional lymph nodes and less commonly hematogentously.

Histologically, the tumor may be seen adjoining benign acrospiroma. Atypia may be marked or minimal, with pleomorphic or monomorphous nuclei and abundant or scant eosinophilic cytoplasm. Most commonly, the cells are smaller and more basophilic than those in benign acrospiromas with a high mitotic rate. Just as in benign acrospiromas, clear cell and custic degeneration may be present. The degree of ductal differentiation is variable. The tumors can be deeply infiltrative.

Mohs surgery can be a valuable technique, particularly on the face. As with other cutaneous neoplasms, margins should be free of tumor islands and tumor stroma to be considered negative.

Spiradenoma

Spiradenoma clinically presents as a solitary, 1-cm, deepseated nodule occurring most frequently on the ventral surface of the body, especially over the upper half. Normal-appearing skin covers the nodule, which may be skin-colored, blue, or pink. Occasionally, multiple lesions may be present and may occur in a linear or segmental pattern. Lesions may be painful, but not universally. Spiradenoma has a generally benign clinical course and occurs most frequently between the ages of 15 and 35, although it has also been reported in infancy and childhood. Familial cases have been described. Rarely, malignant transformation occurs and the subsequent tumor may also have features of a cylindroma (spiradenocylindrocarcinoma).

Microscopically, it demonstrates either a single nodule or multiple basophilic nodules within the dermis. Tumor cells have little to no visible cytoplasm. They are often arranged in characteristic small rosettes. Three cell types are present: cells with large, pale gray nuclei; those with smaller, darker gray nuclei; and jet-black lymphocytes peppered throughout the nodule. Duct-like structures are often present, as are large pink hyaline globules that resemble the bright red hyaline basement membrane material that outlines the islands of cylindromas. In fact, spiradenomas and cylindromas commonly occur together in the same patient and hybrid collision tumors are quite common.

When painful, eccrine spiradenoma may be mistaken for leiomyoma, glomus tumor, neuroma, and angiolipoma. Treatment is simple excision.

Cylindroma

Cutaneous cylindroma, also known as dermal eccrine cylindroma, occurs predominantly on the scalp and face as a solitary lesion. The tumor is firm, but rubber-like, pinkish to blue, and ranging from a few millimeters to several centimeters. The solitary cylindroma is considered to be nonhereditary and may at times be found in areas other than the head and neck. Women are affected more than men. The dominantly inherited form, Brooke-Spiegler syndrome, appears soon after puberty as numerous rounded masses of various sizes on the scalp. The lesions resemble bunches of grapes or small tomatoes. Sometimes they cover the entire scalp like a turban and are frequently associated with trichoepitheliomas and milia. In the familial form the cylindromas may be widespread. This syndrome is due to a mutation in the CYLD1 gene on chromosome 16q12–13.

Histologically, these are cylindrical masses of epithelial cells surrounded and segmented by thick bands of a hyaline material. Cylindroma may be mistaken for pilar cyst, but the distinctive appearance and consistency makes diagnosis easy, especially in the multiple type. Treatment is surgical.

Mixed Tumor (Chondroid Syringoma)

Cutaneous mixed tumor is an uncommon skin tumor, representing about 1 in 1000 skin lesions electively removed. It favors men between the ages of 25 and 65. Mixed tumor presents clinically as a firm intradermal or subcutaneous nodule, virtually always located on the head and neck. These tumors are usually asymptomatic and measure 5 to 30 mm in diameter.

Histologically, nests of cuboidal or polygonal epithelial cells in the dermis give rise to tubuloalveolar and ductal structures and occasionally, keratinous cysts. These structures are embedded in a matrix varying from a faint, bluish chondroid substance to an acidophilic hyaline material. Myoepithelial and lipomatous elements may also be found in the tumor, in addition to the chondroid stroma. Ossification may occur. The treatment is surgical. Mixed tumors may also occur in other organs, especially salivary glands. Tumors with only focal glandular elements, or with no epithelial elements, have been called "cutaneous myoepitheliomas." They are tumors of the myoepithelial cells. Myopeithelial cells surround the sweat glands and by their contraction help deliver the product of the glands to the surface.

Malignant Mixed Tumor (Malignant Chrondroid Syringoma)

This rare tumor favors the trunk and extremities (whereas benign mixed tumor of the skin favors the head and neck). At presentation the masses range from 1 to 10 cm, with a median size of 4 cm, and often grow rapidly. The chance of metastasis is more than 50%, with a predilection for visceral spread. Metastases are usually as an adenocarcinoma and the chondroid stroma found in primary lesions is often not found. Histologic features that distinguish it from chondroid syringoma include cytologic atypia, pleomorphism, increased mitotic activity, and focal necrosis. Treatment is surgical.

Ceruminoma

Ceruminous glands, modified apocrine glands of the external ear, may give rise to both benign and malignant tumors. Their distinction may be very difficult, hence both the malignant and benign tumors have been termed ceruminomas. The tumors present as a firm papule or nodule in the external auditory canal. Ulceration and crusting may occur and continued growth may obstruct the meatus.

Histologically, glands and cysts are present, lined by a tuboglandular proliferation with two layers—an inner layer of ceruminous cells (containing cerumen and with decapitation secretion) and a basal spindled or cuboidal myoepithelial layer. Treatment is excision, which is curative if margins are clear.

Hidradenoma Papilliferum

Hidradenoma papilliferum is a benign apocrine adenoma that is located almost exclusively in the vulvar and perianal

areas. The tumor is covered by normal skin. On palpation it is a firm papule less than 1 cm in diameter.

Microscopically, it is encapsulated and lies in the dermis, and has no connection with the epidermis. There is a cystlike cavity lined with villi. The walls of the cavity and the villi are lined, occasionally with a single layer, but usually a double layer of cells—luminal secretory cells and myoepithelial cells. Electron microscopy shows hidradenoma and myoepithelial cells, confirming the apocrine origin of hidradenoma papilliferum. This is a benign lesion and the diagnosis and treatment are accomplished by excisional biopsy.

Syringadenoma Papilliferum (Syringocystadenoma Papilliferum)

This lesion develops in a nevus sebaceus of Jadassohn on the scalp (Fig. 29-40) or face in about one-third of cases. About half are present at birth and approximately 25% arise on the trunk and genital and inguinal regions during adolescence. The lesions are rose-red papules of firm consistency; they vary from 1 to 3 mm and may occur in groups. Vesicle-like inclusions are seen, pinpoint to pinhead in size, filled with clear fluid. Some of the papules may be umbilicated and simulate molluscum contagiosum. Extensive verrucous or papillary plaques may also be present.

Histologically, the tumor shows ductlike structures that extend from the surface epithelium. Numerous papillary projections may extend into the lumina, which may be cystic. The papillary projections are lined by glandular epithelium, often consisting of two rows of cells. The tumor cells stain positively for carcinoembryonic antigen. The dermal stroma contains numerous plasma cells. Rarely, malignant trans-

Flg. 29-40 Syringocystadenoma papilliferum.

formation may occur. Vertucous carcinoma may develop in syringocystadenoma papilliferum. Excision is recommended and radiation therapy is ineffective.

Papillary Eccrine Adenoma (Tubular Apocrine Adenoma)

This uncommon benign sweat gland neoplasm presents clinically as dermal nodules located primarily on the extremities of black patients, especially on the dorsal hand or foot. Histologic findings consist of a well-circumscribed, dermal, unencapsulated growth composed of dilated ductlike structures lined by two or more layers of cells. Intraluminal papillations may project into the cystic spaces. Because of its tendency to recur locally, complete surgical excision with clear margins is recommended.

Jackson EM, Cook J: Mohs micrographic surgery of a papillary eccrine adenoma. Dermatol Surg 2002;28:1168.

Syringofibroadenoma (Acrosyringeal Nevus of Weedon and Lewis)

First described by Mascaro in 1963, four variants of eccrine syringofibroadenoma (ESFA) are now recognized: 1) the solitary variant; 2) multiple in Schopf syndrome; 3) multiple without other skin manifestations; and 4) nonfamilial unilateral linear type. The solitary type presents frequently as a hyperkeratotic nodule or plaque involving the extremities. The linear type may be linear, blashkoid, or zosteriform in appearance and some cases may represent an acrosyringeal nevus. Multiple lesions have been termed *eccrine syringofibroadenomatosis* and occur in both variants of hidrotic ectodermal dysplasia, Schopf syndrome, and Clouston syndrome. The multiple eccrine syringofibroadenomas may appear in a mosaic pattern. In Clouston syndrome, HPV-10 has been detected in the tumors. Multiple lesions have also been reported without any other associated cutaneous findings. Many cases represent a reactive epithelial proliferation, whereas others represent a true neoplasm of acrosyringeal cells. Histologically, the strands resemble those of the fibroepithelial tumor of Pinkus, but with broader anastomosing cords without the basaloid buds. "Reactive eccrine syringofibroadenoma" most commonly occurs on the lower leg and may show adjacent changes of an associated dermatosis. Carcinomatous transformation of ESFA has been reported.

Microcystic Adnexal Carcinoma (Sclerosing Sweat Duct Carcinoma)

The tumor generally presents as a very slow-growing plaque or nodule. It occurs most commonly on the upper lip (Fig. 29-41) or face. Microcystic adnexal carcinomas have occurred at sites of prior therapeutic radiation. It is very locally aggressive, with local recurrences in 50% of cases. Metastasis probably does not occur. Histologically, the superficial part of the tumor is composed of ducts, keratinous cysts, and small cords of cells, superficially resembling a syringoma. The deeper component consists of nests and strands in a dense stroma. Perineural invasion is common and may be extensive. This explains the frequent recurrence after initial excision. Mohs microsurgery is the treatment of choice. Radiation treatment of the tumor is ineffective and may lead to recurrence with more aggressive behavior.

"Eccrine" Carcinoma (Syringoid Carcinoma)

Eccrine carcinoma is rare and presents as a plaque or nodule on the scalp (Fig. 29-42), trunk, or extremities. Local recurrence is common, but metastases are rare. It is composed of ducts and tubules with atypical basaloid cells. A more cellular tumor with numerous tubules and ducts has been termed *polymorphous sweat gland carcinoma*. Overlap features with microcystic adnexal carcinoma occur, but in general eccrine carcinoma has a less desmoplastic stroma.

Mucinous Carcinoma

This tumor is commonly a round, elevated, reddish, and sometimes ulcerated mass, usually located on the head and neck (75%). Forty percent occur on the eyelid. It grows slowly and is usually asymptomatic. Local recurrence is seen in 36%, but the rate of metastasis and widespread dissemination is low (15%). Rare tumors on the eyelid (derived from the glands of Moll) may express estrogen and progesterone receptors, analogous to mucinous carcinoma of the breast. Mucinous gut carcinomas may also metastasize to skin and must be excluded before diagnosing a primary cutaneous mucinous carcinoma.

Histologically, tumors are characterized by the presence of large areas of mucin in which small islands of basophilic epithelial cells are embedded (blue islands floating in a sea of mucous). Basaloid cells in a cribiform pattern, with duct-

Fig. 29-41 Microcystic adnexal carcinoma.

Fig. 29-42 Eccrine carcinoma.

like structures, is typical. The recommended treatment is local surgical excision.

Aggressive Digital Papillary Adenocarcinoma (Digital Papillary Adenocarcinoma)

This aggressive malignancy involves the digit between the nailbed and the distal interphalangeal joint spaces in most cases, or just proximal to this region. It presents as a solitary cystic nodule. Ulceration and bleeding can occur and rarely the malignancy may be fixed to underlying tissues. Most patients are men in their 50s. Metastases occur in about 15% of cases, particularly pulmonary. The tumor is poorly circumscribed and composed of tubuloalveolar and ductal structures with areas of papillary projections. The tumor is positive for S-100, and the cystic contents are positive for CEA and EMA. Complete excision is the treatment of choice. Cases previously called aggressive digital papillary "adenoma" are best regarded as adenocarcinoma.

Primary Cutaneous Adenoid Cystic Carcinoma

This rare cutaneous tumor presents usually on the chest, scalp, or vulva of middle- to older-aged persons. It is similar histologically to adenoid cystic carcinoma of the salivary gland, with a proliferation of small duct-like islands and larger islands with a "Swiss cheese" or cribriform pattern. It may recur locally or rarely metastasizes. Surgical excision, perhaps with Mohs micrographic surgery, is the treatment of choice.

Apocrine Gland Carcinoma

Apocrine gland carcinoma, unrelated to Paget's disease, is rare. The axilla or anogenital region are the most common sites, but occasionally other areas with apocrine glands may be involved. Lesions present as a mass. Widespread metastases occur in at least 40% of cases.

HAIR FOLLICLE NEVI AND TUMORS

Pilomatricoma (Calcifying Epithelioma of Malherbe)

Also known as Malherbe calcifying epithelioma and pilomatrixoma, this benign tumor is derived from hair matrix cells. It usually occurs as a single lesion which is most commonly found on the face, neck, or proximal upper extremity. Lesions may also be located on the scalp, trunk, and lower extremities. Pilomatricoma is an asymptomatic, deeply seated, 0.5- to 7.0-cm, firm nodule, covered by normal or pink skin, which on stretching may show the "tent sign," with multiple facets and angles (Fig. 29-43). Overlying epidermal atrophy is common, leading to an appearance that may resemble anetoderma or striae. In a review of 209 patients, the youngest was 18 months and the oldest 86 years. There is a bimodal age distribution, in the first and sixth decades. Girls are more commonly affected than boys.

Multiple pilomatricomas are uncommon. They are usually seen in association with myotonic dystrophy—Steinert syndrome. They may also occur in Ruinstein-Taybi syndrome and Turner syndrome. Patients with Gardner syndrome have

Fig. 29-43 Pilomatrixoma.

epidermoid cysts with focal areas of pilomatricoma-like changes. Rarely, multiple pilomatricomas will be inherited in an autosomal-dominant pattern with no other association.

The histopathology shows an encapsulated mass. Basophilic cells with little cytoplasm resemble those of the hair matrix. They evolve into eosinophilic "shadow" cells. Calcification occurs commonly. Ossification, melanin deposits, and foreign-body reaction with giant cells may all be present. Activating mutations in β -catenin are present in the majority of pilomatricomas. It is expressed in the basophilic but not the shadow cells. "Melanocytic matricoma" is a rare lesion presenting as a small papule which histologically is composed of metrical cells, some shadow cells, and numerous dendritic melanocytes containing melanin.

Clinical differential diagnosis is usually impossible in the adult, but in children, since epidermoid cysts are rare, this diagnosis should be considered for any firm cystic mass of the face and upper body. When palpated, pilomatricomas are firmer and more faceted than epidermoid and pilar cysts. Fine needle aspiration has led to misdiagnosis, with the basophilic cells being interpreted as carcinoma. Treatment is surgical excision.

Malignant Pilomatricoma (Pilomatrix Carcinoma, Pilomatrical Carcinoma)

Malignant pilomatricomas are rare tumors. Described as being locally aggressive, but with limited metastatic potential, many cases described as "malignant" may actually have been "proliferating" pilomatricomas. Metastases to regional lymph nodes are most frequent. Mohs micrographic surgery may be considered to obtain clear margins.

Trichofolliculoma

Trichofolliculoma is a benign, highly-structured tumor of the pilosebaceous unit, characterized by a small, dome-shaped nodule some 5 mm in diameter on the face or scalp. From the center of the flesh-colored nodule a small wisp of fine, vellus hairs protrudes through a central pore (Fig. 29-44). It may occur at any age but mostly affects adults.

Histologically, the tumor consists of one or more large follicles with smaller radiating secondary follicular structures (sometimes referred to as the mother follicle with her babies). The secondary follicles range from an immature rudimentary matrix to well-formed follicles with papillae, matrix, trichohyaline, and fine hairs ("fingers of fully formed follicles forming fiber"). The tumor may have little stroma or may be embedded in a fibrous orb. Sebaceous glands may be prominent, a variant termed "sebaceous trichofolliculoma." The follicular structures in trichofolliculomas transition through phases of the hair cycle. In telogen, they may resemble fibrofolliculomas. The presence of hair shafts helps distinguish the two. Folliculosebaceous cystic hamartoma may represent a sebaceous trichofolliculoma in telogen. Treatment is surgical removal.

Fig. 29-45 Trichoepithelioma.

Fig. 29-47 Trichoepithelioma, desmoplastic type.

Fig. 29-46 Trichoepitheliomas.

Giant Solitary Trichoepithelioma

The lesions may be several centimeters in diameter, occurring most commonly on the thigh or perianal regions. They are found in older adults.

Desmoplastic Trichoepithelioma

This lesion, which is difficult to differentiate from morpheiform BCC histologically, occurs as solitary or multiple lesions on the face. Desmoplastic trichoepithelioms are firm, slightly indented (central dell sign), and have a raised, annular border (Fig. 29-47). Young women are most commonly affected and familial solitary and multiple desmoplastic trichoepitheliomas have been described.

Histology

Trichoepithelioma are dermal tumors with multiple nests of basaloid cells, some of which show abortive follicular differentiation. Keratinous cysts, calcification, and amyloid may all be seen. The stroma in most trichoepitheliomas resembles the fibrous sheath of a normal hair follicle. It contains many fine collagen fibers and fibroblasts that surround the tumor islands in a concentric array. Clusters of plump nuclei resembling the cells of the (ollicular papilla (papillary mesechymal bodies) are common. In the desmoplastic variety, the tumor is composed of small cords of epithelium embedded in a dense eosinophilic stroma with fewer fibroblasts. The islands often present a "paisley tie" appearance, and the microscopic differential diagnosis includes morpheaform BCC. syringoma, and microcystic adnexal carcinoma. The clinical features may distinguish these entities. Focal calcification, horn cysts, and a central dell favor trichoepithelioma. In desmoplastic trichopeithelioma, clefts form between collagen fibers in the stroma, while in BCC, clefts form between the tumor islands and stroma. Trichoepitheliomas are best classified as benign tumors of the hair germ. As such, they may be considered variants of trichoblastoma. Histologically, trichoepithelioma must be differentiated from keratotic BCC, for which it is frequently confused.

Treatment

Solitary lesions can be treated by surgical excision. Multiple lesions can be smoothed down by resurfacing the skin with laser, dermabrasion, or electrosurgery. This procedure must be repeated at regular intervals, as the Jesions recur gradually.

Multiple Familial Trichoepithelioma (Epithelioma Adenoides Cysticum, Brooke-Spiegler Syndrome)

This autosomal-dominant condition usually presents in childhood or around puberty. Multiple cystic and solid nodules appear on the face, favoring the upper lip, nasolabial folds, and eyelids. The individual lesions are small, round, smooth, shiny, slightly translucent, firm, circumscribed papules or nodules (Fig. 29-45). The individual lesions average 2 to 4 mm in diameter. The center may be slightly depressed. Most frequently the lesions are grouped but discrete. On the face they are often symmetrical (Fig. 29-46). Other sites may be the scalp, neck, and trunk. Multiple linear and dermatomal trichoepitheliomas may rarely be seen. Cylindromas and multiple spriadenomas may occur in association with multiple trichoepitheliomas. Multiple trichoepitheliomas was originally associated with mutations on the long arm of chromosome 9, near or in the PTCH gene. Recently, mutations of the CYLD gene on 16q12-q13 have been described in families with multiple trichoepitheliomas and cylindromas. Some individuals in these families have primarily trichoepitheliomas and resemble patients with Brooke-Spiegler syndrome.

Solitary Trichoepithelioma

The single occurring trichoepithelioma is nonhereditary and occurs mostly on the face: however, it may also be found on the scalp, neck, trunk, and proximal extremities. It presents as a firm dermal papule or nodule and must be distinguished from BCC.

Trichoblastoma

These benign neoplasms of follicular germinative cells usually present as asymptomatic nodules greater than 1 cm in size in the deep dermis or subcutaneous tissue. The scalp is the most common location. They occur in male and female adults. The lesions may be pigmented. Trichoblastomas arise in organoid nevi and represent the majority of basaloid neoplasms described as "basal cell carcinomas" in nevus sebaceus. Histologically, trichoblastoma is a dermal or subcutaneous tumor composed of basaloid cells with areas of follicular differentiation of the tumor. The islands may connect with the overlying epidermis, especially in the setting of an organoid nevus. The stroma is identical to that seen in trichoepithelioma and typically contains papillary mesechymal bodies. Merkel cells may be prominent within the tumor and amyloid can be found. Cutaneous lymphadenoma is a variant of trichoblastoma with extensive infiltration of the tumor islands by lymphocytes and histiocytes. The stroma resembles that of other trichoblastomas. A single or double row of basaloid tumor cells is seen at the periphery of each island, while the center is composed of histiocytes and lymphocytes. Surgical excision is curative.

Trichilemmoma and Cowden Syndrome (Cowden's Disease, Multiple Hamartoma Syndrome)

Trichilemmoma is a benign neoplasm that differentiates toward cells of the outer root sheath. It may occur as a small solitary papule on the face, particularly the nose and cheeks. Most lesions are clinically misdiagnosed as BCC or benign keratosis.

Trichilemmomas may also occur as multiple facial lesions. When they do, it is a specific cutaneous marker for Cowden syndrome, an autosomal-dominantly inherited condition. Diagnostic criteria for Cowden syndrome have been established and certain of the mucocutaneous manifestations are considered "pathognomic." The trichilemmomas are generally limited to the head and neck; however, unusual sites may be involved. Eighty-seven percent of patients with Cowden syndrome have these facial papules (Fig. 29-48). Most consider all the facial papules variants of trichilemmoma, but some contend that some of the facial lesions are trichilemmomas and others are HPV-induced and contain epidermodysplasia-verruciformis HPV types. Since not all (acial papules have characteristic histology, the presence of "papillomatous" lesions is a diagnostic criteria. The other pathognomic mucocutaneous benign features include oral mucosal papillomas and acral keratotic papules. Some patients may lack cutaneous findings. Malignancies develop in up to 40% of patients with Cowden syndrome. They are major criteria (or the diagnosis and include breast, endometrial, and thyroid carcinoma. Macrocephaly and Lhermitte-Duclos disease are other major criteria. Although not criteria for the diagnosis, gastrointestinal malignancies also occur. Minor criteria included thyroid lesions (adenomas or goiter), mental retardation, fibrocystic disease of the breast, lipomas, fibromas (multiple sclerotic fibromas), and genitourinary tumors. The adult form of Lhermitte-Duclos disease, or

Fig. 29-48 Cowden syndrome.
dysplastic gangliocytoma of the cerebellum, may represent the neurologic manifestation of Cowden's disease. A number of mucocutaneous malignancies have been found in patients with Cowden's disease, including melanoma, BCC, SCC, Merkel cell carcinoma, and trichilemmal carcinoma. Mutations in a tumor suppressor gene (called PTEN) are responsible for Cowden syndrome. Another disorder caused in 60% of cases by mutations in PTEN is Bannayan-Riley-Ruvalcaba syndrome (autosomal-dominantly inherited, macrocephaly, genital lentigines, motor and speech delay, mental retardation, hamartomatous polyps, myopathies, lipomas, and hemangiomas). Some patients with a Proteus-like syndrome also have mutations in PTEN. These diseases have been called the "PTEN hamartoma tumor syndrome."

Microscopically, trichilemmomas show variable hyperkeratosis and parakeratosis. Tumor lobules extend downward from the epidermis and demonstrate glycogen-rich clear cells, peripheral palisading, and a thick hyalinized basement membrane.

Some have advocated bilateral simple mastecotomies in affected females to prevent the development of subsequent malignancies. Women with the syndrome who have lost many loved ones to breast cancer have not regarded this recommendation as excessive. With better screening techniques, this recommendation may be modified. Isotretinoin has been used to treat the cutaneous lesions, but even those that regress tend to recur when it is discontinued. Facial papillomas can be removed with surgical procedures, but new lesions continue to appear throughout life. Some patients get satisfactory cosmetic results from dermabrasion or CO₂ laser.

Trichilemmal Carcinoma

Trichilemmal carcinomas are reported to arise on sunexposed areas, most commonly the face and ears. They present as a slow-growing papule, indurated plaque, or nodule with a tendency to ulcerate. They may arise in the association of immunosuppression. It may be difficult to distinguish trichilemmal carcinoma from invasive Bowen's disease (which often shows adnexal differentiation) or a clear cell SCC. Surgical removal is recommended; Mohs micrographic surgery has been used successfully.

Trichodiscoma, Fibrofolliculoma, Perifollicular Fibromas, Mantleomas and Birt-Hogg-Dubé Syndrome

These benign tumors form a spectrum of neoplasms combining a follicular element and the specialized periadventitial dermis of the upper portion of the hair follicle. They may represent variations of the same tumor cut in different planes of section. All these lesions clinically appear as 2- to 4-mm, asymptomatic, skin-colored, dermal papules, affecting the face and upper trunk. They may be single, but are frequently multiple. When multiple, they are often numerous and are a marker for Birt-Hogge-Dubé syndrome (BHD). The histomorphology of these hair follicle tumors is identical in patients with BHD and in cases unassociated with BHD. Fibrofolliculoma demonstrates cords and strands of two to four cell epithelium eminating from a follicular structure. The epithelial elements may anastomose and sebaceous elements may be present. This follicular structure is surrounded by a collagenous or fibromucinous orb. Trichodiscomas represent a sectioning artifact that demonstrates only the tumor stroma.

BHD syndrome is caused by a mutation in the gene folliculin (FLCN) which is located on chromosome 17p. Many of the mutations occur in a hypermutable region of the gene. This gene is conserved in many species and expressed in many tissues, especially those with secretory function. Homozygous loss of function of the folliculin gene is embryonically lethal, suggesting it has important functions. In addition to the cutaneous lesions noted above, patients are at risk for the development of renal tumors and spontaneous pneumothorax. The renal tumor risk is seven times the general population and especially affects men (at twice the risk) and those over 40. Almost 12% of BHD patients over the age of 40 develop renal tumors. Renal tumors may be multiple and bilateral. BHD patients develop renal oncocytomas and chromophobe renal carcinomas, otherwise rare renal cancers. Persons with BHD have greater than 50 times the risk of developing a spontaneous pneumothorax compared

to unaffected persons. Pneumothorax is inversely related to age and young persons with BHD have a high risk of pneumothorax-17% of BHD patients under 40 will have a spontaneous pneumothorax. Spontaneous pneumothorax results from multiple pulmonary cysts, which affect 83% of BHD patients. Familial spontaneous pneumothorax is also an autosomal-dominant disorder and in at least one kindred was associated with a deletion in the folliculin gene. Colonic polyps and neoplasms, which were initially reported to be associated with BHD syndrome, have been shown not to be increased in BHD syndrome. However, microsatellite stable colonic polyps and carcinomas frequently have loss of heterozygosity for the region of chromosome 17p where the BHD gene is located. The BHD gene may thus be involved in colorectal tumor progression in sporadic colorectal carcinomas. BHD mutations have also been reported in spontaneous renal tumors. Inherited renal cancer in the German shepherd dog and rat is due to mutation in the BHD gene. Although they are often small and not cosmetically problematic, larger lesions in patients with BHD may be treated with laser therapy or shave excisions.

Other Hair Follicle Tumors

Dilated Pore (Winer) This lesion typically presents as a solitary, prominent, open comedo on the face or upper trunk of an elderly individual (Fig. 29-49). Histologically, it is composed of a markedly dilated follicular pore lined by outer root sheath epithelium. Multiple short bulbous, acanthotic projections extend from the central infundibulum-like pore.

Pilar Sheath Acanthoma Most often found on the face, particularly above the upper lip in adults, patients present with a solitary 5- to 10-mm skin-colored nodule with a central keratinous plug. Histologically, pilar sheath acanthoma differs from a dilated pore by having larger tumor lobules radiating from the central infundibulum-like pore.

Trichoadenoma Presenting as a solitary growth ranging from 3 to 15 mm in diameter, clinically it may be mistaken for a seborrheic keratosis, having a vegetative or verucous appearance. Although most frequently found on the face, it may occur at other sites, especially the buttock, which is the second most common location. Trichoadenomas also differentiate towards the follicular infundibulum. Histologically, they are quite distinctive, being composed of a collection of ring-like eosinophilic structures that often occur in pairs (resembling spectacles). No hair shafts are present.

Basaloid Follicular Harnartoma Basaloid follicular hamartoma (BFH) is a distinctive benign adnexal tumor that has four described variants: solitary papule, localized plaque of alopecia, linear or Blashkoid unilateral plaque, and generalized papules. This latter form has also been termed "generalized hair follicle hamartoma." Most often affecting the skin of the face and scalp, BFHs are solitary or multiple skincolored 2- to 3-mm papules or infiltrating plaques associated with progressive hair loss in the affected areas. Congenital and adult appearance has been described. In some generalized cases there is an association with alopecia, myasthenia gravis, and/or circulating autoantibodies (antinuclear and antiacetylcholine receptor antibodies). Cystic fibrosis and generalized follicular hamartomas have been reported in three siblings, suggesting a possible genetic linkage. A familial, autosomal-dominant form with numerous milia; comedolike lesions; hyperpigmented papules of the face, scalp, ears, neck and trunk; hypotrichosis; hypohidrosis; and pinpoint palmar pits has been described. It presents in early childhood.

Histologically, basaloid follicular hamartomas may be indistinguishable from infundibulocystic basal cell carcinoma. They are characterized by thin, branching eosinophilic strands and thick cords with associated basaloid buds and keratin cysts. Unlike most other pilar tumors, the stroma is loose, fibrillar, or mucinous. In nevoid and generalized forms, apparently normal skin may also demonstrate small islands of basaloid cells. Trichoblastomas may occur within nevoid lesions. PTCH gene signaling is upregulated in the cells contacting the dermis in BFH. Generalized basaloid follicular hamartoma syndrome must be distinguished from Bazex-Dupre-Christol syndrome, Brown-Crounse syndrome, Rombo syndrome, basal cell nevus syndrome, and Brooke-Spiegler syndrome. Its differentiation from multiple hereditary infundibulocystic basal cell carcinoma syndrome may be difficult.

Folliculosebaceous Cystic Hamartoma Folliculosebaceous cystic hamartoma is a benign hamartoma of epithelial and mesenchymal elements. It presents as a solitary 0.5- to 1.5-cm papule or nodule virtually always on the head, with two-thirds occurring on or adjacent to the nose. Rare giant lesions up to 15 cm in diameter have been reported. Age of onset ranges from infancy to the sixth decade. Histologically, the lesion is composed of three elements: an intradermal cystic structure lined by squamous epithelium identical to that of the infundibulum; numerous sebaceous lobules radiating from the cystic structure; and a surrounding stroma with fibrous, adipose, vascular, and neural tissues. Stromal spindle cells are positive for CD34. The tumor may represent a sebaceous trichofolliculoma biopsied during telogen phase.

Tumors of the Follicular Infundibulum These flat, keratotic papules of the head and neck are usually solitary but may be multiple. They appear in adulthood. The term eruptive infundibulomas and infundibulomatosis has been used to describe the cases with multiple lesions. In the rare generalized cases there is a strong clinical resemblance to Darier's disease, with accentuation on the neck, central chest, groin, and axillae. Histologically, the solitary and multiple cases are identical. There is a platelike proliferation of epidermal cells growing parallel to the epidermis and connecting to it at multiple sites. Clear gylogenated cells like that of a trichilemmoma, sebaceous differentiation, cystic and ductal structures, and papillary mesenchymal bodies may be seen.

EPITHELIAL CYSTS AND SINUSES

Epidermal Cyst (Epidermal Inclusion Cyst, Infundibular Cyst)

Epidermal inclusion cyst is one of the most common benign skin tumors. It presents as a compressible, but not fluctuant, cystic mass from a half to several centimeters in diameter (Fig. 29-50). The surface of the overlying skin is usually smooth and shiny from the upward pressure. These nodules are freely movable over underlying tissue and are attached to the normal skin above them by a comedo-like central infundibular structure or punctum. The pasty contents of the cysts are formed mostly of macerated keratin which has a cheesy consistency and pungent odor. Epidermal inclusion cysts occur most commonly on the face, neck, and trunk, but may be found almost anywhere. They frequently result from plugging of the follicular orifice, often in association with acne vulgaris. They may also occur by epidermal implantation. Deep penetrating injuries, such as with a sewing machine

Fig. 29-50 Epidermal inclusion cyst.

needle or stapler, may result in epidermoid cysts growing within bone. In pigmented races, the lining of the epidermoid cyst and its contents may be pigmented. Epidermoid cysts rarely appear before puberty and earlier onset should suggest an alternative diagnosis (e.g. pilomatrixoma, dermoid cyst, or Gardner syndrome). Lesions of the scalp are usually trichilemmal cysts. Rare cysts of the soles are due to infection by HPV-60.

Epidermoid cysts may rupture and induce a vigorous loreign body inflammatory response, after which they are firmly adherent to surrounding structures and are more difficult to remove. Rupture is associated with the sudden onset of redness, pain, swelling, and local heat, simulating an abscess. Incision and drainage will confirm the diagnosis of inflamed cyst, when the smelly, cheesy material is evacuated. This will also lead to rapid resolution of symptoms. These episodes are often misdiagnosed as "infection" of the cyst, but cultures are usually negative and antibiotic treatment is not required. Intralesional triamcinolone may hasten resolution of the symptoms.

The epidermoid cyst is a keratinizing cyst the wall of which is stratified squamous epithelium containing keratohyalin granules. It is differentiated from the pilar cyst by the different pattern of keratinization. Idiopathic scrotal calcinosis is the end stage of calcification of epidermoid cysts of the scrotum. Pilomatrical differentiation within an epidermoid cyst should raise a suspicion of Gardner syndrome.

Surgical excision is curative, but the complete cyst and any associated "daughter" cysts must be removed. Enucleation of the cyst through a small incision or a hole made with a 4or even a 2-mm biopsy punch may be attempted. A curette may be used to scrape out and snag all the fragments of the cyst wall. Inflamed cysts may also be treated in this way, but the inflammation makes complete removal of the cyst more difficult. If any fragment of the cyst wall is left behind, the cyst may recur.

Proliferating Epidermoid Cyst

These tumors derived from epidermoid cysts occur more commonly in men (64%) and the most frequent sites are the pelvic/anogenital areas (36%), scalp (21%), upper extremities (18%), and trunk (15%). Carcinomatous changes

on histology, with anaplasia, high mitotic rate, and deep invasion occur in up to 20% of cases. They are locally aggressive, but distant metastasis is rare. Malignant onycholemmal cyst may describe a rare slow-growing tumor arising from a subungual keratinous cyst.

Pilar Cyst (Trichilemmal Cyst, Isthmust-Catagen cyst)

The trichilemmal cyst, also known as a wen, is similar clinically to the epidermoid cyst except that about 90% of pilar cysts occur on the scalp (Fig. 29-51) and inheritance by the autosomal-dominant mode is common. It may be found rarely on the face, trunk, and extremities. An overlying punctum is not present and lesions tend to be more mobile and firmer than epidermoid cysts. Hereditary trichilemmal cysts link to the short arm of cbromosome 3, but not to β -catenin or MLH1.

The trichilemmal cyst is lined by stratified squamous epithelium which is derived from the outer root sheath. The lining cells demonstrate trichilemmal keratinization, increasing in size as they approach the cyst cavity and abruptly keratinizing without forming a granular cell layer. The cyst contents are homogenous and commonly calcify. Hybrid cysts with features of both an epidermoid cyst and pilar cyst can be seen. Treatment is the same as that for the epidermoid cyst. They are much more easily enucleated, so more limited incision is required to remove the lesion.

Proliferating Trichilemmal Cyst/Malignant Trichilemmal Cyst

There is a spectrum of lesions from typical pilar cysts with focal areas of epithelial proliferation to solid proliferating growths with atypia that are best considered SCCs. They are large (up to 25 cm), exophytic neoplasms confined almost exclusively to the scalp and back of the neck. They are approximately five times more common in women and the mean age of patients is 65 years. They gradually enlarge and may undergo ulceration (Fig. 29-52). The vast majority of lesions are cured by local excision. Some lesions may recur and less commonly be locally aggressive. In rare cases, local invasion or metastases occurs, resulting in death.

Proliferating trichilemmal cysts are composed of proliferations of squamous cells with trichilemmal differentiation forming scroll-like structures or small cysts. Lesions are usually well-circumscribed. Focal cellular atypia, mitoses, and necrosis may be present and do not necessarily predict aggressive behavior. Cases with aggressive growth and metastases usually have cytologic atypia as well as an invasive growth pattern. The presence of a clearly benign component and a second anaplastic component growing outward suggests the development of a carcinoma. Proliferating pilar cysts and their malignant counterparts express hair cytokeratins (cytokeratin 7) and malignant trichilemmal tumors express CD34, suggesting fetal hair root phenotype and trichilemmal differentiation.

Dermoid Cyst

Cutaneous dermoid cysts, also called congenital inclusion dermoid cysts, result from local anomalies in embryonic development and occur along embryonic closure zones. On the face they occur above the lateral end of the eyebrow (external angular dermoid) (Fig. 29-53), at the nasal root, along the midline of the forehead, over the mastoid process on the floor of the mouth, and anywhere along the midline of the scalp from the frontal to the occipital region. They may also be found on the chest, back, abdomen, and perianally. Nasal and external angular dermoids may be seen in multiple members of a family, suggesting a genetic component. Lesions usually present within the first year of life, although only 70% of lesions have been identified by age 5 years. The typical lesion is a few millimeters to several centimeters in diameter and located in the subcutaneous fat. A tethering to the underlying tissues and an underlying bony defect may be noted. They are nonpulsatile, firm, and cystic, and do not transilluminate. A punctum or opening to the skin surface may sometimes be present, but they are commonly not attached to the overlying skin. Inflammation of the cyst due to rupture or infection may first bring the patient to the physician. Since the dermoid may connect to underlying structures, including the pleura and CNS, infection may spread to the CNS or lungs, causing potentially serious infections. Patients with spina bifida frequently develop dermoid cysts of the repaired portion of their spinal column. Dermoids overlying the lower spine may be associated with tethered cord and late development of ambulating difficulties.

Histologically, the cyst wall is lined with keratinizing

Fig. 29-52 Pilar cyst, proliferating type.

Fig. 29-53 Dermoid, cystic nodule of the lateral eyebrow.

stratified squamous epithelium containing skin appendages, including lanugo hair. Portions of the cyst lining may demonstrate a wavy eosinophilic (shark tooth) pattern like that of a steatocystoma.

In a child, attempts at surgical removal or biopsy of a cyst over cleavage planes (including along the midline of the back) should not be attempted without proper assessment to rule out a intraspinal or intracranial communication. A CT scan or magnetic resonance imaging (MRI) is required to rule this out. Any underlying bony changes detected by CT scan should be followed up with an MRI scan, since the cranial penetration by the cyst may at times be difficult to identify by CT scan. If an intracranial connection is detected, the patient should be referred to a neurosurgeon.

Pilonidal Sinus

Pilonidal cyst or sinus occurs in the midline sacral region at the upper end of the cleft of the buttocks. A pit may be all that is visible before puberty. Pilonidal cysts/sinuses usually become symptomatic during adolescence. The lesion becomes inflamed due to rupture or, less commonly, infection. Pilonidal sinus/cyst often occurs with nodulocystic acne, dissecting cellulitis, and hidradenitis suppurativa (the acne tetrad). Histologically, the cyst/sinus is lined by stratified squamous epithelium of the type seen in normal epidermis or follicular infundibulum. Some pilonidal cysts/sinuses are composed of epithelium which keratinizes without formation of a granular cell layer, analogous to outer root sheath. Referral to a general surgeon is recommended, as recurrences following simple cystectomy and marsupialization. SCCs have been reported to arise from chronic inflammatory pilonidal disease.

Kurokawa I, et al: Cytokeratin expression in pilonidal sinus. Br J Dermatol 2002;146:409.

Steatocystoma Simplex

Solitary steatocystoma (simple sebaceous duct cyst, steatocystoma simplex) occurs with equal frequency in adult women and men and can occur on the face, trunk or extremities. The oral mucosa may also be involved. It is not familial, and solitary lesions are much less common than multiple ones. The cysts are usually 0.5 to 1.5 cm in size, although rarely solitary steatocystomas over 8 cm have been reported. The cyst contains an oily, yellow fluid and may contain vellus hairs. Histologically, the cyst is lined by stratified squamous epithelium. Small, mature, sebaceous lobules are present along the cyst wall and empty into the cyst. The luminal surface of the cyst is eosinophilic, wavy (shark tooth pattern), and ribbon-like, analogous to the sebaceous duct. "Hydrid" cysts may have portions of their lining of the steatocystoma type, with the other portions resembling pilar cyst, epidermoid cyst, or even pilomatrixoma. Simple excision is curative.

Steatocystoma Multiplex

Steatocystoma multiplex consists of multiple, uniform, yellowish, cystic papules 2 to 6 mm in diameter, located principally on the upper anterior portion of the trunk (Fig. 29-54), upper arms, axillae, and thighs. The lesions lack a punctum. Lesions usually appear in adolescence or early adulthood, when sebaceous activity is at its peak. In severe cases, the lesions may be generalized, with sparing only of the palms and soles. At times the lesions may be limited to the face or scalp, a distinct form termed the facial papular variant. Congenital and adolescent onset linear lesions have rarely been reported. Steatocystoma may be larger (up to 2 cm) and prone to rupture and suppuration (steatocytoma multiplex suppurativum). If these lesions are widespread, the condition can be very disfiguring. Steatocytomas contain a syrup-like, yellowish, odorless, oily material. In the suppurative type, as in hidradenitis suppurativa, colonization with bacteria can occur, leading to foul odor and social isolation.

Histologically, the lining of the cyst is stratified squamous epithelium with the cyst lining containing mature sebaceous

Fig. 29-54 Steatocystoma multiplex.

glands. The epithelial lining is identical to the sebaceous duct. In some instances, hair follicles occur in the cyst wall and vellus hairs may be present in the cavity. A relationship with eruptive vellus hair cysts has been suggested because of a similar clinical appearance, time of onset, and overlapping histologic features. It has been proposed that these clinical entities are a spectrum of the same disease process and should be classified as multiple pilosebaceous cysts.

Steatocystoma multiplex is often familial, demonstrating an autosomal-dominant mode of inheritance. Sporadic cases are not uncommon, however. Keratin 17 missense mutations occur in familial (but not sporadic) steatocytoma multiplex, usually in a hypermutable site of exon 1 of the gene (the helix initiation motif). Keratin 17 is specialization keratin expressed in the nailbed, hair follicles, and sebaceous glands. This same genetic mutation also causes pachyonychia congenita type 2 (PC-2). This form of pachyonychia congenita has milder keratoderma, but also natal teeth, pili torti, angular chelosis, and hoarseness. These patients have multiple cysts, some of which are steatocystomas and some eruptive vellus hair cysts. Milia, flexural abscesses identical to hidradenitis, and scrotal and vulvar cysts can also be seen in these kindreds. Hybrid cysts may occur. It is unclear why patients with hereditary steatocytoma multiplex and keratin 17 mutations identical to those seen in PC-2 have no other stigmata of PC-2.

The definitive treatment of individual lesions is excision. However, the sheer number of the cysts usually precludes this type of treatment. In such instances, incision and complete expression of the cyst contents or aspiration using an 18-gauge needle may be effective in temporarily reducing the lesions. Laser incision of the cysts may also be effective. They may remain clinically improved for many months; however, eventual recurrence is the rule. For inflammatory and noninflammatory lesions, cryotherapy has been reported as beneficial. Isotretinoin orally at a dose of 0.75 to 1 mg/kg has been reported to benefit the suppurative variant of steatocystoma. Long-term follow-up has not been reported.

Eruptive Vellus Hair Cysts

Eruptive vellus hair cysts (EVHCs) appear as multiple (up to hundreds) of 1- to 4-mm skin-colored or hyperpigmented dome-shaped papules of the mid-chest and proximal upper extremities. They may be congenital but usually have their onset between ages 17 and 24. Disseminated lesions have been reported. Hidrotic and anhidrotic ectodermal dysplasia have been associated with EVHC. As noted above, there is debate as to whether steatocystoma multiplex and EVHC are distinct entities. Clinically, EVHCs tend to be smaller than steatocystomas and may have an area of central hyperkeratosis or umbilication, a feature lacking in steatocystoma. Histologically, the cystic epithelium is of the stratified squamous type; the cyst contents are composed of laminated keratin and multiple vellus hairs, and follicle-like invaginations may be present in the cyst wall. Treatment is surgical, with laser or needle evacuation.

Milia

Milia are white keratinous cysts, 1 to 4 mm in diameter, appearing chiefly on the face, especially on the eyelids. They are white and easily seen as cystic through the overlying attenuated skin. Multiple lesions are common, especially in middle-aged women. They occur in up to 50% of newborns.

Primary milia develop without a predisposing condition and are most commonly found in adults or during the newborn period. Secondary milia can develop as a consequence of blistering skin diseases, such as epidermolysis bullosa, pemphigus, bullous pemphigoid, porphyria cutanea tarda, herpes zoster, and contact demnatitis. They also tend to occur after trauma, such as dermabrasion. Long-term topical corticosteroid therapy and the use of occlusive moisturizers may result in the appearance of milia.

Multiple milia have been reported in a number of genodermatoses, such as congenital ectodermal defect; reticular pigmented genodermatosis with milia (Naegeli-Franceschetti-

Jadassohn syndrome); congenital absence of dermal ridges, syndactyly, and facial milia; Rombo syndrome; and Bazex syndrome.

Idiopathic multiple eruptive milia describes the appearance of multiple widespread milia over weeks to months. Rare familial cases have been reported. The etiology of this condition is unknown. Milia en plaque presents with grouped milia forming a plaque. It can affect the face (especially the periauricular area) (Fig. 29-55), trunk, or extremities. Milia en plaque has been reported in association with pseudoxanthoma elasticum, renal failure and chronic cutaneous lupus erythematosus. The cause of Milia en plaque is unknown.

Primary milia are small epidermoid cysts, derived from the infundibulum of the vellus hair. Like epidermoid cysts, they are fixed and persistent. Secondary milia may be derived from eccrine ducts or hair follicles as they attempt to re-epithelialize eroded epidermis. They are often transient and spontaneously disappear. Milia must be distinguished from milia-like idiopathic calcinosis cutis, military osteomas, syringomas with milia-like structures, trichoepitheliomas, comedonal acne, flat warts, and xanthelasma. Lesions of cutaneous T-cell lymphoma with prominent follicular mucinosis may have many milia. Milia can occur on the nasal crease in preadolescent children with allergic rhinitis who frequently rub their noses. These milia may rupture and simulate acne vulgaris. This has been termed "pseudoacne of the nasal crease."

Treatment is incision and expression of the contents with a beveled cutting tipped hypodermic needle, 11 blade, or comedo extractor. No anesthesia is needed for most patients. Topical tretinoin (Retin-A) has been reported as effective in treating milia en plaque and more generalized forms of milia involving the face. Minocycline has been used to treat milia en plaque.

Verrucous Cysts (Cystic Papillomas)

Verrucous cysts resemble epidermoid cysts, except that the lining demonstrates papillomatosis and coarse hypergranulosis. Koilocytes may be present. On the sole, red granules resembling those in myrmecia are commonly seen. They have been shown to contain HPV and probably form as a result of HPV infection of a follicular unit or sweat duct (see Chapter 19).

Pseudocyst of the Auricle (Auricular Endochondral Pseudocyst)

Pseudocyst of the auricle clinically presents as a fluctuant, tense, noninflammatory swelling on the upper half of the ear. Most affected persons are between the ages of 20 and 45 and up to 90% are male. While it may be associated with trauma, especially rubbing due to pruritus, patients frequently deny trauma. Microtrauma or an embryologic defect in the cartilage may play a role. The fluid collection is between the two layers of the bilaminate cartilage of the pinna. There is no cyst lining, with the affected cartilage showing focal degeneration and granulation tissue. Needle aspiration yields serous or bloody fluid. Simple aspiration is ineffective. Aspiration or drainage followed by the application of a bolster or pressure dressing for several weeks is usually effective. Since application of pressure for several weeks is required, a sutured-on bolster with buttons or gauze is easier for the patient than an externally applied dressing. Intracystic injections of corticosteroids, fibrin glue, or minocycline have been used in recurrent cases. Surgical intervention involves removal of the thinner anterior portion of the cyst.

Cutaneous Columnar Cysts

Five types of cysts that occur in the skin are lined by columnar epithelium. *Bronchogenic cysts* are small, solitary cysts or sinuses, most typically located in the region of the suprasternal notch or over the manubrium sterni. They also can occur on the chin, neck, shoulder region, and abdominal wall. Boys are four times more commonly affected than girls. Lesions are typically subcutaneous and rarely connect to deeper structures. Histologically, the cyst is composed of a wall lined by respiratory epithelium and may contain seromucinous glands and underlying fibromuscular connective tissue or cartilage.

Branchial cleft cysts present as cysts, sinuses, or skin tags along the anterior border of the sternocleidomastoid muscle or near the angle of the mandible (Fig. 29-56). Branchial cysts are lined primarily with stratified squamous epithelium. Lymphoid (ollicles are often present and smooth muscle is absent, distinguishing them from bronchogenic cysts, although some evidence suggests that these cysts are related.

Thyroglossal duct cysts virtually always occur on the anterior portion of the neck, near the hyoid bone. They

Fig. 29-56 Brachial cleft cyst.

present as a sinus, cyst, or recurrent abscess of the neck. They are the most common cause of congenital neck anomalies in childhood. Presentation in adult life can occur. Malignancies (papillary adenocarcinoma, follicular adenocarcinoma, mixed papillary/follicular adenocarcinoma, adenocarcinoma, and SCCs) arising from cysts have been reported in 1% of cases. Clinically, thyroglossal duct cysts are deep to subcutaneous tissue and usually are not managed by dermatologists.

Cutaneous ciliated cysts are usually solitary and located on the legs of females. Men account for only 10% of cases. They have also been described in the perineum and vulva (vulvar ciliated cysts). The epithelium lining the cysts is cuboidal to columnar with pseudostratified areas. Cilía are seen and the lining cells stain strongly for dynein. This histology is similar to the normal fallopian tube, suggesting the cysts are of müllerian origin. Ciliated metaplasia of eccrine duct has been proposed for those lesions occurring on the upper half of the body and in men. Like the median raphe cyst, the cavity is often filled with debris.

Median raphe cysts of the penis are developmental defects lying in the ventral midline of the perineum from the anus to the urethra, but most commonly on the distal shaft near the glans. They most commonly present as less than 1-cm dermal lesions in young men and may appear suddenly after sexual intercourse-associated trauma. These cysts are lined by pseudostratified columnar epithelium with focal areas of mucin secreting epithelium present. Ciliated cells may be present and, like ciliated cysts in females, the cavity is typically filled with debris. Melanocytes may occasionally be present in the cyst wall giving the cysts a pigmented appearance. Median raphe cysts do not stain with human milk fat globulin 1, distinguishing them from apocrine cystadenomas. All these forms of cysts are treated with surgical excision.

CONGENITAL PREAURICULAR FISTULA

This anomaly occurs as a pit in the preauricular region, often in several members and generations of a family. On each side, just anterior to the external ear, there is a small dimple, pore, or fistulous opening that may extend even into the middle ear. Most are benign and do not require surgery. Complications of surgery are frequent, and complete excision of both the pit and sinus tract should be the goal if surgery is attempted.

CHAPTER

Melanocytic Nevi and Neoplasms

Melanocytes originate in the embryonal neural crest and migrate to the epidermis, dermis, leptomeninges, retina, mucous membrane epithelium, and inner ear, cochlea, and vestibular system. Nevus cells are a form of melanocyte with a tendency to aggregate into clusters of cells. They lack dendritic processes, but are otherwise similar to other melanocytes.

EPIDERMAL MELANOCYTIC LESIONS

The melanocytes occurring at the dermoepidermal junction are dendritic cells that supply melanin to the skin. These cells contain pigment granules (melanosomes). They stain with the dopa reaction and silver stains because they contain melanin. Immunohistochemical stains, such as S100, HMB-45 and Mart-1, do not depend on the presence of melanin. These stains have largely replaced silver stains for the identification of melanocytes in biopsy specimens. Melanocytes of the epidermis transfer melanosomes through their thin dendritic processes, where they are actively taken up by keratinocytes. Melanocyte numbers vary by anatomic site and are increased in sun-damaged skin, but vary little among racial groups. The type, number, size, dispersion, and degree of melaninizatin of the melanosomes determine the pigmentation of the skin and bair.

Treatment of epidermal pigmented lesions can be directed at pigmented keratinocytes, melanocytes or melanosomes. Q-switched lasers target the melanosome. Lasers with a longer pulse duration lasting milliseconds result in melanocyte destruction. Laser treatment produces consistent lightening of ephelides, but the response is variable for café-aulait macules, Becker nevus, and nevus spilus.

Dierickx CC: IL-37 Lasers in pigmentary disorders. Pigment Cell Res 2003;16:590.

Ephelis

The common freckle occurs in light-skinned individuals in response to sun exposure. Histologically, they demonstrate pigmented basilar keratinocytes, and a mild increase in the number of melanocytes.

Nevus Spilus

Nevus spilus (speckled lentiginous nevus) presents as a light brown or tan macule, speckled with smaller, darker macules or papules (Fig. 30-1). It frequently occurs on the trunk and lower extremities, and is noted in approximately 2% of the population.

The nevus spilus may be small, measuring less than 1 cm in diameter, or may be quite large and follow a segmental distribution, referred to as a *zosteriform lentigo*. Multiple sites may be involved in the same individual, and may be widely separated by normal skin.

Nevus spilus in combination with a nevus flammeus is called *phakomatosis pigmentovascularis* (see Chapter 28). Phakomatosis pigmentokeratotica includes a speckled lentiginous nevus, organoid nevus, hemiatrophy, and neurologic findings such as muscular weakness. Generalized nevus spilus has been associated with nevus anemicus and primary lymphedema.

Histologically, the flat, tan background may show only basilar hyperpigmentation, such as is present in a café-au-lait spot, or lentiginous proliferation of the epidermis with bulbous rete ridges. The darker speckles usually contain nevus cells and may occasionally demonstrate blue nevi or Spitz nevi.

Because nevus cells are often present in the dark speckles, melanoma may rarely arise in them. A changing lesion should be biopsied. Removal by Q-switched (QS) ruby laser or QS alexandrite laser rarely has been reported as effective, but may require many sessions for acceptable results.

Lentigo

Lentigo Simplex These lesions occur as sharply defined, round to oval, brown or black macules. The lesions usually arise in childhood but may appear at any age. There is no predilection for areas of sun exposure.

Histologically, lentigo simplex shows hyperpigmentation of basilar keratinocytes and an increase in the number of melanocytes in the basal layer. Melanophages are commonly present in the upper dermis.

Solar Lentigo (Lentigo Senilis) Solar lentigines are commonly known as *liver spots*. They are persistent, benign, discrete, hyperpigmented round-to-oval macules occurring on sun-damaged skin. The backs of the hands, cheeks, and forehead are favorite sites in the typical older patient. Redhaired, light-skinned individuals, especially those with high solar exposure, may develop many of these on the shoulders and central upper chest, even at an early age. Solar lentigines may be accompanied by depigmented macules, actinic purpura, and other chronic actinic degenerative changes in the skin. They may evolve into benign lichenoid keratoses and reticulated seborrheic keratoses.

Histologically, the rete ridges appear club-shaped or show narrow, budlike extensions. There is a marked increase in pigmentation in the basal cell layer, especially at the tips of the bulbous rete. The number of melanocytes is slightly increased, and the upper dermis often contains melanophages.

Application of liquid nitrogen with a cotton-tip applicator or cryospray unit is often effective. Argon, Q-switched Nd:YAG, frequency doubled Nd:YAG, Q-switched alexandrite, Qswitched ruby, and Er:YAG lasers have been reported as effective.

Sun protection will reduce the number of new lesions. Bleaching creams containing 4% or 5% hydroquinone, used over a period of several months, will induces temporary lightening. Hydroquinone-cyclodextrin (2%), 4-hydroxyanisole (4-HA), chemical peels, local dermabrasion, topical tretinoin, and adapalene are other treatment options. The combination of 2% 4-HA and 0.01% tretinoin is superior to either active component alone.

Early lesions of lentigo maligna (melanoma in situ) may be light-to-medium brown and mimic solar lentigines. When in doubt, a biopsy is appropriate. Lentigo maligna, benign solar lentigo, and pigmented actinic keratosis all occur on sundamaged skin, and collision lesions are common. If a lesion is not homogeneous clinically, representative biopsies should be taken from each area.

PUVA Lentigines Individuals receiving oral methoxsalen photochemotherapy (PUVA) may develop persistent pigmented macules in which there may be melanocytic atypia. These lesions may occur on sites that are normally protected from sunlight. High-dose single exposures to radiation may result in similar radiation lentigines in exposed skin.

Ink Spot Lentigo (Sunburn Lentigo) These lesions commonly occur on the shoulders as small markedly irre-

gular, reticulated, dark gray-black macules resembling spots of ink on the skin. Histologically, there is a mild increase in the number of melanocytes and increased melanin in both the basilar keratinocytes and the stratum corneum.

Labial, Penile, and Vulvar Melanosis (Melanotic Macules, Mucosal Lentigines) Melanotic macules are usually light brown on the oral labial mucosa, but may be strikingly irregular and darkly pigmented in the genitalia. In females, the labia minora are most often affected, while in males, the glans and prepuce are most frequently involved. Histologically, these lesions demonstrate broad "box car" rete ridges with prominent basilar hyperpigmentation, and a normal to slightly increased number of melanocytes. The melanocytes are usually morphologically normal.

Multiple Lentigines Syndrome The lesions appear shortly after birth and develop a distinctive speckled appearance that has given rise to the designation LEOPARD syndrome. LEOPARD is Gorlin's mnemonic acronym for lentigines, electrocardiographic abnormalities, ocular hypertelorism, pulmonary stenosis, abnormalities of genitalia, retardation of growth, and deafness. Inheritance is autosomal dominant. Multiple lentigines occur mainly on the trunk, but other areas may also be involved, such as the palms and soles, buccal mucosa, genitalia, and scalp. PTPN11 gene mutations are seen in both LEOPARD syndrome and Noonan syndrome.

Moynahan Syndrome Moynahan syndrome consists of multiple lentigines, congenital mitral stenosis, dwarfism, genital hypoplasia, and mental deficiency.

Generalized Lentiginosis An occasional patient will have generalized lentiginosis without associated abnormalities.

Centrofacial Lentiginosis Centrofacial lentiginosis is characterized by lentigines on the nose and adjacent cheeks, variously associated with status dysraphicus, multiple skeletal anomalies, and central nervous system (CNS) disorders. Mucous membranes are spared. Onset is in the first years of life. Lentigines of the central face are also typical of Carney complex.

Carney Complex Carney complex is also known as NAME syndrome and LAMB syndrome. This designation comprises cardiocutaneous myxomas, lentigines, blue nevi, and endocrine abnormalities. It is discussed in more detail with myxomas in Chapter 28.

Inherited Patterned Lentiginosis in Black Persons O'Neill and James reported 10 light-complexioned black patients with autosomal-dominant lentigines beginning in infancy or early childhood, but no internal abnormalities (Fig. 30-2). The lentigines were distributed over the central face and lips, with variable involvement of the dorsal hands and feet, elbows, and buttocks. The mucous membranes were spared.

Partial Unilateral Lentiginosis Partial unilateral lentiginosis is a rare disorder of cutaneous pigmentation characterized by the presence of multiple simple lentigines, wholly or partially involving half of the body. Conjunctival involve-

Flg. 30-2 Inherited patterned lentiginosis of Black persons.

Fig. 30-3 Becker nevus.

also been associated with connective tissue nevus and phakomatosis pigmentovascularis.

Hsu S, et al: Becker's melanosis in a woman. J Am Acad Dermatol 2001;45(6 Suppl):S195.

MELANOACANTHOMA

Cutaneous melanoacanthoma is an uncommon lesion first described by Bloch. Clinically, it resembles a pigmented seborrheic keratosis or pigmented basal cell carcinoma, and tends to occur in older white males. Histologically, it is a benign epidermal neoplasm composed of keratinocytes and dendritic melanocytes. It is best considered a form of seborrheic keratosis.

Oral melanoacanthoma is also a proliferation of two cell types, melanocytes and epithelial cells, but appears to be a reactive lesion. It occurs as a macular or slightly raised pigmented area on the buccal mucosa, predominantly in adult black women. Rapid onset and spontaneous resolution is typical.

Fornatora ML, et al: Oral melanoacanthoma: a report of 10 cases, review of the literature, and immunohistochemical analysis for HMB-45 reactivity. Am J Dermatopathol 2003;25:12,

BENIGN MELANOCYTIC NEVI

Common moles, also known as a *nevocytic nevi* or *banal nevi* tend to increase in number during the first three decades of life. They are less common in doubly covered areas, such as the buttocks. They typically begin as sharply defined macular lesions, become papular, then gradually become soft and loose their pigment.

Sun exposure increases the number of moles in the exposed skin. Habitual sun exposure is more significant than intermittant exposure. Australians have more moles than Europeans. White persons have more than black persons, and individuals with a light complexion have more nevi than those with a dark complexion. Women have more total nevi and more nevi on the legs. Men have more on the trunk. Black persons have more nevi on the palms, soles, conjunctivae, and nailbeds.

Eruptive nevi may occur in association with bullous diseases, severe sunburn, immunosuppression, or sulfur mustard gas exposure. The cheetah phenotype refers to patients with more than 100 uniform dark-brown to black pigmented

ment has been reported. Agminated lentiginosis appears to be a similar if not identical entity.

Peutz-Jeghers Syndrome Peutz-Jeghers syndrome is an autosomal-dominant syndrome consisting of pigmented macules on the lips, oral mucosa, and perioral and acral areas. Gastrointestinal polyps, especially prominent in the jejunum, are frequently associated. It is discussed further under disorders of pigmentation in Chapter 36.

Becker nevus

Becker nevus presents as a hyperpigmented, hypertrichotic patch on the upper trunk (Fig. 30-3) or proximal upper extremity. The lesion usually begins before puberty, and almost all patients are males. The lesion may be associated with a smooth muscle hamartoma on histology. Lesions have macules 4 mm or smaller. The evaluation of these patients can be challenging, as similar-appearing lesions range from junctional nevi to melanoma histologically.

Melanocytic lesions with a junctional component are more commonly removed during the summer months, while excision of intradermal nevi is relatively constant during the year. This suggests that some change in these lesions draws more attention during the summer months.

Clinical and Histologic Features

Features of benign nevi include a diameter of 6 mm or less, perfectly uniform pigmentation, flaccid epidermis, smooth, uniform border, and an unchanging size and color. Benign nevi tend to be round to oval, and undergo a predictable course of maturation.

Junctional nevi are smooth brown macules, varying in diameter from 1 to 6 mm. They usually appear between 3 and 18 years of age. During adolescence and adulthood, some become compound or intradermal. Small, well-nested junctional melanocytic proliferations are almost invariably benign. Benign junctional nevi associated with bulbous hyperplasia of the rete ridges are referred to as junctional lentiginous nevi. Lentigo maligna can appear well nested with an appearance similar to that of junctional lentiginous nevi. Any broad junctional melanocytic lesion on sundamaged skin should be viewed with suspicion.

Compound nevi demonstrate both junctional and intradermal melanocytes. Benign compound nevi are well nested at the junction, with dispersion of individual melanocytes at the base of the lesion. They demonstrate bilateral symmetry, but are not symmetrical from top to bottom. Instead, with descent into the dermis, the melanocytes become smaller and spindled in appearance. Nests at the junction tend to be round to oval and are roughly equidistant from one another. Dermal nests are generally smaller than the junctional nests, and become progressively smaller deeper in the dermis. Individual cells rather than nests are present at the base. Pigment is most prominent at the junction, and becomes progressively less prominent deeper in the dermis. Intradermal nevi look similar to compound nevi without the junctional nests.

In most benign nevi, there are no melanocytes above the dermoepidermal junction. Individual melanocytes in a "buckshot" scatter throughout the epidermis are typical of superficial spreading melanoma. Sunburned benign nevi may demonstrate buckshot intraepidermal scatter of melanocytes. Buckshot scatter may also be seen in the central portion of acral nevi and Spitz nevi.

On the palms and soles, the rete pattern follows the dermatoglyphs (Fig. 30-4). Nests in these locations tend to run along the rete ridges. If a benign palmar nevus is bisected across the dermatoglyphs, the nests will appear round to oval. If the same lesion is sectioned parallel to the dermatoglyphs, the nests will appear elongated and may mimic those of melanoma as an artifact of sectioning. Careful communication with the pathologist is essential when submitting an acral melanocytic lesion to the laboratory.

Malignant Degeneration

Almost half of melanomas occur in preexisting nevi, and an increased number of nevi represents a risk factor for melanoma. The signs of malignant transformation in pigmented nevi are recent enlargement, an irregular or scalloped border,

Flg. 30-4 Acral nevus.

asymmetry, changes or variegation in color (especially red, white, or blue), surface changes (scaling, erosion, oozing, crusting, ulceration, or bleeding), development of a palpable thickening, signs of inflammation, or the appearance of satellite pigmentation. Symptoms may include development of pain, itch or tenderness. The "ugly duckling" sign refers to the fact that nevi in an individual generally tend to share a similar appearance, so one that does not share the same characteristics should be considered for biopsy. Moles with small dark dots that do not lie entirely within the lesion, but produce a small extension beyond the border, may represent melanoma arising in association with a preexisting nevus. The clinician should alert the pathologist about these dots and the pathologist should section through the appropriate area. Perifollicular hypopigmentation is a common finding in benign nevi. When it occurs at the edge of the nevus it may give the lesion a notched appearance. Dermatoscopic exam may be of value in this setting.

Nevi commonly darken with pregnancy or with oral contraceptive use. Nevi from normal persons have no estrogen or progesterone receptors, but there may be positive estrogen receptor binding in nevi from pregnant women, as is also found in malignant melanoma. The development of what appears to be a new pigmented nevus in a patient over 35 years of age should alert the physician to possible melanoma, as patients without the dysplastic nevus syndrome usually do not develop new nevi at this age.

Treatment

Acquired nevi should be removed if they show signs of malignant transformation. Nevi of the neckline, beltline, or other areas that are irritated may be removed to relieve the patient of the irritation. Nevi may also be removed if they are in a location where it is impractical to observe them. If a solitary darkly pigmented lesion is present on the oral or genital mucous membrane, a biopsy should be performed, because nevi are uncommon in these locations. Nail matrix nevi and lentigines produce a pigmented nail band. The proximal matrix gives rise to the dorsal nail plate, and the distal matrix gives rise to the ventral nail plate. When the nail is observed end-on, the level of the pigment may be evident, and indicates the location of the pigmented lesion in the matrix. A widening band indicates a matrix lesion increasing in diameter. Biopsy of a solitary expanding acquired longitudinal pigmented band in an adult is typically necessary to ascertain the cause. Hutchinson's sign (pigmentation of the nailfold) is an indicator of melanoma. Nail matrix melanoma in children is exceptional.

Conjunctival nevi occur, and most can be serially followed if the lesion has been present since childhood or has shown no evidence of growth. Changing pigmented lesions and those acquired after childhood are best evaluated by an ophthalmologist or other physician skilled in the evaluation of ocular pigmented lesions. Most conjunctival nevi occur on the bulbar conjunctiva and commonly abut the nasal or temporal corneoscleral limbus. Suspicion of melanoma should arise if a pigmented lesion occurs in the palpebral or forniceal conjunctiva, if they are not hinged at the limbus and are immovable, if they extend into the cornea, if there is canalicular obstruction that leads to tearing, or if adjacent dilated vessels are noted.

Combined melanocytic nevi are common. They consist of a banal nevus together with a blue nevus, Spitz nevus or deep penetrating nevus. Two or more distinct populations of melanocytes are evident.

Melanocytic nevi may occur in lymph nodes and are present in about 10% of sentinel node biopsies. Nodal nevi typically occur in the capsule, in contrast to melanoma metastases which are typically subcapsular. Nodal nevi are commonly associated with cutaneous nevi in the draining basin, especially nevi with congenital features.

Pseudomelanoma (Recurrent Nevus)

Melanotic lesions clinically resembling a superficial spreading melanoma may occur at the site of a recent shave removal of a melanocytic nevus. Melanocytic nevi occurring in areas of lichen sclerosus or bullous disease often have similar features. Histologically, the junctional component often demonstrates a predominance of non-nested melanocytes, confluence of nests, and nests that vary in size and shape. The presence of a superficial dermal scar with remnants of the original nevus beneath this zone of fibrosis is an important clue to the correct diagnosis. Although atypical in appearance, the junctional proliferation remains entirely confined to the area overlying the scar.

Recurrent Spitz nevus is a particular problem because many of the histologic features of benign Spitz nevi overlap with those of melanoma. In benign recurrent Spitz nevi, the dermal component typically retains cytologic maturation, dispersion at the base of the lesion, and an immunostaining pattern typical for benign nevi. Recurrent blue nevi also present special difficulties. High cellularity, cellular pleomorphism, mitotic figures, and a lymphoid host response may be present. In the absence of marked cytologic atypia, frequent mitotic figures or necrosis en mass, the lesions are likely to be benign. Because of the special problems posed by recurrent Spitz and blue nevi, the initial biopsy of these lesions should be a complete excisional biopsy whenever possible.

Balloon Cell Nevus

Clinically, balloon cell nevi are indistinguishable from ordinary nevi. Histologically, they are composed of large, pale, polyhedral balloon cells. Generally, foci of ordinary nevus cells are also evident. Rarely, the lesions are composed entirely of balloon cells. Balloon cell change has been reported in cellular blue nevus as well. Balloon cell melanoma does exist, but the nuclei are large and pleomorphic, and the architecture of the lesion is that of melanoma.

Perez MT, et al: Balloon cell change in cellular blue nevus. Am J Dermatopathol 1999;21:181.

Halo Nevus

Halo nevus is also known as *Sutton nevus*, *perinevoid vitiligo*, and *leukoderma acquisitum centrifugum*. The lesions are characterized by a pigmented nevus with a surrounding depigmented zone (Fig. 30-5). Halo nevi tend to be multiple and occur most frequently on the trunk, mostly in teenagers. The central nevus gradually loses its pigmentation, turns pink, then disappears leaving a round-to-oval area of depigmentation. Over time, the area repigments. Darkening of the central nevus rather than lightening has also been reported in association with the halo phenomenon.

The infiltrate contains many cytotoxic T-cells, and may represent immunologically-induced rejection.-The peripheral

Fig. 30-5 Halo nevus.

blood has been shown to contain activated adhesive lymphocytes that disappear when the lesion is excised. Patients also demonstrate antibodies to melanocytes and cell-mediated immunity to melanoma cells. There may be associated vitiligo.

Regressing melanoma may also have associated leukoderma, but the pattern is usually haphazard and confined to the pigmented lesion. Other lesions that may also have a surrounding zone of leukoderma include blue nevi and neurofibromas.

Histologically, halo nevi demonstrate a band of lymphocytes that extends throughout the lesion, intimately mingling with the melanocytes. In contrast, the lymphoid infiltrate associated with melanoma tends to aggregate at the periphery of the lesion. In early halo nevi, amelanotic melanocytes may be found in the leukodermic halo. Later, melanocytes are absent until repigmentation occurs.

A full mucocutaneous examination at the time of diagnosis is indicated to exclude a concurrent melanoma, but this is rarely found. The decision to remove the nevus at the center of the halo is based on its morphologic features, just as with any other nevus.

Congenital Melanocytic Nevus

Giant Pigmented Nevus (Giant Hairy Nevus, Bathing Trunk Nevus) Giant pigmented nevi appear as large, darkly pigmented hairy patches in which smaller, darker patches may be interspersed or present as small satellite lesions. The skin may be thickened and verrucous. The trunk is a favored site, especially the upper or lower parts of the back. Giant hairy nevi are present at birth and grow proportionally with the body. Widespread congenital dermal nevus with large nodules may affect the entire body, including the palms, soles, and oral mucous membrane. Some congenital melanocytic nevi have associated placental infiltration by benign melanocytes.

The incidence of melanomas developing in giant congenital pigmented nevi is between 2% and 15%. Approximately 60% of these melanomas appear within the first decade of life, and the majority arise in the dermis or subjacent tissue, rather than at the dermoepidermal junction. About 40% of the malignant melanomas seen in children occur in large congenital nevi. The risk is greatest for axial lesions. Large axial lesions may be associated with neurocutaneous melanocytosis. The risk is greatest for large axial lesions with many satellite lesions, and almost half of patients with symptomatic neurocutaneous melanosis develop leptomeningeal melanoma. Neurocutaneous melanosis can be detected by magnetic resonance imaging (MRI).

Histologically, giant congenital nevi extend into the deep dermis, and may involve the subcutis, fascia, muscle, and other underlying structures. Nevus cells are found in a patchy perivascular distribution and often extend in a patchy singlefile fashion between collagen bundles. Nests are commonly seen in association with adnexal structures or nerves. Extensive desmoplasia has been described. Estrogen and progesterone binding has been noted in congenital nevi. These receptors are generally absent from common acquired nevi.

Benign proliferative nodules within giant congenital nevi may be confused histologically with malignant change. Features useful in distinguishing the two include lack of highgrade atypia, lack of necrosis, rarity of mitoses, evidence of transition between the cells of the nodule and those of the adjacent nevus, and lack of compressive expansile growth. Comparative genomic hybridization has demonstrated chromosomal aberrations in atypical nodular proliferations in congenital nevi, but many of these are numerical aberrations of whole chromosomes, suggesting a mitotic spindle defect. These differ from the chromosomal aberrations seen in melanoma.

Treatment decisions must be individualized. Half of all melanomas in giant congenital nevi occur in deep structures. Extensive surgery to remove the upper portions of the lesion reduces, but does not eliminate, the risk of melanoma. In patients with leptomeningeal melanosis, the risk of melanoma remains high. Satellite lesions and extremity lesions have a lower incidence of neoplastic conversion than large axial lesions, and the risk-to-benefit ratio of extensive surgery on these lesions differs accordingly. Some lesions are not amenable to excision as they involve functionally critical areas.

Serial excision is the method of choice whenever possible. Tissue expansion and flap closure are especially useful in the head and neck region. Alternative approaches to treatment, such as dermabrasion, curettage, CO_2 laser ablation or treatment with Q-switched Nd:YAG, nuby, and alexandrite lasers can lead to improvement in appearance. They may also eliminate some nevus cells, with theoretic lowering of the melanoma risk. It is important to note that most melanomas in giant congenital nevi occur in the dermal component, rather than at the dermoepidermal junction. Any treatment that alters the surface may alter detection of deep melanoma. Malignant transformation has been reported 20 years after dermabrasion. Regardless of the method of choice, lifelong periodic cutaneous examinations and general medical evaluations are indicated.

Small and Medium-Sized Congenital Nevocytic Nevus Small congenital nevocytic nevi are generally defined as less than 2 cm in greatest diameter, and mediumsized lesions measure more than 2-cm but less than 20 cm. They are found in about 1% of newborns. About half eventually become hairy.

Histologically, they share many features with giant congenital nevi, but usually do not extend into the subcutaneous tissue. Many of the histologic features associated with congenital nevi also occur in acquired nevi.

The risk of melanoma in small-to-medium sized congenital nevi is extremely low. It may be no greater than the risk of melanoma arising in ordinary acquired nevi. Most of the melanomas that do occur do so after puberty. Excision is recommended for changing lesions, and may be considered for those of cosmetic concern, and those in areas that are difficult to observe.

Epithelioid and Spindle-Cell Nevus (Benign Juvenile Melanoma, Spitz Nevus)

Spitz nevi commonly appear as pink (Fig. 30-6), smoothsurfaced, raised, round, firm papules. Most frequently, Spitz nevi occur during the first two decades of life, although they occur in adulthood in about a third of cases. Infrequently, multiple lesions present as agminate (clustered) (Fig. 30-7) or disseminated lesions in children and adults. Although they usually contain no visible pigment, some lesions are

Fig. 30-7 Agminated Spitz nevi. (Courtesy of Brooke Army Medical Center Teaching File)

pigmented. Occasionally, Spitz nevi can be blue-black in color (Fig. 30-8).

Like other nevi, Spitz nevi may be junctional, compound or intradermal. Compound nevi are most common, and are characterized by compact hyperkeratosis, hypergranulosis,

and pseudoepitheliomatous hyperplasia. The cells are large, with round to spindled nuclei. Epithelioid cells have large vesicular nuclei with prominent nucleoli and ample pink cytoplasm. Adjacent to the nucleus, the cytoplasm typically has a more amphophilic hue, giving it a characteristic twotone appearance, similar to the cytoplasm of the cells in reticulohistiocytic granuloma. The nests tend to be oval, and oriented in a vertical direction, as are the nuclei within the nests, so that they appear to be "raining down" the adjacent rete ridges. Clefts are typically present adjacent to some of the nests, and superficial vascular ectasia is characteristic. Dull pink globules (Kamino bodies) are seen within the epidermis. These represent trapped basement membrane zone material, and stain like collagen with a trichrome stain as well as with immunostains for type IV collagen. Buckshot scatter of melanocytes may be noted within the epidermis overlying the center of the lesion, but the lesion is sharply circumscribed, and cells disperse as individual units between collagen bundles at the base of the lesion. Melanomas may have many of the above features, but generally lack Kamino bodies, and often demonstrate broad lateral extension, deep mitoses, and large nests at the base of the lesion. In questionable cases, adjunctive studies may be of value. S100A6 shows strong and diffuse expression in Spitz nevi. Other melanocytic nevi often express S100A6 weakly and only in the dermal component. Melanomas may express \$100A6, but the expression tends to be weaker and patchy in the dermal component and is often negative in the junctional component. HMB-45 often stains Spitz nevi in a top-heavy fashion, while melanomas stain uniformly top to bottom. MIB-1 (Ki-67), a proliferation marker, may also be helpful as an adjunct to the histopathologic diagnosis of Spitz nevi. Few nuclei mark in the deep portion of a Spitz nevus compared to melanoma. Comparative genomic hybridization demonstrates chromosomal aberrations in the majority of melanomas, but most Spitz nevi show no aberrations. A minority of Spitz nevi show an isolated gain of chromosome 11p, but this aberration is not observed in melanoma. Specific gains or losses can be demonstrated with fluorescent in situ hybridization probes.

Junctional Spitz nevi commonly show some degree of buckshot scatter of melanocytes, and share many histologic features with melanoma. Lesions that lack sharp lateral circumscription are more likely to represent melanoma. Intradernal Spitz nevi lack overlying hyperkeratosis, hypergranulosis, and pseudoepitheliomatous hyperplasia, but the cells disperse as individual units at the deep margin. Dermal spitzoid lesions that remain nested at the deep margin are likely to represent melanoma. Desmoplastic Spitz nevi may be compound or intradermal and are characterized by a dense hypocellular collagenous stroma.

Pigmented spindle cell nevus is regarded by many as a variant of Spitz nevus. The lesions tend to be pigmented macules on the legs of young women. The cells are smaller and uniformly spindled, but other histologic features are similar to those of Spitz nevi.

Because of the histologic overlap with melanoma, Spitz nevi should be completely excised whenever possible. Critical differentiating histologic features include sharp lateral circumscription and dispersion at the base of the lesion. An incomplete excision will fail to demonstrate either the later or deep aspect of the tumor, and these diagnostic features will not be evident. Therefore, whenever possible, complete excisional biopsy is the most appropriate method for sampling. When a lesion is incompletely excised, most authorities recommend re-excision of the site to ensure complete removal. However, there are times when the dogma that all Spitz nevi should be completely excised must be tempered in the best interest of the patient. An otherwise typical Spitz nevus that extends to the deep margin on a young child's nose may be difficult to excise without disfigurement. The risks of anesthesia must also be weighed against the likelihood that the lesion is anything but a benign Spitz nevus.

Dysplastic Nevus

In 1978, Clark et al described families with unusual nevi and multiple inherited melanomas, a condition they referred to as the B-K mole syndrome (after Family B and Family K). About the same time, Lynch et al recognized similar findings in other families, and they designated this the familial atypical multiple mole-melanoma syndrome. The most widely accepted term for the marker lesions is dysplastic nevus, with the patient's condition called the dysplastic nevus syndrome (DNS). The lesions may also be referred to as atypical nevi (Fig. 30-9). Patients with dysplastic nevi who have at least two blood relatives with dysplastic nevi and melanoma have the worst prognosis for development of melanoma. In these individuals, there may be a 100% lifetime risk of melanoma. An associated increased risk of developing pancreatic carcinoma is present in some families. Some studies have indicated ocular melanomas may occur in these patients.

The genetic basis for familial melanoma is being elucidated. A quarter to a third of patients have germline mutations on chromosome 9p in the CDKN2A tumor-suppressor gene (also known as p16, MTS1, and p16INK4A). It encodes for

Fig. 30-9 Fried egg appearance of a dysplastic nevus.

an inhibitor of a cyclin-dependent kinase 4 (CDK4), which functions to suppress proliferation. In patients with mutations that impair the function of the p16 suppressor protein, referred to as the p16M alleles, there is a concomitant predisposition to pancreatic cancer. In other families where this is not present and who have 16W alleles, the predisposition to melanoma does not correlate with an elevated risk of pancreatic cancer.

Mutations in the CDK4 gene have also been found to be responsible for a lesser number of cases of familial melanomas. The products of this gene interact with the same cell growth cycle process as p16.

Dysplastic nevi also occur commonly in patients without a personal or family history of melanoma, with 5% to 20% of patients having at least one clinically dysplastic nevus, depending on the criteria used. During the growth phase, many nevi demonstrate junctional extension beyond the dermal component. This "shouldering" phenomenon is one of the criteria for dysplastic nevi. Many growing nevi will have features of dysplastic nevi. The same is true for many congenital nevi, genital nevi, and breast nevi.

When a biopsy specimen is read as a dysplastic nevus, clinical correlation is needed to determine if the patient has the dysplastic nevus syndrome. Examination of the patient, personal and family history of moles and melanoma, and inspection of other family members may be important in establishing the diagnosis. The presence of many moles and atypical moles are risk factors for melanoma. Other risk factors include skin type, freckle density, eye color, and history of blistering sunburns.

Dysplastic nevi differ from common acquired nevi in several respects. Clinically, dysplastic nevi are characterized by a variegated tan, brown, and pink coloration, with the pink hues seen mainly in the macular portion of the nevus. A macular component is always present and may comprise the entire lesion, but frequently surrounds a papular center. The nevi are larger than common nevi, usually 5 to 12 mm in diameter (common nevi usually measure 6 mm or less). The shape of dysplastic nevi is often irregular, with indistinct borders. Atypical nevi are most commonly seen on the back, and exposure to sun promotes the development of these lesions in individuals with DNS. In patients with the familial variety, it is not uncommon to see 75 to more than 100 pigmented lesions on the trunk. Although dysplastic nevi may not be evident until puberty in affected children, these nevi continue to develop over a lifetime, whereas common

nevocytic nevi usually develop only in childhood or the early adult years. Atypical moles are associated with an increased risk of melanoma, which may be as much as 150-fold greater than that of the general population. Familial atypical moles with inherited melanoma confer a 500-fold greater risk. The lesions appear to be precursors for melanoma as well as serving as a marker for an increased risk of de novo melanoma. Most of the melanomas that occur in these patients will arise in normal appearing skin.

Criteria for histologic diagnosis of dysplastic nevi vary. The National Institutes for Health (NIH) consensus conference published the following as characteristic histologic features: basilar melanocytic hyperplasia with bulbous elongation of the rete ridges; spindle-shaped or epithelioid melanocytes arranged horizontally and aggregating in nests that fuse with adjacent rete ridges; lamellar and concentric superficial dermal fibrosis; and cytologic atypia (usually present but not essential for diagnosis). In compound dysplastic nevi, the junctional component generally extends at least three rete ridges beyond the dermal component. Grading of atypia is variable from one observer to another. Much of the atypia is focal, and localized to the periphery of the lesion. Atypia that extends throughout the lesion is more significant, and lesions with high-grade atypia may be difficult to distinguish from melanoma arising in conjunction with a dysplastic nevus.

When a patient with clinically dysplastic nevi is seen, initial examination should include a total body inspection, including the scalp. A family history should be obtained with special attention paid to items such as moles, skin cancer, and melanoma. In general, excision of individual atypical nevi should be limited to those suspicious for melanoma. In some patients, many lesions may be suspicious for melanoma, and very irregular lesions may be difficult to follow clinically. It is not unreasonable to excise the worst looking lesions in such cases, but this does not eliminate the need for surveillance for changing moles and de novo melanoma. There should be prudent sun avoidance and sunscreen use. Patients should be educated in self-examination and encouraged to examine themselves monthly. Physician examination every year is also prudent. Baseline dermatologic photography may aid surveillance examinations. This is particularly helpful for detecting new lesions. Digital epiluminescence microscopic surveillance of atypical nevi may also be of value. Indications for removal of a lesion include an increase in diameter, focal enlargement, radial streaming, peripheral black dots, and clumping within the pigment network.

In patients with dysplastic nevi and a positive family or personal history of melanoma, physician examination every 3 to 6 months is recommended, with excision of those nevi that change in clinical appearance and of new lesions suspicious for melanoma. The use of photographs or digital images is particularly helpful in patients with the familial syndrome.

Narrow excisional biopsies of dysplastic nevi often fail to remove the subclinical junctional component of the lesion. The pathologist is left to comment on a specimen with melanocytic atypia at a positive margin. When the lesions recur, they often appear atypical both clinically and histologically. Recurrent lesions may easily be misinterpreted as melanoma by someone unfamiliar with the preceding lesion. In general, the most appropriate biopsy technique for a dysplastic nevus is a broad saucerization that-extends 2 mm beyond the clinically evident border of the lesion. After wound contraction, the 2 mm margin results in little difference in the appearance of the final scar, and the risk of a recurrent lesion is far lower. Especially on the upper shoulders and limb girdle area, saucerized biopsies often result in scars with a better appearance than those produced by suture closure. When faced with a positive lateral margin, it is best to re-excise lesions with moderate atypia. The re-excision may take the form of a wider saucerization. When a lesion with low-grade atypia extends to a lateral margin, it is reasonable to observe the lesion for signs of recurrence. Because recurrent lesions can be confused with melanoma, it is best to advise the patient to return to a physician who is familiar with the original lesion. It is also best to send the specimen from the recurrence to a pathologist who is familiar with the original specimen. Clearly indicate on the laboratory request form that the lesion is a recurrence of a dysplastic nevus with low-grade atypia. As high-grade dysplastic nevi may be difficult to distinguish from evolving melanoma in situ, they should be treated as such.

MELANOMA (MALIGNANT MELANOMA)

Except in the setting of giant congenital nevi, melanomas typically originate from melanocytes at the dermoepidermal junction. Almost half will develop in preexisting nevi, but the rest will develop on previously normal appearing skin. Usually there is a prolonged, noninvasive, radially oriented growth phase in which the lesion enlarges asymmetrically. Eventually, a tumor nodule develops, reflecting a vertical growth phase. Although the presence of a vertical growth phase may represent an independent risk factor for metastasis, the single greatest risk factor is the depth of invasion.

The ABCD criteria for melanoma are imperfect, but are simple for lay individuals to understand and have proved helpful for the detection of melanoma. The letters stand for asymmetry, border irregularity, color variegation, and a large diameter (>6 mm). Epiluminescence microscopy is a noninvasive technique for examining pigmented lesions that makes subsurface structures visible. In the hands of experienced users, it can be a helpful technique.

The incidence of melanomas has increased dramatically, probably because of patterns of sun exposure. It occurs most often in light-skinned people, often at the most productive time of their lives. Melanoma is not commonly encountered in the darker races, and acral lesions account for a greater share of melanomas in dark-skinned individuals. The lowest incidence is found among Asians. The incidence of melanoma is low until after puberty. Children rarely manifest congenital or acquired melanoma. The former may occur because of transplacental transmission from an affected mother, as a primary intrauterine lesion, as a melanoma that occurs on a congenital nevus in utero, or as prenatal metastatic lesions from neurocutaneous melanosis. All of these have a poor prognosis. In children, melanomas occur at least half of the time from preexisting normal skin, where the clues to diagnosis are the same as in adults, but there is often delayed recognition because of its overall low incidence in this population. Melanomas may also develop in preexisting nevi, most importantly deep within giant congenital nevi.

During pregnancy, pigmented nevi often become uniformly darker, and may enlarge symmetrically. Estrogen and progesterone receptors develop on the melanocytes and these changes are likely hormonally induced. If, however, changes . occur that would normally incite worry about melanoma, such as irregular pigmentation or asymmetrical growth, a biopsy should be performed. Women who develop melanoma during pregnancy have a shorter disease-free interval following excision; however, there is no adverse survival effect.

Etiologic Factors

A light complexion, light eyes, blond or red hair, the occurrence of blistering sunburns in childhood, heavy freckling, and a tendency to tan poorly and sunburn easily indicate increased risk for melanoma. Large numbers of common nevi, the presence of large nevi, and the presence of clinically dysplastic lesions all increase the risk of melanoma. Axial giant congenital nevi or mutations in the p16-CDK4 gene are potent risk factors. The risk of developing multiple primary melanomas is elevated if there is a family history of melanoma, if there are clinically or histologically atypical nevi, if there are greater than 50 benign nevi, and if the patient is a nonuser of sunscreen. Sunscreens should be applied daily to sun-exposed areas, but must be used in conjunction with sun avoidance.

Other implicated factors include PUVA, tanning lamps, xeroderma pigmentosum, burn scars, and immunodeficiency. An association between administration of levodopa therapy for Parkinson's disease and the onset of melanoma remains unproved.

Melanoma Types

Clinicopathologic types of melanoma include lentigo maligna, superficial spreading melanoma, acral-lentiginous melanoma, nodular melanoma, desmoplastic melanoma, mucosal melanoma, ocular melanoma, primary CNS melanoma, and primary soft tissue malignant melanoma. Clinically, melanomas may be pedunculated, polypoid, amelanotic, or hyperkeratotic.

Fig. 30-10 Lentigo maligna melanoma.

Fig. 30-11 Superficial spreading malignant melanoma.

Fig. 30-12 Malignant melanoma.

Lentigo Maligna (Lentiginous Melanoma on Sun-**Damaged Skin)** Lentigo maligna begins as a tan macule that extends peripherally, with gradual uneven darkening over the course of years. It is more common in older patients with heavily sun-damaged skin, and is more common in sunny climates. The spread and darkening are usually so slow that the patient pays little attention to this insidious lesion. After a radial growth period of 5 to 20 years, a vertical growth phase of invasive melanoma can develop (Fig. 30-10). The lesion is then referred to as *lentigo* maligna melanoma. A palpable nodule within the original macular lesion is the best evidence that this has occurred, though there may be darkening or bleeding as well. Lentiginous types of melanoma also give rise to desmoplastic melanoma, which may appear as a papule, firm plaque or inconspicuous area of induration.

The lentiginous melanomas (lentigo maligna and acral lentiginous melanoma) proliferate principally at the dermoepidermal junction, with little buckshot scatter into the overlying epidermis. Because the junctional involvement is often only one cell thick, they often extend laterally far beyond the clinically apparent margin. The lateral subclinical extension frequently exceeds the "standard" 5-mm margin for in situ melanoma, and asymmetrical growth is common.

Superficially Spreading Melanoma Superficially spreading melanoma affects adults of all ages, with the median age in the fifth decade. Unlike lentigo maligna, it has no preference for sun-damaged skin. The upper back in both sexes and the legs in women are the most common sites. There is a tendency to multicoloration, not just with different shades of tan, but variegated black, red, brown, blue, and white (Fig. 30-11). They may arise de novo or in association with a preexisting nevus. Areas of color change within a nevus, especially dark areas that extend beyond the border of the remainder of the lesion, are suspicious for melanoma arising in a nevus. As a vertical growth phase develops, a papule or nodule usually appears. Skin markings disappear as the lesion expands. Regression may appear as variation in pigmentation or a scalloped margin. The radial growth phase is characterized by buckshot scatter of melanocytes throughout the epidermis. Because of this, the borders tend to be more sharply defined than those of lentiginous types of melanoma.

Acral-Lentiginous Melanoma Acral-lentiginous melanoma is the most common type of melanoma in darkskinned and Asian populations. This is because the frequency of the other types is low in these patients, not because the incidence of acral-lentiginous melanoma is any higher than in white persons. The median age of patients is 50 years, with

Fig. 30-13 Malignant melanoma.

equal sex distribution. The most common site of melanoma in black persons is the foot, with 60% of patients having subungual or plantar lesions. All lentiginous melanomas demonstrate a junctional growth pattern and tend to have indistinct margins. Over time, a vertical growth phase develops. Periungual hyperpigmentation, Hutchinson's sign, a black discoloration of the proximal nailfold at the end of a pigmented streak (melanonychia striata), is an ominous sign suggesting melanoma in the matrix of the nail (Fig. 30-12).

The early changes of acral-lentiginous melanoma may be light brown and uniformly pigmented. The thumb and hallux are more frequently involved than the other digits. In time, the lesion becomes darker, nodular, and may ulcerate. Metastases to the epitrochlear and axillary nodes are common, because there is often a delay in diagnosis. Subungual melanoma (Fig. 30-13) may be misdiagnosed as onychomycosis, verruca vulgaris, chronic paronychia, subungual hyperkeratosis, pyogenic granuloma, Kaposi sarcoma, glomus tumor, or subungual hematoma. **Mucosal Melanoma** Primary melanoma of the mucous membranes is rare, but typically demonstrates a lentiginous (junctional) growth pattern. In the mouth, especially the palate, the lesion is usually pigmented and may be ulcerated. It may occur in the nasal mucosa as a polypoid tumor. On the lip it is apt to be an indolent ulcer. Melanoma of the vulva is manifested by a tumor, often ulcerated, with bleeding and pruritus. It is most often detected after metastasis to the groin has occurred.

Nodular Melanoma These lesions arise without a clinically apparent radial growth phase, but usually large atypical melanocytes can be found in the epidermis beyond the region of vertical growth. Primary dermal melanomas in congenital nevi are also nodular, and lack a radial growth phase. Nodular melanoma constitutes about 15% of all melanomas. It occurs twice as often in men as in women, primarily on sun-exposed areas of the head, neck, and trunk. The tumors may be smooth and dome-shaped, fungating, friable, or ulcerated. Bleeding is usually a late sign.

Polypoid Melanoma This is a variant of nodular melanoma, presenting as a pedunculated tumor. At its base the polypoid melanoma does not appear to descend for any appreciable distance into the dermis. Nevertheless, the 5-year survival rate is only 42%, compared with 57% for other nodular melanomas. The prognosis relates to the thickness (a measure of the volume of the tumor), and the presence of a vertical growth phase.

Desmoplastic Melanoma This deeply infiltrating type of melanoma usually has a spindle-cell pattern histologically in which collagen fibers extend between the tumor cells. It most often occurs on the head or neck of older men, many times within a subtle lentigo maligna. The lesions may also occur on the digits, in association with a subtle acral lentiginous melanoma. One-third of cases present with only a palpable dermal irregularity and are amelanotic. The biopsy demonstrates a spindle cell proliferation with a dense fibrous stroma. Atypia is variable. The lesions are commonly neurotropic, and demonstrate extensive growth along the perineurium beyond the bulk of the tumor. Nodular lymphoid aggregates are frequently present and are an important clue to the diagnosis. S100 protein is the most reliable immunostain. HMB-45 and Mart-1 are commonly negative.

Amelanotic Melanoma Nonpigmented melanoma differs from other melanomas only in its lack of pigment. The lesion is pink (Fig. 30-14), erythematous, or flesh colored, and commonly mimics basal cell carcinoma or granuloma

Fig. 30-14 Amelanolic malignant melanoma.

pyogenicum. Amelanotic melanoma is the typical variant seen in albinos.

Soft-Tissue Melanoma Primary soft-tissue melanoma (clear-cell sarcoma, melanoma of the soft parts) contains melanosomes and stains positively for S-100 and HMB-45. It occurs most frequently on the lower extremities of young people. The average age at onset is 27. The history is of an enlarging often painful mass on an extremity, with the foot or ankle involved 43% of the time. The tumors arise in and are bound to the aponeuroses, tendons, or fascia, and only uncommonly invade the overlying skin. Histologically, there are compact nests and fascicles of polygonal or fusiform cells with a clear cytoplasm present between dense fibrous tissue septa that connect with tendonous or aponeurotic tissue. Multinucleated cells are frequent. Metastases are often present at first diagnosis and the prognosis is poor. Local recurrence or distant metastases after the initial excision are frequent and result in death in more than 50% of reported cases. Treatment is with wide excision and lymph node dissection. Radiotherapy and chemotherapy are used as an adjunct in some cases. The lesion appears to arise from neural crest cells. Frequently translocations of chromosomes 12 and 22 are present.

Differential Diagnosis

Melanoma may clinically simulate a wide variety of lesions, including pigmented basal cell carcinoma, darkly pigmented seborrheic keratosis, pyogenic granuloma, and Kaposi sarcoma. Melanomas may appear pearly, contain horn cysts, and exhibit a collarette, and none of these is sufficient to forego a biopsy. Other melanoma-simulating lesions include subungual traumatic hematoma, cherry angioma, pigmented Bowen's disease, and pigmented Paget's disease.

Biopsy

Complete excision with a 1- to 3-mm margin of skin is the preferred method of biopsy for a lesion suspected to be melanoma. Although the National Comprehensive Cancer Network (NCCN) recommends avoiding wider margins to permit accurate lymphatic mapping for sentinel node biopsy, some evidence suggests that accurate mapping is usually still possible even after wide excision.

In lesions too large for simple excision, an incisional or punch biopsy, deep enough to permit measurement of thickness, has no effect on prognosis. When melanoma is suspected in a giant pigmented nevus, an incisional biopsy should be performed. Biospy of lentigo maligna is problematic, as the lesions tend to be quite large and arise in cosmetically sensitive areas. Skip areas are common in these lesions and may lead to misdiagnosis. Areas of the tumor may undergo lichenoid regression and resemble benign lichenoid keratosis. Collision with other pigmented lesions, such as benign solar lentigo, pigmented large-cell acanthoma, and pigmented actinic keratosis, is common. Because of the potential for sampling error, small biopsies frequently result in misdiagnosis. The best biopsy technique in the setting of suspected lentigo maligna is generally a broad superficial shave biopsy. This results in minimal scarring and provides the pathologist with a broad area of dermoepidermal junction for examination. If the lesion is heterogeneous, multiple areas may need to be sampled. If

lentigo maligna melanoma or desmoplastic melanoma is suspected, an incisional biopsy should be performed. Punch biopsies are more prone to sampling error.

Histopathology

Biopsies should be read by a dermatopathologist or other pathologist experienced in pigmented lesions. The report should include thickness and an assessment of the deep and peripheral margins. The presence of ulceration should be noted. Several studies demonstrate that concordance for assessment of Clark's level is poor, but as Clark's level may add prognostic information, it is still noted in many cases. The presence of satellitosis is a powerful adverse prognostic indicator, and its presence should be noted in the report. Other factors that may be important to note include regression, mitotic rate, tumor infiltrating lymphocytes, vertical growth phase, angiolymphatic invasion, neurotropism and histologic subtype.

Whereas benign nevi are well nested at the junction, melanomas usually demonstrate junctional areas where nonnested melanocytes predominate. Benign nevi demonstrate dispersion of individual melanocytes at the base of the lesion. while nielanomas remain nested at the base. Melanomas may be asymmetrical, but metastatic and nodular melanoma may present as perfectly symmetrical spheres. Benign nevi demonstrate bilateral symmetry and show maturation (smaller more neuroid cells) with descent into the dermis. Most melanomas lack bilateral symmetry and show little maturation with descent into the dermis. In nevi, nests at the junction tend to be round to oval and are roughly equidistant from one another. In melanoma, junctional nests are often elongated or have irregular shapes. They are randomly distributed, and often involve the apex of the dermal papillae as well as the tips and sites of the rete ridges. Confluent runs of melanocytes are frequently seen at the dermoepidermal junction, and often continue down the adnexal structures. In nevi, dermal nests are generally smaller than the junctional nests, and become progressively smaller deeper in the dermis. In melanoma, dermal nests generally fail to become smaller in the deeper dermis. In nevi, pigment is most prominent at the junction, and becomes progressively less prominent deeper in the dermis. Melanomas often retain pigment deep in the lesion. In superficial spreading melanoma, individual melanocytes are present in a "buckshot" scatter throughout the epidermis. Lentiginous types of melanoma tend to proliferate at the dermal epidermal junction with little associated buckshot scatter. Invasive melanoma is commonly associated with a lymphoid infiltrate that forms a band at the periphery of the lesion. Plasma cells may be numerous. A vertical growth phase is identified by the presence of a dermal nest larger than the largest junctional nest, or invasion of the reticular dermis or solar elastotic band. Melanoma depth is measured from the granular layer or base of the ulcer. If invasion has taken place from follicular extension of the tumor, the lesion is measured from the inner root sheath. Rare variants of melanoma include balloon cell melanoma and dendritic "equine type" melanoma.

Some types of benign nevi mimic individual features of melanoma. Sunburned nevi, acral nevi, and Spitz nevi may demonstrate buckshot intraepidermal scatter of melanocytes. Blue nevi typically are pigmented to the base of the lesion, and extend into the dermis as a bulbous projection with little maturation and no dispersion of cells at the base. The silhouette, sclerotic stroma, and bland cytology are key to the diagnosis.

Comparative genomic hybridization has shown that chromosomal aberrations are common in melanoma. They occur earlier in the progression of acral melanoma than in melanomas on the trunk. In general, melanomas tend to have abnormalities involving chromosomes 9, 10, 7, and 6. Acral melanomas are more likely to have aberrations involving chromosomes 5p, 11q, 12q, and 15, and many amplifications are found at the cyclin D1 locus. Lentigo maligna melanomas are more likely to show losses of chromosomes 17p and 13q. Chromosomal aberrations are rare in benign banal nevi. A minority of Spitz nevi may show an isolated gain involving the entire short arm of chromosome 11.

Metastasis

Early metastases typically occur via the lymphatics, and regional lymphadenopathy may be the first sign. Satellite metastases appear as pigmented nodules around the site of the excision (Fig. 30-15). Later, metastases occur via the blood stream, and may become widespread. The chief site for metastatic melanoma is the skin, but all other organs are at risk. CNS metastasis is the most common cause of death. Although most metastatic spread occurs in the first 5 years after diagnosis, late-onset metastases occur, especially in premenopausal women. Melanemia, melanuria, and cachexia are likely to occur in terminal disease. In extreme cases, the entire integument may become deeply pigmented (generalized melanosis), with melanin in melanophages, endothelial cells, and tissue histiocytes. Occasionally, patients present with metastatic melanoma from an unknown source. Fullbody skin examination may reveal a depigmented or irregularly pigmented atrophic patch consistent with a regressed primary lesion. Such patients are estimated to have a 40% chance of 5-year survival.

Staging

The American Joint Committee on Cancer developed a staging system for cutaneous melanoma. The system's categories depend on definitions for primary tumors, lymph

Fig. 30-15 Metastatic malignant melanoma. (Courtesy of Brooke Army Medicat Center Teaching File) Box 30-1 Summary of American Joint Committee on Cancer melanoma staging

T0: No evidence of primary tumor Tis: Melanoma in situ T1: Up to 1.0 mm in thickness T1a: Level II or III T1b: Level IV or V or with ulceration T2: 1.01-2.0 mm in thickness T2a: No ulceration T2b: Ulceration T3: 2.01-4.0 mm in thickness T3a: No ulceration T3b: Ulceration T4: >4.0 mm in thickness T4a: No ulceration T4b: Ulceration NO: No regional lymph node metastasis N1: Metastasis in one lymph node N1a: Clinically occult N1b: Clinically apparent N2: Two to three regional nodes or in-transit metastasis N2a: Clinically occult N2b: Clinically apparent N2c: Satellite or in-transit metastases N3: Four or more nodes, matted nodes or in-transit metastasis with positive nodes M0: No distant metastases M1: Distant metastases M1a: Skin or nodes M1b: Luna M1c: All other viscera or any distant metastases with elevated LDH

node involvement, and distant metastases (Box 30-1; www. cancerstaging.net). The NCCN concensus statement regarding staging and management of melanoma can be found at www. nccn.org/physician_gls/f_guidelines.html.

Prognosis

The prognosis for a patient with stage I melanoma is primarily related to tumor thickness. Cure rates by stage are: Stage I (T1 or T2a, N0, M0) > 80% Stage II (T2b-4, N0, M0) 60-80% Stage III (N1-3, M0) 10-60% Stage IV (M1) <10% Many variables have been reported to influence survival,

Many variables have been reported to influence survival, including the presence of tumor infiltrating lymphocytes (brisk response is best), mitotic rate (0 is best and >6/mm² is worst), ulceration (adverse effect), location (hair-bearing limbs yield a better prognosis than when lesions are present on the trunk, head, neck, palm, or sole), sex (women have a better prognosis than men), age (younger patients have a better prognosis), the presence of leukoderma at distal sites (improves the prognosis), and regression (associated with a poorer prognosis). Multivariant analysis shows that some are not independently predictive and others are of variable significance in different series. Pregnancy does not have an adverse effect on survival in patients with clinically localized melanoma. Tumor thickness, ulceration, and lymph node involvement have the greatest predictive value and are used to determine therapy.

The presence or absence of melanoma in regional lymph nodes is the single most important prognostic factor for melanoma. Sentinel lymph node dissection using lymphoscintigraphy with 99m Tc-labeled colloids is widely used for the staging of clinically node-negative melanomas. The success rate in localizing the sentinel lymph node approaches 98% at centers experienced in the technique. When combined with the vital blue dye technique the success rate can approach 99%. About 20% of patients with melanoma between 1.5 and 4 mm in depth will have metastasis in their sentinel node(s). For desmoplastic and neurotropic melanoma (mean Breslow depth, 4.0 mm; median, 2.8 mm), published data suggest that up to 12% have at least one positive sentinel lymph node. Tumor thickness and ulceration are the major independent predictors of sentinel lymph node metastases. Age and axial tumor location are also significant. Patients with larger metastases to the sentinel node (metastatic deposits >2 mm in diameter) have significantly decreased survival.

Local recurrence related to a positive margin should not be equated to local recurrence representing dermal in-transit lymphatic metastasis. The latter is associated with a poor prognosis, while the former may be cured in many cases by re-excision.

Work-Up and Follow-Up

There is no definite proof that any routine laboratory work or imaging studies affect longevity. Some advocate only ordering studies as prompted by signs or symptoms. Other guidelines recommend limited studies varying by stage. For all stages, studies should be ordered if signs or symptoms occur. Lactic acid dehydrogenase (LDH) is not a sensitive screening tool, but has prognostic value. The yield of computed tomography (CT), MRI, and positron emission toniography (PET) scanning is low. There is broad consensus that no x-rays or blood work are routinely indicated for those with stage IA melanoma. For stage IB and II, a baseline chest x-ray and LDH level are optional in the NCCN guidelines. For stage IIIA disease, a chest x-ray and LDH are recommended by NCCN guidelines. For stage IIIB or IIIC disease, fine needle aspiration should be attempted to confirm nodal involvement. A chest x-ray and LDH are recommended by NCCN guidelines. A pelvic CT scan is recommended in those with inguinofemoral lymphadenopathy. For stage IV disease, the work-up should be similar to that for stage IIIB disease along with consideration of abdominal and pelvic CT scan, head MRI, or PET scanning. The highest yield for CT scans is in the area adjacent to nodal disease. As glucose metabolism is increased in malignant tumors, PET using the glucose analog fluorine-18-fluorodeoxyglucose (F18-FDG) can be used to detect metastases.

Periodic examinations are important to detect second primary tumors as well as metastatic disease. In general, laboratory tests and imaging studies should be performed when prompted by signs or symptoms. For those with stage IB-IV melanoma, periodic evaluations may include chest x-ray, LDH, and complete blood count at the discretion of the physician. Skin and lymph node examination should be performed at least yearly.

Treatment

Early excision remains the most important determinant of outcome. Most published guidelines are based on data that relate largely to superficial spreading melanoma, and may not be applicable to all melanomas. A margin of 0.5 cm is recommended for excision of a melanoma in situ, a 1.0 cm margin for melanomas less than or equal to 1.0 mm thick, a 1- to 2-cm margin for those less than or equal to 2 mm, and a 2-cm margin for those thicker than 2.0 mm. In the case of lentigo maligna and acral lentiginous melanoma, subclinical extension of the in situ tumor commonly exceeds 0.5 cm, and asymmetrical growth is common. In such cases, a symmetrical "standard" margin may do a disservice to the patient. It may result in a positive lateral margin, and difficult closure because excessive uninvolved skin was sacrificed. Mohs micrographic surgery may be useful in this setting. Although H&E-stained frozen sections have been used, immunostains such as Mart-1 are easier to interpret. "Slow Mohs" staged excision with permanent sections is another option. In patients who are poor surgical candidates, nonsurgical treatments such as topical imiquimod and radiotherapy may be utilized. Nail apparatus melanoma may necessitate amputation of a digit or skin grafting. This is another setting where Mohs micrographic surgery may be considered as a tissue sparing technique.

Sentinel node biopsy (SNB) should be discussed with patients whose melanomas are 1 mm or greater in thickness. SNB should be considered for thinner lesions in patients who have ulceration, Clark level IV or V invasion, regression, a vertical growth phase, or a positive deep margin on initial biopsy. Dual-basin drainage from the trunk is not independently associated with an increased risk of nodal metastases, but each basin must be identified and sampled. Those with a positive SNB or nodal metastasis confirmed by fine needle aspiration should receive counseling regarding dissection of the remainder of the nodal basin. Experimental treatments should be approached with careful counseling and full informed consent, usually in the setting of a clinical trial. For in transit metastases, surgical excision, interferon, hyperthermic isolated limb perfusion with melphalan, CO₂ laser ablation, and intralesional BCG are used. Dinitrochlorobenzene in the setting of in-transit melanoma metastases has been reported to induce local remission but did not prevent metastatic lymph node and liver involvement. For stage IV disease, treatment options include resection, radiation, dacarbazine, temazolamide, interleukin-2, and combination chemotherapy. Before surgical intervention, a period of observation to rule out more widespread metastasis may be reasonable.

Adjuvant therapy should be discussed with patients with positive nodes or node-negative melanoma that is 4 mm thick, ulcerated or Clark's level IV or V. Interferon- α 2b is FDA-approved as adjuvant therapy and is used most commonly. Although meta-analysis suggests that interferon therapy may increase relapse-free survival, an advantage for overall survival is uncertain. The results of trials have been mixed. Reports of long-term survival after resection of distant melanoma metastases suggest that cytoreductive surgery may play a role in selected patients.

Clinical vaccine trials are ongoing, and some have shown promising results. However, despite numerous trials only a few patients have been shown to exhibit strong antigenspecific cellular responses. mative case report, and a unique mapping technique. Dermatol Surg 2002;28:656.

DERMAL MELANOCYTIC LESIONS

Mongolian Spot

The Mongolian spot is a bluish-gray macule that varies in diameter from 2 to 8 cm. It occurs typically in the sacral region of the newborn (Fig. 30-16), in 80% to 90% of Asian, Southern European, American black, and Native American persons. The Mayan Indians uniquely take great pride in it as an indicator of pure Mayan inheritance. The Mongolian spot may be situated in other locations. Multiple spots may occur in a widespread distribution. These have been called generalized dermal melanocytosis or dermal melanocytic hamartomas. They may occur in phakomatosis pigmentovascularis types II, IV, and V. Extensive Mongolian spots have been associated with Hunter syndrome and with trisomy 20 mosaicism.

Histologically, the Mongolian spot shows elongated dendritic dermal melanocytes, widely scattered among normal collagen bundles. It usually disappears during childhood, although rarely, it may persist into adulthood.

Nevus of Ota (Oculodermal Melanocytosis)

This nevus is also known as *nevus fuscoceruleus ophthalmo*maxillaris. It is usually present at birth in the two-thirds of patients who have ocular involvement. Other lesions may not appear until the teen years. The conjunctiva and skin about the eye supplied by the first and second branch of the trigeminal nerve, as well as the sclera, ocular muscles, retrobulbar fat, periosteum, and buccal mucosa, may be involved. On the skin, brown, slate gray, or blue-black macules grow slowly larger and deeper in color (Fig. 30-17). It persists throughout life. Eighty percent occur in females; 5% are bilateral. Glaucoma or ipsilateral sensorineural hypoacusia may also occasionally complicate nevus of Ota. Malignant melanoma rarely occurs in nevus of Ota. Malignant degeneration is more frequent in white patients. The most

Fig. 30-17 Nevus of Ola.

common site of malignancy is the choroid. Histologically, elongated dendritic dermal melanocytes are seen scattered in the upper portion of the dermis.

Q-switched lasers have been used successfully to treat nevus of Ota. Nd:YAG laser at 1064 nm is suitable for use in a wide range of skin types. Acquired dermal melanocytosis (acquired bilateral nevus of Ota-like macules, Hori nevus) is recalcitrant to laser therapy compared with nevus of Ota. Good results have been reported after treatment with Q-switched ruby laser. Initial topical bleaching with 0.1% tretinoin and a 5% hydroquinone ointment containing 7% lactic acid was used to reduce epidermal melanin prior to laser treatment. Q-switched ruby laser has also been used after epidermal ablation using a scanned CO_2 laser. Lesions of phacomatosis pigmentovascularis have been treated successfully with Q-switched ruby laser and Q-switched alexandrite laser, with flashlamp pumped pulsed dye laser for the vascular component.

Nevus of Ito

Also known as *nevus fuscoceruleus acromiodeltoideus*, the nevus of Ito has the same features as nevus of Ota except that it occurs in the distribution of the posterior supraclavicular and lateral cutaneous brachíal nerves, to involve the shoulder, side of the neck, and supraclavicular areas.

Fig. 30-18 Blue nevus. the absence of Carney complex, and may occur on the genital nuccosa. The lesions are composed of large polygonal and epithelioid melanocytes often laden with melanin. These cells are admixed with heavily pigmented dendritic melanocytes, spindled melanocytes, and melanophages. Some melanocytes are situated among the dermal collagen bundles singly, in short rows, and small groups. The nuclei are vesicular with very pale chromatin and a single prominent nucleolus. They may demonstrate moderate pleomorphism and rare mitotic figures. In contrast with other blue nevi, they lack the usual sclerotic stroma.

Deep Penetrating Nevus This unique type of nevus is commonly seen in combination with other forms of blue nevus. The fascicles of cells have small hyperchromatic nuclei with a smudged chromatin pattern and inconspicuous nucleoli. Adjacent melanophages are noted.

Amelanotic Blue Nevus (Hypomelanotic Blue Nevus) In the amelanotic or hypomelanotic variant of cellular blue nevus, mild cytologic atypia and pleomorphism may be present. Mitotic activity (up to three mitoses/mm) may also be observed. It is important to recognize the entity so as not to confuse it with a malignant lesion.

Malignant Blue Nevus The term "malignant blue nevus" has been used to refer to melanomas arising in a blue nevus (usually a cellular blue nevus). It has also been used for de novo melanoma resembling a cellular blue nevus. When melanoma occurs in a blue nevus, an abrupt transition can be seen between the nevus and the melanoma. The melanoma demonstrates a sheet-like growth pattern, mitoses, necrosis, and nuclear atypia.

Treatment

Excision is the mainstay of treatment for blue nevi. Successful results have been reported with the Q-switched ruby laser. Treatment of the malignant variety is the same as for a malignant melanoma.

Blue Nevus

Blue nevi appear as well-defined blue papules or nodules (Fig. 30-18). Histologically, they share the silhouette of a bulbous finger-like or wedge-shaped protrusion into the dermis. All variants show little maturation, and no dispersion of melanocytes in the deep portion of the lesion. All except epithelioid blue nevi and some cellular blue nevi are associated with a dense sclerotic stroma. They commonly occur as combined nevi (combinations of various types of blue nevi, blue nevus combined with banal nevus, or blue nevus combined with Spitz nevus).

Blue Nevus of Jadassohn-Tiche (Common Blue Nevus, Nevus Ceruleus) The typical lesion is a steelblue papule or nodule that begins in early life. The slowly growing lesion is rarely more than 2 to 10 mm in diameter, and occurs most frequently on the dorsal hands, feet, and face. Histologically, the lesion is composed of dendritic dermal melanocytes and melanophages. The sclerotic stroma is particularly prominent in this variant.

Cellular Blue Nevus Usually a cellular blue nevus is a large, firm, blue or blue-black nodule. It is most frequently seen on the buttock and sacrococcygeal region, and occasionally is present at birth. Women have cellular blue nevus 2.5 times as frequently as men, and the average age of the patient seen with this lesion is 40 years. Uncommonly, these may invade underlying structures such as the skull in scalp lesions. Histologically, in addition to deeply pigmented melanophages, islands of cells are observed with large fusiform vesicular nuclei, prominent nucleoli, and abundant pale cytoplasm. The cellular islands contain little or no pigment.

Epithelioid Blue Nevus Epithelioid blue nevi are mostly seen in patients with the Carney complex (myxomas, spotty skin pigmentation, endocrine overactivity, and schwannomas). They occur on the extremities and trunk, and less frequently on the head and neck. They may also be noted in

Macrophage/Monocyte Disorders

PALISADED GRANULOMATOUS DERMATOSES

Granuloma Annulare

Granuloma annulare (GA) is a relatively common idiopathic disorder of the dermis and subcutaneous tissue. It occurs in all races and at all ages, but much more frequently affects women (2:1). Granuloma annulare may exhibit the isomorphic response of Koebner, affect healed areas of herpes zoster, and may be restricted to sun-exposed areas. While most cases spontaneously resolve, leaving entirely normal skin, loss of elastic tissue may occur, leaving atrophic lesions resembling mid-dermal elastolysis or anetoderma. GA lesions will sometimes spontaneously resolve when biopsied.

Many clinical morphologies of GA exist. Usually, patients exhibit primarily one clinical type during the course of their illness, except in the subcutaneous form, in which typical papular or localized GA may also occur.

Localized Granuloma Annulare This form of GA tends to affect children and young to middle-aged adults. Usually only one or a few lesions are present at any one time. Localized GA usually appears on the lateral or dorsal surfaces of the fingers or hands, elbows, dorsal feet, and ankles (Figs 31-1 to 31-3). Rarely, the eyelid or even a Becker nevus may be affected. Lesions are erythematous, fawn colored, or violaceous, thinly bordered plaques or papules, which slowly spread peripherally, at the same time

Fig. 31-1 Granuloma annulare, dermal papule on the knuckle.

undergoing central involution, so that roughly annular lesions are formed. The overlying skin usually remains completely normal. Lesions may coalesce and sometimes form scalloped patterns or firm plaques. The lesions never ulcerate and on resolving virtually always leave no residua. The lesions develop slowly and often involute spontaneously. Although more than 50% of patients clear within 2 years, in 40% lesions will recur. Autoimmune thyroiditis may be present in women with localized GA.

Generalized Granuloma Annulare This form of GA affects mostly women in the fifth and sixth decades, adolescents and children. The association of generalized GA with diabetes mellitus has been questioned. The eruption presents as a diffuse but symmetrical, papular or annular eruption of more than 10 lesions, and often hundreds (Fig. 31-4). Lesions favor the nape of the neck, upper trunk, and proximal upper extremities, and rarely exceed 5 cm in diameter. The palms, soles, and eyelids may be affected. The face and genital area are usually spared. In some cases sun exposure

Fig. 31-2 Granuloma annulare, annular, localized type.

Fig. 31-3 Granuloma annulare, annular plaque composed of coalescing papules.

Fig. 31-4 Granuloma annulare, generalized small papules and annular plaques.

seems to be a trigger (see section on actinic granuloma below). Some patients are completely asymptomatic, whereas others complain of severe pruritus. Spontaneous clearing usually occurs but at variable times. The average duration is 3 to 4 years but may be as short as 4 months or longer than a decade.

Patch-Type or Macular Granuloma Annulare This form of GA is significantly more common in women, usually between 30 and 70 years of age. Flat or only slightly palpable erythematous or red-brown lesions occur (Fig. 31-5), especially on the upper medial thighs and in bathing-trunk distribution Lesions may closely simulate cutaneous T-cell lymphoma or morphea. Individual lesions average at least several centimeters in diameter but may be much larger. On careful palpation, small papules can be felt in some cases and on stretching the skin the papules or small annular lesions can be seen. Such papules are the most fruitful sites for biopsies. Both well-formed necrobiotic granulomas and the interstitial pattern of GA may be seen on biopsy.

Flg, 31-5 Granuloma annulare, macular lesion of the medial thigh.

Fig. 31-6 Granuloma annulare, subcutaneous and dermal lesion.

Subcutaneous Granuloma Annulare (Deep Granuloma Annulare, Pseudorheumatoid Nodule) Subcutaneous GA is most common in children, with boys affected twice as commonly as girls. Childhood cases appear at any age from 1 year to adolescence. Lesions tend to occur on the lower legs, but may also occur on the distal upper extremity or scalp. Multiple lesions are usually present. There is often a history of trauma to the affected area preceding the appearance of a lesion. Typically lesions are skin-colored, deep dermal or subcutaneous nodules, and up to several centimeters in diameter (Fig. 31-6). Superficial papular lesions are present in about one-quarter of patients with subcutaneous GA. Lesions in general are asymptomatic and resolve over a few years. The major clinical problem occurs when the initial pathologic interpretation is rheumatoid nodule and an unnecessary extensive rheumatologic work-up is performed.

Perforating Granuloma Annulare Perforating GA usually appears on the dorsal hands and presents as papules with a central keratotic core. This core represents transepidermal elimination of the degenerated material in the center of GA lesions and clinically can resemble a pustule.

Granuloma Annulare in HIV Disease GA may occur in persons with HTV infection at all stages of disease. Lesions are typically papular and generalized GA is more common (60%) than localized GA (40%). Photodistributed and perforating lesions may also occur. The histology is identical to GA in the normal host. The natural history of GA in HIV is unknown.

Granuloma Annulare and Malignant Neoplasms The occurrence of GA and a cancer in the same patient is rare, but has been reported in at least 18 cases. Most of these patients are between 35 and 75, older than the typical GA patient. Half the cases occur in lymphoma/leukemia patients and half in solid tumor patients. The diagnosis of the neoplasm usually predates the diagnosis of GA, but may precede it. Lesions are described as "atypical" in that they may be painful.

Histology

Because there are many clinical patterns of GA, skin biopsies are often performed to confirm the diagnosis. In general, there are two histopathologic patterns that often coexist in the same patient. The classic pattern of GA is a palisading granuloma characterized by histocytes and epithelioid cells surrounding a central zone of altered collagen. In welldeveloped lesions, there is mucin deposition within the foci of altered collagen. Fibrin and nuclear dust may also be present in the degenerated foci. Lesions are most typically located in the upper and mid-reticular dermis, but may involve the deep dermis or subcutaneous tissue. At the periphery of lesions a leukocytoclastic vasculitis may rarely be found. IgM and C3 in the blood vessels of the skin lesions are found in about half of patients.

The second pattern of GA is the interstitial pattern. Lesions may be entirely interstitial or an interstitial pattern may be seen adjacent to well-formed palisaded lesions. A patchy dermal infiltrate of histiocytes and other mononuclear cells with occasional neutrophils is interspersed between collagen bundles. The patchy distribution within the dermis is best appreciated at scanning magnification. Interstitial mucin is often present in the affected areas, and is best demonstrated with a colloidal iron stain. Although these features are sufficient to confirm the diagnosis of GA, further sectioning may reveal typical palisaded granulomas.

Treatment

Patients regularly report that a biopsy of the lesion will cause its involution. Because the lesions are often asymptomatic and spontaneous involution occurs, no treatment is required in many mild cases. The intralesional injection of triamcinolone suspension is effective for individual lesions and is a reasonable initial treatment. Most cases relapse within 3 to 7 months. Superpotent topical steroids or topical tacrolinus 0.1% ointment may be effective in some patients, especially those with more macular lesions.

Generalized cases represent a major therapeutic challenge. Although systemic steroids may be very effective, the high doses required and the usual immediate relapse as the steroids are tapered make this approach untenable in most situations. In addition, because diabetes may be present, systemic steroids may complicate the management of the diabetes. Many systemic agents have been reported as effective, but few have been tested in large numbers of cases or in blinded or controlled fashion. The combination of tetracycline 500 mg twice a day with nicotinamide 500 mg three times a day or PUVA (either oral or bath delivery) are the most dependable options. Anecdotal reports have suggested response from dapsone, 100 mg once or twice a day; pentoxifylline 400 mg three times a day; systemic retinoids (acitretin or isotretinoin); potassium iodide (SSKI) up to 10 drops three times a day; cyclosporin up to 5 mg/kg/day; UVA-1 phototherapy; defibrotide 400 mg/day; tranilast 300 mg/day; and antimalarials. Infliximals may be considered in severe cases. With all treatments, relapse may occur with discontinuation.

Annular Elastolytic Giant Cell Granuloma (Meischer's) and Actinic Granuloma (O'Brien)

Annular elastolytic giant cell granuloma (AEGCG) and actinic granuloma are unified by their histopathologic appearance. Non-diabetes-associated necrobiosis lipoidica of the face has been included in this category. It is currently unclear whether they simply represent variants of GA occurring on sun-damaged skin or are distinct diseases.

AEGCG typically presents in two patterns. One is a single, asymptomatic, atrophic-appearing, yellow, thin plaque on the forehead (Fig. 31-7). Fine wrinkling and loss of elasticity characterize the skin within the ring. Clinically, this pattern resembles facial necrobiosis lipoidica more than GA. The second variant is of multiple trunk lesions, and occurs more frequently in women and largely in sun-exposed areas. In these cases the lesions have an active erythematous border with central clearing. The condition is chronic and refractory to treatment.

Actinic granuloma as described by O'Brien presents as papules and plaques on sun-exposed skin (Fig. 31-8). Lesions are frequently numerous and may coalesce to cover much of the exposed skin. The diagnosis is suspected by a history of onset after significant sun exposure and the distribution on physical examination. A few lesions may occur on sunprotected sites or spill over from affected areas to more photoprotected sites. This condition affects older adults (usually over age 50) and can be intensely pruritic. It is not associated with diabetes mellitus, but there are numerous

Fig. 31-7 Granuloma annulare, annular elastolytic giant cell granuloma (Meischer), atrophic annular plaque.

Fig. 31-8 Granuloma annulare, generalized papular lesions localized to sun-exposed sites.

reports of it occurring in patients with temporal arteritis. It is speculated that the vasculitis is also due to actinic injury to the connective tissue surrounding the temporal artery.

Histologically, both conditions show a characteristic histology. The dermal infiltrate of macrophages is largely interstitial and well-formed palisaded granulomas are rare. Multinucleated giant cells, often quite large, are numerous. Mucin is scant or lacking. The macrophages characteristically contain fragments of actinically-damaged elastic tissue (elastophagocytosis). When this typical histology is seen in concert with the classic clinical features noted above, it may be reasonable to make these specific diagnoses. These conditions cannot, however, be diagnosed based on clinical or histologic grounds alone. Some cases with the clinical features of AEGCG or actinic granuloma will show a histology more characteristic of typical granuloma annulare, suggesting there is a spectrum of both clinical and histologic features in these patients.

Treatment of these conditions has been difficult. Cases with an active erythematous border tend to respond to systemic steroids, but relapse immediately when the steroids are tapered or discontinued. Tranilast 300 mg/day and chloroquine 250 mg/day have been reported as effective.

- Stratigos AJ, et al: Large annular plaques on the trunk and arms. Arch Dermatol 2003;139:657.

Granuloma Multiforme (Leiker)

Granuloma multiforme is seen most commonly in central Africa, where it is a common disorder, and rarely elsewhere. It affects adults aged over 40 and is more common in females. Lesions are most frequent on the upper trunk and arms, and in sun-exposed areas. It begins as small papules that evolve within a year into round or oval plaques up to 15 cm wide. The active edge of lesions may be elevated to as much as 4 mm in height and the center may be slightly depressed and hypopigmented. Pruritus can occur and coalescing lesions may form unusual polycyclic shapes. The course is chronic. It is most importantly separated from tuberculoid leprosy. Histologically, it resembles GA, but multinucleated giant cells are prominent. Giant cells typically contain phagocytosed connective tissue and elastic tissue is decreased in the areas affected by the granulomas. In these regards it shares features with AEGCG and may represent actinic granuloma/GA of sun-exposed skin.

Sandhu K, et al: Granufoma multiforme. Int J Dermatol 2004; 43:441.

Interstitial Granulomatous Drug Reaction

Interstitial granulomatous drug reaction (IGDR) is an uncommon, yet under-recognized, pattern of adverse reactions to medication. While it may occur within a few days of starting the medication, most patients with IGDR have been on the offending medication for months to years. A wide variety of medications have been implicated, including calciumchannel blockers (most common cause reported), lipidlowering agents, angiotensin-converting enzyme (ACE) inhibitors, diuretics, nonsteroidal anti-inflammatory drugs (NSAIDs), antihistamines, allopurinol, gold, sennoside (a common over-the-counter laxative), and even soy. Clinically the lesions are erythematous annular plaques with an indurated border and sometimes a tendency to central clearing. Lesions favor the creases (groin, axillae, popliteal fossae), but may also affect the trunk, proximal extremities, dorsal hands, palms, and soles. Lesions may be photodistributed. Pruritus is minimal or absent. Mucous membranes and the face are spared. Histologically, there is a diffuse deep dermal infiltrate which is pervascular but has a prominent interstitial component. The inflammatory infiltrate is centered in the lower two-thirds of the dermis; contains neutrophils, eosinophils, histiocytes, and multinucleated giant cells; degenerated collagen bundles may be surrounded by histiocytes, neutrophils, and eosinophils forming "Churg-Strauss" granulomas; and mucin is usually scant or absent. Necrobiotic granulomas are usually incomplete, but have at times been reported to resemble those seen in GA. Unique features are an interface component and "atypical" lymphocytes in the infiltrate. The histologic differential diagnosis includes interstitial granulomatous dermatitis associated with arthritis and interstitial GA. Lesions resolve over months once the offending ingestant is stopped.

Necrobiotic Xanthogranuloma

Necrobiotic xanthogranuloma is a multisystem disease with prominent skin findings that affects older adults. The characteristic skin lesions are periorbital yellow (xanthomatous) plaques and nodules, which occur in 80% of cases. These lesions resemble xanthelasmas, except that they are deep, firm, indurated, and may extend into the orbit. The trunk and proximal extremities may have orange-red plaques with an active red border and an atrophic center with superficial telangiectasias (Fig. 31-9). These plaques may grow to 25 cm in diameter. The skin lesions often ulcerate, leading to atrophic scarring. Acral nodules may also occur. The eyes are prominently involved with orbital masses, conjunctivitis, keratitis, scleritis, uveitis, iritis, ectropion or proptosis. Blindness may result. Lymphadenopathy, hepatosplenomegaly,

Fig. 31-9 Necrobiotic xanthogranuloma.

mucosal, myocardial, and pulmonary lesions may occur. There is a monoclonal IgG (usually κ) paraproteinemia in 80% of cases, and rarely an IgA paraproteinemia (one patient had both). Thrombocytopenia, neutrophilia and eosinophilia may be present. The bone marrow may show plasmacytosis and in some cases anemia, leukopenia, myeloma or myelodysplastic syndromes may evolve. The cause is unknown, and the course is chronic and often progressive.

Histologically, there are extensive zones of degenerated collagen surrounded by palisaded macrophages. These macrophages are of various forms—foamy, Touton cells, epithelioid, and giant cells sometimes with more than 50 nucleí. The process extends into the fat, obliterating fat lobules. Cholesterol clefts and extracelluar lipid deposits are prominent. Within this process is a perivascular and interstitial infiltrate of lymphocytes and plasma cells. Lymphoid follicles are present.

The treatment is usually directed at the paraprotein and consists of systemic corticosteroids, low-dose chlorambucil, plasmapheresis, or local radiation therapy (for eye lesions). Anecdotally, interferon (IFN)- α 2b, 3 to 6 MU three times a week, in combination with systemic corticosteroids and pulse cytoxan with dexamethasone both led to dramatic improvement. Topical nitrogen mustard and BCNU as used in mycosis fungoides or simple excision are options.

SARCOIDOSIS

Sarcoidosis is a systemic granulomatous disease that involves the skin and many of the internal organs with an acute or persistent course interrupted by remissions and relapses. In addition to the skin, which is involved in approximately 25% of cases, other sites of involvement are the lungs, mediastinal and peripheral lymph nodes, eyes, phalangeal bones, myocardium, central nervous system (CNS), kidneys, spleen, liver, and parotid glands.

Sarcoidosis occurs worldwide. In Europe it is most prevalent in Scandinavia, especially in Sweden, with a prevalence of 64 in 100,000. In the UK, the rate is 20 in 100,000, and in France and Germany about 10 in 100,000, with lower rates in Spain and Japan of 1.4 in 100,000. In the US the southeastern states and certain areas in urban centers (New York City, Detroit, and Washington DC) show the highest prevalence. In the US there is a marked racial variation with a rate of 10 to 14 in 100,000 for white persons and 35 to 64 in 100,000 for African Americans. The disease begins most frequently between the ages of 20 and 40, and is slightly more common in women. The highest annual incidence is in African American women between the ages of 30 and 39 who have an annual incidence of 107 in 100,000. Children may also develop sarcoidosis. There are two distinct forms of pediatric sarcoidosis. Early-onset disease, usually before the age of 4, is unique and characterized by the triad of skin lesions, uveitis, and arthritis. It may be confused with juvenile rheumatoid arthritis. Older children, aged 8 to 14, present similarly to adults with lymphadenopathy and pulmonary disease.

Cutaneous involvement in sarcoidosis may be classified as specific, which reveals granulomas on biopsy, or nonspecific, which is mainly reactive, such as erythema nodosum. In about 20% of cases the skin lesions appear before the systemic disease, in 50% there is simultaneous appearance of the skin and systemic lesions, and in 30% the skin lesions appear up to 10 years after the systemic disease has occurred. This is often coincidental with the tapering of systemic steroids for pulmonary sarcoidosis. The cutaneous manifestations of sarcoidosis are quite varied and numerous morphologic lesion types have been described. The morphology of the lesions in sarcoidosis might include papules, nodules, plaques, subcutaneous nodules, scar sarcoidosis, erythroderma, and ulcerations. The lesions may be vertucous, ichthyosiform, hypomelanotic, psoriasiform, or alopecic. In sarcoidosis, lesions are usually multiple and firm and elastic when palpated. They extend to involve the entire thickness of the dermis. The overlying epidermis may be slightly thinned, discolored, telangiectatic, or scaly. The color is faint, showing dull tints of red, purple, brown, or yellow according to the stage of development. Usually the lesions are asymptomatic, but approximately 10% to 15% of patients itch. There is a racial difference in the frequency of cutaneous lesions in sarcoidosis. Among white patients erythema nodosum is as frequent as the specific cutaneous manifestations and both types of cutaneous involvement occur in about 10% of patients with sarcoidosis. In black patients, erythema nodosum is much less common; however, specific cutaneous manifestations occur in 50% or more of patients. The skin lesions in general do not correlate with the extent or nature of systemic involvement or with prognosis. The exceptions are erythema nodosum, which is associated with a good prognosis, and lupus pernio which is associated with bone cysts, sarcoidosis of the upper respiratory tract, and pulmonary fibrosis.

Papular Sarcoid

Papules are the most common morphology of cutaneous sarcoidosis and are usually less than 1 cm in diameter. Lesions

Flg. 31-10 Sarcoidosis, hypopigmented papules.

Fig. 31-11 Sarcoidosis, characteristic papules on the nares.

may be localized or generalized, in which case small papules predominate (Figs 31-10 and Fig. 31-11). This is also known as *miliary sarcoid*. The papules are especially numerous over the face, eyelids, neck, and shoulders. Plaques may occur by the expansion or coalescence of papules. In time the lesions involute to faint macules. Hyperkeratosis may rarely be prominent, giving the lesions a vertucous appearance.

Annular Sarcoidosis

Papular lesions may coalesce or be arranged in annular patterns, usually with a red-brown hue (Fig. 31-12). On palpation the lesions are indurated. Central clearing with hypopigmentation, atrophy, and scarring may occur. Lesions favor the head and neck and are usually associated with chronic sarcoidosis.

Hypopigmented Sarcoidosis

Hypopigmentation may be the earliest sign of sarcoidosis and is usually diagnosed in darkly pigmented races (Fig. 31-13). Lesions vary from a few millimeters to more than a centimeter in diameter and favor the extremities. Although they appear macular by visual inspection, on palpation a dermal or subcutaneous component is often palpable in the center of the lesion.

Lupus Pernio

Lesions typically are brown to violaceous, smooth, and shiny plaques on the head and neck, especially the nose, cheeks, lips, forehead, and ears (Fig. 31-14). Lesions can be very disfiguring. Involvement of the nasal mucosa and underlying bone may occur and lead to nasal perforation and collapse of the nasal bridge. Upper aerodigestive tract involvement is

Fig. 31-12 Sarcoidosis, annular plaque.

Fig. 31-13 Sarcoidosis, hypopigmented and annular plaques.

Fig. 31-14 Sarcoidosis, lupus pernio with rhinophymatous nasal changes.

also common. ENT evaluation is recommended. In threequarters of cases of lupus pernio, chronic fibrotic respiratory tract involvement is found. In 43% of cases, lupus pernio is associated with granulomas in the bones (punched-out cysts), most commonly of the fingers. Chronic ocular lesions occur in 37% of cases. Lupus pernio is typically seen in women in
their fourth or fifth decade of life. The skin lesions rarely involute spontaneously. At times, lupus pernio may resemble rhinophyma. It is important to make the correct diagnosis, as ulceration of sarcoidal lesions may occur with laser treatment, even with pulsed dye laser.

Ulcerative Sarcoidosis

Ulcerative sarcoidosis is very rare, affecting about 5% of patients with sarcoidosis. It affects primarily black women in young adulthood. In half of cases it is the presenting finding of sarcoidosis. The ulcerations may occur de novo or in sarcoidal plaques. Lesions favor the lower extremities. The clinical appearance may not be specific, but skin biopsies are diagnostic. Lupus pernio may also be present. Many patients have multisystem sarcoidosis, although uncommonly no other evidence of sarcoidosis is found.

Subcutaneous Sarcoidosis

Subcutaneous sarcoidosis is also known as Darier-Roussy sarcoid and consists of a few to numerous 0.5- to 3-cm deepseated nodules on the trunk and extremities; only rarely do they appear on the face. The overlying epidermis may be slightly violaceous. A biopsy is usually required to confirm the diagnosis. Five percent or fewer patients with sarcoidosis have subcutaneous nodules.

Sarcoidosis in Scars (Scar Sarcoid)

Infiltration and elevation of tattoos and old flat scars are two variants of scar sarcoid. Previously flat scars raise up and may become erythematous or violaceous. These lesions may be confused with keloids. Infiltration of tattoos may be the first manifestation of sarcoidosis and can be confused with a granulomatous hypersensitivity reaction to the tattoo pigment (Fig. 31-15). From 22% to 50% of biopsies from patients with cutaneous sarcoidosis will contain polarizable foreign material, suggesting that scar sarcoidosis is very common. Scar sarcoid may sometimes occur in patients with acute disease and erythema nodosum, especially if the lesions are small papules on the knees. It may also occur in patients with chronic sarcoidosis.

Plaques

These distinctive lesions are flat-surfaced, slightly elevated plaques that appear with greatest frequency on the cheeks, limbs, and trunk symmetrically. Superficial nodules may be

Fig. 31-15 Sarcoldosis, papules and plaques arising in a tattoo.

superimposed and coalescence of plaques may lead to serpiginous lesions. Involvement of the scalp may lead to permanent alopecia.

Erythrodermic Sarcoidosis

Erythrodermic sarcoidosis is an extremely rare form of sarcoidosis. A diffuse infiltrative erythroderma of the skin usually begins as erythematous, scaling patches that merge to involve large portions of the body.

Ichthyosiform Sarcoidosis

Ichthyosiform sarcoidosis resembles ichthyosis vulgaris or acquired ichthyosis, with fine scaling usually on the distal extremities (Fig. 31-16). It is virtually always seen in nonwhite persons, especially African Americans. Virtually all patients have or will develop systemic disease. In 75% of patients, the skin lesions precede or occur at the same time as the diagnosis of systemic sarcoidosis. Although the lesions have no palpable component, a biopsy will reveal dermal noncaseating granulomas.

Alopecia

Alopecia on the scalp due to sarcoidosis can have multiple morphologies. Plaques may extend into and involve the scalp leading to scarring hair loss (Fig. 31-17). More rarely, macular lesions from one to several centimeters in diameter appear on the scalp and closely resemble alopecia areata. This form may be permanent or reversible. Diffuse alopecia, scaly plaques resembling seborrheic dermatitis, and cicatricial lesions may also occur. A biopsy of all forms of alopecic

Fig. 31-16 Sarcoidosis, ichthyosiform type; biopsy showed noncaseating granuloma although there was no palpable dermal component to the lesions.

Fig. 31-17 Sarcoidosis, scarring alopecia of the scalp.

sarcoid will reveal dermal granulomas and sometimes loss of follicular structures. Scalp sarcoidosis is virtually always seen in African or African American women. In cases where sarcoidosis affects the scalp causing alopecia, the patient virtually always has other cutaneous lesions and the vast majority of cases will demonstrate systemic involvement.

Morpheaform Sarcoidosis

Very rarely, specific cutaneous lesions of sarcoidosis may be accompanied by substantial fibrosis and simulate morphea. Lesions are more typically generalized plaques, but may be localized and resemble linear morphea. Skin biopsy will demonstrate noncaseating granulomas. African American women are most commonly affected. Some patients respond to antimalarial therapy.

Mucosal Sarcoidosis

The lesions in the mouth are characterized by pinhead-size papules that may be grouped and fused together to form a flat plaque. The hard palate, tongue, buccal mucosa, or posterior pharynx may be involved. They may simulate Fordyce spots. In lupus pernio the nasal mucosa is frequently involved.

Erythema Nodosum in Sarcoidosis

Erythema nodosum is the most common nonspecific cutaneous finding in sarcoidosis. Sarcoidosis may first appear with fever, polyarthralgias, uveitis, bilateral hilar adenopathy, fatigue, and erythema nodosum. This combination, known as Lofgren syndrome, occurs frequently in Scandinavian white persons and is uncommon in American blacks. The typical red, warm, and tender subcutaneous nodules of the anterior shins are distinctive and are most frequently seen in young women. The face, upper back, and extensor surfaces of the upper extremities may less commonly be involved. There is a strikingly elevated erythrocyte sedimentation rate (ESR), frequently above 50. Erythema nodosum is associated with a good prognosis, with the sarcoidosis involuting within 2 years of onset in 80% of cases. Conversely, the absence of erythema nodosum is a risk factor for persistent disease activity.

Systemic Sarcoidosis

Sarcoidosis may involve virtually every internal organ and its presentations are protean. Many instances of sarcoidosis are asymptomatic and it is only when routine radiographs of the chest reveal some abnormality that sarcoidosis is

Fig. 31-18 Sarcoidosis, fusiform swelling of the digits.

suspected. Fever may be the only symptom of the disease or be accompanied by weight loss, fatigue, and malaise.

Intrathoracic lesions, including parenchymal lung lesions and hilar adenopathy, are the most common manifestation of the disease, occurring in 90% of cases of sarcoidosis. Pulmonary changes are staged as follows: stage 0, normal; stage I, bilateral hilar and/or paratracheal adenopathy; stage II, adenopathy with pulmonary infiltrates; stage III, pulmonary infiltrates only; stage IV, pulmonary fibrosis. Transbronchial lung biopsy and needle aspiration have a high yield in confirming the diagnosis of sarcoidosis, even in patients with only stage I changes on chest x-ray.

Lymphadenopathy, especially of the mediastinal and hilar nodes, and generalized adenopathy, or adenopathy confined to the cervical or axillary areas, may be an initial sign of sarcoidosis or occur during the course of the disease.

Polyarthralgias may be seen with acute sarcoidosis or as a component of chronic disease. Chronic arthritis may occur (Fig. 31-18). Osseous involvement is often present in chronic disease. The most characteristic changes are found radiographically in the bones of the hands and feet, particularly in the phalanges. They consist of round, punched-out, lytic, cystic lesions. These are seen frequently in patients with lupus peroio. The bone lesions represent epithelioid granulomas.

Ocular involvement is present in 30% to 50% of patients, with granulomatous uveitis the most characteristic lesion.

The lacrimal gland may be involved uni- or bi-laterally by painless nodular swellings. Lesions of the iris are nodular and painless. There may also be lesions of the retina, choroid, sclera, and optic nerve. Ophthalmic disease is highly correlated with systemic involvement. All patients, even those who have no ocular symptoms, should be seen by an ophthalmologist. Sarcoidal involvement of the eye can progress to blindness. Conjunctival biopsy is positive in about 50% of patients with sarcoidosis, making it an easy site to sample and confirm the diagnosis.

Parotid gland and lacrimal gland enlargement with uveitis and fever may occur in sarcoidosis; this is known as *uveoparotid fever* or *Heerfordt syndrome* and usually lasts 2 to 6 months if not treated. Facial nerve palsy and CNS disease frequently are seen in this syndrome. Mikulicz syndrome is bilateral sarcoidosis of the parotid, submandibular, sublingual, and lacrimal glands.

Clinically apparent hepatic involvement occurs in about 20% of patients; however, a blind liver biopsy will reveal granulomas in 60% of cases. Hepatomegaly with elevation of serum alkaline phosphatase, biliary cirrhosis with hyper-cholesterolemia, and portal hypertension with esophageal varices are some of the manifestations. Liver biopsy showing hepatic granulomas is an excellent means of confirming the diagnosis of sarcoidosis.

Renal disease may be due to direct involvement with granulomas or secondary to hypercalcemia. Hypercalcemia is due to pulmonary alveolar macrophage secretion of vitamin D. Nephrolithiasis may result. Cardiac involvement occurs in 5% of cases, but in a higher percentage of autopsy cases.

Neurosarcoidosis occurs in 5% to 10% of patients. It can present in numerous ways from focal cranial nerve involvement (most commonly facial nerve palsy), to aseptic meningitis, seizures, psychiatric changes, stroke, and spaceoccupying lesions. Neurosarcoidosis tends to be chronic and relapsing with a higher mortality rate. Vision loss in sarcoidosis after heat exposure is called the Uhthoff phenomenon.

Most patients with sarcoidosis have an increased ESR. Leukopenia, lymphopenia, anemia, eosinophilia, and thrombocytopenia may be found. Elevated serum proteins occur because of polyclonal hyperglobulinemia. With liver or bone lesions, serum alkaline phosphatase may be elevated. If hypercalcemia is present, anorexia, vomiting, muscle weakness, and polyuria may occur. ACE levels may be elevated in all granulomatous diseases, including sarcoidosis. An elevated ACE level is suggestive, but not diagnostic for granulomatous inflammation. A normal ACE level cannot be used to rule out sarcoidosis and an elevated level does not necessarily indicate the presence of multisystem involvement. If elevated, ACE levels may be used to monitor the activity of the disease.

Etiology/Pathogenesis

The cause of sarcoidosis remains elusive. An attractive hypothesis has been that sarcoidosis occurs after exposure to an appropriate environmental or infectious agent in a genetically susceptible individual. Environmental and infectious etiologies have been sought, but identification of a reproducible infectious agent has remained elusive. *Proprionobacteria* remain possible infectious triggers. One case of sarcoidosis appearing after Bacillus Calmette-Guèrin (BCG) immunization has been reported. The strong racial proclivity and increased risk for a person to develop sarcoidosis if other family members are affected suggest a genetic predisposition. Polymorphisms in various molecules involved in the inflammatory cascade that results in granuloma formation have been reported. These include genes in the major histocompatibility complex (MHC), some of which increase susceptibility and some of which are protective. Tumor necrosis factor (TNF)-a activating polymorphisms have been associated with Lofgren syndrome. TNF levels are elevated in sarcoidosis and alveolar macrophages spontaneously release more TNF. The rate of spontaneous TNF release correlates with disease progression and steroid resistance. IFN A genotype polymorphism resulting in increased IFN- α and interleukin-12 production is also associated with the development of sarcoidosis. It is unlikely that a single genetic mutation is sufficient to cause the disease, but rather multiple genetic factors would be required for an individual to develop sarcoidosis.

Histopathology

The histology of sarcoidosis in all affected tissues is identical. The characteristic finding is that of the "naked tubercle" composed of collections of large, pale-staining, epithelioid histiocytes. There may be small foci of necrosis in the center of the granulomas and multinucleate giant cells, sometimes with inclusions (asteroid bodies and Schaumann bodies), may be present. Although classically there are few lymphocytes around the granulomas, they may be numerous. The granulomas may be nodular, diffuse, or tubular along neurovascular structures.

The histologic differential diagnosis is broad and the diagnosis of sarcoidosis cannot be definitely made histologically. Allergic granulomas caused by zirconium or beryllium are histologically identical to sarcoidosis. Other foreign-body granulomas (especially as a result of silica), granulomatous rosacea, granulomatous secondary syphilis, tuberculoid leprosy, and leishmaniasis may closely simulate sarcoidosis.

The diagnosis of sarcoidosis is established by the demonstration of involvement consistent with sarcoidosis in two different organ systems. This is usually done histologically. If cutaneous sarcoidal granulomas are identified in a patient with no prior history of sarcoidosis, the first diagnostic test to be performed should be a chest radiograph. If this is abnormal, further pulmonary evaluation is indicated. Ophthalmologic evaluation and conjunctival biopsy may be useful. Blind biopsy of the minor salivary glands may demonstrate sarcoidosis. Otherwise, histologic evaluation of any involved tissue may be considered.

Sarcoidosis in the Setting of Immunologic Abnormalities

Numerous reports document sarcoidosis occurring in patients with various forms of lymphoma, especially Hodgkin's disease ("sarcoidosis-lymphoma syndrome"). There are numerous reports documenting the appearance of sarcoidisis in association with IFN- α therapy. Cutaneous lesions (50% of patients), pulmonary findings, or both, as well as other features of sarcoidosis, occur in 5% of patients treated with IFN- α for hepatitis C. The addition of ribavirin may increase the risk. However, hepatitis C virus (HCV) infection alone may be associated with the development of sarcoidosis. Treatment of human immunodeficiency virus (HIV) infection with highly active antiretroviral therapy (HAART) has led to the appearance of sarcoidosis or tattoo granulomas, apparently by enhancing the number and function of helper T-cells. Hematopoetic stem cell transplantation, both allogenic or autologous, has been associated with the appearance of pulmonary sarcoidosis. If the transplantation is performed for malignant disease, the presence of hilar adenopathy may be interpreted as recurrent or metastatic disease and inappropriate treatment may be given.

Differential Diagnosis

Granulomatous secondary syphilis may closely simulate sarcoidosis both clinically and histologically. Blau syndrome, an autosomal-dominant granulomatous disease, is similar to childhood sarcoidosis. It can be distinguished from sarcoidosis by the lack of pulmonary involvement. Granulomatous cutaneous T-cell lymphoma can usually be distinguished histologically and by the presence of pulmonary involvement in sarcoidosis.

Treatment

Numerous therapies have been reported as beneficial in cutaneous sarcoidosis, usually after anecdotal observation. There is virtually no information regarding what types of therapy are best for which of the various cutaneous manifestations. The cutaneous disease may spontaneously remit without treatment. Because most skin lesions are asymptomatic, the major indication for treatment is cosmetic (except for disfiguring facial lesions).

Systemic corticosteroids are virtually always beneficial in cutaneous sarcoidosis. Unfortunately, the doses required to control cutaneous disease may be too high (usually in excess of 15 mg/day) to be ideal for long-term use. For limited skin disease, intralesional injection of 2.5 to 5.0 mg/mL of triamcinolone acetonide suspension is very effective. For thinner lesions, superpotent topical steroids, topical tacrolimus, and UVA1 phototherapy may be effective. A trial of minocycline or doxycycline, up to 100 mg twice a day, may be considered in patients with skin lesions in whom systemic disease does not require treatment. Maximum response is reported to occur at 3 months of therapy.

Systemic corticosteroid therapy is indicated when there is acute systemic involvement with fever and weight loss, in active eye disease, in sarcoidal involvement of the myocardium, in active pulmonary disease with functional disability, in hypersplenism, in hypercalcemia, and in symptomatic CNS involvement.

Antimalarials, both chloroquine and hydroxychloroquine, have been used to treat extensive cutaneous sarcoidosis in doses of 250 mg/day or 200 to 400 mg/day, respectively. About three-quarters of patients appear to respond partially or completely. In some cases the associated pulmonary disease also improves. These agents may also be used to reduce the dose of systemic steroids required.

Methotrexate in doses of 15 to 25 mg/week is also efficacious and seems to help patients with severe lupus pernio or ulcerative sarcoidosis who are otherwise very difficult to treat. Methotrexate-induced hepatitis occurs in 15% of patients with sarcoidosis treated with methotrexate. Leflunomide may be used in analogous fashion to methotrexate and may be used in patients with gastrointestinal intolerance

for methotrexate. Response rates are about 75%. The retinoids, principally isotretinoin, have been reported as beneficial in some patients, usually at doses of 0.5 to 1.0 mg/kg. Response is only seen after 6 or more weeks. Thalidomide, 50 to 200 mg/day, has led to improvement of the skin lesions after several months. It should not be used to treat pregnant patients, however, because of possible teratogenic effects to the fetus. Venous thrombosis may complicate thalidomide therapy, especially if doses above 100 mg/day are used. While azathioprine and cyclophosphamide had been used for refractory disease, mycophenolate mofetil, has shown efficacy in mucocutaneous disease and may be considered as an effective form of rescue and steroid-sparing therapy. The combination of thalidomide, an immunosuppressive agent, in combination with an antimalarial may be effective when these agents fail individually.

TNF is an important cytokine in the formation of granulomas. Not surprisingly, TNF inhibitors, primarily infliximab but also etanercept, have been reported to be effective in refractory cutaneous and systemic sarcoidosis.

HISTIOCYTOSES

Certain syndromes that are well-defined clinically and histologically include the term *histiocyte* in their name. This terminology is less than ideal, since there is no cell called a "histiocyte." These disorders are characterized by infiltrates which contain either Langerhans cells (the X-type histiocytoses) or infiltrates of monocytes/macrophages (the non-X histiocytoses).

Zelger B, Burgdorf WHC: The cutaneous "histiocytoses." In: Advances in Dermatology, vol 17, ch 4. St Louis, Mosby, 2001.

Non-X Histiocytoses

Zelger and Burgdorf proposed classifying this group of disorders as the "xanthogranuloma family". Their classification scheme relies on the morphology of the monocyte/ macrophage composing the lesion. With each variant, the lesions may be localized (as a single lesion or in the skin) or generalized (multiple, widespread lesions with the potential for systemic involvement). Current terminology tends to give each of these separate entitites its own designation. This ignores relationships of certain groups, such as juvenile xanthogranuloma (JXG) and Langerhans cell histiocytosis (LCH), both of which are proliferations of dendritic cells (Fig. 31-19). Benign cephalic histiocytosis, generalized eruptive histiocytosis, and xanthoma disseminatum occur along a spectrum of localized benign, to generalized but benign, to visceral and progressive disease of the same cell type histologically and immunohistochemically.

Juvenile Xanthogranuloma

Juvenile xanthogranuloma (JXG) is the most common non-LCH. Eighty percent of lesions occur before the age of 20. Between 5% and 17% are present at birth and 40% to 70% appear in the first year of life. In adults, lesions tend to occur in the late 20s to early 30s. JXG is 10 times more common in white than black persons, but occurs in all races. In childhood, JXG is slightly more common in males than females, but the gender distribution in adults is equal. Multiple cutaneous lesions affect male children much more commonly (12:1).

Ninety percent of cutaneous JXGs are solitary (Fig. 31-20). They begin as well-demarcated, firm, rubbery, round to oval dermal papules or nodules from 5 to 10 mm in diameter. Early lesions are pink to red with a yellow tinge and become tan-brown over time. Most lesions are asymptomatic. The head and neck are the most common locations, followed by the upper trunk and upper extremities. Lesions have been divided into three forms: small nodular (2-5 mm; Fig. 31-21); large nodular (5-20 mm; Fig. 31-22); and giant xanthogranuloma (>20 mm) types. The small-type lesions are more numerous than the large type. However, often one patient will have both types of lesions and the proposed increased risk for ocular involvement in the micronodular type and other internal involvement in the macronodular type has been refuted. Skin lesions regress spontaneously within 3 to 6 years in children. In adults, lesions are usually persistent. Hyperpigmentation, atrophy, or anetoderma may remain after lesions resolve.

Multiple atypical presentations have been described. These include hyperkeratotic nodules; macronodular tumors from 2 to 10 cm in diameter; clustered forms; flat, plaquelike lesions; and pedunculated lesions. Atypical sites of involvement include the genitalia, lips, palms, soles, earlobes, and fingers. The most common location after the dermis for JXGs

Fig. 31-20 Juvenile xanthogranuloma, solitary.

Fig. 31-21 Juvenile xanthogranuloma, multiple small nodular.

Fig. 31-22 Juvenile xanthogranuloma, multiple large nodular.

is the subcutaneous tissue, again most commonly on the head and neck. About 15% of JXGs present in this manner, usually as a solitary mobile mass up to 3 cm in diameter. Subcutaneous JXG most commonly appears before age 1 and often before age 3 months. Oral JXG may develop in infancy or childhood and is most frequently a solitary lesion of the tongue, lip, or palate.

Extracutaneous JXG is uncommon and occurs either as visceral involvement, in association with multiple cutaneous lesions (5% of JXG cases), or a solitary extracutaneous lesion (also 5% of JXG cases). Ocular involvement occurs in about 0.4% of children with multiple JXGs and 41% of children with ocular JXGs have skin lesions. Skin lesions appear after eye lesions in 45% of cases. Eye lesions usually occur during the first 2 years of life. The most common location is the iris, where JXG can present as a tumor, unilateral glaucoma, unilateral uveitis, with spontaneous hyphema, or as heterochromia iridis. The eyelid or posterior eye may also be involved. Ocular screening is recommended for all children with multiple cutaneous lesions before the age of 2 years.

Mass lesions of the nasal, orbital, and paranasal sinus region can occur and can cause erosion of the orbit and extend to the skull. Other extracutaneous sites and their presentations, in order of frequency, include the lung (respiratory distress and nodular opacities on chest radiograph), liver (hepatomegaly and rarely fatal giant cell hepatitis), testis (mass), and rarely, the CNS, kidney, spleen, and retroperitoneum. Other evaluations for extracutaneous JXGs are not indicated unless there are symptoms or findings suggesting their presence. Extracutaneous lesions also spontaneously regress. If surgical intervention is required, extracutaneous lesions tend not to recur, even if they are incompletely excised.

JXGs have been reported in association with neurofibromatosis (NF-1) and juvenile chronic myelogenous leukemia (JCML). JCML and NF-1 are known to be linked, but since JCML occurs in infancy or early childhood, often café-au-lait macules are the only findings of NF-1 at that time. Sometimes all three conditions affect the same patient, with males having a 3:1 predominance and commonly a maternal history of NF-1. Children with JXG should be examined for stigmata of NF-1. If these stigmata are found, especially in a boy with a maternal history of NF-1, the pediatrician should be alerted of the possible, although uncommon, occurrence of JCML. Rarely, JXG in childhood may be associated with mastocytosis. Multiple xanthogranulomas are rare in adults and for them to occur in an eruptive manner is quite unusual. Three such cases have been associated with hematologic malignancy (lymphocytic leukemia and monoclonal gammopathy).

Lesions appear histologically as nonencapsulated, but circumscribed, proliferations in the upper and mid-reticular dermis and may extend more deeply into the subcutaneous tissue or abut directly on the epidermis with no grenz zone. Epidermotropism does not occur. Classically it has been proposed that the histopathology varies in accordance with the age of the lesion. Very early lesions are composed of mononuclear cells with abundant amphophilic cytoplasm that is poorly lipidized or vacualated. Later the cells become more vacuolated and multinucleated forms appear. In mature lesions, foam cells, multinucleated foam cells (Touton giant cells) and foreign-body giant cells are present. Touton giant cells are characteristic of JXG but not specific for it. The inflammatory infiltrate consists of lymphocytes, eosinophils, and neutrophils, and lacks plasma cells. Fibrosis occurs in the older lesions. The histology described above is characteristic of cutaneous JXGs. Soft-tissue and visceral JXGs present with more monomorphous cytology, may have very few of the characteristic Touton giant cells, and can have a prominent spindle cell appearance. Immunohistochemistry is especially valuable in confirming the diagnosis of extracutaneous JXG. The cells of JXG of all anatomic locations stain with factor XIIIa, vimentin, and CD68, rarely with CD1, and not with S-100.

It is noteworthy that the pattern of involvement by JXG and LCH are similar, with childhood onset, primary cutaneous involvement, and when visceral disease occurs, the liver, bone and lungs are commonly involved. Without histologic confirmation, isolated JXG of the bone would be most likely diagnosed as isolated LCH, a much more common condition. These clinical similarities between JXG and LCH may be explained by the fact that both diseases are caused by antigen-presenting dendritic cells. JXG is a proliferation of dermal dendrocytes and LCH is a proliferation of Langerhans cells. The clinical features favoring JXG include lack of crusting or scale and the distribution and uniformity of size of lesions. Histologic evaluation is definitive in difficult cases since JXGs are negative for the Langerhans cell marker CD1. Unlike LCH, JXGs are usually negative for S100, although a few S100-positive JXGs have been reported. Benign cephalic histiocytosis (BCH) may be difficult to distinguish both clinically and histologically, but in BCH lesions tend to be flatter and are mainly on the head and neck. Papular xanthoma can be distinguished histologically. Clinically, mastocytosis will urticate when scratched (Darier's sign) and can be distinguished histologically. Solitary JXG appearing in a child must be distinguished from a Spitz nevus, usually requiring a biopsy.

Benign Cephalic Histiocytosis

BCH is a rare condition affecting boys and girls equally. The onset is between 2 and 34 months of age (rarely up to 5 years), with 50% of cases beginning between ages 5 and 12 months. The disease begins initially on the head in all cases, often the cheeks, eyelids, forehead, and ears. Lesions may later appear on the neck and upper trunk and less commonly more caudad. There are always multiple lesions, but often few in number (5-20), but can number more than 100. Individual lesions are slightly raised, reddish-yellow papules, 2 to 4 mm in diameter. Lesions may coalesce to give a reticulate appearance. The lesions cause no symptoms. The mucosa and viscera are not involved. Lesions spontaneously involute over 2 to 8 years, leaving behind hyperpigmented macules. Some view BCH as a localized childhood variant of generalized eruptive histiocytoma. Histologically, there is a diffuse dermal infiltration of monomorphous macrophages which do not stain with S-100 or CD1a.

Jih DM, et al: Benign cephalic histiocytosis: A case report and review. J Am Acad Dermatol 2002;47:908.

Generalized Eruptive Histiocytoma (Generalized Eruptive Histiocytosis)

The major characteristics of this rare disease are: 1) widespread, erythematous, essentially symmetrical papules, particularly involving the trunk and proximal extremities, and rarely the mucous membranes (there is no visceral involvement); 2) progressive development of new lesions over several years with eventual spontaneous involution to hyperpigmented macules; and 3) a benign histologic picture of monomorphous, vacuolated macrophages. Lesions appear in crops, but are not grouped. They are skin-colored, brown, or violaceous. Generalized eruptive histiocytoma (GEH) is rare in childhood. GEH may be difficult to distinguish from widespread BCH if indeed it is a separate condition. It is separated from xanthoma disseminatum by the lack of visceral disease, the benign course, and by the scalloped appearance of the macrophages in xanthoma disseminatum. GEH may rarely be associated with underlying malignancy, usually leukemia. Histologically, there is a dermal infiltrate of monomorphous vacuolated macrophages and mononuclear histiocytes. The GEH cells stain positively for vimentin, CD68, MAC387, and negatively for S-100, and CD1a. It has been proposed that GEH is an early

indeterminate stage of various non-X histiocytoses, including indeterminate cell histiocytosis, multicentric reticulohistiocytosis, xanthogranuloma, and xanthoma disseminatum.

Xanthoma Disseminatum (Montgomery Syndrome)

Xanthoma disseminatum (XD) is a rare, potentially progressive non-LCH that preferentially affects males in childhood or young adulthood. It is characterized by the insidious onset of small, yellowish-red to brown papules and nodules that are discrete and disseminated. They characteristically involve the eyelids and flexural areas of the axillary and inguinal folds, and the antecubital and popliteal fossae. Over years the lesions increase in number, forming coalescent xanthomatous plaques and nodules. About 50% of cases have mucous membrane involvement, most commonly of the oropharynx (causing dysphagia), larynx (causing dysphonea and airway obstruction), and conjunctiva and cornea (causing blindness). Diabetes insipidus (in 40%) and less commonly other forms of hypopituitarism occur from involvement of the pituitary fossa. CNS involvement with epilepsy, hydrocephalus, and ataxia can occur. In some cases, the disease may spontaneously involute.

The serum lipids are abnormal in 20% of cases, which may lead to confusion with hyperlipidemic xanthomatosis. Histologic examination of early lesions shows surprisingly nonfoamy, scalloped macrophages. Later lesions show xanthoma cells, Touton giant cells, and frequently, a mild inflammatory cell infiltrate of lymphocytes, plasma cells, and neutrophils. The macrophages stain with CD68 and factor XIIIa.

Disseminated xanthosiderohistiocytosis is a variant of XD in which there is a keloidal consistency to the lesions; they have annular borders, a cephalad distribution, and extensive iron and lipid deposition in the macrophages and connective tissue.

Progressive xanthoma disseminatum can produce considerable morbidity and can even be fatal. Therefore, aggressive therapy may be indicated. Cyclophosphamide has led to dramatic improvement in two of three patients so treated.

Progressive Nodular Histiocytosis

Progressive nodular histiocytosis is clinically characterized by the development of two types of lesions: superficial papules and deeper larger subcutaneous nodules. The larger lesions can be up to 5 cm in diameter and are associated with pain and ulceration. The eruption is diffuse and essentially symmetrical without predilection to the flexural areas. On the face, lesions may coalesce, giving the patient a leonine facies. New lesions progressively appear and spontaneous resolution does not occur. Most patients have no mucosal or visceral lesions, although one patient had a hypothalamic lesion leading to precocious puberty and growth hormone deficiency. Histologically, the superficial lesions show foamy macrophages and the deeper lesions a densely cellular proliferation of spindle-shaped histiocytes with multinucleated giant cells. Local excision may be used for symptomatic lesions.

Papular Xanthoma

Papular xanthoma is a rare form of non-LCH that is poorly defined. It occurs in adults and children and in the latter may involute leaving anetoderma-like scars. The primary lesion is a small, yellow papule from 1 to 10 mm in diameter. There are usually multiple lesions that are generalized. The lesions have no tendency to merge into plaques and do not favor the flexors. There is no visceral involvement and no abnormalities are found on lipid profile examination. Histologically, there are aggregates of xanthomatized foamy macrophages in the dermis with Touton giant cells. Inflammatory cells are scant or absent.

Kim SH, et al: Congenital popular xanthoma. Br J Dermatol 2000;142:569.

Hereditary Progressive Mucinous Histiocytosis in Women

Hereditary progressive mucinous histiocytosis is an autosomal-dominant or X-linked hereditary disorder described only in women. The skin lesions consist of a few to numerous skin-colored to red-brown papules up to about 8 mm in diameter that tend to appear on the face, arms, forearms, hands, and legs. Onset is in the second decade of life, with slow progression and no tendency to spontaneous involution. Visceral and mucosal lesions have not been reported. Histologically, in the mid-dermis there is a proliferation of spindle-shaped and epithelioid monocytes, with the later primarily in the upper dermis. Superficial telangiectatic vessels and increased mast cells are found. Abundant mucin is demonstrated by alcian blue staining, indicating the presence of acid mucopolysaccharides. This condition can be distinguished from the other non-LCHs by its familial pattern, lack of lipidized and multinucleated cells, and presence of mucin. Immunoperoxidase studies have been conflicting. The mononuclear cells in one case were factor XIIIa and CD68 positive and in another case were negative for these antigens.

Reticulohistiocytosis

Two distinct forms of reticulohistiocytosis occur. reticulohistiocytoma and multicentric reticulohistiocytosis. The two forms have identical histology but distinct clinical manifestations.

Reticulohistiocytoma Reticulohistiocytoma usually occurs as a solitary, firm, dermal lesion of less than 1 cm in diameter. Multiple lesions may rarely occur and can be quite extensive and diffuse. Solitary lesions and multiple lesions without systemic involvement, in contrast to multicentric reticulohistiocytosis, have been described mainly in adult men and rarely in children.

Multicentric Reticulohistiocytosis Multicentric reticulohistiocytosis is a multisystem disease beginning usually around age 50 (range 6–86). It is twice as common in women as in men and affects all races. About 25% of reported cases have had an associated malignancy, but no specific type of malignancy is more prevalent. The skin lesions usually appear before the diagnosis of the malignancy, but synchronous behavior of the skin lesions and the underlying malignancy is rarely reported. Given the high frequency of underlying malignancy, however, an evaluation for underlying cancer should be undertaken in a patient with multicentric reticulohistiocytosis.

Clinically, there may be a few to a few hundred firm, skin-colored to red-brown papules and nodules, mostly 2 to 10 mm in diameter, but some reaching several centimeters in size (Fig. 31-23). These occur most frequently on the fingers and hands, with a tendency to cause paronychial lesions. In about half the cases, lesions will be arranged about nailfolds, giving a so-called "coral bead" appearance, which may be associated with nail dystrophy. The upper half of the body, including the arms, scalp, face, ears, and neck are also common sites. Ninety percent of patients have lesions on the face and hands. Characteristic are nodular and papular involvement of the pinnae and a symmetrical distribution of the lesions, especially over joints. The nodules on the arms,

Chen CG, et al: Primary papular xanthoma of children. Am J Dermatopathol 1997;19:596.

Fig. 31-23 Multicentric raticulohistiocytosis.

elbows, and knees may resemble rheumatoid nodules. Some patients may complain of pruritus.

Mucous membrane involvement is seen in half the cases and is most frequent on the lips and tongue; other sites are the gingiva, palate, buccal mucosa, pharynx, larynx, and sclera. One-third of cases have hypercholesterolemia and xanthelasma. Rheumatoid factor is negative.

Osteoarticular changes are the most important aspect of multicentric reticulohistiocytosis. In 40% of cases joint symptoms precede the appearance of the skin lesions and in 30% the skin and joint disease occurs simultaneously. The associated arthropathy is an inflammatory, symmetrical, polyarticular arthritis that can affect many joints, including the hands, knees, shoulders, wrists, hips, ankles, elbows, feet, and spine. The arthritis can be rapidly destructive and mutilating, with absorption and telescopic shortening of the phalanges and digits—doigts en lorgnette, opera-glass fingers. In older reports at least 50% of cases developed arthritis mutilans, but this has been reduced to about 12% with aggressive early treatment. The joint involvement may resemble rheumatoid arthritis and psoriatic arthritis. Weight loss and fever occur in one-third of patients.

Other organs and tissues may be involved, such as bone, muscle, lymph nodes, liver, myocardium, pericardium, pleura, and stomach. Myocardial involvement may be fatal. Gallium scans have been proposed as a screening method to assess the extent of disease. The clinical course varies. In many instances there is complete involution after about 8 years. The joint destruction is permanent, however, and is a cause of severe disability.

Histologically, the skin lesions are usually centered in the mid-dermis and tend to occupy much or all of the dermis. The infiltrating cells are mononuclear and multinucleate monocyte/macrophages. The giant cells are most characteristic with an abundant smooth, or slightly granular, eosinophilic or amphophilic "ground-glass" cytoplasm. Their cytoplasm is darker in the center than at the periphery. These cells stain positive for periodic-acid Schiff (PAS) after diastase digestion. The overlying epidermis may be thinned but is usually separated from the dermal process by a narrow zone of collagen (Grenz zone). Characteristically, there is polymorphous infiltrate of lymphocytes, neutrophils, eosinophils, and plasma cells within the lesions.

Given the aggressive nature of the arthritis, early and adequate treatment should be considered. However, associated malignancy is frequent and can be worsened by immunosuppressive therapy. The same would be true if there were underlying asymptomatic tuberculosis. Initially, the patient should be screened for these two conditions and they should be adequately treated if found. In patients free of neoplasia and tuberculosis, the treatment is individualized. Spontaneous remissions are common, making efficacy of treatment hard to determine. Initially, in mild cases, low-dose prednisone with antimalarials or low-dose methotrexate could be considered. In severe cases, more aggressive immunosuppressive therapy with a cytotoxic agent such as cyclophosphamide (Cytoxan), 1 to 2 mg/kg/day with or without corticosteroid treatment, could be considered. The lowest dose of cytotoxic should be used to maintain control of the arthritis and the medications discontinued as soon as possible. Alendronate and etanercept have been reported as effective in controlling the arthritis and improving the skin lesions. For patients with skin lesions only, therapy is not required. PUVA, antimalarials, topical nitrogen mustard, and low-dose methotrexate, alendronate, or etanercept could be considered if symptoms are severe.

Indeterminate Cell Histiocytosis

Indeterminate cells are felt to represent dermal precursors of Langerhans cells. They are S-100 and CD1a positive, but do not contain Birbeck granules. Less than 50 cases of indeterminate cell histiocytosis have been described, half in one report. Children and adults are affected, with males outnumbering females. Solitary and multiple lesions may occur, and the color of lesions varies from yellow to red brown. Lesions may be papules, plaques or nodules from 3 mm to 10 cm in size. Visceral involvement of bone and conjunctiva are rare. Histologically, while the cells in these cases do stain with S-100 and at times with CD1a, the staining is never as intense as Langerhans cells. At times the infiltrating cells in non-LCH can be S-100 positive and weakly and focally CD1a positive. This has led Ratzinger et al to suggest that most cases reported as indeterminate cell histiocytosis are some form of non-LCH or sinus histiocytosis with lymphadenopathy, and indeterminate cell histiocytosis is not a distinct entity. Indeterminate cells may be found as a minor component of the dermal infiltrate in nodular scabies and rarely following pityriasis rosea. Severe cutaneous involvement in indeterminate cell histiocytosis has been treated with chemotherapeutic agents similar to those used for LCH including cyclophosphamide, etoposide, vinblastine, systemic corticosteroids, and 2-chlorodeoxyadenosine.

Sea-Blue Histiocytosis

Sea-blue histiocytosis may occur as a familial inherited syndrome or as an acquired secondary or systemic infiltrative process. The characteristic and diagnostic cell is a histiocytic cell containing cytoplasmic granules that stain blue-green with Giemsa stain and blue with May-Gruenwald stain. The disorder is characterized by infiltration of these cells into the marrow, spleen, liver, lymph nodes, and lungs, as well as the skin in some cases. Skin lesions include papules, eyelid swelling, and patchy gray pigmentation of the face and upper trunk. Similar histologic findings have occurred in patients with myelogenous leukemia, adult Neimann-Pick disease (type B), and following the prolonged use of intravenous fat supplementation. The inherited form may be associated with neurologic symptoms, including ataxia, epilepsy, and dementia.

X-TYPE HISTIOCYTOSES

This group of disorders is caused by infiltration of the skin, and in some cases other organs, by Langerhans cells. The spectrum of disease is similar to that seen in mastocytosis, with solitary, usually benign and autoinvoluting lesions, multicentric skin-limited disease, and visceral disease. In the LCHs, multicentric skin disease and systemic disease are common, and severe morbidity and mortality are unfortunately not uncommon.

Congenital Self-Healing Reticulohistiocytosis (Hashimoto-Pritzker)

Congenital self-healing reticulohistiocytosis (CSHR) is an autoinvoluting, self-limited form of LCH. CSHR is usually present at birth or appears very soon thereafter. It has been described in two forms: a solitary and a multinodular variant. Solitary or generalized lesions can affect any part of the cutaneous surface. Lesions range from 0.2 to 2.5 cm in diameter (Fig. 31-24). Lesions may grow postnatally. Exceptionally large tumors up to 8 cm in diameter can occur. At presentation the lesions can be papules or nodules with or

Fig. 31-24 Congenital self-healing reticulohistiocytosis, solitary lesion.

without erosion or ulceration. Individual lesions are red, brown, pink, or dusky. Lesions may rarely appear as hemorrhagic bullae. Lesions greater than 1 cm characteristically ulcerate as they resolve. Lesions are asymptomatic and spontaneously involute over 8 to 24 weeks, leaving atrophic scarring from the ulcerated nodules. Internal involvement is not found.

On histologic examination large mononuclear cells and multinucleated giant cells with ground-glass or foamy cytoplasm are present in the dermis and epidermis. Immunoperoxidase staining is positive for CD1, HLA-DR, and S-100. By electron microscopy 10% to 25% of cells have Langerhans cell granules. This histology is characteristic but cannot distinguish this entity from other forms of LCH, so a definitive diagnosis cannot be made histologically.

This is a proliferation of Langerhans cells. Because LCH with systemic involvement may present in identical fashion, systemic evaluation is recommended, including a physical examination, complete blood count, liver function tests, and bone survey. A liver-spleen scan and bone marrow biopsy should be considered.

- Thong HY, et al: An unusual presentation of congenital selfhealing reticulohistiocytosis. Br J Dermatol 2003;149:191.

Langerhans Cell Histiocytosis (Histiocytosis X)

LCH, or histiocytosis X, is a disease characterized by proliferation of Langerhans cells. This group of disorders can involve many organ systems but affects primarily the bone, skin, lymph nodes, lungs, liver and spleen, endocrine glands, and nervous system. The separation of these conditions into separate entities—Letterer-Siwe disease, Hand-Schuller-Christian disease, and eosinophilic granuloma—is of historical interest only. Currently, the disease is classified by the number of organ systems involved (single or multisystem) (Box 31-1). This classification, as in staging cutaneous T-cell

Box 31-1 Classification system for Langerhans cell histiocytosis (LCH)

- 1. Single organ involvement
 - Lung
 - Bone
 - Skin
 - Pituitary
 - Lymph node
 - Other sites
- 2. Multisystem disease
 - Multiorgan disease with lung involvement
 - Multiorgan disease without lung involvement
 - Multisystem histiocytic disorder

Alternative classification system (relating to old classification scheme)

- Acute disseminated LCH (multifocal, multisystem disease)
 = Abt-Letterer-Siwe
- Chronic multifocal LCH (multifocal, unisystem disease) = Hand-Schuller-Christian
- Chronic focal LCH (unifocal) = eosinophilic granuloma

lymphoma, is flawed, since Langerhans cells circulate in the blood and small foci of involvement in internal organs may not be detected. The disease affects primarily children from 1 to 4 years of age, but can present from birth to the ninth decade. It is uncommon, with an incidence of between 4 and 40 per million children per year. It is less common in adults, and presents at an average age of 33 years. The range of clinical features of LCH in any organ is identical in children and adults, but the relative percentages of patients with multisystem disease versus single organ disease differs markedly. Localized disease appears more common in children, primarily as localized bone disease (eosinophilic granuloma of bone). In adults, multisystem disease is most common, and prognosis is better for localized versus multisystem disease, except for isolated pulmonary LCH which represents 15% of all adults with LCH and has the worst prognosis.

The pathogenesis of LCH is unknown. There remains debate as to whether the infiltrating cells are truly neoplastic or simply reactive. It is clear that the infiltrating Langerhans cells are clonal. However, aneuploidy is infrequent and histologically the cells do not appear atypical as in lymphoma. These features have led to the suggestion that the proliferation of Langerhans cells is cytokine related. A family history of LCH is found in about 1% of childhood cases and a lesser percentage of adults. Associated lymphomas, solid tumors, and leukemias have occurred in patients with LCH, with acute lymphoblastic leukemia preceding the appearance of LCH and acute myeloblastic leukemia following it.

Skin Lesions About 10% of children have single-organ disease involving only the skin and 50% have skin involvement, making skin the most commonly involved organ in childhood LCH. Skin involvement occurs in 50% of adults with multisystem LCH, being slightly less common than pulmonary and bone lesions. Only 2% of adult patients with LCH have isolated skin disease. In children and adults, the pattern of skin disease does not predict the presence or extent of systemic disease. The most common form of skin disease in children is that described in Abt-Letterer-Siwe disease. The skin lesions are tiny red, red-brown, or yellow papules that are widespread but favor the intertriginous areas, behind the ears, and the scalp (Figs 31-25 and 31-26).

Fig. 31-26 Langerhans cell histiocytosis: seborrheic dermatitis-like eruption with hemorrhage.

Fig. 31-28 Langerhans cell histiocytosis, xanthomatous nodule in a patient with dlabetes insipidus.

Fig. 31-27 Langerhans cell histiocytosis, bullous lesions.

There is a superficial resemblance to seborrheic dermatitis, but on careful inspection the lesions are individual papules and there is focal hemorrhage in the lesions. The papules are often folliculocentric. Lesions may erode or weep. In children this pattern frequently is associated with multisystem disease. In the rare adult cases, one-quarter have disease limited to the skin. A rare variant of this pattern of LCH is one in which vesicles appear (Fig. 31-27). This can occur in infants or adults. The vesicles are due to large intraepidermal collections of Langerhans cells and a Tzanck smear may lead to suspicion of the diagnosis. A less common presentation is with slightly larger papules up to 1 cm in diameter. These lesions tend to be yellow-red and resemble xanthomas or xanthogranulomas (Fig. 31-28). They can be numerous and widespread. A rare variant resembling lichen planopilaris has been reported.

Nail changes can occur, but are uncommon and can include longitudinal grooving, purpuric striae, hyperkeratosis, subungual thinning, deformities, loss of nail plate, and paronychia. Both fingernails and toenails may be affected and nail involvement has occurred in both children and adults. Most patients with nail involvement have multisystem disease.

LCH restricted to the genitalia is rare, but vulvar, inguinal, and perianal disease may be the initial manifestation of LCH. It tends to be painful and ulcerative, and may simulate hidradenitis suppurativa, since axillary and scalp involvement may also be present.

Histologically, there is a dense dermal infiltrate of Langerhans cells. This can be superficial and immediately below the epidermis (in small papular and seborrheic-like lesions), folliculocentric, or deep and diffuse (in papular and nodular lesions). The Langerhans cells are recognized by their abundant, amphophilic cytoplasm and eccentric round or kidney bean-shaped nucleus. There is frequently exocytosis of the abnormal cells into the overlying epidemnis. If this is extensive, macroscopic vesicles can be seen, and erosion can occur secondarily. The dermal infiltrate is accompanied by many other inflammatory cells, including neutrophils, eosinophils, lymphocytes, and plasma cells. Dermal edema and hemorrhage are characteristically present. In larger and older lesions the infiltrating histiocytic cells become foamy and fibrosis may be present. The histologic features of the Langerhans cells, such as nuclear atypia and mitotic indices, do not predict prognosis and are not reproducible. This makes those cases reported as "malignant" Langerhans cell tumor hard to interpret.

Immunohistochemistry is useful in confirming the diagnosis. The infiltrating cells in LCH are S-100 and CD1a positive. Electron microscopy will detect the presence of Birbeck granules. In older lesions and in some organ systems the number of cells staining with these markers and containing Birbeck granules is much diminished. The number of Birbeck granules and the presence of other intracellular structures, such as lamellar bodies, are not useful in classifying LCH cases.

Oral Mucosa Lesions The oral mucosa may be involved. Periodontal involvement is most common, affecting primarily the jaw (Fig. 31-29). Alveolar bone is lost with detachment of the teeth which on x-ray appear to be "floating." Palpable masses and gingival lesions should be looked for and a dental evaluation completed in all patients. Bilateral parotid swelling may occur.

Visceral Involvement The most commonly involved organ is the bone (Fig. 31-30). In various series between one- and two-thirds of pediatric patients and 12% of adult patients have disease limited to one or several bones. The lesions may be asymptomatic or cause pain. The skull is most commonly involved, followed by the long bones, then the

Fig 31-29 Langerhans cell histiocytosis, gingival lesions.

Fig. 31-30 Langerhans cell histiocytosis, eosinophilic granuloma of rib that eroded through to the skin.

flat bones. Bony lesions tend to occur in older children and young adults. Lesions are treated with curettage, intralesional corticosteroids, or radiation. Endocrine dysfunction occurs usually in the form of diabetes insipidus, which is more common in patients with bone disease of the skull and in patients with extensive disease.

Lymph nodes are characteristically involved, especially the cervical nodes. The bone marrow may be affected and the presence of pancytopenia is usually associated with a poor prognosis in childhood LCH. This may present as purpura in the skin.

The liver may be involved directly by infiltration with Langerhans cells or may be indirectly affected by enlarged nodes in the porta hepatis leading to obstructive disease. Either pattern can lead to biliary cirrhosis.

Pulmonary LCH occurs on average at age 33 years. A diffuse micronodular pattern on chest radiograph may progress to cyst formation (honeycomb lung), large bullae, and pneumothorax. More than 90% of adults with pulmonary LCH are smokers. Five-year survival is 88%.

Prognosis

In childhood LCH outcome is determined by the extent of involvement and, more importantly, the function of affected organs. Children younger than 2 years with multisystem disease have the worst prognosis, with a 37% mortality, as opposed to 16% for children over the age of 2 years. Early, initial response to multidrug chemotherapy in childhood multisystem LCH is an important predictor of survival, with 92% of responders and 11% of nonresponders after 6 weeks of treatment surviving. In adults, isolated disease, except pulmonary disease, has the best prognosis. Multisystem LCH in adults has a 5-year survival of 91.7%. Baseline and repeated evaluation are important. Lesions in one organ system may resolve while disease progresses in another organ. Skin lesions may spontaneously resolve, only for the disease to relapse, even years later, so patients must be followed regularly. In addition, if chemotherapeutic agents are used for treatment, a risk of secondary malignancies of less than 5% exists.

Differential Diagnosis

The diffuse small papular form is frequently misdiagnosed as seborrheic dermatitis. The yellow color of the lesions and the presence of hemorrhage in the small papules, if present, should suggest the diagnosis of LCH. Nodular lesions of scabies can closely simulate LCH. This includes the finding of Langerhans or indeterminate cells in the dermal infiltrate by electron microscopy and S100 and CD1a staining. The larger papules resemble juvenile xanthogranulomas and xanthomas. Erosive genital disease may simulate hidradenitis.

Treatment

Treatment is not always required. LCH may spontaneously remit, especially cases of isolated skin or bone disease. For disease limited to the skin, topical corticosteroids may be used. Topical nitrogen mustard 20% (as used for cutaneous T-cell lymphoma) is an effective nonsystemic approach. Some patients with superficial lesions have responded to PUVA. Thalidomide has been successful in doses from 50 to 300 mg/day in skin and genital disease, but associated visceral disease may not respond in parallel. Low-dose methotrexate 20 mg/week has been effective in treatmentresistant cutaneous disease. IFN- α , 3 MU three times a week, has cleared cutaneous lesions and improved visceral disease. Intralesional IFN can be effective. Radiotherapy is less effective for mucocutaneous disease than bone disease.

In multisystem disease of childhood, vinblastine and corticosteroids are the current standard for treatment. Cyclosporin, methotrexate, cytarabine, and 6-mercaptopurine can all be effective. Combination therapy may be used. In refractory cases, 2-chlorodeoxyadenosine has been successful. Etoposide is not currently recommended by the Histiocyte Society, due to concerns regarding secondary leukemias. Autologous or allogenic stem cell rescue has rarely been performed. Liver transplantation for end-stage liver disease resulting from LCH is complicated by an increased risk of acute rejection and, possibly, an increased risk of post-transplant lymphoproliferative disorder. Basiliximab may be used.

CHAPTER

Cutaneous Lymphoid Hyperplasia, 32 Cutaneous T-Cell Lymphoma, Other Malignant Lymphomas, and Allied Diseases

CUTANEOUS LYMPHOID HYPERPLASIA (LYMPHOCYTOMA CUTIS, LYMPHADENOSIS BENIGNA CUTIS, PSEUDOLYMPHOMA)

The term *cutaneous lymphoid hyperplasia* refers to a group of benign disorders characterized by collections of lymphocytes, macrophages, and dendritic cells in the skin. These processes can be caused by known stimuli (such as medications, injected foreign substances, infections, or the bites of arthropods) or they may be idiopathic. They may have a purely benign histologic appearance or resemble cutaneous lymphoma. If there is a histologic resemblance to lymphoma, the term pseudolymphoma was used in the past. Most cases contain a mixed population of T- and B-cells, but they may contain mostly T-cells. By standard techniques, most cases of cutaneous lymphoid hyperplasia will be found to lack clonality. Cases of monoclonal B- and T-cell cutaneous lymphoid hyperplasia do occur. Thus, a finding of monoclonality does not equate to the diagnosis of malignancy or lymphoma, nor does it predict biologic behavior. A subset of polyclonal or monoclonal (T- or B-cell) cutaneous lymphoid hyperplasias does progress to cutaneous B-cell and less commonly T-cell lymphoma. Even when the initial evaluation detects a 'l-cell rich infiltrate (>90%), which may be monoclonal, the lymphoma which eventuates from this form of cutaneous lymphoid hyperplasia may be B-cell. Thus, as in many cancer syndromes, cutaneous lymphoid hyperplasia represents the benign end of a spectrum of cutaneous lymphoid proliferation with cutaneous lymphoma at the other end and cases falling everywhere along that spectrum of progression. Unfortunately, current techniques cannot predict accurately which cases will progress.

Histologically, the cutaneous lymphoid hyperplasias also represent a spectrum of disease. At one end are cases that are benign in appearance. Intermediate cases are histologically atypical but with benign clinical behavior. (In the past, the term "pseudolymphoma" might have been used.) At the other end are cases that are histologically ambiguous, some of which may progress to lymphoma or represent lymphoma from the onset but which cannot reliably be diagnosed. Clonality studies for both T- and B-cell markers may show clonality for either or both in some cases of cutaneous lymphoid hyperplasia. The clonality studies do not correlate directly with cytologic features; cases with clonal T-cell gene rearrangement may progress to cutaneous B-cell or T-cell lymphoma; and both cases with and without clonality may progress to cutaneous B-cell lymphoma. This makes evaluation of some cutaneous lymphoid infiltrates very challenging. The clinician must provide the dermatopathologist with accurate and complete information and an adequate full thickness tissue sample to evaluate. Any change in clinical behavior

or morphology may be an indication for repeat histologic, immunophenotypic, and immunogenetic evaluation to exclude the development of true cutaneous lymphoma. Lymphoid hyperplasias that occur in the setting of immunosuppression may behave aggressively, like lymphomas, but regress with the discontinuation of immunosuppression.

Two clinical patterns of cutaneous lymphoid hyperplasia exist. The nodular form consists of nodular and diffuse dermal aggregates of lymphocytes, macrophages, and dendritic cells. The clinical and histologic differential diagnosis is cutaneous B-cell lymphoma. The diffuse type is usually associated with drug exposure or photosensitivity (actinic reticuloid). Histologically it is to be distinguished from cutaneous T-cell lymphoma.

Cutaneous Lymphoid Hyperplasias (Nodular Pattern)

The nodular pattern of cutaneous lymphoid hyperplasia is the most common pattern. It usually presents in adults and is two to three times more common in women. It favors the face (cheek, nose, or earlobe) and the majority of cases present as a solitary or localized cluster of asymptomatic, erythematous to violaceous papules or nodules (Fig. 32-1). Less commonly, lesions may affect the trunk (36%) or extremities (25%). At times the lesions may coalesce into a plaque or be widespread in one region, in which case they present as miliary papules. Systemic symptoms are not present and except for rare cases with regional lymphadenopathy, there are no other physical or laboratory abnormalities. Etiologically, it is usually idiopathic, but can be caused by tattoos, Borrelia infections, herpes zoster scars, antigen

Fig. 32-1 Reactive lymphoid hyperplasia.

injections or acupuncture, and, in rare cases, drug reactions and persistent insect bite reactions. Lesions that result from a known stimulus tend to be localized to the site of the original process—tattoo, injection, or insect bite.

Borrelia-induced cutaneous lymphoid hyperplasia is an uncommon manifestation of this infection, occurring in 0.6% to 1.3% of cases reported from Europe. The lack of borrelial pseudolymphoma in the US compared with Europe may relate to the fact that there are different borrelial species in Europe, specifically Borrelia afzeli, that cause borreliosis. Lesions occur at the site of the tick bite or close to the edge of a lesion of erythema migrans. Lesions may appear up to 10 months after infection. Lesions may be multiple and favor the earlobes, nipple and areola, nose, and scrotal area and vary from 1 to 5 cm in diameter. Usually there are no symptoms, but associated regional lymphadenopathy may be present. Late manifestations of Borrelia infection are uncommon. The diagnosis is suspected by a history of a tick bite or erythema migrans, the location (earlobe or nipple), and the histologic picture. The diagnosis is confirmed by an elevated anti-Borrelia antibody (present in 50% of cases) and the finding of borrelial DNA in the affected tissue. The treatment is penicillin. Some cases progress to true lymphoma.

Histologic examination of nodular cutaneous lymphoid hyperplasia reveals a dense, nodular infiltrate that occupies primarily the dermis and lessens in the deeper dermis and subcutaneous fat, i.e. it is "top-heavy." The process is usually separated from the epidermis by a clear grenz zone. The infiltrate is composed chiefly of mature small and large lymphocytes, histiocytes, plasma cells, dendritic cells, and eosinophils. In the deeper portions, well-defined germinal centers are usually seen, with central large lymphoid cells with abundant cytoplasm and tingible body macrophages, and a peripheral cuff of small lymphocytes.

The clinical lesions may be nondescript and the differential diagnosis quite broad, usually mandating a biopsy. *Amyloidosis, sarcoidosis, secondary syphilis, and lymphoma* should be considered. Histologically, the primary differential diagnosis is cutaneous lymphoma. Histologic criteria and even immunophenotyping and immunogenetic analysis may not be sufficient to predict biologic behavior. Most cases are mixed B- and T-cell proliferations, but about 10% of cases are primarily T-cell infiltrates (>90% T-cells). CD30+ cells may be prominent, raising the concern about the development of a CD30+ lymphoproliferative disorder.

Because most lesions are asymptomatic, treatment is not required. If the process has been induced by a medication, use of the medication should be discontinued. Infection should be treated and localized foci of infection removed. Intralesional steroidal agents are sometimes beneficial, but lesions may recur in a few months. Potent topical steroids may also be tried for superficial lesions. Cryosurgery, thalidomide 100 mg/day for a few months, interferon (IFN)- α , laser ablation, or surgical excision can all be effective. Lowdose radiation therapy is usually very effective and may be used on refractory facial lesions that cannot be satisfactorily removed surgically. If monoclonality is detected in a localized lesion, complete removal and local radiation has been recommended, but there is no evidence this improves outcome, and lesions that are not initially monoclonal may also progress to lymphoma.

Cutaneous Lymphoid Hyperplasias (Bandlike and Perivascular Patterns)

Cutaneous lymphoid hyperplasias may histologically show a bandlike and perivascular dermal infiltrate, at times with epidermotropism. They may be idiopathic or caused by photosensitivity (formerly called *actinic reticuloid*; now called *chronic actinic dermatitis*), medications (usually anticonvulsants, but also many others), or contact dermatitis (so-called lymphomatoid contact dermatitis).

Clinically, these patients have lesions that clinically resemble mycosis fungoides: they have widespread erythema with scaling. Thicker plaques may occur as well and these cases are frequently caused by medications. The treatment is to stop any implicated medication. If stopping the medication is ineffective, topical and intralesional steroids, PUVA, and, for persistent localized lesions, radiotherapy may be considered.

The cytologic appearance of the atypical lymphocytes is usually adequate to identify cases of small cell lymphoma that may mimic lymphoid hyperplasia. Such lymphomas are usually of B-cell origin, so immunophenotyping is helpful. If T-cells are identified, immunogenetic studies to detect T-cell receptor clonal rearrangements should be considered. If monoclonality is identified, the case must be carefully evaluated for systemic involvement (including computed tomographic [CT] scans of the chest, abdomen, and pelvis, and perhaps a bone marrow biopsy). Distinguishing monoclonal T-cell lymphoid hyperplasia from small cell lymphoma may be very difficult.

Jessner Lymphocytic Infiltrate of the Skin

The existence of this entity has recently been challenged. Even the coauthors of the original paper feel their cases would now best be classified as a variant of lupus erythematosus. Clinically, Jessner is a persistent papular and plaque-like eruption that is photosensitive and occurs primarily on the face. Histologically there is a superficial and deep perivascular and periadnexal lymphocytic infiltrate. Interface dermatitis is absent. The infiltrating lymphocytes are suppressor T-cells (CD8+). It is distinguished from cutaneous lupus erythematosus by the absence of an interface dermatitis, lack of mucin, and negative direct immunofluorescence. Tumid lupus erythematosus has predominantly helper T-cells in the infiltrate. Since the spectrum of chronic cutaneous lupus erythematosus has expanded to include tumid lupus erythematosus and subacute cutaneous lupus erythematosus, however, the diagnosis of lupus erythematosus can now be made in cases lacking an interface dermatitis and with negative serologies and direct immunofluorescence. Polymorphous light eruption (PMLE) is distinguished from Jessner by having edematous papules and plaques that are more transient, and by the presence of dermal edema. In PMLE the infiltrating cells are CD8+. There may still exist true cases of lymphocytic infiltration of the skin. To clearly distinguish them from lupus erythematosus and PMLE, the lesions must contain predominantly CD8+ suppressor T-cells, lack dermal mucin and dermal edema, be fixed (not transient like PMLE), and patients must have negative direct immunofluorescence and serologic testing for lupus erythematosus. Both Jessner and chronic cutaneous lupus erythematosus can respond to antimalarials.

CUTANEOUS LYMPHOMAS

Cutaneous lymphoma can be considered to be either primary or secondary. Primary cutaneous lymphomas are those that occur in the skin and where no evidence of extracutaneous involvement is found for some period after the appearance of the cutaneous disease. Cases of simultaneous skin and lymph node involvement (except for cases of mycosis fungoides with lymph node involvement) cannot always be absolutely classified as primary because the "origin" of the lymphoma cannot be determined. Secondary cutaneous lymphoma includes cases that have simultaneous or preceding evidence of extracutaneous involvement. These cases are best classified and managed as lymph node-based lymphomas with skin involvement. This conceptual separation is not ideal, but it has been important in developing classification schemes and determining prognosis in cutaneous lymphomas.

For many years classification of lymphomas has been based on their histologic appearance, and lesions from all organ systems were classified histomorphologically in an identical manner to lymphomas arising in lymph nodes. It had been recognized that these classification schemes have major shortcomings when applied to extranodal lymphomas. Specifically, they did not uniformly predict clinical behavior. New classification schemes have been developed that are specific for primary cutaneous lymphomas. In the following discussion, the classification scheme followed incorporates the EORTC, REAL, and WHO classifications.

Cutaneous lymphomas are classified based on their cell type of origin. There are B-cell lymphomas, T-cell lymphomas, true histiocytic lymphomas, and rarer types. Cell type is further classified by specific lymphoid markers associated with features of normal lymphocytes. Histologic features used in this classification system include cell size (large versus small) and differentiation features (follicular center cell, immunoblast, and so on). These features are supplemented by immunophenotypic markers such as CD30. Despite these major conceptual and diagnostic advances, the diagnosis and classification of cutaneous lymphomas can still be quite difficult. Because appropriate classification may be prognostically important, experienced dermatopathology consultation should be sought in cases of cutaneous lymphoma.

Primary Cutaneous T-Cell Lymphomas

A major insight into cutaneous lymphoma was the finding that the majority of lymphomas in the skin were of T-cell origin. This is logical, since T-cells normally traffic through the skin and are important in "skin-associated lymphoid tissue." Unfortunately, dennatologists frequently use the term cutaneous T-cell lymphoma synonymously with mycosis fungoides. Although mycosis fungoides represents the large majority of primary cutaneous T-cell lymphomas, it is not synonymous with cutaneous T-cell lymphoma are not mycosis fungoides.

Because cutaneous Hodgkin's disease is very rare to nonexistent, the term *non-Hodgkin lymphoma* has little meaning when speaking of a lymphoma in the skin, because virtually all cutaneous lymphomas are "non-Hodgkin lymphomas." The term *non-Hodgkin lymphoma* may sometimes also be applied in cases of secondary cutaneous lymphoma. The following discussion is divided into mycosis fungoides and related conditions, Sézary syndrome, and lymphomatoid papulosis; and non-mycosis fungoides primary cutaneous Tcell lymphomas.

Mycosis Fungoides Mycosis fungoides is a malignant neoplasm of T-lymphocyte origin, almost always a memory T-helper cell. The incidence is 1 in 300,000 per year. Mycosis fungoides affects all races. In the US black persons are relatively more commonly affected than white persons. The condition is twice as common in males as in females.

Natural History

In general, mycosis fungoides is a chronic, slowly progressive disorder. It usually begins as flat patches (patch stage), which may or may not be histologically diagnostic of mycosis (ungoides (hence the term *premycotic*). This inability to diagnose early cases has more to do with the limits of diagnostic capabilities, rather than a transformation from some non-neoplastic (premycotic) condition to mycosis fungoides, and these cases are best considered mycosis fungoides from the onset. Pruritus, sometimes severe, is usually present at this stage. Over time, sometimes years, the lesions become more infiltrated, and the diagnosis is usually confirmed with repeated histologic evaluation. Infiltrated plaques occur eventually (plaque stage). In some cases tumors may eventually appear (tumor stage). Some patients may present with or progress to erythroderma. Most rarely, patients may present with tumors de novo, the so-called d'emblée form. With immunophenotyping, many of these cases are now recognized as non-mycosis fungoides CD30+ T-cell lymphomas. Eventually, in some patients, noncutaneous involvement is detected. This is most commonly first identified in lymph nodes. Peripheral blood involvement and visceral organ involvement may also occur.

In general, mycosis fungoides affects elderly patients and has a long evolution. For this reason, many patients die of other conditions rather than of mycosis fungoides. However, once tumors develop or lymph node involvement occurs, the prognosis is guarded and mycosis fungoides can be fatal. In most fatal cases the patient dies of septicemia. Early, aggressive chemotherapy in an attempt to "cure" mycosis fungoides is associated with excessive morbidity and mortality and is not indicated.

Evaluation and Staging

The North American Mycosis Fungoides Cooperative Group has developed a staging system. Because mycosis fungoides is a systemic disease from the onset (as lymphocytes naturally traffic throughout the body), concepts used for solid tumors such as tumor burden and metastasis cannot be readily applied. The TNMB system scores involvement in the skin (T), lymph node (N), viscera (M), and peripheral blood (B). Skin involvement is divided into less than 10% (T1), more than 10% (T2), tumors (T3), and erythroderma (T4). Node involvement is normal clinically and pathologically (NO), palpable but pathologically not mycosis (ungoides (N1), not palpable but pathologically mycosis fungoides (N2), or clinically and pathologically involved (N3). Viscera and blood are either not involved (MO and BO) or involved (M1 and B1). Stage IA is T1,N0,M0; stage IB is T2,N0,M0; stage IIA is T1-2,N1,M0; stage IIB is T3,N0-1,M0; stage IIIA is T4,N0,M0; stage IIIB is T4,N1,M0; stage IVA is T1-4, N2-3,M0; and stage IVB is T1-4, N0-3, M1. The "B" or blood status does not alter staging of the disease.

A staging work-up would include a complete history and physical examination, with careful palpation of lymph nodes and mapping of skin lesions; a complete blood cell count with assays for circulating atypical cells (Sézary cells); serum chemistries including renal and liver function tests with lactic dehydrogenase; a chest radiograph evaluation; and a skin biopsy. If lymph nodes are palpable, they should be examined histologically. Fine-needle aspiration is not an ideal mode of evaluation since early lymph node involvement may be localized to certain areas of the affected nodes, and architectural evaluation is often required to detect early lymph node involvement. If any abnormalities are detected through the above evaluations, they should be pursued. CT scans can be performed to assess chest, abdominal, and pelvic lymph nodes, and visceral organs. These are useful in patients with stage II-IV disease, but are not indicated in patients with stage IA disease. Whether patients with stage IB disease should undergo these tests is unknown.

The value of this staging system is confirmed in large series. Stage IA patients have a life-expectancy identical to a control population; only 8% to 9% progress to have more advanced disease; and only 2% die of their disease. By contrast, patients with T2 disease have a shorter survival time than control subjects (median survival of 11.7–15.6 years). Twenty-four percent of T2 patients progress to more advanced disease. T3 patients have a median survival of 3.2 to 8.4 years, and T4 patients of 1.8 to 3.7 years. Palpable adenopathy is associated with a median survival of only 7.7 years, whereas patients without adenopathy have a survival of 21.8 years. Lymphadenopathy, tumors, or cutaneous ulceration are cardinal prognostic factors; no patient dies without having developed one of them and patients with all three (in any order) survive a median of 1 year.

Clinical Features

In the early patch/plaque stage, the lesions are macular or slightly infiltrated patches or plaques varying in size from 1 to 5 cm or more. The eruption may be generalized or begin localized to one area and then spread. The lower abdomen, buttocks, upper thighs, and breasts of women are preferentially affected. The lesions may have an atrophic surface, or present as true poikiloderma with atrophy, mottled dyspigmentation, and telangiectasia. Poikiloderma vasculare attophicans is now recognized as a clinical form of patchstage mycosis fungoides. Likewise, large plaque parapsoriasis and rare cases of small-plaque parapsoriasis are early patchstage lesions of mycosis fungoides (Fig. 32-2). Small-plaque parapsoriasis with poikilodermatous change is suspicious for mycosis fungoides, whereas typical digitate dermatosis probably never evolves into mycosis (ungoides. "Invisible" mycosis fungoides is generalized skin involvement which is not visible to the naked eye, but can be documented histologically. With current diagnostic methods this can usually be confirmed. In general, the patch-stage lesions resemble an eczema, being round or ovoid, but annular, polycyclic, or arciform configurations can occur. Less common forms are the vertucous or hyperkeratotic form, the hypopigmented form (Fig. 32-3), lesions resembling a pigmented purpura, and the vesicular, bullous, or pustular form. The hypopigmented form seems to be more common in persons of color and is a common presentation for adolescents and children with mycosis fungoides.

In the plaque stage, lesions are more infiltrated and may resemble psoriasis, a subacute dermatitis, or a granulomatous dermal process such as granuloma annulare (Fig. 32-4). The palms and soles may be involved with hyperkeratotic, psoriasiform, and fissuring plaques. The infiltration of the plaques, at first recognized by light palpation, may be present in only a few of the lesions (Fig. 32-5). It is a manifestation of diagnostic importance. Different degrees of infiltration may exist even in the same patch and sometimes it is more pronounced peripherally, the central part of the plaque being depressed to the level of the surrounding skin. The infiltration becomes more marked and leads to discoid patches or extensive plaques, which may be as-wide as 30 cm.

Fig. 32-2 Mycosis fungoides, patch stage, with small and large patches.

Fig. 32-4 Mycosis fungoides, patch/ plaque stage.

Fig. 32-3 Mycosis fungoides, hypopigmented patches.

Fig. 32-5 Mycosis fungoides, plaque stage.

Eventually, through coalescence of the various plaques, the involvement becomes widespread, but there are usually patches of apparently normal skin interspersed. When the involvement is advanced, painful superficial ulcerations may occur. During this phase enlarged lymph nodes usually develop. They are nontender, firm, and freely movable.

The tumor stage is characterized by large, various sized and shaped nodules on infiltrated plaques and on apparently normal skin. These nodules have a tendency to break down early and to form deep oval ulcers, with bases covered with a necrotic grayish substance and with rolled edges. The lesions generally have a predilection for the trunk, although they may be seen anywhere on the skin or may involve the mouth and upper respiratory tract. Uncommonly, tumors may be the first sign of mycosis fungoides.

The erythrodermic variety of mycosis (ungoides is a generalized exfoliative process, with universal redness. The hair is scanty, nails dystrophic, palms and soles hyperkerato-

tic, and at times there may be generalized hyperpigmentation. Erythroderma may be the presenting feature.

Alopecia Mucinosa. The infiltrating cells of mycosis fungoides can demonstrate a predilection to involve the hair follicle. This may be observed simply by folliculotropism of the cells (pilotropic or follicular mycosis fungoides) or by the appearance of follicular mucinosis. In all cases of follicular mucinosis, the histologic specimen should be carefully examined and the diagnosis of mycosis fungoides considered. Among patients older than 40 years of age who have follicular mucinosis, a large percentage will have mycosis fungoides or go on to develop it. However, the finding of a T-cell clone in lesions of follicular mucinosis without mycosis fungoides does not increase the likelihood of the development of cutaneous T-cell lymphoma.

Selective tropism of the cutaneous T-cell lymphoma cells to the sweat glands and ducts is termed syringotropic cutaneous T-cell lymphoma. It is often seen in conjunction with follicular involvement. Syringolymphoid hyperplasia may be seen in these cases histologically, and cases previously termed syringolymphoid hyperplasia with alopecia are now considered to have cutaneous T-cell lymphoma. Clinically, the lesions present as discrete follicular and nonfollicular erythema along with alopecia, milia, and follicular cysts. The initial clinical diagnosis in such cases is often discoid lupus erythematosus. The prognosis in mycosis fungoides with adnexal involvement is as predicted by the staging system for other forms of mycosis fungoides.

Systemic Manifestations

Mycosis fungoides as a form of malignant lymphoma may progress to have visceral involvement. Lymph node involvement is most common; it predicts progression of the disease in at least a quarter of patients and reduces survival to about 7 years. Any other evidence of visceral involvement is a grave prognostic sign. An abnormal result on liver-spleen scan, chest radiograph or CT evaluation, abdominal or pelvic CT scans, or bone marrow biopsy is associated with a survival of about 1 year.

Pathogenesis

Mycosis fungoides is a neoplasm of memory helper T-cells in most cases. Rare cases of suppressor cell (CD8+) mycosis fungoides have been reported. These CD8+ cases may behave indolently, like mycosis fungoides, or aggressively. The later aggressive subset tends to present with plaques rather than patches. The events leading to the development of the malignant T-cells are unknown. It has been speculated that it is caused by chronic exposure to an antigen, but this has yet to be confirmed. Patients with atopic dermatitis appear to be at increased risk for the development of mycosis fungoides, suggesting that persistent stimulation of T-cells may lead to development of a malignant clone.

The inflammatory nature of the skin lesions has led to investigation of the interactions of the malignant T-cells and both keratinocytes and antigen-presenting cells (including Langerhans cells) in mycosis fungoides. Mycosis fungoides skin lesions have many features of skin that is immunologically "activated." Mycosis fungoides cells express cutaneous lymphocyte antigen (CLA), the ligand for E selectin, which is expressed on the endothelial cells of inflamed skin. This allows the malignant cells to traffic into the skin from the peripheral blood. CCR4, another homing molecule, is expressed on mycosis fungoides cells and the ligand for this receptor is on basal keratinocytes. Antigen-presenting cells are increased in mycosis fungoides lesions and have increased functional capacity to activate T-cells. There is increased expression of major histocompatibility complex (MHC) class II antigens on the surface of the antigen-presenting cells. Through cytokines, infiltration of neoplastic and reactive Tcells is increased. The pattern in early mycosis fungoides is more T-helper 1 (Th1)-like and the non-neoplastic infiltrating cells (tumor infiltrating lymphocytes [TILs]) may play a role in downregulating and controlling the neoplastic cells. There are more CD8+ cells in these early lesions and these TILs may control the malignant clone. In fact, mycosis fungoides patients with more than 20% CD8+ cells in their skin survive longer than those with less than 15%. In summary, early mycosis fungoides is a condition in which host immunity is intact and the host immune system effectively limits proliferation of the malignant T-cell clone. In more advanced mycosis fungoides and in Sézary syndrome, perhaps through interleukin (IL)-4 and -10, a Th2 environment exists. This downregulates suppressor cell function and allows the malignant clone to proliferate. In addition, the Th2-dominant environment reduces effective helper T-cell function, explaining the increased risk of infection and secondary cancer in patients with advanced cutaneous T-cell lymphoma. Correcting the aberrant immune response in advanced cutaneous T-cell lymphoma is the basis of some treatment approaches.

As mycosis fungoides advances, the number of circulating malignant T-cells increases. Standard cytologic evaluation (the Sézary preparation), even when enhanced by specific labeling techniques, is expensive and not very accurate. Use of standard laboratory tests, such as the CD4/CD8 ratio test, which increases as mycosis fungoides progresses, and assessment of the number of CD4+,CD7- or CD4+,CD26- circulating cells, which relatively specifically identify mycosis fungoides cells, yield indicators of tumor burden with advanced disease.

Histopathology

Perhaps more than in any other situation in dermatopathology, the ability to diagnose mycosis fungoides histologically closely correlates with the skill, training, and experience of the reviewing pathologist. When the clinician is considering a diagnosis of mycosis fungoides, if original histologic reports are nonconfirmatory or nonspecific, consultation with a skilled dermatopathologist should be strongly considered.

In patch-stage lesions there is a superficial perivascular and variably interstitial infiltrate of lymphocytes. There may be a band-like distribution of these cells and a few enter info the epidermis. This may produce the appearance of a vacuolar interface dermatitis with a large dark lymphocyte in every vacuole. The lymphocytes within the epidermis may be numerous or few in number, but are typically larger, darker and more angulated than those in the dermis. Papillary dermal fibrosis is typically present. The superficial perivascular lymphoid infiltrate that surrounds the postcapillary venule is typically more prominent above the vessel than below the vessel. (bear under-belly sign).

Plaques of mycosis fungoides show a more prominent superficial band-like lymphoid infiltrate and a deeper perivascular dermal component than patch-stage lesions. Papillary dermal fibrosis is more prominent and the subpapillary plexus is shifted downward. Epidermotropism is much more marked and is typically associated with very little spongiosis. This helps distinguish patch-stage mycosis fungoides from spongiotic dermatitis. Vesicular variants are an exception to this rule. In vesicular variants, spongiosis is prominent and results in intraepidermal and subcorneal vesiculation. Eosinophils are common in (olliculotropic mycosis fungoides (with or without follicular mucinosis), but are uncommon in other forms of mycosis fungoides.

In thick plaques and tumors, epidermotropism may be substantially diminished. The diagnosis is confirmed by the presence of dense sheets of infiltrating lymphocytes in the dermis and subcutaneous fat. These cells may have cerebriform nuclei.

Cardinal features that should suggest a diagnosis of mycosis fungoides include the following:

- Solitary or small groups of lymphocytes in the basal cell layer
- Epidermotropism of lymphocytes with disproportionately scant spongiosis
- More lymphocytes within the epidermis than would normally be seen in an inflammatory dermatosis
- Lymphocytes in the epidermis larger than those in the dermis
- Lymphocytes in the stratum corneum and stratum granulosum
- Papillary dermal fibrosis with bundles of collagen arranged haphazardly
- Prominent folliculatropism or syringotropism of the lymphocytes, especially with intrafollicular mucin deposition (follicular mucinosis)

Features that should suggest a diagnosis of inflammatory dermatosis over mycosis fungoides include the following:

- Prominent upper dermal and papillary edema
- Marked epidermal spongiosis
- Accumulation of the intraepidermal inflammatory cells in flask-shaped collections with the top open to the stratum corneum

Immunohistochemistry is of some value in assessing mycosis fungoides. Mycosis fungoides cells characteristically are CD4+, but lose the CD7 and CD26 antigens, i.e. they are CD4+,CD7-,CD26-. This phenotype is very unusual for nonmalignant T-cells and thus is useful in evaluating biopsy specimens and peripheral blood lymphocytes. Loss of CD7 expression within the large dark lymphocytes in the epidermis, with normal expression in the benign recruited lymphocytes in the infiltrate below, suggests a diagnossis of mycosis fungoides. DNA hybridization or a Southern blot test is frequently performed in equivocal cases to detect clonal rearrangement of the T-cell receptor (TCR). However, these data must be interpreted with caution; clonality does not confirm a diagnosis of malignancy. Benign processes may contain clonal TCR rearrangements. In early lesions of mycosis fungoides the number of infiltrating cells may be insufficient for a clone to be detected, so a negative test does not exclude the diagnosis of mycosis fungoides. Testing with tresh tissue is somewhat more sensitive than with fixed tissue using current methods. Similar techniques can be used to evaluate lymph nodes in mycosis fungoides patients. Lymph node involvement can be detected by these molecular methods, while the routine histologic evaluation yields normal results. Patients with more advanced disease are more likely to have clones in their lymph nodes and the presence of clonality is predictive of shorter survival.

Differential Diagnosis

In the early patch stage, mycosis fungoides may be difficult to diagnose. The skin lesions usually resemble a nondescript form of eczema with some scale. Interestingly, despite the itching, scratch marks and lichenification are usually absent. Mycosis fungoides presenting as papuloerythroderma of Ofuji is an obvious exception. The multiple morphologies of mycosis fungoides make the differential diagnosis vast. Plaque-like lesions may resemble subacute dermatitis or psoriasis. Tumors must be differentiated from other forms of lymphoreticular malignancy and metastases.

Treatment

Effective therapy that reliably prolongs survival has not yet been documented. Many forms of therapy induce remissions of variable length. The choice among them depends on extent of disease, the patient's overall health and physical status, the physician's experience and preference, and the availability of various options. Topical steroids, topical nitrogen mustard or 1,3-bis (2-chloroethyl)-l-nitrosourea (carmustine) (BCNU), bexarotene gel 1%, and PUVA (or narrow-band UVB) are generally good choices for stage IA, IB, and ΠA disease. Total skin electron beam (TSEB) therapy can be used for refractory stage IIA and IIB cases. Singleagent chemotherapy or photophoresis can be used as initial management for stage III patients. Low-dose methotrexate may control the skin lesions of mycosis fungoides, but has been associated with the development of a secondary aggressive lymphoma in a few patients. Combinations of IFN- α , retinoids (bexarotene or isotretinoin), photophoresis, IFN-y, skin-directed PUVA, sargramostim (granulocyte macrophage colony-stimulating factor), and perhaps IL-2, IL-12, and IFN- α may be effective in stage IV disease, and for patients who have failed the above therapies for stage IIB and III mycosis fungoides. Multiagent systemic chemotherapy is used much less commonly with the advent of immunomodulatory treatments for mycosis fungoides. It should only be considered when all other treatment options have failed. Treatment of early-stage disease is in general restricted to skin-directed treatments. More advanced disease is treated with different modalities at different institutions. Combinations of agents are often used and those combinations and their order of use vary from one institution to the next. In general, therapies that also enhance the patient's immune system are favored in patients with more advanced disease.

Topical Corticosteroids. The availability of superpotent class I topical corticosteroids has led to a reassessment of their possible role in the management of early (patch stage, T1 and T2) mycosis fungoides. Zackheim reported a 63% complete remission for patients with T1 disease and a total response rate of 94% in T1 patients. In T2 patients complete responses were only 25%, but total responses were 82%. The predominant side effect was a temporary and reversible suppression of the hypothalamic-pituitary axis in about 13% of patients. The responses were short-lived if therapy was stopped, but given the limited toxicity, this is not necessary in many patients. The adjunctive value of topical corticosteroids in T1 mycosis fungoides requires reappraisal because the response rates are similar to other modalities used for early mycosis fungoides and the toxicity is very low.

Topical Nitrogen Mustard. The contents of a 10 mg vial of mechlorethamine hydrochloride (Mustargen-MSD) are dissolved in 60 mL of tap water and applied to the entire skin surface, except the face, axillae, and genitalia, with a 2 inch paint brush or gauze pad. The last milliliter may be diluted to half strength or greater dilution for application to the face, axillae, and genitalia. Daily applications are made until complete clearing occurs, which usually takes several months or longer, and may be continued indefinitely. Such treatment leads to complete responses in 80% of patients with stage IA disease, 68% in patients with stage IB, 61% in stage IIA, 49% in stage IIB, and 60% in stage III patients. About 10% of patients obtain a durable and long-lasting remission of over 8 years. The major side effects of topical nitrogen mustard (NH2) therapy is cutaneous intolerance, which occurs in almost 50% of patients, and allergic contact dermatitis, which occurs in 15%. Short (1 h) contact does not reduce this rate of sensitization. This can be reduced by the use of an ointment formulation, but response rates have been reported to be inferior with the ointment form. At least half of patients will relapse when therapy is stopped, but they frequently will respond again to NH2.

The duration of maintenance therapy after achieving remission is different in different centers. Some treat for an additional 6 months and others taper treatment over a year or more, or continue treatment indefinitely. In many centers, topical nitrogen mustard has been proven mainstay of therapy for patch- or plaque-stage mycosis fungoides without lymphadenopathy.

Topical BCNU (Carmustine). BCNU, 2 mg/mL in 150 mL aliquots, dissolved in ethanol, is dispensed to the patient. From this stock solution the patient takes 5 mL and adds it to 60 mL of water at room temperature. This is applied once a day to the whole body, sparing the folds, genitals, hands, and feet (if they do not have lesions). If the extent of disease is limited, only the affected areas are treated. The average treatment course is 8 to 12 weeks. If after 3 to 6 months the patient's condition is not responding, the concentration may be doubled and the treatment repeated for 12 weeks. For small or persistent lesions, the straight stock solution may be applied daily. Patients tolerate BCNU better than nitrogen mustard, contact sensitization is uncommon, and responses are more rapid. Complete blood counts should be monitored monthly during treatment, but marrow suppression occurs in less than 10% of patients treated with the low concentrations. Telangiectasia, which may be persistent and severe, can occur after prolonged BCNU therapy or following an adverse cutaneous reaction to the medication.

Ultraviolet Therapy. Both UVB (narrow or broad band) and PUVA (systemic or bath) have been effective in the management of mycosis fungoides. About 75% of patients with patch-stage disease will have a complete clinical remission with UVB therapy. Home therapy is successful. PUVA has been used more extensively and, because of its deeper penetration, it is perhaps better suited to the treatment of a disorder with a dermal component. Complete clearing is seen in 88% of patients with limited patch/plaque disease and in 52% of patients with extensive disease. Tumor-stage patients do not clear. Erythrodermic patients have poor tolerance for PUVA. Up to 50% of patients with a complete response to PUVA may have a remission of up to 10 years. Retinoids and IFN- α may be added to PUVA. Retinoids may reduce the total number of PUVA treatments required. Lowdose IFN-a plus PUVA may be used in patch-stage patients in whom topical therapy and PUVA alone are ineffective. The eximer laser may be used once or twice a week to deliver the phototherapy if the patient has a limited number of lesions. On average, 5 to 6 weeks of treatment is required and remissions up to 2 years or more can be achieved.

Extracorporeal photochemotherapy (photophoresis, ECP) is a therapeutic modality in which the circulating cells are extracted and treated with UVA outside the body; the patient ingests psoralen before the treatment. Complete responses are seen in a small percentage of mycosis fungoides patients,

about 20%, and a partial response occurs in a similar percentage of patients. In the original reports the overall response rate for erythrodermic patients was 80%, but many of these patients failed to have at least the 50% clearing required to be considered a partial response. In one comparative trial, standard PUVA was significantly more effective than photophoresis alone and photophoresis was judged ineffective in plaque stage (T2) mycosis fungoides. ECP is now used in combination with other agents, especially IFN- α , and appears to have better efficacy. Insulin dependent diabetics respond poorly.

Radiation. TSEB therapy in doses in excess of 3000 Gy is very effective in the management of mycosis fungoides. Stage T1 patients have a 98% complete response; stage T2, 71%; stage T3, 36%; and stage T4, 64%. Long-term remissions occur in about 50% of T1 patients and 20% of T2 patients. Erythrodermic patients tolerate TSEB poorly; other modalities should be attempted initially. Because relapses are frequent, adjuvant therapy with a topical agent or PUVA can be considered if the patient relapses. The most common side effects of TSEB are erythema, edema, worsening of lesions, alopecia, and nail loss. Persistent hyperpigmentation and chronically dry skin are also problems after TSEB. *Orthovoltage* radiation may be used to control tumors or resistant thick plaques in patients whose conditions have been otherwise controlled with another modality.

Biologic Response Modifiers (Multimodality Immunomodulatory Therapy). The appearance of circulating malignantT-cells in mycosis fungoides may indicate failure of the host immune system to control the disease. Immunomodulatory agents are used in an attempt to enhance host immune function and gain control of the disease. It is often combined with treatments that increase malignant cell apoptosis, so that the "tumor antigens" released will be recognized and immunologically "attacked" by the host immune system. These immunomodulatory agents both activate antigen-presenting cells and enhance Th1 immune function directed against the malignant T-cell clone. IFN- α and - γ have been shown to have efficacy against mycosis fungoides. IFN- α is associated with a positive response in about 60% of patients and a complete response in 19%. If used as a single agent, toxicity is high and includes fever, chills, myalgias, neutropenia, and depression. Low-dose IFN- α and -y treatments and granulocyte macrophage colony-stimulating factor are now used in an adjunctive fashion in combination with retinoid therapy, phototherapy, and other modalities. This is termed multimodality immunomodulatory therapy. IL-2 and -12 may be used in a similar fashion in the future.

Retinoids. Both isotretinoin and etretinate have efficacy in the treatment of mycosis fungoides. A clinical response is noted in about 44% of patients. Dosage of isotretinoin is about 1 mg/kg/day to start and may be increased up to 3 mg/kg/day as tolerated. Retinoids may be effective in stage 1B (T2) patients, stage III patients, and as a palliative treatment in patients with stage IVA disease. Bexarotene (Targretin), a synthetic retinoid that is bound preferentially by the RXR (retinoid X receptor), is felt to work by inducing apoptosis in the malignant T-cells. It is available as a 1% topical gel and as an oral tablet. Topical therapy is used in patients with stage IA to IIA cutaneous T-cell lymphoma. Patients improve about 50% with this treatment. Oral bexarotene at a dose of 300 mg/m²-also has a response rate of about 50% in early-stage cutaneous T-cell lymphoma. This dose is complicated by hypercholesterolemia, marked hypertriglyceridemia (at times complicated by pancreatitis), central hypothyroidism, and leukopenia. It may be combined with PUVA and other forms of treatment at a lower dose.

Systemic Chemotherapy. For most forms of cancer, combinations of chemotherapeutic agents are given. In mycosis fungoides, however, multidrug chemotherapy often exacerbates the ongoing immune imbalance and may prevent the patient's immune system from attacking the malignant T-cells. For this reason, and due to the enhanced efficacy of combination immunomodulatory treatment regimens, systemic chemotherapy is now very uncommonly used for mycosis fungoides. Methotrexate in doses from 5 to 125 mg/week is effective for the management of T3 patients. In these patients, Zackheim et al demonstrated that 41% had a complete response, and an additional 17% a partial response, giving a total response of 58%. The median overall survival was 8.4 years and 69% of patients were alive at 5 years. For advanced mycosis fungoides, higher doses of methotrexate with citrovorum-factor rescue were successful in obtaining a response, which was then maintained with lower doses of methotrexate, not requiring rescue. Similarly, pentostatin, etoposide, fludarabine, and 2-chlorodexoyadenosine have been used. Systemic chemotherapy beyond methotrexate, especially multiagent chemotherapy, is best managed by an oncologist. Systemic chemotherapy is only indicated in stage III and IVA patients who have failed all available immunoenhancing treatment protocols noted above.

Fusion Toxin. DAB389IL-2 is the fusion of a portion of the diphtheria toxin to recombinant IL-2. This selectively binds to cells expressing the IL-2 receptor and leads to their death. A series of mycosis fungoides cases that expressed the IL-2 receptor, demonstrated a response rate of 37%, including a complete response in 14% of cases. These patients had failed conventional therapies. Patients in stage 1 to III achieved response, but no patient with stage IV disease achieved a response. Fever, chills, hypotension, nausea, and vomiting were common and at high doses a vascular-leak syndrome occurred. This agent is reserved for advanced-stage patients who have failed other modalities.

Pagetoid Reticulosis Localized epidermotropic reticulosis, Pagetoid reticulosis, or Woringer-Kolopp disease, is an uncommon lymphoproliferative disorder considered be a form of mycosis fungoides. Other terms suggested for these cases have been acral mycoses fungoides or mycosis fungoides palmaris et plantaris. In large mycosis fungoides clinics, such cases represent about 0.6% of all mycosis fungoides cases. Pagetoid reticulosis is divided into classic Woringer-Paget's, which usually describes solitary lesions, and cases with multiple lesions (Ketron-Goodman variant). The unique features of Woringer-Kolopp disease are clinical. The disease presents as a solitary lesion that is often located on an extremity and often has a keratotic rim. If there is more than a single lesion, often there is a propensity for lesions to involve both the palms and soles. Frequently, over months to years, the lesion gradually enlarges, reaching a size of greater than 10 cm. In some cases, the lesions spontaneously come and go over many years. Twenty percent of cases occur in patients who are younger than 15 years of age. The long duration without progression has been a clinical hallmark of Woringer-Kolopp disease. Histologically, there is prominent epidermotropism of lymphocytes, with many lining up in the basal cell layer. This histologic pattern correlates with strong αE - $\beta 7$ and $\alpha 4$ - $\beta 7$ integrin expression by the infiltrating cells. This integrin expression is also seen in the epidermotropic cells of classic mycosis fungoides and contact dermatitis. In mycosis fungoides, most cases are CD4+, but in the acral mycosis fungoides cases they may be CD4+, CD8+, or negative for both. TCR gene rearrangements can be detected in many cases of Woringer-Kolopp disease. Therapeutically, local excision and radiation therapy have been "curative" in many cases. Topical and systemic PUVA have also proved effective. Local recurrence is possible.

Sézary Syndrome Sézary syndrome is the leukemic phase of mycosis fungoides. The characteristic features are generalized erythroderma, superficial lymphadenopathy, and atypical cells in the circulating blood. Although patients with classic mycosis fungoides may progress to Sézary syndrome, usually patients with Sézary syndrome are erythrodermic from the onset. The skin shows a generalized or limited erythroderma of a typical fiery red color (Fig. 32-6). Associated features can include leonine facies, eyelid edema, ectropion, diffuse alopecia, hyperkeratosis of the palms and soles, and dystrophic nails. Some patients develop lesions identical to vitiligo, especially on the lower legs. The symptoms are those of severe pruritus and burning, with episodes of chills. Prognosis is poor, with an average survival of about 5 years.

Superficial lymphadenopathy is usually found in the cervical, axillary, and inguinal areas. Leukocytosis up to $30,000/\text{mm}^3$ is usually present. In the peripheral blood, skin infiltrate, and lymph nodes, helper T-cells with deeply convoluted nuclei are found—the so-called Sézary cells.

Histologically, and by immunohistochemistry, there are no reproducible differences between cases of mycosis fungoides and Sézary syndrome. In a fair number of cases of the latter, the cutaneous histology may be nonspecific, showing a spongiotic dermatitis. Additional hematologic evaluation may be necessary to confirm the diagnosis in the erythroder-

Fig. 32-7 Lymphomatoid papulosis,

Fig. 32-6 Sézary syndrome.

nuic patient. T-cell gene rearrangement studies are frequently used to confirm the diagnosis of Sézary syndrome. In addition, an increased CD4/CD8 ratio in the blood with an increase in the number of CD3+/CD4+/CD7-/CD26- circulating cells is suggestive of leukemic mycosis fungoides.

The erythroderma of Sézary syndrome must be distinguished from chronic lymphocytic leukemia (CLL), psoriasis, atopic dermatitis, photodermatitis, seborrheic dermatitis, contact dermatitis, drug reaction, and pityriasis rubra pilaris. This is done primarily by histopathologic and immunopathologic examination. In Sézary syndrome, the infiltrating T-cells in the skin have a Th2 phenotype and Th2 cytokines are produced by these cells. This explains the reduced delayed-type hypersensitivity, elevated IgE, and eosinophilia seen in these patients.

Sézary syndrome is difficult to treat. Low-dose methotrexate has a reasonable response rate of about 50% and an overall survival of 101 months, suggesting a survival benefit to its use. Photophoresis used in combination with other agents is effective in some patients, but the median survival time is only between 39 and 60 months (see above).

Granulomatous Slack Skin Granulomatous slack skin is a rare variant lymphoma that typically presents in middleaged adults and gradually progresses over years. It occurs more often in men. Lesions are erythematous, atrophic,

bulky, infiltrated, pendulous, and redundant plaques in the axillae and groin. Histologically there is a lymphohistiocytic infiltrate extending though the dermis, into the subcutaneous fat. Focal collections of huge, multinucleated cells with 20 to 30 nuclei arranged in a wreath-like pattern are characteristic. Elastophagocytosis is prominent and elastic tissue is absent in areas of inflammation. Lymphocytes are also found within the multinucleate giant cells and are arranged around them. Epidermotropic lymphocytes are also seen. Immunohistologically, the cells are CD4+. T-cell gene rearrangements can be detected. In most patients, the condition evolves into mycosis fungoides, but about one-third of patients with granulomatous slack skin develop Hodgkin's disease after years to decades.

Noto G, et al: Granulomatous slack skin. Br J Dermatol 1994;131:275.

Lymphomatoid Papulosis Lymphomatoid papulosis (LyP) is an uncommon, but not rare disorder. It occurs at any age, including childhood, but is most common in adults with a mean age of 44. In most typical cases, the lesions and course are very similar to that of Mucha-Habermann disease (pityriasis lichenoides et varioliformis acuta), except the lesions tend to be slightly larger, fewer in number, and have a greater propensity to necrosis (Fig. 32-7). Symptoms are usually minimal. The primary lesion is a red papule up to about 1 cm in diameter. The lesions evolve to papulovesicular, papulopustular, or hemorrhagic, then necrotic papules over days to weeks. Lesions typically heal spontaneously within 8 weeks, somewhat longer in larger lesions. Lesions are usually generalized, although cases limited to one anatomic region have been reported.

There may be crops of lesions or a constant appearance of a few lesions. In most patients, however, the condition tends to be chronic, and lesions are present most of the time if no treatment is given. The average number of lesions present at any one time is usually 10 to 20, but cases with more than 100 lesions occur. Lesions heal with varioliform, hyperpigmented, or hypopignented scars. Cases previously reported as solitary, large nodules of lymphomatoid papulosis would now be classified as CD30+ large cell lymphomas or as overlaps between LyP and lymphoma, termed *borderline cases*. The diagnosis of LyP is confirmed histologically. There is a dermal infiltrate that is wedge-shaped, patchy, and perivascular. In larger lesions the infiltrate may occupy the whole dermis. It may also be band-like. The infiltrate may involve the epidermis, with epidermotropism of inflammatory cells. As lesions evolve, epidermal necrosis and ulceration may occur. The dermal vessels may demonstrate fibrin deposition and more rarely, a lymphocytic "vasculitis." The dermal infiltrate is composed of lymphoid cells, eosinophils, neutrophils, and larger mononuclear cells. Atypical large or small lymphoid cells are present and may represent up to 50% of the infiltrate. Histologically, lesions have been classified into type A, type B, and type C lesions.

Type A lesions contain atypical large cells with abundant cytoplasm and prominent nuclei, with prominent eosinophilic nucleoli. If these cells contain two nuclei, they closely resemble Reed-Sternberg cells. In type B lesions, the atypical cells are smaller, with a smaller cerebriform, hyperchromatic nucleus. These resemble the atypical cells of mycosis fungoides. In both types of lesions, atypical mitotic figures may be observed. Immunophenotypically, the large atypical cells mark as T-cells, usually of the helper type. The atypical cells, especially those of the type A lesions, stain for the activation marker Ki-1 or CD30. Bcl-2 expression occurs in about 50% of cases. When clonal rearrangement studies are performed, clonal rearrangements may be found in up to 40% of LyP lesions, but this finding is not predictive of the behavior of that lesion or the case in general. Type C lesions overlap with primary cutaneous large cell lymphoma with no clear distinction between the two.

Lymphomatoid papulosis types A and B are associated with lymphoma. In the general literature this number is about 5% to 10%, but some reports have documented rates as high as 20%, and at the University of California at San Francisco (UCSF) up to 40% of cases of LyP have an associated lymphoma. The lymphoma may occur before, concurrently, or after the appearance of the LyP. In most cases, the LyP precedes the development of lymphoma, sometimes by a long period-up to 20 years. The associated lymphoma is most commonly mycosis fungoides (40%), a CD30+T-cell lymphoma (30%), or Hodgkin's disease (25%). The lymphoma and LyP may behave quite independently. If the lymphoma is successfully treated and cleared, the LyP typically continues. Despite this independent behavior, the lymphoma and the LyP may contain the same clonal TCR gene rearrangement. Patients with pure type B lesions are much less likely to develop lymphoma than patients with type A lesions.

Therapy may not be necessary; there is no evidence that treatment of LyP prevents the development of secondary lymphoma. When any therapy is stopped, the LyP invariably returns. Therefore, patients only need to be treated if they are moderately symptomatic and the treatment has fewer potential complications than the benefits gained. Superpotent topical corticosteroids have been beneficial in some childhood cases. Topical bexarotene may abort early lesions, and oral bexarotene may suppress lesion formation. PUVA systemically or topically may be effective, although maintenance treatment is usually required. Both narrow- and broadband UVB may be effective. Of all the systemic agents, methotrexate gives the most dependable response, with up to 90% of LyP patients improving significantly. It is given in weekly doses similar to those used for rheumatoid arthritis—usually 7.5 to 15 mg/week. Higher doses may be required in some patients. Response is rapid. Some patients treated with methotrexate may have remissions of the LyP. In most, however, maintenance therapy is required.

Pityriasis Lichenoides

Both the acute and chronic forms of pityriasis lichenoides are lymphocytic vasculitides. The lymphoid infiltrate may contain a clonal proliferation. However, progression to cutaneous lymphoma is rare.

Pityriasis Lichenoides et Varioliformis Acuta (Mucha-Habermann Disease) Pityriasis lichenoides et varioliformis acuta (PLEVA) is a disorder which usually appears suddenly in children or young adults. Individual lesions are erythematous macules, papules, or papulovesicles. Lesions tend to be brownish-red and evolve through stages of crusting, necrosis, and varioliform scarring. Lesions tend to appear in crops, and may number from a few to more than 100 (Figs 32-8 and 32-9). In general PLEVA patients have more and smaller lesions than patients with LyP. The trunk is favored, but even the palms and soles may infrequently be involved. The patient feels otherwise well. The natural history is benign, with spontaneous involution occurring over 1 to 3 years. In children diffuse cases resolved more quickly than cases than were purely central; cases with primarily peripheral lesions took almost twice as long to resolve.

Histologically, PLEVA is characterized by epidermal necrosis together with prominent hemorrhage and a dense perivascular infiltrate in the upper and mid dermis in a wedge-shaped pattern. Lymphocytic, vasculitis may be seen.

Fig. 32-8 Mucha-Habermann disease.

Fig. 32-9 Mucha-Habermann disease.

T-cell gene rearrangements may be detected, but the significance of that finding is unclear at this time. Treatment of PLEVA may include oral erythromycin or tetracyclines and phototherapy (UVB or PUVA). Topical tacrolimus may be effective. Low-dose methotrexate, 5.0 to 15 mg/week, may be required in severe cases.

An unusually severe form of PLEVA (febrile ulceronecrotic Mucha-Habermann disease) is characterized by the acute onset of diffuse, coalescent, large, ulceronecrotic skin lesions associated with high fever and constitutional symptoms. The condition may begin as typical as PLEVA, but the ulceronecrotic lesions usually begin to appear within a few weeks. Skin necrosis may be extensive, especially in the intertriginous regions. Associated symptoms include gastrointestinal and central nervous system (CNS) symptoms, pneumonitis, myocarditis, and even death (in adult cases). This condition favors boys who are 18 years of age or younger. This severe form of PLEVA usually lasts several months with successive outbreaks, then resolves or converts to more classic PLEVA. Treatment is systemic steroids and if response is limited, methotrexate. Dapsone may also be useful, for maintenance and as a steroid-sparing agent.

Pityriasis Lichenoides Chronica Pityriasis lichenoides chronica (PLC) is a chronic form of pityriasis lichenoides, related to PLEVA by its common histology. Lesions are erythematous, scaly macules and flat papules with very slow evolution. Lesions each last several months. This eventual resolution of lesions of PLC distinguishes it from guttate parapsoriasis which it may resemble clinically. Lesions of small plaque parapsoriasis do not spontaneously resolve. Lesions of PLC favor the lateral trunk and proximal extremities. Patients may have from 10 to 100s of lesions, but usually fewer than 50. Resolution may be with persistent areas of hypopigmentation which last for months to years. Unlike PLEVA, PLC tends to last for many years.

Histologically, the changes are similar to PLEVA, but much more subtle. A mild interface or perivascular lymphocytic infiltrate with overlying parakeratosis may be present. T-cell gene rearrangement studies may demonstrate monoclonality; however, the meaning of this finding is unclear at this time. Treatment with phototherapy (natural sunlight, UVB, UVA1 or PUVA) is most effective. Topical steroids or tacrolimus may be tried. No treatment is required.

Pityriasis lichenoides chronica is generally a benign disease. There are mare patients who have progressed to develop cutaneous T-cell lymphoma. The authors recommend that patients with PLC be followed regularly and changes in lesion morphology, including induration, erosion, atrophy, persistent erythema, or poikiloderma, should trigger repeat pathologic evaluation.

Primary Cutaneous T-cell Lymphomas Other Than Mycosis Fungoides

Once a cutaneous lymphoma has been identified to be of T-cell origin and the diagnosis of mycosis fungoides and its variants has been excluded, the most important evaluation is

738 CUTANEOUS LYMPHOID HYPERPLASIA, CUTANEOUS T-CELL LYMPHOMA

to determine the CD30-staining pattern. CD30 is a marker found on some activated, but not resting, T- and B-cells. It also marks the Reed-Sternberg cells of Hodgkin's disease. Monoclonal antibodies Ki-1 and Ber H2 are used to identify CD30 positivity. A cutaneous lymphoma is considered CD30+ if there are large clusters of CD30+ cells or more than 75% of the anaplastic T-cells are CD30+. Systemic CD30+ lymphoma with cutaneous involvement has a poor prognosis. Those that express anaplastic lymphoma kinase (ALK-1) associated with a 2:5 translocation have a somewhat better prognosis. Primary cutaneous large T-cell lymphomas that are CD30+ are typically ALK-1 negative, have a very good prognosis, and tend to run a relapsing course similar to that of lymphomatoid papulosis. Individual lesions respond to irradiation and the relapsing course may remit with low-dose methotrexate. Large cell lymphomas of the skin have similar histologic and clinical features, so immunophenotyping is essential for prognosis. Clonal TCR gene rearrangements are present in large cell T-cell lymphoma. The group of T-cell lymphomas that are not large cell and CD30+ are together classified in the WHO system as peripheral T-cell lymphomas.

CD56 is rapidly becoming the second most important immunophenotypic marker for cutaneous lymphomas. Four important variants of CD56+ cutaneous lymphomas have been identified: a subset of subcutaneous panniculitis-like Tcell lymphoma; natural killer (NK)/T-cell lymphoma; blastic NK cell lymphoma; and CD8+ aggressive epidermotrophic cytotoxic T-cell lymphoma.

Peripheral T-cell lymphoma is an heterogeneous grouping that includes primary cutaneous CD30+ nonanaplastic large cell lymphoma, primary cutaneous CD30- anaplastic and nonanaplastic large cell lymphoma, and primary cutaneous CD30- pleomorphic small/medium cell lymphoma.

CD30+ Cutaneous T-Cell Lymphoma (Primary Cutaneous Anaplastic Large Cell Lymphoma) Clinically, these lymphomas present as solitary or localized skin lesions that have a tendency to ulceration (50%), spontaneous regression (25%), and relapse. These lymphomas are rare in children and occur with slightly greater frequency in males. Lesions are usually firm, red to violaceous tumors up to 10 cm in diameter (Fig. 32-10). Tumors may grow in a matter of weeks. There is no favored anatomic site.

Relapses in the skin are common, but the development of extracutaneous or lymph node involvement is uncommon. Lymph node involvement is associated with a poorer prognosis. The "pyogenic lymphoma" of the skin is a neutrophilrich CD30+ lymphoma with skin lesions that clinically resemble Sweet syndrome, pyoderma gangrenosum, halogenoderma, leishmaniasis or deep fungal infection. IL-8 overexpression by the anaplastic CD30+ cells causes the neutrophilic infiltration. The number of neutrophils present may make histologic interpretation difficult. Cases with features of both lymphomatoid papulosis and CD30+ anaplastic T-cell lymphoma have been described, sometimes under the designation type C lymphomatoid papulosis. Histologically, there is a dense dermal nonepidermotropic infiltrate with atypical tumor cells with large nuclei with one or several prominent nucleoli and abundant cytoplasm. The malignant cells can be further characterized as anaplastic, pleomorphic, and immunoblastic, but this distinction may be difficult and has yet to be determined to be of prognostic or

Fig. 32-10 Large cell anaplastic lymphoma.

therapeutic value. This form of primary cutaneous T-cell lymphoma has an excellent prognosis with a 5-year survival of 90%. Lesions are highly responsive to radiotherapy. Early individual lesions can even be surgically excised. Topical imiquimod has been therapeutically successful. Chemotherapy causes regression of lesions, but a rapid relapse usually occurs. Other than low-dose methotrexate, chemotherapy has little role in the treatment of this disease.

Secondary Cutaneous CD30+ Large Cell Lympho-

ma CD30+ large cell lymphomas may arise in cases of mycosis fungoides, in patients with lymphomatoid papulosis, and in patients who have documented extracutaneous disease (secondary cutaneous anaplastic large cell lymphoma). Skin lesions of pyogenic lymphoma may be seen secondary to a pyogenic lymphoma of other organs. The prognosis is poor in patients who have extracutaneous disease preceding or near the time of cutaneous involvement. Among those with systemic disease, the expression of Alk-1 associated with a t(2;5) translocation is a favorable prognostic feature. Patients with lymphomatoid papulosis who develop cutaneous CD30+ lymphoma and who do not have systemic lymphoma or mycosis fungoides typically have an excellent prognosis. The prognosis for patients with mycosis fungoides who develop CD30+ anaplastic large cell lymphoma is poor.

Non-Mycosis Fungoides CD30- Cutaneous Large T-Cell Lymphoma Non-mycosis fungoides CD30cutaneous large T-cell lymphomas usually present as solitary or generalized plaques, nodules, or tumors of short duration. There is no preceding patch stage that distinguishes it from MF. The prognosis is poor, with a 5-year survival rate of 15%. The malignant cells are pleomorphic large or medium cell types or are immunoblastic. The cells may be cerebriform and epidermotropism may be present. Some cases previously called d'eniblée mycosis fungoides are better classified in this group. Multiagent chemotherapy is recommended.

Pleomorphic T-Cell Lymphoma (Non-Mycosis Fungoides CD30– Pleomorphic Small/Medium Sized Cutaneous T-Cell Lymphoma)

This group comprises about 3% of all primary cutaneous lymphomas. Pleomorphic small/medium sized cutaneous T-cell lymphoma is distinguished from the large cell type

by having less than 30% large pleomorphic cells. It is distinguished from mycosis fungoides by clinical features (lack of patch or plaque lesions). These primary cutaneous lymphomas usually present with one or several red-purple papules, nodules or tumors (5 mm to 15 cm in size). Immunophenotypically, they are usually of helper T-cell origin and clonal rearrangements of the TCR gene are usually present. A CD4 versus a CD8 phenotype is associated with a more favorable prognosis, but a CD4/CD56 phenotype has a poorer prognosis. The presence of a mixed population of suppressor cells, B-cells, and histiocytes, usually favors the diagnosis of reactive lymphoid hyperplasia. The overall prognosis is intermediate, with a 5-year survival rate of 62%. The optimal therapy for this form of lymphoma has not been determined. Therapeutically, localized lesions have been treated with radiation therapy or surgical excision. Chemotherapy, retinoids, interferons, and monoclonal antibodies have been used in widespread or progressive disease.

Lennert Lymphoma (Lymphoepitheliod Lymphoma)

Lennert lymphoma is a rare CD4+ systemic T-cell lymphoma. Cutaneous lesions occur in less than 10% of cases and present as papules, plaques, or nodules. The skin lesions may not represent lymphoma cutis because palisaded granulomatous and nonspecific dermal infiltrates may occur. The clinical and histologic appearance may resemble granuloma annulare very closely. The course is low-grade until the lymphoma transforms to a high-grade, large cell lymphoma.

Subcutaneous (Panniculitis-Like) T-Cell Lymphoma

Clinically, patients are usually young adults who present with subcutaneous nodules, usually on the lower extremities, and are frequently diagnosed as having erythema nodosum or some other form of panniculitis. Weight loss, fever, and fatigue are common and may herald the onset of a rapidly progressive hemophagocytic syndrome which is often fatal. Extracutaneous involvement is rare, even in fatal cases. An indolent chronic course can also be seen, but even in these cases the prognosis is poor. This variant of lymphoma may also rarely be seen in childhood.

Histologically, there is a lace-like infiltration of the lobules of adipocytes, mimicking panniculitis, especially lupus profundus. A characteristic feature is rimming of neoplastic cells around individual adipocytes. The infiltrate contains primarily small cells with hyperchromatic, irregular nuclei and large anaplastic cells in varying proportions. The small cells are atypical, karyorrhexis is prominent, and mitotic figures are frequent. Benign histiocytes are present in large or small numbers and demonstrate erythrophagocytosis (beanbag cells). Immunophenotypically, the neoplastic cells mark as T-cells (CD2+, CD3+). Most cases are derived from α/β T-cells and are CD56-. They have a less aggressive course. A subset of subcutaneous (panniculitis-like) T-cell lymphomas (SPTCLs) are derived from γ/δ T-cells and are CD56+. These cases have been misdiagnosed as lupus profundus or alopecia areata and histologically prominent dermal and even epidermal (interface) involvement may be seen. They have a more aggressive course. SPTCL may evolve from the benign variant of cytophagic histiocytic panniculitis, which may also have a hemophagocytic syndrome. The prognosis for a patient with SPTCL is poor, with a median survival of less than 3 years. Multiagent chemotherapy is recommended,

at times with stem cell support. Denileukin diftitox (Ontak) was reported to produce a favorable response in one case.

Nasal/Nasal Type NK/T-Cell Lymphoma (Angiocentric Lymphoma) NK/T-cell lymphoma most frequently presents in extranodal tissue and is characterized by a high incidence of nasal involvement. It is more common in Asia, where it affects primarily women with a mean age of 40. In Korea it is reported to be the most common form of cutaneous lymphoma after mycosis fungoides. It is uncommon in the US. It presents clinically as dermal or subcutaneous papules or nodules that may ulcerate. Lesions are usually widespread and involve the lower extremities. A hydroa vacciniforme-type has been described in children in Mexico and in adults and children in Japan and Korea. Skin lesions are facial and extremity papulovesicles ulcerate and heal with scarring. Skin lesions are exacerbated by sun exposure and are reproduced with UVA irradiation.

Histologically, the dermis and subcutaneous fat are infiltrated with intermediate-sized, atypical lymphocytes, within and around the walls of small and medium sized vessels. Epidermotropism may be noted. The lymphoma cells express a spectrum of T- and NK-cell immunophenotypic markers, variably expressing CD2, CD3, CD4, CD8 and the NK-cell marker CD56. CD56 is not cell-lineage specific and a subset of CD56 cutaneous lymphoma cases are classified under the SPTCL category. Epstein-Barr virus is present in the NK variants and variably present in the T-cell variants. T-cell clonality is detected if the T-cell immunophenotype is present. The prognosis is poor.

Blastic NK-Cell Lymphoma The majority of patients are males, with a mean age of about 60 years. All patients present with multiple, rapidly expanding plaques and/or nodules on noncontiguous sites. Lesions are characteristically purple in color. The course is aggressive in most patients with rapid cutaneous relapse after chemotherapy with systemic involvement. Histologically, the cells infiltrate the dermis or subcutaneous fat, with a tendency for the neoplastic cells to "Indian file" in dermal collagen. There is usually a grenz zone below the epidermis. The lymphoma cells are small/ medium to large blastic lymphocytes. Angiocentricity may be noted, but is not prominent. Immunophenotyping is CD4+, CD56+. MIB-1 shows a proliferation activity of greater than 50%. T-cell gene rearrangements are negative.

Adult T-Cell Leukemia/Lymphoma

Infection with human lymphotropic virus type 1 (HTLV-1) may lead to acute T-cell leukenia/lymphoma (ATL) in 0.01% to 0.02% of infected persons. This virus is endemic in Japan,

Southeast Asia, the Caribbean, Latin America, and equatorial Africa. ATL usually has an acute onset with leukocytosis, lymphadenopathy, and HOTS (hypercalcemia, osteolytic bone lesions, T-cell leukemia, and skin lesions). Lesions resemble mycosis fungoides, except patches are uncommon and plaques and nodules predominate. Histologically the skin lesions contain lichenoid infiltrates of medium sized lymphocytes with convoluted nuclei. Epidermotropism and involvement around and within adnexa occur. Granuloma formation may occur in the dermis. ATL cells are usually CD4+/CD7- and show T-cell gene rearrangements.

CUTANEOUS B-CELL LYMPHOMA

Primary cutaneous B-cell lymphomas (Figs 32-11 and 32-12) occur less commonly than cutaneous T-cell lymphomas, but more frequently than generally believed (25% of cases of primary cutaneous non-Hodgkin lymphomas are B-cell in origin). Although the morphologic appearance of the malignant lymphocytes composing these primary cutaneous lymphomas is identical to lymphomas based in lymph nodes, they have a distinctly different clinical behavior and immunophenotypic profile. This renders the classification systems based on lymph node histology of limited benefit

Fig. 32-11 Lymphoma, B-cell.

Fig. 32-12 Lymphoma, B-cell.

clinically in the diagnosis of primary cutaneous B-cell lymphomas. More simplified schemes have thus been proposed that apply to primary cutaneous lymphomas only. These new systems have not been universally adopted and some controversy exists regarding classification of some forms of cutaneous B-cell lymphoma. This is illustrated by the fact that some authors state that follicular center cell lymphoma is the most common form of primary cutaneous B-cell lymphoma, while others say marginal zone lymphoma is the most common.

The great majority of primary cutaneous B-cell lymphomas are composed of cells with the morphologic characteristics of the B-cells normally found in the germinal centers of lymph nodes. Classification schemes used primarily for lymph node-based lymphomas divide these lymphomas into multiple types based on histomorphology. Fewer distinctions are made for primary cutaneous B-cell lymphomas, since the behaviors of most of the lymphomas of follicular center cell origin are similar. Secondary cutaneous involvement can occur with all forms of B-cell lymphoma based primarily in lymph node or other sites. The clinical features are similar to those of primary cutaneous lymphoma, with violaceous papules or nodules. Typically, the histologic structure of secondary lesions in the skin is similar to that of the lymphoma at the site of origin, usually lymph nodes. The pattern in the skin may not, however, be sufficient to accurately classify the lymphoma, making lymph node biopsy necessary in most cases. In secondary cutaneous B-cell lymphomas the prognosis is, in general, poor. It is therefore critical to completely evaluate and stage any patient suspected of having primary cutaneous B-cell lymphoma to exclude involvement at another site. Primary large B-cell lymphoma of the leg also appears to have a relatively poor prognosis.

Diffuse Large B-Cell Lymphoma (Primary Cutaneous Large B-Cell Lymphoma)

This group of lymphomas is high-grade histologically, but when the disease is restricted to the skin, high-grade does not correlate with prognosis. High-grade follicular lymphoma and immunoblastic lymphoma may be classified in this category by some (WHO), but others (EORTC) favor grouping follicular center cell lymphomas of large cells and diffuse histology with follicular lymphoma. Clinically, lesions present as solitary or localized red or purple papules, nodules or plaques. In general, solitary or localized lesions are typical of primary disease and widespread lesions suggest secondary cutaneous involvement of primary nodal lymphoma. Lesions on the head and neck have an excellent prognosis. Lesions on the leg have a poorer prognosis with a 5-year survival of about 50% and are considered in some classifications as a separate entity. Histologically, a diffuse dermal infiltrate is composed of large centroblasts and immunoblasts. Round cell morphology is an adverse prognostic feature. Immunophenotypically, cells usually express CD19, CD20, and monotypic immunoglobin, and leg lesions express bcl-2. Secondary cutaneous involvement with nodal large B-cell lymphoma is associated with a poor prognosis.

Primary Cutaneous Follicular Lymphoma (Follicular Center Lymphoma, Follicular Center Cell Lymphoma)

Clinically, most patients present with single or multiple papules, plaques or nodules, with surrounding erythema, in one anatomic region. About two-thirds of cases present on the trunk, about one-fifth on the head and neck (the vast majority of these on the scalp), and about 15% on the leg. These lymphomas are more common in men than women. Males outnumber females 4:1 in trunk lesions, whereas women disproportionately have head and leg lesions. Untreated, the lesions gradually increase in size and number, but extracutaneous involvement is uncommon. The prognosis is excellent with 5-year survival with treatment approaching 100%. Secondary cutaneous involvement of systemic follicular lymphoma has a poor prognosis.

Histologically, the infiltrate is nodular or diffuse within the dermis and spares the epidermis. Follicular growth pattern with primary cutaneous follicular lymphoma is uncommon. In early lesions, the neoplastic cells are of smaller size and there is a substantial portion of normal T-cells surrounding and mixed with the neoplastic B-cells. Over time, the neoplastic B-cells become a more predominant portion of the infiltrate, the neoplastic cells are larger in size and tumorinfiltrating T-cells diminish. Immunophenotypically, the neoplastic cells stain with B-cell markers (CD20 and others) and are monotypic for immunoglobulin production, i.e. they stain for either κ or λ light chains, but not both. Immunoglobulin staining may be negative in tumorous lesions. Clonal rearrangement of the immunoglobulin gene can be demonstrated. The absence of expression of IgH/bcl-2 rearrangement, no adenopathy, and lack of involvement of the bone marrow excludes the presence of nodal follicular center lymphoma. Bcl-2 expression in cutaneous follicular lymphoma does not affect outcome, however. In contrast, nodal follicular lymphoma usually expresses bcl-2 and there is a t(14:18) translocation in more than 80% of cases.

Radiation therapy totaling 30 to 40 Gy and including all erythematous skin and a 2-cm margin of normal skin is very effective for lesions of the head and trunk. A combination of intralesional IFN- α 5 MU every 4 weeks and topical becarotene gel 1% twice a day cleared one patient. Anthracyclinebased chemotherapy or rituximab may be used for relapses. In Europe some cases of primary cutaneous follicular center cell lymphoma are associated with *Borreliu* infection and may arise in lesions of acrodermatitis chronica atrophicans.

Primary Cutaneous Marginal Zone Lymphoma (Primary Cutaneous Immunocytoma, Marginal Zone B-Cell Lymphoma, MALT Lymphoma)

These lymphomas present as solitary or multiple dermal or subcutaneous nodules or tumors primarily on the upper part of the body, trunk, or extremities. Widespread lesions suggest secondary skin involvement by systemic lymphoma. Women are affected more than men. Histologically, the infiltrate is nodular or diffuse and composed of small lymphocytes and cells showing plasma cell differentiation. The atypical cells are often located at the periphery of aggregates of reactive T- and B-cells. The lymphoma cells may contain "Dutcher bodies," intranuclear collections of immunoglobin. Initially, the malignant cells may represent a very small proportion of the infiltrate and the diagnosis of pseudolymphoma is made. Over time the "marginal zone" cells predominate and the germinal centers are diminished. Immunophenotypically, the cells are monotypic for immunoglobulin and are CD79+ and CD19+. Clonal immunoglobulin gene rearrangements can be demonstrated. The prognosis is excellent, with 5-year

survival close to 100%. Local radiation therapy or excision if lesions are few is recommended. In some *Borellia*-endemic areas in Europe up to one-third of cutaneous marginal zone lymphomas are associated with *Borrelia* infection.

Intravascular Large B-Cell Lymphoma (Malignant "Angioendotheliomatosis," Angiotropic Large Cell Lymphoma)

Clinically, these cases present with variable cutaneous morphologies, often very subtle and nonspecific. Some cases resemble classic lymphoma with violaceous papules or nodules. Other cases more closely resemble intravascular thrombotic disorders with livedo reticularis-like lesions or telangiectatic patches. Sclerotic plaques may also occur. Even normal skin when biopsied can be diagnostic. Patients often present with fever of unknown origin. CNS symptoms are prominent with progressive dementia or multiple cerebrovascular ischemic events which may precede the findings of lymphoma by many months. Histologically, the features are characteristic and diagnostic. Dermal and subcutaneous vessels are dilated and filled with large neoplastic cells. Focal extravascular accumulations may be seen. The neoplastic cells are CD20+ and CD79a+, and monotypic for immunoglobulin. Clonal immunoglobulin gene rearrangements may be detected. Despite the large number of intravascular cells in the skin and other affected organs, the peripheral blood smears and bone marrow may be normal histologically. The prognosis is very poor. Multiagent chemotherapy is recommended. Rare cases of intravascular lymphoma may be of T-cell origin.

Plasmacytoma (Multiple Myeloma)

Cutaneous plasmacytomas, or localized neoplasms of plasma cells in the skin, are seen most commonly in the setting of myeloma. They are, however, rare, occurring in only 2% of inveloma cases. These cases are called secondury cutaneous plasmacytoma. They may also occur by direct extension from an underlying bone lesion. They may appear at sites of trauma, such as biopsies or intravenous catheters (inflammatory oncotaxis). Most commonly, secondary cutaneous plasmacytomas occur in the setting of advanced myeloma and the prognosis is poor. Less commonly, the skin lesions may be the initial clinical finding, leading to the diagnosis of myeloma. Histologically there are nodular and diffuse collections of plasma cells with varying degrees of pleomorphism and atypia. The degree of atypia may predict prognosis. The cells are monotypic for immunoglobin production and produce the same light chain as the myeloma. The immunoglobulin produced is most commonly IgG or IgA and rarely IgD or IgE. CD79 is positive, but CD19 and CD20 are negative.

In addition to plasmacytomas, patients with myeloma may develop a vast array of cutaneous complications. These include normolipemic plane xanthomas, amyloidosis, vasculitis, and calcinosis cutis. An unusual but characteristic skin finding in myeloma is multiple follicular spicules of the nose, forehead, cheeks and chin. They are yellowish and firm to palpation and can be removed without bleeding. Numerous small ulcerations may occur on the trunk. Both the spicules and ulcers contain an eosinophilic material composed of the abnormal monoclonal protein produced by the malignant cells. The spicules are *not* made of keratin. Similar cutaneous spicules composed of keratin can be seen in vitamin A deficiency, chronic renal failure, acquired immunodeficiency syndrome (AIDS), Crohn's, and other malignant diseases.

More rarely, solitary or multiple skin lesions may be seen with no evidence of involvement in any other tissue. They represent 4% of extramedullary plasmacytomas (EMP) and present as skin-colored or violaceous dermal or subcutaneous papules, nodules or plaques. EMPs are threefour times more common in men than women. The diagnosis of EMP requires a negative skeletal survey and no evidence of plasma cell proliferation in the bone marrow. The cutaneous lesions may produce a monoclonal protein. Such skin lesions are termed primary cutaneous plasmacytomas. The prognosis for isolated primary cutaneous plasmacytoma is excellent (>90% chance of 5-year survival) and progression to myeloma is uncommon. Neither the clinical nor histologic appearance of the cutaneous lesions predicts the course and their histologic appearance is identical to plasmacytomas seen in association with myeloma. Cutaneous plasmacytomas may occur following treatment of EMP at another site, as a secondary cutaneous recurrence. Rarely, soft-tissue extramedullary plasmacytomas may be associated with post-transplantation plasma cell dyscrasia. Anetoderma may show plasmacytoma on biopsy. A rare manifestation of a solitary plasmacytoma of bone is an overlying erythematous skin patch which may be 10 cm or more in diameter. The chest is the most common location. Lymphadenopathy is present and some of the patients have or develop POEMS syndrome (polyneuropathy, organomegaly, endocrinopathy, monoclonal protein, and skin changes). This syndrome has been called adenopathy and extensive skin patch overlying a plasmacytoma, or AESOP.

The appropriate treatment of plasmacytomas is determined by the presence or absence of associated systemic disease. Solitary or pancilesional primary cutaneous plasmacytomas have been treated successfully with local surgery and radiation therapy. Systemic chemotherapy may be required if these modalities fail. The treatment for secondary plasmacytomas and for patients with numerous primary cutaneous plasmacytomas is chemotherapy.

Cutaneous and Systemic Plasmacytosis

Cutaneous and systemic plasmacytosis occur largely in Asians, slightly favoring males. They typically occur between the ages of 20 and 55. These conditions are characterized by polyclonal proliferations of plasma cells and hyperglobulinemia and were originally considered variants of Castleman's disease. Cutaneous plasmacytosis affects only the skin but patients may have lymphadenopathy, and systemic symptoms of fever and malaise. Systemic plasmacytosis has involvement in two or more organ systems, usually, in addition to skin, the lung, bone marrow, and liver. Dyspnea may occur due to interstitial pneumonia. Uncommonly, cases of systemic plasmacytosis may progress to lymphoma. The course is chronic and benign and response to various cytostatic and immunosuppressive treatments has been poor. PUVA and topical tacrolimus have been reported effective for skin lesions. The skin lesions in cutaneous and systemic plasmacytosis are identical. They consist of multiple brown-red plaques, mostly of the central upper trunk, but also the face. Lesions range from 1 to 3 cm in diameter. They are often considered simply postinflammatory hyperpigmentation until they are palpated. Histologically they show a dense perivascular infiltrate of mature plasma cells, which stain for both κ and λ light chains (polyclonality). Elevated IL-6 has been reported in some patients.

HODGKIN'S DISEASE

The vast majority of reports of cutaneous Hodgkin's disease actually represent type A lymphomatoid papulosis (LyP). These two diseases have a considerable number of overlapping features. The type A cells of LyP have similar morphology and share immunophenotypic markers with Reed-Sternberg cells. LyP can be seen in patients with Hodgkin's disease. Primary cutaneous Hodgkin's disease without nodal involvement is thus difficult to prove and is very, very rare, if it exists.

Most cases of Hodgkin's disease of the skin usually originate in the lymph nodes, from which extension to the skin is either retrograde through the lymphatics or by direct extension. Lesions present as papules or nodules with or without ulceration. Lesions resembling scrofuloderma may occur. Miliary dissemination to the skin can occur in advanced disease.

Nonspecific cutaneous findings are common in patients with Hodgkin's disease. Generalized, severe pruritus may precede by many months other findings of Hodgkin's disease or may occur in patients with a known diagnosis. Secondary prurigo nodules and pigmentation may occur as a result of scratching. An evaluation for underlying lymphoma should be considered in any patient with severe itching, no primary skin lesions, and no other cause identified for the pruritus. Acquired ichthyosis, exfoliative dermatitis, and generalized and severe herpes zoster are other cutaneous findings in patients with Hodgkin's disease.

Takagawa S, et al: Skin invasion of Hodgkin's disease mimicking scrofuloderma. Dematology 1999;199:268.

MALIGNANT HISTIOCYTOSIS (HISTIOCYTIC MEDULLARY RETICULOSIS)

Most cases considered malignant histiocytosis in the past are now considered to be other forms of lymphoma or lymphomas with large components of reactive histiocytes. Very rare cases of true malignancies of histiocytes may still occur and can have cutaneous lesions, most characteristically erythematous nodules. Often, the bone marrow examination in these cases is initially normal, but cases are rapidly progressive and fatal and the bone marrow becomes involved.

LEUKEMIA CUTIS

Clinical Features

Cutaneous eruptions seen in patients with leukemia may be divided into specific (leukemia cutis) and nonspecific lesions (reactive and infectious processes). Overall, about 30% of biopsies from patients with leukemia will show leukemia cutis. All forms of leukemia can be associated with cutaneous findings, but skin disease is more common in certain forms of leukemia. The vast majority of dermatologic manifestations are seen in patients with acute myelogenous leukemia (AML) or myelodysplastic syndrome (MDS). AML includes types M1 through M5. In AML and MDS patients, only about 25% of skin biopsies will show leukemia cutis, the remainder showing complications of the leukemia. These include infections, graft-versus-host disease, drug reactions, or the reactive conditions associated with leukemia that were formerly called *leukemids*. By contrast, in patients with acute lymphocytic leukemia (ALL), chronic myelogenous leukemia (CML), and CLL, about 50% of biopsies will show leukemia cutis.

Specific Eruptions

The most common morphology of leukemic infiltrations of the skin in all forms of leukemia is multiple papules or nodules (60% of cases) or infiltrated plaques (26%). These lesions are usually flesh-colored, erythematous, or violaceous (plum-colored) (Fig. 32-13). They are rubbery on palpation and ulceration is uncommon. Extensive involvement of the face may lead to a leonine facies.

Less common manifestations of leukemia cutis are subcutaneous nodules resembling erythema nodosum or panni-

Fig. 32-13 Leukemia cutis.

culitis, arciform lesions (in juvenile CML), ecchymoses, palpable purpura, erythroderma, ulcerations (which may resemble pyoderma gangrenosum or venous stasis ulceration), and urticaria-like, urticaria pigmentosa-like (in ALL), and guttate psoriasis-like lesions. Rare manifestations are a lesion resembling Sister Mary Joseph nodule and cutaneous sarcoidal lesions. Myelogenous leukemia may be complicated by lesions resembling stasis dermatitis or chilblains. Gingival infiltration causing hypertrophy is common in and relatively unique to patients with acute myelomonocytic leukemia.

Leukemia cutis most commonly occurs concomitant with the diagnosis of leukemia or following the diagnosis of leukemia. The skin may also be a site of relapse of leukemia after chemotherapy, especially in patients who present with leukemia cutis. Uncommonly, leukemia cutis may be identified while the bone marrow and peripheral blood are normal. These patients are classified as "aleukemic leukemia cutis," as they have normal bone marrow evaluations and no circulating blasts. These cases are often misdiagnosed as cutaneous lymphomas and undertreated. They eventually relapse with fullblown leukemia. Systemic involvement occurs within 3 weeks to 20 months (average 6 months). Leukemia cutis is a poor prognostic finding in patients with leukemia, with 90% of such patients having extramedullary involvement and 40% having meningeal infiltration.

The term congenital leukemia applies to cases appearing within the first 4 to 6 weeks of life. Leukemia cutis occurs in 25% to 30% of such cases, the vast majority being congenital myelogenous leukemia. The typical morphology is multiple, red or plum-colored nodules. In about 10% of cases of congenital leukemia cutis (or 3% of all cases of congenital leukemia), the skin involvement occurs while the bone marrow and peripheral blood are normal. Systemic involvement is virtually always identified in 5 to 16 weeks. Unlike other forms of leukemia, in congenital leukemia, cutaneous infiltration does not worsen prognosis. Congenital leukaemia cutis has been complicated by disseminated linear calcinosis cutis.

Granulocytic Sarcoma (Chloroma)

Granulocytic sarcomas are rare tumors of immature granulocytes. They occur in about 3% of patients with myelogenous leukemia. Granulocytic sarcoma is seen in four settings: in patients with known AML; in patients with CML or MDS as a sign of an impending blast crisis; in undiagnosed patients as the first sign of AML; or after bone marrow transplantation as the initial sign of relapse. Most lesions occur in the soft tissues, periosteum, or bone. Skin lesions represent 20% to 50% of reported cases. They may be solitary or multiple. They appear as red, mahogany, or violaceous firm nodules with a predilection for the face, scalp, or trunk.

The name *chloroma* comes from the green color of fresh lesions, which can be enhanced by rubbing with alcohol; this is caused by the presence of myeloperoxidase. This appearance is variable, so the preferred term is now *granulocytic sarcoma*.

The diagnosis is not difficult if the diagnosis of leukemia has been established. Such patients are treated with appropriate chemotherapy. However, if the skin lesion is the initial manifestation of leukemia, and the blood and bone marrow are normal, the lesion may be misdiagnosed as a large cell lymphoma. The treatment of such patients is controversial, but most go on to develop AML within months, so chemotherapy is often given.

Hairy-Cell Leukemia

Skin involvement is rare in hairy-cell leukemia and violaceous papules and nodules, which are the characteristic morphology of other forms of leukemia cutis, are extremely rare in hairy-cell leukemia. Rather, often in the setting of a systemic mycobacterial infection or a drug reaction, a diffuse erythematous, nonpruritic eruption occurs. This may progress to erythroderma or a severe blistering eruption. Stopping the offending medication usually leads to resolution of the eruption. This is especially common in patients treated with 2-chlorodeoxyadenosine and allopurinol. The former treatment alone does not lead to these severe skin reactions, suggesting the allopurinol is the cause. Patients with hairy cell leukemia also develop lesions of pustular vasculitis of the dorsal hands, a neutrophilic dermatitis closely related to bullous Sweet syndrome. This is sometimes termed a "vasculitis" in the oncology literature.

Nonspecific Conditions Associated with Leukemia (Leukemids)

Leukemia and its treatment is associated with a series of conditions which may also be seen in patients without leukemia, but which are seen frequently enough in leukemic patients to be recognized as a complication of that condition or its treatment.

When a dermatologist or dermatopathologist is consulted to evaluate a patient with leukemia and skin lesions, the differential diagnosis usually includes four groups of conditions: drug reactions, leukemia cutis, an infectious complication, and a reactive condition. Drug reactions include all forms of reactions, but are most commonly erythema multiforme, morbilliform reactions, or acral erythema. Infections may present in many ways but are usually purpuric papules, pustules, or plaques if they are caused by bacteria or fungi. Ulceration is typical. Herpes simplex and herpes zoster should be considered in all erosive, ulcerative, or vesicular lesions. The reactive conditions include a group of neutrophilic dermatoses with considerable clinical overlap. These include Sweet syndrome, pyoderma gangrenosum, neutrophilic hidradenitis, and leukocytoclastic vasculitis. Transient acantholytic dermatosis and eosinophilic reactions resembling

insect bites may occur, most commonly in patients with CLL. In CLL a pruritic and unremitting exfoliative erythroderma is a unique feature.

Evaluation of these patients must be complete and often extensive diagnostic tests and empiric treatment are pursued until the diagnosis is established. In the acute setting, a clinical diagnosis is made based on morphology. Possible infectious complications are covered by appropriate antibiotics, especially if the patient is febrile or the diagnosis of a herpes virus infection is made. Diagnostic tests are submitted, often including a skin biopsy. For herpes infections, a direct fluorescent antibody should be done, as the results are virus specific and rapid, so appropriate treatment can be given quickly. Once the diagnostic tests return, the therapy is tailored to the appropriate condition. Except for herpes infections, a skin biopsy is often required. If infection is considered, a portion of the biopsy should be sent for culture.

CUTANEOUS MYELOFIBROSIS

Myelofibrosis is a chronic myeloproliferative disorder characterized by a clonal proliferation of defective multipotential stem cells in the bone marrow. Overproduction and premature death of atypical megakaryocytes in the bone marrow produce excess amounts of platelet-derived growth factor, a potent stimulus for fibroblast proliferation and collagen production. Extramedullary hematopoiesis (EMH) is a hallmark of myelofibrosis. Blast cells and committed stem cells escape the marrow in large numbers, enter the circulation, and form tumors of the same atypical clone in other organs, especially the spleen, liver, and lymph node. EMH in the skin of neonates is usually caused by intrauterine viral infections. In adults, cutaneous EMH has rarely been reported, characteristically associated with myelofibrosis. Skin lesions are dermal and subcutaneous nodules. Histologically, the cutaneous lesions are composed of dermal and subcutaneous infiltrates of mature and immature myeloid cells, erythroid precursors (in only half of cases), and megakaryocytic cells (which may predominate). There is marked production of collagen fibers in the cutaneous lesions by the mechanism described above. Myelolibrosis must be distinguished from CML, since both have elevated white blood cell counts with immature myeloid forms, defective platelet production and marrow fibrosis. Both may terminate in blast crisis and myelofibrosis may rarely convert to CML. CML is associated with the Philadelphia chromosome, whereas chromosomal abnormalities occur in 40% of myelofibrosis cases on various chromosomes.

HYPEREOSINOPHILIC SYNDROME

Idiopathic hypereosinophilic syndrome (HES) is defined as eosinophilia with more than 1500 eosinophils/mm³ for more than 6 months, with some evidence of parenchymal organ involvement; there must also be no apparent underlying disease to explain the hypereosinophilia and no evidence of vasculitis. Ninety percent of patients reported have been men, mostly between the ages of 20 and 50. Childhood cases are rare. Presenting symptoms include fever (12%), cough (24%), fatigue, malaise, muscle pains, and skin eruptions. Two pathogenic variants of HES have been defined: m-HES (myeloproliferative HES) and I-HES (lymphocytic HES). M-HES patients are overwhelmingly males, and anemia. thrombocytopenia, elevated serum B12 levels, mucosal ulcerations, splenomegaly, and endomyocardial fibrosis are the clinical features. Eosinophil clonality and interstitial deletion on 4q12 result in fusions of FIP1qL1 and PDGFRa genes, forming an F/P fusion protein displaying constituitive activity, are pathogenically related to m-HES cases. Increased mast cells and elevated tryptase levels with myeloid precursors in peripheral blood and myelofibrosis may be found, suggesting mast cells may be pathogenically related to this form of HES. Leukemia may develop in patients with m-HES. L-HES has been associated with circulating T-cell clones of CD4+ phenotype which secrete Th2 cytokines, especially IL-5. Females and males are equally affected by 1-HES and cutaneous manifestations are observed in virtually all patients. Skin manifestations include urticaria, angioedema, pruritus, eczema, and erythroderma. Splinter hemorrhages and necrotic skin lesions are seen in some HES patients as well. Endomyocardial fibrosis is uncommon, but pulmonary and digestive symptoms are common. Some patients with I-HES are clinically identical to Gleich syndrome or episodic angioedema and hypereosinophilia. Over time some patients with I-HES will develop lymphoma.

Treatment is determined by classifying cases appropriately as m-HES or I-HES. M-HES patients may be treated with corticosteroids, hydroxyurea, IFN-a, and chemotherapeutic agents. Imatinib mesylate (Gleevac, 100 mg/day or less) can be highly effective for m-HES patients with the F/P mutation, as imatinib inhibits the phosphorylation of the F/P protein and leads to apoptosis of cells producing this protein. This has rapidly become first-choice treatment for this subset of patients. Response may be dramatic, with eosinophil levels, and skin and gastrointestinal manifestations clearing in days. For I-HES patients, systemic glucocorticoids, and perhaps IFN- α with glucocorticoids, can be used and are usually effective. Monoclonal anti-IL-5 antibody, cyclosporin A, anti-IL-2R- α , and CTLA-4-Ig may be treatment options. If lymphoma supervenes, intense chemotherapy and allogenic stem cell transplantation can be considered.

ANGIOIMMUNOBLASTIC LYMPHADENOPATHY WITH DYSPROTEINEMIA (ANGIOIMMUNOBLASTIC T-CELL LYMPHOMA)

Angioimmunoblastic lymphadenopathy with dysproteinemia (AILD) is an uncommon lymphoproliferative disorder. Patients are middle-aged or elderly and present with fever (72%), weight loss (58%), hepatomegaly (60%), polyclonal hyperglobulinemia (65%), and generalized adenopathy (87%). Pruritus occurs in 44% and a skin rash in 46%. The skin eruption usually is morbilliform in character, resembling an exanthem or a drug reaction. Petechial, purpuric, nodular, ulcerative, and erythrodermic eruptions have also been reported. In about 30% of cases the eruption is associated with the ingestion of a medication. The eruptions usually resolve with oral steroids, misleading the clinician to believe the eruption was benign.

Histopathologically, there is a patchy and perivascular dermal infiltrate of various types of lymphoid cells, plasma cells, histiocytes (enough to rarely give a "granulomatous" appearance), and eosinophils. The lymphoid cells are usually helper T-cells (CD4+). Some portion of the lymphoid cells is atypical in most cases, suggesting the diagnosis. Blood vessels are increased and the endothelial cells are prominent, often cuboidal. Unfortunately, these changes may not be adequate to confirm the diagnosis. However, clonal T-cell gene rearrangement is found in three-quarters of these skin lesions and is the same as the clone in the lymph node. Immunophenotyping of the skin lesions does not give a consistent pattern. At times the skin lesions will show leukocytoclastic vasculitis on biopsy. Lymph node biopsy is usually required to confirm the diagnosis and exclude progression to lymphoma.

AILD appears to develop in a stepwise fashion. Initially there is an immune response to an unknown antigen. This immune reaction persists, leading to oligoclonal T-cell proliferation. Monoclonal evolution may occur, eventuating in lymphoma (angioimmunoblastic lymphoma [AILD-L]). These are usually T-cell lymphomas, but B-cell lymphomas can also occur. In the case of AILD-L, skin lesions may contain the neoplastic cells (secondary lymphoma cutis). In up to 50% of cases multiple unrelated neoplastic cell clones have been identified. Clones identified in the skin may be different from clones found in lymph node. Trisomy 3 or 5, or an extra X chromosome, may be found. AILD is an aggressive disease, with mortality ranging from 48% to 72% in various series (average survival time is 11 to 60 months). The cause of death is usually infection. Epstein-Barr virus and human herpesviruses 6 and 8 have been implicated in AILD.

Treatment of AILD has included systemic steroids, methotrexate plus prednisone, combination chemotherapy, fludarabine, 2-chlorodeoxyadenosine, IFN- α , and cyclosporin. Early treatment with systemic steroids during an oligoclonal or prelymphomatous stage may induce a long-lasting remission. Asymptomatic patients may not be treated initially but must be watched very closely. More aggressive chemotherapy achieves better remission. Nonetheless, recurrence rates are high, and average survival is between 1 and 3 years.

Sinus Histiocytosis with Massive Lymphadenopathy (Rosai-Dorfman Disease)

Sinus histiocytosis with massive lymphadenopathy (SHML), or Rosai-Dorfman disease, usually appears in patients in the first or second decade of life as a febrile illness accompanied by massive cervical (and commonly other) lymphadenopathy, polyclonal hyperglobulinemia, leukocytosis, anemia, and an elevated sedimentation rate. Males and black persons are especially susceptible. Extranodal involvement occurs in 40% of cases, with skin being the most common site. Ten percent of patients with SHML have skin lesions and 3% of patients have disease detectable only in the skin. The terms cutaneous sinus histiocytosis or cutaneous Rosai-Dorfman disease have been applied to these cases. Skin lesions consist of isolated or disseminated yellow-brown papules, pustules, or nodules; or macular erythema. Large annular lesions, resembling granuloma annulare, may occur. Most patients with cutaneous Rosai-Dorfman are older (40 to 60 years).

Histologically, there is a superficial and deep perivascular infiltrate of lymphocytes and plasma cells. Nodular and diffuse infiltration of the dermis by large, foamy histiocytes is present. A very important diagnostic feature is the finding of intact lymphocytes (and less commonly plasma cells) in the cytoplasm of the histiocytic cells. This is called *emperipolesis*. Foamy histiocytes may be seen in dermal lymphatics. The cutaneous histology in some cases may be very nonspecific (except for the finding of emperipolesis) and only on evaluation of lymph node or other organ involvement does the diagnosis become clear. Immunohistochemistry and electron microscopy may be very useful as the infiltrating cells are positive for CD4, factor XIIIa, and S-100, but do not contain Birbeck granules.

The cause of this condition is unknown, but numerous reports have identified human herpesvirus 6 in involved lymph nodes. The condition usually clears spontaneously, so no treatment is required. Numerous agents have been used therapeutically with variable success, but are only indicated if the condition puts the patient at risk for death or a significant complication (usually by compressing a vital organ). Treatments have included radiation, systemic corticosteroids, and thalidomide. Single and multiagent chemotherapy is met with mixed to poor response. To treat skin lesions, cryotherapy, topical steroids, and intralesional steroids may be tried.

POLYCYTHEMIA VERA (ERYTHREMIA)

Polycythemia vera (PCV) is characterized by an absolute increase of circulating red blood cells, with a hematocrit level of 55% to 80%. Leukocyte and platelet counts are also increased. The skin changes are characteristic. There is a tendency for the skin to be red, especially on the face, neck, and acral areas. The mucous membranes are engorged and bluish. The phrase "red as a rose in summer and indigo blue in winter" has been ascribed to Osler in describing PCV. Telangiectases, bleeding gums, and epistaxis are frequently encountered. Cyanosis, purpura, petechiae, hemosiderosis, rosacea, and koilonychia may also be present.

In 50% of patients with PCV, aquagenic pruritus occurs. In about two-thirds of patients this is of limited severity and does not require treatment. The pruritus is typically triggered after a bath or shower and the feeling induced may be itching, burning, or stinging. It usually lasts 30 to 60 min and is independent of the water temperature. Pruritus unassociated with water exposure may also occur. There is a concurrent elevation of blood and skin histamine. Pruritus is present in about 20% of patients at presentation and develops in the remaining 30% over the course of their disease. Patients with pruritus have lower mean corpuscular volumes and higher leukocyte counts. Some have suggested that iron deficiency plays a role in PCV-associated pruritus, so a ferritin level, and a trial of iron therapy, may be indicated. Platelet counts are no different between PCV patients who itch and those who do not.

The treatment of PCV-associated pruritus may be difficult. Initial therapy would include first- or second-generation H_1 antihistamines. Hydroxyzine was reported as the most effective antihistamine by a group of PCV patients. H_2 blockers can be added. Narrow-band UVB has been reported to be effective in 80% of patients. Topical therapy is of limited benefit. Phlebotomy may be useful in patients with elevated hematocrits. Paroxetine (Paxil) 20 to 60 mg/day may be dramatically effective.

CHAPTER

Diseases of the Skin Appendages

DISEASES OF THE HAIR

Normal human hairs can be classified according to cyclical phases of growth. Anagen hairs are growing hairs, catagen hairs are those undergoing transition from the growing to the resting stage, and telogen hairs are resting hairs, which remain in the follicles for variable lengths of time before they fall out (teloptosis). The lag period between loss of the telogen hair and growth of a new anagen hair has been referred to as kenogen.

Anagen hairs grow for about 3 years (1000 days), with a range between 2 and 6 years. The follicular matrix cells grow, divide, and become keratinized to form growing hairs. As the matrix produces the hair shaft, it incorporates substances that may be useful in medical or forensic analysis. Catagen hairs are in a transitional phase, lasting 1 or 2 weeks, in which all growth activity ceases, with the eventual formation of the telogen "club" hair. Many apoptotic cells are present in the outer root sheath of the catagen hair as it involutes. Telogen club hairs are resting hairs, which continue in this state for 3 to 5 months (about 100 days) before they are released.

Among human hairs plucked from a normal scalp, 85% to 90% are anagen hairs and 10% to 15% are telogen hairs. Catagen hairs normally comprise less than 1% of scalp hairs. It has been estimated that the scalp normally contains about 100,000 hairs, and the average number of hairs shed daily is 100 to 150. The hair growth rate of terminal hairs is about 0.37 mm/day. Contrary to popular belief, neither shaving nor menstruation has any effect on hair growth rate. The average uncut scalp hair length is estimated to be 25 to 100 cm, although exceptional hairs may be as long as 170 cm (70 inches).

Human hair is also designated as lanugo, vellus, or terminal hair. Lanugo hair is the fine hair present on the body of the fetus. This is replaced by the vellus and terminal hairs. Vellus hairs are fine, usually light-colored, and have a narrow hair shaft thinner than the width of the inner root sheath. Terminal hairs are coarse, thick, and dark, except in blonds. Hair occurs on all skin surfaces except the palms, soles, labia minora, lips, nails, glans, and prepuce. Terminal hairs are commonly present on a man's face, chest, and abdomen, but vellus hairs usually predominate on these sites in women.

Causes of alopecia are generally divided into the broad categories of cicatricial and noncicatricial alopecia. The evaluation should take into account the patient's age and ethnicity. Examination of hair shafts can establish a diagnosis of trichodystrophy. Hair counts, hair pull, and hair pluck (trichogram) can establish the degree of hair shedding, the type of hairs that are shed, and the anagen-to-telogen ratio. Biopsies can also the determine anagen-to-telogen ratio, and provide information regarding the potential for regrowth as well as providing a diagnosis. Biopsies are particularly valuable in the evaluation of cicatricial alopecia. Often, a correct diagnosis hinges on a synthesis of clinical, histologic, serologic, and immunofluorescent data.

Noncicatricial Alopecia

Alopecia Areata

Clinical Features

Alopecia areata (in French, *pelade*) is characterized by rapid and complete loss of hair in one or more round or oval patches, usually on the scalp, bearded area (Fig. 33-1), eyebrows, eyelashes, and less commonly, on other hairy areas of the body. Often the patches are from 1 to 5 cm in diameter. A few resting hairs may be found within the patches. Early in the course there may be sparing of gray hair, and white hairs are rarely affected. Sudden whitening of hair may represent widespread alopecia areata in a patient with salt and pepper hair. In about 10% of cases of alopecia areata, especially in long-standing cases with extensive involvement, the nails develop uniform pits that may form transverse or longitudinal lines. Trachyonychia, onychomadesis, and red or spotted lunulae occur, but less commonly.

Complete loss of scalp hair is referred to as alopecia totalis, and complete loss of all hair as alopecia universalis.

Fig. 33-1 Alopecia areata.

Fig. 33-2 Alopecia areata.

In most cases, hair loss is confined to the scalp and is patchy in distribution. Loss may occur confluent along the temporal and occipital scalp (ophiasis) (Fig. 33-2) or on the entire scalp except for this area (sisaipho). Rarely, alopecia areata may present in a diffuse pattern that may mimic pattern alopecia (Fig. 33-3). Clues to the correct diagnosis include a history of periodic regrowth, nail pitting, and the presence of tapered fractures or *exclamation point* hairs (Fig. 33-4). Alopecia areata generally presents as an anagen effluvium, with an inflammatory insult to the hair matrix resulting in tapering of the hair shaft, and resulting in fracture of anagen hairs. As the hair miniaturizes or converts from anagen to telogen, the remaining lower portion of the hair rises above the level of the scalp, producing the exclamation point hair.

Alopecia areata is associated with a higher incidence than usual of atopic dermatitis, Down syndrome, lichen planus, and autoimmune diseases, such as systemic lupus erythematosus, thyroiditis, diabetes mellitus, myasthenia gravis, and vitiligo. However, most cases of alopecia areata occur without associated disease, and routine screening for these disorders is of little value unless prompted by signs or symptoms.

Migratory poliosis of the scalp may represent a forme fruste of alopecia areata. Patients with this disorder present with migrating circular patches of white hair (Fig. 33-5), but never loose hair. The histology resembles alopecia areata.

Etiologic Factors

The preponderance of evidence supports an autoimmune etiology. Oligocional and autoreactive T-lymphocytes are

Fig. 33-3 Alopecia areata.

Fig. 33-4 Exclamation point hairs of alopecia areata.

Fig. 33-5 Migratory poliosis.

present in the peribulbar inflammatory infiltrate, and many patients respond to immune-modulating drugs. Affected alopecia areata scalp skin grafted onto nude mice with severe combined immunodeficiency demonstrates loss of infiltrating lymphocytes and hair growth. In this model, injecting T-lymphocytes with scalp homogenate can reproduce the alopecia. Follicular melanocytes substitute for scalp homogenates to produce alopecia areata in this model, providing evidence that follicular melanocytes are the targets for activated T-cells in this disease. This hypothesis is also supported by the observations that white hair is rarely affected and regrowing hair is often depigmented.

In early alopecia areata, the perifollicular and intrafollicular inflammatory infiltrate is composed of activated CD4+ and CD8+ T-cells, together with macrophages and Langerhans cells. The early phase of hair loss appears to be mediated by type 1 cytokines, including interleukin (IL)-2, interferon (IFN)- γ , and tumor necrosis factor (TNF)- α . The hair bulb normally represents an area of relative immune privilege during anagen, as evidenced by a very low level of expression of major histocompatibility complex (MHC) class Ia antigens. This immune privilege may prevent antigen recognition by autoreactive CD8+ T-cells. Alopecia areata may be related to collapse of this immune privilege.

Neuropeptides modify immune reactivity and may play a role in the disease. Heredity also plays a role. Overall, nearly 25% of patients have a positive family history; there are reports of twins with alopecia areata. Patients with "early onset, severe, familial clustering alopecia areata" have a unique and highly significant association with the HLA antigens DR4, DR11, and DQ7. The "later onset, milder severity, better prognostic" subsets of patients have a lower frequency of familial disease and do not share these HLA antigens.

Histology

In early disease there is a lymphoid infiltrate in the peribulbar area of anagen or early catagen follicles. Eosinophils may be present in the infiltrate, and lymphocyte-mediated damage to the bulb produces melanin pigment incontinence in the surrounding stroma. The hair structures enter an abnormal catagen phase, followed by telogen. During this phase, the presence of many catagen hairs and pigment casts within the follicular canal can cause histologic confusion with trichotillomania. In alopecia areata, the follicles eventually miniaturize, appearing as small dystrophic anagen hairs high in the dermis, often with a persistent lymphocytic peribulbar infiltrate. The presence of a peribulbar infiltrate helps to distinguish the miniaturized follicles of alopecia areata from those of androgenetic alopecia. Fibrous tract remnants beneath the miniaturized bulbs of alopecia areata may contain lymphoid cells, eosinophils, and melanin pigment. These findings are never present in trichotillomania or androgenetic alopecia. With time, the lymphocytes disappear, but focal eosinophils and pigment remain. Finally, only focal melanin pigment remains in the fibrous tract remnants. Hair fiber granulomas and scarring never occur. Every histologic feature of alopecia areata may be seen in syphilis. The presence of plasma cells is suggestive of syphilis, but plasma cells are lacking in about one-third of syphilis biopsies. Plasma cells may be present in biopsies from any form of inflammatory alopecia if the biopsy is taken from the occipital scalp, as this site readily recruits plasma cells.

Differential Diagnosis

The sharply circumscribed patch of alopecia with exclamation point hairs at the periphery and the absence of scarring are indicative of alopecia areata. Tinea capitis, androgenetic alopecia, early lupus erythematosus, syphilis, congenital triangular alopecia, alopecia neoplastica, and trichotillomania should be kept in mind when alopecia areata is considered. A biopsy will generally help to distinguish alopecia areata from these other entities, except syphilis which may be indistinguishable. In endemic areas of southwest Asia, *Pheidole* ants shear hair shafts during the night, resulting in overnight loss of clumps of hair. The resulting round patches of hair loss closely mimic alopecia areata.

Treatment

The natural course of the hair loss is highly variable. Some patches will regrow in a few weeks without any treatment. Various treatments can induce growth, but the inherent risks and cost must be weighed against the benefit of earlier regrowth. Arnold found, in his series of 63 consecutive responders to a follow-up questionnaire, that after reassurance only, hair had regrown in all but four patients after 1 year and in all but one after 2 years. The great majority had recovered in 3 months after their only office visit. Therefore, anecdotal reports of success must be interpreted carefully in the light of the high rate of spontaneous recovery.

Intralesional injections of corticosteroid suspensions are the treatment of choice for localized cosmetically conspicuous patches, such as those occuring in the frontal hairline or involving an evebrow. Injections of triamcinolone, 2 to 10 mg/mL, are typically given intradermally or in the superficial subcutaneous tissue. Large volumes and higher concentrations of triamcinolone present a greater risk of atrophy. High-strength topical steroids may be used as first-line therapy, but are less reliable than injections. Several investigators have reported the use of pulsed oral corticosteroids in rapidly progressing or widespread disease. However, longterm treatment is frequently needed to maintain growth, and the attendant risks should be carefully weighed against the benefits. In a study of 66 patients aged 9 to 60 years, monthly methylprednisolone was administered at a dose of 500 mg/day during 3 days or 5 mg/kg twice a day over 3 days in children. More than 60% of patients with widespread patchy alopecia responded. Half of the patients with alopecia totalis had a good response, while a quarter of those with universal alopecia responded. Patients with ophiasic alopecia areata did not respond.

Induction of contact sensitivity to squaric acid dibutyl ester, dinitrochlorobenzene, and diphencyprone can be useful in refractory cases. In mice, contact immunotherapy is associated with a decrease in cutaneous activated T-cells, a reduction in intrafollicular CD8+ lymphocytes, and reduced expression of CD44v3+ and CD44v10+ cells. These results suggest that blockade of leukocyte trafficking and extravasation is an important mechanism of action. Topical or oral methoxsalen and ultraviolet A (PUVA) therapy are options for refractory or widespread lesions. Short contact topical anthralin 1% cream (applied for 15-20 min and then shampooed off) can be of benefit. Topical minoxidil may be combined with other treatments or utilized as a single agent. The 308-nm xenon chloride excimer laser (300-2300 mJ/ cm²/session) has been reported to produce regrowth after 11 and 12 sessions over a 9- to 11-week period.

AA can cause tremendous psychological stress. Education about the disease process, cosmetically acceptable alternatives (especially information about wigs), and research into innovative therapies should all be made available to the patient. In addition to the information conveyed by the dermatologist, an excellent resource is the National Alopecia Areata Foundation (NAAF): PO Box 150760, San Rafael, CA 94915–0760, E-mail: NAAF@contpuserve.com, website: www.alopeciaareata.com.

Prognosis

The tendency is for spontaneous recovery in patients who are postpubertal at onset. At first, the regrowing hairs are downy and light in color; later, they are replaced by stronger and darker hair with full growth. Predictors of a poor prognosis are the presence of atopic dermatitis, childhood onset, widespread involvement, ophiasis, duration of longer than 5 years, and onychodystrophy.

Telogen Effluvium Telogen effluvium presents with excessive shedding of normal telogen club hairs. This excessive shedding of telogen hairs has several possible

mechanisms. It most commonly occurs 3 to 5 months after the premature conversion of many anagen hairs to telogen hairs induced by surgery, parturition, fever, drugs, dieting, or traction. Local patches of early telogen conversion may be induced by papulosquamous diseases affecting the scalp. Alternatively, (ollicles may remain in prolonged anagen rather than normally cycling into telogen. This occurs during pregnancy. On delivery, many follicles are then released simultaneously into telogen, and shedding occurs 3 to 5 months later. Prolongation of telogen also occurs during pregnancy, and results in an initial wave of hair loss soon after delivery or heralding early termination of a pregnancy. Shortening of the anagen phase occurs in pattern (androgenetic) alopecia, and results in telogen effluvium. Normally, anagen lasts about 1000 days and telogen about 100 days. This results in a 10:1 ratio of anagen-to-telogen hairs in the scalp. With progression of pattern alopecia, anagen shortens, and the ratio of anagen-to-telogen hairs falls. A greater proportion of hairs are in telogen at any one time, resulting in a chronic increase in telogen shed. Administration of topical minoxidil may produce a telogen effluvium by premature termination of telogen necessary to initiate anagen in responding follicles. This causes early telogen release and a briel telogen effluvium.

Whatever the cause of the telogen loss, the hair is lost "at the root." Each hair will have a visible depigmented clubshaped bulb and will lack a sheath (Fig. 33-6). In most cases, loss is diffuse. Patients commonly have more than one mechanism for telogen hair loss. Patchy or diffuse telogen may be associated with papulosquamous diseases of the scalp. Perceptible thinning of the hair is more common in patients with preexisitng pattern alopecia. In patients with pattern alopecia, shortening of the hair cycle results in increased telogen shed. Superimposed papulosquamous disease, iron-deficiency or thyroid disease can result in even more telogen shed and accentuate the pattern loss.

Trichodynia is a common symptom in patients with telogen effluvium, as it is in pattern hair loss. Trichodynia

Fig. 33-6 Anagen and telogen hair (anagen hair has a pigmented bulb and is surrounded by a gelatinous root sheath; telogen hair has a nonpigmented bulb and lacks a root sheath). often coexists with signs of depression, obsessive personality disorder, and anxiety.

Telogen shed may be estimated by the pull test: grasping 40 hairs firmly between thumb and forefinger, followed by a slow pull that causes minimal discomfort to the patient. A count of more than four to six club hairs is abnormal, but the result is influenced by recent shampooing (a count of two or three hairs being abnormal in a freshly shampooed scalp), combing, and the phase of telogen effluvium (whether it is resolving or entering a chronic phase). The clip test may also be useful: 25 to 30 hairs are cut just above the scalp surface and mounted. Indeterminate and telogen hairs are short and of small diameter. Many hairs of this type may be present in telogen effluvium or pattern alopecia. Trichogram evaluation (50 hairs plucked with a Kelly clamp with rubber drains over the teeth) can also provide information on the anagen-to-telogen ratio.

Age, sex, race, and genetic factors influence the normal average daily hair loss in an individual. A full head of hair numbers about 100,000; of these, approximately 100 to 150 are lost daily. In telogen effluvium, estimates of loss vary from 150 to more than 400. Patients may be instructed to collect and count the hair daily; however, they should make sure to collect all small hairs and those that come out in washing and in the bed, as well as those present on the comb or brush. When the pull test is positive, hair shed counts are not needed. An alternative is to collect all hairs lost during a 1-min combing session. For this technique, developed by Dr Jeffrey Miller, the patient combs for 1 min prior to shampooing on 3 consecutive days. The patient is instructed to comb from the vertex to the anterior hairline. The normal range of lost hairs with this technique is 10 to 15. Loss of more than 50 is common in telogen effluvium. Serial 1-min hair counts can be performed to monitor progress.

Telogen effluvium is commonly related to protein or other nutrient deprivation. Assessment of dietary habits and determination of iron saturation and ferritin are the simplest ways to determine nutritional status. Iron replacement is advisable if saturation or ferritin are low, but in one study iron replacement alone did not result in resolution of telogen effluvium. Iron may merely serve as a marker for overall nutritional status. Patients with evidence of deficiency should be given supplements to correct the identified deficiency and encouraged to eat a varied diet. Sources of blood loss, such as menstrual bleeding and gastrointestinal blood loss, should be investigated. Hypothyroidism, allergic contact dermatitis to hair dyes, and renal dialysis with secondary hypervitaminosis A may also be associated with telogen effluvium. Druginduced telogen effluvium has been noted with the use of amphetamines, aminosalicyclic acid, bromocriptine, captopril, coumarin, carbamazepine, cimetidine, danazol, enalapril, etretinate, lithium carbonate, levodopa, metyrapone, metoprolol, propranolol, pyridostigmine, and trimethadione. Postnatal telogen effluvium of infants may occur between birth and the first 4 months of age. Usually, regrowth occurs by 6 months of age. Telogen counts by Kligman in six infants varied from 64% to 87%. He also found a tendency for the alopecia to occur in the male-pattern distribution. Idiopathic chronic telogen effluvium has been described by Whiting in a group of 355 patients (346 women and 9 men) with diffuse generalized thinning of scalp hair. Most were 30- to 60-years old, and their hair loss started abruptly, with increased

shedding and thinning. There was a fluctuating course and diffuse thinning of the hair all over the scalp, accompanied by bitemporal recession. He found high telogen counts on horizontal sections of scalp biopsies and considers these patients to have a chronic form of telogen effluvium. This chronic form may respond to 5% minoxidil solution.

If a 4-mm punch biopsy is performed, 25 to 50 hairs are normally present for inspection in transverse (horizontal) sections. If more than 12% to 15% of terminal follicles are in telogen, this indicates a significant shift from anagen to telogen. Pattern (androgenetic alopecia) demonstrates miniaturization, variable hair shaft diameter, and an increased proportion of telogen hairs. Traction alopecia and trichotillosis (trichotillomania) result in an increased number of catagen and telogen hairs. Pigment casts, empty anagen follicles, trichomalacia, and catagen hairs help distinguish these entities from simple telogen effluvium.

No specific therapy is required for most patients with telogen effluvium. In the majority of cases the hair loss will stop spontaneously within a few months and the hair will regrow. The prognosis is good if a specific event can be pinpointed as a probable cause. Papulosquamous scalp disorders may precipitiate telogen hair loss and should be addressed. Iron and thyroid status should be determined if the course is prolonged or if history or physical examination suggest an abnormality. Patients should be encouraged to eat a balanced diet. In a mouse model, sonic stress can produce catagen. This model may be useful in the study of agents for the treatment of telogen effluvium.

Anagen Effluvium Anagen effluvium usually results from hair shaft fracture. It is seen frequently following the

administration of cancer chemotherapeutic agents, such as the antimetabolites, alkylating agents, and mitotic inhibitors. These agents result in temporary shutdown of the hair matrix with resultant tapering of the shaft (Pohl-Pinkus constrictions). Trichograms reveal tapered fractures. Only anagen hairs are affected. The 10% of scalp hairs in telogen have no matrix and are unaffected. Severe loss is frequently seen with doxorubicin, the nitrosureas, and cyclophosphamide. When high doses are given, loss of anagen hairs becomes most apparent clinically in 1 to 2 months. The hair shafts are abruptly narrowed at the time of maximum drug effect, and when the very thin portion reaches the surface, the hair shafts all break at about the same time. With cessation of drug therapy, the follicle resumes its normal activity within a few weeks; the process is entirely reversible. It is apparent that mitotic inhibition merely stops the reproduction of matrix cells but does not permanently destroy the hair. A pressure cuff applied around the scalp during chemotherapy and scalp hypothermia have been reported to prevent such anagen arrest, but as the scalp may be a site of metastasis, it may be better not to spare the scalp from the effects of chemotherapy. Topical minoxidil has been shown to shorten the period of baldness by an average of 50 days.

In addition to the cytotoxic chemotherapeutic agents, various agents, such as INH, thallium, and boron may induce anagen effluvium. Anagen effluvium with tapered fractures also occurs in alopecia areata and syphilis. In these diseases, an inflammatory insult to the hair bulb results in Pohl-Pinkus contrictions and tapered fracture.

Anagen loss may also occur at the root. Loose anagen syndrome, described by Price in 1989, is a disorder in which anagen hairs may be pulled from the scalp with little effort. It occurs mostly in blond girls and usually improves with age. The syndrome appears to be related to a defect in the hair cuticle. Instead of anchoring the hair firmly, the cuticle simply folds back like a rumpled sock (Fig. 33-7), allowing the hair shaft to be extracted. Woolly hair can be associated with loose anagen hair syndrome. A keratin mutation, E337K in K6HF, was identified in three of nine families studied. Colobornas have also been associated with loose anagen hair.

Fig. 33-7 Loose anagen hair with "rumpled sock" cuticle.

Anagens hairs may be easily extracted from active areas of lupus erythematosus and lichen planopilaris. They commonly lack the root sheath that normally surrounds a plucked anagen hair (Fig. 33-8). Anagen effluvium has also been described in lesions of pemphigus.

Androgenetic Alopecia

Male-Pattern Baldness

Male-pattern alopecia or male-pattern androgenetic alopecia (common baldness) shows itself during the teens, 20s or early 30s with gradual loss of hair, chiefly from the vertex and frontotemporal regions. The process may begin at any time after puberty, and the presence of "whisker" or kinky hair may be the first sign of impending male-pattern alopecia. The anterior hairline recedes on each side, in the Geheimratswinkeln ("professor angles"), so that the forehead becomes high. Eventually the entire top of the scalp may become devoid of hair. Several patterns of this type of hair loss occur, but the most frequent is the biparietal recession with loss of hair on the vertex. The rate of hair loss varies among individuals. Sudden hair loss may occur in the 20s and then proceed relentlessly, though very slowly, for a number of years. The follicles produce finer and lighter hairs

Fig. 33-8 Stain for citruillne demonstrates the inner root sheath (red) surrounded by an outer root in a plucked anagen hair from a normal scalp. with each hair cycle until terminal hairs are eventually replaced by vellus hairs. During evolution of the process, hair shafts vary significantly in diameter. The parietal and occipital areas are usually spared permanently from this process of progressive miniaturization.

Early onset male pattern alopecia is related to the androgen receptor gene. There is no doubt that inherited factors and the effect of androgens such as dihydrotestosterone on the hair follicle are important. Arguments for regarding the inheritance as polygenic include the high prevalence, gaussian curve of distribution in the population, increased risk with number of affected relatives, increased risk in relatives of severely affected women compared with mildly affected, and greater import of an affected mother than an affected father. The possibility that the early-onset (before the age of 30) and later-onset (after the age of 50) forms may be inherited separately by single genes is also hypothesized.

Male-pattern alopecia is dependent on adequate androgen stimulation and appears to be related to the androgen receptor gene. Eunuchs do not develop baldness if they are castrated before or during adolescence. If they are given androgen therapy, baldness may develop. The 5- α reduction of testosterone is increased in the scalp of balding individuals, yielding increased dihydrotestosterone. Androgen-inducible TGF- β 1 derived from dermal papilla cells appears to mediate hair growth suppression. In congenital 5- α -reductase deficiency, the type 2 isoenzyme is lacking and baldness does not occur. Pattern alopecia does occur in males with X-linked ichthyosis, indicating that steroid sulfatase is not critical for the production of alopecia.

Progressive shortening of the anagen phase of hair growth is noted as the hair shaft diameter decreases, so hairs are not only narrowing, but shorter. A higher proportion of telogen hairs in the affected area results in greater telogen shed. There may also be an increase in the duration of the lag phase between telogen and anagen (the kenogen lag phase).

Histologically, a decrease in anagen and increase in telogen follicles is present. Follicular miniaturization and variability in shaft diameter are noted. These features are particularly evident in transverse sections. Below the level of the miniatured or telogen follicle, a vascular or fibromucinous fibrous tract remnant is present. These appear numerous in crosssection. Many mast cells may be noted in the fibrous tract remnant, but inflammatory cells are absent. Sebaceous glands may be enlarged, and hair thinning may be associated with solar elastosis. Sparse lymphoid inflammation with spongiosis may be noted at the level of the follicular infundibulum. This may represent associated seborrheic folliculitis. A sparse lymphoid infiltrate may also be noted at the level of the hair bulge.

Miniaturized human hair follicles grafted onto immunodeficient mice can quickly regenerate and grow as well as or better than terminal follicles from the same individual. This suggests that even advanced pattern alopecia may be reversible. Unfortunately, available pharmacologic interventions produce little effect in advanced pattern alopecia.

Minoxidil, an oral hypotensive drug that causes hypertrichosis when given systemically, is available as topical solutions (Rogaine). Minoxidil promotes the survival of dermal papilla cells, prolongs anagen phase, and results in enlargement of shaft diameter. Clinically, apparent success is best in early cases (<10 years) of limited extent (<10-cm diameter bald area on the vertex) in whom pretreatment hair density is above 20 hairs/cm². Minoxidil is available without a prescription as a 2% or a 5% solution. With the 2% solution, 26% of men studied showed moderate-to-dense regrowth, while 33% showed minimal regrowth after 4 months. Studies show a 45% increase in hair weight with the 5% solution compared to the 2% solution. In those who respond, regrowth can occur as early as 2 months after the first application. Those who respond must continue to use minoxidit indefinitely to maintain a response.

Finasteride, a type 2 5 α -reductase inhibitor, given as a 1-mg tablet daily, is effective in preventing further hair loss and in increasing the hair counts to the point of cosmetically appreciable results in men aged 18 to 41 with mild-tomoderate hair loss at the vertex, in the anterior midscalp, and the frontal region. It has been shown to stop hair loss in up to 90% of men for at least 5 years. Approximately 65% of men demonstrate hair regrowth. As with monoxidil, continued use of the product is required to sustain benefits. Hair patterning on the temples is not improved. It has been shown to lower dihydrotestosterone in the scalp and the serum of treated patients. Hair growth will be evident only after 6 months or more on the drug. If no effect is seen after 12 months, further treatment is unlikely to be of benefit. In one study, regimens that included finasteride were more effective than minoxidil alone, and therapeutic efficacy was enhanced by combining the two drugs. Short-term side effects related to finasteride are infrequent; however, the need to take this medication indefinitely suggests that study of long-term side effect profiles is critical. A prostate cancer prevention trial with a different dosage form of the same drug showed a decrease in the incidence of cancer. However, those cancers that did occur in the treatment group had a higher average Gleason score. Other treatments that show some promise in preliminary studies include fluridil (a topical antiandrogen that suppresses the human androgen receptor) and hormone-enriched topical cell culture medium. Hair transplantation using micrografts of hair follicles from the occipital area to the anterior scalp may satisfactorily recreate hairlines and give excellent cosmetic results.

Androgenetic (Pattern) Alopecia in Women

Women generally have diffuse hair loss throughout the apical scalp with the part wider anteriorly. There is typically sparing the frontal hairline, although a subset of women exhibits a "male" pattern of temporal recession. Although maintenance of the frontal hairline is the rule in women, a progressive decrease in hair density from the vertex to the front of the scalp does occur. The midline part is an important clinical clue, revealing a "Christmas tree pattern" of hair loss with the part tapering from the anterior to posterior scalp. Phototrichograms and measurement of shaft diameter can be used to assess female-pattern alopecia. The same basic changes reduced hair density and diameter, and diminished anagen and increased telogen hair—occur in women as in men. Sebaceous gland hyperplasia may be present, but is less common than in men.

The cause is now believed to be a genetic predisposition with an excessive response to androgens. Both women and men with pattern alopecia have higher levels of 5α -reductase and androgen receptor in frontal hair follicles compared to the levels in occipital follicles. Most women with pattern alopecia have normal menses and fertility. If other evidence of androgen excess is present, such as hirsutism, menstrual irregularities, or acne, or the onset is sudden, evaluation as outlined for hirsutism (see below) should be performed.

Topical minoxidil is of benefit. Although some data suggest that 5% minoxidil may be of greater benefit than 2% minoxidil, the data are mixed. Given the higher cost of 5% minoxidil, the 2% formulation may be the best choice for many women. Oral antiandrogens, including spironolactone and cyproterone acetate, have been used to treat androgenetic alopecia in women. In one study, cyproterone acetate was more effective than minoxidil when there were other signs of hyperandrogenism, hyperseborrhea, and menstrual abnormalities, and when the body mass index was high. When these other factors were absent, minoxidil was the more effective treatment.

Treatment with finasteride is of no benefit for most women, although the subset with temporal recession may show some benefit. Finasteride treatment is contraindicated in women who may become pregnant. Hair transplantation, wigs or interwoven hair may give satisfactory cosmetic results. In a pilot study, topical melatonin appeared to prolong anagen phase and may prove to be of some benefit. In some women, telogen effluvium may produce worsening of preexisiting pattern alopecia. Reversible causes of telogen effluvium, such as seborrheic dermatitis, nutrient deficiency, and thyroid disease, should be addressed.

Trichotillomania (Trichotillosis) Trichotillomania is the compulsive practice of plucking hair from the scalp, brows or eyelashes. Typical areas are irregular patches of alopecia that contain hairs of varying length (Fig. 33-9). The scalp has a rough texture, resulting from the short remnants of brokenoff hairs. Trichotillomania is seen mostly in girls under the age of 10, but boys, or adults of either sex, may engage in the practice also. Some patients relate exquisite pain localized to a follicle that can only be relieved by plucking the hair.

Fig. 33-9 Trichotillosis.

Fig. 33-10 Trichobezoar being extracted from the stomach of a patient with compulsive trichophagia. (Courtesy of Wilford Hall Air Force Medical Center Teaching File)

When speaking with a patient with characteristic areas of alopecia, it has been suggested that it be asked not *if* but rather *how* removal of the hair is done. If this fails to uncover a history of hair pulling, shaving a 3-cm² area in the involved part of the scalp will result in hairs too short for plucking, and normal regrowth in the "skin window" within 3 weeks. Finally, a biopsy, especially if cut horizontally, may demonstrate empty anagen follicles, catagen hairs, pigment casts within the infundibulum, trichomalacia, and hemorrhage. Alopecia areata shares many of these histologic features, and care must be taken to search for the presence of peribulbar lymphocytes or inflammatory cells within the fibrous tract remnants.

Trichotillomania is usually a manifestation of an obsessive-compulsive disorder, but may also be associated with depression or anxiety. It may be associated with compulsive swallowing of the plucked hairs (trichophagia), and may result in formation of a gastric bezoar (Fig. 33-10). Behavior modification, psychotherapy, and appropriate psychopharmacologic medication (such as serotoninreuptake inhibitors) may be helpful.

Other Forms of Noncicatricial Alopecia Alopecia syphilitica may have a typical moth-eaten appearance on the occipital scalp (Fig. 33-11), a generalized thinning of the hair, or may resemble alopecia areata. Other areas such as the eyebrows, eyelashes, and body hair may be involved. The alopecia may be the first sign of syphilis.

Follicular mucinosis (alopecia mucinosa) most commonly occurs on the scalp or beard area and munifests as a boggy red plaque or hypopigmented patch with hair loss. Comedonelike lesions may exude mucin when expressed. Biopsy demonstrates deposition of mucin in the outer root sheath and sebaceous glands. The mucin stains as hyaluronic acid, rather than epithelial sialomucin. Primary cases (unassociated with underlying disease) usually occur as localized lesions of the head or neck. Young people are primarily affected. The secondary type is associated with mycosis fungoides-type cutaneous T-cell lymphoma or a chronic inflammatory skin disease. Lesions associated with mycosis fungoides are generally widespread and chronic, and occur in older patients.

Vascular or neurologic alopecia, most often of the lower extremities, may be seen in diabetes mellitus or athero-

Fig. 33-12 Triangular alopecia. (Courtesy of Brooke Army Medical Center Teaching File)

sclerosis. In meralgia paresthetica there may be alopecia of the anesthetic area of the outer thigh.

Endocrinologic alopecia may occur in various endocrinologic disorders. In hypothyroidism the hair becomes coarse, dry, brittle, and sparse. The proportion of telogen hairs has been shown to be three to seven times higher than the normal 10%. In hyperthyroidism the hair becomes extremely fine and sparse. Oral contraceptives have been implicated in some instances of androgenetic alopecia. It develops in predisposed women who are usually taking androgenic progestogens. It is advisable to discontinue the androgen-dominant pill and substitute an estrogen-dominant oral contraceptive. Some women develop telogen effluvium 2 to 4 months after discontinuing anovulatory agents, which is analogous to postpartum alopecia.

Congenital alopecia occurs either as total or partial loss of hair, or a lack of initial growth, accompanied usually by other ectodermal defects of the nails, teeth, and bone. The hair is light and sparse, and grows slowly. Congenital triangular alopecia (Fig. 33-12) and aplasia cutis congenita are examples of congenital localized absence of hair, while hidrotic ectodermal dysplasia is an example of a diffuse abnormality of hair associated with dental and nail changes.

Lipedematous alopecia consists of thickening of the scalp that gives the impression of thick cotton batting. The hair may be normal or shortened and sparse. Biopsy shows an increase in thickness of the subcutaneous fat and variable lymphoid inflammation. This disease appears to affect black persons primarily.

Lee JH, et al: Lipedematous scalp. Arch Dermatol 1994;130:802.

Cicatricial Alopecia

Cicatricial alopecia appears as areas of hair loss with absence of follicular ostia (Fig. 33-13). Acute lesions may appear as erythematous plaques, perifollicular papules, keratotic follicular spines, or pustules. Deep inflammatory lesions may be boggy or may resemble noncicatricial areata clinically. The inflammatory nature of the lesion may only be evident on biopsy.

Discoid lupus erythematosus, lichen planopilaris, sarcoidosis, and folliculitis decalvans are the most common inflammatory causes of cicatricial alopecia. Chronic bacterial and fungal infections may produce inflammatory alopecia that mimicks primary scarring alopecia. For example, fungal folliculitis may mimic lupus erythematosus.

Biopsy can confirm the diagnosis and provide prognostic information regarding the potential for new growth. A 4-mm punch biopsy will provide the pathologist with an adequate specimen. Smaller specimens are of limited value. The punch should be placed parallel to the direction of hair growth to avoid transecting follicles, and the punch should be advanced to the deep subcutaneous fat. The biopsy site will typically bleed profusely, but a 4-mm wide strip of gel foam advanced into the defect will generally provide rapid hemostasis. Sutures are rarely necessary, and as the scar from a sutured biopsy site generally stretches back to the original dimensions of the biopsy, suturing provides little benefit to the patient.

Where to biopsy, how many biopsies to obtain, and how to process the tissue depends on the suspected diagnosis and the preference of the pathologist. In all cases, a pathologist experienced in the interpretation of scalp biopsies is an advantage. The pathologist may prefer vertical or transverse

(horizontal) sectioning of the specimen. Each has advantages. Every follicular unit in the specimen will be demonstrated in transverse sections. Vertical sections are superior to demonstrate changes in the surface epidermis, dermoepidermal junction, superficial dermis, and subcutaneous fat. In general, the features of androgenetic (pattern) alopecia, telogen effluvium, and trichtillomania are better demonstrated in transverse (horizontal) sections through the specimen. Alopecia areata and syphilitic alopecia are well demonstrated in transverse sections if serial step sections are obtained to demonstrate deeper planes of section or if the block is cut horizontally in a bread-loaf fashion prior to embedding. They are equally well demonstrated with serial vertical sections through the block. Lupus erythematosus and lichen planopilaris are more easily demonstrated in serial vertical sections.

The diagnostic yield can be enhanced by pairing vertical and transverse sections. If two biopsies are done, one specimen can be bisected vertically for direct immunofluorescence (DIF) and hematoxylin and eosin (H&E) processing. It is most easily split by laying it on its side and bisecting it with a 15 blade pushed cleanly through the specimen in a single downward motion. Sawing at the specimen will not produce a satisfactory result. One-half of the bisected specimen is placed in formalin, and the other half in immunofluorescent media. The second specimen can be bisected for transverse sections in the clinic or left for the laboratory to bisect after processing. If it is to be bisected in the clinic, it should be placed on its side. The 15 blade should be pushed downward through the specimen in a single motion at the level of the mid-dermis. All pieces for vertical and transverse sections may be placed in a single bottle to be embedded in a single cassette.

In many forms of cicatricial alopecia, a biopsy of an active inflammatory lesion will be most diagnostic. In lupus erythematosus, the biopsy must be from a lesion of several months' duration in order to demonstrate hyperkeratosis, follicular plugging, basement membrane thickening (Fig. 33-14), and dermal mucin. Only biopsies from established lesions of lupus will demonstrate reliable immunofluorescence.

When biopsies of the most active area of alopecia have failed to yield a definite diagnosis, a biopsy from a scarred area may provide additional information. Scars show loss of elastic tissue with the Verhoff van Geison stain. The pattern

Fig. 33-13 Loss of follicular ostia in scarring alopecia.

Fig. 33-15 Scarring alopecia (H&E stain).

permanent disfigurement. Surgical revision of the hairless plaque is an option for stable end-stage alopecia, but unless the underlying disease is controlled, surgery may only lead to a flare of the underlying disease with progression of hair loss. Therapy may be forestalled by the inability to establish a definite diagnosis. To help guide therapy for patients who defy diagnosis, work groups of the North American Hair Research Society have proposed a classification scheme based on the type and pattern of inflammation. Some forms of destructive alopecia are lymphocyte mediated, while some are suppurative processes. The type of infiltrate and the portion of the pilosebaceous unit affected can be used to guide therapy. This classification system may also allow patients to enroll in clinical trials, even in the absence of a definite diagnosis.

Lymphoid-Mediated Disorders

Lupus Erythematosus

Chronic cutaneous lupus of the scalp (discoid lupus erythematosis [DLE]) is a common cause of cicatricial alopecia. In active disease, anagen hairs may be easily extracted from the involved area. Usually, erythema, atrophy, follicular plugging and mottled hyper- and hypo-pigmentation are present. Patients with chronic cutaneous lupus of the scalp may or may not have accompanying systemic lupus erythematosus (SLE) or skin lesions of DLE on other parts of the body. The external ear canal and concha should always be examined, as they are common sites for discoid lesions. Occasionally, alopecia occurs in a plaque of tumid lupus. Lupus panniculitis may occasionally result in alopecia in the absence of surface skin changes. SLE is often associated with discoid lesions of the scalp. Patients with SLE may also have short miniaturized "lupus hairs" on the anterior scalp.

Biopsy of early lesions of DLE is often nondiagnostic. Patchy lymphoid inflammation and perifollicular mucinous fibrosis may be the only histologic findings. Focal vacuolar inferface dermatitis may or may not be noted. Active established lesions, present for several months, have a higher diagnostic yield. Active established lesions usually demonstrate hyperkeratosis, follicular plugging, vacuolar interface dermatitis, basement membrane zone thickening, pigment incontinence, and dermal mucin. Peri-vascular and -adnexal lymphoid infiltrates are patchy and involve the eccrine coil and fibrous tract remnants. Fibrous tract involvement creates dense vertical columns of lymphocytes. The underlying subcutaneous tissue may demonstrate nodular lymphoplasmacytic infiltrates and fibrin or hyaline rings around necrotic fat. Hypertrophic lesions of chronic cutaneous lupus erythematosus often demonstrate lichenoid dermatitis. DIF may be nonspecific, but active established lesions typically demonstrate a "full house" (continuous granular deposition of IgG, IgA, JgM, and C3) at the dermoepidermal junction. When present, this pattern is particularly helpful in distinguishing lichenoid hypertrophic lupus erythematosus from lichen planopilaris. Burn-out lesions of DLE demonstrate loss of elastic fibers throughout the dermis, which differs from the focal periinfundibular wedge-shaped scars of lichen planopilaris. In systemic lupus, there may be follicular atrophy associated with pronounced dermal mucinosis.

Chronic cutaneous lupus may respond to intralesional or potent lopical corticosteroids, but systemic therapy is

Fig. 33-16 Scarring alopecia (elastic stain). Normal elastic fibers (black) indicate the nonscarred portions of the dermis.

of elastic tissue loss is the "footprint" of the preceding inflammatory process (Figs 33-15 and 33-16). Lichen planopilaris and folliculitis decalvans both affect the infundibulum. Both result in wedge-shaped superficial dermal scars. Discoid lupus erythematosus results in scarring of both the follicular units and the intervening dermis. Morphea does not produce a scar, but rather hyalinization of collagen bundles with preservation of the elastic fibers. In idiopathic pseudopelade, the fibrous tract remnants are widened, but the elastic tissue sheath at the periphery of the fibrous tract is preserved.

Most patients with cicatricial alopecia experience gradual progression of the alopecia, and the prolonged course of the disease may lead to inappropriate therapeutic complacency. The progressive destruction of hairs will result in ever expanding areas of permanent alopecia. Therefore, cicatricial alopecia must be treated aggressively and early to avoid

Fig. 33-17 Lichen planopilaris.

frequently required. Antimalarials, retinoids, dapsone, thalidomide, sulfasalazine, mycophenolate mofetil, and methotrexate have been used successfully. Topical tazarotene and topical calcineurin inhibitors are generally disappointing.

Lichen Planopilaris

Lichen planopilaris presents with perifollicular erythema (Fig. 33-17) and progressive scarring. Small follicular papules may be noted, or the lesion may resemble the ivory white irregular patches of pseudopelade. In some patients, typical polygonal flat-topped papules are present on the wrists and ankles, and lacy white lesions are noted on the oral and gential mucosa. Widespread follicular papules may be present on the trunk or extremities. In most patients, however, only the scalp is involved. Frontal fibrosing alopecia appears to be a variant of LPP. Most patients are older women with bandlike frontotemporal alopecia. Graham Little-Piccardi-Lassueur syndrome includes cicatricial alopecia on the scalp, keratosis pilaris in the skin of the trunk and extremities, and noncicatricial hair loss in the pubis and axillae. It has been described in association with complete and rogen insensitivity syndrome, a condition that also presents with noncicatricial alopecia in the axillary and pubic hair.

Diagnostic biopsies demonstrate lichenoid interface dermatitis of the follicular unit and sometimes the intervening epidermis. The entire fibrous tract may be filled with cytoid bodies (Fig. 33-18). The changes commonly occur focally and may be best visualized with serial vertical sections. Perifollicular mucinous fibrosis is common and focal perifollicular lymphoid infiltrates tend to involve the infundibulum (the infiltrates of lupus erythematosus tend to involve the isthmus). DIF may be negative or may reveal cytoid bodies and shaggy linear fibrin at the dermoepidermal junction.

Lichen planopilaris responds to oral and intralesional corticosteroids. Topical corticosteroids may be adequate in a few patients, but the activity of the disease waxes and wanes, and slow progression should not lead to therapeutic complacency. Oral retinoids can be effective. Alternative therapies include the other oral agents used to treat lupus; however, there are fewer data regarding their use in lichen planopilaris. As in lupus, topical tazarotene and topical macrolactams are generally disappointing.

Hot Comb Alopecia and Central Centrifugal Cicatricial Alopecia

Hot comb alopecia was reported in the late 1960s as a scarring alopecia seen in black women who straightened their hair with hot combs for cosmetic purposes. It develops characteristically on the crown and spreads peripherally to form a large oval area of partial hair loss. The hot petrolatum used with the iron was thought to cause thermal damage to

Fig. 33-18 Lichen planopilaris, note cytoid bodies completely fill the fibrous tract remnant.

the hair follicle. However, Sperling et al reported a similarappearing scarring alopecia in both men and women who did not report the use of hot combs. Some authors now regard hot comb alopecia, Sperling's disease (follicular degeneration syndrome), central centrifugal cicatricial alopecia (CCCA), and idiopathic pseudopelade to be one entity or overlapping entities that can be indistinguishable.

CCCA is slowly progressive, usually begins in the crown, and advances to the surrounding areas. The term is often used as a broad category that includes cases once classified as hot comb alopecia, follicular degeneration syndrome, and central elliptical pseudopelade in white women. CCCA is seen most commonly in African American women, and shows significant overlap with other causes of cicatricial alopecia in this group. In particular, some will demonstrate crops of crusts at the periphery of the patches, a feature of folliculitis decalvans. Treatment of CCCA is difficult and often unsatisfactory. Discontinuation of chemical and heat processing, and reduction of traction are routinely recommended, but the effectiveness of these recommendations has yet to be substantiated. Cases with overlapping features of folliculitis decalvans may respond to long-term antibiotic therapy and topical corticosteroids. In such overlapping cases, the histology shows a lymphocytic infiltrate during the chronic stage, but periodic crops of pustules demonstrate a neutrophilic folliculitis.

Neutrophil-Mediated Disorders

Folliculitis Decalvans

Follicular decalvans presents with crops of pustules that result in cicatricial alopecia. Successive crops of pustules, crusts, or erosions lead to expansion of the alopecic patches. Staphylococci are sometimes cultured from the lesions, and some authors have suggested that folliculitis decalvans merely represents a chronic staphylococcal infection. It is more likely that follicular destruction is the result of an abnormal suppurative immune response. Staphylococci and other organisms probably play a role in inciting the response. The lesions often respond to long-term treatment with tetracycline. The improvement may reflect the antineutrophil effects of the drug or its antimicrobial effects. Many patients also respond to other forms of antistaphylococcal therapy, but the lesions generally recur after the antibiotic is discontinued. Chronic antibiotic treatment generally results in a continued response. Some sustained responses have been noted after combination therapy with rifampin and clindamycin. Rifampin alone has been used, but may promote the emergence of resistance. Selenium sulfide shampoo and topical corticosteroids may be useful as adjunctive therapy. Oral retinoids, oral and topical fusidic acid, and oral zinc sulphate have sometimes produced sustained responses.

A variant of folliculitis decalvans occurs in African American patients who present with pseudofolliculitis of the beard, acne keloidalis nuchae, and scarring alopecia in the vertex and parietal scalp. The scalp demonstrates ingrown hairs, crops of pustules or crusts, and permanent scarring alopecia. While pseudofolliculitis barbae is generally accepted to be the result of ingrown hairs, the pathogenesis of acne keloidalis nuchae remains in question. Histologically, ingrown hairs are common in advanced lesions. Early lesions may not demonstrate the hair. Some patients merely develop small papules on the nape of the neck, while others develop pustules, crusts, and progressive alopecia. This latter group overlaps with folliculitis decalvans.

Acne Necrotica

Acne necrotica presents with discrete excoriated follicular papules in the scalp. Biopsy demonstrates an inflammatory crust and suppurative folliculitis. Usually there is no associated scarring alopecia, but occasional cases overlap with folliculitis decalvans.

Erosive Pustular Dermatitis of the Scalp

This often presents as expanding eroded patches with moist granulation tissue. The lesions often follow trauma or a surgical procedure and tend to be chronic and progressive. They do not respond to 10-day courses of antibiotics but may respond to sustained treatment, as for folliculitis decalvans. Some lesions have responded to tacrolimus or calcipotriene.

Dissecting Cellulitis (Perifolliculitis Capitis Abscessens et Suffodiens of Hoffman)

This often coexists with acne conglobata and hidradenitis suppurativa. It may also occur with folliculitis decalvans. The lesions are deep, boggy, and suppurative. They may respond to tetracyclines, retinoids, and intralesional corticosteroids.

Tufted folliculitis

Tufted folliculitis presents with doll's hair-like bundling of follicular units. It is seen in a wide range of scarring conditions, including chronic staphylococcal infection, chronic lupus erythematosus, lichen planopilaris, Graham-Little syndrome, folliculitis decalvans, acne keloidalis nuchae, immunobullous disorders, and dissecting cellulitis. Compound hairs (two or more hairs sharing a common infundibulum) occur physiologically on the scalp and legs. They are common in the occipital scalp. Recurrent staphylococcal infection is more common in patients with many compound hairs and commonly leads to tufted folliculitis.

Other Forms of Permanent Alopecía

Pseudopelade of Brocq

Also known as alopecia cicatrisata, this is a rare form of cicatricial alopecia in which destruction of the hair follicles produces multiple round, oval, or irregularly shaped, hairless, cicatricial patches of varying sizes. They are usually coinsized and are white or slightly pink in color, with a smooth, shiny, marble-like or ivory, atrophic, "onion skin" surface. Interspersed in the patches may be a few spared follicles with hairs growing from them. A clinical inflammatory stage is completely absent. No pustules, crusts, or broken-off hairs are present. The onset is, as a rule, insidious, with one or two lesions appearing on the vertex. It affects females three times more commonly than males, and has a prolonged course. In advanced cases large irregular patches are formed by coalescence of some of the many small macules, a pattern referred to as "footprints in the snow." The alopecia is permanent and the disease is slowly progressive. Histologically, the majority of patients with clinical lesions of pseudopelade demonstrate true scarring (indicated by loss of elastic tissue) in a wedge-shaped pattern in the superficial dennis. The pattern is similar to that seen in lichen planopilaris and suggests that many cases classified as pseudopelade represent an end stage of lichen planopilaris. A subset of patients, however, demonstrates no perifollicular or interfollicular scarring at all. This subset has been called idiopathic pseudopelade. It shows significant clinical overlap with CCCA. In these patients, the dermis is contracted into a thin band of dense collagenous tissue. Elastic fibers are intact and quite thick as a result of elastic recoil related to dermal contraction. Fibrous tract remnants are wide and hyalinized with an intact elastic sheath. Lymphoid and neutrophilic inflammation is absent, but loss of the inner and outer root sheathes with subsequent hair fiber granuloma formation is noted. Sebaceous glands are decreased or absent, as they are in most forms of permanent alopecia. DIF is negative.

The end stage of many forms of cicatricial alopecia can resemble pseudopelade clinically, but, like lichen planopilaris, they demonstrate distinct patterns of elastic tissue loss in the dermis. Folliculitis decalvans is distinguished by periodic crops of pustules or crusts at the periphery of the alopecic patches. It produces superficial wedge-shaped scars similar to those of lichen planopilaris.

Topical and intralesional corticosteroids and long-term tetracycline in anti-inflammatory doses may be tried but are not often successful. The disease usually reaches an inactive end stage after many years.

Traction Alopecia

Traction alopecia occurs from prolonged tension on the hair, either from wearing the hair tightly braided or in a ponytail, pulling the hair to straighten it, rolling curlers too tightly, or from the habit of twisting the hairs with the fingers. Traction alopecia most commonly involves the periphery of the scalp, especially the temples and above the ears.

Sarcoidosis

Sarcoidosis of the scalp presents with diffuse or patchy hair loss. The involved scalp is often indurated and a raised peripheral border may be present. The lesions are often red-brown in color and may have an apple jelly appearance with diascopy. Biopsy reveals noncaseating granulomas. Treatment is as for other forms of sarcoidosis.

Pressure Alopecia

Pressure alopecia occurs in adults after prolonged pressure on the scalp during general anesthesia, with the head fixed in one position. It may also occur in chronically ill persons after prolonged bed rest in one position, which causes persistent pressure on one part of the scalp. It probably arises because of pressure-induced ischemia.

Tumor Alopecia

Tumor alopecia refers to hair loss in the immediate vicinity of either benign or malignant tumors of the scalp. Syringomas, nerve sheath myxomas, and steatocystoma multiplex are benign tumors that may be limited to the scalp and cause alopecia. Alopecia neoplastica is the designation given to hair loss from metastatic tumors, most often from breast or renal carcinoma.

Keratosis Pilaris Atropicans

Keratosis pilaris atropicans includes many forms of keratosis pilaris with cicatricial alopecia. Variants include keratosis pilaris atrophicans faciei, atrophoderma vermiculatum, keratosis follicularis spinulosa decalvans, and ichthyosis follicularis.

Keratosis pilaris atrophicans faciei (ulerythema ophryogenes, keratosis pilaris rubra atrophicans faciei, folliculitis rubra, lichen pilare, or xerodermi pilaire symmetrique de la face) begins in infancy as follicular papules with perifollicular erythema. Initially, the lesions are restricted to the lateral eyebrows. With time, they spread to involve the cheeks and forehead. There may be associated keratosis pilaris on the extremities and buttocks. The condition may also be associated with an atopic diathesis, ectodermal dysplasia, or Noonan syndrome.

Atrophoderma vermiculatum (acne vermoulanti, honeycomb atrophy, folliculitis ulerythema reticulata, ulerythema acneiforme, folliculitis ulerythematous reticulata, atrophodermia reticulata symmetrica faciei, atrophoderma reticulatum) presents with erythematous follicular paplules on the cheeks in childhood. With time, the lesions develop into pit-like depressions (reticulate atrophy). Autosomal-dominant inheritance has been described. This condition generally spares the scalp and eyebrows.

Keratosis follicularis spinulosa decalvans is a rare X-linked disorder described by Siemens in 1926. The gene has been mapped to Xp21.2-p22.2. It begins in infancy with keratosis pilaris localized on the face, then evolves to more diffuse involvement. Progressive cicatricial alopecia occurs on the scalp, eyebrows, and sometimes eyelashes. The alopecia starts during childhood and active disease may remit during the early teenage years. Corneal and conjunctival inflammation, corneal dystrophy, and blepharitis occur, and photophobia is usually a prominent finding.

Ichthyosis follicularis also demonstrates extensive spiny follicular hyperkeratosis, permanent alopecia, and photophobia. Palmar plantar keratosis, nail deformities, atopy, and recurrent chilitis have been described.

Atrichia with Papular Lesions

Atrichia with papular lesions is a rare autosomal-recessive disorder with early onset of atrichia, followed by a papular eruption appearing within the first years of life. The condition has been linked to chromosome 8p21 and mutations have been detected in what is now referred to as the hairless gene. It is discussed in more detail in Chapter 27.

HAIR COLOR

Melanin in the hair follicles is produced in the cytoplasm of the melanocytes. Organelles involved include the endoplasmic reticulum, ribosomes, and Golgi apparatus. Melanocytes producing hair pigment are associated with the hair matrix, and melanogenesis occurs only during anagen. This cyclic melanin synthesis distinguishes follicular melanogenesis from the continuous melanogenesis of the epidermis. With age, cyclic melanocytic activity in the follicular unit declines. By 40 years of age most individuals show evidence of graying. Graying results primarily from a reduction in tyrosinase activity within hair bulb melanocytes. Defective migration of melanocytes from a diminishing reservoir in the outer root sheath may play a role. Physiologic graying may also be related to reactive oxygen species-mediated damage to nuclear and mitochondrial DNA in bulbar melanocytes. The melanocortin 1 receptor gene (MCR1) is closely related to red hair, freckling, and sun-sensitivity.

The pigment in black and dark brown hair is composed of eumelanin, whereas in blond and red hair it is pheomelanin. In black hair the melanocytes contain the densest melanosomes. Brown hair differs only by its smaller melanosomes. Light brown hair consists of a mixture of the melanosomes of dark hair and the incomplete melanosomes of blond hair. Many of the melanosomes in blond hair develop only on the matrix fibers and not in the spaces between the fibers.

Red hair shows incomplete melanin deposits on the matrix fibers to produce a blotchy-appearing melanosome. Phaeomelanin is distinguished by its relatively high content of sulfur, which results from the addition of cysteine to dopaquinone along the biosynthetic pathway of melanin synthesis.

In gray hair (canities), melanogenic activity is decreased as a result of fewer melanocytes and melanosomes, as well as a gradual loss of tyrosinase activity. Graying of the scalp hair is genetically determined and may start at any age. Usually it begins at the temples and progresses with time. The beard usually follows, with the body hair graying last. Premature whitening of scalp hair is usually caused by vitiligo, sometimes without recognized, or actually without, lesions of glabrous skin.

Early graying (before age 20 in white or before age 30 in black persons) is usually familial; however, it may occur in progeria, Rothmund-Thomson syndrome, Böök syndrome, and Werner syndrome.

In poliosis, gray or white hair occurs in circumscribed patches. This may occur in Waardenburg syndrome and piebaldism, Tietze syndrome, Alezzandrini syndrome, neurofibromatosis, and tuberous sclerosis. Poliosis is also found in association with regressing melanoma, vitiligo, and Vogt-Koyanagi syndrome, and may be seen in alopecia areata when the new hairs grow. Migratory poliosis without hair loss may represent a forme-fruste of alopecia areata.

Green hair has been traced to copper in the water of a swimming pool. This occurs only in blond or light hair, and may be treated with topical EDTA, penicillamine-containing shampoos, or 1.5% aqueous 1-hydroxyethyl diphosphonic acid. Tars and chrysarobin stain light-colored hair brown.

Changes in hair color occur in various disorders. The hair is blond in phenylketonuria and homocystinuria. Light hair is also seen in oasthouse disease (familial methionine malabsorption), Menkes kinky hair syndrome, and albinism. In Griscelli and Chédiak-Higashi syndromes the hair has a silvery sheen. In kwashiorkor the hair assumes a red-blond color and may demonstrate periodic banding (flag sign, segmental heterochromia). Alternating light and dark bands may also occur in iron-deficiency anemia. In vitamin B_{12} deficiency and with interferon therapy, whitening may occur. The disorder has been called canities segmentata sideropenica. It responds completely to iron supplementation. Triparanol is associated with hypopigmented hair. Minoxidil (by changing vellus to terminal hairs) causes darkening of hair, another hypotensive agent, diazoxide, gives the hair a reddish tint. Chloroquine therapy may cause hair whitening, usually in redheads and blonds, not in brunettes. Pigmentation of the eyelashes and irides has been described with latanoprost.

Many black patients with acquired immunodeficiency syndrome (AIDS) have experienced softening, straightening, lightening, and thinning of their hair. Patients with human immunodeficiency virus (HIV)-1 infection may also experience elongated eyelashes and telogen effluvium.

HAIR STRUCTURE DEFECTS

Examination of hairs for structural defects is greatly facilitated by a method devised by Shelley: putting a piece of double-stick tape on a microscope slide and aligning 5-cm segments of hair in parallel on it. Hairs are best examined under a dissecting microscope or polarized light. Gold-coating and scanning electron microscopy can also be done on hairs so mounted.

Hair Casts (Pseudonits)

Hair casts represent remnants of the inner root sheath. They often occur in great numbers and may mimic nits in the scalp. While nits are firmly cemented to the hair shaft, hair casts slide freely along the shaft. Taeb et al reviewed 36 published cases and distinguished two groups: girls between 2 and 8 years of age with diffuse involvement and no scalp disease, and children and adults with psoriasis, lichen planus, seborrheic dermatitis, or trichotillomania. Keipert made a similar distinction, separating a large group of cases with some keratinizing disorder of the scalp and dark, oddly shaped masses of keratin adherent to or surrounding the hairs, which he called parakeratotic hair casts; and lighter colored tubular casts, 2 to 4 mm long, which he called peripilar hair casts. Taeb et al found 0.025% tretinoin lotion effective.

Pili Torti

Also known as *twisted hairs*, pili torti is a malformation of hair characterized by twisting of the hair shaft on its own axis (Fig. 33-19). The hair shaft is segmentally thickened, and light and dark segments are seen. Scalp hair, eyebrows, and eyelashes may be affected. The hairs are brittle and easily broken.

In the classic type, unassociated with other disorders, onset is usually in early childhood; by puberty, it has usually improved. Clinically, it may be associated with patchy alopecia and short, broken hairs. It usually follows a dominant inheritance pattern, though recessive and sporadic cases have been reported. Acquired cases have been described in young women with anorexia nervosa.

Pili torti may be seen with associated abnormalities. The Björnstad syndrome consists of congenital deafness of the cochlear type, with pili torti. Both autosomal-dominant and -recessive inheritance patterns have been described. Pili torti also may occur in citrullinemia (argininosuccinate synthetase deficiency), Menkes kinky hair syndrome, Bazex follicular atrophoderma syndrome, ectodermal dysplasias, Crandall syndrome (pili torti, nerve deafness, hypogonadism), Netherton syndrome (along with bamboo hair), with isotretinoin and etretinate therapy, in anorexia nervosa, and in trichothiodystrophy.

Fig. 33-19 Pili torti.

Laron syndrome is an autosomal-recessive disease with primary insulin-like growth factor 1 deficiency and primary growth hormone insensitivity. Affected children have sparse hair and frontal recession. Pili torti et canaliculi, tapered hair, and trichorrhexis nodosa have been noted.

Menkes Kinky Hair Syndrome

Pili torti, and often monilethrix and trichorrhexis nodosa, are all common in the hairs in this sex-linked recessivelyinherited disorder. It has also been called steely hair disease, because the hair resembles steel wool. The characteristic ivory color of the hair appears between 1 and 5 months of age. Drowsiness, lethargy, convulsive seizures, and severe neurologic deterioration, and periodic hypothermia ensue with death at an early age. Hairs become wiry, sparse, fragile, and twisted about their long axes. Osteoporosis, and dental and ocular abnormalities are common. The skin is pale and the face pudgy, and the upper lip has an exaggerated "Cupid's bow" configuration. The occipital horn syndrome, primarily a connective tissue disorder, is a milder variant of Menkes syndrome.

Patients have a deficiency of serum copper and copperdependent enzymes, resulting from mutations in the ATP7A gene. The gene encodes a trans-Golgi membrane-bound copper transporting P-type ATPase. Loss of this protein activity blocks the export of dietary copper from the gastrointestinal tract and causes the copper deficiency. Low serum copper and ceruloplasmin are characteristic, but are not seen in all patients. They are particularly variable in the first weeks of life. Other tests helpful for screening include the ratio of catechols, such as dihydroxyphenylalanine to dihydroxyphenylglycol. High levels of the catechols DOPA, dihydrophenylacetic acid, and dopamine, and low level of dihydroxyphenylglycol are characteristic. Studies of copper egress in cultured fibroblasts have also been used. Early detection allows for genetic counseling and the institution of copper histidine treatment, which is being studied and has shown promising results in some infants. Pamidronate treatment is associated with an increase in bone mineral density in children with Menkes' disease.

Uncombable Hair Syndrome

First reported in 1973 by Dupre et al as cheveux incoiffable (undressable hairs) and Stroud and Mehergan as spun-glass hair, the microscopic abnormality of a triangular crosssectional appearance with a longitudinal groove gives the disease its other name, pili triangulati et canaliculi.

Clinically, the defect is noted in the first few years of life as dry, blond, shiny hair that stands straight out from the scalp and cannot be combed. On light microscopy it may appear quite normal when viewed lengthwise, but on horizontal sectioning and on scanning electron microscopy it shows the longitudinal grooves that make it abnormally rigid. These depressions are sometimes seen in unaffected persons so that 50% of hairs need to be affected to be clinically detectable.

Autosomal-dominant, -recessive, and sporadic forms have been described. Uncombable hair has been associated with angel-shaped phalango-epiphyseal dysplasia. It has also been seen in combination with retinal dystrophy, juvenile cataract, and brachydactyly. It has also been reported in a patient who acquired the abnormality at age 39 after an episode of diffuse alopecia treated with spironolactone. Although there are usually no associated ectodermal defects, isolated cases have been reported in which uncombable hair is one component of several clustered findings. Until more experience is available in the literature grouping of these cases into new syndromes is premature.

One of the Shelley's cases responded clinically (although without apparent change in the hair structure) to biotin 0.3 mg orally three times a day. Some cases improve spontaneously in late childhood.

- Shelley WB, et al: Uncombable hair syndrome: observations on response to biotin and occurrence in siblings with ectodermal dysplasia. J Am Acad Dermatol 1985;13:97.

Monilethrix

Monilethrix, also known as *beaded hairs*, is a rare hereditary disease. It is characterized by dryness, fragility, and sparseness of the scalp hair, with fusiform or spindle-shaped swellings of the hair shaft separated by narrow atrophic segments. The hair tends to break at the delicate internodes. There is an occasional rupture at the node and longitudinal fissuring of the shaft, which also involves the nodes.

The disease is often associated with keratosis pilaris of the extensor surfaces, temples, and back of the neck. Hair on regions other than the scalp may be affected. Leukonychia

Gasch AT, et al: Menkes' syndrome: ophthalmic findings. Ophthalmology 2002;109:1477.

Fritz TM, et al: Uncombable hair syndrome with angel-shaped phalango-epiphyseal dysplasia. Pediatr Dermatol 2000;17:21.

may occur. Inheritance of monilethrix is an autosomaldominant trait. It has been described in association with Menkes syndrome. Several cases of monilethrix have been linked to the type II keratin gene cluster on chromosome 12q13. Causative heterozygous mutations of a highly conserved glutamic acid residue of the type II hair keratins hHb6 and hHb1 occur. Both hHb1 and hHb6 are largely coexpressed in cortical trichocytes of the hair shaft, confirming monilethrix is a disease of the hair cortex. There is no effective treatment. Improvement of the hair may occur during pregnancy, but after delivery the hair returns to its original state. Improvement may also occur with age and there may be seasonal improvement during the summer.

Trichorrhexis Nodosa

The affected hair shafts fracture easily and may have small white nodes arranged at irregular intervals. These nodes are the sites of fraying of the hair cortex. The splitting into strands produces a microscopic appearance suggestive of a pair of brooms stuck together end to end by their bristles. The hairs soon break at these nodes. The number of these nodes along one hair shaft varies from one to several, depending on its length. These fractured hairs are found mostly on the scalp, often in just a small area or areas, but other sites such as the pubic area, axillae, and chest may be involved.

Several categories or types of trichorrhexis nodosa have been described. Proximal trichorrhexis nodosa involves the proximal shafts of the hairs of black patients who traumatize their hair with styling or chemicals. The involved hairs break a few centimeters from the skin surface, resulting in patches of short hair. It appears to occur in genetically predisposed patients. Distal trichorrhexis nodosa affects primarily Asians and white patients, and occurs several inches from the scalp, and is associated with trichoptilosis, or longitudinal splitting, known as split ends. Acquired localized trichorrhexis nodosa is a common type in which the defect occurs in a localized area, a few centimeters across. A number of diseases accompany this type of trichorrhexis nodosa in which pruritus is a prominent symptom; scratching and rubbing may be the cause. Among such diseases are circumscribed neurodermatitis, contact dermatilis, and atopic dermatitis.

The occurrence of trichorrhexis nodosa in some patients with argininosuccinicaciduria has suggested an etiologic connection. Trichorrhexis nodosa has been described in Menkes kinky hair syndrome, Netherton syndrome, hypothyroidism, ectodermal dysplasia, the syndrome of intractable infant diarrhea, and trichothiodystrophy. Trichoschisis, a clean transverse fracture across the hair shaft, is more commonly present in trichothiodystrophy. The curly hair that may result from isotrelinoin therapy has been attributed to extensive trichorrhexis nodosa. Because trauma may induce this hair shaft abnormality, the specificity of this finding in the above conditions may simply be fortuitous.

Treatment is directed toward the avoidance of trauma to the hair.

- Smith RA, et al: Localized trichorrhexis nodosa. Clin Exp Dermatol 1994;19:441.

Trichorrhexis Invaginata

Also known as *bamboo hair*, trichorrhexis invaginata is caused by intussusception of the hair shaft at the zone where keratinization begins. The invagination is caused by softness of the cortex in the keratogenous zone. The softness may be caused by inadequate conversion of -SH to S-S proteins in the cortex. The patient with bamboo hair will have nodose ball-and-socket deformities, with the socket forming the proximal and the ball part forming the distal portion of the node along the hair shaft. This type of hair is associated with Netherton syndrome. Occasionally, only the proximal half of the abnormality is seen; this has been called *golf tee hairs*.

Trichorrhexis invaginata associated with congenital ichthyosiform erythroderma or ichthyosis linearis circumflexa constitutes Netherton syndrome. Atopic manifestations and high IgE levels are commonly present. The bamboo hairs may be present not only on the scalp but also on the eyebrows, evelashes, and rarely in other hairy areas. Hair sparsity is noted all over the body. The bamboo hairs may become normal within a few years. Other reported findings include pili torti, trichorrhexis nodosa, moniliform hairs, urticaria, angioedema, growth retardation, recurrent infections, multiple epithelial neoplasms, and mental retardation. An autosomalrecessive mode of inheritance has been suggested, although reported cases involving women far outnumber men. Pathogenic mutations have been identified in serine protease inhibitor Kazal-type 5 (SPINK5) on chromosome 5q32, a gene encoding lymphoepithelial Kazal-type-related inhibitor (LEKTI), a serine protease inhibitor involved in skin barrier formation and immunity, PUVA has been reported to help the circumflex linear ichthyosis while etretinate has been reported to both exacerbate and improve skin findings.

Menne et al reported the baniboo hair defect in very thin, probably vellus, hairs in a 7-year-old boy with short, thin, brittle scalp hairs and no eyebrows. They termed this a canestick deformity.

Muller FB, et al: Genetic analysis of a severe case of Netherton syndrome and application for prenatal testing. Br J Dermatol 2002;146:495.

Pili Annulati (Ringed Hair)

Pili annulati is a peculiar disease in which the hair seems banded by alternating segments of light and dark color when seen in reflected light. The light bands are caused by clusters of abnormal air-filled cavities, which scatter light, and reduplicated lamina densa in the region of the root bulb.

Hair growth is normal in patients with pili annulati, although it is rarely associated with trichorrhexis nodosa-like breaks of the hair shaft. There are no other associated abnormalities of skin or other organ systems. It is inherited by autosomal-dominant mode, begins in infancy, and requires no treatment, since the spangled appearance of the hair is not unattractive (Fig. 33-20). The condition has been reported to disappear following recovery from alopecia totalis.

- Feldmann KA, et al: Newly described weathering pattern in pili annulati hair shafts: a scanning electron microscopic study. J Am Acad Dermatol 2001;45:625.
- Giehl KA, et al: Alterations in the basement membrane zone in pili annulati hair follicles as demonstrated by electron microscopy and immunohistochemistry. Br J Dematol 2004; 150:722.
- Green J, et al: Disappearance of pili annulati following an episode of alopecia areata. Clin Exp Dermatol 2002;27:458.

Pili Pseudoannulati

This anomaly of human hair mimics pili annulati. The two differ in that the light bands in pili annulati are caused by internal effects, whereas the bright segments in pili pseudoannulati are caused by reflection and refraction of light by flattened, twisted surfaces of hair. This latter type is a variant of normal hair.

Price VH, et al: Pseudo pili annulati. Arch Dermatol 1970;102:54.

Fig. 33-20 Spangled hair of pill annulati.

Kinking Hair

Acquired progressive kinking of the hair, first described and named by Wise and Sulzberger in 1932, has a structural abnormality of kinking and twisting of the hair shaft at irregular intervals. The main recognized variant of this disorder begins in men in their late teens or early 20s on the frontotemporal or vertex regions, and then progresses to both the parietal and frontal areas. Usually straight, light brown hair becomes curly, frizzy, and lusterless.

When this occurs in the androgen-dependent areas of young men it is a precursor of male-pattern hair loss; usually these men have a strong family history of androgenetic alopecia. Treatment with topical minoxidil has not prevented development of hair thinning. "Whisker" hairs, the short dark hairs that grow anterior to the ears in young people who eventually develop androgenic alopecia, is felt to be a variant of acquired kinking of the hair.

Acquired hair kinking has been described in other clinical situations. Some reports detail prepubertal patients or women, as well as men, in whom kinking develops in nonandrogen-dependent areas. In these reports alopecia has not developed, and the curly, frizzy hair may remain present or reverse to its previous condition.

Widespread kinking of the hair may be induced by drugs, notably retinoids, and it may also occur in patients with AIDS.

- Tran JT, et al: What syndrome is this? Acquired progressive kinking of the hair. Pediatr Dermatol 2004;21:265.

Woolly Hair

Woolly hair is present at birth and is usually most severe during childhood, when it is often impossible to brush the hair. In adult life there is a variable amelioration in the condition. There is a clear distinction between the appearance of the affected and nonalfected members of a family. Both autosomal-dominant and -recessive inheritance have been described. Woolly hair nevus has partial scalp involvement by woolly hair, which has a markedly reduced diameter. Naxos' disease is an autosomal-recessive syndrome with arrhythmogenic right ventricular cardiomyopathy, diffuse nonepidermolytic palmoplantar keratoderma, and woolly hair. Hair abnormalities are a reliable marker for subsequent heart disease. The disease is caused by a mutation in the gene encoding plakoglobin. Carvajal syndrome is a familial cardiocutaneous syndrome consisting of woolly hair, palmoplantar keratoderma, and heart disease. It is caused by a recessive deletion mutation in desmoplakin.

Woolly hairs tend to unite into tight locks, whereas the hairs of black persons remain individual. The hair may not grow beyond a length of 12 cm, but may attain a normal appearance in adult life. In the familial group the eyebrows and hairs on the arms, legs, pubic, and axillary regions may be short and pale. There are no associated cutaneous or systemic diseases. A Dutch kindred has been described with premature loss of curly, brittle hair, premature loss of carious teeth, nail dystrophy, and acral keratoderma. It has been designated the curly hair-acral keratoderma-caries syndrome. The microscopic findings of wooly hair include a decreased diameter, an ovoid shape on cross section, a pili torti-like twisting about a longitudinal axis, trichorrhexis nodosa, and pili annulati.

Plica Neuropathica (Felted hair)

This is a curling, looping, intertwisting, and felting or matting of the hair in localized areas of the scalp. Predisposing factors include kinky hairs, changes in hair care, and a neurotic mental state. Plica polonica is an older name for this condition.

Ramanan C, et al: Plica neuropathica after using herbal soap. Int J Dermatol 1993;32:200.

Sarkar R, et al: "Plica neuropathica": matting of hair. Dermatology 2000;201:184.

Pseudofolliculitis Barbae

Pseudofolliculitis barbae are hairs that, after appearing at the surface, curve back and pierce the skin as ingrowing hairs. This results in inflammatory papules and pustules, which may scar. In severe cases large deforming keloids may result in the beard area. Pseudofolliculitis of the beard is seen in more than 50% of black men, who must sometimes give up shaving to alleviate the disorder. A single-nucleotide polymorphism, giving rise to a disruptive Ala12Thr substitution in the 1A α -helical segment of the companion layer-specific keratin K6hf appears to be partially responsible for the phenotype. White persons are uncommonly affected; however, shaving of the pubic hair will often result in pseudofolliculitis. Tendemess responds to mid-strength topical steroids. The use of clippers or chemical depilatories, glycolic acid lotion, and adjunctive antibiotic therapy may be helpful. Benzoyl peroxide 5%/clindamycin 1% gel has been shown effective in double-blind evaluation. Laser hair removal with the long-pulse Nd:YAG laser is suitable for a wide range of skin types. The diode laser has also been used.

Pili Multigemini

This rare malformation is characterized by the presence of bifurcated or multiple divided hair matrices and papillae, giving rise to the formation of multiple hair shafts within the individual follicles. It sometimes follows lines of Blaschko. Mehregan et al reported a patient with cleidocranial dysostosis and extensive pili multigemini over the heavily bearded chin and cheek areas. There is no treatment.

Cambiaghi S, et al: Scanning electron microscopy in the diagnosis of pili multigemini. Acta Derm Venereol 1995;75:170.

Mehregan AH, et al: Pili multIgemini. Br J Dermatol 1999; 100:315.

Pili Bifurcati

In this disorder, bifurcation is found in short segments along the shafts of several hairs. Each branch of the bifurcation is covered with its own cuticle. It has been seen in association with the trisomy 8 mosaic syndrome. Pili bifurcati differs from pili multigemini in which a single follicular matrix produces two different-sized hair shafts with separate cuticles that do not fuse again. Trichoptilosis is characterized by split distal ends that are never surrounded by a complete cuticle.

Camacho FM, et al: The different faces of pili bifurcati. A review. Eur J Dermatol 2000;10:337.

Trichostasis Spinulosa

Trichostasis spinulosa is a common disorder of the hair follicles that clinically gives the impression of blackheads (Figs 33-21 and 33-22), but the follicles are filled with funnel-shaped, horny plugs within which are bundles of vellus hairs (Fig. 33-23). The hairs are round at their proximal ends and shredded distally. The disease occurs primary on the nose and forehead, but may also occur on the trunk and be accompanied by pruritus.

Trichostasis spinulosa results from retention of telogen hairs, which are derived from a single hair matrix. It is primarily caused by a hyperkeratosis of the follicular infundibulum, which leads to a partial obstruction of the follicular orifice and thus does not permit shedding of small telogen hairs.

Fig. 33-22 Trichostasis spinulosa. (Courtesy of Richard Vinson, MD)

Fig. 33-23 Trichostasis spinulosa. The plugs may be removed with hydroactive adhesive (Biore) pads. Keratolytics are also effective after using a wax depilatory. The pulsed diode laser has been used successfully, and application of 0.05% tretinoin solution, applied daily for 2 or 3 months, may also produce satisfactory results.

Intermittent Hair-Follicle Dystrophy

Birnbaum et al reported a disorder of the hair follicle leading to increased fragility of the shaft, with no identifiable biochemical disturbance. The prevalence of this disorder is unknown.

Birnbaum PS, et al: Hereditable diseases of the hair. Dermatol Clin 1987;5:137.

Bubble Hair Deformity

Bubble hairs appear as areas of hair with altered texture. Fragility has been reported. The hairs may be curved or straight and stiff. Small, bubble-like defects are found within the hair shafts on light and electron microscopy. The condition is produced by overheating of wet hair with a malfunctioning hair dryer, analogous to the popping of popcorn. All damp hair will develop bubbles of gas when exposed to high heat.

Detwiler SP, et al: Bubble hair. J Am Acad Dermatol 1994;30:54. Gummer CL: Bubble hair. Br J Dermatol 1994;131:901.

HYPERTRICHOSIS

Hypertrichosis is an overgrowth of hair not localized to the androgen-dependent areas of the skin. Several forms exist. The excessive hair growth can be managed with bleaching, trimming, shaving, plucking, waxing, chemical depilatories, and electrosurgical epilation. Laser treatment with longpulse Nd:YAG, diode, ruby, long- and short-pulse alexandrite lasers, and intense pulsed light sources can be effective. Skin type must be considered when choosing a laser system. The greatest experience in dark skin types has been with the long-pulse Nd:YAG laser.

Localized Acquired Hypertrichosis

Dermal tumors, such as melanocytic nevi, smooth muscle hamartoma, meningioma, or Becker nevi, may have excessive terminal hair growth. Repeated irritation, trauma, occlusion under a cast, eczematous states, topical steroid use, linear melorheostotic scleroderma, lymphedema associated with filariasis, the Crow-Fukase (POEMS) syndrome, and pretibial myxedema may be other situations in which there is a localized increase in hair growth. Porphyrias generally show a localized hypertrichosis over the malar area, such as in porphyria cutanea tarda or variegate porphyria; however, in

Fig. 33-24 Sacral hair tuft. (Courtesy of Brooke Army Medical Center Teaching File)

the Gunther variety of erythropoietic porphyria it may be generalized or more diffuse in nature.

Localized Congenital Hypertrichosis

Hypertrichosis cubiti (hairy elbows) consists of long vellus hair on the extensor surfaces of the distal third of the upper arm and the proximal third of the forearm bilaterally. It is a progressive, excessive growth of lanugo hairs that often begins in infancy; the hairs may reach a length of 10 cm. Later they become coarser, but regression has been observed during adolescence. There appears to be familial cases and a sporadic form. Short stature and some developmental abnormalities are present in some cases; however, there is no need for endocrine studies or other evaluation. The condition appears to be of cosmetic significance only.

Other causes of localized congenital hypertrichosis include congenital nevocytic nevi, anterior cervical hypertrichosis, and simple nevoid hypertrichosis. Localized hypertrichosis may be a sign of underlying spinal dysraphism when it occurs over the sacral midline (Fig. 33-24).

Generalized Congenital Hypertrichosis (Congenital Hypertrichosis Lanuginosa)

This rare type of excessive and generalized hairiness is a fully penetrant X-linked dominant trait. The entire body is covered with fine vellus hairs 2 to 10 cm long (Fig. 33-25). The scalp hair appears to be normal. Except for the palms and soles, all other areas are covered. Congenital hypertrichosis lanuginosa may be associated with dental anomalies and gingival fibromatosis. This type of hairiness has attracted considerable attention over the centuries. Hair removal by laser may be quite useful.

Other cases of congenital generalized hypertrichosis may be secondary to drug ingestion by the mother. The fetal hydantoin syndrome is characterized by hypertrichosis, depressed nasal bridge, large lips, a wide mouth, and a short, webbed neck. The fetal alcohol syndrome includes hypertrichosis, a small face, capillary hemangiomas, and physical and mental retardation. A case of generalized hypertrichosis and multiple congenital defects was reported by Kaler et al in a baby born to a mother who used minoxidil throughout pregnancy. Fetal valproate syndrome is characterized by generalized hypertrichosis, sparing the palms and soles,

Fig. 33-25 Hypertrichosis lanuginose. (Courtesy of Brooke Army Medical Center Teaching File).

Fig. 33-26 Hypertrichosis lanuginose associated with an internal malignancy (malignant down).

coarse facies, gum hypertrophy, hypotonia, club feet and club hands, and abnormal dermatoglyphics.

Generalized or Patterned Acquired Hypertrichosis

These cases include those caused by acquired hypertrichosis lanuginosa, those associated with various syndromes, and those secondary to drug intake. Acquired hypertrichosis lanuginosa (Fig. 33-26) is an ominous sign of internal malignancy. Syndromes associated with increased hair growth include lipoatrophic diabetes, stiff skin syndrome, Down syndrome, Rubenstein-Taybi syndrome, Laband syndrome, Cornelia de Lange syndrome, Hurler syndrome, Morogu syndrome, leprechaunism, Winchester syndrome, the Schynzel-Giedier syndrome, and hypertrichosis with acromegalic features. Drugs associated with hypertrichosis include minoxidil, cyclosporin, diphenylhydantoin, diazoxide, streptomycin, penicillamine, corticosteroids, danazol, psoralens, hexachlorobenzene, PUVA, topical bimatoprost, topical steroids, and topical androgens.

HIRSUTISM

Clinical Features

Hirsutism is an excess of terminal hair growth in women in a pattern more typical of men. Androgen-dependent growth areas affected include the upper lip, cheeks, chin, central chest, breasts, lower abdomen, and groin. This altered growth pattern of the hair may be associated with other signs of virilization, which include temporal balding, masculine habitus, deepening of the voice, clitoral hypertrophy, and amenorrhea. Acne is an additional sign of hyperandrogenism.

Pathogenesis

When virilization accompanies hirsutism, especially when progression is rapid, a neoplastic cause is likely. In the absence of virilization, a neoplastic cause is extremely unlikely. Most medically significant hirsutism is related to the polycystic ovarian syndrome (PCOS, hyperinsulinemic hyperandrogenism with anovulation). In a study of 873 patients with medically significant hirsutism, PCOS was present in 82%. Idiopathic hirsutism was present in 4.7%, and 6.75% of the patients had elevated androgen levels and hirsutism with normal ovulation. Ethnic variation should be considered when evaluating hirsutism. Women of Southwest Asian, Eastern European and Southern European heritage commonly have facial, abdominal, and thigh hair; whereas Asian and Indian women generally have little terminal hair growth in these areas.

In women, androgen biosynthesis occurs in the adrenal and ovary. Testosterone and the androgen precursor androstenedione are secreted by the ovary. The adrenal contributions are preandrogens: dehydroepiandrosterone (DHEA), DHEA sulfate, and androstenedione. They require peripheral conversion in the skin and liver to testosterone.

Testosterone is converted to dihydrotestosterone, the androgen that promotes androgen-dependent hair growth, in the hair follicle by 5- α -reductase. Receptor molecules in the end organ are necessary for binding and hormone action at that level. Because testosterone is normally bound to carrier molecules in the plasma at a 99% level, and it is the unbound testosterone that is active, the levels of free testosterone correlate with clinical evidence of androgen excess.

Hirsutism may result from excessive secretion of androgens from either the ovary or the adrenal gland. The excessive secretion may be from functional excesses or, rarely, from neoplastic processes. Ovarian causes include polycystic ovary syndrome (PCOS, Stein-Leventhial syndrome), and a variety of ovarian tumors, both benign and malignant. PCOS is defined by anovulation (fewer than nine periods a year or periods longer than 40 days apart) with clinical evidence of hyperandrogenism. Ovarian cysts are not required for the diagnosis, and laboratory and imaging studies are not required to establish the diagnosis. The pathogenesis of PCOS may relate to insulin resistance with resultant elevated insulin levels leading to ovarian overproduction of androgens. Prevalence rates of PCOS for black and white women in the US are 8.0% and 4.8%, respectively.

Ovarian tumors include unilateral benign microadenomas, arrhenoblastomas. Leydig cell tumors, hilar cell tumors, granular/theca cell tumors, and luteomas are rare causes of hirsutism. In tumor-associated hirsutism, the onset is usually rapid, occurs with other signs of virilization, and begins between the ages of 20 and 40.

Adrenal causes include congenital adrenal hyperplasia and adrenal tumors, such as adrenal adenomas and carcinomas. The adrenogenital syndrome or congenital adrenal hyperplasia (CAH) is an autosomal-dominant disorder that may result from deficiencies of the following enzymes: 21-hydroxylase (most common form), 11 β -hydroxylase, or 3 β -hydroxy steroid dehydrogenase. Onset is generally in childhood, with ambiguous genitalia, precocious growth, and virilism. Nonclassic (adult-onset) CAH may present with hirsutism.

Pituitary causes include Cushing's disease, acromegaly, and prolactin-secreting adenomas. Prolactin-secreting microadenomas have a 20% incidence of hirsutism and acne. Prolactin elevations may be seen in patients with PCOS. Other conditions in which prolactin levels may be elevated and that may lead to hirsutism include hypothyroidism, phenothiazine intake, and hepatorenal failure.

Other causes of hirsutism include the exogenous intake of androgens. End-organ hypersensitivity may be a mechanism in patients with a normal evaluation. Drugs such as minoxidil, diazoxide, corticosteroids, and phenytoin, which have been reported to cause hirsutism, generally cause hypertrichosis—a generalized increase in hair that is not limited to the androgen-sensitive areas.

Evaluation

Most hirsutism is related to ethnic heritage or PCOS. 21-Hydroxylase-deficient nonclassic adrenal hyperplasia, the hyperandrogenic insulin-resistant acanthosis nigricans syndromes, and androgen-secreting tumors are relatively uncommon causes. A careful history and physical examination are essential. The history should focus on onset and progression, virilization, menstrual and pregnancy history, and family/racial background. Physical examination may reveal signs of Cushing's disease, hypothyroidism, or acromegaly. Other signs to be evaluated are the distribution of muscle mass and body fat, clitoral dimensions, voice depth, and galactorrhea.

Laboratory evaluation is controversial. In the authors' opinion, testing is of value only when it affects management. If this is accepted, there is no mandatory hormonal testing for stable hirsutism in patients who have no signs of virilization. A diagnosis PCOS does not require laboratory confirmation. Determination of serum lipids and testing for glucose intolerance may be the most important laboratory evaluations in patients with PCOS as they have the greatest impact on management and long-term prognosis. When the history and physical examination suggest the possibility of a neoplasm, laboratory evaluation should include a total testosterone level. A dehydroepiandrosterone sulfate level is commonly performed if an adrenal cause is suspected. A 24-h urine cortisol is the gold standard for the diagnosis of Cushing's disease. Thyroid stimulating hormone (TSH), growth hormone, and somatomedin C levels are indicated if the history and physical examination suggest hypothyroidism or acromegaly.

Dexamethasone suppression tests are recommended by some authorities, but the results often do not affect management. A baseline 17-hydroxyprogesterone and adrenocorticotropic hormone (ACTH) stimulation test can screen for late-onset CAH, but steroid replacement has not been proved to result in better outcomes than empiric treatment with antiandrogens. Baseline 17-hydroxyprogesterone may be normal in some women with nonclassic 21-hydroxylase deficiency, and ACTH-stimuation may result in overdiagnosis of the syndrome. An exaggerated 17-hydroxyprogesterone response to ACTH stimulation is common in PCOS at a pharmacologic dose (250 µg) but not at a physiologic dose (1 µg) of ACTH. An ovarian origin of hirsutism can be identified by a buserelin test in 30% of patients with hirsutism and by dexamethasone in 22% of patients, but data proving that buserelin challenge results in better outcomes is lacking. A prolactin level will screen for prolactin-secreting tumors, but will also lead to further expensive testing in many patients ultimately diagnosed with PCOS. A prolactin level should be obtained in any patient with galactorrhea, but is of limited value as a routine screening test for patients with hirsutism alone.

If signs of acromegaly, Cushing's disease, or virilization are present clinically, referral to an endocrinologist is recommended. The presence of major menstrual irregularities is also an indication for referral to an endocrinologist or gynecologist. Although 90% of women with hirsutism have an elevated testosterone level, elevations above 200 ng/dL and rapid onset or progressive virilization suggest serious underlying disease. A major elevation in the DHEA sulfate level (>7000 ng/mL) suggests an adrenal neoplasm, and imaging of the adrenal gland is recommended. Many patients wth late-onset congenital adrenal hyperplasia will have normal screening DHEAS. Patients with prolactin levels above 20 ng/mL should likewise be referred for further evaluation with a MRI or CT scan. Polymorphisms in the gene coding for sex hormone-binding globulin have been identified in some families with hirsutism, but such testing does not affect management.

Treatment

Various forms of mechanical, chemical, and laser epilation can be performed, as for hypertrichosis. Spironolactone with various oral contraceptives, cyproterone acetate plus ethyniloestradiol, gonadotropin-releasing hormone agonists such as leuprolide and nafarelin, flutamide, finasteride and topical effornithine have been used successfully alone and in various combinations to treat hirsutism. The optimal combination and dosage remain to be determined. Finasteride at doses of 2.5 to 5 mg/day has been shown to decrease hair number and diameter in women with hirsutism. The combination of spironolactone (100 mg/day) plus finasteride (5 mg/day) has been shown to be superior to spironolactone (100 mg/day) alone. An analysis of the current literature suggested that spironolactone alone (100 mg/day) is superior to finasteride alone (5 mg/day) and low-dose cyproterone acetate alone (12.5 mg/day for the first 10 days of a cycle) in the treatment of hirsutism. As spironolactone is commonly used at a dose of 100 mg twice a day, further studies are needed comparing this higher dose with other modes of therapy. In a prospective, randomized study of Diane 35 (cyproterone acetate (CPA) [2 mg] and ethinyl estradiol [35 µg]), Diane 35 plus spironolactone, and spironolactone alone, all treatments were well tolerated. Combination therapy resulted in superior measured endocrine responses, but the authors concluded that spironolactone alone was the most cost-effective treatment. The choice of an oral contraceptive (OC) is also controversial. Third-generation OCs result in a significant increase in sex hormone-binding globulin and decrease in free testosterone, but both second- and third-generation OCs are clinically effective in treating hirsutism. When flutamide is used, initial treatment with 250 mg/day is followed by a long maintenance treatment period using 125 mg/day.

Insulin sensitizers are being studied in the treatment of hirsutism, particularly PCOS. The best data to date are for metformin. Metformin therapy has been shown to control menstrual cycles and improve fertility in women with PCOS. It causes a decline in testosterone and insulin levels. Oligomenorrheic women with an increased luteinizing hormone (LH)-to-follicle-stimulating hormone (FSH) ratio and lower testosterone levels respond best. Spironolactone (50 mg/day) was superior to metformin (1000 mg/day) in the treatment of hirsutism and menstrual cycle frequency in a study of 82 adolescent and young women with PCOS. Doses of 200 mg/day are commonly used to treat hirsutism. At this dose, menstrual irregularities induced by the drug are common, and it may be best used in combination with an OC pill. Yasmin, which contains the progestogen drosperinone has been shown to provide good cycle control for women with PCOS, with an improvement in acne but not in other symptoms of the syndrome. Good correlation has been noted between an increase in ovulation frequency with clomiphene citrate and the chance of pregnancy in women with PCOS. Other options include the use of gonadotrophins and laparoscopic ovarian drilling. Infertility is best managed by a specialist is this field. Empiric treatment with an antiandrogen may be as good as steroid replacement for the management of hirsutism in patients with nonclassic CAH.

TRICHOMYCOSIS AXILLARIS

One- to 2-mm discrete nodules attached firmly to the hair shafts of the axillary or pubic areas characterize trichomycosis. The color of the nodules may be yellow (Fig. 33-27), red or black. Hyperhidrosis of the affected regions is usually present. A yellowish discoloration of the axillae is sometimes noted. Large numbers of corynebacterium are present in the concretions.

Treatment with topical antibiotic preparations, such as topical clindamycin or erythromycin, or naftifine which has antibacterial properties, combined with any modality that will decrease the hyperhidrosis is effective, but shaving is faster.

ASSOCIATED HAIR FOLLICLE DISEASES

Pityriasis Amiantacea (Tinea Amiantacea)

Thick, asbestos-like (amiantaceous), shiny scales on the scalp characterize pityriasis amiantacea. The silvery-white or dull gray crusting may be localized or, less often, generalized over the entire scalp. The proximal parts of the hairs are matted together by the laminated crusts (Fig. 33-28). There are no structural changes in the hair, but in some patches where the crusting is thick, there may be some purulent exudate under the crust and temporary alopecia such as occurs after some cases of furunculosis of the scalp.

The cause is most often a secondary infection occurring in seborrheic dermatitis or psoriasis. In a prospective study of 85 patients, psoriasis was documented in 35% and an eczematous process suggesting seborrheic dermatitis or atopic dermatitis occurred in another 35%. Tinea capitis was the eventual diagnosis in 13%. Staphylococcus was found in 96.5% compared with 15% of controls. The patient should shampoo daily or every other day with selenium sulfide suspension, or a tar or steroid-containing shampoo, for a couple of weeks. Prior application of peanut oil or a keratolytic a few hours before shampooing facilitates removal of the scales and crusts. With such debridement the secondary bacterial infection usually resolves without the need for oral antistaphylococcal therapy.

Fig. 33-28 Tinea amiantacea.

Folliculitis Nares Perforans

Perforating folliculitis of the nose is characterized by small pustules near the tip of the inside of the nose. The lesion becomes crusted, and when the crust is removed it is found that the bulbous end of the affected vibrissa is embedded in the inspissated material. The affected hairs are typical of those occurring inside the nostril. Staphylococcus aureus may at times be cultured from the pustules. The hair should be removed and antibiotic ointment such as mupirocin applied.

White SW, et al: Pseudofolliculitits vibrissae. Arch Dermatol 1981;117:368.

Acquired Perforating Dermatosis

Perforating folliculitis, Kyrle's disease, and acquired perforating collagenosis, are designations that have been supplanted by the more inclusive term *acquired perforating* dermatosis. The condition is not uncommon and is often associated with renal failure or diabetes or both. Between 4% and 10% of dialysis patients develop umbillicated domeshaped papules on the legs, or less often on the trunk, neck, arms, or scalp, with variable itchiness (Fig. 33-29A). Early lesions may be pustular, late lesions resemble prurigo nodularis both clinically and histologically. There is a central hyper-

774

Fig. 33-29 A and B, Acquired perforating disease in uremia. (Courtesy of Curt Samlaska MD)

keratotic cone that projects into the dermis (Fig. 33-29B), so that when it is removed a pitlike depression remains. Usually the papules are discrete, but they may coalesce to form circinate plaques. Coalescing verticous plaques are frequently seen, especially on the lower extremities. Koebner's phenomenon may also be observed, in which case plaques or elevated verticous streaks are formed. The latter are seen primarily in the antecubital and popliteal spaces. Atrophic scars are seen on involution of these lesions.

Histologically, the epidermis becomes edematous, the granular layer disappears, and parakeratosis develops. Eventually the epidermis becomes atrophic, with disruption of the sites over the papillae. Through these sites necrobiotic connective tissue, degenerating inflammatory cells, and collagen bundles are extruded into a cup-shaped epidermal depression.

The condition is felt to be a response to trauma, usually the scratching or rubbing in response to the pruritus of the associated renal failure or dry skin. Other predisposing conditions reported include HIV infection, sclerosing cholangitis or other liver diseases, hypothyroidism, hyperparathyroidism, in areas of healed herpes zoster, and as a reaction to laser hair removal.

Ultraviolet treatment of either PUVA or UVB type helps the pruritus of renal disease and improves the perforating disorder. Hydration of the skin with a soaking tub bath in plain water followed immediately (without drying) by triamcinolone ointment is also useful. Topical retinoic acid (0.1% cream), allopurinol, doxycycline, isotretinoin, and etretinate have been effective in flattening lesions. HIVinfected patients may respond well to thalidomide. The disease may remit promptly after renal transplantation.

Reactive Perforating Collagenosis

Reactive perforating collagenosis is an inherited condition characterized by pinhead-sized, skin-colored papules that grow to a diameter of 4 to 6 mm and develop a central area of umbilication in which keratinous material is lodged (Fig. 33-30). The discrete papules may be numerous and involve sites of frequent trauma such as the backs of the hands, forearms, elbows, and knees. The lesion reaches a maximum size of about 6 mm in 4 weeks and then regresses spontaneously in 6 to 8 weeks.

It is believed that this is caused by a peculiar reaction of the skin to superficial trauma. Koebnerization is often observed. Young children are most frequently affected. Most reports support an autosomal-recessive mode of inheritance; however, a family in which it appeared to be inherited by autosomal dominance has been reported.

No specific treatment is indicated, since the lesions involute spontaneously. Tretinoin 0.1% cream may be effective.

Kumar V, et al: Familial reactive perforating collagenosis. J Dermatol 1998;25:54.

Traumatic Anserine Folliculosis

Traumatic anserine folliculosis is a curious gooseflesh-like follicular hyperkeratosis that may result from persistent pressure and lateral friction of one skin surface on another. Such friction is often caused by habitual pressure of elbows, chin or jaw, or neck, often while watching television. Twothirds of patients who develop this are atopic.

Padilha-Gonalves A: Traumatic anserine folliculosis. J Dermatol 1979;6:365.

Erythromelanosis Follicularis Faciei et Colli

Erythromelanosis follicularis faciei et colli is an erythematous pigmentary disease involving the follicles. A reddish-

brown, sharply demarcated, symmetrical discoloration involves the preauricular and maxillary regions. At times the pigmentation may be blotchy. In addition, follicular papules and erythema are present. Under diascopic pressure the reddish-brown area, containing telangiectases, becomes pale and the light brown pigmentation becomes more apparent. Pityriasiform scaling and slight itching may occur. Keratosis pilaris on the arms and shoulders is frequently found. It preferentially a{fects Asian patients.

Histologically, a slight hyperkeratosis occurs, with epidermal hyperpigmentation and dilation of the upper dermal vessels. The hair follicles may be enlarged in the infundibular area and the sebaceous glands may be hypertrophic. A lymphocytic infiltration surrounds the adnexa.

- Sodaify M, et al: Erythromelanosis follicularis faciei et colli. Int J Dermatol 1994;33:643.

Disseminate and Recurrent Infundibulofolliculitis

Hitch and Lund described a disseminate follicular eruption on the torso of a black man that involved all the pilosebaceous structures (Fig. 33-31). The lesions were irregularly shaped papules pierced by a hair. They likened the eruption to cutis anserina viewed through a magnifying glass. The eruption is mildly pruritic at times, and is chronic, with recurrent exacerbations. The papules are uniform, 1 or 2 mm

Fig. 33-30 Reactive perforating collagenosis.

Fig. 33-31 Disseminated infuldibulofolliculitis.

in diameter, and involve all the follicles in the affected areas, which are usually the upper trunk and neck, though the entire trunk and proximal extremities may be involved. Rarely, pustules may occur.

Histologically, the infundibular portion of the follicles is chiefly affected, and the lesions are inflammatory rather than hyperkeratotic. Edema, lymphocytic and neutrophilic infiltration, and slight fibroblastic infiltration surround the affected follicles.

Treatment with isotretinoin or PUVA may be effective.

Lichen Spinulosus

Lichen spinulosus (keratosis spinulosa) is a disease chiefly of children and is characterized by minute filiform horny spines, which protrude from follicular openings independent of any papules. The spines are discrete and grouped. The lesions appear in crops and are symmetrically distributed over the trunk, limbs, and buttocks (acne corne). There is a predilection for the neck, buttocks, abdominal wall, popliteal spaces, and the extensor surfaces of the arms. Little or no itching is present.

Histologic evaluation shows simple inflammatory changes and follicular hyperkeratosis. The lesions may respond to keratolytics and emollients, such as salicylic acid, lactic acid, or urea gels or ointments. Tretinoin is another alternative. The lesions tend to involute at puberty.

DISORDERS OF THE SWEAT GLANDS

Hyperhidrosis

Hyperhidrosis, or excessive sweating, may be localized to one or several areas or it may be more generalized. True generalized hyperhidrosis is rare, and even hyperhidrosis caused by systemic diseases is usually accentuated in certain regions.

Palmoplantar Hyperhidrosis (Emotional Hyperhidrosis) This type of hyperhidrosis is usually localized to the palms, soles or/or axillae (Fig. 33-32), and may be worse during warm temperatures. Patients with palm and sole hyperhidrosis may also have axillary hyperhidrosis, but only 25% of patients with axillary hyperhidrosis have palmoplantar hyperhidrosis. The hands may be cold and show a dusky hue. The soggy keratin of the hyperhidrotic soles is Irequently affected by pitted keratolysis and has a foul odor. Sweating may be intermittent; in these cases anxiety, stress, or fear may trigger it. When sweating is constant, usually emotion is not as important.

This type of sweating can be autosomal-dominantly inherited. Its onset is in childhood for the palmar type and adolescence for axillary disease. It tends to improve with age. Sweating typically ceases during sleep.

Gustatory Hyperhidrosis Certain individuals regularly experience excessive sweating of the forehead, upper lip, perioral region, or sternum a few moments after eating spicy foods, tomato sauce, chocolate, coffee, tea, or hot soups. Gustatory sweating may be idiopathic or caused by hyperactivity of the sympathetic nerves (Pancoast tumor or postoperatively), sensory neuropathy (diabetes mellitus or subsequent to zoster), parotitis or parotid abscess, and surgery or injury of the parotid gland (auriculotemporal syndrome of von Frey). Frey syndrome occurs in one-third or more of patients following parotid surgery. Fortunately, only 10% of affected patients require treatment.

Fig. 33-32 Axillary hyperhidrosis.

Other Localized Forms of Hyperhidrosis Localized sweating can occur over lesions of blue rubber bleb nevus, glomus tumors, hemangiomas (sudoriferous hemangioma), and in POEMS syndrome, Gopalan syndrome, complex regional pain syndrome, as a result of spinal cord tumors (especially when unilateral palmar hyperhidrosis is the complaint), and pachydermoperiostosis.

Generalized Hyperhidrosis Febrile diseases, vigorous exercise or a hot, humid environment, such as a tropical milieu, may induce generalized hyperhidrosis. Hyperthyroidism, acromegaly, diabetes mellitus, pheochromocytoma, hypoglycemia, salicylism, substance abuse, lymphoma, pregnancy, and menopause may also produce generalized hyperhidrosis. Additional causes of hyperhidrosis include concussion, Parkinson's disease, other disturbances of the sympathetic nervous system, and metastatic tumors producing a complete transection of the spinal cord.

Treatment

The therapy of generalized hyperhidrosis is aimed at treating the underlying systemic disease. Virtually all cases of hyperhidrosis seen by dermatologists are of the palmoplantar or axillary types, and the treatments discussed below relate primarily to these conditions.

Topical Medication. Topical aluminum chloride or aluminum chlorhydroxide are the most commonly used agents for hyperhidrosis. For the axillae, application of a 10% to 35% solution nightly to a very dry axilla (blown dry with a hair dryer) is usually very effective. To limit irritation, lower concentrations should be tried first. Also, it should be washed off in 6 to 8 h. Occlusion is usually not required. Baking soda may be used instead of deodorant. In palmar hyperhidrosis the application of aluminum chloride nightly, alone or occluded with plastic gloves, has produced good results for some patients but is less effective than the same technique in the axilla. If topical treatment is effective when performed nightly, the frequency may be reduced to as little as once or twice a week with continued benefit. Topical formaldehyde and glutaraldehyde, which can sensitize and tan the skin respectively, are not routinely recommended.

lontophoresis. Iontophoresis with plain tap water is an alternative for patients for whom topical treatments fail. It is frequently effective, using either a Drionic device or a Fischer unit. Treatments generally require 20- to 30-min sessions each day or twice a day. Once response has occurred, treatments may be used intermittently (as little as once every 2 weeks) for maintenance. Use of glycopyrrolate 0.01% and aluminum chloride 2% in the iontophoresis medium may hasten the response.

Botulinum Toxin. Injection of Botox (botulinum A toxin) into 4 cm² areas on the palms, soles, or axillae dramatically reduces sweating at the treated areas to at least 25% and often to less than 10% of baseline rates. Complications are rare but include some grip weakness when higher doses are used in the palms. This problem, the expense, and the painful injections limit its use in the palms and soles especially. The hypohidrosis continues for an average of 7 months, with some patients continuing to have substantial benefit at 16 months after one injection. Repeated injections generally do not lose efficacy and result in similar response and complication rates. This form of treatment should be offered to all patients who fail topical treatments before surgical modalities are considered. Frey syndrome remits for 1 to 1.5 years in nearly every patient treated. This treatment may be considered for other rare forms of localized hyperhidrosis. Myobloc (botulinum toxin B) is also effective, but with more limited duration of response.

Internal Medication. The use of anticholinergic agents such as Pro-Banthine or glycopyrrolate may be helpful. The dosage of each is regulated by the patient's tolerance and response. Often, sweating is suppressed just as anticholinergic side effects reach intolerable levels, and this approach has to be abandoned. Side effects of acetylcholine-blocking agents may also cause or aggravate such conditions as glaucoma and convulsions. The effects on sweating generally last 4 to 6 h, and many patients prefer to use the medication to ensure dryness for special occasions only rather than as continuous treatment. Other agents reported to reduce localized hyperhidrosis include diltiazem and clonidine.

Surgical Treatment. Axillary hyperhidrosis may be effectively controlled by excision of the most actively sweating portion of the axillary skin, followed by undercutting and subcutaneous resection of the sweat glands for 1 to 2 cm on each side of the elliptical excision. This procedure is virtually always effective. Alternatively liposuction removal may be used. The most important preoperative consideration is the accurate mapping of the most active sweating areas of the axillae. The responsible eccrine glands are not necessarily located in the same areas as the axillary hair and are often in a reasonably limited area. Mapping may be performed with cobalt chloride or starch iodide.

Upper thoracic sympathectomy has been found to be effective in excessive palmar sweating when all other measures have failed. Sympathetic denervation of the upper extremities is performed via endoscopy by resection of the second thoracic sympathetic ganglion. Acute surgical complications occur in less than 2% but include chronic pain, infection, pneumothorax, hemothorax, bleeding, pneumonia, and even death. Sweating of the hands is stopped completely. Only two of three patients are satisfied, however, since compensatory and gustatory hyperhidrosis occurs in more than two-thirds of patients. This may be severe and as debilitating as the original problem. Horner syndrome may rarely result. Endoscopic thoracic sympathetic block at T4 is being evaluated as another alternative.

Anhidrosis (Hypohidrosis)

Anhidrosis is the absence of sweating. Hypohidrosis, or reduced sweating, is part of the spectrum of these disorders. Dysfunction in any step in the normal physiologic process of sweating can lead to decreased or absent sweating. It may be localized or generalized. Generalized anhidrosis occurs in anhidrotic ectodermal dysplasia, miliaria profunda (tropical asthenia), Sjögren syndrome, hereditary sensory neuropathy (type IV) with anhidrosis, and in some patients with diabetic neuropathy, and multiple myeloma. Drugs such as quinicrine, topiramate, and zonisamide may cause hypohidrosis. Atopic dermatitis is frequently associated with reduced sweating and pruritus when sweating is triggered. Patients with psoriasis may have similar symptoms, but less frequently.

Anhidrosis with provitus is a rare syndrome of young adults. Severe itching occurs whenever they are stimulated to sweat. No sweat is delivered to the skin surface, but when the body temperature is raised about 0.5° C, fine papules appear at each eccrine orifice. The associated pruritus is so severe that patients feel completely incapacitated and distracted. Cooling immediately resolves the symptoms. This may represent one form of tropical asthenia. The natural history is unknown, but spontaneous resolution may occur after several years. These patients are frequently misdiagnosed as having cholinergic urticaria. A patient with acquired anhidrosis was shown to have obsruction of the coiled ducts with an amorphous eosinophilic substance.

Segmental anhidrosis may be associated with tonic pupils (Holmes-Adie syndrome); this is called *Ross syndrome*. Patients have heat intolerance and segmental areas of anhidrosis on the trunk, arms, or legs. Loss of deep tendon reflexes in the arms, trunk, and legs is consistently seen. Compensatory segmental hyperhidrosis of functionally intact areas may occur. A selective degeneration of the cholinergic sudomotor neurons is the hypothesized abnormality.

Anhidrosis localized to skin lesions occurs regularly over plaques of tuberculoid leprosy. This is also true of segmental vitiligo (but not generalized type), in the hypopigmented streaks of incontinentia pigmenti, in lesions of syringolymphoid hyperplasia with alopecia and anhidrosis, and on the face and neck of patients with the rare Bazex's syndrome consisting of follicular atrophoderma, basal cell carcinomas, and hypotrichosis, an X-linked dominant disorder.

Bromidrosis

Also known as *fetid sweat* and *malodorous sweating*, bromidrosis is chiefly encountered in the axillae. Bacterial decomposition of apocrine sweat, producing fatty acids with distinctive offensive odors is considered to be the cause. Often, patients who complain of offensive axillary sweat actually have no offensive odor; the complaint represents a delusion, paranoia, phobia, or a lesion of the central nervous system. Intranasal foreign body and chronic mycotic infection in the sinuses are additional causes. True bromidrosis is usually not recognized by the patient.

Fish odor syndrome should be considered in patients presenting with complaints of offensive odor. It is caused by excretion of trimethylamine (which smells like rotten fish) in the eccrine sweat, urine, saliva, and other secretions. This chemical is produced from carnitine and choline in the diet and is normally metabolized in the liver. An autosomaldominant defect in the ability to metabolize trimethylamine because of a defect in flavin-containing monooxygenase 3 is the cause of this syndrome. Dietary reduction of foods high in carnitine and choline is beneficial.

Antibacterial soaps and many commercial deodorants are quite effective in controlling axillary malodor. Frequent bathing, changing of underclothes, shaving of the axillae, and topical application of aluminum chloride (Drysol) are all helpful measures. Surgical removal of the glands is possible, as in axillary hyperhidrosis, but this is very rarely indicated.

Plantar bromidrosis is produced by bacterial action on eccrine sweat-macerated stratum corneum. Hyperbidrosis is the chief associated factor, and pitted keratolysis is often present. Careful washing with an antibacterial soap and the use of dusting powders on the feet are helpful in eliminating bromidrosis. Use of topical antibiotics, such as clindamycin, may be beneficial. Previously described measures to control plantar hyperhidrosis should be instituted.

Ruocco V, et al: Fish-odor syndrome. Int J Dermatol 1995;34:92.

Chromhidrosis

Chromhidrosis, or colored sweat, is an exceedingly rare functional disorder of the apocrine sweat glands, frequently localized to the face or axilla. It has been less often noted on the abdomen, chest, thighs, groin, genitalia, and lower eyelids. The colored sweat may be yellow (most common), blue, green, or black. The colored secretion appears in response to adrenergic stimuli, which cause myoepithelial contractions. Colored apocrine sweat fluoresces and is caused by lipofuscin.

Eccrine chromhidrosis is caused by the coloring of the clear eccrine sweat by dyes, pigments, or metals on the skin surface. Examples are the blue-green sweat seen in copper workers and the "red sweat" seen in flight attendants from the red dye in the labels in life-vests. Brownish staining of the axillae and undershirt may occur in ochronosis. Bile secretion in eccrine sweat occurs in patients with liver failure and marked hyperbilirubinemia. Small, round, brown or deep-green macules occur on the palms and soles.

Wenzel FG, et al: Nonneoplastic disorder of the eccrine glands. J Am Acad Dermatol 1998;38:1.

Fox-Fordyce Disease

Fox-Fordyce disease is rare, occurring mostly in women during adolescence or soon afterward. It is characterized by conical, flesh-colored or grayish, intensely pruritic, discrete follicular papules in areas where apocrine glands occur (Fig. 33-33). The axillae and areolae are the primary sites o(involvement, but the umbilicus, pubes, labia majora, and

Fig. 33-33 Fox-Fordyce disease. perineum may be allected. Apocrine sweating does not occur in affected areas, and hair density may be decreased. In some cases there is no itching. Ninety percent of cases occur in women between the ages of 13 and 35, but the disease may present postmenopausally or in males. Pregnancy invariably leads to improvement.

Histologically, Fox-Fordyce disease is characterized by obstruction of the follicular ostia by orthokeratotic cells. An inflammatory infiltrate of lymphocytes surrounds the upper third of the hair follicles and upper dermal vessels. There is an associated spongiosis of the infundibulum at the site of entrance of the apocrine duct into the hair follicle. In one case, detached apoeccrine cells obstructed the duct.

Treatment of Fox-Fordyce disease is difficult, and no form of therapy is universally effective. Estrogen therapy, usually in the form of oral contraceptive pills, is most uniformly effective. Topical tretinoin, topical and intralesional steroids, topical clindamycin solution, isotretinoin, and UV phototherapy have all been effective in small numbers of patients. Excision or liposuction-assisted curettage may be successful in axillary sites.

Granulosis Rubra Nasi

Granulosis rubra nasi is a rare familial disease of children, occurring on the nose, cheeks, and chin. It is characterized by diffuse redness, persistent hyperhidrosis, and small dark red papules that disappear on diascopic pressure. The tip of the nose is red or violet. There may be a few small pustules. Hyperhidrosis precedes the erythema (Fig. 33-34). The tip of the nose is cold and is not infiltrated. The disease disappears spontaneously at puberty without leaving any traces. The cause is unknown. Histologically, blood vessels are dilated and there is an inflammatory infiltrate about the sweat ducts.

Treatment is with local preparations for relief of the inflammation, and reassurance that with puberty there is usually involution of the process.

Wenzel FG, et al: Nonneoplastic disorder of the eccrine glands. J Am Acad Dermatol 1998;38:1.

Fig. 33-34 Early granulosa rubra nasi.

Hidradenitis

Hidradenitis is a term used to describe diseases in which the histologic abnormality is primarily an inflammatory infiltrate around the eccrine glands. This group includes neutrophilic eccrine hidradenitis and idiopathic plantar hidradenitis (recurrent palmoplantar hidradenitis).

Neutrophilic Eccrine Hidradenitis Ninety percent of patients with neutrophilic eccrine hidradenitis (NEH) have a malignancy. It has been described primarily in patients with acute myelogenous leukemia; however, other leukemias, lymphomas, and uncommonly solid tumors may be present. It usually begins about 10 days after the start of chemotherapy. While the majority of patients have been treated with cytarabine, it has not been uniformly linked to any chemotherapeutic agent and may occur in patients who have not been treated. Granulocyte colony-stimulating factor (G-CSF), imatinib mesylate, zivoduvine, acetaminophen, and various antibiotics have also been implicated as triggers for this neutrophilic dermatosis.

The lesions are typically erythematous and edematous papules and plaques of the extremities, trunk, face (periorbital), and palms (in decreasing frequency). Pigmentatiom, purpura, or pustules may be present within the papules and plaques. Fever and neutropenia are often present. Histologically, there is a dense neutrophilic infiltrate around and infiltrating eccrine glands. Necrosis of sweat glands may be present, with or without the inflammatory infiltrate. Syringosquamous metaplasia may occur. This finding can also occur in fibrosing alopecia, in burn scars, adjacent to various nonmelanoma skin cancers and ischemic and surgical ulcers, in alopecia mucinosa, and in ports of radiation therapy.

The lesions may recur with repeated courses of chemotherapy, but many do not. Lesions resolve over 1 to 4 weeks (average, 10 days). Nonsteroidal anti-inflammatory drugs or oral corticosteroids may hasten the healing. Prophylactic administration of dapsone prevented recurrence in one patient.

Infectious neutrophilic hidradenitis may present as a recurrent, pruritic, papular eruption. Serratia, Enterobacter cloacae, Nocardia, and S. aureus have been implicated, and appropriate antibiotics for bacterial agents are curative. Multiple HIV-infected patients have developed neutrophilic eccrine hidradenitit. The diagnosis is confirmed by bistologic evaluation and culture of affected tissue (surface cultures may not be adequate).

Recurrent Palmoplantar Hidradenitis Recurrent palmoplantar hidradenitis is primarily a disorder of healthy children and young adults. Lesions are primarily painful, subcutaneous nodules on the plantar surface, resembling erythema nodosum. Rarely, palmar lesions also occur. In some children *Pseudomonas* infection may be the cause (Pseudomonal hot foot, see Chapter 14). Children may present refusing to walk because of plantar pain. The condition is typically recurrent, and may be triggered by exposure to wet shoes or cold, damp weather. The use of oral and topical steroidal preparations may be beneficial.

Nail-Associated Dermatoses

Numerous dermatoses are associated with characteristic, sometimes specific, nail changes. Many are considered elsewhere.

Lichen Planus of Nails The reported incidence of nail involvement in lichen planus varies from less than 1% to 10%. Lichen planus of the nails may occur without skin changes, but 25% with nail disease will have lichen planus at other locations. Although it may occur at any age, most commonly it begins during the fifth or sixth decade of life. The various nail changes are irregular longitudinal grooving and ridging of the nail plate, thinning of the nail plate, pterygium formation (Fig. 33-35), shedding of the nail plate with atrophy of the nailbed, subungual keratosis, longitudinal erythronychia (red streaks), and subungual hyperpigmentation. The plate may be markedly thinned, and at times distinct papules of lichen planus may involve the nailbed. Twenty-nail dystrophy (trachyonychia) may be the sole manifestation of lichen planus.

The histologic changes of lichen planus may be evident in any individual nail constituent or a combination of them. The one most frequently involved is the matrix.

Treatment is mostly unsatisfactory. Intralesional injection of corticosteroids may be of help in some patients. Digital nerve blocks should be considered before infiltration of the matrix or nailbed. Topical corticosteroids under polyethylene occlusive dressings are usually inadequate. Oral prednisone

(0.5-1 mg/kg for 3 weeks) or oral retinoids in combination with topical steroids applied to the involved sites have been successful in some patients. Tosti et al reported that typical lichen planus of the nails in children responded to 0.5 to 1 mg/kg/month of intramuscular triamcinolone acetonide given for 3 to 6 months, until the proximal balf of the nail was normalized. Only two patients recurred during the follow-up period. While twenty-nail dystrophy was not treated, they spontaneously improved; those with idiopathic atrophy of the nails were unchanged. (See Chapter 12 for additional therapeutic considerations.)

Psoriatic Nails Nail involvement in psoriasis is common, with reported incidences varying from 10% to 78%. Older patients, those with active exacerbations of disease, and in many studies patients with psoriatic arthritis are more likely to express nail abnormalities. In the nail plate there may be pits (Fig. 33-36), or much less often, furrows or transverse depressions (Beau's lines), crumbling nail plate, or leukonychia, with a rough or smooth surface. Splinter hemorrhages are found in the nailbed, with reddish discoloration of a part or all of the nailbed, and horny masses. In the hyponychium, yellowish-green discoloration may occur in the area of onycholysis. Many studies find patients with psoriatic arthritis will often have psoriatic nail changes.

Fig. 33-36 Pitting caused by psoiasis.

The severity of nail disease may correlate with the severity of skin and joint disease. Pustular psoriasis may produce onycholysis, with lakes of pus in the nailbed or in the perionychial areas. Rarely, anonychia may result. Other papulosquamous diseases may affect the nails like psoriasis, with the exception of nail pitting. Reiter's disease, pityriasis rubra pilaris, Sézary syndrome, and acrokeratosis paraneoplastica produce as a rule hypertrophic nails with subungual hyperkeratosis.

Successful systemic treatment of psoriasis will usually also improve or clear the nail changes. Methotrexate, PUVA, cyclosporin, the biologics, or acitretin may be effective. Psoriatic nail disease may be only one area involved; the eventual treatment options selected depend on the degree of cutaneous and nail involvement. (See Chapter 10 for additional information and therapeutic options.) All local therapies have limitations, and the condition is frequently mistaken for onychomycosis. Intralesional injection of triamcinolone acetonide suspension, 3 to 5 mg/mL, with a 30-gauge needle is frequently helpful. Digital nerve block facilites adequate injection. Topical 5-fluorouracil (5-FU) applied to the proximal nailfold has been reported to be effective. It is best to avoid the free edge of the nail when applying 5-FU as it may cause distal onycholysis. Topical cyclosporin and topical tazarotene 0.1% gel have also been reported to be helpful. Topical calcipotriol improves about 50% of patients with localized pustular psoriasis of the nails and may be used as a maintenance treatment after successful intervention with systemic retinoids.

Darier's Disease Longitudinal, subungual, red or white streaks, associated with distal wedge-shaped subungual keratoses, are the nail signs diagnostic for Darier-White disease. Keratotic papules on the doisal portion of the nailfold clinically

Flg. 33-37 Clubbing, (Courtesy of Lawrence Lleblich, MD)

may resemble acrokeratosis verruciformis, but histologically have features of Darier's disease. Other nail findings include splinter hemorrhages and leukonychia. All of these findings are less pronounced on the toenails.

De Berker DA, et al: Localized longitudinal erythronychia. Arch Dermatol 2004;140:1253.

Clubbing

Clubbing is divided into two types: idiopathic and acquired, or secondary. The changes occur not only in the nails but also in the terminal phalanges. The nails bulge and are curved in a convex arc in both transverse and longitudinal directions, like a watch crystal. The eponychium is thickened. The angle formed by the dorsal surface of the distal phalanx and the nail plate (Lovibond's angle) is approximately 160°; however, with clubbing this angle is obliterated and becomes 180° or greater (Fig. 33-37). The soft tissues of the terminal phalanx are bulbous, resembling drumsticks. These tissues are mobile when pressure is applied over the matrix.

Idiopathic clubbing is either of the isolated dominantly inherited type or of the pachydermoperiostosis type with its associated findings. Secondary (acquired) clubbing is usually a consequence of pulmonary, cardiac, thyroid, hepatic, or gastrointestinal disease. Typically, there is periostitis, with periosteal new bone formation in the phalanges, metacarpals, and distal ulna and radius. This is called *hypertrophic osteoarthropathy* and is responsible for the painful clubbing. It typically occurs in men with bronchogenic carcinoma. Unilateral or asymmetrical clubbing may also occur, reported in cases of Takayasu arteritis and sarcoidosis. Solitary clubbing may be associated with a digital mucous cyst.

- Kaditis AG, et al: Takayasu's arteritis presenting with unilateral digital clubbing. J Rheumatol 1995;22:2346.
- Myers KA, et al: The rational clinical examination. Does this patient have clubbing? JAMA 2001;286:1972.
- Richter T, et al: Idiopathic clubbing of the fingers, pathogenetic mechanisms and differential etiologic diagnosis. Hautarzt 1994;45:866.

Shell Nail Syndrome

Cornelius et al described a shell nail in association with bronchiectasis. The nail resembles a clubbed nail, but the nailbed is atrophic instead of being a bulbous proliferation of the soft tissue.

Cornelius CE: Shell nail syndrome. Arch Dermatol 1969;100:118.

Koilonychia (Spoon Nails)

Spoon nails are thin and concave, with the edges everted so that if a drop of water were placed on the nail, it would

Fig. 33-38 Koilonychia.

not run off (Fig. 33-38). Koilonychia may result from faulty iron metabolism and is one of the signs of Plummer-Vinson syndrome, as well as of hemochromatosis. Spoon nails have been observed in coronary disease, syphilis, polycythemia, and acanthosis nigricans. Familial forms are also known to occur.

Other associations include psoriasis, lichen planus, Raynaud's disease, scleroderma, acromegaly, hypothyroidism and hyperthyroidism, monilethrix, palmar hyperkeratoses, and steatocystoma multiplex. A significant number of cases are idiopathic. Manual trauma in combination with cold exposure may result in seasonal disease. Sherpas are Tibetan people living in the Nepalese Himalayas who often serve as porters on mountain-climbing expeditions. Chronic cold exposure, in combination with hypoxemia, may contribute to the frequency with which koilonychia is observed among them.

Gao XH, et al: Familial koilonychia. Int J Dermatol 2001;40:290. Murdoch D: Koilonychia in Sherpas. Br J Dermatol 1993; 128:592.

Congenital Onychodysplasia of the Index Fingers

Congenital onychodysplasia of the index fingers is defined by the presence of the condition at birth, index finger involvement (unilateral or bilateral), variable distortion of the nail or lunula, and polyonychia, micronychia, anonychia, hemionychogryphosis, or malalignment (Fig. 33-39). It may also involve adjacent fingers, such as the middle fingers and thumbs. An underlying bone dysplasia may be present beneath the involved nail. Cases have occurred in an autosomal-dominant pattern; other proposed causes include in utero ischemia or exposure to teratogens.

- De Smet L: Congential oncychodystroplasia of the index finger. Genet Couns 2000;11:37.
- Prais D, et al: Prevalence and new phenotypic and radiologic findings in congenital onychodysplasia of the index finger. Pediatr Dermatol 1999;16:201.

Twenty-Nail Dystrophy (Trachyonychia)

All 20 nails may become opalescent, thin, dull, fragile, and finely longitudinally ridged (and as a result, distally notched) at any age from $1^{1/2}$ years to adulthood, although it is most commonly diagnosed in children. It can be idiopathic or caused by alopecia areata, psoriasis, lichen planus, atopy, ichthyosis vulgaris, or other inflammatory dermatoses.

Fig. 33-39 Congenital onychodystrophy of the index finger. (Courtesy of James Fitzpatrick, MD)

Familial forms exist. In some cases spongiosis may be found on nail biopsy. Trachyonychia has also been reported associated with autoimmune processes such as selective IgA deficiency, vitiligo, and graft-versus-host disease. Thus, twenty-nail dystrophy is caused by a heterogenous group of inflammatory conditions. Childhood cases may resolve spontaneously by the time the patient is 20 to 25 years of age.

- Tosti A, et al: Idiopathic trachyonychia (twenty-nail dystrophy): a pathological study of 23 patients. Br J Dermatol 1994;131:866.

Onychauxis

In onychauxis the nails are thickened but without deformity (simple hypertrophy). Simple thickening of the nails may be the result of trauma, acromegaly, Darier's disease, psoriasis, or pityriasis rubra pilaris. Some cases are hereditary.

Treatment involves periodic partial or total debridement of the thickened nail plate by mechanical or chemical (40% urea paste) means. Matricectomy and nail ablation are options, as they are in onychogryphosis, congentital nail dystrophies, and chronic painful nails such as recalcitrant ingrown toenails or splits within the medial or lateral third of the nail.

Baran R, et al: Matricectomy and nail ablation. Hand Clin 2002; 18:696.

Bartolomei FJ: Onychauxis. Clin Podiatr Med Surg 1995;12:215.

Onychogryphosis

Hypertrophy may produce nails resembling claws or a ram's horn. Onychogryphosis may be caused by trauma or periph-

eral vascular disorders but is most often caused by neglect (failure to cut the nails for very long periods). It is most commonly seen in the elderly.

Some recommend avulsion of the nail plate with surgical destruction of the matrix with phenol or the CO_2 laser, if the blood supply is good.

Baran R, et al: Matricectomy and nail ablation. Hand Clin 2002; 18:696.

Mohrenschlager M, et al: Onychogryphosis in elderly persons. Cutis 2001;68:233.

Onychophosis

A common finding in the elderly, onychophosis is a localized or diffuse hyperkeratotic tissue that develops on the lateral or proximal nailfolds, within the space between the nailfolds and the nail plate. It may involve the subungual area, as a direct result of repeated minor trauma, and most frequently affects the first and fifth toes.

The use of comfortable shoes should be encouraged. The areas involved should be debrided and treated with keratolytics. Emollients are also helpful.

Cohen PR, et al: Geriatric nail disorder. J Am Acad Dermatol 1992;26:521.

Anonychia

Absence of nails, a rare anomaly, may be the result of a congenital ectodermal defect, ichthyosis, severe infection, severe allergic contact dermatitis, self-inflicted trauma, Raynaud phenomenon, lichen planus, epidermolysis bullosa, or severe exfoliative diseases. Permanent anonychia has been reported as a sequel of Stevens-Johnson syndrome. It may also be found in association with congenital developmental abnormalities, such as microcephaly, and wide-spaced teeth (autosomal-recessive inheritance), the autosomal-dominant Cooks syndrome (bilateral nail hypoplasia of digits 1 through 3, the absence of nails of digits 4 and 5 of the hands, total absence of all toenails, and absence or hypoplasia of the distal phalanges of the hands and feet), DOOR syndrome (deafness, onychoosteodystrophy, mental retardation), and the glossopalantine syndrome (abnormal mouth, tongue being attached to the temporomandibular joint).

Al Hawsawi K, et al: Anonychia congenital totalis. Int J Dermatol 2002;41:397.

- Ozdemir O, et al: Total anonychia congenita. Genet Couns 2004; 15:43.

Pall A, et al: Twenty-nail anonychia due to lichen planus. J Dermatol 2004;31:146.

Onychoatrophy

Faulty underdevelopment of the nail may be congenital or acquired. The nail is thinned and smaller. Vascular disturbances, epidermolysis bullosa, lichen planus, Darier's disease, multicentric reticulohistiocytosis, and leprosy may cause onychatrophy. It is also seen in congenital syndromes such as Apert, Goltz, Turner, Ellis van-Creveld, nail-patella, dyskeratosis congenital, cartilage-hair hypoplasia, progeria, hypohidrotic ectodermal dysplasia, incontinentia pigmenti, popliteal web, trisomy13 and trisomy 18, and as a side effect of etretinate therapy.

Al Hawsawi K, et al: Anonychia congenital totalis. Int J Dermatol 2002;41:397.

Onychomadesis

Onychomadesis is a periodic idiopathic shedding of the nail beginning at its proximal end. The temporary arrest of the function of the nail matrix may cause onychomadesis. Neurologic disorders, peritoneal dialysis, and cutaneous T-cell lymphoma, Kawasaki's disease, pemphigus vulgaris, drug allergy, and keratosis punctata palmaris et plantaris have been reported causes. It may appear as a periodic finding in runners. Immobilization from casting for fractures may cause onychomadesis and pyogenic granuloma (ormation. Medications such as antineoplastic agents and retinoids may cause onychomadesis also.

Mehra A, et al: Idiopathic familial onychomadesis. J Am Acad Dermatol 2000;43:349.

- Piraccini BM, et al: Drug-induced nail abnormalities. Am J Clin Dermatol 2003;4:31.
- Tosti A, et al: Onychomadesis and pyogenic granuloma following cast immobilization. Arch Dermatol 2001;137:231.

Beau's Lines

Beau's lines are transverse furrows that begin in the matrix and progress distally as the nail grows (Fig. 33-40). They are ascribed to the temporary arrest of function of the nail matrix. Although usually found to be bilateral, unilateral Beau's lines may occur. Various systemic and local traumatic factors may cause this. Some are childbirth, measles, paronychia, acute febrile illnesses, and drug reaction. When the process is intermittent the nail plate may resemble corduroy. They may result from almost any systemic illness or major injury, such as a broken hip. Shelley "shoreline" nails appear to be a very severe expression of essentially the

Fig. 33-40 Beau's lines.

Fig. 33-41 Half and half nails.

Fíg. 33-42 Meuhke's lines.

Fig. 33-43 Terry nails.

same transient growth arrest. They have been reported in all 20 nails of a newborn.

- Koh B-K, et al: Transverse nail ridging (Beau's lines) and rough nails after bone marrow transplantation. Int J Dermatol 2004; 43:77.
- Piraccini BM, et al: Drug-induced nail abnormalities. Am J Clin Dermatol 2003;4:31.

Half and Half Nails

Half and half nails show the proximal portion of the nail white and the distal half red, pink, or brown, with a sharp line of demarcation between the two halves (Fig. 33-41). Seventy percent of hemodialysis patients and 56% of renal transplant patients have at least one type of nail abnormality. Absence of lunla, splinter hemorrhage, and half and half nails were significantly more common in hemodialysis patients, while leukonychia was significantly more common in transplant patients.

Saray Y, et al: Nail disorders in hemodialysis patients and renal transplant recipients: a case control study. J Am Acad Dermatol 2004;50:197.

Muehrcke's Lines

Muchrcke described narrow white transverse bands occurring in pairs as a sign of chronic hypoalbuminemia. The lines may resolve when serum albumin is raised to or near normal (Fig. 33-42). Unlike Mees' lines, the disturbance appears to be in the nailbed, not in the nail plate. Similar lines have been reported in patients with normal albumin levels who are receiving chemotherapy. In a case of unilateral Muchrcke's lines associated with trauma, it was suggested that edema effects this change by inducing microscopic separation of the normally tightly adherent nail from its bed. Alam M, et al: Muehrcke's lines in a heart transplant recipient. J Am Acad Dermatol 2001;44:316.

- Fawcett RS, et al: Nail abnormalities: clues to systemic disease. Am Fam Physicían 2004;15:1417.
- Feldman SR, et al: Unilateral Muehrcke's lines following trauma. Arch Dermatol 1989;125:133.

Mees' Lines

Mees described single or multiple white transverse bands in 1919 as a sign of inorganic arsenic poisoning. They have also been reported in thallium poisoning, septicemia, dissecting aortic aneurysm, parasitic infections, chemotherapy, and both acute and chronic renal failure.

Hall AH: Chronic arsenic poisoning. Toxicol Lett 2002;128:69.

Hepburn MJ, et al: Mees' lines in a patient with multiple parasitic infections. Cutis 1997;59:321.

- Quecedo E, et al: Mees' lines: a clue for the diagnosis of arsenic poisoning. Arch Dermatol 1996;132:349.
- Uede, K, et al: Skin manifestations in acute arsenic poisoning from the Wakayama curry-poisoning incident. Br J Dermatol 2003;149:757.

Terry Nails

In Terry nails the distal 1 to 2 mm of the nail shows a normal pink color (Fig. 33-43), the entire nail plate or proximal end has a white appearance as a result of telangiectases in the nailbed. These changes have been noted in 25% of hospitalized patients, most commonly those with cirrhosis, chronic congestive heart failure, and adult-onset diabetes, and in very elderly patients.

Holzberg M, et al: Terry's nails: revised definition and new correlations. Lancet 1984;1:896.

Fig. 33-44 Onychoschizia.

Onychorrhexis (Brittle Nails)

Brittleness with breakage of the nails may result from excessive strong soap and water exposure, nail polish remover, hypothyroidism, anorexia or bullemía, or after oral retinoid therapy. It affects up to 20% of the population. Fragilitas unguium (nail fragility) is part of this process. In a series by Hochman et al of 35 patients treated with B-complex vitamin biotin, 63% showed clinical improvement. The nail plate thickness in patients treated with biotin increases in thickness by 25%. Daily application of white petrolatum may also be helpful.

Hochman LG, et al: Brittle nails: response to daily biotin supplementation. Cutis 1993;51:303.

Scher RK, et al: Brittle nails. Semin Dermatol 1991;10:21.

Uyttendaele H, et al: Brittle nails: pathogenesis and treatment. J Drugs Dermatol 2003;2:48.

Onychoschizia

Splitting of the distal nail plate into layers at the free edge (Fig. 33-44) is a very common problem among women and represents a dyshesion of the layers of keratin, possibly as a result of dehydration. Longitudinal splits may also occur.

Nail polish should be discontinued; nail buffing can be substituted. Frequent application of emollients may be helpful. Biotin has also been shown to be effective in doses up to 2.5 mg/day.

Wallis MS, et al: Pathogenesis of onychoschizia (lamellar dystrophy). J Am Acad Dermatol 1991;24:44.

Stippled Nails

Small, pinpoint depressions in an otherwise normal nail characterize this type of nail change. This may be an early change seen in psoriasis. Stippled nails are also seen with some cases of alopecia areata, in early lichen planus, psoriatic or rheumatoid arthritis, chronic eczematous dermatitis, perforating granuloma annulare, and in some individuals with no apparent disease. The deeper, broader pits are more specific for psoriasis or Reiter syndrome. The pitting in alopecia areata tends to be shallower and more regular, suggesting a "Scotch plaid" (tartan) pattern.

Tosti A, et al: Prevalence of nail abnormalities in children with alopecia areata. Pediatr Dermatol 1994;11:12.

Racquet Nails (Nail en Raquette)

In racquet nails, the end of the thumb is widened and flattened, the nail plate is flattened as well, and the distal phalanx is abnormally short (Fig. 33-45). Racquet nails occur on one or both thumbs and are apparently inherited as an autosomal-dominant trait.

Baran R, et al: Baran and Dawber's diseases of the nails and their management. Oxford: Blackwell Scientific, 2001.

Chevron Nail (Herringbone Nail)

This entity appears to be a rare transient fingernail ridge pattern of children. The ridges arise from the proximal nailfold and converge in a V-shaped pattern toward a midpoint distally.

Parry EJ: Chevron nail/herringbone nail, J Am Acad Dermatol 1999;40:497.

Zaiac MN, et al: Chevron nail. J Am Acad Dermatol 1998;38:773.

Hapalonychia

Softened nails result from a defect in the matrix that makes the nails thin and soft so that they can be easily bent. This type of nail change is attributed to malnutrition and debility. It may be associated with myxedema, rheumatoid arthritis, anorexia, bullemia, leprosy, Raynaud phenomenon, oral retinoid therapy, or radiodermatitis.

Baran R, et al: Baran and Dawber's Diseases of the nails and their management. Oxford: Blackwell Scientific, 2001.

Platonychia

The nail is abnormally flat and broad. It may be seen as part of an autosomal-dominant condition in which multiple nail abnormalities are present in many members of a large family.

Hamm, H, et al: Isolated congenital nail dysplasia: a new autosomal dominant condition. Arch Dermatol 2000;136:1239.

Nail-Patella Syndrome (Hereditary Osteoonychodysplasia, Fong Syndrome)

Nail-patella syndrome comprises numerous anomalies and is characterized by the absence or hypoplasia of the patella and congenital nail dystrophy. Triangular lunulae are characteristic (Fig. 33-46). Other bone features are thickened scapulae, hyperextensible joints, radial head abnormalities, and posterior iliac horns. The skin changes may also include

Fig. 33-45 Raquet nails.

Fig. 33-46 Nail-patella syndrome. (Courtesy of Marshall Guill, MD)

webbing of the elbows. Eye changes such as cataracts and heterochromia of the iris may also be present. Hyperpigmentation of the pupillary margin of the iris ("Lester iris") is a characteristic finding in about half the cases. These patients may exhibit glomerulonephritis with urinary findings of albuminuria, hematuria, and casts of all kinds, especially hyaline casts. They may be predisposed to developing hemolytic-uremic syndrome. Forty percent of patients have renal dysplasia, and 25% suffer from renal failure. It is an autosomal-dominant trait localized to chromosome 9q34.1. Limb and kidney defects seen in L1M-homeodomain protein Lmx1b mutant mice are similar to those present in patients with nail-patella syndrome. Mutations of the human LMX1B gene result in this syndrome.

Buddin D, et al: What syndrome is this? Nail-patella syndrome. Pediatr Dermatol 2002;19:454.

Schulz-Butulis BA, et al: Nail-patella syndrome 2003;49:1086. Sweeney E, et al: Nail patella syndrome. J Med Genet 2003; 40:153.

Onychophagia

Nail biting (Fig. 33-47) is a common compulsive behavior that may markedly shorten the nail bed, sometimes damages the matrix, and leads to pterygium formation. It is a difficult habit to cure.

If there is strong motivation, habit reversal training with awareness training, competing response training, and social support may help. Psychopharmacologic intervention with medications, such as fluoxetine, or hypnosis are other options.

Stein DJ, et al: Dermatology and conditions related to obsessivecompulsive disorder. J Am Acad Dermatol 1992;26:237.

Twohig MP, et al: Evaluating the efficacy of habit reversal: comparison with a placebo control. J Clin Psychiatry 2003;64:40.

Onychotillomania

Onychotillomania is a compulsive neurosis in which the patient picks constantly at the nails or tries to tear them off. Like oncyhophagia, this obsessive-compulsive disorder may be treated by biofeedback, cognitive-behavioral methods, hypnosis, or psychopaharmacologic agents.

Fig. 33-47 Onychophagia.

Inglese M, et al: Onychotilloomania. Cutis 2004;73:171. Shenefelt PH: Biofeedback, cognitive-behavioral methods and hypnosis in dermatology. Dermatol Ther 2003;16:114.

Onycholysis

Onycholysis is a spontaneous separation of the nail plate, usually beginning at the free margin and progressing proximally. Rarely, the lateral borders may be involved, with spread confined to these. Less often separation may begin proximal to the free edge, in an oval area 2 to 6 mm broad, with a yellowish-brown hue ("oil spot"); this is a lesion of psoriasis, as is often the case with ordinary onycholysis. The nail itself is smooth and firm with no inflammatory reaction. Underneath the nail a discoloration may occur from the accumulation of bacteria, most commonly *Pseudomonas*, or yeast, most commonly *Candida*. Color changes, such as green, a result of pyocyanin from *Pseudomonas*, black, or blue may be seen. One or more nails may be affected.

Onycholysis is noted most commonly in women, probably secondary to traumatically induced separation. It is common in patients with hand dermatitis. Keratinization of the distal nailbed, chronic exposure to irritants, untreated dermatitis, and secondary infection with *Candida albicans* are potential reasons for the failure of the nail to reattach itself.

Systemic causes are many: hyper- and hypo-thyroidism, pregnancy, porphyria, pellagra, and syphilis. Onycholysis has also been associated with atopic dermatitis, eczema, lichen planus, congenital abnormalities of the nails, trauma induced by clawing, pinching, stabbing (manicuring), and foreignbody implantation. It may be caused by mycotic, pyogenic, or viral (herpes) infections. Women should be checked for vaginal candidiasis, because that anatomic location may be the source of the infection opportunistically invading and aggravating onycholysis. Chemical causes may include the use of solvents, nail polish base coat, nail hardeners containing formalin derivatives, artificial fingernails, and allergic or irritant contact dermatitis from their use. Rarely, photoonycholysis may occur during or soon after therapy with tetracycline derivatives, psoralens, fluoroquinolones, or chloramphenicol, and subsequent exposure to sunlight. Chemotherapeutic agents and systemic retinoids may induce onycholysis. On rare occasions it may be a sign of metastasis. Autosomal-dominant hereditary forms are also known.

Trauma and chemical irritants should be completely avoided and the nailbed should be kept completely dry. The

Bongers EM, et al: Nail-patella syndrome. Overview on clinical and molecular findings. Pediatr Nephrol 2002;17:703.

Fig. 33-48 Median

nail dystrophy.

affected portion of the nail should be kept clipped away. Drying by exposing the nailbed in this way will rid the area of *Pseudomonas* and assist greatly in eliminating *Candida*. For additional treatment options, refer to the text on the specific cause (see Chapter 14 for *Pseudomonas*, Chapter 15 for *Candida*, and Chapter 10 for psoriasis).

Median Nail Dystrophy (Dystrophia Unguis Mediana Canaliformis, Solenonychia)

Median nail dystrophy consists of longitudinal splitting or canal formation in the midline of the nail. The split, which often resembles a fir tree, occurs at the cuticle and proceeds outward as the nail grows (Fig. 33-48). Trauma has been suspected of being the chief cause; however, many of these cases will persist for years even with scrupulous avoidance of trauma. The deformity may result from a papilloma or glomus tumor in the nail matrix, forcing the production of a structure like a tube (solenos) distal to it. Familial cases and an onset with isotretinoin therapy are other associations.

Griego RD, et al: Median nail dystrophy and habit tic deformity: are they different forms of the same disorder? Int J Dermatol 1995;34:799.

Sweeney SA, et al: Familial median canaliform nail dystrophy. Cutis 2005;75:161.

Fig. 33-49 Ptyrigium inversus ungium.

Pterygium Unguis

Pterygium unguis forms as a result of scarring between the proximal nailfold and matrix. The classic example is lichen planus. It has been reported to occur as a result of sarcoidosis and Hansen's disease. Peripheral circulatory disturbances may also be causative.

Richert BJ, et al: Pterygium of the nail. Cutis 2000;66:343.

Pterygium Inversum Unguis

Pterygium inversum unguis is characterized by adherence of the distal portion of the nailbed to the ventral surface of the nail plate (Fig. 33-49). The condition may be present at birth or acquired and may cause pain with manipulation of small objects, typing, and close manicuring of the nail. It is a condition resulting from the extension of the zone of the nailbed that normally contributes to the formation of the nail plate. This eventually leads to a more ventral and distal extension of the hyponychium. The most common forms of pterygium inversum unguis are the acquired secondary forms caused by systemic connective tissue diseases, particularly progressive systemic sclerosis and systemic lupus erythematosus. If a curved nail is present on the fourth toe only as a congenital lesion, this is an entity unto itself and occurs as an autosomalrecessive trait.

Caputo R, et al: Pterygium inversum unguis: report of 19 cases and review of the literature. Arch Dermatol 1993;129:1307.

Yotsumoto S, et al: Curved nail of the fourth toe. J Am Acad Dermatol 1999;40:123.

Hangnail

Hangnail is an overextension of the eponychium (cuticle), which becomes split and peels away from the proximal or lateral nailfold. These lesions are painful and annoying, so that persistent cuticle biting frequently develops. Trimming these away with scissors is the best solution. The use of emollient creams to keep the cuticle soft is also recommended.

Lee HJ, et al: Minor cutaneous features of atopic dermatitis in South Korea. Int J Dermatol 2000;39:337.

Pincer Nails

Pincer nails, trumpet nails, or omega (from the shape of the Greek letter) nails are alternative terms for a common

Fig. 33-50 Pincer nails.

toenail disorder in which the lateral edges of the nail slowly approach one another, compressing the nailbed and underlying dermis (Fig. 33-50). It may less often occur in the fingernails and is surprisingly usually asymptomatic. It may be an autosomal-dominantly inherited condition or acquired after trauma, Kawasaki's disease or use of β -blockers.

Some treatment success has been obtained with the use of commercial plastic braces after flattening of the nail. Urea ointment under occlusion, or chemical matricectomy with phenol and surgical nailbed repair has also been reported to be effective.

- Bostanci S, et al: Pincer nail deformity: inherited and caused by a beta-blocker. Int J Dermatol 2004;43:316.
- Kim KD, et al: Surgical pearl: nail plate separation and splint fixation – a new non-invasive treatment of pincer nails. J Am Acad Dermatol 2003;48:791.

Onychocryptosis (Unguis Incarnatus, Ingrown Nail)

Ingrown toenail is one of the most frequent nail complaints. It occurs chiefly on the great toes, where there is an excessive lateral nail growth into the nailfold, leading to this painful, inflammatory condition. The lateral margin of the nail acts as a foreign body and may cause exuberant granulation tissue. Unguis incarnatus may be caused by wearing improperly fitting shoes and by improper trimming of the nail at the lateral edges so that the anterior portion cuts into the flesh as it grows distally. Drugs such as isotretinoin, lamivudine, and indinavir may induce periungual granulation tissue mimicking onychocryptosis.

Treatment in mild cases with insertion of a cotton pad, dental floss or a flexible plastic tube beneath the distal corner of the offending nail may make surgery unnecessary. When surgical intervention is necessary, simple removal of the lateral portion of the nail plate can produce significant relief. Another simple operation involves removal of the overhanging lateral nailfold so that the nail does not cut into it. When healed, the nail edge resembles that of the thumb, and an excellent functional result occurs. The nail is not altered, since it is not touched. With the patient under local anesthesia (and with use of a rubber band tourniquet or infiltration of the proximal nailfold for hemostasis), a linear incision is made at the edge of the lateral nailfold perpendicular to the nail plate. A convex incision is made in a curvilinear plane parallel to the nailbed to meet the initial incision. The involved wedge of tissue is removed. The lateral

flap is then approximated by one or two sutures and a petrolatum gauze dressing is applied. Healing is complete in 10 to 14 days.

Partial or complete nail avulsion with ablation of the nail matrix will prevent recurrence. Ablation can be accomplished surgically, with phenol, 10% sodium hydroxide, or with a CO_2 laser. When phenol is used, the proximal nailfold should be incised and reflected to avoid burning the nailfold. As an alternative, it can be left in place and injected with a corticosteroid to reduce the subsequent inflammation. Liquid nitrogen spray to the area of tissue and nail involved for a freeze time of 20 to 30 s has been successful in some patients, but may be painful and is reserved for patients in whom other surgical approaches are not appropriate.

NAIL DISCOLORATIONS

Leukonychia or White Nails

Four forms of white nails are recognized: leukonychia punctata, leukonychia striata, leukonychia partialis, and leukonychia totalis. The punctate variety is common in completely normal persons with otherwise normal nails. Symmetrical sympathetic punctate leukonychia in contralateral or adjacent nails following a current episode of traumatic leukonychia has been described. Leukonychia striata (Fig. 33-51) may be hereditary or of traumatic or systemic origin. Partial leukonychia may occur with tuberculosis, nephritis, Hodgkin's disease, chilblains, metastatic carcinoma, or leprosy, or be idiopathic.

Leukonychia totalis may be hereditary and is of a simple autosomal-dominant type. It may also be associated with typhoid fever, leprosy, cirrhosis, ulcerative colitis, nail biting, use of emetine, cytostatic agents, and trichinosis. Leukonychia may result from abnormal keratinization, with persistence of keratohyalin granules in the nail plate.

A syndrome comprising leukonychia totalis, multiple sebaceous cysts, and renal calculi in several generations has been reported. Other reports have linked total leukonychia with deafness, or with koilonychia; however, it is most often inherited or is an isolated finding.

Claudel CD, et al: (diopathic leukonychia totalis and partialis in a 12-year-old patient. J Am Acad Dermatol 2001;44:379. Zaun H: Leukonychias. Semin Dermatol 1991;10:17.

Fig. 33-51 Leukonychia striata.

Fig. 33-52 Zidovudine-induced hyperpigmentation of the nail.

Longitudinal Erythronychia

Longitudinal red bands in the nail plate that commence in the matrix and extend to the point of separation of the nail plate and nailbed may occur on multiple nails with inflammatory conditions such as lichen planus or Darier's disease. When only a localized single or bifid streak is present, this may signal a benign or malignant tumor of the matrix. The fingernails of middle-aged persons are most commonly affected, with the thumbnail being most frequently involved. There may be a distal keratosis seen, as with Darier, human papilloma virus (HPV) infection, or a squamous cell carcinoma. Excision of this distal keratosis, however, usually does not result in cure or diagnostic findings; biopsy of the affected matrix is necessary. Since this may lead to a scar with a permanent split of the nail plate, observation may be indicated. As in longitudinal melanonychia, if the band broadens over time, then an excisional biopsy is indicated.

de Berker DAR, et al: Localized longitudinal erythronychia. Arch Dermatol 2004;140;1253.

Melanonychia

Black or brown pigmentation of the normal nail plate is termed *melanonychia*. It may be present as a normal finding on many digits in black patients, as a result of trauma, systemic disease, or medication, or as a postinflammatory event from such localized events as lichen planus or fixeddrug reaction.

Longitudinal black or brown banding of the nails has been reported to occur in 77% to 96% of black persons and 11% of Asians. It is a rare finding in white children; however, it is not uncommon in white adults. In a series by Duhard the prevalence of melanonychia was 12.6 in 100 in a white hospitalized population, and 1.4 in 100 in 4400 white clinic-based patients. The risk increased with age, the peak occurring between ages of 56 and 65.

Pigmentation of the nails may occur with acanthosis nigricans, Addison's disease, Peutz-Jeghers syndrome, vitamin B_{12} deficiency, after adrenalectomy for Cushing syndrome, as a part of Laugier-Hunziker syndrome (pigmentation of the nails associated with buccal and lip hyperpigmentation), with

Fig. 33-53 Longitudinal melanonychia.

PUVA or ionizing radiation treatment, and as a drug-induced melanocyte activation with such medications as chemotherapy, antimalarials, minocycline, zidovudine (Fig. 33-52), or gold. Friction may cause longitudinal pigmented bands in the toenails, and subungual hemorrhage or black nail caused by *Proteus mirabilis* or *Trichophyton rubrum* may enter into the differential diagnosis of a dark nail.

When only one nail is affected by melanonychia striata (a single longitudinal band of brown or black color [Fig. 33-53]) a tumor of the nail matrix is the most important consideration. The location in the matrix can be inferred from the location of the pigment in the nail plate when viewed on end. Dorsal nail-plate pigmentation results from a proximal matrix lesion. Ventral nail-plate pigmentation is the result of a lesion in the distal matrix. Leaute-Labreze et al, Goettmann-Bonvallot et al, and Tosti et al found longitudinal melanonychia that appeared in children to be benign in nature, and it is recommended that since an ungual melanonychia.

cytic band can appear at an age when other nevi appear, surgical excision should be undertaken only in the event of progressive change.

Tosti et al studied 100 white adult patients with a single band of longitudinal melanonychia of unknown cause. Biopsies revealed melanocytic hyperplasia in 65, nevi in 22, melanocytic activation in 8, and melanoma in 5. Whereas they were unable to ascertain any clear clinical criteria that would exclude melanoma, they recommended a 3-mm biopsy of any white adult with the appearance of a longitudinal band of pigment in one nail without a clear relation to a definite cause. They excised all melanoma, nevi or melanocytic hyperplasia lesions. Retracting the proximal nailfold to expose the origin of the streak at the matrix allows selection of the best biopsy site.

Melanoma is most likely to be present if the longitudinal band is enlarging in width, if dermoscopy reveals a brown coloration of the background and the presence of irregular longitudinal lines, or if there is periungual extension of brown-black pigmentation onto the proximal or lateral nailfold (Hutchinson's sign). The latter is not pathognomonic, however, as Bowen's disease may produce this appearance, and pigmentation of the nail matrix and proximal nailbed may reflect through the nailfold (pseudo-Hutchinson's sign).

Green Nails

When onycholysis is present, a green discoloration may occur in the onycholytic area as a result of an infection with *Pseudomonas aeruginosa* (see Chapter 14). The color change may also occur as transverse green stripes. The stripes are ascribed to intermittent episodes of infection. Green nails may also result from copper in tap water.

Agger WA, et al: *Pseudomonas aeruginosa* infections of intact skin. Clin Infect Dis 1995;20:302.

Staining of the Nail Plate

Nicotine, dyes (including hair dyes and nail polish), potassium permanganate, mercury compounds, hydroquinone, elemental iron, mepacrine, photographic developer, anthralin, chrysarobin, glutaraldehyde, or resorcin may cause nail-plate staining. This is only a partial list; a complete listing is given in the article by Jeanmougin et al. A helpful diagnostic maneuver to distinguish nail-plate staining from exogenous sources and nail-plate pigmentation from melanin or endogenous chemicals is to scrape the surface of the nail plate several times firmly with a glass slide or scalpel blade. Exogenous stains frequently scrape off completely if the agent has not penetrated the entire nail plate. If the stain follows the curvature of the lunulae, it is probably endogenous; if it follows the curvature of the proximal and lateral nailfolds, it is exogenous.

Coulson IH: "Fade out" photochromonychia. Clin Exp Dermatol 1993;18:87.

Jeanmougin M, et al: Nail dyschromia. Int J Dermatol 1983;22:279. Olsen TG, et al: Contact exposure to elemental iron causing chromonychia. Arch Dermatol 1984;120:102.

Red Lunulae

Dusky erythema confined to the lunulae has been reported in association with alopecia areata. Twenty percent of patients with systemic lupus erythematosus have been reported to have this abnormality. It may also be seen in patients on oral prednisone for severe rheumatoid arthritis or dermatomyositis, in cardiac failure, cirrhosis, lymphogranuloma venereum, psoriasis, vitiligo, chronic urticaria, lichen sclerosus et atrophicus, CO_2 poisoning, chronic obstructive pulmonary disease, twenty-nail dystrophy, and reticulosarcoma. The cause may be vascular congestion.

- Bergner T, et al: Red lunulae in severe alopecia areata. Acta Derm Venereol 1992;72:203.

- Wollina U, et al: Lupus erythematosus-associated red lunula. J Am Acad Dermatol 1999;41:419.

Spotted Lunulae

This distinctive change occurs with alopecia areata.

Cohen PR: The lunula. J Am Acad Dermatol 1996;34:943. Shelley WB: The spotted lunula: a neglected nail sign with alopecia areata. J Am Acad Dermatol 1980;2:385.

Purpura of the Nail Beds

Purpura beneath the nails usually results from trauma. Causes of toe involvement include physical pressure on the toes, such as that seen in surfboarding by a windsurfer trying to maintain his balance, or exogenous pressure exerted from poorly fitting shoes. It may simulate a melanoma if the patient does not communicate the acuteness at onset.

- Adams BB: Dermatologic disorders of athletes, Sports Med 2002;32:309.
- Pierson JC, et al: Pen push purpura: iatrogenic nail bed hemorrhages in the intensive care unit. Cutis 1993;51:422.

Blue Nails

A blue discoloration of the lunulae is seen in argyria and cases of hepatolenticular degeneration (Wilson's disease). The blue color in the latter is probably related to the changes in the copper metabolism by the patient. It has also been reported in hemoglobin M disease and hereditary acrolabial telangiectases.

Lunular blue color, as well as blue discoloration of the whole nailbed, occurs with some therapeutic agents, especially 5-FU, minocycline, imipramine, mepacrine and other antimalarials, hydroxyurea, phenothalein and azidothymidine. Blue discoloration may also result from subungual hematoma and melanotic whitlow. Mepacrine and other antimalarials may stain the nails blue. Blue nails are a normal variant finding in blacks.

- Glaser DA, et al: Blue nails and acquired immunodeficiency syndrome: not always associated with azidothymidine use. Cutis 1996;57:243.
- Piraccini BM, et al: Drug-induced nail abnormalities. Am J Clin Dermatol 2003;4:31.

Yellow Nail Syndrome

The yellow nail syndrome is characterized by marked thickening and yellow to yellowish-green discoloration of the nails often associated with systemic disease, most commonly lymphedema and compromised respiration. The nails are typically over-curved both transversely and longitudinally, grow very slowly (<0.2 mm/week), are often subject to onycholysis, and lose both lunulae and cuticles (Fig. 33-54). Lymphedema, pleural effusions, chronic pulmonary infections, and chronic sinusitis most commonly precede the nail changes. Other less frequent associated conditions include autoimmune disorders, immunodeficiency states, the use of

Fig. 33-54 Yellow nail syndrome.

gold or D-penicillamine, and malignancies. In the latter cases, treatment of the underlying lymphoma or solid tissue tumor has resulted in improvement of the nail findings. Clinical responses have been shown with taking 800 IU/day of D- α -tocopherol and topical vitamin E solution. Itraconazole, alone or in combination with vitamin E, and oral zine supplementation have also been used with success in individual cases.

- Williams HC, et al: Successful use of topical vitamin E solution in the treatment of nail changes in yellow nail syndrome. Arch Dermatol 1991;127:1023.

NEOPLASMS OF THE NAILBED

Various benign and malignant neoplasms may occur in or overlying the nail matrix and in the nailbed. Signs heralding such neoplasms are paronychia, ingrown nail, onycholysis, pyogenic granuloma, nail-plate dystrophy, longitudinal erythronychia, bleeding, and discolorations. Symptoms of pain, itching, and throbbing may also occur with various neoplasms.

Benign tumors of the nails include vertuca, pyogenic granuloma, fibromas, nevus cell nevi, myxoid cysts, angiofibromas (Koenen tumors), and epidermoid cysts. Pyogenic granuloma-like lesions may occur during treatment with isotretinoin, lamivudine or indinavir. Glomangioma is readily recognized by exquisite tenderness in the nailbed. Enchondroma of the distal phalanx has been described. It often presents as a paronychia. Subungual exostoses may also present as an inflammatory process, but more commonly resemble a vertuca or fibroma at the start. Most of these are on the great toe, and radiographic evaluation will aid in the diagnosis of these last two entities. Tender swelling of the distal finger with nail distortion and radiographic evidence of solitary lytic changes can be caused by intraosseous epidermoid cysts.

Squamous cell carcinoma of the nailbed is uncommon, and often mistaken for a pyogenic granuloma initially. Radiographs may reveal lytic changes in the distal phalanx. Metastases are rare. Mohs surgery is the treatment of choice. Bowen's disease may occur here, and on more than one digit; often the condition occurs secondary to HPV infection (Fig. 33-55). When keratoacanthoma occurs, there is often

Fig. 33-55 Bowen's disease.

lysis of underlying bone, which fills in after excision of the tumor.

Subungual melanoma (Fig. 33-56) is frequently diagnosed late in the course of growth, since it simulates onychomycosis or subungual hematoma, with which it is confused. Amelanotic melanoma may occur and may be mistaken (or granuloma pyogenicum. Although melanoma is rare among Japanese, periungual and subungual melanoma is more fre-

Fig. 33-56 Subungual melanoma.

quently found in Japanese than in other ethnic populations. Discussion of melanoma in this location may be found in Chapter 30 and in the melanonychia section of this chapter.

CHAPTER

Disorders of the Mucous Membranes

Lesions on the mucous membranes may be more difficult to diagnose than lesions on the skin, and not merely because they are less easily and less often seen. There is less contrast of color and greater likelihood of alterations in the original appearance because of secondary factors, such as maceration from moisture, abrasion from food and teeth, and infection. Vesicles and bullae rapidly rupture to form greyish erosions, and the epithelium covering papules becomes a soggy lactescent membrane, easily rubbed off to form an erosion. Grouping and distribution are less distinctive in the mouth than on the skin, and not infrequently it is necessary to establish the diagnosis by observing the character of any associated cutaneous lesions or by noting subsequent developments.

CHEILITIS

Cheilitis Exfoliativa

The term *cheilitis exfoliativa* has been used to designate a primarily desquamative, mildly inflammatory condition of the lips, of unknown cause, and also a clinically similar reaction secondary to other disease states. The former is a persistently recurring lesion that produces scaling and sometimes crusting; it most often affects the upper lip. The recurrent exfoliation leaves a temporarily erythematous and tender surface.

In the latter form, the lips are chronically inflamed and covered with crusts that from time to time tend to desquamate, leaving a glazed surface on which new crusts form. Fissures may be present, and there may be burning, tenderness, and some pain. The lower lip is more often involved, with the inflammation limited to the vermilion part. The cheilitis may be secondary to seborrheic dermatitis, atopic dermatitis, psoriasis, retinoid therapy, pyorrhea, longterm actinic exposure, or the habit of lip licking (Fig. 34-1). Uncommonly, the initial or only manifestation of atopic dermatitis may be a chronic cheilitis. Irritating or allergenic substances in lipsticks, dentifrices, and mouthwashes may be causative factors. Dyes in lipsticks may photosensitize. Candidiasis may be present. Cheilitis may be part of the Plummer-Vinson syndrome or Sjögren syndrome. Cheilitis is not uncommon in patients with AIDS, and is a known common complication of protease inhibitor therapy. These and other uncommon causes of cheilitis are discussed in more detail within the specific entities.

The only uniformly effective treatment is the elimination of causes when they can be found. Topical tacrolimus ointment, pimcrolimus cream, or low strength corticosteroid ointments and creams are usually helpful. If the underlying etiology is determined, specific therapy may be instituted. When there are fissures, petrolatum or zinc oxide ointment may be useful.

Allergic Contact Cheilitis

The vermilion border of the lips is much more likely to develop allergic contact sensitivity reactions than is the oral mucosa. Allergic cheilitis is characterized by dryness, fissuring, edema, crusting, and angular cheilitis.

Over 90% of patients are women and over half of the reactions are due to lipsticks. While patch testing will reveal a relevant positive in approximately 25% to 30% of patients, about one in five will only react to their own product. It may

Fig. 34-1 Cheilitis secondary to lip licking.

result from use of topical medications, dentifrices and other dental preparations, antichap agents, lipsticks, and sunscreencontaining lip balms; from contact with cosmetics, nail polish, rubber, and metals; or from eating foods such as mangoes. Exotic or occupational causes may occur, such as an allergic response to cane reed among saxophonists or clarinetists.

Treatment includes discontinuation of exposure to the offending agent and administration of topical tacrolimus, pimecrolimus or corticosteroid preparations.

Actinic Cheilitis

Actinic cheilitis is an inflammatory reaction of the lips to chronic excessive sunlight exposure over many years. The lower lip, which is usually the only one involved, becomes scaly, fissured, and at times eroded and swollen; leukoplakia and even squamous cell carcinoma may develop (Fig. 34-2). Painful erosions may occur; actual ulceration is very rare unless carcinoma has developed. Hereditary polymorphous light eruption can resemble chronic actinic cheilitis, but it has no malignant potential.

Avoiding sun exposure and the use of sunscreen containing lip pomades suffice to minimize further damage. A biopsy should be performed on any suspicious, thickened areas that persist; preferably, a shave technique should be used to avoid scarring.

Cryosurgical treatment may be effective, particularly for localized lesions. In cases with diffuse involvement, application of topical 5-fluorouracil (5-FU), imiquimod, or photodynamic therapy using 5-aminolevulinic acid may be curative. Treatment with a CO_2 laser or electodessication

Fig. 34-2 Actinic cheilitis.

may be required for severe disease and provides excellent results. The latter is a less expensive ablative therapy, but takes longer to heal (23 days compared to 14 with the laser). Should this treatment fail, vermilionectomy of the lower lip may be necessary. Excision of the exposed vermilion mucous membrane with advancement of the labial mucosa to the skin edge of the outer lip is effective, but this is performed less frequently since the advent of laser therapy. Refer to Chapter 29 for more information on actinic cheilitis.

Cheilitis Glandularis

Cheilitis glandularis is characterized by swelling and eversion of the lower lip, patulous openings of the ducts of the mucous glands, cysts, and general enlargement of the lips (Fig. 34-3). Mucus exudes freely to form a gluey film that dries over the lips and causes them to stick together during the night. When the lip is palpated between the thumb and index finger, the enlarged mucous glands feel like pebbles beneath the surface. The lower lip is the site of predilection.

In general, two types are recognized, namely, cheilitis glandularis simplex and cheilitis glandularis apostematosa. (Apostematosa means "with abscess formation.") The latter type probably stems from the simplex form by the development of infection. Cheilitis glandularis is a chronic inflammatory reaction that is due to an exuberant response to chronic irritation, atopic, factitious, or actinic damage.

On biopsy, there is a moderate histiocytic, lymphocytic, and plasmocytic infiltration in and around the glands. Some believe it to be a disorder of ductal ectasia. Cheilitis glandularis has been reported to eventuate in squamous cell carcinoma, but these cases may be attributed to chronic sun exposure, which frequently precedes cheilitis glandularis.

Treatment depends on the nature of the antecedent irritation; in most cases, treatment as described for actinic cheilitis is appropriate. Surgical debulking may be necessary. Intralesional triamcinolone may be beneficial in some cases.

Angular Cheilitis

Angular cheilitis is synonymous with *perlèche*. Fissures radiate downward and outward from the labial commissures. It is an intertriginous dermatitis caused by excessive wetness or dryness. It is often complicated with secondary infection by *Candida albicans* or *Staphyloccocus aureus*.

The disease usually occurs in elderly people who wear dentures, but it may develop simply from an overhanging of the upper lip and cheek, and recession and atrophy of the alveolar ridges in old age. Measuring the facial dimensions with a ruler and tongue blade will help with objective assessment of the importance of decreased vertical [acial dimension in the development of perlèche. If the distance from the base of the nose to the lower edge of the mandible is 6 mm or more less than the distance from the center of the pupil to the parting line of the lips, the vertical dimension is decreased. In these circumstances, drooling is usually a factor. In children, angular cheilitis occurs commonly in thumb suckers, gum chewers, and lollipop eaters. Other inciting factors include ribollavin deficiency, anorexia nervosa, Down syndrome, intraoral candidiasis, especially in patients with diabetes, acquired immune deficiency syndrome (AIDS), or clironic mucocutaneous candidiasis, Sjögren syndrome, druginduced xerostomia, and atopic dermatitis.

Opening the "bite" by improving denture fit, capping teeth, replacing lost teeth, or increasing denture height, combined with topical use of nystatin and iodochlorhydroxyquin (Vioform) in hydrocortisone ointment, is usually effective when the condition is associated with anatomically predisposing factors. Stubborn cases typically respond to a slightly stronger corticosteroid, such as desonide, in combination with a topical anticandidal agent. Injection of collagen or insertion of Softform implants to obliterate the angular creases may be beneficial. Therapy for underlying diseases should be maximized. If *S. aureus* is present mupirocin ointment may be needed. Excision of the region, followed by a rotating flap graft, is another therapeutic option, but surgery should not be the first treatment tried. oral soft tissue pathologies. Parts I and II. Plasma Cell Cheilitis

This is also referred to as *plasma cell orificial mucositi* or when the gingival is the site of involvement, *plasma cell gingivitis*. It is characterized by a sharply outlined, infiltrated, dark red plaque with a lacquer-like glazing of the surface of the involved area.

This lesion has the same lesion microscopic features as Zoon balanitis plasmacellularis. There is plasma cell infiltration in a bandlike pattern. Plasma cell cheilitis is not a response that is specific for any stimulus but rather represents a reaction pattern to any one of a variety of stimuli. Successful therapies include application of topical tacrolinus ointment or clobetasol propionate ointment twice a day.

Plasmoacanthoma Plasma cell cheilitis and plasmoacanthoma have been reported in the same patient and are believed to represent a spectrum of the same disease. Plasmoacanthoma is a verrucous tumor with a plasma cell infiltrate involving the oral mucosa, particularly along the angles. C. albicans has been found within the tissue, suggesting that it may be implicated as a cause of this disease.

Drug-Induced Ulcer of the Lip

Painful or tender well-defined ulcerations without induration on the lower lip may heal after withdrawal of oral medications. The causative drugs may be phenylbutazone, chlorpromazine, phenobarbital, methyldopa, or thiazide diuretics.

Solar exposure appears to be a predisposing causative influence; in some cases this reaction may represent a fixed drug photoeruption. On rare occasions, fixed drug eruptions may also involve the lip; usually the culprit is naproxen or one of the oxicams (Fig. 34-4).

Ozkaya-Bayazit E: Specific site involvement with fixed drug eruptions. J Am Acad Dermatol 2003;49:1003.

Other Forms of Cheilitis

Several diseases discussed elsewhere may affect the lips, including lichen planus, lupus erythematosus, atopic dermatitis and psoriasis. A high percentage of patients with Down syndrome have cheilitis of one or both lips. Lip biting may be a factor.

ORAL AND CUTANEOUS CROHN'S DISEASE

Crohn's disease is a chronic granulomatous disease of any part or parts of the bowel, to which the names *terminal ileitis*, *regional enteritis*, *ileocolitis*, *segmental colitis*, and granulomatous colitis have also been given. Patients with Crohn's disease may develop inflammatory hyperplasia of the oral mucosa, with metallic dysgeusia and gingival bleeding.

Reported typical changes include diffuse oral swelling, focal mucosal hypertrophy and fissuring (cobble-stoning), persistent ulceration, polypoid lesions, indurated fissuring of the lower lip, angular cheilitis, granulomatous cheilitis, or pyostomatitis vegetans. Oral involvement occurs in 10% to 20% of cases of Crohn's disease, and 90% have granulomas on biopsy. Males with early-onset disease are most often affected. Concomitant involvement of the anal and esophageal mucosa is common.

Many cases of Crohn's disease with other cutaneous manifestations have been reported, notably pyoderma gangrenosum (more closely associated with ulcerative colitis) and erythema nodosum, polyarteritis nodosa, pellagra, pernicious anemia, an acrodermatitis-like eruption, urticaria, and necrotizing vasculitis. Direct extension to perianal skin may occur.

Metastatic Crohn's disease denotes noncaseating granulonatous skin lesions in patients with Crohn's disease. In the absence of bowel involvement, the diagnosis cannot be made. Genital swelling, leg ulceration, pyogenic granuloma-like lesions of the retroauricular skin, or erythematous nodules, plaques, or ulcers in other locations are the morphologic appearances seen.

Treatment of the gastrointestinal manifestations with sulfasalazine, systemic corticosteroids, infliximab or immunosuppressive medications can improve the cutaneous findings. Several delivery systems use only the active ingredient of sulfasalazine, mesalamine. These include Asacol, Pentasa, Rowasa, and olsalazine, and they may be useful in treating the skin involvement of Crohn's disease. A mouthwash containing triamcinolone acetonide, tetracycline, and lidocaine may provide symptomatic and objective improvement. Budesonide, a well-absorbed oral corticosteroid that has a high rate of first-pass metabolism in the liver, has been shown to be effective in treating Crohn's disease while causing fewer long-term side effects. Cyclosporin, azathioprine, and oral metronidazole have also been shown to be effective as firstline agents. Mycophenolate mofetil and methotrexate may also be considered. Cutaneous ulcerated granulomas and

Fig. 34-5 Pyostomatits vegetans. (Courtesy of Charles Casima, MD)

erythematous plaques caused by Crohn's disease may respond to high-potency topical corticosteroids or tacrolimus ointment. Curettage and zinc by mouth have resulted in healing in several reported patients. Dietary manipulation is another measure that can be helpful in select individuals. The course is often prolonged over several years.

PYOSTOMATITIS VEGETANS

Pyostomatitis vegetans, an inflammatory stomatitis, is most often seen in association with ulcerative colitis but may also occur in other inflammatory bowel diseases, such as Crohn's disease. Edema and erythema with deep folding of the buccal mucosa characterize it, together with pustules, small vegetating projections, erosions, ulcers, and fibrinopurulent exudates (Fig. 34-5). Eroded pustules fuse into shallow ulcers, resulting in characteristic "snail-track" ulcers. It has also been associated with sclerosing cholangitis. Several cases have been reported without any underlying systemic disorder.

Histologically, there are dense aggregates of neutrophils and eosinophils. At times, crusted erythematous papulopustules that coalesce into asymmetrical annular plaques may occur with or after the oral lesions. The associated skin lesions favor the axilla, groin, and scalp. Topical corticosteroids may be effective; systemic steroids or infliximab, however, are usually necessary.

CHEILITIS GRANULOMATOSA

Miescher in 1945 reported six cases of swelling of the lips with progressive changes resulting in permanent macrocheilia. Cheilitis granulomatosa is characterized by a sudden onset and progressive course terminating in chronic enlargement of the lips. Usually the upper lip becomes swollen first: several months may elapse before the lower lip becomes swollen. Usually only enlargement is present, without ulceration, fissuring, or scaling. The swelling remains permanently. It may be a part of the Melkersson-Rosenthal syndrome when associated with facial paralysis and plicated tongue.

The cause is unknown. Histologically, it is characterized by an inflammatory reaction of lymphocytes, histiocytes, and plasma cells and tuberculoid granulomas consisting of epithelioid and Langerhans giant cells. In the differential diagnosis, solid edema, angioedema, cheilitis glandularis, sarcoidosis, oral Crohn's disease, infectious granulomas, and Ascher syndrome must be considered. This may be the presenting sign in a patient who will develop Crohn's disease or sarcoidosis at a later time.

Treatment with intralesional injections of corticosteroids is sometimes successful. In the firmly established case, surgical repair of the involved lip through a mucosal approach and in some cases, concomitant intralesional steroid treatment give best results. Other anecdotally effective medications include tetracyclines, hydroxychloroquine, clofazimine, and sulfasalazine.

MELKERSSON-ROSENTHAL SYNDROME

Melkersson in 1928 and Rosenthal in 1930 described a triad consisting of recurring facial paralysis or paresis, soft nonpitting edema of the lips, and scrotal tongue.

Attacks usually start during adolescence, with permanent or transitory paralysis of one or both facial nerves, repeated migraine attacks, and recurring edema of the upper lip, cheeks, and occasionally the lower lip and circumoral tissues. Swelling of the skin and mucous membranes of the face and mouth is the dominant finding and the most important diagnostic feature (Fig. 34-6). In order of frequency, the swelling occurs first on the upper lip, then the lower lip, and then other regions.

Fig. 34-6 Melkersson-Rosenthal syndrome. (Courtesy of Curt Samlaska, MD)

Extrafacial swellings appear on the dorsal aspect of the hands and feet, and in the lumbar region. The pharynx and respiratory tract may be involved, with thickening of the mucous membrane. The relapsing condition produces an overgrowth of connective tissue, edema, atrophy of the muscle fibers, and inflammatory infiltrates, with permanent deformities of the lips, cheeks, and tongue.

The cause is unknown. The association at times with megacolon, otosclerosis, and craniopharyngioma supports the theory of a neurotrophic origin. It may be familial.

Histopathologic evaluation shows a tuberculoid type of granuloma with lymphedema and a banal perivascular infiltrate. In the differential diagnosis, a number of diseases characterized by edema of the lips, must be considered. Ascher syndrome consists of swelling of the lips with edema of the eyelids (blepharochalasis) and is inherited. Melkersson-Rosenthal syndrome must also be differentiated from the acute swellings produced by angioedema, trauma, and infections of all sorts. Lymphangioma, hemangioma, neurofibroma, and sarcoidosis are some of the diseases to be considered on a clinical basis.

Melkersson-Rosenthal syndrome is frequently seen in an incomplete form, and other granulomatous diseases may present as swellings of the lips or oral-facial tissues. It is worthwhile to consider these as a group called *orofacial* granulomatosis so that various underlying disease states or etiologic factors will not be missed when evaluating such patients. Oral Crohn's disease, patients who will develop typical Crohn or sarcoidosis in the future, cheilitis granulomatosa, sarcoidosis, granulomatous infiltrates associated with tooth infections, and patients with food or contact allergic reactions should all be considered.

There is no satisfactory treatment, although intralesional injections of corticosteroids may be beneficial. Decompression of the facial nerve may be indicated in those patients with recurrent attacks of facial palsy. Surgery alone or combined with intralesional steroid injections may be more successful than either alone. Odontogenic infection has been reported to initiate this condition and antibiotic therapy for this may lead to remission. Clofazimine, thalidomide, and prednisone combined with minocycline or tetracycline have been reported to improve individual patients.

FORDYCE'S DISEASE (FORDYCE SPOTS)

Fordyce spots are ectopically located sebaceous glands, clinically characterized by minute orange or yellowish pinheadsized macules or papules in the mucosa of the lips, cheeks, and, less often, the gums. Similar lesions may occur on the areola, glans penis, and labia minora. Prominent lip involvement may result in a lipstick-like mark left on the rim of a glass mug after consuming a hot beverage (Meffert's sign). Involvement of the labial mucosa with pseudoxanthoma elasticum may simulate Fordyce spots.

Because the anomaly is asymptomatic and inconsequential, treatment should be undertaken only if there is a significant cosmetic problem. CO_2 laser or isotretinoin are therapeutic options.

STOMATITIS NICOTINA

Also known as *smoker's keratosis* and *smoker's patches*, stomatitis nicotina is characterized by distinct umbilicated papules on the palate. The ostia of the mucous ducts appear as red pinpoints surrounded by milky white, slightly umbilicated asymptomatic papules. The intervening mucosa becomes white and thick and has a tendency to desquamate in places, leaving raw, beefy red areas. Ulceration and the formation of aphthous ulcers may occur.

This condition is attributed to heavy smoking in middleaged men, although it has also been reported in nonsmokers who habitually drink hot beverages. Heat may be the causative event. Indeed, the most severe cases are associated with the type of tobacco use that produces intense heat pipe and reverse smoking.

Treatment consists of abstaining from the use of tobacco or ingestion of hot liquids.

Mirbod SM, et al: Tobacco-associated lesions of the oral cavity. J Can Dent Assoc 2000;66:252.

Fig. 34-7 Torus palantinus. (Courtesy of James Fitzpatrick, MD)

Taybos G: Oral changes associated with tobacco use. Am J Med Sci 2003;326:179.

TORUS PALATINUS

Torus palatinus is a bony protuberance in the midline of the hard palate, marking the point of junction of the two halves of the palate (Fig. 34-7). It is asymptomatic. Exostosis also commonly occurs in the floor of the mouth, involving the inner surface of the mandible.

Cagirankaya LB, et al: Is torus palatinus a feature of a welldeveloped maxilla? Clin Anat 2004;17:623.

Piera-Navarro N, et al: Clinical evaluation of hard tissue proliferations of the mouth. Med Oral 2002;7:97.

FISSURED TONGUE

Also known as *furrowed tongue*, scrotal tongue or lingua plicata, fissured tongue is a congenital and sometimes familial condition in which the tongue is generally larger than normal and there are plicate superficial or deep grooves, usually arranged so that there is a longitudinal furrow along the median raphe, reminiscent of scrotal rugae (Fig. 34-8).

Fissured tongue is seen in Melkersson-Rosenthal syndrome and in most patients with Down syndrome. Individual case reports have been seen in association with pachyonychia congenita, pemphigus vegetans, and Cowden syndrome. Geographic tongue occurs together with fissured tongue in 50% of patients, and both may appear in the setting of pustular psoriasis.

The condition gives rise to no difficulty, and treatment is not necessary, except that the deep furrows should be kept clean by use of mouthwashes.

Byrd JA, et al: Glossitits and other tongue disorders, Dermatol Clin 2003;21:123.

Leston JM, et al: Oral mucosa. Cutis 2002;69:215.

GEOGRAPHIC TONGUE

Geographic tongue is also known as *lingua geographica*, transitory benign plaques of the tongue, glossitis areata exfoliativa, and benign migratory glossitis. In some patients it is a manifestation of atopy, and in others, of psoriasis. However, in most it is an isolated finding.

Rossie KM, et al: Thermally induced nicotine stomatitis. Oral Surg Oral Med Oral Pathol 1990;70:597.

Fig. 34-8 Fissured tongue. (Courtesy of James Fitzpatrick, MD)

The dorsal surface of the tongue is the site usually affected. Geographic tongue begins with a small depression on the lateral border or the tip of the tongue, smoother and redder than the rest of the surface. This spreads peripherally, with the formation of sharply circumscribed ringed or gyrate red patches, each with a narrow vellowish-white border, making the tongue resemble a map. The appearance changes from day to day; patches may disappear in one place and manifest themselves in others. The disease is characterized by periods of exacerbation and quiescence. The lesion may remain unchanged in the same site for long periods. The condition is frequently unrecognized because it produces no symptoms except for the occasional complaint of glossodynia.

There are two clinical variants of geographic tongue. In one type, discrete, annular "bald" patches of glistening, erythematous mucosa with absent or atrophic filiform papillae are noted. Another type shows prominent circinate or annular white raised lines that vary in width up to 2 mm. The clinical appearance and histopathologic findings of the tongue lesions in pustular psoriasis, reactive arthritis (Reiter syndrome), and geographic tongue are identical; when occurring with psoriasis or reactive arthritis, the name annulus migrans has been suggested for this entity (Fig. 34-9). It has been reported to be acquired in patients with AIDS or as a result of lithium therapy.

Histologically, the main features are marked transepidermal neutrophil migration with the formation of spongiform pustules in the epidermis and an upper dermal mononuclear infiltrate.

Although treatment is not usually necessary, a 0.1% solution of tretinoin solution (Retin-A) applied topically has produced clearing within 4 to 6 days.

BLACK HAIRY TONGUE

Black or brown hairy tongue occurs on the dorsum of the tongue anterior to the circumvallate papillae, where black, vellowish, or brown patches form, consisting of hairlike intertwining filaments several millimeters long (Fig. 34-10). The "hairs" result from a benign hyperplasia of the filiform papillae of the anterior two-thirds of the tongue, resulting in retention of long conical filaments of orthokeratotic and parakeratotic cells. It occurs far more frequently in men than in women.

Black hairy tongue may be associated with several conditions that may be predisposing factors in its causation: excessive smoking, use of oral antibiotics, and presence of Candida on the surface of the tongue.

This lesion may be differentiated both clinically and histologically from oral hairy leukoplakia, which is seen in human immunodeficiency syndrome (HIV)-infected patients. Hairy leukoplakia is usually seen on the lateral surface of the tongue in at first corrugated patches, then with time as solid white plaques that are adherent. Microscopic examination reveals acanthosis, parakeratosis, irregular projections of keratin, and vacuolated keratinocytes with Epstein-Barr virus present within them.

A toothbrush may be used to scrub off the projections, either alone, with 1% to 2% hydrogen peroxide, or after application of Retin-A gel, 40% aqueous solution of urea, or papain (meat tenderizer). Such predisposing local factors as smoking, antibiotics, and oxidizing agents should be eliminated, if possible, and scrupulous oral hygiene should be maintained.

ERUPTIVE LINGUAL PAPILLITIS

Lacour and Perrin first described this acute, self-limiting inflammatory stomatitis in 1997. It affects children of both sexes equally with a mean age of onset of 31/2 years. It has a seasonal distribution with the majority of cases occurring in the spring. Fever (40%), difficulties in feeding (100%), and intense salivation (60%) are common symptoms. The tongue examination reveals inflammatory hypertrophy of the fungiform papillae on the tip and dorsolateral sites. Additional signs include submandibular or cervical adenopathy (40%) and angular cheilitis (10%). Associated skin eruptions have not been described. Spontaneous involution occurs in a mean of 7 days with a range of 2 to 15 days. Recurrence is noted in 13%. It is felt to be the result of a viral infection, and the 50% transmission among family members further supports this theory.

SMOOTH TONGUE

Also known as bald tongue or atrophic glossitis, the smooth glossy tongue is often painful and results from atrophy of the filiform and eventually the fungiform papillae (Fig. 34-11). When present with vitamin B_{12} deficiency it has been termed *Moeller* or *Hunter glossitis*. It begins with the tip and lateral surfaces of the tongue becoming intensely red, well-defined irregular patches in which the filiform papillae are absent or thinned and the fungiform papillae are swollen. The disease is chronic and the patches are painful and sensitive so that eating may be difficult and taste impaired. With time the entire tongue becomes smooth and a leukoplakia may result. Treatment is directed against pernicious (macrocytic) anemia. With specific vitamin B_{12} therapy, there will be improvements in the appearance and sensitivity of the tongue.

Atrophic glossitis is also a distinctive sign of pellagra; it results from a deficiency of niacin or its precursor, tryptophan. The sides and tip of the tongue are erythematous and edematous, with imprints of the teeth. Eventually, the entire tongue assumes a beefy-red appearance. Small ulcers appear, and all the mucous membranes of the mouth may be involved. Later the papillae become atrophied to produce a smooth, glazed tongue, as seen in pernicious anemia. Burning or pain in the ulcers may be present. Increased salivary flow early in the disease may lead to drooling and angular cheilitis. In malabsorption syndrome, riboflavin

MEDIAN RHOMBOID GLOSSITIS

Median rhomboid glossitis is characterized by a shiny oval or diamond-shaped elevation, invariably situated on the dorsum in the midline immediately in front of the circumvallate papillae (Fig. 34-12). The surface is abnormally red and smooth. In some instances a few pale yellow papules surmount the elevation. On palpation the lesion feels slightly firm, but it usually causes no symptoms. It persists indefinitely with little or no increase in size. There is no relationship to cancer.

It may result from abnormal fusion of the posterior portion of the tongue, but it is nearly always chronically infected with *Candida*. If there is palatal inflammation above the inflamed part of the tongue, AIDS should be suspected and an HIV test obtained. Histologically, the changes are those of a simple, chronic inflammation with fibrosis, and usually with fungal hyphae in the parakeratin layer. Treatment with oral antifungals, such as itraconazole, may lead to improvement.

EOSINOPHILIC ULCER OF THE ORAL MUCOSA

Eosinophilic ulcer occurs most commonly on the tongue, but may occur anywhere in the oral mucosa. It is characterized by an ulcer with indurated and elevated borders that is usually covered by a pseudomembrane. It develops rapidly, most commonly on the posterior aspect of the tongue, and spontaneously resolves in a few weeks. A traumatic cause has been postulated for this benign, self-limited disorder. The histopathologic findings show a predominantly eosinophilic infiltrate in company with some histiocytes and neutrophils.

In some multifocal, recurrent cases, CD30+ cells have been reported. These patients may have the oral counterpart of primary cutaneous CD30+ lymphoproliferative disease. HIV-infected patients may develop ulcerations of the oral mucosa, resulting from a variety of infectious agents, such as herpes simplex virus (HSV), candidiasis, and histoplasmosis. However, 5 of the 16 patients they reported had no evidence of infection and simply showed eosinophilic infiltrates below the ulcer.

Fig. 34-13 Ondontogenic sinus.

CAVIAR TONGUE

William Bean gave the picturesque name caviar tongue to the purplish venous ectasias so commonly found on the undersurface of the tongue after the age of 50. They are attributed to elastic tissue deterioration with aging and may be associated with Fordyce angiokeratomas of the scrotum. Phleboliths or thrombophlebitis may occasionally complicate this condition.

Kocsard E, et al: The histopathology of caviar tongue. Dermatologica 1970;140:318.

CUTANEOUS SINUS OF DENTAL ORIGIN (DENTAL SINUS)

In dental (or odontogenous) sinus, chronic periapical infection about a tooth produces a burrowing, practically asymptomatic, occasionally palpable, cordlike sinus tract that eventually appears beneath the surface of the gum, palate, or periorificial skin. It forms a fistulous opening with an inflamed red nodule at the orifice. It may appear anywhere from the inner ocular canthus to the neck but is most often seen on the chin or along the jawline (Fig. 34-13). Bilateral involvement has been reported. Dental radiography is diagnostic. Pyogenic granuloma, actinomycosis, squamous cell carcinoma, osteomyelitis of the mandible, congenital fistulas, the deep mycoses, and foreign body reactions must be considered in the differential diagnosis.

Treatment requires the removal of the offending tooth or root canal therapy of the periapical abscess.

NEOPLASMS

Many tumors may involve the oral cavity. Most are discussed elsewhere in this book, and several are uncommon entities that affect specialized oral structures, such as the many subtypes of benign and malignant proliferations that occur in the major and minor salivary glands. These will not be covered further here, and only a few selected neoplasms will be presented.

Leukoplakia

Clinical Features

Leukoplakia presents as a whitish thickening of the epithelium of the mucous membranes, occurring as lactescent superficial patches of various shapes and sizes that may coalesce to form diffuse sheets (Fig. 34-14). The surface is generally glistening and opalescent, often reticulated, and may even be somewhat pigmented. The white pellicle is adherent to the underlying mucosa and attempts to remove it forcibly cause bleeding. At times it is a thick, rough, elevated plaque The lips, gums, cheeks, and edges of the tongue are the most common sites, but the lesion may arise on the anus and genitalia. Leukoplakia is found chiefly in men over the age of 40.

Biopsy of these white lesions may reveal orthokeratosis or parakeratosis with minimal inflammation, or there may be evidence of varying degrees of dysplasia. There is a benign form that is usually a response to chronic irritation and that has very little chance of conversion into the precancerous dysplastic form. Premalignant leukoplakia, with atypical cells histologically, is present in only about 10% to 20% of leukoplakia. Unfortunately, clinically it is not possible to predict which lesions will be worrisome histologically, except that if ulceration, red areas or erosions are scattered throughout, the lesion is most likely precancerous. Therefore, biopsy is indicated.

When the lesion occurs on the lip, leukoplakia is closely related to chronic actinic cheilitis, which consists of a circumscribed or diffuse keratosis, almost invariably on the lower lip. It is preceded by an abnormal dryness of the lip and may be caused by smoking (especially pipe smoking) or chronic sun exposure. This type of leukoplakia is distinguished from squamous cell carcinoma of the lip by the absence of infiltration, from lichen planus and psoriasis of the lips and mouth by the absence of lesions elsewhere, and from lupus erythematosus by the absence of telangiectases. Biopsy is necessary, however, to fully differentiate these conditions.

Fig. 34-15 Oral halry leukoplakia of HIV.

Intraoral leukoplakia appears to progress to squamous cell carcinoma in not more than 1% per year. In time, an extensive, thick, white pellicle may cover the tongue or oral mucosa. In old lesions the epithelium may be desquanated and there may be fissures or ulcerations. Such changes are associated with more or less hyperemia and tenderness, and with a tendency to bleed after slight trauma. If transformation to carcinoma occurs, it generally follows a 1- to 20-year lag time, with the exception that immunosuppressed transplant patients may have a rapid course of transformation.

Oral hairy leukoplakia is a term used to describe white, corrugated plaques that occur primarily on the sides of the tongue of patients with acquired immunodeficiency syndrome (AIDS) (Fig. 34-15). This is a virally-induced lesion, discussed in Chapter 19, which has a characteristic histology.

Leukoplakia of the vulva usually occurs in obese women after menopause as grayish white, thickened, pruritic patches that may become fissured and edematous from constant rubbing and scratching. Secondary infection with edema, tenderness, and pain may occur. It is differentiated from lichen planus by the absence of discrete, rectangular or annular flat papules of violaceous hue in the mucosa outside the thickened patches, about the anus or on the buccal mucosa. Lichen planus may involve the skin as well as the mucocutaneous areas. Leukoplakia of the vulva is most frequently confused with lichen sclerosus et atrophicus and other vulval *atrophies*. On the penis, though leukoplakia may occur, a similar precancerous process called *erythroplasia* (of Queyrat) is usually seen instead.

Etiology

Numerous factors are involved in the cause of leukoplakia. It may develop as a result of tobacco smoking, use of smokeless tobacco, areca or betel nut chewing, reverse smoking, alcohol, poorly fitting dentures, sharp and chipped teeth, or improper oral hygiene. Extensive involvement of the lips and oral cavity with leukoplakia may exist for years without any indication of carcinoma. On the other hand, small inflamed patches may be the site of a rapidly growing tumor, which, with relatively insignificant local infiltration, may involve the cervical lymphatics. Carcinoma in leukoplakia usually begins as a localized induration, often about a fissure, or as a warty excressence or a small ulcer. There is a 6% to 10% transformation rate of intraoral leukoplakia into squamous cell carcinoma. The red lesions of leukoplakia (erythroleukoplakia) have a much higher risk of malignant degeneration than uniform white lesions.

The degree of epithelial atypia correlates with increased labeling with ³H-thymidine and may be considered in staging the risk of developing malignancy. Aneuploid leukoplakia has a high rate of transformation into aggressive squamous cell carcinoma, and the cancers derived from them are more likely to be lethal.

Treatment

It must be remembered that cancer develops frequently on histologically dysplastic leukoplakia so that its complete removal should be the goal in each case—first by conservative measures, then by surgery or destruction, if necessary. The use of tobacco should be stopped, and proper dental care obtained. Fulguration, simple excision, cryotherapy, and CO_2 laser ablation are effective methods of treatment. Medical therapies that have been the subject of randomized clinical trials may lead to temporary resolution of the lesions, but relapses and adverse effects are common and there is no evidence they prevent the transformation to malignancy.

Leukoplakia with Tylosis and Esophageal Carcinoma

Leukoplakia associated with tylosis and esophageal carcinoma is extremely rare but may occur.

Epidermization of the Lip

Relatively smooth leukokeratosis of the lower vermilion, blending evenly into the skin surface distally and having a steep, sharp, irregular proximal margin, may easily be mistaken for precancerous leukoplakia clinically. Histologically, it shows only hyperkeratosis, without parakeratosis or cellular atypia. A shallow shave excision suffices to cure it and to rule out precancerous leukoplakia; no fulguration is required.

Erythroplakia

The term *erythroplakia* is applied to leukoplakia that has lost (or has not developed) the thick keratin layer that makes leukoplakia white; it is the usual pattern in mucocutaneous junctions. A focal red patch with no apparent cause should be suspected of being precancerous when found on the floor of the mouth, soft palate, or buccal mucosa, or under the tongue (Fig. 34-16). Histologically, there is cellular atypia,

Fig. 34-16 Erythroplakia. (Courtesy of James Fitzpatrick, MD)

pleomorphism, hyperchromatism, and increased mitotic figures. Carcinoma in situ or invasive carcinoma is found in 90% of lesions.

Oral Florid Papillomatosis

Oral florid papillomatosis was originally described by Rock and Fisher in 1960 as a confluent papillomatosis covering the mucous membranes of the oral cavity. The distinctive picture is that of a white mass resembling a cauliflower, covering the tongue and extending onto the other portions of the mucous membranes, including the oropharynx, larynx, and trachea. Usually there is no lymphadenopathy.

The course of the disease is progressive. Some lesions eventuate in squamous cell carcinoma, whereas others continue for many years, the patient dying of some intercurrent disease. Oral florid papillomatosis should be regarded as a verrucous carcinoma, which has been defined as a distinctive, slowly growing fungating tumor representing a welldifferentiated squamous cell carcinoma in which metastases occur very late or not at all. The histologic features are those of papillomatosis, acanthosis, and varying degrees of dysplasia of the epithelium, without disruption of the basement membrane. It is reasonable to expect the eventual development of epidermoid carcinoma in most patients. Esophageal involvement and keratotic papules of the extremities may occur. In the differential diagnosis, leukoplakia, proliferative vertucous leukoplakia, candidiasis, acanthosis nigricans, and condyloma acuminatum should be considered. Treatment recommended is surgical excision; however, it is often followed by recurrence and spread. Recombinant interferon- α 2a in combination with a CO₂ laser has also been used.

Proliferative Verrucous Leukoplakia

Proliferative vertucous leukoplakia is a slowly progressive condition that begins as multifocal sites of hyperplasia of the oral mucous membranes and proceeds to thicken and enlarge until squamous cell carcinoma results. Women outnumber men 4:1. Initially flat, usually white patches are present, but the lesions relentlessly become warty exophytic masses. The patches may involve the lips and chin. Seventy percent develop squamous cell carcinoma (most frequently of the palate and gingiva), with 40% of the total dying of proliferative vertucous leukoplakia-associated carcinoma. It has been associated with human papillomavirus (HPV)-16 infection, but it remains to be proven whether this is the primary cause. Treatment is difficult because of the multifocal nature of the lesions. Aggressive early surgical therapy is best. Many patients develop recurrence after only a short interval. Laser treatment or photodynamic therapy should be considered primary options.

Squamous Cell Carcinoma

Squamous cell carcinoma is the most common oral malignancy, comprising 2% to 3% of all new cancers. With nearly 30,000 yearly cases in the US, it is the tenth most common malignancy. It occurs primarily in older men. The most frequent sites are the lower lip, tongue, soft palate, and floor of the mouth (Fig. 34-17). Squamous cell carcinoma of the lip develops from actinic damage with 95% of the cases involving the lower lip. Intraoral lesions frequently develop from leukoplakia, erythroplakia, at sites of-frequent irrita-

Fig. 34-17 Oral squamous cell carcinoma.

tion, or long-standing mucosal inflammatory disease such as ulcerative lichen planus. About 20% of oral squamous cell cancers have an associated focus of leukoplakia; these tend to be diagnosed at a less advanced stage than those where no associated leukoplakia exists. Verrucous carcinomas occur in the oral mucosa as they do on the skin. Tobacco smoking, the use of smokeless tobacco, areca or betel nut chewing, reverse smoking, and the use of alcohol are risk factors for the development of intraoral squamous cell carcinoma. They may also complicate xeroderma pigmentosa (the tip of the tongue), dyskeratosis congenita, dystrophic epidermolysis bullosa, erosive lichen planus, and oral submucous fibrosis. Unfortunately, the survival rate has remained at 50% for many years because it is often discovered late, after it has metastasized to the cervical lymph nodes. Exfoliative cytology is a practical and accurate aid to oral cancer screening.

Acquired Dyskeratotic Leukoplakia

James and Lupton reported a patient with acquired dyskeratotic leukoplakia, which manifested as distinctive white plaques on the palate, gingivae, and lips (Fig. 34-18). There were similar lesions of the genitalia of the patient. Histologically, there was a unique finding of clusters of dyskeratotic cells in the prickle-cell layer in all affected sites.

Aggressive laser treatment was followed by recurrence. Use of etretinate afforded some improvement, but the condition continues unabated after 15 years.

James WD, et al: Acquired dyskeratotic leukoplakia. Arch Dermatol 1988;124:117.

White Sponge Nevus

The mouth, vagina, or rectum may be the site of this spongy, white overgrowth of the mucous membrane, with acanthosis,

Fig. 34-18 Oral dyskeratotic leukoplakia.

vacuolated prickle cells, and acidophilic condensations in the cytoplasm of keratinocytes, which have been shown by electron microscopy to be aggregated tonofilaments. The buccal mucosa is the most common site of involvement. There are no extramucosal lesions. There is no treatment. Progression of the disorder generally stops at puberty. The disease is inherited as an autosomal-dominant disorder. A mutation in the mucosal keratin pair K4 and K13 has been identified as the inherited defect. HPV-16 DNA has been identified in some patients, the significance of which remains to be determined. Antibiotics, particularly tetracycline, give significant improvement.

Melanocytic Oral Lesions

A wide variety of melanocytic lesions appear on the mucous membranes. Nevi of the oral mucosa in general are very uncommon. Among the melanocytic nevi of the cellular type, the intramucosal type is the most frequent, with the compound nevus next and the junction nevus occurring only rarely. Ephelis, lentigo, blue nevus, and labial melanotic macules are other types of focal hyperpigmentation. Ephelides darken on sun exposure and are usually limited to the lower lip. The blue nevus has dendritic cells in the submucosa. Lentigines show acanthosis of rete ridges on biopsy. Oral melanotic macules are solitary, sharply demarcated, flat, pigmented lesions that occur chiefly in young women, do not change on sun exposure, and show only acanthosis and basal-layer melanin on biopsy.

Oral melanoacanthoma is a simultaneous proliferation of keratinocytes and melanocytes. It is most commonly observed in young black patients (average age, 23) on the buccal mucosa. It seems to be a reactive process, usually following trauma and resolving spontaneously in 40% of patients.

Melanoma occurs rarely, mostly in older patients. It is recognized by being larger than the usual benign pigmented lesion, more irregular in shape, with a tendency to ulcerate and bleed. A peripheral areola of erythema and satellite pigmented spots may be present. There is a striking predilection for palatal (or, less often, gingival) involvement. The overall prognosis is poor (<5% survival at 5 years), because the lesions are usually deeply invasive by the time they are discovered. Whereas oral nevi are uncommon, biopsy of solitary pigmented oral lesions is indicated when the clinical diagnosis is uncertain.

Oral Melanosis

Pigmentation of the oral cavity tends to occur most frequently in black persons. In other races, the darker the skin, the more mucosal pigmentation may be expected. Oral melanosis may occur with Albright syndrome, Peutz-Jeghers syndrome, Carney complex, Laugier-Hunziker disease, and Addison's disease, or rarely, as an idiopathic process with no associated disease.

James et al reported a patient with inflammatory acquired oral hyperpigmentation that first occurred at age 30 with numerous distinct pigmented macules, similar to those seen in Peutz-Jeghers syndrome. However, the condition progressed rapidly to a diffuse oral hyperpigmentation (Fig. 34-19). This appeared to be caused by an undefined inflammation, and slow partial resolution occurred after several years of observation.

In the differential diagnosis of oral hyperpigmentation, these other entities should be included. The amalgam tattoo is a focal, brownish-blue macule incurred from (ragments of dental silver or amalgam being implanted into the gums (Fig. 34-20). Heavy-metal poisoning may also induce such

Fig. 34-19 Oral melanosis.

Fig. 34-20 Amalgum tattoo.

lesions. Bismuth, lead, and cis-platinium may produce a pigmented line along the gums near their margin. A multitude of medications will cause pigmentation. Amodiaquine, chloroquine, oral contraceptives, phenothiazines, phenolphthalein, quinacrine, quinidine, thallium, tobacco and zidovudine are among the most common of these.

- Abdollahi M, et al: A review of drug-induced oral reactions. J Contemp Dent Pract 2003;15:10.

- Leanane P, et al: Oral pigmentation. J Eur Acad Dermatol Venereol 2000;14:448.

Osseous Choristoma of the Tongue

Osseous choristoma of the tongue presents as a nodule on the dorsum of the tongue containing mature lamellar bone without osteoblastic or osteoclastic activity. This does not recur after simple excision.

Supiyaphun P, et al: Lingual osseous choristoma. J Med Assoc Thai 2000;83:564.

Peripheral Ameloblastoma

This is a neoplasm of the gingivae, which appears most often on the lower jaw. Basal cell carcinoma can be simulated histologically; however, this does not occur intraorally; those reported are examples or ameloblastoma.

- Hope L, et al: Peripheral ameloblastoma. J Oral Maxillofac Surg 2001;59:811.
- Collangettes D, et al: Oral florid papillomatosis. Eur J Cancer B Oral 1993;29B:81.

- Schwartz RA: Verrucous carcinoma of the skin and mucosa. J Am Acad Dermatol 1995;32:1.

TRUMPETER'S WART

Trumpeter's wart is a firm, fibrous, hyperkeratotic, pseudoepitheliomatous nodule on the upper lip of a trumpet player. A similar callus may grow on the lower lip of trombone players.

Fisher AA: Dermatitis in a musician. Cutis 1998;62:214, 261.

EPULIS

The term *epulis* means any benign lesion situated on the gingiva. The majority of these are reactive processes that display varying degrees of fibrosis, inflammation, and vascular proliferation on biopsy.

Giant cell epulis (peripheral giant cell granuloma) is a solitary, bluish-red, 10- to 20-mm tumor occurring on the gingiva between or about deciduous bicuspids and incisors. They may be induced by dental implants. Similar lesions may occur in the autosomal-dominantly inherited syndrome, cherubism. Histologically, they resemble giant cell tumor of the tendon sheath. Bischof M, et al: Peripheral giant cell granuloma associated with a dental implant. Int J Oral Maxillofac Implants 2004;19:295.

Pyogenic Granuloma

Pyogenic granuloma is an exuberant overgrowth of granulation tissue, frequently occurring in the oral cavity, most often involving the gingiva. It may also occur on the buccal mucosa, lips, tongue, or palate. It is a red to reddish-purple, soft, nodular mass that bleeds easily and grows rapidly, but is usually not painful. When it develops during pregnancy it is called *pregnancy tumor* or granuloma gravidarum.

Harris MN, et al: Lobular capillary hemangiomas. J Am Acad Dermatol 2000;42:1012.

GRANULOMA FISSURATUM

Granuloma fissuratum is a circumscribed, firm, whitish, fissured, fibrous granuloma occurring in the labioalveolar fold. The lesion is discoid, smooth, and slightly raised, about 1 cm in diameter. The growth is folded like a bent coin so that the fissure in the bend is continuous on both sides with the labioalveolar sulcus. Symptoms are slight. It is an inflammatory fibrous hyperplasia that usually results from chronic irritation caused by poorly fitting dentures. In the dental literature it is called *epulis fissuratum*, particularly when there is a deep cleft traversing the lesion. Treatment is by surgical extirpation, CO_2 laser ablation, or electrodesiccation after biopsy.

Gaspar L, et al: Manifestation of the advantages and disadvantages of using the CO₂ laser in oral surgery. J Clin Laser Med Surg 1990;8:39.

ANGINA BULLOSA HAEMORRHAGICA

The sudden appearance of one or more blood blisters of the oral mucosa characterizes this entity. There is no associated skin or systemic disease. The blisters may be recurrent, occur most often in the soft palate, and usually present in middleaged or elderly patients. No treatment is necessary.

- Dominguez JD, et al: Recurrent oral blood blisters. Arch Dermatol 1999;135:593.
- Giuliani M, et al: Angina bullosa haemorrhagica. Oral Dis 2002; 8:54.
- Yip HK: Angina bullosa haemorrhagica. Gen Dent 2004;52:162.

MUCOCELE

The term *mucocele* refers to a lesion that occurs as a result of trauma or obstruction of the minor salivary ducts. The most common type is the mucous extravasation phenomenon, which is usually seen inside the lower lip because it is caused by trauma from biting (Fig. 34-21). The inside of the upper lip and buccal mucosa are uncommonly involved. It presents as a soft, rounded, translucent projection; it commonly has a bluish tint. The lesion varies from 2 to 10 mm in diameter. It is painless, fluctuant, and tense. Incision of it, or sometimes merely compression, releases sticky, straw-colored fluid (or bluish fluid if hemorrhage has occurred into it).

Fig. 34-21 Mucocele.

The cause is rupture of the mucous duct, with extravasation of sialomucin into the submucosa to produce cystic spaces with inflammation. Granulation tissue formation is followed by fibrosis. Excisional biopsy will document the diagnosis and eliminate the problem. Cryotherapy and argon laser ablation have also been reported to be successful.

There are true mucous retention cysts where there is true obstruction of the duct leading to an epithelial lined cavity. They are seen more in the posterior portions of the oral mucosa. A ranula (from Rana, the frog genus) is a mucocele of the floor of the mouth.

Two other cysts that may be present in the mouth are the parotid duct cyst, which occurs in musicians who use wind instruments (the cyst develops opposite the upper second molar on the buccal mucosa), and the dermoid cyst, which may occur on the floor of the mouth, especially in the sublingual area.

ACUTE NECROTIZING ULCERATIVE GINGIVOSTOMATITIS (TRENCH MOUTH, VINCENT'S DISEASE)

Acute necrotizing ulcerative gingivitis (ANUG) is characterized by a rapid onset of characteristic punched-out ulcerations appearing on the interdental papillae and marginal gingivae. A dirty white pseudomembrane may cover the ulcerations. The lesions may spread rapidly and involve the buccal mucosa, lips, and tongue, as well as the tonsils, pharynx, and entire respiratory tract. The slightest pressure causes pain and bleeding. There is a characteristic foul, fetid odor that is always present. ANUG may lead to loss of clinical attachment of the gingiva and alveolar bone (necrotizing ulcerative periodontitis).

Trench mouth begins in a nidus of necrotic tissue, which provides an anaerobic environment for the infection by fusospirochetal organisms (*Bacteroides fusiformis*) in association with *Borrelia vincentii* and other organisms. Poor dental hygiene, smoking, poor nutrition, ingestion of methylenedioxymethamphetamine (ecstasy), and immunosuppression are predisposing factors. It may be seen as a component of the oral infections and inflammatory lesions that occur in immunocompromised HJV-infected patients.

Acute herpetic gingivostomatitis, primary HSV infection, may be confused with ANUG. Young children are susceptible to this severe febrile stomatitis with lymphadenitis. It is not primarily gingival in location and does not cause necrosis of the interdental papillae. Noma is a form of fusospirillary gangrenous stomatitis occurring in children with low resistance and poor nutrition. The onset is often triggered by measles. At the onset there is ulceration of the buccal mucosa; this rapidly assumes a gangrenous character and extends to involve the skin and bones, with resultant necrosis. It may end in the patient's death.

Treatment consists of thorough dental hygienic measures under the supervision of a dentist. Penicillin and debridement is the treatment of choice. Use of a 3% hydrogen peroxide mouthwash is also helpful.

ACATALASEMIA

Acatalasemia (Takahara's disease) is a rare disease in which the enzyme catalase is deficient in the liver, muscles, bone marrow, erythrocytes, and skin. There are several forms. The absence of catalase leads to progressive gangrene of the mouth, with recurrent ulcerations resulting from increased susceptibility to infection by anaerobic organisms.

Nearly 60% of affected individuals develop alveolar ulcerations, beginning in childhood. The mild type of the disease is characterized by rapidly recurring ulcers. In the moderate type, alveolar gangrene develops, with atrophy and recession of the alveolar bone, so that the teeth fall out spontaneously. In the severe type, widespread destruction of the jaw occurs. After puberty all lesions heal, even in individuals who have the severe type.

There is no gross difference in appearance between the blood of an acatalasic patient and that of a normal individual, but when hydrogen peroxide is added to a sample of blood, acatalasic blood immediately turns blackish-brown and the peroxide does not foam. Normal blood remains bright and causes the peroxide to foam exuberantly because of the presence of erythrocyte catalase.

Acatalasia is a rare peroxisomal disorder and is inherited as an autosomal-recessive trait. Treatment consists of extraction of the diseased teeth and the use of antibiotics to control the harmful effects of the offending bacteria.

Perner H, et al: Acatalasemia-Takahara's disease. Hautazrt 1999;50:590.

CYCLIC NEUTROPENIA

Cyclic, or periodic, neutropenia is characterized by a decrease of circulating neutrophils and dermatologic manifestations. At regular intervals (21 days), neutropenia and mouth ulcerations develop, usually accompanied by fever, malaise, and arthralgia. Ulcerations of the lips, tongue, palate, gums, and buccal mucosa may be extensive. The ulcers are irregularly outlined and are covered by a grayishwhite necrotic slough. The anterior teeth may show a grayishbrown discoloration. Premature alveolar bone loss and periodontitis occur. In addition, opportunistic cutaneous infections, such as abscesses, furuncles, noma, pyomyositis, and cellulitis, may develop during the neutropenic stage. Urticaria and erythema multiforme have been reported.

There is a cyclic depression of neutrophils occurring at intervals of 12 to 30 days (average, 21 days) and lasting 5 to 8 days. The neutrophils in the peripheral blood regularly fall to low levels or completely disappear. Some cases have been associated with agammaglobulinemia. The cause of cyclic neutropenia is a germline mutation of the gene encoding neutrophil elastase (ELA2). This is thought to produce apoptosis of bone marrow progenitor cells. Both the autosomaldominant disease and sporadic cases have this abnormality. Severe congenital neutropenia is caused by a mutation in the same gene but at a different site. The latter condition predisposes to the development of myelodysplasia and acute myelogenous leukemia, while cyclic neutropenia does not.

In the differential diagnosis are other periodic fever syndromes, including periodic fever, aphthous stomatitis, pharyngilis and adenopathy (PFAPA) syndrome, Mediterranean fever, Hibernian fever and hyperimmunoglobulin D syndrome. PFAPA syndrome is defined clinically and is characterized by 4 days of high fevers (>40° C) that recur at regular intervals every 2 to 8 weeks separated by wellbeing between episodes. Associated with fevers are aphthous stomatitis (70%), pharyngitis (72%), and cervical adenitis (88%). It is not familial, begins before 5 years of age, and responds to small doses of prednisone for 1 to 2 days. Tonsillectomy has been reported to cure it.

Use of recombinant human granulocyte colony-stimulating factor (G-CSF) has been successful in the treatment of cyclic neutropenia patients. If the potential side effects limit use of this therapy, cyclosporin has been reported to be effective also. Administering antibiotics during infections seems to expedite recovery. Careful attention to oral hygiene, including plaque control, helps improve mouth lesions and reduces the risk of infections. Death may occur from pneumonia, sepsis, gangrenous pyoderma, or granulocytopenia.

Fig. 34-22 Chronic herpes in a patient on cancer chemotherapy.

RECURRENT INTRAORAL HERPES SIMPLEX INFECTION

Recurrent intraoral infection with HSV is characterized by numerous small, discrete vesicles occurring in one or a few clusters. The site of involvement is a key feature in suspecting the diagnosis. The keratinized or masticatory mucosa (the palate, gingiva, and tongue) are affected. The grouped vesicles rupture rapidly to form punctate erosions with a red base. Smears from the base prepared with Wright stain will show giant multinucleated epithelial cells. Immunofluorescent tests and viral cultures are also confirmatory.

The differential diagnosis of this uncommon manifestation of HSV includes oral herpes zoster, herpangina, and oral aphthosis. The latter two involve nonattached mucosa, whereas recurrent HSV involves mucosa fixed to bone. Differentiation from zoster is made on clinical grounds or by culture and immunofluorescent testing.

Chronic progressive ulcerative and nodular intraoral herpes are seen occasionally in HIV-infected patients, or those with leukemia or neutropenia (Fig. 34-22).

RECURRENT APHTHOUS STOMATITIS (CANKER SORES, APHTHOSIS)

Clinical Features

Aphthous stomatitis is a painful, recurrent disease of the oral mucous membrane. It begins as small, red, discrete or grouped papules, which in a few hours become necrotizing ulcerations. They are small, round, shallow, white ulcers (aphthae) generally surrounded by a ring of hyperemia (Fig. 34-23). As a rule, they are tender; they may become so painful that they interfere with speech and mastication. They are mostly about 5 mm in diameter but may vary in size from 3 to 10 mm. When larger, they are called *major aphthae*. Usually, one to five lesions occur per attack; however, they may occur in any number. They are located in decreasing frequency on the buccal and labial mucosa, edges of the tongue, buccal and lingual sulci, and soft palate. There is a marked predilection for the nonkeratinized mucosa (any not bound to underlying periosteum). This and the fact that they

Fig. 34-23 Apthous stomatitis.

are rarely confluent, even when they occur as small crops of 1- or 2-mm lesions (herpetiform aphthae), help to distinguish them from the uncommon recurrent intraoral HSV infection. Aphthae may also occur on the vagina, vulva, penis, anus, and even the conjunctiva.

The lesions tend to involute in 1 to 2 weeks, but recurrences are common. These recurrences may be induced by trauma, such as self-biting, toothbrush injury, and dental procedures, spicy foods, citrus, fresh pineapple, walnuts, allergy, emotional stress, or hormonal changes in women, such as in menstruation, pregnancy, menarche, and menopause. A familial predisposition has also been described as familial epidemic aphthosis.

Recurrent aphthous stomatitis is the most common lesion of the oral mucosa, affecting from 10% to 20% of the population. It starts commonly in the second or third decade and patients may experience recurrent bouts of lesions several times yearly for many decades. A not uncommon presentation in children is a syndrome characterized by periodic fever, aphthous stomatitis, pharyngitis, and adenitis (PFAPA). The high fevers and associated findings occur with striking periodicity every 4 weeks, last 4 to 6 days, and resolve only to recur the following month. The children are otherwise well. One or two dose of prednisone (2 mg/kg) aborts the attack and tonsillectomy may cure it.

Ulcerations such as these may also be the presenting sign in Beçhet syndrome. HIV infection, malabsorption, syndromes, gluten-sensitive enteropathy, pernicious anemia, cyclic neutropenia, neutropenia, ulcerative colitis, and Crohn's disease. History, physical examination, complete blood count, and long-term follow-up documenting the recurrent course in the absence of other symptoms will secure the diagnosis. Some patients have aphthosis associated with low folate or iron levels, so testing should include evaluation of these.

Etiologic Factors

Although individual patients often suspect one of the factors mentioned above is responsible for precipitating their recurrence, infectious or immunologic causation is favored by investigators. The true cause is unknown.

Histologically, the lesion consists of a lymphocytic inflammatory infiltration with occasional plasma cells and eosinophils, which suggests delayed hypersensitivity.

Diagnosis

Aphthous stomatitis must be differentiated from mucous patches of early syphilis, candidiasis, Vincent angina, the avitaminoses (particularly pellagra and scurvy), erythema multiforme, pemphigus, cicatricial pemphigoid, lichen planus, primary HSV infection of the mouth, recurrent labial herpes, and recurrent intraoral HSV infection.

Treatment

No permanent cure is available. Several topical agents will lessen the pain. A mixture of equal parts of elixir of Benadryl and Maalox held in the mouth for 5 min before meals is soothing. Kaolin may also be added to the mixture. Lidocaine (Xylocaine Viscous) 2% solution, keeping 1 teaspoonful in the mouth for several minutes, is helpful in allaying pain. Another useful topical anesthetic is dyclonine hydrochloride (Dyclone) 0.5% applied to the lesions. A large number of reasonably effective over-the-counter remedies are also available. Triggers, such as spicy foods, citrus, walnuts, pineapple, and other irritating substances should be avoided.

One may use other measures to shorten the course and induce healing of lesions. A mixture of equal parts of fluocinonide ointment and Orabase applied to the ulcers three or four times a day is effective in aiding the healing of existing ulcer, however, it does not prevent new ulcers. Some patients object to the thick sticky texture of Orabase and prefer flucinonide gel. Clobetasol ointment can also be very effective. Intralesional steroids and short 3- or 4-day courses of oral steroids may help, particularly for indolent or large lesions. Nonsteroidal alternatives include 5 mL of an oral suspension of containing 250 mg of tetracycline; this is held in the mouth for 2 min and then swallowed. This is done four times daily for 1 week. Amlexanox 5% oral paste (Aphthasol) is a useful topical therapy to both induce healing and relieve pain. Sucralfate suspension, alone or compounded with a topical steroid, may be useful as has been described in peptic ulcer disease and the ulcerations of Behçet's disease.

To try to prevent new lesions known triggers for the individual patient should be avoided as much as possible. Dapsone in doses of 25 to 50 mg/day or colchicine 0.6 mg two or three times a day, may be tried. Thalidomide is another effective alternative, but caution regarding teratogenicity and neurotoxicity is necessary if this is to be considered. One method is thalidomide, 300 mg/day to start, 200 mg/day after 10 days, and 100 mg/day after 2 months. Relapses were treated with 100 mg/day for 12 days.

Several investigators have reported finding low folate, iron, or B_{12} levels in about 20% of aphthosis patients investigated, but others do not see this with such high frequency. Still, it is worth investigating as correction of the abnormality clears or improves the condition in most cases where an abnormality exists.

MAJOR APHTHOUS ULCER (PERIADENITIS MUCOSA NECROTICA RECURRENS)

In Sutton's disease, a major aphthous ulcer begins as a small shotlike nodule on the inner lip, buccal mucosa, or tongue, which breaks down into a painful sharply circumscribed ulcer with a deeply punched out and depressed crater.

It may at times begin in the faucial pillars or oropharynx (Fig. 34-24). It may persist for 2 to 12 weeks before healing with a soft, pliable scar. There are seldom more than one to three lesions present at one time. However, remissions tend to be short, and new lesions may appear before old ones have quite healed. The term *major aphthous ulcers* has supplanted the unwieldy Latin name for this disease.

The cause is unknown, but evidence favors an immunologic or infectious etiology. These painful lesions are frequently present in HIV-infected patients who may experience similar lesions in the esophagus, rectum, anus, and genítals.

Treatment is difficult, and the general measures discussed under recurrent aphthae should be employed. Intralesional or systemic steroids in short courses, which may be effective, are often given. If recurrences are such that systemic steroids are prescribed for more than two or three short courses per year, alternative oral medications such as colchicine, dapsone or thalidomide may be tried. BEHÇET SYNDROME (OCULO-ORAL-GENITAL SYNDROME)

Clinical Features

Behçet syndrome consists of recurrent oral aphthous ulcerations that recur at least three times in one 12-month period in the presence of any two of the following: recurrent genital ulceration, retinal vasculitis or anterior or posterior uveitis, cutaneous lesions (erythema nodosum; pseudofolliculitis or papulopustular lesions; or acneiform nodules in postadolescent patients who are not receiving corticosteroid treatment), or a positive pathergy test.

Oral lesions occur on the lips, tongue, buccal mucosa, soft and hard palate, tonsils, and even in the pharynx and nasal cavity. The lesions are single or multiple, 2 to 10 mm or larger in diameter, and sharply circumscribed, with a dirty grayish base and a surrounding bright red halo. Other patients show deep ulcerations that leave scars resembling those caused by Sutton major aphthous ulcers. The lesions are so painful that eating may be difficult. A foul mouth odor is in most cases markedly noticeable.

Genital lesions occur in men on the scrotum (Fig. 34-25) and penis or in the urethra; in women, on the vulva, cervix, or vagina; they may be found in both sexes on the genitocrural fold, anus, perineum, or in the rectum. These ulcerations are similar to those seen in the mouth. In addition, macules, papules, and folliculitis may develop on the scrotum. Lesions in women may lead to deep destruction of the vulva. Swellings of the regional nodes and fever may accompany oral and genital attacks.

The ocular lesions start with intense periorbital pain and photophobia. Retinal vasculitis is the most classic eye sign and the chief cause of blindness. Conjunctivitis may be an early, and hypopyon a late, accompaniment of uveitis. Iridocyclitis is frequently seen. Both eyes are eventually involved. Untreated disease leads to blindness from optic atrophy, glaucoma or cataracts.

Flg. 34-24 Major apthae.

Fig. 34-25 Behçet disease.

Neurologic manifestations are mostly in the central nervous system and resemble most closely those of multiple sclerosis. Remissions and exacerbations are the rule. Thrombophlebitis occurs with some frequency. Thrombosis of the superior vena cava may also occur. Arthralgia is most often present in the form of polyarthritis.

Unfortunately, the international criteria include nonspecific common cutaneous lesions (pseudofolliculitis, papulopustular or acneiform lesions). Demonstration of either leukocytoclastic vasculitis or a neutrophilic vascular reaction on histologic examination of a lesion would make the cutaneous criteria more specific.

There is a relatively high prevalence of Behçet's disease in the Far East and Mediterranean countries, whereas in the US and Western Europe it is much less common. In large series of patients from areas of high prevalence, men with an age of onset in the 30s predominate. Mangelsdorf et al reported on 25 patients seen in a university dermatology referral practice in the US; 22 of their patients were young women with a high frequency of mucocutaneous lesions and a low prevalence of ocular involvement. This may reflect referral bias or could indicate the disease is less severe in the US.

On histologic examination, the early lesions show a leukocytoclastic vasculitis. There is perivascular infiltration, which is chiefly lymphocytic in older lesions, with endothelial proliferation that obliterates the lumen. The cause of Behçet's disease has been postulated to have an infectious, immunologic and/or genetic basis but the evidence is still inconclusive for any of these.

Diagnosis

Usually the disease starts with one oral ulceration, followed by others. It may take years before additional lesions develop. Therefore, the diagnosis requires two classic signs in addition to oral ulcerations. In women anal and genital lesions predominate, often with subsequent involvement of the eyes.

Behçet's disease must be differentiated from herpetic or aphthous stomatitis, pemphigus, oral cancer, and Stevens-Johnson syndrome (erythema multiforme). A skin puncture or pathergy test may be used to investigate patients further; however, it is not reliable in that it may be negative in otherwise well-documented cases. It is done by injecting 0.1 mL of normal saline solution into the skin or by simply pricking the skin with a sterile needle. A pustule appears at the site within 24 h. If results are negative, the test should be repeated at two to five points before results are accepted. Pathergy has been observed in patients with Behçet's disease, pyoderma gangrenosum, Sweet syndrome, and bowel-associated dermatosis-arthritis syndrome.

Treatment

Usually the ulcerations heal spontaneously. Mild mouthwashes and toothpastes and restricted use of the toothbrush should be prescribed when there are oral lesions. With regard to treating the symptoms and healing of the aphthae, local treatments as described for aphthae may be used. Sucralfate suspension has been studied in Behçet oral and genital ulcers and was found to decrease pain and healing time. On the whole, the therapeutic problem of aphthosis is not the healing of the individual lesions but the prevention of new attacks. For that purpose several options exist, none of which is optimal. Colchicine, 0.6 mg twice a day, may be started for 2 weeks. In the absence of response and gastrointestinal side effects, the dose may be increased to three times a day. Although this may not totally alleviate the mucocutaneous lesions, it may decrease their recurrence rate by 50% or more. Dapsone may be substituted or added to this for improvement of response. The usual therapeutic final dose is 100 mg/day. Thalidomide has been found to be effective in many patients. One dosing method is thalidomide 200 mg twice a day for 5 days and 100 mg twice a day for 15 to 60 days. It had no effect on iridocyclitis. Of course, long-term treatment will commonly be complicated by neurotoxicity and the teratogenicity of this medication is well known.

Methotrexate in a weekly oral dose of 7.5 to 20 mg should be reserved for severe refractory cases, as should more aggressive systemic treatments such as systemic corticosteroids, azathioprine, chlorambucil, cyclosporin, and cyclophosphamide.

The long-term outlook is for intermittent recurrent flares that may be life-long. Blindness, neurologic impairment and vascular thromboses are potential serious complications.

CHAPTER

Cutaneous Vascular Diseases

RAYNAUD PHENOMENON AND RAYNAUD'S DISEASE

Raynaud phenomenon occurs in the presence of an associated disease, usually collagen vascular disease. Raynaud's disease occurs in the absence of such disease. In a series of 165 patients with Raynaud, 51 had primary disease (Raynaud's disease). A defined connective tissue disease was present in about a third of the remaining patients, but 54 had undefined connective tissue disease (35 with positive antinuclear antibody [ANA] titer). In another study of 142 patients with idiopathic Raynaud phenomenon followed for more than 10 years, 14% progressed to a definite connective tissue disease. The initial presence of ANAs, thickening of fingers, older age at onset, and female sex were predictors of connective tissue disease.

Raynaud Phenomenon

Raynaud phenomenon is produced by an intermittent constriction of the small digital arteries and arterioles. The digits have sequential pallor, cyanosis, and rubor (Fig. 35-1). The involved parts are affected in paroxysms by the attacks of ischemia, which cause them to become pale, cold to the touch, and numb. The phenomenon is more frequently observed in cold weather. When exposed to cold the digits become white (ischemic), then blue (cyanotic), and finally red (hyperemic). In time the parts may fail to regain their normal circulation between attacks and become persistently cyanotic and painful. If this phenomenon persists over a long period, punctate superficial necrosis of the fingertips develops; later, even gangrene may occur.

Raynaud phenomenon occurs most frequently in young to middle-aged women. It occurs with scleroderma, dermatomyositis, lupus erythematosus, mixed connective tissue disease (MCTD), Sjögren syndrome, rheumatoid arthritis, and paroxysmal hemoglobinuria. Scleroderma is the underlying diagnosis in more than half of patients in one series. Occlusive arterial diseases such as embolism, thromboangitis

Fig. 35-1 Raynaud disease.

obliterans, and arteriosclerosis obliterans may be present. In addition, various diseases of the nervous system, cervical rib and the scalenus anticus syndrome, may produce the disorder. Physical trauma such as pneumatic hammer operation and that incurred by pianists and typists may also induce this phenomenon. Medications such as bleomycin or ergot may also be the cause. The clumping of red blood cells is believed to be responsible for the induction of Raynaud phenomenon with high titers of circulating cold agglutinins. It may occur in cryoglobulinemia and polycythemia vera.

Simple tests and physical examination will generally distinguish between Raynaud's disease and Raynaud phenomenon. Sclerodactyly, digital pitted scars, puffy fingers with telangiectases, positive ANA, subcutaneous calcifications, basilar lung fibrosis, and changes on nailfold capillary microscopy (avascular "skip" areas with irregularly dilated capillary loops) are signs of connective tissue disease. Nailfold capillary changes are helpful prognostic indicators and periodic acid-Schiff (PAS)-positive globules in the proximal nailfold detected on biopsy correlate with connective tissue disease. An anticentromere antibody is an indicator of CREST syndrome.

Raynaud's Disease

Raynaud's disease is a primary disorder of cold sensitivity primarily seen in young women. The intermittent attacks of pallor, cyanosis, hyperemia, and numbress of the fingers are identical to those in Raynaud phenomenon. The disease is usually bilateral, and gangrene occurs in less than 1% of cases.

The diagnosis requires the absence of the diseases enumerated under Raynaud phenomenon. Although the current dictum is that Raynaud's disease should be present for 2 years before being classified as a primary process, it may take as long as 11 years for some systemic disorders to manifest. Overall, fewer than half of patients presenting with Raynaud symptoms will prove to have a connective tissue disease. The prognosis is good for idiopathic Raynaud's disease, although pulmonary hypertension has been reported.

Etiology

The cause of Raynaud phenomenon/disease is multifactorial. Increased α -2 sympathetic receptor activity on vessels, endothelial dysfunction, deficiency of calcitonin gene-related peptide protein-containing nerves and a central thermoregulatory defect have been implicated. Increased tyrosine phosphorylation by protein tyrosine kinase mediates cooling-induced contraction in Raynaud's disease. Elevated endothelin-1, a vasoconstrictor, has been found in Raynaud phenomenon/disease and systemic sclerosis. Women receiving unopposed estrogen replacement are twice as likely to experience Raynaud phenomenon as women not receiving estrogen replacement or women receiving estrogen and progesterone. Infusion of calcitonin gene-related peptide in patients with Raynaud phenomenon demonstrates increased hand temperatures compared with saline controls, suggesting it opposes the vasoconstrictive mediators of the disease. Patients with ulcers healed with infusions, compared with none of the patients treated with saline controls.

Treatment

In both Raynaud phenomenon and Raynaud's disease, exposure to cold should be avoided. This includes avoidance of exposure to cold not only of the extremities but also of other parts of the body, since vasospasm may be induced by cooling of the body alone. Warm gloves should be worn whenever possible. Residence in a warm climate is helpful. Trauma to the fingertips should be avoided. Smoking is forbidden.

Vasodilating drugs may be helpful, including nifedipine, 10 to 20 mg three times a day, or prazosin, 1 mg three times a day increased to 3 mg three times a day. Nifedipine is considered to be the gold standard, and two-thirds of treated patients will respond favorably. The newer second-generation dihydropyridines, such as amlodipine, isradipine, nicardipine, and felodipine, have also been shown effective and are associated with few side effects. Silenafil and related drugs have been used. Pentoxifylline and stanozolol have shown variable success. An angiotensin II-receptor type I antagonist (losartan) or a selective serotonin-reuptake inhibitor (fluoxetine) may be useful in refractory cases. Tolazoline hydrochloride (Priscoline), 50 mg three times a day, can be helpful in mild cases. Preliminary data on low level laser irradiation appear promising in an open case series, suggesting that physical modalities could supplement or replace drug therapy in some patients.

The local application of 2% nitroglycerin in an ointment base (Nitro-Bid, Nitrostat) will give relief to some patients, but topical vasodilators may shift the blood supply to more vascularized areas and must be used cautiously. Sublingual administration of nitroglycerin was effective in only 2 of 10 patients in one study, while 8 of 10 were improved by biofeedback training, even 8 weeks after the sessions were over.

In severe, disabling cases of Raynaud with trophic changes, sympathectomy has been successful. Sympathetic ganglionectomy with resection of the sympathetic trunk for both the upper and lower extremities has produced good or excellent results in some series. Unfortunately, the effect is often temporary, lasting for only 6 months to 2 years.

ERYTHROMELALGIA

Also called *erythermalgia* and *acromelalgia*, this rare form of paroxysmal vasodilation affects the feet with burning, localized pain, redness, and high skin temperature. Infrequently, the upper extremities may be involved. The burning paroxysms may last from a few minutes to several days, and are usually triggered by an increase in environmental temperature. Erythromelalgia is sometimes associated with Raynaud phenomenon, an interesting paradox as one manifests with vasodilatation and the other with constriction.

The disease may be primary or secondary to diseases such as polycythemia vera, thrombotic thrombocytopenic purpura, thrombocythemia, peripheral neuritis, myelitis, multiple sclerosis, systemic lupus erythematosus (SLE), hypertension, or diabetes mellitus. Acquired disease has been reported after topical exposure to isopropyl alcohol and after mushroom poisoning with *Clitocybe acromelalga* and Clitocybe amoenolens. Calcium-channel blockers and cyclosporin have been used to treat patients, but may exacerbate or even induce the condition. Childhood erythromelalgia often appears without an underlying disorder, may be familial, and tends to be resistant to aspirin. Autosomaldominant inheritance has been linked to chromosome 2q, and mutations in SCN9A, a gene encoding a voltage-gated sodium channel α subunit expressed in sensory and sympathetic neurons. The pathophysiology is poorly understood. Many believe the disorder is related to peripheral small fiber neurotransmission and disturbed platelet function. Defective conduction in sympathetic peripheral fibers (C fibers) has been demonstrated in the majority of patients studied.

Erythromelalgia caused by thrombocytosis often responds to aspirin. Erythromelalgia caused by underlying disease processes tends to respond to treatment of the primary disorder. The symptoms may be relieved by measures, such as immersion in cold water, that cool the skin. Good results have been obtained with serotonin antagonists (methysergide, pizotifen, and sertraline) in some patients, which suggests that this may be a disease of peripheral serotonin activity. Misoprostol, 0.4–0.8 mg/day, was effective in a blinded trial. lloprost, a synthetic prostacyclin analog, was effective in a small double-blinded trial. Other treatment modalities have been anecdotally successful, including propranolol, clonazepam, cyproheptadine, tricyclic antidepressants, anticonvulsants such as gabapentin, epinephrine, ephedrine, sublingual isoproterenol hydrochloride, nitroglycerin ointment, prednisone, phlebotomy, sodium nitroprusside, venlafaxine, oral magnesium, lumbar ganglionectomy, and peripheral nerve block or section.

LIVEDO RETICULARIS

Livedo reticularis is a netlike mottled or reticulated pink or reddish-blue discoloration of the skin, mostly on the extremities, especially the legs. Exposure to cold usually accentuates the intensity of discoloration, although the lesions may be fixed and remain present on warming (sometimes referred to as *livedo racemosa*) (Fig. 35-2). The lesions are often asymptomatic; in other cases, coldness, numbness, paresthesia, or a dull ache may be present. Necrotizing livedo reticularis may be associated with cutaneous nodules and ulcerations.

Most cases are unassociated with any underlying cause, but livedo reticularis may be a manifestation of lupus erythematosus, dermatomyositis, scleroderma, rheumatic fever, or rheumatoid arthritis. It may be seen with hepatitis C, parvovirus B19, syphilis, meningococcemia, pneumococcal sepsis, tuberculosis, pancreatitis, decompression sickness, various forms of arteritis, Wegener granulomatosis, polycythemia vera, hypercalcemia, pheochromocytoma, mycosis fungoides, breast cancer, and thrombocytopenic purpura. It is a side effect of amantadine (Symmetrel), and has been reported as a photosensitivity phenomenon in patients taking quinidine. Some patients on long-term minocycline therapy have been shown to develop drug-induced arthritis, fever, livedo reticularis, and positive peripheral antineutrophil cytoplasmic autoantibodies (P-ANCA) titers. Livedo reticularis may be a complication of arteriography.

Cholesterol emboli resulting from severe atherosclerotic disease may cause uni- or bi-lateral livedo reticularis. Patients frequently have concomitant cyanosis, purpura, nodules, ulceration, or gangrene. Peripheral eosinophilia is common. Older men with severe atherosclerotic disease are most affected. They are often on anticoagulant therapy, and many have recently undergone vascular surgery or instrumentation. The differential diagnosis includes vasculitis, septic staphylococcal emboli resulting from endocarditis or an infected aneurysm, and periarteritis nodosa. Mortality is 72%. Deep biopsy with serial sections may demonstrate the characteristic cholesterol clefts within thrombi. Frozen section evaluation with polarized microscopy is particularly sensitive. Livedo reticularis of recent onset in an elderly person warrants consideration of this diagnosis.

Necrotizing livedo reticularis has been reported with leukocytoclastic vasculitis, heparin-associated thrombosis, cryoglobulinemia, calciphylaxis, calcifying panniculitis, oxalosis, compressed air injury, bismuth or pentazocine injections, atrial myxomas, Wegener granulomatosis, Graves' disease, acute lymphocytic leukemia, renal cancer, SLE, and other connective tissue diseases.

Sneddon syndrome usually presents in young to middleaged women. They present with livedo reticularis, then develop cerebrovascular infarcts. The prognosis is poor. Some patients have antiphospholipid antibodies and may have SLE. Up to 35% will be positive for antiendothelial cell antibodies (AECA). In some families, Sneddon syndrome may be inherited in an autosomal-dominant fashion.

Patients with SLE and livedo reticularis are apt to have more severe disease manifestations, such as renal disease, vasculitis, and anticardiolipin antibodies, even in the absence of Sneddon syndrome. Patients with antiphospholipid syndrome and livedo reticularis are more likely to develop epilepsy than those without livedo reticularis. Among patients with chronic headaches, the presence of livedo reticularis may be a marker for an increased risk of stroke.

Moyamoya's disease is a rare, chronic cerebrovascular occlusive disease characterized by progressive stenosis of the
arteries in the circle of Willis. Patients present with ischemic strokes or cerebral hemorrhages. Both idiopathic Moyamoya's disease and disease associated with factor V Leiden mutation have been associated with livedo reticularis.

Oxalosis may lead to livedo reticularis from deposition of oxalate crystals in and around blood vessel walls. The primary type comprises two rare autosomal-recessive disorders, each lacking one specific enzyme. Secondary forms also occur. The characteristic crystals are seen on biopsy.

Cutis marmorata is physiologic mottling of the skin. The skin resembles marble because of its mottled bluish discoloration. It is commonly seen on the lower extremities in young children and women exposed to cold. The mottling usually disappears when the extremities are warmed.

LIVEDOID VASCULOPATHY

Synonyms for livedoid vasculopathy include livedoid vasculitis, atrophie blanche, and PURPLE (painful purpuric ulcers with reticular pattern of the lower extremities). The histologic features of leukocytoclastic vasculitis are absent, so the term vasculopathy is preferred over vasculitis. The vasculopathy is characterized clinically by early, focal, painful purpuric lesions of the lower extremities that frequently ulcerate and heal slowly (Fig. 35-3). The ulcers heal with small, stellate and reticulated, white scars referred to as atrophie blanche. They may also show telangiectasis, hemosiderin-induced hyperpigmentation, and fivedo

Fig. 35-3 Livedoid vasculopathy.

racemosa. Atrophy blanche also occurs in patients with only stasis dermatitis and ulceration.

Livedoid vasculopathy may be associated with various systemic diseases, including primary or secondary hypercoagulable states, particularly those associated with anticardiolipin antibody syndrome, protein C deficiency, antithrombin III deficiency, other fibrinolytic anomalies (including prothrombin and factor V Leiden gene mutations), and hepatitis C. Clinical evaluation should exclude these disorders, as well as venous and arterial peripheral vascular diseases. Mononeuropathy multiplex has been reported in association with livedoid vasculopathy. In some patients, atrophie blanche and mononeuropathy multiplex may be associated with polyarteritis nodosa rather than hyalinizing vasculopathy; biopsy is recommended.

Histologically, livedoid vasculopathy is characterized by hyaline thickening of the walls of the small blood vessels. Fibrin, C3, and IgM are often found in the vessel walls. The vessels may demonstrate endothelial proliferation and thrombosis. Perivascular hemorrhage may be present. Endothelial thrombomodulin expression is elevated in many patients and platelet (P-selectin) and lymphocyte activation have been demonstrated.

Low-dose aspirin (325 or even 162 mg once or twice a day) and dipyridamole have been effective in some patients. The addition of a third antiplatelet drug may provide additional benefit. Beraprost sodium (120 µg/day) or minidose heparin, as little as 5000 U every 3 days, has been reported to be effective. Nifedipine, 10 mg three times a day, produced healing in a patient in whom dipyridamole and aspirin had failed. Pentoxifylline, 400 mg two or three times a day, with 400 mg/day for maintenance, is another treatment option. Treatment with metformin has shown mixed results. Intravenous iloprost has been effective in some patients with refractory disease. PUVA has been reported as useful in a few patients. Some patients with severe disease have responded to prednisolone, colchicine, azathioprine, or intravenous immunoglobulin (IVIG). The mode of action of these agents is unclear, as vasculitis is not present histologically. Low molecular weight dextran is used for hypofibrinolytic disease. Secondary infection of ulcers should be treated with systemic antibiotics.

Livedoid Dermatitis

Livedoid "dermatitis" is an embolic phenomenon (infarction) leading to temporary or prolonged local ischemia as a result of accidental arterial obliteration from the intragluteal injections of various drugs. (See Chapter 6 for a discussion of injection site reactions.)

Perinatal Gangrene of the Buttock

Perinatal gangrene of the buttock is similar to livedoid dermatitis. It usually is a complication of umbilical artery catheterization, exchange transfusion. or cord injections by means of a syringe. It may also be a spontaneous event.

CALCIPHYLAXIS

Patients with end-stage renal disease with metastatic calcification are almost exclusively affected by this disease. Calciphylaxis appears as reticulated, violaceous, mottled patches, later progressing to ecchymosis, cordlike nodules (usually located on the abdomen and thighs), and livedo reticularis. Progression occurs with ecchymosis, central necrosis, and black eschars that may have a reticulated appearance (Fig. 35-4). Gangrene and self-amputation of digits or extremities has been reported. Necrosis may involve other sites, such as the penis, tongue, or breast. Ischemic myopathy may produce symptoms suggestive of dermatomyositis. Patients with diabetes and chronic renal failure have a much higher chance of developing acral gangrene, and central lesions are associated with a worse prognosis than peripheral lesions.

A serum calcium-phosphorus product of more than 60 mg/dL indicates great risk for calciphylaxis. Calcification occurs when an appropriate challenging factor is then introduced. Identified factors include vitamin D compounds, parathyroid hormone, phosphates, calcium salts, infections,

high levels of matrix metalloproteinases, local trauma, intramuscular tobramycin, corticosteroids, intramuscular iron dextran complex, calcium heparinate, human immunodeficiency virus (HIV) infection, and cryofibrinogenemia. Crohn's disease in combination with short-bowel syndrome has been reported to cause calciphylaxis.

The prognosis is guarded, and most patients experience significant morbidity and mortality. Death is usually caused by staphylococcal sepsis after infection of the chronic ulcerations. Patients with secondary hyperparathyroidism benefit from parathyroidectomy with autotransplantation of parathyroid tissue. Hyperbaric oxygen has been used with some success. Rapid improvement has been reported after intravenous pamidronate therapy in a patient with chronic renal failure. Intravenous sodium thiosulfate has also been used.

MARSHALL-WHITE SYNDROME AND BIER SPOTS

The marbled mottling produced in the forearm and hand by occluding the brachial artery with a tight sphygmomanometer cuff is characterized initially, and chiefly, by pale

Fig. 35-4 Calciphylaxis. macules 1 or 2 cm in diameter. These were described by Bier in 1898 and are known as *Bier spots*. Wilkin re-examined this phenomenon with laser Doppler velocimetry and concluded that the red spots on the hand are caused by relative vasodilatation, with vasoconstriction in the pale areas.

Marshall-White syndrome consists of Bier spots associated with insomnia and tachycardia. This syndrome has been noted in white middle-aged men. The pale macules are cooler than the surrounding pink skin and become more apparent when the hands are lowered for some time.

Marshall W, et al: Dermatologic and psychosomatic aspects of Marshall-White syndrome. Cutis 1965;1:184.

Wilkin JK, et al: Bier's spots reconsidered: a tale of two spots, with speculation in a humerous vein. J Am Acad Dermatol 1986;14:411.

PURPURA

Purpura is multifocal extravasation of blood into the skin or a mucous membrane. It is manifested by distinctive brownish-red or purplish macules a few millimeters in diameter. Several types of purpura are recognized.

Petechiae are superficial, pinhead-sized (<3 mm), round, hemorrhagic macules, bright red at first, then brownish or rust colored. They are most commonly seen in the dependent areas, are evanescent, occur in crops, regress over a period of days, and most often imply a disorder of platelets rather than a coagulation factor disorder. These disorders typically give rise to ecchymoses or hematomas rather than petechiae. Petechiae may also be a sign of a blood vessel disease such as scurvy or amyloidosis.

Ecchymoses are better known as bruises or "black and blue marks." These extravasations signify a deeper and more extensive interstitial hemorrhage, which forms a flat, irregularly shaped, bluish-purplish patch. Such patches gradually turn yellowish and finally fade away.

Vibices (singular, vibex) are linear purpuric lesions.

Hematoma designates a pool-like collection of extravasated blood in a dead space in tissue that, if of sufficient size, produces a swelling that fluctuates on palpation. Hematomas are usually walled off by tissue planes.

Pathogenesis

Purpura may result from hyper- and hypo-coagulable states, vascular dysfunction, and extravascular causes, including idiopathic thrombocytopenic purpura, thrombotic thrombocytopenic purpura, disseminated intravascular coagulation (DIC), drug-induced thrombocytopenia, bone marrow failure, congenital or inherited platelet function defects, acquired platelet function defects (aspirin, renal or hepatic disease, or gammopathy), and thrombocytosis secondary to myeloproliferable diseases. Most of these disorders produce findings of nonpalpable purpura. Ecchymosis predominates in procoagulant defects, such as hemophilia, anticoagulants, DIC, vitamin K deficiency, and hepatic disease resulting in poor procoagulant synthesis. There is often a component of trauma. Increased frequency of ecchymotic skin can be the result of poor dermal support of blood vessels, most often localized to the area of trauma, and may result from actinic (senile) purpura, topical or systemic corticosteroid therapy, scurvy, systemic amyloidosis, Ehlers-Danlos syndrome, or pseudoxanthoma elasticum.

Occlusive disorders are those in which fibrin, cryoglobulin, or other material occludes vessels. Representative causes include monoclonal cryoglobulinemia, cryofibrinogenemia, DIC, purpura fulminans, protein C deficiency, warfarininduced necrosis, heparin necrosis, cholesterol emboli, oxalate crystal occlusion, and antiphospholipid syndrome.

Evaluation

A history and physical examination is often all that is necessary. A family history of bleeding or thrombotic disorders, duration of symptoms, use of drugs and medications that might affect platelet function and coagulation, as well as a review of medical conditions that may result in altered coagulation, should be documented. Physical examination should stress the size, type, and distribution of purpura; a search for telangiectases; a joint examination; and an evaluation of skin elasticity, unusual scars, and unusual body habitus. Correlation of purpura morphology with pathogenesis allows for a more focused approach.

A complete blood cell count and differential can be used to assess for microangiopathic anemia, screen for myeloproliferative disorders, and assess the number and morphology of platelets. A bleeding time is the preferred method of assessing platelet function. The partial thromboplastin time (PTT) or the prothrombin time (PT) are tests to evaluate abnormal coagulation states.

Lotti T: The purpuras. Int J Dermatol 1994;33:1.

Piette WW: The differential diagnosis of purpura from a morphologic perspective. Adv Dermatol 1994;9:3.

THROMBOCYTOPENIC PURPURA

Thrombocytopenic purpura may be classified into two large categories: states resulting from accelerated platelet destruction and states resulting from deficient platelet production. Accelerated platelet destruction may be immunologic or nonimmunologic. The former may be due to antibodies (autoimmune or drug-induced thrombocytopenia), isoantibodies (congenital or post-transfusion), immune complex disease, or other immunologic processes such as erythroblastosis fetalis, neonatal lupus, scleroderma, other connective tissue diseases, or acquired immunodeficiency syndrome (AIDS). The group of thrombocytopenias with accelerated platelet destruction caused by nonimmunologic processes includes thrombotic thrombocytopenic purpura and DIC. Deficient platelet production may be related to diseases such as aplastic anemia and leukemia.

"Idiopathic" Thrombocytopenic Purpura

"Idiopathic" thrombocytopenic purpura (ITP) is also known as *autoimmune thrombocytopenic purpura*, or *Werlhof's disease*. It is characterized by either an acute or gradual onset of petechiae or ecchymoses in the skin and mucous membranes, especially in the mouth. Epistaxis, conjunctival hemorrhages, hemorrhagic bullae in the mouth, and gingival bleeding may occur. Melena, hematemesis, and menorrhagia also occur, and the latter may be the first sign of this disease in young women. Chronic leg ulcers occasionally develop. The presence of splenomegaly usually excludes the diagnosis of immune thrombocytopenic purpura. Bleeding occurs when the platelet count drops below 50,000/mm³. Post-traumatic hemorrhage, spontaneous hemorrhage, and petechiae may appear. The risk of serious hemorrhage is greatly increased at levels below 10,000/mm³, and the gravest complication, intracranial hemorrhage, most often occurs with counts below 2000/mm³. Bleeding time is usually prolonged and coagulation time is normal, whereas the clot retraction is abnormal and capillary fragility is increased. Increased numbers of megakaryocytes are found in the bone marrow.

The acute variety most often occurs in children, and follows a viral illness in 50% of patients. Parvovirus B19 is frequently associated. The average lag between purpura and the preceding infection is usually 2 weeks. Most of these cases resolve spontaneously. A few patients will develop chronic thrombocytopenia, and deaths, usually from cerebral hemorrhage, have been reported. In a series of 332 children with ITP, 58 (17%) had episodes of major hemorrhage. One death resulted from sepsis. In another series of 427 cases, 323 (72%) had mild-to-benign disease. Roughly 85% of patients who undergo splenectomy experience remission. More than half of the remaining patients spontaneously remit within 15 years.

The chronic form occurs most often in adults, is persistent, and has a female-to-male ratio of between 2:1 and 4:1. In cases not responding to splenectomy, an evaluation for an accessory spleen should be performed using ^{99m}Tc radionuclide scan. Breast cancer has been associated with ITP, with a parallel course in one-third of cases. Other malignancies have also been associated with ITP. *Helicobacter pylori* infection and varicella have been reported in association with adult ITP.

ITP is the result of platelet injury by antibodies of the IgG class. Antiplatelet antibodies coat the platelets, triggering their removal by the spleen after a greatly reduced survival time, which may last from minutes to a few hours. Antiphospholipid antibodies are found in some patients.

Splenectomy is the most common form of therapy. Systemic corticosteroids are also used, but steroid treatment is associated with bone demineralization in both adults and children with the disease. Platelet transfusions may be lifesaving in acutely ill patients who are actively bleeding; however, they do not produce a sustained increase in the platelet count and thus are only indicated for emergencies. IVIG is used to treat and possibly postpone or eliminate the need for splenectomy in some patients. Patients responsive to IVIG are more likely to respond to splenectomy than those unresponsive to IVIG. In chronic ITP, laparoscopic splenectomy is an option. Anecdotal reports support the use of intravenous anti-D (anti-Rh_o), danazol, rituximab, vinca alkaloids, and other immunosuppressive agents (such as azathioprine, cyclophosphamide, and cyclosporine), interferon- α , plasma exchange, staphylococcal protein A immunoadsorption, dapsone, ascorbic acid, and colchicine.

Drug-Induced Thrombocytopenia

Thrombocytopenic purpura resulting from drug-induced antiplatelet antibodies may be caused by drugs such as heparin, sulfonamides, digoxin, quinine, quinidine, chlorothiazides, penicillin, cephalosporins, minocycline, phenylbutazone, acetaminophen, allopurinol, methyldopa, furosemide, gold salts, rifampin, and lidocaine. Ticlopidine, an antiplatelet agent used to reduce the occurrence of atherothrombotic arterial events, has been associated with neutropenia, aplastic anemia, thrombocytopenia, and thrombotic thrombocytopenic purpura.

Heparin-induced thrombocytopenia (HIT) is associated with life-threatening arterial and venous thrombosis and, to a lesser extent, hemorrhagic complications. HIT is mediated by an antibody to the platelet factor 4 (PF4)-heparin complex. The antibody cross-links FcyRII receptors on the platelet surface, resulting in platelet activation, aggregation, and simultaneous activation of blood-coagulation pathways. Tests for HIT antibodies include immunoassays (such as ELISA) and functional tests (such as the ¹⁴C-serotonin release assay).

Treatment for drug-induced thrombocytopenia consists of removal of the offending agent. Corticosteroids are helpful in moderately high dosage (60 mg/day prednisone) and are usually only necessary as a brief course. When a clinical diagnosis of HIT is made, heparin should be stopped immediately and treatment with an alternative anticoagulant (such as hirudin) should be started. Warfarin therapy can begin when the patient is clinically stable.

Thrombotic Thrombocytopenic Purpura

Also known as Moschcowitz syndrome, thrombotic thrombocytopenic purpura (TTP) is a pentad of thrombocytopenia. hemolytic anemia, renal abnormalities, fever, and disturbances of the central nervous system (CNS). Focal neurologic symptoms may be the presenting feature. Multiple ecchymoses, jaundice, pallid mucous membranes, and an enlarged spleen may be found. Other associated findings include arthritis, pleuritis, Raynaud phenomenon, abdominal pain, and hepatomegaly. The presence of schistocytes on a blood smear is the morphologic hallmark of the disease, and a schistocyte count of greater than 1% in the absence of other known causes of thrombotic microangiopathy strongly suggests a diagnosis of TTP. Tests may show a decreased hematocrit and decreased platelets. A delay in diagnosis may lead to a mortality rate as high as 90%. TTP has been associated with several drugs, including cyclosporin, tacrolimus, sirolimus, mitomycin-C, ticlopidine, clopidogrel, statins, Plavix, and the Norplant contraceptive system. Cases have been reported in association with HIV infection.

Biopsies demonstrate hemorrhage and fibrin occlusion of vessels. Inflammation is absent. Studies of plasma samples from patients with active TTP have often shown the presence of unusually large von Willebrand factor multimers. In some cases, there has been an absence of the large forms during acute disease, secondary to binding of unusually large von Willebrand factor multimers to platelets with subsequent aggregation. The underlying pathogenesis is a deficiency of the von Willebrand factor cleaving protease ADAMTS13.

Until exchange plasmapheresis was instituted as the treatment of choice, 80% of these patients died; now, 80% survive. Cascade filtration is also highly effective and supplemental immunosuppressive therapy may be required. In recurrent or refractory disease, extracorporeal immunoadsorption, rituximab therapy or splenectomy may be needed. Cyclosporin, a drug associated with onset of TTP, has also been used to treat cases not associated with the drug.

NONTHROMBOCYTOPENIC PURPURA (DYSPROTEINEMIC PURPURA)

Cryoglobulinemia and Cryofibrinogenemia

The term cryoglobulinemia refers to the presence in the serum of proteins that precipitate at temperatures below 37° C and redissolve on rewarming. Abnormal serum proteins behaving as cryoglobulins and cryofibrinogens may be IgG, IgM, or both. Cryoglobulinemic purpura occurs most frequently in multiple myeloma and macroglobulinemia and is of a monoclonal IgM, IgG, or Bence Jones cryoglobulin form. Mixed cryoglobulinemia, in which the cryoglobulins are of various classes, may be seen in hepatitis C infection, hepatitis B infection, SLE, rheumatoid arthritis, and Sjögren syndrome. Mixed cryoglobulinemia is associated with hepatitis C virus infection in greater than 90% of cases, and the prevalence of thyroid disorders is increased in these patients.

Purpura is most apt to occur on exposed surfaces after cold exposure. Marked brown hyperpigmentation of the dorsal feet results (Fig. 35-5). In monoclonal disease, the biopsy reveals amorphous jelly-like eosinophilic material in the vessel lumen. In the mixed type, biopsy reveals classic leukocytoclastic vasculitis. In cryocrystalglobulin syndrome, vasculitic skin lesions occur and crystalline deposits are seen in the corneas and joint spaces. Follicular hyperkeratosis, purpura, acral blisters, and ulceration have also been reported.

Purpura secondary to these abnormal serum proteins tends to be chronic. Deaths have been related to nephropathy, cardiac failure, widespread vasculitis, B-cell lymphoma, and other associated malignancies. Chromosomal translocation (t 14, 18) and Bcl-2 activation have been demonstrated in B-lymphocytes of 80% of patients with hepatitis C virus (HCV)-related cryoglobulinemic vasculitis, and HCV infection is the main etiologic factor associated with hematologic malignancies in patients with cryoglobulinemia.

Treatment options include plasmapheresis, systemic steroids, immunosuppressors, and colchicine. Prolonged remission after treatment with high-dose gamma globulin

Flg. 35-5 Cryoglobulinemia. infusion has been reported. Interferon, alone or in combination with ribavirin, has been used for hepatitis B- and Cassociated disease. Peginterferon produced an exacerbation of vasculitis in one reported patient. Mixed cryoglobulinemia with severe renal and cardiac disease refractory to corticosteroid therapy, plasmapheresis, chlorambucil and cyclophosphamide has responded to rituximab. Simple plasma exchange can be helpful, but cryofiltration apheresis is the best method to remove cryoproteins in the treatment of cryoprecipitate-induced diseases.

In contrast to cryoglobulinemia, cryofibrinogenemia is rarely symptomatic. The precipitating cryofibrinogen is a cold insoluble complex of fibrin, fibrinogen, and fibrin split products with albumin, cold insoluble globulin, factor VIII, and plasma proteins. Associated collagen-vascular disorders, infections, and malignancies are significantly more frequent in patients with combined cryofibrinogen and cryoglobulin than those with isolated cryofibrinogenemia. Cryofibrinogen has been associated with calciphylaxis in the setting of renal disease. The frequency of this association is unknown. Familial primary cryofibrinogenemia manifests as painful purpura with slow healing ulcerations and edema of both feet during the winter months.

Waldenström Hyperglobulinemic Purpura (Purpura Hyperglobulinemica)

Waldenström hyperglobulinemic purpura presents with episodic showers of petechiae occurring on all parts of the body, most profusely on the lower extremities. The dorsum of the feet are intensely involved, and the petechiae diminish on the ascending parts of the leet (Fig. 35-6). A diffuse

Fig. 35-6 Waldenström hyperglobulinemic purpura.

"peppery" distribution is commonly noted, resembling Schamberg's disease. The petechiae may be induced or aggravated by prolonged standing or walking, or by wearing constrictive garters or stockings.

Serum protein electrophoresis demonstrates a broadbased peak (polyclonal hypergammaglobulinemia). The bulk of the protein increase is IgG, though occasionally increased amounts of IgA are also found. IgM is usually normal or decreased. Rheumatoid factor in varying amounts is present in almost all patients. Antithyroglobulins, increased erythrocyte sedimentation rate (ESR), leukopenia, antinuclear factors, and proteinuria may be found. Almost 80% of patients with hypergammaglobulinemic purpura of Waldenström have antibodies to Ro/SSA.

Hyperglobulinemic purpura occurs most commonly in women and is frequently seen with Sjögren syndrome, hepatitis C, keratoconjunctivitis sicca, rheumatoid arthritis, and multiple myeloma. It may also be a primary chronic benign illness. Hypergammaglobulinemic purpura associated with hepatitis C has a predilection for men, and has manifestations that usually last longer than those associated with Sjögren syndrome.

In about a third of patients, leukocytoclastic vasculitis is present. Patients with leukocytoclastic vasculitis have a higher prevalence of articular involvement, peripheral neuropathy, Raynaud phenomenon, renal involvement, antinuclear antibodies, rheumatoid factor, and anti-Ro/SS-A antibodies. Biopsy in patients without leukocytoclastic vasculitis demonstrates a perivascular infiltrate of mononuclear cells.

The course of the disease is essentially benign, but chronic. Rare deaths are related to associated cryoglobulin disease. Hyperglobulinemic purpura may be a manifestation or harbinger of connective tissue or hematopoietic diseases, and rarely, progression to myeloma has been reported.

Patients often improve with support stockings. Steroids should be reserved for severe disease. Indomethacin and hydroxychloroquine may be of value in the treatment of milder disease. Chlorambucil reduces the purpura but does not effect gross changes in the protein abnormality. Thioguanine, dipyridamole (Persantine), aspirin, and colchicine have been used with some success.

Waldenström Macroglobulinemia

In 1944, Waldenström described an entity characterized by bleeding from the mucous membranes of the mouth and nose, lymphadenopathy, hepatosplenomegaly, hemorrhage of the retina, and cutaneous purpura. Gastrointestinal bleeding and anemia may occur. This disease occurs mostly in elderly white men who present with oronasal bleeding as a manifestation of plasma cell dyscrasia. Nonspecific cutaneous findings include Raynaud phenomenon, amyloidosis, pruritus, xanthomatosis, and urticaria. Some patients with Schnitzler syndrome (urticaria, bone pain, and paraproteinemia) satisfy the criteria for Waldenström macroglobulinemia. Waldenström macroglobulinemia may be associated with chronic liver disease and hepatocellular carcinoma. Hepatitis G, a new member of the *Flaviviridae* family, and hepatitis C infection have been implicated in some cases.

The histopathologic feature in most cases is a perivascular infiltrate containing lymphocytes and in some cases neutrophils and eosinophils. Two types of skin lesions may occur: violaceous to red indurated plaques, infiltrated with atypical lymphoid cells; or alternatively, translucent papules full of amorphous eosinophilic material that has proved on direct immunofluorescence (DIF) to be IgM. Basement membrane deposits of IgM have also been detected. Leukocytoclastic vasculitis associated with Waldenström macroglobulinemia has been rarely reported. Large amounts of monoclonal IgM are responsible for the variable clinical pattern. Fibrinogenopenia, fibrinolysis, circulating anticoagulants, coagulation factor deficiencies, intravascular or perivascular deposition of paraprotein, or associated cryoglobulinemia or cryofibrinogenemia may result in the bleeding tendencies. Age, hemoglobin, and serum albumin are among the most important prognostic factors.

Plasmapheresis is recommended until adequate doses of chlorambucil have been administered. Cyclophosphamide and corticosteroids or 2-chlorodeoxyadenosine (cladribine) have also been shown to be effective. PUVA has been used to alleviate symptoms of pruritus. Rituximab has shown a response rate of about 30%. Autologous and allogeneic stem cell transplantation may be considered for patients with refractory or relapsing disease.

PURPURA SECONDARY TO CLOTTING DISORDERS

Hereditary disorders of blood coagulation usually result from a deficiency or qualitative abnormality of a single coagulation factor, as in hemophilia or von Willebrand's disease. Acquired disorders commonly result from multiple coagulation factor deficiencies, as in liver disease, biliary tract obstruction, malabsorption, or drug ingestion. Acquired clotting disorders may also involve platelet abnormalities, as in DIC. Hemorrhagic manifestations are common and may be severe, especially in hereditary forms. Ecchymoses and subcutaneous hematomas are common, especially on the legs. Severe hemorrhage may follow trauma, and hemarthrosis is frequent. Other hemorrhagic manifestations include respiratory obstruction resulting from hemorrhage into the tongue, throat, or neck; epistaxis; gastrointestinal and genitourinary tract bleeding; and, rarely, CNS hemorrhage.

Sham RL, et al: Evaluation of mild bleeding disorders and easy bruising. Blood Rev 1994;8:98.

DRUG- AND FOOD-INDUCED PURPURA

Drug-induced purpura may be related to platelet destruction, vessel fragility, interference with platelet function or vasculitis. Drug-induced thrombocytopenic purpura was discussed earlier in this chapter. Examples of purpurogenic drugs are: aspirin and other nonsteroidal anti-inflammatory drugs (NSAIDs), allopurinol, thiazides, gold, sulfonamides, cephalosporins, hydralazine, phenytoin, quinidine, ticlopidine, and penicillin. Combinations of diphenhydramine and pyrithyldione can induce purpuric mottling and areas of necrosis. Cocaine-induced thrombosis with infarctive skin lesions is associated with skin popping. The Rumpel-Leede sign (a distal shower of petechiae that occurs immediately after the release of pressure from a tourniquet or sphygmomanometer) has been reported in association with druginduced erythema multiforme.

Topical EMLA cream can induce purpura within 30 min of application, a result of a toxic effect on the capillary endothelium. Purpura has been associated with the use of acetaminophen in patients afflicted with infectious mononucleosis. Small-vessel vasculitis, including urticarial vasculitis, has been caused by the ingestion of tartrazine dye and benzoates. Escherichia coli O157:H7 in food has been associated with diarrhea, hemorrhagic colitis, hemolytic-uremic syndrome, and thrombotic thrombocytopenic purpura. Consumption of undercooked beef is the most common risk factor.

SOLAR PURPURA (SENILE PURPURA, ACTINIC PURPURA)

Solar purpura is characterized by large, sharply outlined, 1- to 5-cm, dark purplish-red ecchymoses appearing on the dorsa of the forearms and less often the hands. Usually the skin over the forearms is thin and inelastic. This is discussed in greater detail in Chapter 7.

PURPURA FULMINANS

Also known as *purpura gangrenosa*, this is a severe, rapidly fatal reaction occurring most commonly in children after an infectious illness. The sudden appearance of large ecchymotic areas, especially prominent over the extremities, progressing to acral hemorrhagic skin necrosis is characteristic (Fig. 35-7). Fever, shock, and DIC usually accompany the skin lesions, which on biopsy show noninflammatory necrosis, with platelet-fibrin thrombi occluding the blood vessels.

Purpura fulminans usually follows an acute infectious disease, such as scarlet fever and, rarely, streptococcal pharyngitis, meningococcal meningitis, pneumococcal sepsis, Capnocytophaga canimorsus (DF-2) infection, Xanthomonas maltophilia sepsis, or varicella. Purpura fulminans may also occur without any preceding illness. Asplenic patients, who are at risk for pneumococcal or meningococcal sepsis, are also predisposed to purpura fulminans. Neonates with homozygous protein C or protein S deficiencies may suffer purpura fulminans as a result of the lack of these natural anticoagulanta. Some patients develop transient deficiencies of proteins C and S in response to infection. IgG paraproteins may inhibit the functional anticoagulant activity of activated protein C. Autoimmune protein S deficiency has also been shown to be a mechanism in causing postinfectious idiopathic purpura fulminans. Other disease, such as the fibrinolysis syndrome, may have purpura fulminans as part of the symptom complex. An acquired form has been reported secondary to alcohol and acetaminophen

Fig. 35-7 Purpura fulminans.

ingestion. When purpura fulminans occurs in the setting of systemic lupus erythematosus, the catastrophic antiphospholipid antibody syndrome (CAPS) must be considered. Purpura fulminans has been reported as a presenting feature of the Churg-Strauss syndrome.

Approximately 5% of white persons of European origin have a mutation in coagulation factor V. A number of cases of purpura fulminans associated with infections and this factor V Leiden mutation, with normal protein C and protein S levels, have been reported. Factor V Leiden deficiency may be a more frequent cause of purpura fulminans than previously appreciated.

Management is usually supportive, with treatment of the underlying disease process, such as antibiotics, and replacement therapy using fresh frozen plasma. Protein C and antithrombin replacement is useful in treating patients shown to have deficiencies. In fulminant meningococcennia, some data suggest that the doses of supplementation should be at least 150 IU/kg of antithrombin and 250 IU/kg of protein C as a loading dose, followed by 150 IU/kg and 200 IU/kg, respectively, as daily maintenance therapy. Despite these measures, amputations and deaths continue to occur in patients with severe disease. Fasciotomy during the initial management of these patients may reduce the depth of soft-tissue involvement and the extent of amputations. Tissue plasminogen activator has been used in meningococcal-associated disease, but is associated with a risk of intracerebral hemorrhage.

DISSEMINATED INTRAVASCULAR COAGULATION

Up to two-thirds of patients with DIC have skin lesions, which may be the initial manifestation of the syndrome. Minute, widespread petechiae, ecchymoses, ischemic necrosis of the skin, and hemorrhagic bullae are the usual findings. Purpura fulminans may supervene and progress to symmetrical peripheral gangrene. DIC may be initiated by a variety of disorders, including septicemic hypotension, hypoxemia, acidosis, malignancies, chemotherapy, obstetric crises, antiphospholipid antibody syndrome, SLE, arthropod envenomation, and leukemia. Long-term treatment with granulocyte colony-stimulating factor (G-CSF) has also been reported to precipitate DIC. Children with kaposiform hemangioendotheliomas are at risk for consumptive coagulopathy (Kasabach-Merritt syndrome).

DIC is the result of widespread intravascular coagulation in which certain coagulation factors are consumed faster than they can be replaced. Laboratory findings include decreased platelets, decreased fibrinogen, elevated PT, PTT, and fibrin degradation products. Control of the underlying disease is the paramount consideration, together with correction of hemostatic abnormalities, usually through the use of intravenous heparin. Vitamin K replacement will exclude vitamin K deficiency as a cause, and replace vitamin K stores, which are rapidly depleted in patients with DIC. Fresh frozen plasma, platelet transfusions, protein C, and, at times, select replacement of specific coagulant factors may be beneficial. The sepsis-related organ failure assessment (SOFA) score is useful for predicting outcome in DIC patients in the intensive care unit.

FIBRINOLYSIS SYNDROME (HYPOFIBRINOGENEMIA, DEFIBRINATING SYNDROME)

The fibrinolysis syndrome is characterized by an acute hemorrhagic state brought about by inability of the blood to clot. Massive hemorrhages into the skin produce blackish, purplish swellings and sloughing. There is an increased tendency to thrombosis and hemorrhage. It occurs as a complication of pregnancy in cases of placenta previa, eclampsia, and fetal death. It may be a complication in certain surgical operations, particularly in lobectomy and during extracorporeal circulation of blood. The syndrome has been repeatedly reported in amyloidosis, thrombotic thrombocytopenic purpura, liver disease, Waterhouse-Friderichsen syndrome, carcinoma of the prostate with metastases to bone marrow, and in other types of malignant disease. It may also follow snake bite. Treatment is by transfusions of fibrinogen concentrates.

BLUEBERRY MUFFIN BABY

Originally coined to describe the characteristic appearance of the purpuric lesions observed in newborns with congenital rubella, blueberry muffin baby is associated with many disorders that produce extramedullary erythropoiesis. The eruption consists of generalized dark blue to magenta, nonblanchable, indurated, round to oval, hemispheric papules ranging from 1 to 7 mm. Lesions favor the head, neck, and trunk.

Etiologic factors include congenital infections (rubella, cytomegalovirus, and parvovirus B19), hemolytic disease of the newborn (Rh incompatibility, blood group incompatibility), hereditary spherocytosis, twin transfusion syndrome, neuroblastoma, rhabdomyosarcoma, Langerhans cell histio-cytosis, and congenital leukemia. Evaluation should include a peripheral blood cell count, hemoglobin level, TORCH serologies, viral cultures, and a Coomb test. A skin biopsy may also be helpful in determining the cause. Rhabdomyo-sarcoma may present with a blueberry muffin-like appearance.

MISCELLANEOUS PURPURIC MANIFESTATIONS

Deep Venous Thrombosis

Immobilization is an important risk factor, and malignant neoplasms are the most common underlying condition, with bronchogenic carcinoma by far the most frequent. In 35% of cancer-associated cases, the thrombosis is the first sign of the cancer. Extensive venous thrombosis, almost always affecting at least the femoral vein, can cause reversible ischemia, or frank gangrene. Patients may develop severe pain, extensive edema, and cyanosis of the extremity. The left leg is more often affected than the right. Female patients slightly outnumber male, and the mean age is 52 years. Significant superficial vein thrombosis is considered a risk factor for deep vein thrombosis. The risk of pulmonary embolism from deep vein thrombosis is the major concern. Chronic complications include venous incompetence, with stasis dermatitis or ulcers, and postphlebitic syndrome.

Bates SM, et al: Clinical practice. Treatment of deep-vein thrombosis. N Engl J Med 2004;351:268.

Cushman M, et al: Deep vein thrombosis and pulmonary embolism in two cohorts: the longitudinal investigation of thromboembolism etiology. Am J Med;117:19.

Superficial Thrombophlebitis

Samlaska and James have reviewed the vast number of primary and secondary hypercoagulable states that can present with superficial vein thrombosis. Painful induration with erythema, often in a linear or branching configuration

Bick RL, et al: Syndromes of hypercoagulability and thrombosis: a review. Semin Thromb Hemostat 1994;20:109.

forming cords, is the classic presentation (Fig. 35-8). Patients may also exhibit indurated subcutaneous nodules and overlying purpura or brown discoloration indicative of postinflammatory hyperpigmentation.

Primary hypercoagulable states that may be associated with superficial thrombophlebitis include deficiencies of antithrombin III, heparin cofactor II, protein C, protein S, and factor XII; disorders of tissue plasminogen activator; abnormal plasminogen; dysfibrinogenemia; and lupus anticoagulant. Secondary hypercoagulable states include varicosities, malignancy (Trousseau syndrome), pregnancy, oral contraceptive use, infusion of prothrombin complex concentrates, Behçet's disease, thromboangiitis obliterans, acute thrombophlebitis of superficial veins of the breast (Mondor's disease), septic thrombophlebitis, psittacosis, secondary syphilis, intravenous catheters, intravenous drugs (sugar solutions, protein hydrolysates, calcium, potassium, hypertonic concentrates, diazepam, nitrogen mustard, acridinylaniside, dacarbazine, and carmustine), and street drugs (cocaine, bulking agents such as paregoric, quinine, dextrose, sucrose, and lactose).

In the evaluation of superficial thrombophlebitis, one should consider the possibility of underlying deep venous disease. Superficial femoral vein involvement should alert the physician to underlying deep venous disease requiring anticoagulation. Lesser saphenous vein thrombophlebitis is also frequently associated with underlying deep vein thrombosis. Elliptic biopsies across the palpable cord may be required to exclude other considerations such as sarcoidal granulomas, cutaneous polyarteritis nodosa, Kaposi sarcoma, and vasculotropic metastasis.

Treatment is directed at the underlying cause. Leg elevation and local heat will help to promote the dissolution of clots, which may take up to 8 to 12 weeks to resolve. Heparin therapy may reduce the incidence of thromboembolic complications in high-risk individuals.

Mondor's Disease

migratory thrombophlebitis.

Mondor's disease occurs three times as frequently in women as in men, and most patients are between 30 and 60 years of age. The sudden appearance of a cordlike thrombosed vein along the anterior-lateral chest wall is characteristic. It is at first red and tender and subsequently changes into a painless, tough, fibrous band. There are no systemic symptoms. Both sides of the chest have the same incidence of involvement. Mondor's disease may be associated with strenuous exercise, pregnancy, intravenous drug abuse, jellyfish stings, breast cancer, and breast surgery. The condition represents a localized thrombophlebitis of the veins of the thoracoepigastric area. The veins involved are the lateral thoracic, thoracoepigastric, and superior epigastric. In the end stage a thickwalled vein remains that has a hard, ropelike appearance and, on occasion, may result in a furrowing of the breast. Exceptionally, a vein coursing up the inside of the upper arm may be involved. Similar string-like phlebitis findings have been described in the penis, antecubital fossa, groin, abdomen, and axilla.

Treatment is symptomatic, with hot, moist dressings and analgesics or NSAIDs. The disease process runs its course in from 3 weeks to 6 months.

Postcardiotomy Syndrome

Two to 3 weeks after pericardiotomy, lever, pleuritis, pericarditis, or arthritis may appear together with petechiae on the skin and palate. This syndrome may be confused with infectious mononucleosis and bacterial endocarditis.

Orthostatic Purpura (Stasis Purpura)

Prolonged standing or even sitting with the legs lowered (as in a bus, airplane, or train) may produce edema and a purpuric eruption on the lower extremities. Elevation of the legs and the use of elastic stockings are helpful preventive strategies.

Obstructive or Traumatic Purpura

Purpura may also be evoked by mechanical obstruction to the circulation, with resulting stress on the small vessels. This may be encountered in cardiac decompensation, or after convulsions, vomiting episodes, the Valsalva maneuver, pertussis, or sexual climax. Nonpalpable purpura has been reported associated with the use of a mucus-clearing device, which requires the patient to exhale forcefully through a flutter valve (flutter valve purpura). Local obstruction of the blood flow with purpura may result from compression of the veins by tumors or a gravid uterus, by occlusions from thrombosis, or by a weakening of the elastic coat as in varicose veins.

Purpuric lesions in children brings into question the possibility of the battered child. Bruises and ecchymoses on the genital area, buttocks, or hands are suggestive of an abused child. Linear lesions on accessible areas raise the question of factitial disease. Ecchymoses of bizarre shapes may also correspond to trauma inflicted during religious rituals or cultural practices. Coin-rubbing and cupping performed as remedies for common diseases are examples. "Passion purpura" on the palate may result from fellatio, or on the neck or upper arms (a "hickey") from biting and sucking. Facial, cheek, and periorbital purpura can occur postictal and may be mistaken for spousal abuse. Bathtub suction-induced purpura occurs on the lower back location in a U-shaped distribution. It may be mistaken for abuse.

Epidemic Dropsy

Epidemic dropsy manifests with eruptive angiomas, purpura, dyspnea, tachycardia, diarrhea, and fever. It has been reported in parts of India, Africa, and the Fiji Islands, and is the result of ingested mustard oil adulterated with sanguinarine (Argemone mexicana oil). A major outbreak of epidemic dropsy occurred in Delhi, India, in August-September 1998. The patients presented with pitting pedal oedema (100%), skin erythema (75%), limb tenderness (63%), diarrhea (51%) and hepatomegaly (34%). There were six deaths related to cardiac failure. Toxic alkaloids of Argemone mexicana oil induce capillary leakage with resulting renal hypoperfusion, restrictive ventilatory dysfunction, and rightsided failure.

Sharma BD, et al: Epidemic dropsy: observations on pathophysiology and clinical features during the Delhi epidemic of 1998. Trop Doct 2002;32:70.

Paroxysmal Nocturnal Hemoglobinuria

This acquired intravascular hemolytic anemia usually occurs in young adults. It is an acquired clonal disorder resulting from a somatic mutation in the hematopoietic stem cell that produces intravascular hemolysis, cytopenias, infections, bone marrow hypoplasia, and life-threatening venous thrombosis. Some cases evolve into acute leukemia. Initial erythematous cutaneous plaques may progress to hemorrhagic bullae. Vascular thrombi are found on biopsy. The physiologic drop in pH that occurs with sleep appears to be responsible for the hemolysis and is the basis for the specific Ham (acid hemolysis) test. Hematopoietic stem cell transplantation may be curative. Antilymphocyte globulin and cyclosporin have also been used.

Purpura-Associated Dermatoses

Purpura may be noted at times in erythema multiforme, dermatitis medicamentosa, serum sickness, pityriasis rosea, lichen nitidus, and herpes zoster. Petechiae or ecchymoses may be associated with measles, scarlet fever, and smallpox, and may appear extensively in cerebrospinal meningitis, typhus, parvovirus B19, and Rocky Mountain spotted fever. Disseminated strongyloidiasis can cause widespread thumbprint purpura by the passage of the larvae through vessel walls. Purpura may occur also in septicemia, Waterhouse-Friderichsen syndrome, bacterial endocarditis, malaria, miliary tuberculosis, and anthrax.

- Yanez S, et al. Purpuric generalized lichen nitidus: an unusual eruption simulating pigmented purpuric dermatosis. Dermatology 2004;208:167.

Paroxysmal Hand Hematoma (Achenbach Syndrome)

Spontaneous focal hemorrhage into the palm or the volar surface of a finger may result in transitory localized pain, followed by rapid swelling and localized bluish discoloration. The lesion resolves spontaneously within a few days. Spontaneous hemorrhage from an arteriole appears to be responsible. The acute nature, purpuric findings, and rapid resolution are distinguishing features of Achenbach syndrome.

Easy Bruising Syndromes

Young women who bruise easily despite normal coagulation profiles and normal platelet counts may have antiplatelet antibodies or increased megakaryocytes. They are divided into groups I (vasculitis) and II (qualitative platelet function abnormalities). A screen for bleeding time and blood eosinophilia should be performed on white children who develop easy bruising, particularly in Southeast Asia and East India. They should be screened periodically for as long as 12 months after arrival. An infectious etiology is suspected for the syndrome of acquired platelet dysfunction associated with eosinophilia. Bernard-Soulier syndrome is a rare inherited disorder characterized by giant platelets, thrombocytopenia, and a prolonged bleeding time. It is caused by genetic defects of the glycoprotein Ib-IX complex that constitutes the von Willebrand factor receptor. Sebastian syndrome consists of giant platelets, leukocyte inclusions, and thrombocytopenia. Fechtner syndrome is a rare type of familial thrombocytopenia associated with large platelets, leukocyte inclusions, and features of Alport syndrome. The May-Hegglin anomaly consists of easy bruising with giant platelets and Dohle-like cytoplasmic inclusions in granulocytes. The inclusions appear as electron-dense long rods and needles oriented along the long axis of the spindle.

Painful Bruising Syndrome (Autoerythrocyte Sensitization, Gardner-Diamond Syndrome, Psychogenic Purpura)

Painful bruising syndrome is a distinctive localized purpuric reaction occurring primarily in young to middle-aged women who usually manifest personality disorders. There may be depression, anxiety, hysterical, or masochistic character traits, or inability to deal with hostile feelings. A recurrent type of eruption, it is characterized by extremely painful and tender, ill-defined ecchymoses about the extremities and sometimes on the face or trunk. The lesions evolve in a few . hours and resolve within 5 to 8 days. New lesions may appear in crops. Emotional upsets are generally associated with the appearance of these painful sheets of purpura. It has been noted that some patients have a premonition as to when they will develop new lesions a few hours ahead of time by the tingling and burning sensation at the site of a future lesion. Extracutaneous somatic symptoms are common, such as headache, paresthesias, transient paresis, syncope, diplopia, abdominal distress, diarrhea, nausea and vomiting, and arthralgia.

Gardner and Diamond reported that intracutaneous injections of erythrocyte stroma evoked typical lesions. Since then, many have reported similar reactions to autologous whole blood, packed or washed red cells, or fractions of erythrocyte stroma. These are hard to assess, because similar reactions have been reported to substances as diverse as hemoglobin, phosphatidyI serine, histamine, histidine, trypsin, purified protein derivative (PPD), autologous serum, and platelets. Blinded, controlled testing, trying to avoid factitial trauma, has given mixed responses. Abnormalities in tissue plasminogen activator-dependent fibrinolysis, thrombocytosis, and anticardiolipin antibodies have also been implicated. Many believe this syndrome to be artifactual, whereas others believe the lesions are spontaneous.

Treatment has been mostly unavailing, though psychotherapy directed at emotional problems has helped in some cases. The disease follows an irregularly intermittent course, possibly exacerbated by emotional stress or physical injury.

A similar syndrome, reported as DNA autosensitivity, has been described in eight patients who were reactive to intracutaneous injections of purified calf thymus DNA or frozen and thawed buffy coat. Further case studies are needed to fully assess this syndrome. Documentation to date suffers from the same inconsistencies and lack of controlled, blinded studies as does the Gardner-Diamond syndrome.

PIGMENTARY PURPURIC ERUPTIONS (PROGRESSIVE PIGMENTARY DERMATOSIS, PROGRESSIVE PIGMENTING PURPURA, PURPURA PIGMENTOSA CHRONICA)

The pigmented purpuric eruptions of the lower extremities present with several clinical patterns. Clinical overlap between the various disorders may occur, and the histologies differ only by minor features.

The most common variant of progressive pigmentary dermatosis is Schamberg's disease. The typical lesions are thumbprint sized and composed of aggregates of pinhead-sized petechiae resembling grains of cayenne pepper along with golden-brown hemosiderin staining. The lesions commonly begin on the lower legs with slow proximal extension. These lesions seldom itch. The favored sites are around the lower shins and ankles, but lesions may be more widespread and occasionally affect the upper extremities or trunk.

Majocchi's disease is also known as purpura annularis telangiectodes. The early lesions are bluish-red 1- to 3-cm annular patches composed of dark red telangiectases with petechiae and hemosiderin staining (Fig. 35-9). Central involution and peripheral extension produce ringed, semicircular, target-like, or concentric rings such as are seen on the crosscut section of a tree trunk. The eruption begins symmetrically on the lower extremities, spreads up the legs, and may extend onto the trunk and arms. Involution of individual patches is slow and because new lesions continue to form, it may continue indefinitely. The lesions are asymptomatic.

Gougerot-Blum syndrome (pigmented purpuric lichenoid dermatitis) is characterized by minute, rust-colored to violaceous, lichenoid papules that tend to fuse into plaques of various hues between red, violaceous, and brown (purpura with lichenoid dermatitis). Favorite locations are on the legs, thighs, and lower trunk. The chief difference between this and Schamberg's disease is the deeper color and presence of induration, both of which relate to the presence of a lichenoid band of lymphoid inflammation. Similar lesions have also occurred during interferon therapy-for hepatitis C.

Ducas and Kapetanakis pigmented purpura is scaly and eczematous. The eczematous patches also demonstrate petechiae and hemosiderin staining. It is distinguished histologically by the presence of spongiosis.

Lichen aureus is characterized by the sudden appearance of one or several golden or rust-colored, closely packed macules or lichenoid papules. The macules may be grouped into a patch and may occur on any part of the body. The patches are usually solitary and asymptomatic, but may occasionally be painful. Adults predominate, but children may also be affected. Many cases are related to an incompetent perforator valve causing a local increase in venous and capillary pressure. Linear segmental lesions may occasionally occur, and a single case of evolution to linear morphea has been reported.

Histologically, all forms of pigmenting purpura demonstrate lymphoid capillarities with erythrocyte extravasation. As lesions evolve, hemosiderin deposition becomes prominent. There may be a lichenoid band of lymphoid inflammatory cells (Gougerot-Blum type) or spongiosis (Ducas and Kapetanakis type). An iron stain (Perl, Prussian blue, ferricyanide) is sometimes used to demonstrate the hemosiderin deposition. Lichenoid purpura must be distinguished from mycosis fungoides, which it can closely resemble both clinically and histologically. The absence of epidermotropism or the presence of only a few lymphocytes with spongiosis favors the diagnosis of pigmented purpura. Purpuric pityriasis rosea my resemble Ducas and Kapetanakis pigmenting purpura.

Anecdotal reports of benefit from topical steroids make a therapeutic trial for 4 to 6 weeks reasonable. Pentoxifylline, 400 mg three times a day, has also been reported to provide significant improvement within 2 to 3 weeks. Oral rutoside, 50 mg twice a day, and ascorbic acid, 500 mg twice a day, have cleared a few patients. Pigmenting purpura frequently occurs in the setting of venous stasis, and support stockings may be of benefit. Paradoxically, some cases represent an allergic response to textile dyes in stockings, especially the azo dyes Disperse Blue 124, 106, and 85. Positive patch reactions have also been noted to Disperse Red 17, and Basic Red. Fabric resins, including ethyleneurea melamine formaldehyde, dimethylol dihydroxyethyleneurea, dimethylol propyleneurea, tetramethylol acetylenediurea, and urea formaldehyde have also been implicated. The finding of a purpuric reaction of patch testing is diagnostic in such cases. Sometimes, the positive patch site does not develop clinical purpura, but the dermatosis fades with elimination of the allergen.

PURPURIC AGAVE DERMATITIS

Agave americana is a large, thick, long-leaved, subtropical plant with a striking blue-gray color. It is commonly used in ornamental beddings in the southwestern US. The plant grows up to 8 feet in diameter and may overgrow the surrounding landscape. As they are very deep-rooted and difficult to remove, some individuals have attempted

Fig. 35-9 Pigmented purpuric dermatosis.

removal with the help of a chain saw. A striking purpuric dermatosis occurs in a pattern corresponding to the splatter of the plant's sap. Histologically, there is vascular damage at the level of the capillary and postcapillary venule with a sparse infiltrate of neutrophils and karyorrhectic debris, suggesting low-grade leukocytoclastic vasculitis. Papulovesicular lesions have also been described. The plant's sap contains calcium oxalate crystals as well as various acrid oils and saponins. The causative component is unknown.

VASCULITIS

Vasculitis is a clinicopathologic process characterized by inflammation and necrosis of blood vessels. Since the clinical morphology correlates with the size of the affected blood vessel(s), these disorders are classified by the blood vessel(s) affected. Diseases may involve vessels of overlapping size. In general, small-vessel disease (affecting postcapillary venules) causes urticarial lesions and palpable purpura; small-artery disease manifests as subcutaneous nodules; medium-sized

Box 35-1 Classification of vasculitis

- I Cutaneous small-vessel (postcapillary venule)
- A. Idiopathic cutaneous small-vessel vasculitis
 - B. Henoch-Schönlein purpura
 - C. Acute hemorrhagic edema of Infancy
 - D. Urticarial vasculitis
 - E. Cryoglobulinemic vasculitis
 - F. Erythema elevatum diutinum
 - G. Granuloma faciale
 - H. Other diseases with leukocystoclastic vasculitis: drug-induced vasculitis, malignancy (lymphoreticular more common than solid tumor), connective tissue diseases, hyperglobulinemic purpura, inflammatory bowel disease, bowel-associated dermatitis-arthritis syndrome (bowel bypass), HIV infection, and neutrophilic dermatoses (Behçet; Sweet; erythema nodosum leprosum; septic vasculitis; autoinflammatory conditions-familial Mediterranean fever, and serum sickness)

II. Medium-vessel

- A. Polyarteritis nodosa
 - 1. Benign cutaneous forms
 - 2. Systemic form
- III. Mixed Size (medium and small) vessel disease
 - Connective tissue disease associated (usually rheumatold vasculitis)
 - B. Septic vasculitis
 - C. ANCA-associated
 - 1. Microscopic polyangiitis
 - 2. Wegener granulomatosis
 - 3. Allergic granulomatosis (Churg-Strauss)
 - Occasional drug-induced (most are post-capillary venule only)
- IV. Large-vessel vasculitis
 - A. Giant-cell arteritis
 - B. Takayasu arteritis

arteries with necrosis of major organs, livedo reticularis, purpura, and mononeuritis multiplex; and large-vessel disease with symptoms of claudication and necrosis.

Classification

Numerous classification schemes have been proposed, all of which have limitations. It is important to remember that infectious and thrombotic conditions, which histologically "classically" show thrombosis of vessels, may also at times show true leukocytoclastic vasculitis. Hence, infectious, embolic, and thrombotic causes of vessel damage must always be considered before unequivocally diagnosing a case as an "inflammatory" vasculitis. Leukocystoclastic vasculitis is also commonly seen adjacent to suppurative folliculitis and at the base of chronic ulcers. The discovery of the association of some forms of small- and medium-vessel vasculitides with positive ANCAs has made their diagnosis and classification much easier (Box 35-1).

Fiorentino DF: Cutaneous vasculitis. J Am Acad Dermatol 2003;48:311.

SMALL-VESSEL VASCULITIS

Cutaneous Small-Vessel Vasculitis (Cutaneous Leukocytoclastic Angiitis)

The vast majority of cases of cutaneous leukocytoclastic vasculitis follow an acute infection or exposure to a new medication. Palpable purpura is the hallmark of this disease, with lesions ranging from pinpoint to several centimeters in diameter (Figs 35-10 and 35-11). Annular, vesicular, bullous,

Fig. 35-10 Leukocytoclastic vasculitís, palpable purpura.

Fig. 35-11 Leukocytoclastic vasculitls, concentration of lesions along the dividing line between the dorsal foot and sole (Wallace line).

pustular, or ulcerated lesions may develop. They predominate on the ankles and lower legs, affecting mainly dependent areas or areas under local pressure. Edema, especially of the ankles, is usually noted. Mild puritus, fever, and malaise may occur. Arthralgias or, less commonly, frank arthritis may be seen. Other systemic involvement is rare and should raise the consideration of another diagnosis.

The lesions usually resolve within 3 to 4 weeks with residual postinflammatory hyperpigmentation. Because the inciting event is time limited, usually the disease is selflimited. Ten percent of cases of cutaneous leukocytoclastic vasculitis may have recurrences. A persistent underlying cause must be sought in cases which are chronic.

Histology

There is angiocentric segmental inflammation of the postcapillary venule with expansion of the vessel wall, fibrin deposition, and infiltration by neutrophils that show fragmentation of their nuclei (karyorrhexis or leukocytoclasia). Endothelial cell swelling is common, but endothelial necrosis suggests more serious illness (including septic vasculitis, ANCA-associated vasculitis). Vascular thrombosis may be present. Immunofluorescence and ultrastructural studies have shown the presence of immunoglobulins, complement components, and fibrin deposits within postcapillary venule walls if the biopsy is taken within the first 24 h. Later, fibrin is prominent, but immunoglobulin deposits may have been destroyed. An important exception is Henoch-Schönlein purpura, which usually demonstrates prominent IgA deposits even in more advanced lesions.

Pathogenesis

Cutaneous small-vessel vasculitis is felt to be caused by circulating immune complexes. These complexes lodge in vessel walls and activate complement. Various inflammatory mediators are produced, contributing to endothelial injury. Cocaine use may cause or exacerbate small-vessel vasculitis.

Etiology

The types of antigens inducing immune complexes vary, but infections and drugs are most common. A host of infectious agents, such as beta-hemolytic *Streptococcus* group A and rarely *Mycobacterium tuberculosis* may cause palpable purpura. Patients with lymphoproliferative neoplasms (Hodgkin's disease, mycosis fungoides, adult T-cell leukemia, and multiple myeloma), as well as solid tumors (lung, colon, ovarian, renal, prostate, head and neck, and breast cancer) may experience cutaneous small-vessel vasculitis at some time during the course of their disease.

Clinical Evaluation

Given the vast number of conditions that may result in smallvesse) vasculitis a detailed history and physical examination are essential. The history should focus on possible infectious disorders, prior associated diseases, drugs ingested, and a thorough review of systems. Screening laboratory tests may help to elucidate the underlying cause or extent of organ involvement. When the history suggests a recent drug and the patient is clinically well, nothing more than a urinalysis may be required. A complete blood count, urinalysis, strep throat culture or ASO titer, hepatitis B and C serologies, and antinuclear antibodies are a reasonable initial screen for patients with no obvious cause for their vasculitis. Serum protein electrophoresis, serum complements, ANCAs, and cryoglobulins may be required in some cases. A skin biopsy should be performed to confirm the diagnosis of leukocytoclastic vasculitis.

Treatment

The initial treatment of most cases of leukocytoclastic vasculitis in patients who are clinically well and have a normal urinalysis should be nonaggressive, since the majority of cases are acute and self-limited, affect only the skin, and do not threaten progressive deterioration of internal organs. Rest and elevation of the legs is likely to be helpful. Analgesics and avoidance of trauma and cold are prudent general measures. An identified antigen or drug should, of course, be eliminated and any identified infectious, connective tissue or neoplastic disease treated.

A variety of systemic treatments may be required for severe, intractable, or recurrent disease, especially if significant organ involvement is present. For disease limited to the skin, NSAIDs can be considered for the arthralgias. Colchicine, 0.6 mg two to three times a day, or dapsone, 50 to 200 mg/day, as trials of 2 to 3 weeks each, may be useful for chronic vasculitis. Low doses of colchicine and dapsone may be combined, if either medication alone is unsuccessful or effective doses of either drug cannot be reached. Although one controlled trial suggested that colchicine was ineffective in leukocytoclastic vasculitis, even in that trial a portion of the patients did respond and flared when the drug was stopped. Systemic corticosteroids in doses ranging from 60 to 80 mg/day are recommended for patients with serious systemic manifestations or necrotic lesions. Usually a brief course leads to resolution, and chronic treatment is rarely required. In refractory patients immunosuppressive agents, such as mycophenolate mofetil, 2 to 3 g/day; methotrexate, 5 to 25 mg/week; or azathioprine, 50 to 200 mg/day (2-3.5 mg/kg/day) may be considered. Azathioprine dosing is based on thiopurine methyltransferase levels. In more difficult cases cyclophosphamide, monthly intravenous pulses of steroids or cyclophosphamide, or cyclosporin, 3 to 5 mg/kg/day, may be effective. The tumor necrosis factor (TNF)-blockers, especially infliximab and to a lesser degree etanercept, may be effective in cutaneous small-vessel vasculitis. These agents may also cause vasculitis.

Subtypes of Small-Vessel Vasculitis

Henoch-Schönlein Purpura Henoch-Schönlein purpura (HSP) is characterized by purpura, arthralgias (74–84%), abdominal pain (61–76%), and renal disease (44–47%). Typically, mottled purpura appears on the extensor aspects of the extremities, which become hemorrhagic within a day and start to fade in about 5 days (Fig. 35-12). New crops may appear over a period of a few weeks. Urticarial lesions, vesicles, necrotic purpura, and hemangioma-like lesions may also be present at some stages. It occurs primarily in male children, with a peak age between 4 and 8 years; however, adults may also be affected. A viral infection or streptococcal pharyngitis is the usual triggering event. Other possibilities include other bacterial infections, foods, drugs, and lymphoma.

In about 40% of cases the cutaneous manifestations are preceded by mild fever, headache, joint symptoms, and abdominal pain for up to 2 weeks. Arthralgia progressing to arthritis produces periarticular swelling around the knees and ankles. There may be pulmonary hemorrhage, which can be fatal. Abdominal pain and gastrointestinal bleeding

Fig. 35-12 Henoch-Schönlein purpura.

may occur at any time during the disease; severe abdominal pain may even suggest—or portend—an acute surgical abdomen. Paralytic ileus may occur. Vomiting, rebound tenderness, and distension are other manifestations. Gastrointestinal radiographs may show "spiking" or a marbled "cobble-stone" appearance. Renal involvement manifests as microscopic or even gross hematuria and may occur in 25% or more of patients. The long-term prognosis in children with gross hematuria is very good; however, progressive glomerular disease and renal failure may develop in a small percentage, so that careful follow-up is necessary for those with hematuria.

IgA, C3, and fibrin depositions have been demonstrated in biopsies of both involved and uninvolved skin by immunofluorescence techniques. Uninvolved skin is a preferable site for biopsy because tissue morphology is better. There may be raised levels of IgA immune complexes even in the absence of nephritis or purpura.

Treatment is supportive. The usual duration of illness is 6 to 16 weeks. Between 5% and 10% of patients will have persistent or recurrent disease. Dapsone 50 to 200 mg/day or colchicine 0.6 mg/day to 1.2 mg twice a day can be used initially if treatment is required and skin lesions are the primary concern. For abdominal pain an H_2 blocker and/or corticosteroids (prednisone at 1 mg/kg/day) can be effective. Corticosteroids are more effective for abdominal pain than is analgesia. The value of systemic corticosteroids in the treatment of renal disease is controversial, but it may be used preventively or to treat active nephritis. IVIG can be used in refractory skin disease and persistent abdominal pain, and to arrest rapidly progressive glomerulonephritis. NSAIDs are best avoided as they may cause renal or gastrointestinal complications.

Acute Hemorrhagic Edema of Infancy Also known as Finkelstein's disease, Seidlmayer syndrome, medallion-like purpura, infantile postinfectious iris-like purpura and edema, and purpura en cocarde avec oedema, acute hemorrhagic edema (AHE) of infancy affects children under the age of 2 with a recent history of an upper respiratory illness (75%), a course of antibiotics, or both. The children are often nontoxic in appearance. There is abrupt onset of large cockade, annular, or targetoid purpuric lesions involving the face, ears, and extremities (Fig. 35-13). Scrotal purpura may also occur. Early in the course there may first be acral edema, with subsequent proximal spread. The edema is nontender and may be asymmetrical. A low-grade fever is common, and involvement of internal organ systems (joint pains, gastro-

Fig. 35-13 Acute hernorrhagic edema, typical large annular hemorrhagic plaques.

intestinal symptoms, and renal involvement) is rare. Routine laboratory tests are unremarkable. Spontaneous recovery without sequelae occurs within 12 to 20 days. The differential diagnosis includes HSP, meningococcemia, erythema multiforme, urticaria, and Kawasaki's disease. There are some similarities between HSP and AHE (postinfectious, seasonal, favors males), but it is different in that it favors younger children (<2 years), resolves more quickly, lacks IgA on DIF in most cases, and is rarely associated with systemic symptoms. From a clinical point of view the most urgent need is to exclude the possibility of septicemia, especially meningococcemia.

Urticarial Vasculitis A significant percentage of patients (reported as high as 5-10%, but probably less) with fixed urticarial lesions will have vasculitis histologically. This is termed "urticarial" vasculitis (Fig. 35-14). This urticarial morphology is maintained throughout the course of the illness. Microscopic hemorrhage into the urticarial plaques may occur, resulting in a bruise-like appearance as the lesions fade. Determination of the serum complement levels (CH50, C3, C4, and anti-C1q precipitins) is critical in the evaluation of urticarial vasculitis. Patients with normal complement levels usually have a leukocytoclastic vasculitis, which is idiopathic, limited to the skin, self-resolving, and is best considered a subset of cutaneous small-vessel vasculitis. Hypocomplementemic urticarial vasculitis is a distinctive syndrome seen virtually always in women. Clinical features include arthritis (50%), arthralgias, angioedema, eye symptoms, asthma, and obstructive pulmonary disease (20%), and gastrointestinal symptoms (20%). Glomerulonephritis may be present.

Underlying diseases associated with all forms of urticarial vasculitis include gammopathies (IgG and IgM gammopathy), SLE, Sjögren syndrome, serum sickness, and viral infections, especially hepatitis C. All patients with hypocomplementemic urticarial vasculitis have anti-C1q antibodies

Fig. 35-14 Urticarial vasculitis.

directed against the collagen-like region of that molecule, a feature used to define this disease. Patients with SLE may also have these autoantibodies. Many patients with hypocomplementemic urticarial vasculitis will have positive ANAs and up to a quarter will have positive anti-dsDNA antibodies. The vast majority (96%) will have a positive "lupus band test." Over time more than 50% will meet the criteria for the diagnosis of SLE. For this reason some consider hypocomplementemic urticarial vasculitis a form of SLE.

Three clinical features distinguish the skin lesions of urticarial vasculitis from true urticaria: 1) the lesions are often painful, rather than pruritic; 2) the lesions last longer than 24 h and are fixed, rather than migrating; and 3) on resolving there is postinflammatory purpura or hyperpigmentation. More difficult is the distinction of urticarial vasculitis from neutrophilic urticaria, as patients with the latter condition can have painful, more persistent lesions. Histologic evaluation is critical.

Histologically, patients with hypocomplementemic uriticarial vasculitis will show both leukocytoclastic vasculitis and diffuse interstitial neutrophils. Eosinophils are more likely to be seen in patients with neutrophilic urticaria or normocomplementemic urticarial vasculitis. Sweet syndrome shows a more intense dermal infiltrate with marked upper dermal edema. Sweet syndrome and vasculitis share the presence of karyorrhexis. While virtually all biopsies of idiopathic urticaria demonstrate neutrophils, karyorrhexis is usually distinctly absent.

The treatment of hypocomplementemic urticarial vasculitis is directed at the symptomatology and severity of the disease. Indomethacin has been particularly effective. Antihistamines, dapsone, and colchicine may be tried. The addition of pentoxyphylline to dapsone may be effective. Antimalarials can be beneficial, as would be expected in this autoimmune connective tissue disease. Immunosuppressive therapy with prednisone and the steroid-sparing agent mycophenolate mofetil (2 g/day) can be considered in refractory and severe cases.

Cryoglobulinemic Vasculitis About 15% of patients with a circulating cryoprecipitable protein are symptomatic and have cryoglobulinemic vasculitis. They typically have mixed cryoglobulinemia. Mixed cryoglobulinemia follows a benign course in half of cases, but in about one-third liver or renal failure occur. Fifteen percent of cases develop malignancy, usually B-cell lymphoma, and less frequently hepatocellular or thyroid cancer. By far the most common cause of cryoglobulinemic vasculitis is HCV infection, but autoimmune diseases and lymphoproliferative disorders can also be associated with cryoglobulinemic vasculitis. Cryoglobulinemic vasculitis usually presents with macular or palpable purpura, typically confined to the lower extremities. Lesions may be limited or severe. Two-thirds of patients show confluent areas of hemosiderosis of the feet and lower legs, characteristic of prior episodes of purpura. While only 30% of patients report an exacerbation with cold exposure, up to 50% will have Raynaud phenomenon and cold-induced acrocyanosis of the ears. Other morphologies include ecchymoses, livedo reticularis, urticaria, and ulcerations. Widespread systemic vasculitis occurs in about 10% of patients. Neuropathy, and other neurologic complications occur in 40% of patients. Arthralgias, xerostomia, and xerophthalmia are frequent complaints. Laboratory evaluation will reveal a cryoglobulin, hypocomplementemia (90%), and a positive rheuniatoid factor (70%). ANCAs are rarely positive. A skin biopsy will show leukocytoclastic vasculitis.

The treatment of cryoglobulinemic vasculitis is the treatment of the underlying disease if possible. In the case of HCV infection this usually is interferon- α plus ribavirin. Cryoglobulinemic vasculitis associated with HCV may also be flared by interferon treatment. Colchicine, dapsone, cyclosporin, IVIG, infliximab, and rituximab (anti-CD20 monoclonal antibody) can be attempted.

Erythema Elevatum Diutinum A rare condition, erythema elevatum diutinum (EED) is considered to be a chronic fibrosing leukocytoclastic vasculitis. Classically, multiple orange-to-yellow papules and plaques develop over the joints (Fig. 35-15), particularly the elbows, knees, hands, and feet. Lesions may also involve the buttocks and areas over the Achilles tendon. Petechiae and purpura can be associated with early lesions. More rarely, large plaques, with nodules at the periphery may affect the trunk and extremities. With time the papules take on a doughy to firm consistency and develop a red or purple color. In HIV infection, skincolored or red nodules affect the soles, producing lesions resembling keloids, Kaposi sarcoma, or bacillary angiomatosis. Pruritus, arthralgias, and pain have been reported; however, most patients are asymptomatic. Systemic complications are rare, but an unusual and potentially rapidly destructive keratitis can lead to blindness. EED has been associated with HIV infection, SLE, hematologic disease (IgA monoclonal gammopathy and lymphoma), and celiac disease. Chronic and recurrent streptococcal infections cause exacerbations of the disease in some patients. These may all represent conditions with persistent circulating immune complexes which might trigger a chronic vasculitis. Pathogenically, ANCAs (60% JgA and 33% JgG) are found in EED and not in Sweet or pyoderma gangrenosum. ANCA-positive vasculitides such as Wegener have rarely been reported to have EED-like lesions.

Histologically, early lesions are a leukocytoclastic vasculitis, but with prominent interstitial neutrophils. Wellformed lesions are composed of nodular and diffuse mixed infiltrates of neutrophils and nuclear dust, eosinophils, histocytes, and plasma cells that often extend into the subcutaneous fat. The prominence of eosinophils; the chronicity of the process, which results in an onion skin-like perivascular fibrosis; and the admixture of plasma cells and many lymphocytes are the hallmarks of EED. Erythrocyte extravasation may lead to extracellular cholesterol crystals in long-standing cases.

Dapsone is the treatment of choice. Patients with celiac disease may respond to a gluten-free diet. Intermittent plasma

Fig. 35-15 Erythema elevatum diutinum.

exchange has been used successfully in patients with IgA paraproteinemia. The interstitial keratitis also responds to dapsone. Unfortunately, the late nodular lesions may not resolve with dapsone treatment.

Granuloma Faciale Characterized by brownish-red, infiltrated papules, plaques, and nodules, granuloma faciale involves the facial areas, particularly the nose. Healthy, middle-aged (mean 53 years) white men (male-to-female ratio, 5:1) are most typically affected. Childhood cases have been reported. Extrafacial disease occurs in up to 20% of cases, usually affecting the upper trunk and extremities.

The pathology of granuloma faciale is similar to that of EED, with focal leukocytoclastic vasculitis, diffuse dermal neutrophilia with leukocytoclasia, tissue eosinophilia, and perivascular fibrosis.

A variety of treatment options are available. Intralesional corticosteroids are the recommended first approach. Cryotherapy in combination with intralesional corticosteroids has been shown to be very effective. Topical corticosteroids may also be useful. Although controlled clinical trials are lacking, if the patient remains unresponsive, dapsone, colchicine, or antimalarials could be considered. Laser treatment with pulsed dye and argon lasers has been effective in multiple cases, making it a reasonable consideration as first-line treatment.

POLYARTERITIS NODOSA

Polyarteritis nodosa (PAN) is characterized by necrotizing vasculitis affecting primarily the medium-sized arteries, but PAN may affect small vessels as well. Muscular arteries of such caliber as the renal, hepatic, and coronary vessels, and the arteries in the subcutaneous tissue and sometimes adjacent veins can be affected. There are two major forms: the benign cutaneous and the systemic, although even long-standing benign cutaneous disease can evolve into systemic disease.

PAN is four times more common in men than in women and the mean age of presentation is 45 years. It has been seen in intravenous drug abusers and in association with SLE, inflammatory bowel disease, hairy cell leukemia, familial Mediterranean fever, and Cogan syndrome (nonsyphilitic interstitial keratitis and vestibulo-auditory symptoms). Infectious associations include hepatitis B, hepatitis C, and antecedent streptococcal infections. HBV is present in 5% to 7% of cases overall, but in up to 50% of cases in some series, but this percentage is falling with HBV immunization. The identification of associated hepatitis virus infection has therapeutic implications.

The skin is involved in up to 50% of patients with the systemic form of PAN with wide-ranging findings. The most striking and diagnostic lesions (15% of patients) are 5- to 10-mm subcutaneous nodules occurring singly or in groups distributed along the course of the blood vessels, above which the skin is normal or slightly erythematous (macular arteritis). These nodules are often painful and may pulsate and, in time, ulcerate (Fig. 35-16). Common sites are the

Fig. 35-16 Polyarteritis nodosa with multiple leg ulcerations.

lower extremities, especially below the knee. Ecchymoses and peripheral gangrene of the fingers and toes may also be present. Livedo reticularis in combination with subcutaneous nodules strongly suggests the diagnosis of PAN. Palpable purpura with histologic features of cutaneous leukocytoclastic vasculitis with endothelial necrosis may be seen in PAN.

Classic systemic PAN may involve the vessels throughout the entire body. It has a particular predilection to affect the skin, peripheral nerves, gastrointestinal tract, and kidneys. Hypertension, tachycardia, fever, edema, and weight loss are cardinal signs of the disease. Hepatomegaly, icterus, lymphadenopathy, hematuria, and leukocytosis are also frequently found. Arthralgia, myocardial and intestinal infarctions, glomerulosclerosis, and peripheral neuritis are also seen. Mononeuritis multiplex, most often manifested as foot drop, is a hallmark of PAN. Involvement of the meningeal, vertebral, and carotid arteries may lead to hemiplegia and convulsions. The lungs and spleen are rarely involved. Aneurysms develop, which may result in multiorgan infarcts.

A leukocytosis of as high as 40,000/mm³ may occur, with neutrophilia to 80%; thrombocytosis, progressive normocytic anemia, and an elevated sedimentation rate may also be found. Hypergammaglobulinemia with macroglobulins and cryoglobulins may be present. Hepatitis B and C studies should be performed. Urinary abnormalities such as proteinuria, hematuria, and casts are present in 70% of patients.

The histology is that of an inflammatory necrotizing and obliterative panarteritis that attacks the small and mediumsized arteries. Focal vasculitis forms nodose swellings that become necrotic, producing aneurysms and rupture of the vessels. Hemorrhage, hematoma, and ecchymosis may result. Obliteration of the lumen may occur, with ischemic necrosis of surrounding tissue. Characteristically, the arteries are affected at their branching points.

The mainstay of diagnosis is the presence of these histologic features. The preferable site for biopsy is an accessible site such as skin, muscle, or testis. If these are not involved, angiography may detect aneurysmal dilations as small as 1-cm wide in the renal, hepatic, or other visceral vessels.

Treatment

Untreated classic PAN can be fatal; death usually occurring from renal failure or cardiovascular or gastrointestinal complications. Death usually occurs early in the course of the disease and there is only a 5% to 10% chance of serious sequelae or death occurring beyond the first few years of diagnosis. Treatment with corticosteroids and cytotoxic agents has increased the survival rate to more than 90%. Corticosteroids in the range of 1 mg/kg/day are given initially. Once the disease remits the dose should be reduced. After an average of 3 to 6 months, with the patient in remission, the steroids are slowly tapered to discontinuation.

Cyclophosphamide is given with steroids or sometimes as a single agent. An initial dose of 2 mg/kg/day as a single dose is recommended. Twice this dosing may be required for severely ill patients. The oral dose is then adjusted to maintain the white blood cell count between 3000 and 3500/mm³ and the neutrophil count above 1500 cells/mm³. When the disease has been quiescent for at least a year, the cyclophosphamide may be tapered and stopped. On average, 18 to 24 months of therapy is required. Pulsed intravenous cyclophosphamide is associated with a lower incidence of hemorrhagic cystilis. In cases of HBV-associated PAN, lamivudine may be given in combination with immunosuppressive treatment, improving outcome.

Ulcerations in PAN can be very painful due to the associated neuropathy. They should be managed like nonhealing leg ulcers. The use of bioengineered skin equivalents and cultured keratinocytes may lead to healing of the ulcers and improvement of the pain.

Cutaneous Polyarteritis Nodosa About 10% of patients present with PAN localized to the skin and with limited systemic involvement, usually neuropathy. Over time they may have few complications and a good prognosis, and may require less aggressive treatment to control their disease. This form of PAN is the most common childhood pattern of PAN. It is controversial as to whether there are two clear subsets of patients, cutaneous or systemic PAN, or rather a spectrum of disease. Patients with "cutaneous" PAN must be followed carefully and regularly evaluated to exclude the development of systemic involvement.

Patients usually have recurrent skin, joint, muscle and nerve involvement. The cutaneous findings are almost always subcutaneous nodules associated with livedo reticularis. Atrophie blanche-like lesions around the ankles may be the sole cutaneous manifestation of cutaneous PAN. On superficial biopsies the diagnosis of livedoid vasculopathy may be made, but on deeper biopsies, the features of a mediumsized vessel vasculitis are seen. Some of these patients have neurologic involvement with neuropathic and lesional pain and dysesthesia, allowing the clinician to separate these cases from other conditions causing atrophie blanche-like scars (venous insufficiency, cryoglobulinemia, antiphospholipid syndrome).

Cutaneous PAN has been associated with HBV surface antigenemia, HCV infection, Crohn's disease, Takayasu arteritis, relapsing polychondritis, streptococcal infections, tuberculosis, and medications (minocycline). Typically the only laboratory abnormality is an elevated ESR. In some cases a P-ANCA may be present. Most patients respond well to aspirin, NSAIDs, prednisone, pentoxyphylline, sulfapyridine, or methotrexate, alone or in combination, usually resulting in clinical responses within a few days. In childhood cutaneous PAN, since streptococcal infection is common, penicillin treatment may be used. In refractory cases IVIG may be used.

ANCA-POSITIVE SMALL-VESSEL VASCULITIDES

ANCAs have become an important laboratory finding used in the diagnosis and in some cases the prognosis of systemic vasculitis. ANCAs occur in three patterns: cytoplasmic (C-ANCA); perinuclear (P-ANCA); and atypical ANCA. C-ANCA is associated with antibodies directed against proteinase 3 (PR3). Antibodies against myeloperoxidase result in the P-ANCA pattern, but antibodies against other antigens may also give this pattern. Atypical ANCAs are not directed against myeloperoxidase or PR3. Most laboratories now perform specific tests to determine whether positive ANCAs are reactive against myeloperoxidase or PR3. Anti-PR3 antibodies are relatively specific for Wegener granulomatosis and microscopic polyarteritis. Antibodies against myeloperoxidase are less specific and can be found in microscopic polyarteritis, Churg-Strauss syndrome, and drug-induced vasculitis. Usually either antimyeloperoxidase or anti-PR3 antibodies are found, but not both. If both patterns are found, drug-induced vasculitis should be suspected. ANCAs have been used to delineate a group of small-vessel vasculitides called "ANCA small-vessel vasculitides" or ANCA-SVV. These include microscopic polyangiitis, Wegner granulomatosis, and Churg-Strauss Syndrome. These diseases have overlapping features, but characteristically pulmonary hemorrhage and necrotizing glomerulonephritis (pulmonary-renal syndrome) and 60% of patients with the pulmonary-renal syndrome will have ANCA-SVV. With ANCA testing, ANCA-SVV can be diagnosed with 85% sensitivity and 98% specificity. While ANCAs are usually negative in Takayasu arteritis, giant-cell arteritis, Kawasaki's disease, and Behçet; positive ANCAs can be found in cryoglobulinemia and other forms of skin-limited vasculitis, in 20% of patients with SLE, and in a higher percentage of patients with rheumatoid arthritis. ANCAs are used in the setting of vasculitis with systemic features or in situations where the clinical findings suggest ANCA-SVV. ANCA testing does not replace other tests or more importantly histologic confirmation of the presence of vasculitis. While the ANCA-SVV are of unknown etiology, in multiple cases a solid tumor has been identified at the time of the diagnosis of the vasculitis.

Microscopic Polyangiitis

Most patients with microscopic polyangiitis have systemic symptoms, such as fever, weight loss, myalgias, and arthralgias for months to years before an explosive phase of their disease. Most patients with microscopic polyangiitis will have segmental necrotizing and crescentic glomerulonephritis with pulmonary involvement in 25% to 50% of cases. Pulmonary hemorrhage occurs in 12% to 29%. The skin is involved in 62%. Palpable purpura is present in 46% of cases and cutaneous ulceration may result. Urticarial lesions, purpura and petechiae, livedo and erythema of the hands and/or fingers have been described. Skin biopsies may not be specific, except in cases with typical palpable purpura. Vasculitic neuropathy is common (58%) and eye disease may occur. Eosinophilia and asthma are not seen. ANCAs are positive in 70% of cases, P-ANCA more frequently than C-ANCA. Microscopic polyangiitis is separated from PAN by the presence of glomerulonephritis, pulmonary symptoms, and the absence of hypertension and microaneurysms. ANCAs are usually negative in PAN. Microscopic polyangiitis is managed like other forms of ANCA-SVV with systemic corticosteroids and often cytotoxic agents from the disease onset. In cases with limited involvement, less aggressive treatment may be considered. Cyclophosphamide is usually used in the early induction phase of treatment (6–12 months) as monthly pulses (as opposed to daily treatment). Lower toxicity immunosuppressives (methotrexate, azathioprine, mycophnolate mofetil) may be used as maintenance or in milder cases. IVIG and anti-TNF agents (infliximab/ etanercept) may be considered in refractory cases. Relapses are frequent, the 5-year survival is about 75%, and 7-year survival is 62%.

Wegener Granulomatosis

Wegener granulomatosis is a syndrome consisting of necrotizing granulomas of the upper and lower respiratory tract, generalized necrotizing angiitis affecting the mediumsized blood vessels, and focal necrotizing glomerulitis. By far the most common initial manifestation, present in 90% of patients, is the occurrence of rhinorrhea, severe sinusitis, and nasal mucosal ulcerations, with one or several nodules in the nose, larynx, trachea, or bronchi. Fever, weight loss, and

Fig. 35-17 Wegener granulomatosis, strawberry gingival.

malaise occur in these patients, who are usually 40 to 50 years of age and more often male than female (1.3:1). Obstruction in the nose may also block the sinuses. The nodules in the nose frequently ulcerate and bleed. The parenchymal involvement of the lungs produces cough, dyspnea, and chest pain. Granulomas may occur in the ear and mouth, where the alveolar ridge becomes necrotic and ulceration of the tongue and perforated ulcers of the palate develop. The combination of nasal and palatal involvement may lead to saddle-nose deformity. The "strawberry gums" appearance of hypertrophic gingivitis is characteristic and biopsy from these lesions may be diagnostic (Fig. 35-17).

Cutaneous findings occur in 45% of patients. Nodules may appear in crops, especially along the extensor surfaces of the extremities. The firm, slightly tender, flesh-colored or violaceous nodules may later ulcerate. These may be mistaken for ulcerating rheumatoid nodules. The necrotizing angiitis of the skin may present as a petechial or hemorrhagic pustular eruption, subcutaneous nodules, or ulcers. Livedo reticularis is rare in Wegener granulomatosis. Patients may present with pyoderma gangrenosum-like lesions and several patients have been reported presenting with features of temporal arteritis. The condition previously described as "malignant pyoderma" is now felt to represent Wegener granulomatosis.

Limited forms involving the upper respiratory tract without renal involvement may also occur and have a better prognosis. Cutaneous findings can be associated with limited disease. Focal necrotizing glomerulitis occurs in 85% of patients. It may be fulminant from the outset or may become more severe as the disease progresses. Renal failure was the most frequent cause of death before cyclophosphamide treatment. Other organs frequently involved include the joints (arthralgia in two-thirds); eyes (conjunctivitis, episcleritis, and proptosis) in 58%; and CNS and cardiac involvement in 22% and 12% of patients, respectively.

Histologically, the cutaneous lesions may demonstrate a leukocytoclastic vasculitis with or without granulomatous inflammation. Granulomatous vasculitis may be seen. Palisaded granulomas with multinucleated giant cells and a central core of neutrophils and debris are a characteristic finding. Often, if the lesions are ulcerated they are nonspecific histologically. Biopsy of another affected organ may be required to confirm the diagnosis. The early detection of Wegener granulomatosis has improved with the availability of ANCA testing, as 75% to 80% of patients are C-ANCA (anti-PR3) positive.

Untreated Wegener granulomatosis has a mean survival time of 5 months and a 90% mortality over 2 years. Cyclophosphamide therapy has dramatically changed the prognosis. Treatment recommendations are cyclophosphamide, 2 mg/kg/day, and prednisone, 1 mg/kg/day, followed by tapering of the prednisone to an alternate-day regimen. Complete remission is achieved in up to 93% of patients and lasts an average of 4 years for still living patients. In more limited disease, patients may respond to methotrexate alone or methotrexate in combination with prednisone. After initial induction therapy and a remission, methotrexate, azathioprine, leflunomide, or mycophenolate mofetil may be used instead of cyclophosphamide. Treatment should be continued for at least 1 year. Trimethoprim-sulfamethoxazole may decrease the relapse rate and can be considered for long-term treatment of patients with limited upper respiratory tract involvement in remission in combination with conventional immunosuppressive protocols. In refractory cases, IVIG and anti-TNF therapy (infliximab) may be used. Tacrolimus, 0.1 mg/kg/day, was successful in treating a pyoderma gangrenosum-like ulceration in a patient with Wegener.

Churg-Strauss Syndrome

Churg-Strauss syndrome occurs in three phases. The initial phase, often lasting many years, consists of allergic rhinitis, nasal polyps, and asthma. The average age of onset of the asthma is 35 years in Churg-Strauss syndrome (as opposed to allergic asthma which often presents in childhood). A debilitated asthmatic begins after 2 to 12 years to experience attacks of fever and eosinophilia (20–90%) with pneumonia and gastroenteritis (second phase). After a few more months or years, but on average 3 years after the initial symptoms, a diffuse angiitis involves the lungs, heart, liver, spleen, kidneys, intestines, and pancreas. Mononeuritis multiplex is common. Triggers of this third phase have included vaccination, desensitization, leukotriene inhibitors, cocaine use, azithromycin, or rapid discontinuation of corticosteroids. Renal involvement is less common than in Wegener granulomatosis or microscopic polyangiitis. A fatal outcome is likely in most untreated patients, with congestive heart failure resulting from granulomatious inflammation of the myocardium the most frequent cause of death.

Cutaneous lesions are present in two-thirds of patients. Palpable purpura is seen in nearly 50% of patients. Subcutaneous nodules on the extensor surfaces of the extremities and on the scalp are seen in 30%. Firm, nontender papules may be present on the fingertips. Urticaria and livedo reticularis can occur in Churg-Strauss syndrome. Plaques with the histologic features of eosinophilic cellulitis (Well syndrome) can be seen.

Laboratory studies are significant for a peripheral eosinophilia, which correlates with disease severity. ANCAs are frequently positive (55–70%), most commonly for antimyeloperoxidase (P-ANCA) and less frequently for anti-PR3 (C-ANCA), and tend to correlate with disease severity.

Histologically, a small-vessel vasculitis is present that involves not only superficial venules, but also larger and deeper vessels. The tissue is often diffusely infiltrated with eosinophils and granulomas may be present. Palisaded granulomas differ from those in Wegener granulomatosis in that they generally lack multinucleated giant cells and the core contains eosinophils. In some patients, flame figures, similar to those in Well syndrome, are noted in the dermis.

Corticosteroids alone may be used in patients with CSS. Cyclophosphamide alone or in combination with corticosteroids should be used in cases of neuropathy, refractory glomerulonephritis, myocardial disease, severe gastrointestinal disease, and CNS involvement. Methotrexate can be used as a steroid sparing agent, especially for maintenance. Interferon alfa, mycophenolate mofetil, and the anti-TNF agents (infliximab and etanercept) have also been used successfully in CSS.

GIANT-CELL ARTERITIS/TEMPORAL ARTERITIS

Giant-cell arteritis is a systemic disease of people over the age of 50, favoring women (2:1). It is uncommon in African Americans and favors whites. Its best known location is in the temporal artery, where it is known as temporal arteritis, cranial arteritis, and Horton's disease. It is characterized by a necrotizing panarteritis with granulomas and giant cells. which produce unilateral headache and exquisite tenderness in the scalp over the temporal or occipital arteries in 50% to 75% of patients. Temporal headaches are characteristically constant, severe, and boring. Ear and parotid pain and mastication-induced jaw claudication may occur. Fever, anemia, and a high sedimentation rate are usually present. Proximal, symmetrical, and severe morning and even daylong stiffness, soreness, and pain occur in 50% of patients. It is rarely fatal. The disease has also been shown to involve the vessels of the coronary arteries, breast, uterus, legs, abdomen, retina, and hand. Blindness may develop and is the most feared complication of the disease. Many patients who develop visual loss have premonitory symptoms allowing for the diagnosis and intervention, which may prevent permanent visual loss. Aortic aneurysms resulting in aortic rupture have been reported.

The cutaneous manifestations may be only inflammatory. The affected artery becomes evident as a hard, pulsating, tender, tortuous bulge under red or cyanotic skin. Another manifestation is gangrene of the scalp. The lesions may first appear as ecchymoses with a zonal distribution over the affected area. Later they may become vesicular or bullous and are followed by gangrene. Urticaria, purpura, alopecia, tender nodules, prurigo-like nodules, and livedo reticularis may be seen. Lingual artery involvement may cause an accompanying red, sore or gangrenous tongue.

Polymyalgia rheumatica (PMR) has a significant clinical association with giant-cell artenitis. Prompt treatment may forestall serious disease. About 10% of central retinal artery occlusions are due to giant-cell arteritis. ESRs are elevated in more than 90% of patients with giant-cell arteritis. Temporal artery biopsy is generally diagnostic provided that at least a 2-cm segment is provided. Even arteries which are normal to palpation may show diagnostic findings. Magnetic resonance angiography is a noninvasive diagnostic method that may aid in confirming the clinical suspicion and identify the best site to biopsy. Not all patients with arteritis of the temporal artery have giant cell arteritis, as temporal arteritis may be a manifestation or part of the systemic vasculitides such as PAN, Wegener granulomatosis, or microscopic polyarteritis. Pathogenically, the presence of TNF polymorphisms in patients with PMR and temporal arteritis suggests a genetic predisposition.

Treatment is usually begun with prednisone, 60 mg/day, continued for 1 month or until all reversible clinical and laboratory parameters (such as the ESR) have returned to normal. The disease is quite steroid responsive and tapering to a dose of 7.5 to 10 mg/day is usually possible. Daily therapy seems to be important and is-usually necessary for a minimum of 1 to 2 years. Most patients achieve complete remission that is often maintained after therapy is withdrawn. Anti-TNF agents may be used in refractory cases, but relapses occur when infusions are stopped, and corticosteroid therapy is usually required.

Takayasu Arteritis

Known also as *aortic arch syndrome* and *pulseless disease*, Takayasu arteritis is a thrombo-obliterative process of the great vessels stemming from the aortic arch, occurring generally in young women (female-to-male ratio, 9:1) in the second or third decade of life. It is more common in Japan, Southeast Asia, India, and South America. Radial and carotid pulses are typically obliterated. Skin changes are due to the disturbed circulation. There may be loss of hair and atrophy of the skin and its appendages, with underlying muscle atrophy. Occasional patients with cutaneous necrotizing or granulomatous vasculitis of small vessels have been reported. Erythema nodosum may rarely occur. Pyoderma gangrenosumlike ulcerations are well-described in Japan with more than 35 cases reported. Pyoderma gangrenosum lesions precede the diagnosis of the arteritis by an average of 3 years. These lesions are more commonly generalized and in threequarters of cases occur on the upper extremities.

Treatment of Takayasu arteritis with prednisone 1 mg/kg/ day tapered in 8 to 12 weeks to 20 mg/day or less is recommended. Methotrexate may be used for its steroid-sparing effects. With active medical and surgical intervention the aggressive course of this disease can be modified. The pyoderma gangrenosum-like lesions are also treated with systemic steroids, but azathioprine, cyclophosphamide, mycophenolate mofetil, cyclosporin, and tacrolimus have also been effective.

MALIGNANT ATROPHIC PAPULOSIS

Papulosis atrophicans maligna, also known as *Degos'* disease, is a potentially fatal obliterative arteritis syndrome. Some affected patients have a long benign course, while in others, death occurs within a few years. Degos' disease occurs three times more frequently in men than in women, often presenting between the ages of 20 and 40. Familial kindreds are well-reported. In patients with the more aggressive variant, survival averages 2 to 3 years after the disease has developed.

Skin lesions are usually the first sign of the disease. Clinically, Degos' disease is characterized by the presence of pale rose, rounded, edematous papules occurring mostly on the trunk. Similar lesions may occur on the bulbar conjunctiva and oral mucosa. Later, the lesions become umbilicated, with a central depression, which enlarges. The center becomes distinctively porcelain-white, while the periphery becomes livid red and telangiectatic. Atrophy occurs eventually. The eruption proceeds by crops in which only a few new lesions appear at any one time. One patient was reported to develop panniculitis. Lesions characteristic of Degos' disease may be seen in patients with lupus erythematosus or dermatomyositis.

Systemically, anemic infarcts involve the intestines producing acute abdominal symptoms, including epigastric pain, fever, and hematemesis. Death is usually due to fulminating peritonitis caused by multiple perforations of the intestine. Less commonly, death occurs from cerebral infarctions.

Wedge-shaped necroses brought on by the occlusion of arterioles and small arteries account for the clinical lesions. Proliferation of the intima and thrombosis is the typical histologic picture. The thrombosing process is usually pauciinflammatory, although neutrophils or lymphocytes may be found associated with the thrombosis. The overlying dermis, which is infarcted, contains abundant mucin, especially early in the lesion's evolution. Adnexae are typically necrotic and the depressed central portion may be noted histologically.

The etiology of this disease is unknown, but based on the infarctive nature of the lesions and the universal presence of arteriolar thrombosis, a hyperthrombotic state or endothelial abnormality is suggested. While most patients have not had abnormalities identified, abnormal platelet aggregation, and abnormal coagulation have been identified in some patients. The response of this condition to anticoagulant regimens in some patients supports this hypothesis. In some patients with lupus erythematosus and Degos-like lesions, antiphospholipid antibodies have been found.

Administration of immunosuppresssives has not been beneficial. Ingestion of low-dose acetylsalicylic acid alone or in combination with dipyridamole (Persantine) has been effective in some patients. Heparin, as described by Degos, has been helpful, and should be considered if antiplatelet therapy is ineffective. Nicotine patches (5 mg/day) were effective in one case. In severe crises, fibrinolytic therapy should be considered.

THROMBOANGIITIS OBLITERANS (BUERGER'S DISEASE)

Thromboangiitis obliterans is a nonatherosclerotic segmental inflammatory disease affecting the arteries, veins and nerves of multiple extremities. As opposed to classic atherosclerotic disease, the upper extremities are commonly affected. It is most often seen in men between the ages of 20 and 40 who smoke heavily. Smoking and, rarely, the use of smokeless tobacco is intimately tied to Buerger's disease. Various diagnostic criteria have been proposed; they usually include: age younger than 45 (or 50); history of tobacco use; distal extremity (infrapopliteal segmental arterial occlusion with sparing of the proximal vasculature); frequent distal upper extremity involvement (Raynaud or digital ulcers); consistent angiographic findings; superficial thrombophlebitis; exclusion of autoimmune disease, diabetes mellitus, and hypercoagulable or embolic states.

The vasomotor changes in early cases may be transitory or persistent; they produce blanching, cyanosis, burning, and tingling. Superficial thrombophlebitis in the leg and foot occurs in 38% of cases and 44% of patients may have Raynaud phenomenon. The color of the part may change when it is elevated or lowered below heart level, being red when dependent and white when elevated. An Allen test will be positive, confirming distal artery occlusion.

Pain is a constant symptom, coming only at first after exercise and subsiding on resting. Instep claudication is the classic complaint. Ultimately, the dorsalis pedis and posterior tibial pulses disappear, followed by others. In thromboangiitis obliterans, skin supplied by affected arterioles tends to break down, with central necrosis and ulceration, and eventual gangrene. Gastrointestinal involvement has been reported. Exposure to cold may cause exacerbations.

Arteriography should be done to investigate for central atherosclerotic disease, which may be operable, rather than the inoperable distal damage of Buerger's disease. A characteristic tapering and occlusion of the major arteries with "corkscrew" collateral arteries is found in Buerger's disease on angiography. Biopsy demonstrates a thrombosed vessel that characteristically contains prominent neutrophilic inflammation within the thrombus. A vasculo-occlusive syndrome similar to Buerger's disease has been reported in cannabis smokers, but venous occlusion (thrombophlebitis) does not occur.

The most important therapeutic aspect is the cessation of *smoking*. Even one to two cigarettes/day, smokeless tobacco, or nicotine replacement may keep the disease active. Intravenous Iloprost (a prostaglandin analog) may help the patient with critical limb ischemia get through an acute episode. In patients who stop smoking and do not have gangrene, major amputations are rare. In continued smokers at least 43% will require amputations. Sympathectomy or implantation of a

spinal cord stimulator may be tried. Ultimately, serial amputations are often necessary if the patient continues to use tobacco.

ARTERIOSCLEROSIS OBLITERANS

Arteriosclerosis obliterans is an occlusive arterial disease most prominently affecting the abdominal aorta and the small- and medium-sized arteries of the lower extremities. The symptoms are due to ischemia of the tissues. There is intermittent claudication manifested by pain, cramping, numbness, and fatigue in the muscles on exercise; these are relieved by rest. There may be "rest pain" at night when in bed. Also, sensitivity to cold, muscular weakness, stiffness of the joints, and paresthesia may be present. Sexual impotence is common and there is an increased frequency of coronary artery disease.

Impaired to absent pulses (dorsalis pedis, posterior tibial, or popliteal arteries) may be found on physical examination, confirming the diagnosis. The feet, especially the toes, may be red and cold. Striking pallor of the feet on elevation and redness when dependent are compatible findings. Decreased to absent hair growth may be observed on the legs. Ulceration and gangrene may supervene. If present, they usually begin in the toes and are quite painful. Arteriography may be indicated as a preliminary to corrective surgery (arterial grafts). Occasionally, subclavian atherosclerosis may give rise to these signs in the distal upper extremity, producing painful nails and loss of digital skin. Diabetes mellitus, smoking, and hyperlipidemia are risk factors for the development of atherosclerosis.

Claudication and diminished blood pressure in the affected extremity are findings that may lead to earlier diagnosis and thus to curative surgical intervention. Usually, bypass of the affected artery or sympathectomy, or both, are the preferred treatment. Balloon angioplasty or stent placement may also be effective.

Matsumoto K, et al: Insulin resistance and arteriosclerosis obliterans in patients with NIDDM. Diabetes Care 1997;20:1738.

MUCOCUTANEOUS LYMPH NODE SYNDROME (KAWASAKI'S DISEASE)

The typical presentation is an irritable, ill-appearing, febrile infant or child younger than 5 years old. Clinical findings (four of which plus fever for 5 days are diagnostic of Kawasaki syndrome) include a skin eruption; stomatitis (injected pharynx, strawberry tongue) and fissuring cheilitis; edema of the hands and feet; conjunctival injection; and cervical lymphadenitis. The skin eruption is polymorphous and may be macular, morbilliform, urticarial, scarlatiniform, erythema multiforme-like, pustular, or resemble erythema marginatum. An early finding (within the first week) is the appearance of an erythematous, desquamating perianal eruption in about two-thirds of patients. Periorbital edema has been reported. Pincer nail deformities may appear and resolve spontaneously. Intestinal pseudo-obstruction may occur. The acute illness evolves over 10 to 20 days. A week or two following the acute illness, the fingers and toes desquamate, starting around the nails. Coronary artery aneurysms occur in 20% to 25% of untreated children. This may lead to immediate cardiac complications, the major cause of morbidity and mortality. In addition, over time, those with aneurysms can develop coronary artery stenosis and as a result acute cardiac events can occur in young adulthood.

Pathogenesis

Recently, a corona virus has been identified as the cause in a cohort of patients. A viral pathogenesis is attractive for the following reasons: 1) cases were rare before 1950; 2) it affects children older than 3 months but younger than 8 years; 3) seasonal peaks occur in the winter and spring; 4) focal epidemics have been reported; and 5) oligoclonal IgA immune responses are found, suggesting a respiratory portal of entry of an infectious agent.

Coronary arterial disease occurs, in combination with thrombocythemia (up to 1 million). This combination of an altered endovascular surface and too many platelets leads to occlusion of the vessels and the subsequent cardiac events, which occur as the child is recovering from the acute illness.

Treatment

IVIG is the cornerstone of therapy, given in a single dose of 2 g/kg infused over 10 to 12 h. Response to treatment is best if given during the first 5 to 6 days of the illness; however, children with persistent fever beyond this period may benefit from later treatment. Aspirin is used to reduce inflammation and platelet aggregation. The dose is 80 to 100 mg/kg/day in four divided doses. Once the child has been afebrile for 3 to 7 days, the aspirin dose is decreased to a single daily dose of 3 to 5 mg/kg. If the child remains febrile, a second 2 g/kg dose of IVIG should be given. A single dose of infliximab 5 mg/kg has been reported to be effective in refractory cases, but response, as with other treatments, is not universal. Angioplasty, thrombolytic therapy, or coronary artery bypass surgery may be required for patients with severe disease.

TELANGIECTASIA

Telangiectasia are fine linear vessels coursing on the surface of the skin: the name given to them collectively is *telangiectasia*. Telangiectasia may occur in normal skin at any age, in both sexes, and anywhere on the skin and mucous membranes. Fine telangiectases may be seen on the alae nasi of most adults. They are prominent in areas of chronic actinic damage. In addition, persons long-exposed to wind, cold, or heat are subject to telangiectasia. Calcium-channel blockers may lead to telangiectatic lesions in a generalized or photodistribution and contribute to the appearance of photoaging. Telangiectasias may also be found on the legs as a result of heredity, varicosities, pregnancy, and birth control pill use.

Telangiectases can be found in conditions such as radjodermatitis, xeroderma pigmentosum, lupus erythematosus, scleroderma and the CREST syndrome, rosacea, pregnancy, cirrhosis of the liver, AIDS, poikiloderma, basal cell carcinoma, necrobiosis lipoidica diabeticorum, lichen sclerosis et atrophicus, sarcoid, lupus vulgaris, keloid, and adenoma sebaceum. Kaposiform hemangioendothelioma, angioma serpiginosum, angiokeratoma corporis dilfusum, hereditary benign telangiectasia, Cockayne syndrome, ataxia-telangiectasia, and Bloom syndrome.

Altered capillary patterns on the finger nailfolds (cuticular telangiectases) are indicative of collagen vascular disease, such as lupus erythematosus, scleroderma, or dermatomyositis. They may infrequently be present in rheumatoid arthritis. These disorders are reviewed in Chapter 8.

Generalized Essential Telangiectasia

Generalized essential telangiectasia is characterized by the dilation of veins and capillaries over a large segment of the body without preceding or coexisting skin lesions. Characteristic features include: 1) widespread cutaneous distribution; 2) progression or permanence of the lesions; 3) accentuation in dependent areas and by dependent positioning; and 4) absence of coexisting epidermal or dermal changes such as atrophy, purpura, depigmentation, or follicular involvement. The telangiectases may be distributed over the entire body or localized to some large area such as the legs, arms, and trunk. They may be discrete or confluent. Distribution along the course of the cutaneous nerves may occur. Systemic symptoms are absent, although conjunctival telangiectasias can also be seen. Generalized essential telangiectasia is usually not believed to be associated with an increased risk of bleeding.

Generalized essential telangiectasia develops most frequently in women in their 40s and 50s. The initial onset is on the lower legs and then spreads to the upper legs, abdomen, and arms. The dilations persist indefinitely. Families with this disorder have been reported, inherited as an autosomaldominant trait. The cause of essential telangiectasia is unknown. Treatment is with vascular lasers, if required.

Unilateral Nevoid Telangiectasia

In this disorder, fine, thread-like telangiectases develop in a unilateral, sometimes dermatomal (or following the lines of Blaschko) distribution. The condition is rare in men and tends to be associated with conditions with increased levels of estrogen: puberty, pregnancy, and cirrhosis. Hepatitis C-associated unilateral nevoid telangiectasia has been reported.

HEREDITARY HEMORRHAGIC TELANGIECTASIA (OSLER'S DISEASE)

Also known as Osler-Weber-Rendu disease, hereditary hemorrhagic telangiectasia (HHT) is characterized by small tufts of dilated capillaries scattered over the mucous membranes and the skin. These slightly elevated lesions develop mostly on the lips, tongue, palate, nasal mucosa, ears, palms, fingertips, nailbeds, and soles. They may closely simulate the telangiectases of the CREST variant of scleroderma, which may be distinguished by the lack of other features of CREST syndrome and by anticentromere antibodies, which are not found in HHT. Diagnostic criteria have been proposed and include: 1) epistaxis-spontaneous, recurrent nosebleeds; 2) telangiectases-multiple at characteristic sites (lips, oral cavity, fingers, nose) (Figs 35-18 to 35-20); 3) visceral lesions-gastrointestinal telangiectasia, pulmonary, hepatic, cerebral or spinal arteriovenous malformation (AVM); and 4) family history-one affected first-degree relative. The presence of three of the four criteria indicates a definite diagnosis and two of four, a possible diagnosis. There are at least two variants, HHT1 and HHT2. A third variant may be associated with juvenile polyposis.

Frequent nosebleeds and melena are experienced because of the telangiectasia in the nose and gastrointestinal tract. Epistaxis is the most frequent and persistent sign. Gastrointestinal bleeding is the presenting sign in up to 25% of

Fig. 35-18 Hereditary hemorrhagic telangiectasia.

Fig. 35-19 Hereditary hemorrhagic telangiectasia.

Fig. 35-20 Hereditary hemorrhagic telangiectasia.

cases; however, 40% to 50% develop gastrointestinal bleeding sometime during the course of their disease. The spleen may be enlarged. Pulmonary and CNS AVMs may appear later in life. Liver failure can result from diffuse intrahepatic shunting. Pulmonary hypertension can occur, especially in HHT2. Retinal arteriovenous aneurysms occur only rarely. Other sites of bleeding may be the kidney, spleen, bladder, liver, meninges, and brain. The risk of cerebral hemorrhage from cerebral AVMs, cerebral abscesses, and pulmonary hemorrhage from pulmonary AVMs is probably high enough that asymptomatic patients should be screened for the presence of cerebral and pulmonary AVMs. Because of the risk of cerebral abscess, some have advocated antibiotic prophylaxis for dental and contaminated skin procedures.

The telangiectases tend to increase in number in middle age; however, the first appearance on the undersurface of the tongue and floor of the mouth is at puberty. Pulmonary or intracranial arteriovenous fistulas and bleeding in these areas may be a cause of death.

HHT is inherited as an autosomal-dominant trait. The vascular abnormalities (ound in HHT consist of direct arteriovenous connections without an intervening capillary bed. Affected patients have mutations in one of two different genes, endoglin (ENG) or ALK-1 (activin A receptor type II, ACVRL1). They encode a homodimeric integral membrane glycoprotein which is a TGF- β receptor. TGF- β mediates vascular remodeling. HHT1 is associated with ENG mutations, and HHT2 associated with ALK-1 mutations. HHT1 patients have a higher prevalence of pulmonary AVMs and HHT2 patients tend to have a milder phenotype and later age of onset. Patients with HHT and juvenile polyposis have mutations in the MADH4 gene, a downstream effector of TGF- β signaling.

Treatment is directed at controlling the specific complication, and identifying and treating AVMs before they become symptomatic. The tendency to epistaxis has been reduced by estrogen therapy and some recommend oral contraceptives for affected postpubertal females. Dermoplasty of the bleeding nasal septum may be performed by replacing the mucous membrane with skin from the thigh or buttock. Repeated laser treatments of the nasal and gastrointestinal mucosa are often required. Topical tranexamic acid has been used to control epistaxis. Bleeding episodes are treated supportively. Interventional radiology with selective embolization can treat AVMs and episodes of bleeding, avoiding invasive surgeries.

LEG ULCERS

Leg ulcers are a common medical condition, affecting 3% to 5% of the population over the age of 65. The cause of chronic leg ulceration is venous insufficiency alone in 45% to 60% of cases, arterial insufficiency in 10% to 20%, diabetes mellitus in 15% to 25%, or combinations in 10% to 15%. Smoking and obesity increase the risk for ulcer development and persistence, independent of the underlying cause. Defining the cause of the leg ulceration is important in healing the ulceration. However, except in the case of significant arterial insufficiency, most leg ulcers can be healed without treating the anatomic underlying cause.

The wound healing response is complex, involving intricate interactions between different cell types, structural proteins, growth factors, and proteinases. Normal wound repair consists of three phases—inflammation, proliferation, and remodeling—that occur in a predictable sequence and comprise a series of cellular and biochemical events. Abnormalities in any one of these components can produce delayed or ineffectual wound healing.

VENOUS DISEASES OF THE EXTREMITIES

Stasis Dermatitis

Stasis dermatitis presents as erythema and a yellowish or light-brown pigmentation of the lower third of the lower legs, especially in the area just superior to the medial malleolus. An associated eczematous dermatitis may occur. The dermatitis may be weepy or dry, scaling or lichenified; it is almost invariably hyperpigmented by melanin and hemosiderin. Varicose veins are usually present, though they need not be numerous or conspicuous. Stasis dermatitis is a cutaneous marker for venous insufficiency. The approach to management should be two-fold: relief of symptoms and treatment of the underlying venous insufficiency. Patients with pruritus and an eczematous component should be treated with emollients and class IV or V topical corticosteroids. The daily use of support stockings is strongly recommended.

Venous Insufficiency Ulceration

Stasis dermatitis and venous ulceration result from increased pressure in the venous system of the lower leg. The most common cause is insufficiency of the valves in the deep venous system and lower perforating veins of the lower leg. With each contraction of the calf, blood should be pumped to the heart (muscle pump). Intact valves in the lower leg are required to prevent this "pumped" blood from refluxing out through the perforators into the superficial system. The hypertrophy of these superficial veins is marked by the development of "varicose veins." Increased pressure on the iliac veins from pregnancy or obesity, or simple inactivity may also result in the appearance of "venous insufficiency" as well. The valvular insufficiency results in disorder in the venous and capillary circulation in the leg. Valve insufficiency may occur from prior thrombophlebitis or congenital "weakness." Prolonged standing in one position, sitting for long periods, anemia, zinc deficiency, and a defective fibrinolytic system may accelerate the process. If a history of thrombophlebitis is present, an evaluation for a hypercoagulable state, such as a deficiency of Leiden Factor V, should be considered

Edema and fibrosis develop in the skin over the medial aspect of the ankle and lower third of the shin (Fig. 35-21). Following minor trauma, a macular hemorrhage appears. This is the premonitory sign of an impending ulceration. Venous ulcers usually occur on the lower medial aspect of the leg. They may appear on the background of stasis dermatitis with lipodermatosclerosis.

Fig. 35-21 Stasis dermatitis, venous insufficiency.

In most cases the diagnosis of a venous ulceration can be made on clinical grounds. If there is no clear history or physical findings of venous insufficiency, venous rheography can be performed. An ABI (ratio of blood pressure in the leg to the arm) should be considered in cases where peripheral pulses are diminished, and hair on the lower legs is lost. This will identify coexistent arterial disease. In most leg ulcers of the lower medial leg, even if cutaneous findings of venous insufficiency are absent, venous insufficiency will still be the most common cause of the ulcer. Lesions in atypical locations, those that do not respond appropriately to therapy, and those in which venous rheography is normal, may require a biopsy to exclude other causes, including a cutaneous neoplasm. Additional work-up may also be required to identify other, less common causes of leg ulcers, such as cholesterol emboli, atherosclerotic disease, diabetes mellitus, sickle cell disease, vasculitis, infection, and pyoderma gangrenosum.

Treatment is primarily to improve venous return and reduce edema. Compression therapy is the mainstay of treatment. This involves the use of pressure wraps, such as Unna boots covered with coban or elastic wraps. Elevation of the leg above the heart as much of the time as possible (a miniumum of 2 h twice a day) is also beneficial. Elastic support of the legs must be continued after the ulcer heals. Other causes of edema, such as cardiac failure, must be addressed, especially if there is associated bullous lymphedema. The avoidance of long, cramped sitting (in airplanes or vehicles) or prolonged standing is advisable. Diuretics are overused and not proven to be of benefit. If there is a central cause of fluid retention (cirrhosis, heart failure, renal failure), diurctics may be beneficial, but otherwise they are best avoided. Avoidance of trauma is important. Pentoxyphylline 400 to 800 mg three times a day, in addition to compression, is beneficial in healing refractory venous ulcerations. A cooperative patient and a patient physician are necessary in the long-term management of venous disease. Topical antiinfectives are usually not necessary (except metronidazole gel to prevent anaerobic overgrowth). There is a high risk of allergic contact dermatitis from other topical antibiotics. Oral antibiotics should only be used to treat associate invasive infection. A rim of erythema commonly surrounds an ulcer. Expanding erythema, an enlarging ulcer, or increasing pain or tenderness may be signs of infection. Surface cultures and gram stains may demonstrate colonizing, but not pathogenic, bacteria. Biopsy for histology and tissue homogenate culture is the most effective way to demonstrate a true invasive pathogen.

Many treatment options have been developed for chronic ulcers. Unfortunately, conclusive comparative studies between the various treatment alternatives are lacking. All are to be used in combination with compression treatment. Occlusive and semipermeable biosynthetic wound dressings can be very effective when combined with compression. They can speed healing, reduce pain, make dressing changes infrequent, and help debridement. If a hard eschar is present over the ulcer when first seen, a dressing will assist in its removal. Enzymatic debridement with or without the addition of chlorophyll may be helpful. Dressings containing dilute acetic acid or silver may help reduce bacterial overgrowth in the wound, as will the application of topical metronidazole gel 0.075%. Becaplermin (Regranex) is expensive, but promotes wound healing. Granulation tissue formation is enhanced. It may be useful in wounds which have stopped healing. Injection of granulocyte-macrophage colony-stimulating factor (GM-CSF) into the ulcer base may also stimulate refractory ulcers to heal. It is very expensive. Grafts and skin substitutes should be reserved for refractory ulcers which have failed conservative therapy.

Risk factors that predict failure to heal within 24 weeks of limb-compression therapy include a large wound area, history of venous ligation or stripping, history of hip or knee replacement, ankle brachial index (ABI) of less that 0.80, fibrin on 50% or more of the wound surface, and the presence of the ulcer for an extended time. For every 6 months of duration, the ulcer healing time doubles.

ARTERIAL INSUFFICIENCY (ISCHEMIC) ULCER

Ischemic ulcers are mostly located on the lateral surface of the ankle or the distal digits. The initial red, painful plaque breaks down into a painful superficial ulcer with a surrounding zone of purpuric erythema. Granulation tissue is minimal, little or no infection is present, and a membranous inactive eschar forms over the ulcer. Patients at risk are those with long-standing hypertension, smokers, diabetics, and those with hyperlipidemia. The presence of an arterial ulceration identifies patients at increased risk for limb loss.

Signs and symptoms indicative that arterial disease is the cause of the ulceration include thinning of the skin, absence of hair, decreased or absent pulses, pallor on elevation, coolness of the extremity, dependent rubor, claudication on exercise, and pain on elevation (especially at night) relieved on dependency. In progressive disease the diagnosis of thromboangiitis obliterans, or Buerger's disease, should be considered.

The diagnosis of arterial insufficiency can usually be confirmed by physical examination and careful palpation of the pulses in the legs. For more accurate evaluation, take the blood pressure in the arm and leg. They should be nearly identical. The ratio of the popliteal-to-brachial pressure is called the ABI. If it is less than 0.75, arterial insufficiency exists, and if less than 0.5, the insufficiency is substantial.

Surgical intervention may be required to heal the ulceration. If the blood supply cannot be improved, little can be done except to prevent infection by the measures described under venous ulcers. The area should be protected from injury and cold, and smoking and tight socks should be avoided. Hyperbaric oxygen may be of some use, but it is limited by availability and cost.

NEUROPATHIC ULCERS

Foot ulcers in diabetics are usually related to sensory neuropathy. Offloading the ulcer is the primary principal of management. Necrotic tissue should be debrided back to bleeding viable tissue. As the foot is typically insensate, this can be done in the office without the need for anesthetic. Associated osteomyelitis is best treated by removal of the infected bone. Consultation with or referral to a podiatrist or orthopedic surgeon may be indicated. Various shoes and padded boots can be used to offload different areas of the foot. An orthotics consultation is usually indicated. Clinical infection should be treated, but simple colonization typically does not require treatment. After the ulcer heals, a shoe of appropriate depth and width will help to prevent recurrence. Frequent foot inspections for the presence of "hot spots" as well as debridement of dystrophic nails are important facets of prevention.

LEG ULCERS OF OTHER CAUSES

Hematopoietic ulcers are those occurring with sickle cell anemia, Cooley anemia (thalassemia), congenital hemolytic anemia, polycythemia vera, thrombocytopenic purpura, macroglobulinemia, and cryoglobulinemia. In addition, cryofibrinogenemia may also be manifested by ulcerations on the lower extremities.

The diagnosis is usually established by the accompanying signs and symptoms of the original disease. Treatment of the underlying disease should be maximal and then general measures used for leg ulcers should be followed.

Leg ulcers resulting from collagen vascular disease are most common in rheumatoid vasculitis, although ulcers may sometimes be seen with SLE, Felty syndrome, scleroderma, dermatomyositis, and mixed connective tissue disease. The ulcers are deep, indolent, and dry. Basal cell and squamous cell carcinoma, malignant melanoma, Kaposi sarcoma, and malignant lymphomas may be the cause of leg ulcers. Diagnosis of neoplastic causes of leg ulcers requires biopsy of the ulcer margin. Burns, radiodermatitis, decubitus ulcers, neurotic excoriations, factitial ulcers, and trophic ulcers are in this category.

Necrobiosis lipoidica, gout, diabetes, pellagra, prolidase deficiency, Gaucher's disease, Klinefelter syndrome, ulcerative colitis, and primary amyloidosis form another group in which leg ulcers may be found. The ulcers of lupus vulgaris, mycobacterial ulcers, sporotrichosis, blastomycosis, coccidioidomycosis, cryptococcosis, histoplasmosis, and schistosomiasis are some of the more important infectious leg ulcers. The gummatous ulcers of late syphilis should not be forgotten.

LYMPHEDEMA

Lymphedema is the swelling of soft tissues in which an excess amount of lymph has accumulated. Chronic lymphedema is characterized by long-standing, nonpitting edema. A working classification of lymphedema is shown in Box 35-2.

The most prevalent worldwide cause of lymphedema is filariasis. In the US the most common cause is postsurgical. If lymphedema is long-standing, a vertucous appearance to the affected extremity develops (elephantiasis vertucosa nostra).

Types

Lymphedema is classified by clinical type (Box 35-2). Primary types include congenital, early and late onset types. Other primary types of lymphedema are associated with characteristic features or syndromes. Some cutaneous disorders are associated with or are a complication of primary lymphedema. Secondary lymphedema can occur from numerous causes, including neoplasia and its treatment, infections, and physical factors.

Lymphedema Praecox Lymphedema praecox develops in females between the ages of 9 and 25. Swelling appears around the ankle and then extends upward to involve the entire leg. With the passage of time the leg becomes painful, with a dull, heavy sensation. Once this stage has been reached, the swollen limb remains swollen. Primary lymphedema is caused by a defect in the lymphatic system. Lymphangiography demonstrates hypoplastic lymphatics in Box 35-2 Classification of lymphedema

Primary lymphedema

- Congenital lymphedema (Milroy's disease)
- Lymphedema praecox
- Lymphedema tarda

Syndromes associated with primary lymphedema

- Yellow nail syndrome
- Turner syndrome
- Noonan syndrome
- Pes cavus
- Phakomatosis pigmentovascularis
- Distichiasis-lymphedema

Cutaneous disorders sometimes associated with primary lymphedema

- Yellow nails
- Hemangiomas
- Xanthomatosis and chylous lymphedema
- Congenital absence of nails

Secondary lymphedema

- Postmastectomy lymphedema
- Melphalan isolated limb perfusion
- Malignant occlusion with obstruction
- Extrinsic pressure
- Factitial lymphedema
- Postradiation therapy
- Following recurrent lymphangitis/cellulitis
- Lymphedema of upper limb in recurrent eczema
- Granulomatous disease
- Rosaceous lymphedema
- Primary amyloidosis

Complications of lymphedema

- Cellulitis of lymphedema
- Elephantiasis nostras verrucosa (Fig. 35-22)
- Ulceration
- Lymphangiosarcoma

Fig. 35-22 Elephantiasis verrucosa nostra.

Fig. 35-23 Milroy's disease. (Courtesy Lawrence Lieblich MD).

Fig. 35-24 Distichiasis. (Courtesy of Curt Samlaska, MD)

Primary Lymphedema Associated with Yellow Nails and Pleural Effusion (Yellow Nail Syndrome) Primary lymphedema is confined mostly to the ankles, although other areas may be involved. The nails show a distinct yellowish discoloration and thickening. Recurrent pleural effusion or bronchiectasis may be a feature.

Secondary Lymphedema In some malignant diseases, involvement of the lymph nodes will produce blockage and lymphedema. Malignant disease of the breast, uterus, prostate, skin, bones, or other tissues may cause such changes. Hodgkin's disease and, especially, Kaposi sarcoma may be accompanied by chronic lymphedema. Chronic lymphedema is frequently seen after mastectomy and the removal of the axillary nodes; it may occur after varying lengths of time.

Postmastectomy Lymphangiosarcoma (Stewart-Treves Syndrome) This type of vascular malignancy usually arises in chronic postmastectomy lymphedema. The lesions are bluish or reddish nodules arising on the arm. Similarly, primary or secondary lymphedema of the lower extremity may be complicated by angiosarcoma. Angiosarcoma arising in a lymphedematous extremity often presents with multiple lesions. Metastasis and death commonly result. Early aggressive surgical treatment with amputation may be life-saving. The treatment of breast cancer with lumpectomy and local radiation therapy may be complicated by angiosarcoma of the breast with minimal or no associated lymphedema. This is called cutaneous postradiation angiosarcoma of the breast. This form of angiosarcoma also frequently results in metastasis and death.

Postinflammatory Lymphedema The lymphedematous extremity may be caused by and worsened by repeated bacterial infections. It is these recurrent attacks, when they complicate filariasis, which cause the elephantiasis. Streptococcal cellulitis following venectomy in patients who had undergone coronary bypass surgery is a well-documented cause. However, almost any chronic or recurrent infection can cause this. Chronic antibiotic therapy can halt the progression by preventing the attacks of bacterial cellulitis.

Bullous Lymphedema Commonly misdiagnosed as an immunobullous disease, bullous lymphedema usually occurs

87%, aplasia in approximately 5%, and hyperplasia with varicose dilation of the lymphatic vessels in 8%.

Nonne-Milroy-Meige Syndrome (Hereditary Lymph-

edema) Milroy hereditary edema of the lower legs is characterized by a uni- or bi-lateral lymphedema present at birth and inherited as an autosomal-dominant trait. The edema is painless, pits on pressure, is not associated with any other disorder, and persists throughout life (Fig. 35-23). It may involve the genitalia and produce lymphangiectasias superficially. Chylous discharge can occur. Most frequently the affection is unilateral, and females are predominantly affected.

Treatment of this particular type of edema is extremely difficult since the disease is an anomaly of the lymphdraining vessels. Decongestive physiotherapy can be considered. In some cases, surgical procedures to remove affected tissue can be performed. This condition may be linked to a mutation that inactivates VEGFR3.

Lymphedema-Distichiasis Syndrome The association of distichiasis (double row of eyelashes) and late-onset lymphedema is a form of hereditary lymphedema called lymphedema-distichiasis syndrome (Fig. 35-24). It is an autosomal-dominant syndrome with the appearance of bilateral lymphedema beginning between the ages of 8 and 10 in affected boys, and 13 and 30 in affected girls. Lymphatic vessels are increased (not hypoplastic or absent as in other forms of congenital lymphedema) in the affected legs. Associated findings are varicose veins in 50% by age 64; congenital ptosis (31%); and congenital heart disease (6.8%), cleft palate (4%), scoliosis, and renal abnormalities. There may be phenotypic heterogeneity in this syndrome, as different types of mutations may lead to slightly different phenotypes, especially with regards to the ancillary features associated with the syndrome. This syndrome is due to a inutation in the FOXC2 transcription factor. This factor is expressed in both developing eyelids and lymphatics and other tissues with abnormalities in this syndrome.

with poorly controlled edema related to heart failure and fluid overload. Compression results in healing.

Factitial Lymphedema Also known as hysterical edema, lymphedema can be produced by wrapping an elastic bandage, cord, or shirt around an extremity, and/or holding the extremity in a dependent and immobile state. Selfinflicted causes of lymphedema are usually difficult to prove and may occur in settings of known causes of lymphedema, such as postphlebitic syndrome or surgical injury to the brachial plexus. Factitial lymphedema caused by blunt trauma localized to the dorsum of the hand or forearm is referred to as Secretan syndrome and l'oedeme blue, respectively. It often is unilateral and there may be significant purpura. Effective care of such patients requires psychiatric intervention. Occupational causes must be excluded.

Other Causes Occupational persistent hand edema in divers, related to the constrictive action of the divers' suits and pricks from sea urchin spines, can occur.

Evaluation

The diagnosis is usually based on a classic presentation; however, in the early stages the disease may require further investigation. Considerations include isotopic lymphoscintigraphy, indirect and direct lymphography, magnetic resonance imaging, computed tomography, and ultrasonography.

Treatment

Most cases are treated conservatively by means of various forms of compression therapy, complex physical therapy, pneumatic pumps, and compressive garments. Chronic antibiotic treatment may be beneficial in patients suffering repeated episodes of erysipelas or cellulitis. In diabetics with insensate feet, the frequency of infection can be reduced by wearing properly fitting shoes. Volume-reducing surgery and lymphatic microsurgery are rarely performed, although a few centers consistently report favorable results. It is best to refer these patients to a center versed in the treatment of these complicated conditions, to optimize patient compliance and customize therapy to the patient's lifestyle.

CHAPTER

Disturbances of Pigmentation

The visible pigmentation of the skin or hair is a combination of the amount of melanin, type of melanin (eumelanin versus pheomelanin), degree of vascularity, presence of carotene, and thickness of the stratum corneum. Other materials can be deposited abnormally in the skin leading to pigmentation. Eumelanin is the primary pigment producing brown coloration of the skin. Pheomelanin is yellow or red and is also produced solely in melanocytes. Melanin is formed from tyrosine, via the action of tyrosinase, in the melanosomes of melanocytes. Melanosomes are lysosomerelated organelles. Melanosome formation and the end result, pigmentation, require both the adequate manufacture of melanin and the appropriate transport of melanosomes within the melanocyte. The melanosomes are transferred from a melanocyte to a group of 36 keratinocytes called the epidermal melanin unit, to which they provide melanin. The variations in skin color between persons and races are related to the degree of melanization of melanosomes, their number, and their distribution in the epidermal melanin unit. Disorders of loss or reduction of pigmentation may be related to loss of melanocytes or the inability of melanocytes to produce melanin or transport melanosomes correctly. Wood's light examination is often performed to evaluate lesions of hyper- or hypo-pigmentation. Hyperpigmented lesions which enhance with Wood's light usually have increased epidermal melanocyte number or activity. If the lesions do not enhance, the melanin is located in the dermis. Wood's light will markedly enhance depigmented lesions (complete loss of pigment), but not enhance lesions with partial pigment loss (hypopigmentaton).

PIGMENTARY DEMARCATION LINES

Pigmentary demarcation boundaries of the skin can be classified into six groups, as follows:

- 1. Group A: Lines along the outer upper arms with variable extension across the chest
- Group B: Lines along the posteromedial aspect of the lower limb (Fig. 36-1)

- 3. Group C: Paired median or paramedian lines on the chest, with midline abdominal extension
- 4. Group D: Medial, over the spine
- 5. Group E: Bilaterally symmetrical, obliquely oriented, hypopigmented macules on the chest
- 6. Group F: Facial pigmentary demarcation lines.

More than 70% of black patients have one or more lines; they are much less common in white patients. Type B lines often appear for the first time during pregnancy.

Pigmentary demarcation lines must be distinguished from the much rarer condition acquired dermal melanocytosis. This rare condition affects primarily Asians and Hispanic women (male-to-female ratio, 1:17). It often first appears during pregnancy or the therapeutic use of estrogen/ progesterone. Lesions present as blue-gray patches with superimposed brown macules affecting the face trunk or extremities. Lesions do not enhance with Wood's light. They may be localized (following trauma) or more diffuse. Biopsy shows melanocytes in the dermis, similar to the findings in Mongolian spot, Nevus of Ota, and Nevus of Ito.

ABNORMAL PIGMENTATION

Hemosiderin Hyperpigmentation

Pigmentation due to deposits of hemosiderin occurs in purpura, hemochromatosis, hemorrhagic diseases, and stasis dermatitis. Clinically, hemosiderin hyperpigmentation is distinguished from postinflammatory dermal melanosis by a golden brown hue versus the brown or gray-blue pigmentation of epidermal and dermal melanin, respectively.

Fig. 36-1 Pigmentary demarcation lines.
Postinflammatory Hyperpigmentation

Any natural or iatrogenic inflammatory condition can result in hyper- or hypo-pigmentation. Postinflammatory dyspigmentation is more frequent in persons with Fitzpatrick skin types IV, V, and VI, especially those of skin types IV and V. It is equally common in males and females. Hyperpigmentation may result from two mechanisms: 1) increased epidermal pigmentation via increased melanocyte activity; or 2) dermal melanosis from melanocyte damage and melanin drop out from the epidermis into the dermis. Wood's light examination will distinguish these two patterns of postinflammatory hyperpigmentation. Lesions of hyperpigmentation tend to be tan to brown and may have a gray hue (due to dermal melanin). Hypopigmented lesions are prominently lighter than the surrounding skin. If the prior inflammatory process is treated, the dyspigmentation may improve. Histologically, there is melanin in the upper dermis and around upper dermal vessels, located primarily in macrophages (melanophages). The pattern of the dermal melanosis does not predict whether the lesion will be lighter or darker as a result of the prior inflammatory process-hence the tendency of pathologists to provide a diagnosis of "postinflammatory pigmentary alteration" in such cases. Postinflammatory dyspigmentation is treated initially by treating the underlying skin disease, if possible. Hydroquinone may be used in hyperpigmented cases which enhance with Wood's light. Tretinoin application may enhance the effect of hydroquinone. Laser treatments and chemical peels may also be beneficial, but in most cases, the best course is observation and support.

Lacz NL, et al: Postinflammatory hyperpigmentation: a common but troubling condition. Int J Dermatol 2004;43:362,

HEMOCHROMATOSIS (BRONZE DIABETES)

Hemochromatosis is a disorder caused by mutations in at least five different genes involved in iron absorption. It is very common in the white European population. At least four different phenotypes are described. Many of the patients with the most common genetic defects do not develop any disease (perhaps 25% of men and 6% of women). Men are affected more frequently and at an earlier age (usually between 30 and 50 years). The characteristic cutaneous manifestation is gray to brown mucocutaneous hyperpigmentation. It is enhanced in sun-exposed areas of the forearms, dorsal hands, and face, as well as in the inguinal area. The mucous membranes are pigmented in up to 20% of patients. koilonychia occurs in 50%, and localized ichthyosis in 40%. Alopecia is common and pruritus can occur. Porphyria cutanea tarda may be present. Biopsy of affected skin shows dermal iron deposition, but the visible pigmentation is actually increased epidermal melanin in the basal cell layer.

The most commonly affected organ is the liver. Hepatomegaly and elevated liver function tests are the first signs of hepatic iron overload. Cirrhosis and hepatocellular carcinoma may develop. The endocrine system is also affected with diabetes mellitus, impotence, and amenorrhea being most common. Arthropathy is seen in 20% to 70% of patients. Cardiac abnormalities include heart failure and cardiac arrhythmias. Consuming alcohol and smoking, as well as coexistent hepatitis C infection, all make it more likely that persons with genetic predisposition will develop clinical disease. Laboratory evaluation should be pursued in persons with appropriate clinical findings, suggesting the diagnosis of hemochromatosis. Levels of plasma iron and the serum ironbinding protein are elevated. The transferrin saturation (TS) is a useful screening measure calculated as $100 \times$ (serum *iron/total iron-binding capacity*). Forty-five or less is normal, except in premenopausal women where greater than 35 may be considered abnormal. High serum ferritin levels are also present. Genotyping is now performed in persons with a TS greater than 45 and an elevated ferritin, and confirms the diagnosis. Liver biopsy is reserved for persons with elevated liver function tests, a ferritin greater than 1000, or age older than 40.

Four different genes cause autosomal-recessive hemochromatosis and one causes autosomal-dominant disease. The most common autosomal-recessive form is due to a mutation in the HFE gene, most frequently C282Y, and less commonly H63D. The incidence of homozygosity for C282Y is 5 in 1000 persons of northern European descent, making it 10 times more common than cystic fibrosis. Compound heterozygotes (C282Y/H63D) also develop disease. Two autosomalrecessive forms of juvenile hereditary hemochromotosis are described, due to mutations in the Hemojuvelin and Hepcidin genes, respectively. Mutations in the transferrin receptor 2 gene lead to a form of autosomal-recessive adult onset hemochromatosis. Ferroportin mutation leads to an adult-onset form of autosomal-dominant hemochromatosis.

All forms of hemochromatosis are treated with phlebotomy until satisfactory iron levels are attained. Vitamin C supplementation must be avoided as it can worsen the disease. Raw seafood should be avoided as Vibrio vulnificus infection may occur. Phlebotomy can prevent cirrhosis. Once cirrhosis is present, phlebotomy does not prevent the development of hepatocellular carcinoma which occurs in 30% of patients.

MELASMA (CHLOASMA FACIEI)

Melasma is characterized by brown patches, typically on the malar prominences and forehead. There are three clinical patterns: 1) centrofacial, 2) malar, and 3) mandibular. The centrofacial and malar patterns comprise the majority of patients (Fig. 36-2). The pigmented patches are usually quite sharply demarcated. It tends to affect darker-complexioned individuals, especially Asians and Hispanics with Fitzpatrick skin types IV and V. It may at times be found on the forearms. Subtle melasma, as identified by ultraviolet (UV) light examination, may be seen in up to 30% of middle-aged Asian females.

Melasma occurs frequently during pregnancy and with the ingestion of estrogen, as may occur in oral contraceptives or with hormone replacement therapy (HRT) at menopause. It may also be seen in other endocrinologic disorders. It is seen most frequently in young women, but men make up 10% of

reported cases. Use of dilantin may induce melasma. Discontinuing the use of contraceptives rarely clears the pigmentation and it may last for many years after discontinuing them. In contrast, melasma of pregnancy usually clears within a few months of delivery. While melasma has classically been classified as epidermal- or dermal-based on the presence or absence of Wood's light enhancement, respectively, most cases show both epidermal and dermal melanin. Dermal melanophages are a normal finding in Asian sun-exposed skin. Independent of Wood's light findings, a therapeutic trial of some form of hypopigmenting agent should be recommended if the patient requests it.

A number of topical therapies are available. Exposure to sunlight should be avoided and a complete sunblock with broad-spectrum UVA coverage should be used daily. Bleaching creams with hydroquinone are the gold standard and are moderately efficacious; they contain from 2% (available over the counter) to 4% hydroquinone. Tretinoin cream may be added to increase efficacy. While tretinoin alone may reduce melasma, it may also increase pigmentation via its irritant effect. The combination of hydroquinone and tretinoin, administered in conjunction with a topical steroid, has been called "Kligman's formula" and is excellent. This is now available as a commercial product, Triluma, used once a day. The efficacy of this product has been reported to be superior to any combination of two of its ingredients, with a more rapid and complete response with the triple combination. Glycolic acid is at times added to hydroquinone to enhance its efficacy. In some patients with melasma 4% hydroquinone is insufficient and higher doses of hydroquinone must be compounded. Satellite pigmentation and local ochronosis are potential complications from use of these higher-concentration preparations. Azelaic acid, kojic acid, N-acetyl-4-cysteaminyphenol, licorice extract, and Arbutin are other therapies with efficacy, although generally not as effective as hydroquinone. Various surgical procedures such as peels and laser treatment have variable results, with some authors strongly supporting their use and others documenting lack of efficacy. These variable results may be in part technique dependent. The use of surgical modalities for the

Fig. 36-2 Melasma of the cheek. treatment of melasma should be approached with caution. Pretreatment with hydroquinone seems to enhance the longterm result of some surgical treatments.

PIGMENTED ANOMALIES OF THE EXTREMITIES

Dyschromatosis Symmetrica Hereditaria (Reticulate Acropigmentation of Dohi)

Originally described in and still reported primarily in the Japanese, acropigmentation of Dohi has been found to affect individuals from Europe, India, and the Caribbean. It is also referred to as dyschromatosis symmetrica hereditaria (DSH) or symmetrical dyschromatosis of the extremities. It is inherited most commonly as an autosomal-dominant trait, although autosomal-recessive kindreds have been reported. Patients develop progressive pigmented and depigmented macules, often mixed in a reticulate pattern, concentrated on the dorsal extremities. Freckle-like macules are present on the face. Lesions appear in infancy or early childhood and commonly stop spreading before adolescence. The pigmentary lesions last for life. The autosomal-dominant form of DSH is due to a mutation in the DSRAD gene which encodes a double-stranded RNA-specific adenosine deaminase, an RNA editing enzyme.

Dyschromatosis Universalis Hereditaria

Dyschromatosis universalis hereditaria is a rare genodermatosis characterized by reticulate hyper- and hypo-pigmented macules in a generalized distribution. Lesions appear in childhood, often in the first few months of life. The palms, soles, and mucous membranes of the mouth and tongue may be diffusely pigmented, with hypopigmented macules interspersed. Nail, teeth, and hair abnormalities may be associated. The patients are otherwise well.

Reticular Pigmented Anomaly of the Flexures (Dowling-Degos' Disease)

Reticular pigmented anomaly of the flexures is a rare autosomal-dominant pigmentary disorder; it is sometimes called Dowling-Degos' disease or dark dot disease. Pigmentation appears in adolescence or adulthood, affecting the axillae, neck, and inframammary/sternal areas. In some cases the dorsal hands are involved. The pigmentation is reticular; at the periphery, discrete, brownish-black macules surround the partly confluent central pigmented area. In more mildly affected patients the pigmentation is dappled. The pigmentation progresses very gradually. There are frequently acneiform pitted scars, sometimes pigmented, about the mouth. Comedonal and cystic lesions have been described on the flexures and axilla. Hidradenitis suppurativa-like lesions in the groin and axilla may occur. Patients may complain that it is worse during hot weather. Squamous cell carcinoma of the buttocks or perianal area have been described.

Histologically, the appearance is distinctive—elongation, tufting, and deep hyperpigmentation of the rete ridges, with protrusion of similar tufts even from the sides of the follicles. Small hom cysts may be present, so that the pattern resembles that of a reticulated seborrheic keratosis. Comedones may be present. Erbrium: YAG laser has treated the pigmented lesions of the chest.

Loo WJ, et al: Hydradenitis suppurativa, Dowling-Degos and multiple epidermal cysts: a new follicular occlusion triad. Clin Exp Dermatol 2004;29:622.

Galli-Galli Disease

This rare condition has close resemblance clinically to Dowling-Degos' disease, but is histologically distinct. The condition appears in adult life and favors males. The skin lesions are 1- to 2-mm slightly keratotic red to dark brown papules which are focally confluent in a reticulate pattern. The skin lesions favor skinfolds but also other skin sites. The neck, axillae, upper extremities, dorsal hands, trunk, groin, and even the scrotum and lower extremities may be affected. Histologically there is prominent digitate downgrowth of the rete ridges, identical to that seen in Dowling-Degos. The characteristic histologic feature is a suprabasilar cleft and suprapapillary thinning of the epidermis. There is no dyskeratosis as is seen in Grover's disease. Treatment is unsuccessful. Since two brothers were initially reported, the syndrome may have a genetic component.

Braun-Falco M, et al: Galli-Galli disease: an unrecognized entity or an acantholytic variant of Dowling-Degos' disease? J Am Acad Dermatol 2001;45:760.

Reticulate Acropigmentation of Kitamura

Reticulate acropigmentation of Kitamura consists of linear palmar pits and pigmented macules 1 to 4 mm in diameter on the volar and dorsal aspects of the hands and feet. It is usually an autosomal-dominantly inherited disorder. Acropigmentation of Dohi, Dowling-Degos' disease, and reticulate acropigmentation of Kitamura in most cases can be distinguished, but cases with overlapping features have been reported.

- Singal A, et al: Is the heredity of reticulate acropigmentation of Kitamura always autosomal dominant? J Dermatol 1998; 25:57.

DERMATOPATHIA PIGMENTOSA RETICULARIS

Dermatopathia pigmentosa reticularis is composed of the triad of generalized reticulate hyperpigmentation, noncicatricial alopecia, and onychodystrophy. Additional associations include adermatoglyphia, hypo- or hyper-hidrosis, palmoplantar hyperkeratosis, and nonscarring blisters on the dorsa of the hands and feet. An autosomal-dominant inheritance pattern has been reported.

- Maso MJ, et al: Dermatopathis pigmentosa reticularis. Arch Dermatol 1990;126:935.

TRANSIENT NEONATAL PUSTULAR MELANOSIS

Also called *transient neonatal pustulosis*, this disorder is present at birth. Newborns present with 1- to 3-mm flaccid,

superficial fragile pustules. Some of the pustules may have already resolved in utero, leaving pigmented macules. Lesions affect the chin, neck, forehead, back and buttocks, but can occur anywhere. In dark-skinned infants, pigmented macules may persist for weeks or months after the pustules have healed, whereas in affected lighter-skinned neonates, dyspigmentation less commonly occurs. The condition is observed in 4.4% of black and 0.6% of white newborns.

Histologically, there are intracorneal or subcorneal aggregates of predominantly neutrophils, but eosinophils may also be found. Dermal inflammation is composed of a mixture of neutrophils and eosinophils. The differential diagnosis includes erythema toxicum neonatorum, neonatal acne, and acropustulosis of infancy.

Wagner A: Distinguishing vesicular and pustular disorders in the neonate. Curr Opin Pediatr 1997;9:396.

PEUTZ-JEGHERS SYNDROME

Peutz-Jeghers syndrome (PJS) is characterized by hyperpigmented macules on the lips and oral mucosa and polyposis of the small intestine. The dark brown or black macules appear typically on the lips, especially the lower lip, in infancy or early childhood (Fig. 36-3). Similar lesions may appear on the buccal mucosa, tongue, gingiva, and genital mucosa; macules may also occur around the mouth, on the central face, and on the backs of the hands, especially the fingers, toes, and tops of the feet. Once suspected, conventional imaging work-up should be performed. Capsule endoscopy may aid in establishing the diagnosis, since the polyps may be in regions of the intestine not directly accessible to routine endoscopy.

The associated polyposis involves the small intestine by preference (64–78%), but hamartomatous polyps may also occur in the stomach (38–49%), colon (42–53%), and rectum (28–32%). The polyposis of the small intestine may cause repeated bouts of abdominal pain and vomiting; bleeding is common; intussusception is frequent.

Patients with PJS have a 10- to 18-fold greater lifetime cancer risk than the general population. Half of patients with PJS will develop cancer at a mean age of 40 years. The greatest risk is for gastrointestinal malignancy of the colon and duodenum, but cancers both in the gastrointestinal tract and extraintestinal sites occur. Pancreas, breast (bilateral), lung, cervix, uterus, and thyroid carcinomas may develop. The lifetime risk for pancreatic cancer is 10%. Mucinous

Fig. 36-3 Peutz-Jeghers, macular pigmentation of the lower lip. ovarian cystadenofibromas, Sertoli-Leydig cell stromal tumors, and sex cord tumors with annular tubules can occur.

The syndrome is transmitted as a simple mendelian dominant trait. At least 50% to 75% of patients with PJS have a germline mutation of the STK11/LKB1 tumor suppressor gene on chromosome 19p13. The gene product is a serinethreonine kinase involved in signal transduction. Patients have one inactive copy of this gene. About 5% of pancreatic cancers unassociated with PJS also have inactivation of both alleles of this gene, supporting its role as a tumor suppressor.

Patients with PJS should have routine colonoscopy from the time of diagnosis. Upper gastrointestinal endoscopy and upper gastrointestinal studies with small bowel followthrough should be performed every 2 years. Screening for pancreatic cancer should also be considered.

Laugier-Hunziker syndrome and Cronkhite-Canada syndrome should be considered in the differential diagnosis. Laugier-Hunziker syndrome presents with mucosal pigmentation and pigmented nail streaks. Cronkite-Canada syndrome consists of melanotic macules on the fingers and gastrointestinal polyposis. Also there is generalized, uniform darkening of the skin, extensive alopecia, and onychodystrophy. The polyps that occur are usually benign adenomas and may involve the entire gastrointestinal tract. A protein-losing enteropathy may develop and is associated with the degree of intestinal polyposis. Onset is typically after age 30 in this sporadically occurring, generally benign condition. Hypogeusia is the dominant initial symptom, followed by diarrhea and ectodermal changes. Seventy-five percent of all cases have been reported from Japan. Zinc therapy may improve the hypogeusia and other symptoms.

RIEHL MELANOSIS

This pigmentary disease, first described by Riehl, is a form of contact dermatitis. It begins with pruritus, erythema, and pigmentation gradually spreads and, after reaching a certain extent, becomes stationary. The melanosis occurs mostly in women and develops slowly over the course of several months. Most reported cases occur in Japan. The characteristic feature is spotty light to dark brown pigmentation. This is most intense on the forehead, on the malar regions, behind the ears, on the sides of the neck, and on other sun-exposed areas. The pathogenesis of Riehl metanosis is believed to be sun exposure following the use of some perfumes or creams (a photocontact dermatitis). Serrano et al reported a positive patch test to lemon oil, geraniol, and hydroxycitronellal. Treatment is removal of the contactant.

Serrano G, et al: Riehl's melanosis. J Am Acad Dermatol 1989; 21:1057.

TAR MELANOSIS (MELANODERMATITIS TOXICA LICHENOIDES)

Tar melanosis is an occupational dermatosis that occurs among tar handlets after several years' exposure. Severe widespread itching develops and is soon followed by the appearance of reticular pigmentation, telangiectases, and a shiny appearance of the skin. In addition, there is a hyperhidrotic tendency. Small, dark, lichenoid, follicular papules become profuse on the extremities, particularly the forearms. Bullae are sometimes observed. This represents a photosensitivity or phototoxicity induced by tar.

Lehowhl M, et al: Tar melanosis. Mt Sinai J Med 1995;62:412.

FAMILIAL PROGRESSIVE HYPERPIGMENTATION

Familial progressive hyperpigmentation (FPH) is characterized by patches of hyperpigmentation, present at birth, which increase in size and number with age. Later, hyperpigmentation appears in the conjunctivae and the buccal mucosa. Eventually, a large portion of the skin and mucous membranes becomes involved. Inheritance is in an autosomaldominant pattern with variable penetrance. A focus in a stnall village in Germany has recently been reported. FPH is differentiated from other hyperpigmentations mainly by the presence of bizarre, sharply marginated patterns of hyperpigmented skin.

- Zanardo L, et al: Progressive hyperpigmentation and generalized lentigiosis without associated systemic symptoms: a rare hereditary pigmentation disorder In south-east Germany. Acta Derm Venereol 2004;84:57.

PERIORBITAL HYPERPIGMENTATION

Dark circles around the eyes are not uncommon, often familial, and are frequently found in individuals with dark

pigmentation or Mediterranean ancestry. Atopic patients may also exhibit periorbital pigmentation (allergic shiners). Treatment is ineffective.

METALLIC DISCOLORATIONS

Pigmentation may develop from the deposit of fine metallic particles in the skin. The metal may be carried to the skin by the blood stream or may permeate into it from surface applications.

Argyria

Argyria is a localized or widespread slate-colored pigmentation resulting from the presence of silver in the skin. The pigmentation is most noticeable in parts exposed to sunlight (the face and hands) and spares the skinfolds; however, it also occurs in the conjunctivae, sclerae, mucous membranes, and nails. The binding of silver to protein is enhanced by light and the tissue silver is felt to stimulate melanocytes, explaining the photoaccentuation. At first the discoloration is hardly perceptible, it has a faint bluish-gray tone, but as it becomes more pronounced, a slate-gray color develops. The oral mucous membranes and the scleize are usually pigmented in a distinctive diffuse manner. Most cases of systemic argyria are due to nose or eye drops containing silver or to the ingestion of silver in "tonics." These "tonics" are no longer regulated by the US Food and Drug Administration and can be sold as "food supplements" over the internet. Local treatment with a silver-containing product may produce argyria localized to the region of use: for example, the conjunctivae, from eye drops; a wound, from silver sulfadiazine cream; the earlobes, from silver earrings; and from silver acupuncture needles. It can also occur from occupational exposure, usually in jewelers. In these localized exposures, the appearance may be separated by many years from the exposure.

Histologically, systemic argyria and localized argyria have the same features. The skin appears relatively normal at lower magnifications. Fine black granules are found in the lamina propria surrounding the sweat glands, as well as surrounding blood vessel walls, the dermoepidermal junction, and along the arrector pili muscles. Examination of an unstained biopsy section by darkfield illumination demonstrates silver granules outlining the basement membrane of the epidermis and the eccrine sweat glands. Electron probe microanalysis can be used to confirm the diagnosis. There is no effective treatment and the pigmentation may last for many years.

Arsenic

Acute arsenic poisoning is associated with flushing on day one of exposure, and facial edema on days 2 through 5. A morbilliform eruption appears on days 4 through 6. Hepatic dysfunction occurs simultaneously with the appearance of an eruption of discrete red-brown, erythematous papules in the intertrigionous areas (areas of friction) of the lower abdomen, buttocks, and lateral upper chest. It regresses after 2 to 3 weeks, at times accompanied by acral desquamation. Three months after exposure Mee's lines, total leukonychia, Beau's lines, and onychodystrophy may be seen. Periungual pigmentation occurs in up to half of acutely poisoned patients at 3 months. Arsenic is an elemental metal that is ubiquitous, existing in nature as metalloids, alloys, and a variety of chemical compounds. These various forms of arsenic may be deposited into water, soil, and vegetation, producing serious health risks. In West Bengal, India, an estimated 200,000 people have arsenic-induced skin disorders and more than 1 million Indians are drinking arsenic-laced water from contaminated wells. Arsenic-contaminated water sources are a worldwide health concern also affecting countries such as Japan, Chile, Taiwan, and Mongolia. It is not known what are safe levels of arsenic in drinking water. The World Health Organization (WHO) current permissible levels are under 0.01 mg/L.

Industries using arsenical compounds place their workers at risk of exposure. Use of arsenic pesticides and exposure to sodium arsenite, used as a veterinary pesticide exposing sheep-dip workers, has resulted in chronic arsenism. In the US arsenic is used for pesticides, rodenticides, herbicides, insecticides, desiccants, feed additives, and wood preservatives. Pressure-treated lumber, particularly the marinetreated plywood, exposes carpenters and shipbuilders. The largest risk from wood products, however, occurs when pretreated wood is burned and the arsenic fumes are inhaled. Electroplating silver may also require arsenic. Another potential source of exposure during the 1960s was American tobacco, resulting mostly from the use of arsenic-containing insecticides.

Chronic exposure to inorganic arsenic may lead to cutaneous hyperpigmentation. It is often accentuated in the inguinal folds and the areolae. Areas of hypopigmentation may be scattered in the hyperpigmented areas, giving a "raindrop" appearance. The pigmentation may resolve or persist indefinitely. Punctate keratoses on the palms and soles are characteristic. Diffuse palmoplantar keratoderma may rarely occur. The most common source of current exposure is from drinking water contaminated with arsenic (hydroarsenicism). In the past, elixirs to treat asthma (Fowler's solution, Bell's Special Asthma Mixture) were a source of exposure. Histologically, the arsenical keratosis on the palms and soles show hyperkeratosis, acanthosis, and minimal-to-moderate basilar atypia. Arsenic exposure leads to the development of nonmelanoma skin cancers 2 to 20 years after exposure. In most reports Bowen's disease represents the majority of arsenic-induced skin cancers and may appear on sun-exposed or -protected skin. Basal cell carcinomas are frequent, usually multiple, most common on the trunk, and can be in sun-protected sites. Squamous cell carcinoma may also occur. Acetretin may improve "arsenical" keratoses. Increased risk for lung, bladder, and renal carcinoma may also occur.

Lead

Chronic lead poisoning can produce a "lead hue," with lividity and pallor, and a deposit of lead in the gums may occur: the "lead line."

Iron

In the past, soluble iron compounds were used in the treatment of allergic contact and other dermatitides. In eroded areas iron was sometimes deposited in the skin, like a tattoo. The use of Monsel solution can produce similar tattooing, so aluminum chloride is now preferred. If Monsel is used, to minimize tattooing, it is best applied with a cotton-tipped applicator barely moistened with the solution, then rolled across a wound that has just been blotted dry.

Titanium

A titanium-containing ointment caused yellowish papules on the penis in a patient. Titanium screws used for orthopedic procedures, if they come in close proximity to the skin, can cause cutaneous blue-black hyperpigmentation.

Gold

Chrysiasis may be induced by the parenteral administration of gold salts, usually for the treatment of rheumatoid arthritis. It appears to be more commonly recognized in white patients. A mauve, blue, or slate-gray pigmentation develops initially on the eyelids, spreading to the face, dorsal hands, and other areas. The severity of chrysiasis is related to the total dose received and it is rare below a total dose of 20 mg/kg of elemental gold. The pigmentation is accentuated in light-exposed areas, and sun-protected areas do not histologically demonstrate gold, even when the patient has documented chrysiasis at other sites. Localized chrysiasis has been induced by Q-switched ruby laser treatment in a patient who had received parenteral gold therapy. Melanin is not increased in the areas of hyperpigmentation. Therefore, it appears the gold itself contributes to the visible hyperpigmentation. Mucous membrane and scleral pigmentation is verv uncommon.

Histologically, there is no inflammation in the skin and gold is deposited in the dermis predominantly in a perivascular pattern. The epidermis and dermoepidermal junction are spared, but the granules are accentuated in the basement membrane zone of sweat glands. Darkfield examination will demonstrate the granules and electron probe microanalysis can be used to confirm the presence of gold. Patients with chrysiasis are not at increased risk of developing other gold-related cutaneous complications, namely lichenoid and psoriasiform drug eruptions.

CANTHAXANTHIN

The orange-red pigment canthaxanthin is present in many plants (notably algae and mushrooms) and in bacteria, crustaceans, sea trout, and feathers. When ingested for the purpose of simulating a tan, its deposition in the panniculus imparts a golden orange hue to the skin. Stools become brick red and the plasma orange, and golden deposits appear in the retina. Its use is not recommended since it may be associated with liver and retinal damage.

Lober CW: Canthaxanthin: the "tanning" pill. J Am Acad Dermatol 1985;13:660.

IDIOPATHIC GUTTATE HYPOMELANOSIS (LEUKOPATHIA SYMMETRICA PROGRESSIVA)

Idiopathic guttate hypomelanosis is a very common acquired disorder that affects women more frequently than men. It usually occurs after age 40 and its prevalence increases with age. The lesions occur chiefly on the shins and forearms, suggesting sun exposure may play a role. Individual lesions are small (2–5 mm on average) hypopigmented macules. They usually number between 10 and 30, but numerous lesions may occur. Lesions spare the trunk and face. The lesions are irregularly shaped and very sharply defined, like depigmented ephelides, and are of only minor cosmetic significance. Cryotherapy can improve the appearance of the lesions.

Arrunategui A, et al: HLA-DQ3 is associated with idiopathic guttate hypomelanosis, whereas HLA-DR8 is not, in a group of renal transplant patients. Int J Dermatol 2002;41:744.

VITILIGO

Vitiligo usually begins in childhood or young adulthood, with about half of cases beginning before the age of 20. The prevalence ranges from 0.5% to 1%. Although females are

disproportionately represented among patients seeking care, it is not known whether they are actually more commonly affected or simply are more likely to seek medical care. Vitiligo has developed in recipients of bone marrow transplant or lymphocyte infusions from patients with vitiligo.

Clinical Features Vitiligo is an acquired pigmentary anomaly of the skin manifested by depigmented white patches surrounded by a normal or a hyperpigmented border. There may be intermediate tan zones or lesions halfway between the normal skin color and depigmentation—so-called trichrome vitiligo. The hairs in the vitiliginous areas usually become white also. Very rarely, the patches may have a red, inflammatory border. The patches are of various sizes and configurations.

Four types have been described according to the extent and distribution of the involved areas: localized or focal (including segmental), generalized (common symmetric), universal (Fig. 36-4), and acrofacial (Fig. 36-5). The generalized pattern is most common. Involvement is symmetrical. The most commonly affected sites are the face, upper part of the chest, dorsal aspects of the hands, axillae, and groin. There is a tendency for the skin around orifices to be affected, namely the eyes, nose, mouth, ears, nipples, umbilicus, penis, vulva, and anus. Lesions appear at areas of trauma, so vitiligo favors the elbows and knees. Universal

Fig. 36-4 Vitiligo, generalized.

Fig. 36-5 Vitiligo, characteristic periorificial location.

vitiligo applies to cases where the entire body surface is depigmented. The acrofacial type affects the distal fingers and facial orifices (lips and tips). Focal vitiligo may affect one nondermatomal site (such as the glans penis) or asymmetrically affect a single dermatome or band. This segmental form of vitiligo is treatment resistant, has an earlier onset, and is less frequently associated with other autoimmune phenomena. It represents 5% of adult vitiligo and 20% of childhood vitiligo.

Local loss of pigment may occur around nevi and melanomas, the so-called halo phenomenon. Vitiligo-like leukoderma occurs in about 1% of melanoma patients. In those with previously diagnosed melanoma, it suggests metastatic disease. Paradoxically, however, as the reaction indicates an autoimmune response against melanocytes, patients who develop it have a better prognosis than patients without leukoderma. Halo nevi are also common in patients with vitiligo. Lesions of vitiligo are hypersensitive to UV light and burn readily when exposed to the sun. It is not unusual to note the onset of vitiligo after a severe sunburn.

Ocular abnormalities are increased in patients with vitiligo, including iritis and retinal pigmentary abnormalities. Patients have no visual complaints. Eight percent of patients with idiopathic uveitis have vitiligo or poliosis. The conditions most frequently associated with vitiligo are other "autoimmune" diseases. These include insulin-dependent diabetes mellitus, pernicious anemia, Hashimoto thyroiditis, Graves' disease, Addison's disease, and alopecia areata. Screening should be directed by signs and symptoms. Vitiligo occurs in 13% of patients with the autoimmune polyendocrinopathy-candidiasis-ectodermal dystrophy (APECED) syndrome.

Although familial aggregation of vitiligo is seen—up to 30% of vitiligo patients have an affected relative—it is not inherited as an autosomal-dominant or -recessive trait, but rather seems to have a multifactorial genetic basis.

The psychologic effect of vitiligo should not be underestimated. Patients are frequently anxious or depressed because of the appearance of their skin and the way it affects their social interactions. Referring the patient to a mental health professional or the National Vitiligo Foundation (www.nvfi.org) may be helpful in this situation.

Occupational Vitiligo

Thiols, phenolic compounds, catechols, mercaptoamines, and several quinines (including chloroquine) can produce depigmentation. These compounds have a structure similar

to tyrosine and may be converted by tyrosine-related protein-1 to compounds toxic to the melanocyte. The clinical pattern may be very similar to idiopathic vitiligo, but lesions tend to be concentrated in areas of contact with the incriminated substance. Occupational vitiligo may occur in individuals who work in rubber garments or wear gloves that contain an antioxidant, monobenzyl ether of hydroquinone. Many phenolic compounds can produce leukoderma, with or without antecedent dermatitis. Examples are paratertiary butylphenol, amylphenol, and butylcatechol; alkyl phenols; sulfhydryls; and monobenzyl ether of hydroquinone. One source of these is phenolic antiseptic detergents used in hospitals. Adhesives and glues containing them may be found in shoes, wristbands, adhesive tape, and rubber products used in brassieres, girdles, panties, or condoms may also be at fault. Self-sticking bindis (the cosmetic used by many Indian women on the forehead) has been reported to induce leukoderma from the adhesive material. Also, electrocardiograph electrodes may cause similar round hypopigmented spots at the site of contact. A similar pattern of postinflaminatory hypopigmentation simulating vitiligo is observed around the mouth, in persons with no prior history of allergic dermatitis but with a positive patch test to cinnamates.

Pathogenesis Four possible mechanisms have been proposed as inducing vitiligo: autoimmunity (currently favored), neurohumoral factors, autocytotoxicity (increased susceptibility to oxidative stress), and melanocytorrhagy. This later theory proposes that vitiligo results from defective adhesion (with altered response [detachment] to friction). None of these mechanisms has been conclusively proven and several may be operative in various forms of vitiligo.

Histopathology There is a complete absence of melanocytes. Usually there is no inflammatory infiltrate.

Differential Diagnosis Vitiligo must be differentiated from morphea and lichen sclerosis, both of which are hypopigmented, but associated with a change in the skin texture. Pityriasis alba has a fine scale, is slightly papular, and poorly defined. Tinea versicolor (avors the center back and chest, bas a fine scale, and yeast and hyphal forms are demonstrable with potassium hydroxide (KOH) examination. The tertiary stage of pinta might easily lead to diagnostic confusion, but a travel history and serologic testing will help elucidate the diagnosis.

Treatment Vitiligo is a frustrating condition to treat. Spontaneous repigmentation occurs in no more than 15% to 25% of cases. Response is slow, and response rates are low. In addition, some forms of treatment, such as phototherapy, actually worsen the appearance of the vitiligo initially by pigmenting surrounding skin, accentuating the depigmented areas.

Because the major concern is cosmetic, various cover-up strategies have been developed. There are various brands of make-up available to temporarily conceal the lesions. Topical dyes are more resistant to washing off and are very acceptable to some patients. The newer self-tanning creams containing dihydroxyacetone are useful for light-skinned and olive complexioned patients with acral lesions. Fair-skinned patients (skin types I and II) with vitiligo may sometimes effectively manage their disease with sunblock. If the patient can prevent tanning of the skin around the vitiligo lesions, the lesions will appear similar to the untanned skin and require no additional treatment. Sun protection is mandatory in all patients with vitiligo because of the increased risk for skin cancer in depigmented areas.

Topical steroids may be useful on focal or limited lesions. The thinner skinned areas of the face seem to respond best. Trunk and acral lesions are often resistant to this treatment. Mid to super high-potency steroids are often required, with the strength tapered as the lesions respond. A 2-month trial should be attempted. Topical calcipotreinene once a day may increase the efficacy of topical steroid treatment. Although systemic steroids lead to temporary repigmentation, this is usually lost as the steroidal agents are tapered, so this is usually not a viable long-term strategy.

Tacrolimus ointment 0.1% has been particularly efficacious in treating facial vitiligo. It is as effective as topical steroids and avoids the complications of atrophy and acne induced by topical steroids. Head and neck lesions improve by 75% or more in half of children treated, whereas only 25% of trunk and extremity lesions resolve by 75% or more. Patients who initiate treatment in the summer have a higher rate of response. Continual application may be required to maintain the response. New areas of vitiligo appear in untreated areas, suggesting there is no systemic effect.

Narrow-band UVB twice weekly has become the preferred form of phototherapy to treat vitiligo. It avoids the need for prolonged eye protection and the occasional psoralen-induced nausea. About half of patients will achieve more than 50% repigmentation of the face, trunk, arms and legs. Hand and foot lesions repigment in less than 25% of patients. Children may have slightly higher response rates than adults. Long courses of treatment may be required. PUVA therapy can also be used to treat vitiligo. The addition of calcipotriene 0.005% once a day adds significantly to the rate and extent of response to narrow-band UVB and PUVA phototherapy, and should be used if there is no contraindication. Repigmentation from phototherapy may begin after 15 to 25 treatments; however, significant improvement may take as many as 100 to 200 treatments (6-24 months). If follicular repigmentation has not appeared after 3 to 6 months or approximately 50 treatments, phototherapy treatments should be discontinued. Known photosensitivity, porphyria, and systemic lupus erythematosus are contraindications to phototherapy.

Topical application of 8-methoxypsoralen at a concentration of 0.05% to 0.1%, followed by UVA exposure, may lead to repigmentation. Topical PUVA is used for focal or limited lesions. Inadvertent burns with blistering are frequent during treatment, even when the patient is treated by professionals. For this reason, topical PUVA is very difficult for the patient to do at home. The combination of topical tacrolimus plus the 308-nm xenon chloride eximer laser appears effective for local lesions and avoids the toxicity of topical PUVA. This combination is more effective than the laser alone and can even be effective in lesions which tend to be UV resistant.

Surgical treatments can be applied to limited lesions if the above methods do not prove beneficial, but these are time consuming. They are recommended primarily in patients with segmental vitiligo (which is relatively treatment resistant) and in patients who have failed other forms of treatment and have stable disease (no new lesions or expansion of lesions for 1 year). Surgical procedures are not effective in patients who exhibit Koebner phenomenon at the donor site or have active vitiligo. Epidermal grafting, autologous minigrafts, and transplantation of cultured melanocytes and noncultured melanocytes/keratinocytes have all been reported.

Total Depigmentation

If more than 50% to 80% of the body surface area is affected by vitiligo, the patient can consider depigmentation. This form of treatment should be considered permanent and the goal of treatment is total depigmentation. Limited areas (such as those exposed daily) may be treated, but satellite and distant depigmentation may occur, so the action of the medication cannot be limited to the applied area. Monobenzone (monobenzyl ether of hydroquinone) 20% is applied twice a day for 3 to 6 months to residual pigmented areas. Up to 10 months may be required to complete the treatment. About one in six patients treated experiences acute dermatitis, usually confined to the still-pigmented areas, but this rarely limits treatment. Topical 20% 4-methoxyphenol cream (mequinol, monomethylether of hydroquinone) can also be used for depigmentation. The Q-switched laser selectively destroys melanocytes and can also achieve depigmentation. It can be combined with a topical depigmenting agent for added efficacy.

VOGT-KOYANAGI-HARADA SYNDROME

Vogt-Koyanagi-Harada (VKHS) syndrome is a disease complex affecting the eyes, skin, auditory system, and central nervous system (CNS). It affects primarily pigmented races and is rare in white persons. It is more common in females, and affects all ages. The disease occurs in four phases. The prodromal phase or meningoencephalitic phase occurs with fever, malaise, headache, nausea, and vomiting. The CNS involvement can include meningismus, headaches, mental status changes, cerebrospinal fluid pleocytosis, tinnitus, and dysacusis. Recovery is usually complete. The second phase, the uveitic phase is characterized by anterior and/or posterior uveitis and inflammation of many other parts of the eye. The third or convalescent phase begins 3 weeks to 3 months after the uveitis appears, usually as it begins to improve. This phase is characterized by alopecia, vitiligo, and poliosis of scalp, eyebrows, eyelashes, and hairs of the axillae. The fourth phase is one of recurrent attacks of uveitis. Most ocular complications occur as a result of this phase of the disease, and include permanent decreased visual acuity, cataracts, and glaucoma. Revised diagnostic criteria have been developed.

VKHS is a cell-mediated autoimmune disease with the autoantigen(s) felt to be solely expressed in melanincontaining cells. The target antigens may be the tyrosinase family proteins, as immunization of mice with several of these proteins can induce a syndrome similar to VKHS. Supporting this hypothesis are the rare observations that skin trauma that was followed by vitiligo, erythroderma, interferon therapy for hepatitis C, and melanoma can all be associated with the appearance of VKHS. Treatment of the ocular inflammatory disease with immunosuppressives may prevent ocular complications.

ALEZZANDRINI SYNDROME

Alezzandrini syndrome is a very rare syndrome characterized by a unilateral degenerative retinitis, followed after several months by ipsilateral vitiligo on the face and ipsilateral poliosis. Deafness may also be present.

Hoffman MD, Dudley C: Suspected Alezzandrini's syndrome in a diabetic patient with unilateral retinal detachment and ipsilateral vitiligo and poliosis. J Am Acad Dermatol 1992;26:496.

LEUKODERMA

Postinflammatory leukoderma may result from many inflammatory dermatoses, such as pityriasis rosea, psoriasis, herpes zoster, secondary syphilis, and morphea. Sarcoidosis, tinea versicolor, mycosis fungoides, scleroderma, and pityriasis lichenoides chronica may all present with hypopigmented (only rarely, actually depigmented) lesions, as may leprosy. Burns, scars, postdermabrasion, and intralesional steroid injections with depigmentation are other examples of leukoderma.

Friedman SJ, et al: Perilesional linear atrophy and hypopigmentation after intralesional corticosteroid therapy. J Am Acad Dermatol 1988;19:537.

ALBINISM

Albinism is a partial or complete congenital absence of pigment in the skin, hair, and eyes (oculocutaneous albinism), or the eyes alone (ocular albinism). The cutaneous phenotype of the various forms of albinism is broad, but the ocular phenotype is reasonably constant in most forms. This includes decreased visual acuity, nystagmus, pale irides that transilluminate, hypopigmented fundi, hypoplastic foveae, and lack of stereopsis. The recent discovery of the genetic basis of many of the forms of albinism has dramatically changed the classification scheme. Genetic disorders of pigment cells can now be defined as caused by 1) disruption of melanoblast migration to target tissues during development (Waardenburg syndrome and piebaldism); 2) disruption of melanin synthesis (oculocutaneous albinism, ocular albinism); 3) disruption of melanosome formation (Chédiak-Higashi and Hermansky-Pudlak syndromes); or 4) disruption of melanosome transport and melanin transfer to keratinocytes (Griscelli syndrome). The most serious sequelae of albinism are gross visual disturbances and the increased risk for the development of skin cancer. A number of syndromes associated with albinism can also cause premature mortality due to impairment of the functioning of other involved organs and systems.

Disorders of Melanin Synthesis

Oculocutaneous Albinism Four types of oculoculaneous albinism (OCA) have been described, all caused by disruption of melanin synthesis and all autosomal-recessive disorders. Historically, the term tyrosinase-negative OCA was used if the mutation was in the tyrosinase gene (encoding an enzyme absolutely required for pigment synthesis). However, some "tyrosinase-positive" patients were found to

Fig. 36-6 Albinism, with light skin, blue eyes and white hair.

be compound heterozygotes for mutations in tyrosinase as well (Fig. 36-6).

Oculocutaneous Albinism 1

Oculocutaneous albinism 1 (OCA1) results from mutations in the tyrosinase gene and accounts for approximately 40% of OCA worldwide. Affected patients are homozygous for the mutant gene or are compound heterozygotes for different mutations in the tyrosinase gene. OCA1 is divided into two forms: OCA1A and OCA1B. At birth they are indistinguishable. OCA1A is the most severe form, with complete absence of tyrosinase activity and complete absence of melanin in the skin and eyes. Visual acuity is decreased to 20/400. In OCA1B, tyrosinase activity is greatly reduced but not absent. Affected patients may show increase in skin, hair, and eye color with age and can tan. OCA1B was originally called "yellow mutant" albinism. Temperature-sensitive OCA (OCA1-TS) results from mutations in the tyrosinase gene that produce an enzyme with limited activity below 35° C (95° F) and no activity above this temperature. Affected patients have white hair, skin, and eyes at birth. At puberty, dark hair develops in cooler acral areas.

Oculocutaneous Albinism 2

Oculocutaneous albinism 2 (OCA2) has a prevalence of 1 in 15,000 and is the most common form of OCA, accounting for approximately 50% of OCA worldwide, most frequently in Africa. Patients were formerly called "tyrosinase-positive" albinos. Inheritance is autosomal recessive and results from mutations in the P gene. The P gene codes a putative membrane transport protein that spans melanocyte internal membranes, likely the endoplasmic reticulum. The cutaneous phenotype of OCA 2 patients is broad, from nearly normal pigmentation to virtually no pigment. Pigmentation increases with age and visual acuity improves from infancy to adolescence. Prader-Willi and Angleman syndromes are caused by deletions in the chromosomal region contiguous to and sometimes including the P gene. One percent of patients with these syndromes also have OCA2.

Oculocutaneous Albinism 3

Oculocutaneous albinism 3 (OCA3) is caused by mutations in the tyrosine-related protein 1 (TRP-1) gene, located on chromosome 9. To date, this form of OCA has only been described in African patients and is characterized by light brown hair, light brown skin, blue-brown irides, nystagmus, and decreased visual activity. Brown rather than black melanin is formed. This type of albinism was previously referred to as "rufous" albinism.

Oculocutaneous Albinism 4 (OCA4)

Oculocutaneous albinism 4 (OCA4) is due to mutations in the MATP gene on chromosome 5 encoding a membraneassociated transporter protein, predicted to span the membrane 12 times and to function as a transporter. Patients are hypopigmented to a variable degree, similar to patients with OCA2. Visual acuity is decreased and nystagmus is found in many but not all patients. This is the most common form of tyrosinase-positive albinism in Japan; it has also been reported in a Turkish patient and several German patients.

Ocular Albinism There are multiple forms of ocular albinism, which are clinically similar. Ocular albinism type 1 (OA1) is X-linked, and characterized by depigmented fundi, with resultant strikingly apparent choroidal vessels; associated findings can include nystagmus, head nodding and impaired vision. Female carriers have "mud-splattered" or mosaic pigmentation of the fundi due to lyonization of the X chromosomes. Macromelanosomes are found in the skin, so skin biopsy may be used to help establish this diagnosis; patients may present with lighter skin than expected. It is suggested that "ocular" albinism may be somewhat of a misnomer and that cutaneous involvement is present but clinically subtle. Data suggest that the melanocyte-specific OA1 gene product is the first described G-protein coupled receptor to reside exclusively on an intracellular membrane, likely an endosomal compartment. In one large South African kindred, OA1 is associated with late-onset deafness.

Disorders of Melanosome Formation

These are multisystem syndromes that are associated with albinism. These syndromes are caused by genes that function in intracellular organelle formation and movement in a variety of specialized cell types, such as melanocytes, neurons, immune cells, and type II epithelial cells in lungs.

Chédiak-Higashi Syndrome Chédiak-Higashi syndrome is an autosomal-recessive disorder characterized by oculocutaneous albinism and immunologic deficiency, including defective phagocyte, lymphocyte, and natural killer (NK) cell function. Antibody-dependent cellular cytotoxicity is also defective. Early childhood is marked by recurrent bacterial infections. Eighty-five percent of Chédiak-Higashi syndrome patients develop an accelerated phase characterized by a lymphocyte and macrophage activation syndrome. The results of liver function tests will be abnormal, and fever, hepatosplenomegaly, lymphadenopathy, pancytopenia, and infiltration of the CNS occur. Although the accelerated phase may respond to etoposide plus systemic steroid and intrathecal methotrexate, relapses invariably occur. These relapses are less responsive to treatment and are eventually fatal. Unless patients undergo successful stem cell transplantation, most die in childhood.

The causative gene is LYST (lysosome trafficking regulator), located on chromosome 1; its function is unknown. Lysosomal protein transport is defective and giant intracytoplasmic inclusion bodies are seen in most granulated cells. Giant melanosomes are observed and cause pigment dilution (hypopigmentation of skin, hair, and fundi), possibly secondary to impaired melanin transport. The hair has a metallic gray sheen. Microscopic examination of hair samples reveals multiple small granules of pigment dispersed throughout the shaft.

Hermansky-Pudlak Syndrome Hermansky-Pudlak syndrome (HPS) is an autosomal-recessive disorder consisting of oculocutaneous albinism, a hemorrhagic diathesis secondary to the absence of dense bodies in platelets, and accumulation of a ceroid-like material in the reticuloendothelial system, visceral organs, oral mucosa, and urine. Patients with this disorder have a history of easy bruisability, epistaxis, gingival bleeding, hemoptysis, and bleeding after various surgical procedures and childbirth.

Currently, seven human genes (HPS1-7) have been identified, which when independently mutated, lead to a clinical picture consistent with HPS. It is anticipated that more HPS genes will be identified in humans since in mice there are at least 14 non-allelic genes that when singly defective give rise to HPS. While the HPS subtypes 1 to 7 all share the clinical signs and symptoms noted above, a few subtypes have additional unique features that serve to distinguish them from the other HPS subtypes.

The most common subtype is HPS1, and together with HPS4, comprises 50% of the known worldwide cases of HPS, HPS1 and HPS4 are clinically very similar (reflecting the biochemical studies that demonstrate that HPS1 and 4 proteins are associated together in a complex) and are the most severe forms of HPS. Interstitial pulmonary fibrosis, inflammatory bowel disease, renal failure, and cardiomyopathy are late complications and can cause premature mortality between the ages of 20 and 50 years old. A recent study suggests that pirfenidone, an antifibrotic agent, can slow the progression of pulmonary fibrosis in HPS1 patients with significant residual lung function (initial forced ventilatory capacity >50%). One in 21 Puerto Ricans has a mutation (usually a 16-bp duplication) in the HPS1 gene, which is located at 10q23. HPS accounts for 80% of albinos in Puerto Rico, and 1 in 1800 Puerto Ricans in the northwest region of the country has HPS. Patients may have completely absent to normal pigmentation and the majority have the ocular findings typical of albinism. Atypical nevi, acanthosis nigricans-like lesions in the axillae and neck, and trichomegaly also occur. Solar damage as evidenced by solar lentigines, actinic keratoses, and nonmelanoma skin cancers occurs in 80% of patients with the 16-bp duplication in HPS1 (Fig. 36-7).

HPS2 is caused by a mutation in the gene coding for a subunit of AP3, a molecule necessary for normal protein trafficking to the lysosome. HPS2 is notable for immunodeficiency and persistent neutropenia, with patients suffering recurrent bacterial infections of the upper respiratory system and middle ear, possibly due to the lack of antigen presentation by the CD1b molecule, since CD1b fails to gain access to the lysosome. Mild pulmonary fibrosis and a mild balance defect are also associated with HPS2.

HPS3, HPS5, and HPS6 have mild clinical findings, without reported pulmonary or gastrointestinal involvement. Patients with HPS3 have been reported to be initially misdiagnosed as having ocular albinism.

Fig. 36-7 Hermansky-Pudlak syndrome, freckling of the "V" of the neck, and a basal cell carcinoma In a Puerto Rican man.

The clinical similarity found for HPS3, HPS5, and HPS6 also reflects the biochemical observation that the respective proteins associate together in a complex.

Only a single patient has been reported with HPS7—a 48-year-old Portuguese woman with OCA, ease of bruising, and a bleeding tendency, who had mild pulmonary symptoms and reduced lung compliance, but otherwise normal pulmonary function and no evidence of fibrosis on highresolution computed tomography (CT) chest scans. The HPS7 gene encodes dysbindin, a protein of unknown function.

Disorders of melanosome transport

Griscelli Syndrome (Partial Albinism with Immunodeficiency) Some groups refer to this disorder as *Griscelli Syndrome, type 2 (GS2).* GS2 is a rare autosomalrecessive syndrome characterized by variable pigmentary dilution, hair with a silvery metallic sheen, frequent pyogenic infections, neutropenia, and thrombocytopenia. Defective NK cell function, impaired delayed-type hypersensitivity, and hypogammaglobulinemia are present. Patients develop an accelerated phase termed hemophagocytic syndrome characterized by an uncontrolled, lifethreatening activation of T-cells and macrophages. Some patients have severe neurologic involvement, thought to be secondary to infiltration of immune cells into the CNS. Bone marrow transplantation is the only effective therapy for GS2.

Histologically, melanocytes are hyperpigmented and filled with stage IV melanosomes, whereas adjacent keratinocytes contain only sparse melanosomes. The giant cytoplasmic granules seen in Chédiak-Higashi syndrome are absent. Giant melanosomes are not seen. On microscopic examination, hair samples contain uneven clumps of aggregated melanin pigment in the medulla of the shaft.

The gene defective in this disorder encodes Rab27a, a small GTPase molecule in the Ras family, which associates with melanosomes in a molecular complex together with the motor protein myosin Va (defective in Griscelli syndrome type 1/Elejalde syndrome) and the linker protein melanophilin (defective in Griscelli syndrome type 3). This complex facilitates movement of melanosomes on actin filaments located at the periphery of melanocytes; disruption of the complex blocks transfer of melanin to neighboring keratinocytes and results in hypopigmentation. Similarly, the movement of cytoplasmic organelles in immune cells is impaired, leading to immune dysfunction.

Elejalde Syndrome Also referred to as *Griscelli Syndrome, type 1 (GS1)*, Elejalde syndrome is a rare autosomalrecessive syndrome consisting of moderate pigment dilution, profound primary neurologic defects, no immune defects, and hair with a metallic silvery sheen. This syndrome was first reported as *neuroectodermal melanolysosomal* disease. Patients have severe developmental delay and mental retardation early in life. Many patients do not survive into the second decade of life. Microscopic examination of hair shafts reveals irregular clumps of pigment, similar to that seen in Griscelli syndrome type 2. Skin biopsy reveals an increased melanization of the epidermal basal layer detected with Fontana-Masson staining, due to the retention of melanin in melanocytes.

The gene underlying this disorder encodes myosin Va, a motor protein involved in the movement of melanosomes along actin filaments at the periphery of the melanocyte. When transport to the cell periphery is disrupted, melanin cannot be transferred to keratinocytes, resulting in a pigment dilution phenotype. The myosin Va protein is also found in brain tissue, functions in the short-range axonal/dendritic transport in neuronal cells, and binds to synaptic vesicles; the neurologic manifestations are likely due to impaired movement of intracellular organelles/vesicles in neuronal tissue.

Griscelli Syndrome, Type 3 The two patients reported in the literature to have Griscelli syndrome, type 3 (GS3), aged 16 and 12 years old, have only manifested hypopigmentation. Whether late-onset signs and symptoms involving other organs and systems will develop has yet to be determined. The gene underlying this disorder encodes melanophilin, which associates on melanosomes in a complex with Rab27a and myosin Va (see above); gene mutations result in a block in the transfer of melanin to neighboring keratinocytes; hypopigmentation results.

Disorders of Melanoblast Migration and Survival

These disorders cause "spotting," i.e. patches of white hair and/or unpigmented skin.

Waardenburg Syndrome Four genotypic variants of Waardenburg syndrome exist, with overlapping phenotypic features; all are autosomal dominant. Types 1 and 3 are caused by mutations in the PAX3 gene, encoding a transcription factor. Type 2 is caused by mutations in the MITF gene, also encoding a transcription factor, and type 4 is due to either a heterozygous mutation in the SOX10 gene (encoding a transcription factor), or homozygous mutations in the endothelin-3 (EDN3) or the endothelin B receptor (EDNR3) gene. These mutations impair the ability of melanoblasts to reach their final target sites (inner ear, eye, skin) during embryogenesis.

Patients with this syndrome have features of piebaldism, with a white forelock, hypopigmentation, premature graying, and other characteristic findings including synophrys, congenital deafness, dystopia canthorum (broad nasal root),

Fig. 36-8 Waardenburg syndrome with heterochromia iridis.

Fig. 36-9 Piebaldism, white forelock.

Fig. 36-10 Piebaldism, vitiligo-like depigmentation.

and ocular changes, including heterochromia irides (Fig. 36-8). Type 1 and 3 are both characterized by dystopia canthorum, but in type 1 white forelock and depigmented skin patches are more frequent while in type 3, limb anomalies occur. In type 2, no dystopia canthorum is observed, but hearing loss and heterochromia irides are more frequent. In type 4, aganglionic megacolon can occur.

Piebaldism Piebaldism is a rare, autosomal-dominant syndrome with variable phenotype, presenting at birth. The characteristic clinical features are a white forelock and patchy absence of skin pigment (Figs 36-9 and 36-10). The depigmented lesions are static and characteristically occur on the anterior and posterior trunk, mid-upper arm to wrist, mid-thigh to mid-calf, and shins. A characteristic feature of piebaldism is the presence of hyperpigmented macules within the areas lacking pigmentation and also on normally pigmented skin. The white forelock is a triangular or diamond-shaped midline white macule on the frontal scalp or forehead. The medial portions of the eyebrows and eyelashes may be white. Histologically, melanocytes are completely absent in the white macules.

Piebaldism is caused by mutations in the KJT gene, encoding a cell surface membrane receptor for the stem cell growth factor. The phenotypic differences between families are caused by different locations of mutations in the gene. A mild phenotype occurs in cases associated with mutations in the ligand-binding region, whereas more severe phenotypes occur from mutations in the tyrosine-kinase region of the receptor. The white lesions may respond to surgical corrections (see discussion under vitiligo).

Cross-McKusick-Breen Syndrome Also known as Cross syndrome, oculocerebral-hypopigmentation syndrome, or hypopigmentation and microphthalmia, this extremely rare disorder is characterized by white skin, blond hair with a yellow-gray metallic sheen, small eyes with cloudy corneas, jerky nystagmus, gingival fibromatosis, and severe mental and physical retardation. The genetic basis of Cross-McKusick-Breen syndrome remains undetermined.

CHAPTER

37 Dermatologic Surgery

Dermatology has always been a surgically oriented field, including such procedures as curettage, biopsy, destruction, and excision. Over the years, the practice of dermatology has evolved to include a greater number and extent of surgical procedures. This evolution has been due to many factors, including dermatologists' greater understanding of cutaneous pathology and the fact that outpatient dermatologic surgery is more cost-effective, safer, and provides a greater degree of patient convenience. As a result, the American Board of Dermatology mandates certain surgical exposure and experience for all residents in dermatology residency programs. Furthermore, with the recent ACGME accreditation of Procedural Dermatology fellowships, dermatologic surgery has become recognized as a main stream medical option for patients. This chapter and Chapter 38 provide a survey of procedures, indications, and appropriate management within the spectrum of dermatologic surgery.

PREPARATION FOR SURGERY

Before any surgical procedure, preoperative evaluation should include a detailed medical history. Questions about drug allergies, medications, herbal supplements, presence of a pacemaker or implantable cardioverter-defibrillator, prior wound infections, recently implanted prosthetics, or history of endocarditis are critical in order to appropriately manage the surgical patient.

Anticoagulants

There is much debate regarding the role of antiplatelet and/or anticoagulants and surgical bleeding. Dermatologists are frequently presented with the dilemma of whether to discontinue blood thinners in the setting of surgery. Data suggest that continuous treatment with blood thinners perioperatively in patients undergoing Mohs and cutaneous surgery is not associated with an increase in surgical complications. However, discontinuation of these medications may increase the risk of cerebral and cardiovascular complications. Kovich and Otley reported a series of thrombotic complications in a group of patients who had discontinued aspirin or warfarin prior to surgery, including stroke, transient ischemic attack, myocardial infarction, pulmonary embolus, and death. Furthermore, West et al demonstrated that blinded cutaneous surgeons were unable to intraoperatively identify which patients were taking a blood thinning agent based on the subjective amount of surgical oozing. As such, it is recommended to maintain patients on all medically necessary blood thinners during cutaneous surgery. Patients taking aspirin for primary prevention may discontinue it 2 weeks prior to any surgical procedure.

Ginkgo, garlic, ginseng, ginger, and vitamin E may increase the risk of perioperative bleeding. As these herbal supplements are not medically necessary, patients should discontinue them for several weeks prior to undergoing dermatologic surgery.

Antibiotic Prophylaxis

Dermatologists performing cutaneous surgery are often faced with the decision of whether to prescribe prophylactic antibiotics. Wounds are categorized into four groups. Clean wounds (class I) are created on normal skin using clean or sterile technique. Examples include excision of neoplasms, noninflamed cysts, biopsies, and most cases of Mohs surgery. The majority of dermatologic surgery falls into this category. The infection rate of these wounds is less than 5%. Cleancontaminated wounds (class II) are created on contaminated skin or any mucosal or moist intertriginous surface, such as the oral cavity, upper respiratory tract, axilla, or perineum. The infection rate of these wounds is 10%. Contaminated wounds (class III) involve visibly inflamed skin with/without nonpurulent discharge and have an infection rate of 20% to 30%. Examples included inflamed cysts or traunatic wounds. Infected wounds (class IV) have contaminated foreign bodies, purulent discharge or devitalized tissue. Examples included necrotic tumors, ruptured cysts, or active hidradenitis suppurativa. These wounds have an infection rate of 40%.

Clean (class I) wounds do not require antibiotic prophylaxis. Antibiotics are not routinely required in cleancontaminated (class II) wounds in dermatologic surgery. It is preferable to treat infections as they arise, rather than expose all patients to antibiotics and the increased rate of drugrelated adverse events. The exception to this would be those surgery cases which violate mucosal membranes (i.e. oral and nasal mucosa), anogenital and inguinal areas, patients with heavily colonized skin (i.e. atopic dermatitis or infected skin), patients with a history of prior wound infection, as well as in those patients in whom a wound infection would result in significant morbidity (Table 37-1). In contaminated (class III) and infected (class IV) wounds, antibiotics serve a therapeutic role and should be used.

First-generation cephalosporins are a good initial choice for the treatment of wound infection because of their coverage of staphylococcal organisms, common Gram-negative organisms such as *Escherichi coli*, and certain *Proteus* species. Macrolides are an alternative (or patients who are allergic to penicillin or cephalosporins. Culture should be performed to identify the infectious agent and ensure that appropriate antibiotic therapy is used.

Risk factors associated with wound infections include impaired immune status, poor glucose control in diabetics, alcoholism, and chronic medical problems, such as renal failure or chronic obstructive pulmonary disease.

The American Heart Association (AHA) has divided patients into high, medium, and low endocarditis risk

Situation	Antibiotic	Regimen (1 hour pre-operative dose)
Skin	cephalexin	1 g orally
	dicloxacillin	1 g orally
	clindamycin	300 mg orally
	vancomvcin	500 mg IV
Oral/Respiratory mucosa	cephalexin	1 g orally
and the second second second second second	amoxicillin	1 g orally
	clindamycin	300 mg orally
GastroIntenstial/Genitourinary mucosa	cephaexin	1 o orally
and the state of the	trimethoprim/sulfamethoxazole	1 double strength tablet orally
	ciprofloxacin	500 mg orally

Table 37-1 Antibiotic prophylaxis for heavily colonized or high risk patients

Box 37-1 Endocarditis risk

High-risk category

- Prosthetic cardiac valves
- Previous bacterial endocarditis
- Complex cyanotic congenital heart disease (e.g. single ventricle states, transposition of the great arteries, tetralogy of Fallot)
- Surgically constructed systemic pulmonary shunts or conduits

Moderate-risk category

- Most other congenital cardiac malformations (other than listed above)
- Acquired valvular dysfunction (e.g. rheumatic heart disease)
- Hypertrophic cardiomyopathy
- Mitral valve prolapse with valvular regurgitation or thickened leaflets

Low-risk category

- Physiologic heart murmurs
- Mitral valve prolapse without valvular regurgitation
- Cardlac pacemakers and implanted defibrillators
- Isolated secundum atrial septal defect
- Surgical repair of atrial septal defect, ventricular septal defect, or patent ductus arteriosus (without residua beyond 6 months)
- Previous rheumatic fever without valvular dysfunction
- Previous coronary artery bypass graft surgery
- Previous Kawasaki's disease without dysfunction

(Box 37-1). The AHA recommends that incision or biopsy of surgically scrubbed skin does not require antibiotic prophylaxis, even if the patient is categorized as being at high risk for endocarditis. However, if surgery is performed on contaminated or heavily colonized skin, and violates respiratory, oral, or genitourinary mucosa, antibiotics are indicated (Table 37-2). Standard antibiotic recommendation for endocarditis prophylaxis in procedures involving oral or respiratory mucosa is amoxicillin 2.0 g (in children, 50 mg/kg) 1 h prior to the procedure. Revised AHA guidelines do not require repeat antibiotic dosing several hours later. Cephalexin is an appropriate alternative for procedures involving skin only. Penicillin allergic patients can be treated with clindamycin 600 mg (in children, 20 mg/kg) at the same timepoints.

There are no formal guidelines regarding the use of antibiotics in patients with orthopedic prosthetic devices. Patients with joint replacement probably do not need prophylactic antibiotics for clean wounds. If mucosa is invaded, prophylaxis is appropriate and reasonable in these cases. Consultation with orthopedic surgery is appropriate in determining whether antibiotic prophylaxis is necessary.

Preoperative Antisepsis

Many surgical preparations are available. Alcohol is commonly used for minor clean procedures such as biopsies. However, since it has only weak antimicrobial activity, it is not recommended for more extensive sterile procedures. Chlorhexidine has a broad spectrum against Gram-positive and -negative organism, has a rapid onset of activity, sustained residual activity, and is nonstaining. Chlorhexidine has been reported to cause both ototoxicity and keratitis from direct ocular contact. However, this is mainly in patients under general anesthesia who cannot respond to immediate irritation associated with ocular contact. Betadine and all iodine-containing preparations are often irritating to the skin, leave a residual color, can be absorbed in very premature infants, and must dry before the procedure to act as an effective antimicrobial agent. Hexachlorophene should not be used on children or pregnant women, because of potential neurotoxicity and teratogenicity, respectively. Hydrogen peroxide has no significant antiseptic properties, and thus it is not suitable for sterile skin preparation.

If hair must be removed prior to surgery, this should be performed in a manner that does not leave open skin (i.e. cuts or scratches) which can serve as a conduit for infection. Preoperative shaving has been associated with a higher rate of bacterial infection secondary to cutting of the skin surface.

Anesthesia

Anesthetics work by blocking sodium influx into neurons and preventing depolarization and blockage of action potential. Small unmyelinated C-fibers, which carry pain and temperature, are more easily blocked than larger myelinated A-fibers, which carry pressure sensation and motor function. Local anesthetics are divided into two group, amides and esters, based on the structural linkage between the aromatic hydrophobic portion and the hydrophilic amine end. Amides are metabolized by hepatic microsomal enzymes. Esters are metabolized in plasma by pesudocholinesterase and excreted by the kidney. The workhorse anesthetic of dermatologic surgery is lidocaine. Longer-acting anesthetics, such as bupivacaine, are also employed for special procedures such as nerve and digital blocks.

Table 37-2

Situation	Antibiotic	Regimen (1 hour pre-operative dose)
Contaminated skin	cephalexin	Adults: 2 g; children: 50 mg/kg orally
	dicloxacillin	Adults: 2 g; children: 50 mg/kg orally
	clindamycin	Adults: 600 mg; children: 20 mg/kg orally
	vancomycin	Adults:1 g; children: 20 mg/kg IV
Oral/Respiratory mucosa	amoxicillin	Adults: 2 g; children: 50 mg/kg orally
	ampicillin	Adults: 2 g; children: 50 mg/kg IM/IV
	clindamycin	Adults: 600 mg; children: 20 mg/kg orally
	cephalexin	Adults: 2 g; children 50 mg/kg orally
	azithromycin/clarithromycln	Adults: 500 mg; children: 15 mg/kg orally
Gastrointestinal/Genitourinary mucosa		
High risk patients	ampicillin + gentamicIn	Adults: 2 g + 1.5 mg/kg IM/IV Children: 50 mg/kg + 1.5 mg/mg IM/IV
	vancomycin + gentamicin	Adults: 1 g IV + 1.5 mg/kg IM/IV Children: 20 mg/kg IV + 1.5 mg/kg IM/IV
Moderate risk patients	amoxicillin	Adults: 2 a: children: 50 ma/kg orally
	ampicillin	Adults; 2 g; children: 50 mg/kg IM/IV
	vancomycin	Adults:1 g; children: 20 mg/kg IV

All local anesthetics, with the exception of cocaine and prilocaine, cause vasodilation due to relaxation of smooth muscle. This results in increased surgical bleeding and shorter duration of action as the anesthesia is cleared from the surgical site due to vasodilation. Epinephrine, which causes vasoconstriction, is often added to local anesthetics in order to decrease bleeding and increase duration of anesthesia. The vasoconstrictive effect of epinephrine takes 15 min for onset. Large amounts of epinephrine are contraindicated in patients with hypertension, hyperthyroidism, and pheochromocytoma, and in the digits. Epinephrine is safe to use in well vascularized areas, such as the ear, nose, and genitals.

Sodium bicarbonate (8.3%) can be added (1:10 ratio) in order to reduce the pain and burning associated with the lower pH of lidocaine. However, sodium bicarbonate can reduce epinephrine activity with time, thus requiring freshly mixed preparations on a regular basis.

The issues of maximum dosages are not well documented. Maximum dosage of anesthesia has traditionally been accepted as 5 mg/kg of 1% plain lidocaine and 7 mg/kg of 1% lidocaine with epinephrine. These numbers have been based on old industry-based studies, not found in the medical literature. Experience with tumescent liposuction has taught that dosages up to 55 mg/kg are well tolerated and safe in certain clinical situations. Bupivacaine has a greater risk of cardiac toxicity than lidocaine, because of its longer duration of action.

Allergic reactions to local amide anesthetics are quite rare. The metabolite *p*-aminobenzoic acid (PABA) is responsible for ester allergies. Therefore, ester types are rarely used today. There is no cross-reactivity between ester and amide classes of anesthetics. True systemic amide allergy is extremely rare. Thorough questioning of patients who report allergy often reveals a vasovagal reaction or epinephrine sensitivity. If local anesthetics use is precluded, intradermal injection with diphenhydramine can be used. Drowsiness can be a side effect when large doses of this agent are used. Bacteriostatic saline, with the benzyl alcohol preservative acting as the anesthetic agent, is often sufficient to provide brief anesthesia needed to perform small procedures.

Topical anesthetics can be effectively used for many laser procedures, as well as decreasing pain associated from pinpricks of local anesthesia. Eutectic mixture of 2.5% lidocaine and 2.5% prilocaine is one such agent. In addition, there are numerous lidocaine-containing products on the market. Prilocaine-induced methemoglobinemia has been reported in children due to the increased systemic absorption of prilocaine with certain topical products. All agents are applied thickly for about an hour prior to the procedure. The level of anesthesia obtained with these topical agents is often inconsistent.

Equipment

The choice of instruments and suture depends on the procedure being performed. Most simple, in-office biopsies are performed in a "clean" rather than sterile manner, and require minimal instrumentation. More complex excisional and reconstructive surgery is generally performed with sterile technique and employs a surgical tray with a wider range of instruments (Box 37-2). For procedures requiring sulures, absorbable material is used for deeper, layered closures, whereas surface sutures are generally nonabsorbable or fastabsorbing (Box 37-3). The large number of suture choices relates to both the type of procedure performed and anatomic location treated. Choices include absorbable and nonabsorbable, synthetic and nonsynthetic, monofilament and braided. All have appropriate applications and a detailed discussion is beyond the scope of this chapter. In general, for procedure requiring buried suture, a synthetic braided suture is the standard choice. The 50% tensile strength for this class of suture is about 3 months. Additionally, they are less palpable under the skin. For procedures on the trunk and extremities (i.e. areas under tension), a monofilament absorbable suture may be a better choice as the tensile strength may last for a greater length of time. The thicker skin in these areas may hide the palpability of this class of suture, making it more acceptable to patients. Epidermal approximation in more delicate areas is more appropriately closed with smaller 5-0 or 6-0 sutures. Absorbable sutures (i.e. gut), may be considered in sensitive areas where suture removal may be painful or difficult (i.e. eyelids) and children. Facial sutures are often taken out in 4 to 7 days to decrease the chance of forming track marks from epitheliazation of the

Box 37-2 Cutaneous surgical instruments and supplies

- Scalpel handle (flat No 3)
- Blade (No 15)
- Needle holder (appropriate size)
- Sharp curved iris scissors, tissue cutting scissors
- Blunt undermining scissors
- Skin hook (dull tipped, 2-4 prong)
- Hemostats
- Forceps (1 × 2 teeth, with suture platform)
- Skin preparatory scrub in sterile basin
- Sterile towels
- Sterile gauze and cotton-tipped swabs
- Hyfrecator cover
- Suture
- Suture scissors
- Blade remover

Box 37-3 Examples of common skin suture material

Absorbable	
 Gut (chromic, plain) 	twisted
 Polyglycolic acid (Dexon[®]) 	braided
 Polygalactin 910 (Vicryl[®]) 	braided
 Polydioxanone (PDS[®]) 	monofilament
 Polytrimethylylene carbonate (Maxon[®]) 	monofilament
 Poliglecaprone 25 (Monocryl[®]) 	monofilament
■ Glycomer 631 (Blosyn [®])	monofilament
Nonabsorbable	
 Silk (braided) 	
 Nylon (Ethilon[®], Dermalon[®]) 	monofilament
Nylon (Surgilon [®] , Nurolon [®])	braided
 Polypropylene (Prolene[®], Surgipro[®]) 	monofilament
 Polvester (Ethibond[®], Mersilene[®]) 	braided
Dacron [®])	
 Polybutester (Novafil[®]) 	monofilament

suture puncture site, whereas sutures on the scalp, neck, and body are often left in for 2 weeks. Running subcuticular sutures can be left in for 3 weeks to add tensile strength to wounds without the risk of track marks.

BIOPSIES

When performing a skin biopsy, the clinician should consider the lesion, reason for biopsy (e.g. diagnostic versus cosmetic), and site. Shave biopsies can range from a superficial scissor snip of an epidermal growth to deep shave excisions of papillary dermal processes. Punch biopsies are most often used for dermal lesions, sampling deeper than shave biopsies, but requiring sutures. Excisional biopsies remove an entire clinical lesion and are the biopsy of choice for pigmented lesions suspicious for melanoma. Incisional biopsies remove a portion of a clinical lesion and are often performed on larger plaques or patches when an excisional biopsy is not cosmetically acceptable or feasible. A wedge biopsy is a deep incisional biopsy that can sample pathologic tissue and adjacent normal tissue, and is especially useful for pathologic diagnosis of certain inflammatory conditions (e.g. panniculitis, fasciitis).

Shave biopsies are best suited for pedunculated, papular, or otherwise exophytic lesions. However, using a deep or rolled shave, samples can also be obtained of macular or indurated lesions, provided the necessary histologic changes reside in the epidermis or papillary dermis. Infiltration of local anesthesia distends and elevates the lesion, increases skin turgor, affords greater resistance to the blade, and facilitates undercutting the lesion. Using either a 15 blade scalpel or a razor blade, which can be flexed to achieve the desired depth, a horizontal incision is made and the lesion removed with sweeping strokes (Fig. 37-1). Hemostasis is

Fig. 37-1 Shave biopsy, lesion is plnched up with thumb and linger and biopsy performed with sweeping strokes.

easily attained with 35% aluminum chloride solution. Sharp scissor excision is a variant of shave excisions and is best suited for pedunculated lesions.

The dermatologic punch is commonly used for both excisional and incisional biopsies (Fig. 37-2). When performing a punch biopsy, the skin should be stretched perpendicular to the relaxed skin tension lines. The elliptical wound resulting from the release of the tension can be suture closed in a linear fashion without redundancy or puckering associated with circular wounds. The punch is placed on the skin perpendicular to the surface. While applying gentle pressure, it is rotated back and forth and advanced to the hub. The specimen is carefully grasped to avoid crush artifact and the base is cut.

Narrow hole extrusion is a surgical technique that uses a punch biopsy to make a small cutaneous portal through which larger benign growths (e.g. lipoma) can be extruded (Fig. 37-3). This technique allows the evacuation of large subcutaneous growths with a relatively small surface incision.

Fig. 37-3 Narrow hole extrusion of lipoma. A, 4 mm punch in center of lipoma. B, Hemostat used to loosen lipoma. C, Extrusion of lipoma through narrow hole. D, Entire lipoma removed.

CRYOSURGERY

Cryosurgery is used for the treatment of numerous benign, premalignant, and malignant skin lesions. This modality is extensively used by almost every dermatologist owing to its ease of use, cost-effectiveness, and versatility. Postoperative wound care is relatively simple and complications are infrequent. Although a number of cryogens have been used (including ethyl chloride, CO_2 , and NO), liquid nitrogen, with a boiling point of -195.6° C, is most widely utilized.

The mechanism of injury in cryosurgery is the result of multiple factors, including mechanical damage to cells resulting from intra- and extra-cellular ice crystal formation, exposure to high electrolyte concentrations in surrounding nonfrozen or thawing fluid, recrystallization patterns during thaw, and ischemia caused by vascular stasis and damage. Rapid freezing causes intracellular ice crystals which are more destructive than the extracellular crystals formed during slow freezing. Tissue damage is maximized with a slow thaw time, which causes increased solute gradients and greater cell destruction. Multiple freeze-thaw cycles can further increase damage to the target lesion.

There are several techniques for cryosurgery. The simplest is the use of a cotton-tipped applicator. Varying the amount of pressure applied and the length of contact

by the applicator to the skin can control the depth of freeze. Additionally, the volume of liquid nitrogen can be increased or decreased by adding or removing cotton from the applicator tip. As viruses have been shown to survive in liquid nitrogen, cotton-tipped applicators should never be reintroduced to the storage container. Rather, a small amount of liquid nitrogen should be transferred to an individual container and discarded after use.

Spray application is one of the most commonly used methods of cryosurgery. This technique uses a hand-held liquid nitrogen spray unit with an adjustable nozzle to vary the size of the stream delivered. An insulating cone or a disposable otoscope speculum can be used to focus the delivery of liquid nitrogen, resulting in a deeper freeze and finer control (Fig. 37-4).

Basal cell carcinomas (BCCs) can effectively be treated with cryosurgery. Freezing to reach a target temperature of approximately -50° C, as measured by a thermocouple, is appropriate for management of these tumors. This translates to a thaw time of approximately 60 seconds, with a freeze margin of approximately 5 mm (Fig. 37-5). It is important to recognize that the pain associated with such treatment requires local anesthesia. In a review of published data, Kokoszka et al found a recurrence rate of less than 10% for

Fig. 37-4 A, Cryoplate with multiple sized openings. B, Disposable otoscope speculum with tip cut off.

Fig. 37-5 Cryosurgery. A, Basal cell carcinoma on the posterior helix. B, Cryosurgery to neoplasm. C, 1 week later with necrosis and sloughing of treatment area. D, Final result several months later.

primary small, noninfiltrating (i.e. superficial and nodular) BCC treated with cryosurgery. Some have suggested that initially treating the tumor with curettage, following this with cryosurgery with a 1-min thaw time, can lead to cure rates consistent with curettage and electrodessication.

Side effects of cryosurgery are similar to other ablative procedures (i.e. curettage and electrodessication), and include blistering, crusting, pain, a 3- to 4-week healing period, and scaring. As melanocytes are more susceptible to thermal damage than keratinocytes, hypopigmentation can often be seen, especially in individuals with darker skin tones. While pigment alterations are more frequently seen with longer freeze-thaw times, these changes can be observed even with very brief treatment cycles. A self-limited hyperplastic or pseudoepitheliomatous healing response may occur approximately 2 to 4 weeks after freezing. Nerve injury can occur during cryosurgery. Anatomic locations with superficial nerves (e.g. lateral aspects of the fingers, ulnar groove of the elbow, pre- and post-auricular skin) are especially susceptible to this complication. Techniques to limit this risk include tenting the skin up and away from the nerve, ballooning the skin with lidocaine, or sliding the skin back and forth over the underlying fascia during treatment. Alopecia can occur when treating hair-bearing areas. Both atrophic and hypertrophic scars can be seen following cryosurgery.

CURETTAGE

The curette has long been a standard tool in the dermatologist's surgical armamentarium. This round, semi-sharp knile is available in sizes from 0.5 to 10 mm, allowing for the removal of a variety of lesions. Since it is not as sharp as a scalpel, the curette does not easily cut through normal epidermis and will not enter the dermis. Therefore, it is best suited for use on soft or friable lesions, such as warts, seborrheic and actinic keratoses, the papules of molluscum contagiosum, or selected basal and squamous cell carcinomas. The proper selection of lesion, its location, and the size of the curette, combined with the surgeon's technique, all play a role in both the therapeutic and cosmetic outcome.

The skin should be stabilized with the nondominant hand while the curette is held like a pencil. Curettage should be performed in a centripetal manner (from the outside in) to avoid stripping sun-damaged skin and creating a larger wound. To ensure complete excision, curettage should be performed in multiple directions to produce symmetrical wound margins. A large curette is used for initial debulking, followed by a smaller curette to remove any residual foci or extensions. Curettage is complete when the "gritty," firm sensation of normal dermis is felt and slight punctuate dermal bleeding occurs.

Curettage, combined with electrodessication (C&E), is widely used for the treatment of BCC and squamous cell carcinomas (SCC) (Fig. 37-6). Silverman et al reviewed the cure rates of primary BCC treated with C&E over a 27-year period at New York University. This experience stratified low-, middle-, and high-risk anatomic locations and the risk of recurrence following C&E of primary BCC. Low-risk anatomic sites (neck, trunk, and four extremities) had a 5-year recurrence rate of 3.3%. Middle-risk sites (scalp, forehead, pre- and post-auricular, and malar areas) had an overall recurrence rate of 12.9%, but this was reduced to 5% when limited to noninfiltrative carcinomas of less than 1 cm. High-risk sites (nose, paranasal, nasal-labial groove, ear, chin, mandibular, and peri-oral and -ocular areas) had an overall recurrence rate of 17.5%, but a more acceptable 5% recurrence rate was achieved when treatment was limited to lesions of less than 6 mm.

In addition to size and anatomic location, the histologic subtype is an important factor in the effectiveness of C&E. Infiltrative and micronodular carcinomas are not appropriate for C&E, while it is a therapeutic option in superficial and nodular subtypes. SCC in situ may be appropriately treated with C&E, while invasive SCC would not be amenable to this modality.

There is little agreement regarding the requisite number of cycles of C&E. Indeed, treating all lesions identically with a particular number of cycles may lead to overtreatment of some lesions and undertreatment of others. In general, accepted therapy employs three cycles to treat most malignant lesions. However, smaller superficial malignancies may be treated with fewer cycles; the rational is to improve cosmetic outcome, while still achieving acceptable cure rates. Nonetheless, the success of C&E relies on the operator's ability to identify by feel and appearance the tissue to be ablated. Kopf et al demonstrated that physician experience is an important factor in the cure rate of carcinomas treated by C&E, with residents having a higher rate of recurrence as compared to attendings. Finally, C&E should be replaced by excision if curettage extends into subcutaneous tissue. As such, lesions that have been biopsied using a punch which has extended into the subcutaneous fat, may be less amenable to C&E.

ELECTROSURGERY

Electrosurgery comprises a variety of surgical techniques, applications, and apparatus. In general, the tissue effect is created by heat delivered to or generated in the tissue as a result of an electrical current. Some form of electrosurgery is routinely used by dermatologists for destruction, hemostasis, excisions, and cosmetic procedures. An understanding of the different modalities and their applications can improve the surgical outcome (Fig. 37-7).

Electrocautery

Electrocautery is most often performed today with batterypowered, hand-held, disposable units. Direct current is passed through a metal treatment tip. Resistance to the flow of current causes beat to be generated, which can be adjusted by the intensity of the current. Hemostasis is achieved by direct heating of the tissue; no electrical current passes through the patient. As such, this device may be considered in patients with implantable devices sensitive to electric current.

Electrodesiccation, **Electrofulguration**

Electrodesiccation (from the Greek *dessicate*, meaning "dry") and electrofulguration (from the Greek *fulgur*, meaning "lightning") represent the most commonly employed uses of electrosurgery in dermatology. In electrodesiccation, the electrode tip is in contact with the tissue; with electrofulguration, a 1- to 2-mm separation between the tip and the tissue produces a spark. Electrodessication causes a deeper wound, while electrofulguration is more superficial.

A highly damped (decreasing amplitude) waveform is produced, of high voltage and low amperage produced by a spark-gap generator. As this is a monoterminal current, a grounding electrode on the patient is not required. Electrodesiccation/fulguration produces superficial destruction as the carbonization on the treated surface limits damage to deeper tissue.

This type of electrosurgery has numerous applications in the daily practice of dermatology. Superficial, small dermal tumors, such as syringomas or seborrheic keratoses, may be treated with electrodesiccation. Insertion of the fine epilating needle into the tumor is followed by the application of low current until a surface bubbling occurs. The small amount of char is then removed with a curette, resulting in a smooth surface appearance. In addition, skin tags, warts, and fine telangiectases may all be effectively removed by this technique. Electrodesiccation or fulguration is commonly employed in treatment of many BCCs and SCCs (see above section on curettage). It is also useful in excisional surgery to obtain hemostasis. The field must be dry, since the destruction by this current is superficial and will not be transmitted through blood.

Electrocoagulation

Electrocoagulation employs moderately damped current with a lower voltage and higher amperage. The patient is incorporated into biterminal circuit. Electrocoagulation causes greater tissue damage and deeper penetration than electrodessication or electrofulguration.

Electrosection

Electrosection employs an undamped, low-voltage, highamperage current in a biterminal fashion. This technique has the advantage of cutting with simultaneous hemostasis. As such, it is used for bloodless excisional surgery of protuberant masses and growths, such as rhinophyma. There is vaporization of tissue with little heat spread. Care must be taken with this technique, as maintaining an appropriate depth can be difficult given the ease with which the device can cut through skin. When properly used, fine surgical excisions can be produced with minimal trauma to surrounding tissue and excellent hemostasis. Various handpiece attachments, including scalpels, needles, wire loops, and balls, can further adapt the instrument to the specific procedure.

Care must be taken when using electrosurgery in a patient with a pacemaker or implantable cardioverter-defibrillator, especially if the procedure is performed within a few centimeters of the device. Although modern devices are better shielded and less likely to respond to external electrical interference, it is always prudent to deliver current in short bursts of less than 5 s. Additionally, consideration should be given to the use of electrocautery (heat only, no electrical transmission) or a bipolar device (current transmitted between two tips) when treating these patients. Yu et al recently reviewed the use of electrosurgery in patients with cardiac devices and offer a complete discussion of the subject.

EXCISIONAL TECHNIQUE

The fusiform or elliptical excision is the workhorse procedure used to treat invasive skin cancers as well as benign skin lesions needing extirpation (Fig. 37-8). The basic principle of the fusiform ellipse is excision of a specimen oriented with its longest axis along skin tension lines and its width not exceeding one-third of its length. The ellipse can be curved in a crescentic or "lazy-S" pattern to better align the final scar with skin tension lines. If performed with the correct dimensions (usually length-to-width ratio of 3:1) and a 30° angle at each pole, standing cutaneous cones at the two extremes of the excision is generally avoided. Standing cutaneous cones represent excess tissue bunching at the poles of a skin closure and should be "sewn out" or excised by triangulation or M-plasty if needed. Undermining, using sharp or blunt dissection of the skin from underlying subcutaneous tissue, reduces wound tension and creates wound edge eversion.

SKIN FLAPS AND GRAFTS

Choosing whether to close a wound by linear closure, local skin flap, skin graft, or allow it to heal by second intention can be complex. Important considerations include patient concerns, local tissue movement, consideration of adjacent anatomic structural preservation and function, and cosmetic outcome.

Second Intention

Years ago, second intention healing was common and accepted. In the current medical climate, patients desire more cosmetically elegant reconstruction. As there is contraction in wound healing, wounds that are adjacent to a free margin may result in a pull and distortion. This may effect surrounding anatomic structures (i.e. pull on a nasal rim or eyelid). The wounds may heal with hypertrophic or pigmentary changes. However, there are areas and situations where allowing a wound to heal by second intention is appropriate. These include superficial wounds in concave areas (i.e. medial canthus, conchal bowl, and junction between the nose and cheek) or certain clinical situations, such as elderly or frail patients without cosmetic concerns. Wound care is simple and postoperative restrictions are minimized.

Flaps

Local skin flaps are geometric segments of tissue contiguous with a skin defect that are advanced, rotated, or transposed to close a wound. Advantages of flaps include better approximation of skin texture and color, hiding incision lines, redirecting tension vectors, and covering exposed cartilage and bone. Flap survival is based on the preservation of the random blood supply along the pedicle. It is important to consider both the primary movement of the flap (the actual movement of the flap into the defect) and secondary movement (movement of surrounding tissue in reaction to the flap movement) (Fig. 37-9).

An advancement flap moves almost entirely in one linear direction (Fig. 37-10). Variations of this flap are often named by the appearance of the final defect and are frequently termed the O-T, O-L, O-Y, and island pedicle flap (Fig. 37-11). The rotation flap is often used to close large defects when there is insufficient tissue laxity (Fig. 37-12). The flap has the advantage of good survival secondary to the large pedicle and the ability to borrow skin from a great distance. A back cut can be used to reduce pivotal restraint and provide greater tissue movement, but may compromise the vascular pedicle. Variations include O-Z (Fig. 37-13) or dorsal nasal rotation flap (Fig. 37-14). Advancement and rotation flaps are best described as sliding flaps which are pulled into position over the primary defect in either a linear (advancement) or arcuate (rotation) manner. Tension vectors resulting from this pulling action are directed 180° back in advancement flaps or along the arc of rotation in reverse fashion for rotation flaps.

In the case of the transposition flap, the flap in elevated, transposed over intervening tissue, and sutured into the primary defect (Fig. 37-15). The tension vector is directed across the closure of the secondary defect (i.e. the area originally occupied by the flap), and thus is a useful flap to redirect the wound tension. The prototype of this flap is the rhombic flap (Fig. 37-16). Other examples include bilobed flaps, nasolabial/melolabial flaps, banner flap, Z-plasty, and Webster's 30° flap (Fig. 37-17).

Choice of a particular type of flap must take multiple factors into consideration, including location of defect, availability of tissue movement, surrounding structures, effects of tissue movement, and blood supply. Full discussion of flaps is available in multiple referenced texts and decisions regarding their use requires appropriate and extensive training.

Skin Grafts

Skin grafts are employed when primary closure or flap closure is not an available option. By definition, a graft is completely excised from the donor site and is devitalized (i.e. no intrinsic blood supply). Success is predicated on the reattachment of vascular supply to the graft from the defect. Grafts offer the advantage of less local scaring as compared to local flaps. However, the lack of color and texture match due to the remote donor location of grafts is a potential disadvantage.

Grafts can be categorized as full, split, and composite. Choice for using each of these depends on the depth of the defect, vascular supply, and concern of recurrence of skin cancer. Full-thickness skin grafts have a full dermis and are the most common grafts used in dermatologic surgery. The graft is defatted, trimmed to fit the defect, anchored in place with peripheral and basting sutures, and secured with a tie-over dressing (Fig. 37-18).

Split thickness skin grafts have only a partial dermis and are useful for covering large areas or for improved surveillance in tumors with a high risk of recurrence (Fig. 37-19 and 37-20). In comparison to full-thickness skin grafts, they have a higher rate of survival, shorter healing time, do not require repair of the donor site, and are a good choice for poorly

Fig. 37-12 Rotation flap. A, Rotation flap designed. Redundant skin from cheek is borrowed to repair defect. B, Final wound closure.

Fig. 37-13 O-Z rotation flap. A, Flap designed. B, Final wound closure.

vascularized areas. However, they have a higher degree of contraction and provide a poorer cosmetic match

Composite grafts most commonly consist of skin and underlying structure (i.e. cartilage) and are predominately used to repair such wounds as full-thickness alar rim defects. These grafts have an increased nutrient requirement and thus are more likely to fail. Free cartilage grafts can be used for reconstruction of the ear, and nasal ala or tip.

MOHS MICROGRAPHIC SURGERY

Frederic Mohs initially developed this technique at the University of Wisconsin in the 1930s. The original technique used zinc chloride paste to fix tissue in vivo followed by surgical excision. Drs Theodore Tromovitch and Samuel Stegman modified this in the 1970s to a fresh-frozen tissue variant which continues to be used today. While the basic surgical principles in Mohs micrographic surgery are similar to those used in standard excision, there are unique challenges encountered with Mohs surgery. A complete understanding of pathology, anatomy, cutaneous oncology, advanced surgical reconstruction, and management of surgical complications are critical to a successful patient outcome. Any dermatologist performing Mohs micrographic surgery should be well trained in this technique and all the surrounding challenges of surgical and post-operative care.

Mohs micrographic surgical excision is a tissue-sparing technique that employs frozen-section control of 100% of the surgical margin. This evaluation of the entire surgical margin using horizontal sections (not vertical as used in standard sectioning), combined with precise mapping, allows for the highest cure rate of cutaneous neoplasms (Fig. 37-21). In addition, the sparing of normal adjacent tissue can improve cosmesis and decrease the risk of functional defects in a sensitive anatomic location. Any tumor that has a contiguous growth pattern would be a candidate for Mohs micrographic surgical excision.

There are multiple indications for Mohs micrographic surgical excision (Box 37-4, Fig. 37-22). Mohs surgery provides cure rates of 99% for primary and 95% for recurrent BCCs. SCCs on the skin and lip treated with Mohs surgery have a 5-year recurrence rate of 3.1% (vs 10.9% for other modalities). SCC on the ear treated with Mohs surgery had a 5-year recurrence rate of 5.3% (vs18.7% for other

Fig. 37-14 Dorsal nasal rotation flap. A, Mohs defect. B, Final wound closure. C, 3 weeks post-op.

modalities). Locally recurrent SCC also had a reduced recurrence rate when treated with Mohs surgery as compared to other modalities (10% vs 23.3%). Other tumors which can be successfully treated by Mohs surgery include dermatofibrosarcoma protuberans, atypical fibroxanthoma, and microcystic adenexal carcinoma. Mohs micrographic surgical excision of melanoma continues to be debated. Bricca et al demonstrated comparable 5-year local recurrence rates, metastasis rates, and disease-specific survival rates in head and neck melanomas treated with Mohs micrographic surgery as compared to standard excision.

PHOTODYNAMIC THERAPY

Photodynamic therapy (PDT) involves the activation of a photosensitizer by visible light in the presence of oxygen, resulting in the activation of reactive oxygen species, which selectively destroy the target tissue.

The first requirement for PDT is delivery of either a systemic or topical photosensitizing drug. Systemic photo-

Fig. 37-16 Transposition flap. *A*, Rhombic flap designed and incised. *B*, Flap is moved into position. *C*, Final wound closure. (Photographs courtesy of Christopher B Zachary, MD)

sensitizing molecules are large, lipophilic molecules that require intravenous administration to reach the target site. One of the major disadvantages of these systemic drugs is the prolonged period of phototoxicity. Examples include porfimir sodium and hematoporphyrin derivative. The benzoporphyrin derivative monoacid ring A (verteporfin) has a shorter period of photosensitivity (<72 h) compared to other systemic agents.

Topical agents offer the advantage of limiting photosensitivity to only the application site and have become widely used in dermatology. Delta-aminolevulinic acid (ALA) is applied and left on the skin for a sufficient period of time to allow for accumulation within the target cells. ALA is subsequently converted to the photosensitizer protoporphyrin IX (PpIX), which can then be stimulated through the controlled use of a light source. Tumor cells are thought to be selectively targeted by increased penetration of ALA

Fig. 37-21 A diagram of the Mohs Surgery process.

Box 37-4 Indications for Mohs surgery

- Recurrent or incompletely excised nonmelanoma skin cancer
- Tumors with aggressive histologic subtypes (i.e. infiltrative, morpheaform, micronodular, perivascular or perineural involvement)
- Tumors with poorly defined clinical margins
- High-rlsk location >0.4 cm (H-zone of the face, eyes, ears, nose)
- Large tumors (>1.0 cm on face; >2.0 cm on trunk or extremities)
- Cosmetically and functionally important areas, including genital, anal, perianal, hand, foot, and nail units
- Tumors arising in immunosuppressed patients
- Tumors arising in previously irradiated skin or scar
- Genetic conditions with increased risk of neoplasms (i.e. basal cell nevus syndrome or xeroderma pigmentosa)

through the abnormal epidermis overlying the tumor cells. In addition, the iron-deficient, rapidly proliferating tumor cells have an increased production of PpIX as compared to normal epidermal cells, resulting in selective photosensitivity and damage to the target site. Methyl aminolevulinate (mALA) is also used as a topical photosensitizing agent. Gentle scraping or curettage prior to application is performed to increase penetration. Once absorbed, mALA is converted to ALA within the target tissue.

The second requirement of PDT is an appropriate light source to activate the photosensitizer. The light source must match the absorption peak of the photosensitizer. Lasers,

Fig. 37-22 H-zone of the face.

intense pulsed light devices, and an incoherent light source can be used. Red light uses the 630-nm peak of PpIX as its target, and has a deeper penetration, which is appropriate for dermal processes. Blue light targets the 417-nm peak and has a more superficial penetration, making it an appropriate choice for the treatment of epidermal lesions like actinic keratoses.

Following absorption of light, the photosensitizer is converted from a stable ground state to a short-lived excited triplet state, which may then be converted to a longer-lived excited triplet state. The excited triplet state electrons interact with tissue oxygen, creating singlet oxygen. Singlet oxygen causes oxidative damage to cellular membranes (i.e. mitochondria and other cellular organelles) and direct cell death, the key mechanism of action in topical PDT. This entire process occurs in the course of microseconds. In comparison, PDT using systemic photosensitizers predominantly causes destruction of target sites via vascular injury that leads to tissue ischemia.

Actinic Keratosis

Numerous studies have demonstrated the efficacy of PDT in the treatment of actinic keratoses. Acral lesions do not appear to respond as well to PDT as facial lesions. Several studies have demonstrated that a topical ALA applied for 14 to 18 h, followed by activation with a variety of light sources is an effective treatment of actinic keratoses on the scalp and face. Touma et al showed that short incubation periods of 1 to 3 h with ALA may be an effective protocol for the treatment of actinic keratoses, vastly improving the convenience of this therapy. Kurwa et al demonstrated similar reduction in dorsal actinic keratoses with a single ALA PDT and red light treatment as compared to a 3-week course of twice a day topical 5-fluorouracil (5-FU) (70% vs 73% reduction).

mALA may offer several advantages over ALA, including improved skin penetration due to its increased lipophilic quality, greater selectivity for neoplastic cells, and possibly less pain and discomfort associated with treatment. However, there are no comparative studies for ALA and mALA PDT in the treatment of actinic keratosis. Pariser et al showed the mALA applied for 3 h followed by noncoherent red light resulted in an almost 90% response rate in the treatment of actinic keratosis. Szeimies et al demonstrated a similar response rate for mALA PDT compared to cryotherapy, although PDT gave better cosmetic results and had a higher degree of patient satisfaction. Given the absence of a stratum corneum on the lips and the increased penetration of topical ALA, PDT has effectively been used for the treatment of actinic cheilitis. This may be an option in patients with recalcitrant disease. Alexiades-Armenakas et al demonstrated about a 70% clearance with an excellent cosmetic result using ALA PDT activated by the long-pulsed dye laser in patients with refractory actinic cheilitis. Stender and Wolf reported successful treatment in a small group of patients who had not previously responded to conventional therapy.

Basal Cell Carcinoma

Studies suggest that topical PDT for the treatment of BCC can have initial clearing and excellent cosmetic result, but often have a higher recurrence rate with long-term followup. Rhodes et al compared topical mALA PDT and excision surgery for the treatment of nodular BCC. Seventy-five percent of cancers treated with PDT cleared with one cycle, while the remaining 25% required a second cycle of treatment. Complete response rates were similar at 3 months (91% for PDT vs 98% for excision) and a better cosmetic result was seen with PDT. However, PDT resulted in a higher rate of recurrence at 2-year follow-up. Additionally, more frequent visits and treatments were required with PDT, raising the question of practicality for this modality.

Haller et al demonstrated effective treatment of superficial BCC with two sessions of ALA PDT using red light spaced 1 week apart, and had a 96% clearance rate at over 2-year follow-up. Morton et al used the same double treatment methods for the treatment of large and/or multiple BCC and reported an 85% clearance rate at a mean 34-month follow-up. Soler et al conducted a follow-up study of superficial and nodular BCCs that had responded completely to mALA PDT alone and with prior curettage. Of 350 treated BCCs followed for a mean period of 35 months, the overall cure rate was 79%.

Lui et al demonstrated that systemic PDT using verteporfin could effectively treat patients with multiple nonmelanoma skin cancers. Histopathologic clearance rates up to 93% were seen. At 2-year follow-up, a clinical complete response of up to 95% was seen in patients.

Squamous Cell Carcinoma in Situ

SCC in situ is quite responsive to PDT. In a randomized study, Salim et al compared topical ALA PDT with 5-FU. At 1-year follow up, PDT achieved an 82% clinical response rate compared to 48% with 5-FU. Morton et al demonstrated a 78% clearance rate of large patches of Bowen's disease (diameter >20 mm) with ALA PDT. Additionally, ALA PDT results in a clearance rate of 89% for patients with multiple patches of Bowen's disease. Varma et al showed initial clearing in 88% of Bowen's disease lesions using ALA PDT. However, at 12-month follow-up, complete response decreased to 69%.

There are few reports of the use of PDT for invasive cutaneous SCC. Given the limited success in treating these tumors, PDT is not recommended as standard therapy for invasive SCC.

RADIATION THERAPY FOR SKIN CANCER

Radiation therapy (XRT) has a long history of use for treatment of both benign and malignant skin conditions. Ionizing radiation in dermatologic therapy of benign conditions has decreased markedly owing to highly effective medical therapies, balanced against the potential genetic and somatic hazards of radiation. However, XRT for malignant skin conditions continues to remain an important primary

Alexiades-Armenakas MR, Geronemus RG: Laser-mediated photodynamic therapy of actinic cheilitis. J Drugs Dermatol 2004;3:548.

and adjuvant therapeutic modality. When used in the proper clinical situation, XRT can provide effective treatment while sparing normal tissue and eliminating the need for surgical reconstruction.

XRT is an appropriate primary treatment for skin cancer in patients who refuse surgery or are poor surgical candidates secondary to numerous medical comorbidities. In contrast, patients who are relatively young should not be candidates for XRT due to the increased risk of developing additional primary tumors within the radiation field and the long-term cosmetic complications associated with this therapy. Tumors located on the eyelids, nose, ears, and lips do well with XRT, while lesions on the extremities are better treated by surgical excision. Treatment of primary BCC with XRT can produce cure rates of greater than 90%, while primary SCC may have a slightly higher recurrence rate. It is important to stress that Mohs micrographic surgical excision of primary tumors can achieve cure rates of 97% to 99%, often with excellent long-term cosmetic outcomes.

XRT may also be considered if margins show microscopic evidence of residual tumor following surgical excision. Recurrent BCC and SCC that had been treated previously by nonradiologic methods can be treated by radiation, although not with the same success as primary tumors. Caccialanza et al demonstrated an 84% 5-year cure rate for recurrent BCC and SCC in a group of nearly 250 recurrent tumors, with almost all having an acceptable cosmetic result. Locke et al showed that primary tumors treated with radiation had a response rate of 93% as compared to an 80% control rate for recurrent neoplasms. Mohs micrographic surgical excision of recurrent nonmelanoma skin cancer produces higher cure rates (95%).

In a prospective, randomized trial, Avril et al demonstrated that primary facial BCCs treated by surgical excision (almost all with frozen tissue examination) had a 4-year recurrence rate of 0.7%, as compared to 7.5% with XRT. In addition, a cosmetic result of "good or better" was achieved in 87% of surgically treated patients, as compared to 69% with XRT. Several studies indicate that recurrence of nonmelanoma skin cancer after primary XRT may be more aggressive and invasive than recurrence after primary surgical treatment. Smith et al treated BCCs recurrent following radiotherapy and subsequently excised by Mohs micrographic surgery to a control group of BCC recurrent following other treatment modalities and similarly excised. They demonstrated that BCCs that recurred following primary radiation therapy had deeper subcutaneous tissue invasion and larger percentage increase between clinical preoperative tumor area and final postoperative defect area, as compared to recurrent tumors that had initially been treated with other modalities.

XRT offers a valuable adjunctive treatment option for particularly aggressive perineural SCC and BCC. Detection of single-cell tumor spread may be particularly difficult following excisional surgery. In addition, perineural carcinoma may spread more rapidly along nerve sheaths than by contiguous growth. Given the increased risk of metastasis and recurrence in this group of tumors, adjuvant XRT should be considered as prophylactic treatment following surgical excision.

CHAPTER

38 Laser Surgery and Cosmetic Dermatology

CUTANEOUS LASER SURGERY

Almost no area of dermatology is changing as rapidly as that of cutaneous laser surgery. Development of new lasers, as well as improvements in existing lasers, continues to advance the field. As a result of this progress, laser surgery has become an effective therapeutic modality for a variety of dermatologic conditions.

Laser is an acronym for light amplification by stimulated emission of radiation. The first laser, a ruby laser, was operated in 1960 by Theodore Maiman. Medical applications were quickly recognized, and Leon Goldman pioneered their dermatologic use. While technology has advanced through the years, several distinctive characteristics have remained in all lasers. As compared to other light sources, laser light is defined as monochromatic, collimated (i.e. nondivergent) and in phase (i.e. peaks and troughs of the light are all aligned) (Fig. 38-1). The wavelength is determined by the active medium of each particular laser. Active medium can consist of a gas (i.e. argon or CO_2), liquid (i.e. dye), or a solid (i.e. ruby or yttrium-aluminum-garnet crystal) (Table 38-1; Fig. 38-2).

Light can interact with incident targets in one of three ways: transmitted, reflected, or absorbed (Fig. 38-3). In the first two cases, the light has no effect. When absorbed, the light energy is transformed into heat. In most cases of laser therapy, it is the heat generated by absorption that produces the desired effect. One notable exception is photodynamic therapy (see Chapter 37).

Lasers in cutaneous surgery are selected by matching their particular wavelength with the absorption spectrum of a

Fig. 38-1 Laser characteristics.

desired target. The goal is to deliver a wavelength that is specifically absorbed by the chromophore (the most common in skin being water, hemoglobin, and melanin), inducing heat build up and destruction of that target. In an ideal situation, that wavelength would have little or no absorption by surrounding structures. By controlling exposure times and energy delivered (fluence), the amount of heat build up can be confined to the desired target with minimal or no damage to surrounding structures (a property defined as thermal relaxation time). This concept of selective photothermolysis was originally promoted by Parish and Anderson and is the basis for all laser-tissue interactions.

The laser is a technologically advanced instrument. However, as with any surgery, side effects can occur. Hypertrophic scarring and pigmentary changes are the most common, but infection, pain, and lack of efficacy are possible. Appropriate instruction and supervision in the use of lasers must be obtained by dermatologic surgeons in order to ensure optimum safety and surgical outcome.

Argon Laser

The argon laser was one of the first lasers used for the treatment of vascular and pigmented lesions. Because its wavelengths (488 and 514 nm) do not precisely correspond to absorption peaks of either hemoglobin or melanin, and also because of its continuous-wave nature, thermal damage to surrounding tissue may be significant. Other lasers have been developed which have largely replaced the argon laser, due to their greater efficacy and improved side effect profile (i.e. less scarring and dyspigmentation). In addition, the newer technology has resulted in smaller and more reliable laser devices.

Copper Vapor/Copper Bromide Laser

These devices with wavelengths of 578 and 511 nm were effective in treating vascular and pigmented lesions, respectively. Due to technical concerns regarding size of the device, reliability, and cost of maintenance, they have been replaced by several of the lasers discussed below.

Pulsed Dye Laser

The pulsed dye laser (PDL) was the first laser developed to specifically take advantage of the theory of selective photothermolyis. The laser medium is a rhodamine dye which initially was developed to deliver a wavelength of 577 nm, coinciding with a specific hemoglobin absorption peak. Older lasers used a wavelength of 585 nm, but for various technical and clinical reasons, the wavelength has evolved in the current generation of PDL to be 595 nm. Initial pulse durations were in the order of 500 μ s/pulse. This was based on calculations that the target, hemoglobin, had a thermal
Laser	Wavelength (nm)	Color	Applications
Argon	488-514	Blue-green	Vascular lesions
Intense pulsed light (IPL)	515-1200	Green-red and infrared	Vascular lesions, pigmented lesions, epilation, photodamage
Potassium titanyl phosphate (KTP)	532	Grean	Vascular lesions, pigmented lesions
Q-switched Nd:YAG (frequency doubled)	532	Green	Vascular lesions, pigmented lesions, tattoo-red
Copper vapor	578/511	Yellow-green	Vascular lesions, pigmented lesions
Flashlamp pumped pulsed dye (PDL)	585-600	Yellow	Vascular lesions
Q-switched ruby	694	Red	Deep and superficial pigmented lesions; tattoo-black, blue, green
Long pulsed ruby	694	Rød	Epllation
Q-switched alexandrite	755	Infrared	Tattoo-blue, black, green
Long pulsed alexandrite	755	Infrared	Epilation
Diode	810	Infrared	Epilation
Q-switched Nd:YAG	1064	Infrared	Deep and superficial dermal pigment; tattoo-black, blue
Long pulsed Nd:YAG	1064	Infrared	Epilation, vascular lesion
Er:YAG	2940	Infrared	Superficial skin resurfacing and destruction of superficial growths
Carbon dloxide	10,600	Infrared	Skin resurfacing and destruction of warts, keloids, superficial cancers, and benign growth

Fig. 38-2 Laser penetration.

relaxation time of 1 ms or less. Newer configurations of the laser allow for pulse durations from 0.45 to 40 ms, based on newer understandings of thermal relaxation times in the context of the size of the target (e.g. capillaries vs larger vessels) and clinical effects (purpuric vs nonpurpuric treatments). By using longer pulse durations, more gentle and uniform heating results in reduced or absent post-treatment purpura (more acceptable to patients) than the earlier PDL configurations, while still maintaining clinical efficacy. The PDL is an extremely useful instrument for the treatment of vascular lesions. These lasers have traditionally been used for port-wine stains, telangiectasias, erythematotelangiectatic rosacea, and hemangiomas. The risk of scarring and pigment change is very slight, and infants as young as a few weeks old can be treated. The newer long pulsed and longer wavelength lasers allow for treatment of larger and deeper vessels. By associating these treatments with surface cooling devices, the epidermis car be protected, which

Fig. 38-3 Laser interaction with skin.

allows for delivering greater energy in a safer and less painful manner.

PDL has been effectively used for the treatment of warts, producing similar cure rates as traditional therapy. Several reports address the use of PDL for hypertrophic scars. Manuskiatti and Fitzpatrick demonstrated that PDL, intralesional corticosteroid, and 5-fluorouracil (5-FU) produced similar beneficial effects in the treatment of hypertrophic sternotomy scars. The mechanism of action in both incidences is not clear. It may be related to injury to vessels supporting the lesions or simply heat-related injury. As with other treatment modalities for these two conditions, results are variable.

KTP (Potassium Titanyl Phosphate) Laser

The KTP laser produces a visible green beam of 532 nm. Since there is significant hemoglobin and melanin absorption of this wavelength, KTP can be used to treat both vascular

and superficial pigmented lesions. The KTP laser is actually an Nd:YAG (see below) laser which emits a wavelength of 1064 nm. The beam is passed through a crystal of KTP which reduces the wavelength by 50%, producing the 532 nm wavelength. The laser can be Q-switched (quality switched), emitting a beam in the range of 10 to 50 ns, and is useful for treating superficial pigment lesions and red tattoos. Alternatively, it can be delivered in a quasi-continuous mode (pulse durations as high as 50 ms), which can be used for the treatment of both vascular and pigmented lesions. In the longer continuous mode, they need to be delivered in a very narrow beam or in conjunction with a cooling device in order to minimize surface injury. Since individual vessels must be traced out using a narrow beam diameter, there are limitations to the number of vessels treated in any given session. In addition, the 532 nm wavelength has a limited depth of penetration, making it an excellent choice for the treatment of fine facial vessels.

Many KTP lasers employ a cooling tip to limit surface epidermal damage. This permits delivery of wide beam diameters and pulse durations, allowing for deeper penetration and more rapid treatment of a larger area. Unlike PDLs, KTP lasers do not produce postoperative purpura. KTP lasers can be quite compact, allowing for easy transport between various locations. With few moving parts they are relatively maintenance free.

These lasers are best suited for treatment of individual telangiectasias of the face, cherry angiomas, small spider angiomas, and small pigmented lesions, such as lentigos, ephileds, and thin seborrheic keratosis, including dermatosis papulosa nigra.

Q-Switched Ruby Laser

The Q-switched ruby laser emits a red 694 nm beam. The first laser developed was a ruby laser; however, this long pulsed laser was shown to have little application in deimatology due to excessive cutaneous injury. The development of Q-switching allowed for production of extremely high energies and short nanosecond pulse durations. This technology resulted in damage to the selected target while minimizing injury to surrounding tissue. The Q-switched ruby laser can effectively treat tattoos with black, blue, and green pigment. In addition, the ruby laser is successful in treating macular pigmented lesions, such as lentigines, ephelids, and nevus of Ota (Figs 38-4 and 38-5). For unknown reasons, other lesions such as café-au-lait macules, Becker nevus, and postinflammatory pigment alteration can respond, but the success is unpredictable. Treatment of melasma is very disappointing, with some patients improving, some showing no response, and others with temporary worsening. The main immediate side effects include crusting, which takes approximately 7 to 10 days to resolve. Longer-term side effects can include both hypo- and hyper-pigmentation.

Q-Switched Alexandrite Laser

This laser uses the semiprecious stone, alexandrite, as the active medium. In addition to the Q-switched ruby and Q-switched Nd:YAG lasers, the Q-switched alexandrite laser effectively treats tattoos. The long wavelength (755 nm) penetrates deeply into the dermis with absorption by blue, black, and green tattoo pigment. These lasers show a similar therapeutic profile to the Q-switched ruby laser. One advant-

Fig. 38-4 Nevus of Ota A, prior to treatment and B, after treatment with a Q-switched ruby laser.

Fig. 38-5 Peutz-Jeghers syndrome A, prior to treatment and B, after treatment with a Q-switched ruby laser.

age, however, is the ability to deliver the alexandrite laser at 10 pulses/s, allowing for more rapid therapy compared with the single pulse/s delivery with the suby laser. Disadvantages include a smaller beam diameter and less power.

Neodymium:Yttrium-Aluminum-Garnet Laser

The neodymium:yttrium-aluminum-garnet (Nd:YAG) laser can be used in three modes: continuous wave, Q-switched, and frequency doubled (KTP, see above). Both continuous and Q-switched modes emit an invisible near-infrared beam (1064 nm). As compared to shorter wavelength energies, the Nd:YAG laser is poorly absorbed by hemoglobin and melanin. Therefore, much higher fluences are required to treat lesions containing these chromophores. Because of the longer wavelength, the Nd:YAG laser penetrates much deeper and therefore is useful in treating more deeply seated or thicker lesions compared to shorter wavelength lasers.

In the Q-switched mode, it is highly effective for black and blue tattoos. In its frequency doubled mode, the green 532 nm beam, it treats red tattoos (Fig. 38-6). The Q-switched Nd: YAG laser can also be used to treat nevus of Ota, and in the frequency doubled mode, superficially pigmented lesions (i.e. vertigos, upholds, CALM).

The continuous or long pulsed mode extends the applications for the Nd:YAG laser. By extending the pulse duration, this laser can safely be used for hair removal in darkly pigmented patients (see below). In addition, as hemoglobin has a small peak at 1064 nm, the longer pulsed Nd:YAG laser has been used for vascular lesions, especially larger and deeper vessels. Hemangiomas, vascular malformations such as port-wine stains, and deeper larger caliber vessels have all been treated with this technology. Groot et al reviewed an algorithm for use of the long pulsed Nd:YAG laser for the effective treatment of vascular lesions of various type, size, and depth.

Intense Pulsed Light

The intense pulsed light (IPL) is a device that uses a flashlamp which emits a noncoherent broad spectrum of light (from 400->1200 nm) at various pulse durations and

Fig. 38-6 Tattoo A, prior to treatment and B, after eight treatments with a Q-switched 532- and 1064-nm laser.

intervals. By employing filters to eliminate the lower wavelengths, light from 560 nm and above can be used to treat various cutaneous conditions. This technology has the advantage of treating more than one specific chromophore at a time.

IPL has been used for the rejuvenation of photoaged skin. Weiss et al demonstrated significant improvement in telangiectasias, pigment, and skin texture of the face, neck, and chest with IPL. IPL has been combined with topical aminolevulinic acid for photodynamic rejuvenation. By using IPL as the activating light source, patients benefit from the treatment of actinic keratoses as part of photorejuvenation. IPL has also been effectively used for hair removal (see below).

Laser Hair Removal

Laser hair removal is widely used for the permanent reduction of hair and this is one of the most popular laser procedures performed. Most lasers for hair removal target the melanin within the follicle, although some believe that they may work by targeting hemoglobin and damaging the microvasculature of the follicle. White, blond, and grey hairs generally respond poorly. As melanin is the target for these lasers, care must be taken in treating more darkly pigmented patients to avoid epidermal damage. In this patient population, the longer pulsed Nd:YAG laser has allowed safe treatment with fewer complications.

As hair is the target, patients must avoid waxing, electrolysis, or plucking of hairs prior to laser hair removal. Shaving prior to laser treatment is acceptable (and is mandatory immediately prior to treatment to avoid epidermal injury) and will not interfere with efficacy. It appears that only hairs in the anagen growth phase are permanently injured. Therefore, sufficient time must elapse between treatments for hair to regrow and provide an appropriate chromophore for subsequent laser treatment, generally 8 to 12 weeks.

Currently used devices for hair removal include the long pulsed ruby, alexandrite, diode, and Nd:YAG lasers, and the IPL. In addition, these longer pulsed lasers can produce a significant reduction in both hair and papules/pustules in patients with pseudofolliculitis barbae.

Effective laser treatment of white and blond hairs remains a challenge. Early evidence by Sadick et al demonstrated an approximately 50% reduction in the number of blond and white hairs using combined radiofrequency and IPL. Further research is necessary to evaluate the long-term success of this technology.

Ablative Laser Resurfacing

Both CO_2 and erbium: YAG (Er:YAG) lasers are absorbed by water. Since water makes up 72% of the skin, they effectively ablate the skin to varying depths depending on the energy delivered. They can be used therapeutically to treat conditions such as warts, adnexal tumors, and skin cancers. They may also be employed to remove very superficial external layers and resurface the skin for cosmetic enhancement.

Early systems employed a continuous wave mode of emission, which lead to a greater degree of thermal damage and risk of scarring. Newer high energy ultra-pulsed and computerized scanning systems have allowed a greater degree of control with laser ablation, resulting in more predictable outcomes.

Carbon Dioxide Lasers The CO_2 laser emits an invisible infrared beam of 10,600 nm and can be used in continuous-wave or super-pulsed mode. Water nonselectively absorbs laser energy, turning it instantly into steam, and producing ablative and thermal damage. Used in the super-pulsed mode, the laser beam can be delivered in short bursts, allowing thermal destruction of the epidermis and papillary dermis while limiting deeper thermal damage. Delivery in this mode is more uniform and markedly faster when the optomechanical scanner is employed. Super-pulsed CO_2 lasers are extremely useful in the treatment of actinic damage and photoaging. The thermal injury causes conformational changes within the collagen, leading to clinical tightening. As such, ablative laser resurfacing is extremely effective at

Fig. 38-7 Rhinophyma A, prior to treatment and B, immediately following treatment with a Er:YAG laser. C, Final result 3 months later, with marked improvement in shape and appearance.

improving wrinkling, scarring, and skin tone. Side effects include postinflammatory pigmentary changes, scarring and textural changes, and prolonged erythema. In addition, patients must be educated regarding the morbidity of the postoperative course and prolonged recovery associated with ablative resurfacing.

Used in the quasi continuous-wave mode, it is an excellent therapeutic choice for very large plantar and periungual warts, which have failed to respond to routine office modalities. Both a cutting mode and a defocused ablative mode can be used with these systems to effectively excise the visible verrucae and treat any residual human papillomavirus in surrounding skin. The CO₂ laser is also an excellent treatment option for ear lobe keloids but may not be as successful for keloids elsewhere. Other benign lesions amenable to CO_2 laser ablation include xanthelasma, rhinophyma, and syringomas. Various malignant and premalignant lesions also are effectively treated by laser ablation, including actinic chelitis, and superficial basal and squamous cell carcinomas.

Erbium: Yttrium-Aluminum-Garnet Laser The Er: YAG laser emits an invisible near-infrared beam of 2940 nm. resulting in significantly more efficient absorption (16 times) by water, and a more explosive ablative effect, as compared to the CO_2 laser. As such, the ErrYAG laser results in tissue ablation with less surrounding thermal damage. In addition, this wavelength is close to a collagen absorption peak, thus allowing for collagen ablation much more efficiently than the CO_2 . The decreased thermal injury and collagen ablation is an advantage for treatment of scars, photodamaged skin, and rhytids (Fig. 38-7). Some maintain that healing may be slightly faster, with less risk of prolonged erythema and scarring (especially below the jawline). Nonetheless, depth of injury is the primary determinant for prolonged erythema and scarring. The decreased thermal damage can result in poor hemostasis with the Er:YAG laser. To address this limitation, certain systems have a coagulation feature to limit the amount of intraoperative bleeding. In addition, the collagen-tightening effect may not be as pronounced as with the CO₁ laser. However, when similar clinical injuries and depth are achieved, studies have shown that the Er:YAG and CO_2 lasers have comparable photorejuvinating effects, and similar postoperative healing times and complication profiles.

COSMETIC DERMATOLOGY

Dermatologists have been leaders in the field of cosmetic surgery. Many procedures, products, and technologies in cosmetic dermatologic surgery have been advanced and researched by dermatologists. Patients are increasingly turning to dermatologists for the management and treatment of cosmetic issues. As a result, dermatologists must continue to be at the forefront of cosmetic procedures and remain committed to advancing the field through innovation and scientific progress.

Soft-Tissue Augmentation

Soft-tissue augmentation has been gaining popularity in recent years as patients seek cosmetic improvement without undergoing major surgery. There are numerous fillers available to correct soft-tissue contour abnormalities and provide cosmetic enhancement. While they provide numerous advantages over surgical techniques, the temporary nature of most fillers requires repeated treatment to maintain a desired outcome. While some find the temporary nature of these agents to be a problem, any undesired reactions that occur are also temporary. In the last few years, there has been an increase in the number of available agents. In Europe there are as many as 30 different filler choices. In contrast, in the US the FDA has approved very few, although in the past few years several more have become available.

Bovine Collagen

Bovine-derived collagen has been used for over 20 years and is the gold standard against which all filler substances are compared. There are three FDA-approved products for use in soft-tissue augmentation: Zyderm I, Zyderm II, and Zyplast. The source for all three types is a closed herd in the US, and there have been no cases of bovine spongiform encephalopathy associated with these products. All are composed of 95% type I collagen and the remainder type III collagen, suspended in buffered saline and 0.3% lidocaine. Zyderm I consists of 35 mg/mL of collagen, while Zyderm II has a higher concentration of 65 mg/mL of collagen. Zyplast is cross-linked with glutaraldehyde, making it more resistant to proteolytic degradation which provides longer duration. Preexisting bovine collagen hypersensitivity occurs in about 3% of the population. As such, a skin test is required prior to using this product. Additionally, 1% to 2% of patients with a negative skin test will subsequently develop an allergic reaction following treatment. Therefore, many dermatologists recommend a second skin test after an initial negative test. However, patients may develop allergy after multiple treatments. In patients who have previous experience with bovine collagen, but not in the previous 2 years, a single skin

test is recommended. Patients can expect 3 to 5 months of improvement, depending on the location of placement. Dynamic rhytids (i.e. due to muscular activity) may have a shorter duration of correction, as opposed to more static conditions (i.e. acne scars). Zyplast may have a longer duration due to its relative protection from enzymatic degradation. However, it must be placed deeper in the dermis to avoid a beaded surface appearance and is therefore less useful for correction of superficial rhytids. Zyplast placed in the glabellar complex has resulted in vascular occlusion and necrosis. This may be due to the deeper placement required of this product and the associated adverse pressure-related effects on cutaneous vasculature.

Human Collagen

Cosmoderm I and II, and Cosmoplast are FDA-approved bioengineered human collagen derived from neonatal foreskin. Their concentrations correspond to those of Zyderm and Zyplast. The main advantage of these products is that they do not require a pretreatment test for hypersensitivity. They do not have any greater longevity than the bovine-derived products.

Autologous Fat Transplantation

Autologous lipotransfer allows for soft-tissue augmentation without the risk of allergy, rejection, or infectious transmission. Unlike other filler techniques, fat transfer is truly a grafting procedure. As such, its success is predicated on the survival of the transferred adipocytes. Fat is harvested from a choice of donor sites, typically the abdomen, buttock, thigh, or knee. There is no consensus as to the advantages of harvesting with a liposuction cannula, syringe extraction with a large-bore needle, or open surgical method. The fat is then separated from anesthetic fluid and blood, and then injected through a large-bore needle (16- to 18-gauge) into the desired location. Any remaining fat can be frozen for use at a later time with varying claims regarding loss of efficacy. Storage requires a -70° C freezer.

However, the variable rate of graft survival, the recipient site reaction (i.e. bruising, swelling), and the added morbidity of a donor site are limiting factors in patient satisfaction with this technique. In some instances, partial survival results in uneven correction which may require additional treatments. Some argue that multiple, smaller volume injections spaced out over two to three treatments are more effective than single large volume lipotransfer. If the fat survives, it certainly provides the most natural correction. However, local factors such as motor activity and gravitational effects will mitigate against permanent correction. This technique is not useful for the correction of superficial rhytids, and mainly corrects deeper defects such as the nasolabial folds, hypolabium, buccal depression, and deep scars.

Hyaluronic Acid

Hyaluronic acid, a natural polysaccharide, is a component of human connective tissue. A member of the family of glycosaminoglycans, hyaluronic acid is composed of repeating disaccharide units. This molecule has the advantage of being identical across all species. As such, hypersensitivity reactions should not occur and skin testing is not required prior to treatment. However, Friedman et al demonstrated a local hypersensitivity reaction in 1 in every 1400 patients treated, although the incidence has declined with the introduction of a more purified product. Hyaluronic acid avidly binds water and patients may experience redness, swelling, and bruising in the first few days after treatment. Most of the volume is maintained following placement and over correction is not necessary when injecting. Hyaluronic acid products consist of a clear gel and contain no lidocaine. As such, local anesthesia and regional blocks are often used for patient comfort.

There are two types of hyaluronic acid filler substances. Streptococcal derived, which includes Restylane[®], Restylane Fine Line[®], Perlane[®] (the latter two are not yet FDA approved at the time of this publication) and Captique[®]. The other source is the rooster comb, which includes Hylaform[®] and Hylaform Plus[®] gel. There is a difference between these products based on their viscosity, which is determined by the size and concentration of the molecule within each preparation. The denser products are effective for the treatment of deeper contour abnormalities. Hyaluronic acid fillers can produce a more durable aesthetic improvement as compared to collagen, often lasting from 5 to 8 months (Fig. 38-8).

Synthetic Fillers

Microparticles of poly-L-lactic acid (Sculptra) are used as an injectable implant that is FDA approved for correcting facial lipoatrophy in patients with human immunodeficiency virus (HIV). This is a biodegradable, biocompatible, and immuno-logically inert product that does not require skin testing. Polylactic acid has been used as absorbable suture material (i.e. Vicryl). Polylactic acid is absorbed gradually in the skin, inducing a fibroblastic response that leads to collagen formation. Repeat injections can be given at 4-week intervals. Side effects include foreign body granulomas at injection sites, which can occur at a delayed time point. Injections of 5-FU or triamcinolone (10 mg/mL) may be used for the treatment of these papules.

Hydroxyapatite (Radiesse) are fine particles $(30 \ \mu m)$ of material traditionally used to reconstruct bone. Injected into the dermis or subcutaneous tissue, it stimulates a fibrotic reaction which results in correction of soft-tissue depressions and enhancement of hypolabium. Experience with this product is limited and long-term risks and length of time of correction are not well known. Caution must be exercised as any product that requires a fibrotic reaction in order to be effective can result in a hyperraction leading to an untoward result.

Silicon has been used in the past for soft-tissue augmentation by dermatologists. This product was never FDA approved and issues of purity and safety limited its widespread use. In 1994 it was removed from the market by the FDA. Recently, 1000 centistoke liquid silicone (Silikon 1000) has been approved by the FDA for the treatment of retinal detachment. It is currently being used off-label as a permanent filler for HIV-associated facial lipoatrophy, scars, and rhytids. The potential for delayed and severe complications with this permanent filler, as well as legal concerns and restrictions, has limited its use. Adverse reactions associated with silicone injections include granuloma formation and migration of implant, which are compounded by the permanent nature of the product. Many of the past reported complications of silicone injection are the result of either using an impure and nonmedical grade substance or the failure to use a multisession, microdroplet technique. One precaution is that the current FDA-approved product is more concentrated than the older silicone products previously used. Further study is needed to evaluate the long-term salety and efficacy of silicon oil injections for correction of soft-tissue contour deficiencies.

Expanded polytetrafluoroethylene (ePTFE) is a synthetic solid material that is solt and pliable, is not degraded, and has the advantage of being permanent. The material is placed through a small skin incision and positioned in the desired location. Areas commonly treated with this include lip margins or the muscular portion of the vermillion for enhancement, nasolabial folds, and soft-tissue depressions. Some complications associated with ePTFE include extrusion, migration, shrinkage, and hardening.

Other Fillers

Many other filler substances are available outside the US. Artecoll[®] (FDA approved) is a suspension containing 20% polymethylmethacrylate (PMMA) microspheres of 30 to 40 μ m in diameter suspended in 80% bovine collagen for soft-tissue augmentation. The carrier collagen is degraded over several months, leaving the permanent PMMA microspheres, which serve as a framework for connective tissue deposition. Technique is critical to successful outcomes. If injected too deeply, the implant is ineffective, while superficial placement can cause prolonged erythema. Granuloma formation and hypertrophic scarring can occur and have been reported as a delayed reaction. Intralesional triam-

Fig. 38-8 Hyalurinic acid filler. Nasolabial fold A, prior to treatment and B, immediately following placement of hyaluronic acid with marked improvement and reduction of rhytids.

cinolone can be used for treatment of these reactions. Additionally, a patient who developed a delayed foreign body granuloma 6 years after injection with Artecoll[®] was successfully treated with a 24-week course of 600 mg/day of allopurinol.

BOTULINUM TOXIN

The use of botulinum toxin in dermatology has rapidly increased over the years, and at present is the most common cosmetic procedures performed in the US. Produced by *Clostridium botulinum*, there are seven different serotypes of botulinum neurotoxin (BTX): A, B, C1, D, E, F, and G. All these serotypes inhibit the release of acetylcholine from the presynaptic motor neuron, resulting in chemodenervation and paralysis of the treated muscle.

Botulinum toxin type A (Botox Cosmetic[®]; Dysport[®]) is the most commonly used serotype. Its mechanism of action is via the cleavage of the SNAP-25, a presynaptic membrane protein required for fusion of neurotransmitter-containing vesicles. Effect is generally noted 2 to 5 days after treatment with botulinum toxin type A (BTX- A), but can be as long as 2 weeks in some cases. Results can last from 3 to 6 months. For dosing purposes, 1 U of Botox[®] is equivalent to about 3 to 5 U of Dysport[®].

The only other serotype that is commercially available is botulinum toxin type B (Myobloc)[®]. Its mechanism of action is via the cleavage of a vesicle-associated membrane protein (VAMP), also known as synaptobrevin. This serotype has a much more rapid onset of effect as compared to BTX- A. In addition, differences in potency suggest that approximately 100 U of Myobloc are equivalent to 1 U of Botox. Given the efficacy, experience, FDA approval and safety profile of Botox[®], it has emerged as the leading choice of botulinum toxin amongst practitioners. Botox[®] is distributed as a vacuum dried powder in 100-U vials, which is reconstituted with 1.0 to 5.0 mL of saline. Despite package insert recommendations, experience suggests that there is little loss of potency over an extended period of time following reconstitution. The use of preserved saline for reconstitution reduces the burning and pain associated with injection. This is due to the benzyl alcohol in preserved saline which has anesthetic properties.

Botulinum toxin is predominantly used in dermatology for treatment of dynamic rhytids on the upper third of the face. The key for successful treatment is an understanding of the anatomy involved in facial expression, rather than performing the procedure by rote. Having the patient frown, squint, and raise their brows prior to treatment, helps identify the active muscles and serves as a guide for proper placement.

For the treatment of the glabellar brow furrow, approximately 20 to 35 U of BTX-A are typically injected into the corrugators and procerus (Figs 38-9 and 38-10). Ptosis of the upper lid is a rare complication, but can be quite problematic for the patient. These effects are temporary and generally occur from the diffusion of the toxin. The use of apraclonidine 0.5% or phenylephrine 2.5% eye drops can stimulate Müller's muscles in the lid, providing some relief until the effects of the botulinum toxin disappear.

Horizontal forehead lines can be treated with BTX-A as well. The frontalis is a brow elevator and care must be taken to avoid brow ptosis when treating this area. One way to limit this effect is to only paralyze a portion of the frontalis muscle, maintaining activity. For instance, injection may be limited to the superior half of the frontalis; 10 to 25 U, delivered in multiple injections across the forehead, is typically used for this area.

Crow's feet are dynamic rhytids produced from contraction of the lateral orbicularis oculi. Superficial blebs are raised approximately 1 cm lateral to the lateral canthus (Fig. 38-11). Bruising is limited by injecting superficially and limiting the total number of injections. Other sites that can be treated with BTX-A include platysmal bands, diagonal creases along the nasal sidewall (i.e. "sniff lines" or "bunny lines"), mental crease, and depressor anguli oris (for frowning of the lateral corners of the mouth). Care must be taken when treating the lower third of the face to avoid complications with mouth and lip control.

In addition to cosmetic uses, BTX-A is FDA approved for the treatment of hyperhidrosis. Axillary hyperhidrosis can effectively be treated with doses of 50 U/axilla. A starch iodine test can map the area of activity prior to treatment (Fig. 38-12). Intradermal injections are spaced 1 cm apart over the entire area. The effect generally lasts between 6 and 12 months, and appears to be related to the dosage used. Treatment of palmar hyperhidrosis with BTX-A requires higher doses due to the greater surface area involved, typically 100 to 150 U/palm. The pain associated with palmar injections requires the use of wrist nerve blocks. Lastly, a slight muscle weakness of the hands is typically seen for several weeks following treatment. Although this weakness is typically not functionally significant, patients must be informed of this.

VARICOSE AND TELANGIECTATIC VEINS

Sclerotherapy

Patients frequently present to dermatologists seeking treatment of telangiectasias and reticular veins in the lower extremity. The treatment of choice for telangiectatic and reticular veins is sclerotherapy (Fig. 38-13). Despite recent technologic advances, laser treatment for lower extremity telangiectasias should be reserved for those vessels which

Fig. 38-13 Sclerotherapy, injection technique using fine needle to cannulate vain.

can not be cannulated with a needle. In addition, laser therapy can be considered in patients who have failed to respond to sclerotherapy or had significant complications from sclerotherapy.

There are three broad classes of sclerosing agents available to dermatologists—hyperosmotic agents, detergents, and chemical irritants (Table 38-2).

Hypertonic saline is an FDA-approved agent that is commonly used in sclerotherapy. Used in concentrations of 10% to 30%, this agent has the advantage of a complete lack of allergenicity when used alone. The disadvantage of hypertonic saline is the pain associated with injections and the ulcerogenic potential. Often, anesthetic agents such as lidocaine are added to the mixture to minimize the discomfort involved, both by decreasing the concentration of the saline and by the direct anesthetic effect. The authors' formulation is to mix two parts hypertonic saline (23.4%) with one part 1% lidocaine, resulting in an approximate concentration of 16% NaCl.

Hypertonic saline (10%) and dextrose (25%) is another hyperosmolar agent that has been used in vein sclerosing. This agent has the advantages of low allergenicity and decreased pain compared to higher concentrations of plain hypertonic saline. However, this mixture is currently not FDA approved and is a relatively weak sclerosant as compared to other options available.

Sodium tetradecyl sulfate (STS) is a detergent sclerosant that has been FDA approved for over 50 years. Typical concentrations used for superficial telangiectasias and reticular veins are 0.1% to 0.5%. One advantage of STS is the lack of pain with injections; however, extravascular injection can be painful. Also, as with all detergents, STS can be made into a foam. This is typically done with a three-way stopcock and a syringe filled with air (Fig. 38-14). Foam can increase contact between the agent and the vessel wall and result in more effective sclerosis at a lower concentration. One disadvantage with this agent is the isolated reports of anaphylaxis and death associated with STS.

Polidocanol, a detergent, is not currently FDA approved for use in sclerotherapy. It possesses many of the same advantages as STS, including lack of pain with injection and the ability to use it as a foam. Goldman demonstrated comparable efficacy and a similar adverse event profile between polidocanol and STS.

Sodium morrhuate is a detergent approved by the FDA for treatment of varicose veins. However, this sclerosing agent is not generally used for the treatment of cutaneous telangiectasias due to its highly caustic nature and higher anaphylaxis potential.

Table 38-2 Scierotherapy agents						
Agent	Class	FDA approved	Comments			
Hypertonic saline	Hyperosmotic	Yes	No allergenicity, painful			
Hypertonic saline (10%) + `dextrose (25%)	Hyperosmotic	No	Lower allergenicity, painful			
Sodium tetradecyl sulfate	Detergent	Yes	Can use as foam, painless except with extravascular injection			
Polidocanol	Detergent	No	Painless, can use as foam			
Sodium morrhuate	Detergent	Yes	High risk of allergic reaction			
Chromated glycerin	Chemical Imitant	Νο	Weak agent			
Polyiodinated iodine	Chemical initant	No	Highly caustic			

Table 38-2 Sclerotherapy agents

Fig. 38-14 Sclerosing foam, sodium tetradecyl sulfate foam made by mixing air with liquid using a three-way stopcock and two syringes.

Glycerin and polyiodide iodide are chemical irritants used as sclerosing agents. Though not FDA approved for sclerotherapy, these act as corrosive agents and cause a direct injury to the vessel endothelium. Leach and Goldman report a significant decrease in bruising, swelling, and postprocedural hyperpigmentation with glycerin as compared to STS.

Side effects and complications can be associated with all types of sclerotherapy agents. Ulceration can occur despite the meticulous technique of the dermatologist and regardless of the sclerosing agent used. Extravasation of sclerosing solution from the vein may occur or injection into a dermal arteriole or arteriovenous anastomosis may result in cutaneous necrosis. If it is suspected that extravasation has occurred, injection of normal saline to dilute the sclerosing agent may prevent ulceration. Alternatively, application of 2% nitroglycerin ointment may prove beneficial. If ulceration does occur, conservative wound management should be undertaken until healed.

Hyperpigmentation along the course of treated veins has been reported to occur in 10% to 30% of patients. This pigmentation is due to hemosiderin deposition and has been reported with a variety of sclerosing agents, including hypertonic saline, polidocanol, and STS. Pigmentation often improves with time, with approximately 70% improvement over a 6-month period. Treatment options include trichloracetic acid, hydroquinone, retinoic acid cream and intense pulsed light, and laser treatments. Tafazzoli et al report excellent results with the Q-switched ruby laser.

Telangiectatic matting is the appearance of fine telangiectatic blush at the site of previously treated veins. This has been reported in 10% to 15% of patients treated with sclerotherapy. Risk factors associated with this include estrogen therapy, obesity, and a family history of telangiectasia. Low injection pressures and limiting the amount of sclerosant per injection site may help reduce the incidence of telangiectatic matting. Spontaneous resolution often occurs within 3 to 12 months. Treatment options include intense pulsed light, pulsed dye laser, and injection of sclerosant into the matted vessels.

Arterial injection of sclerosant is the most feared complication of vein sclerosing. While extremely rare, it has significant morbidity and immediate action must be undertaken. Classically, the patient reports significant pain immediately following injection, accompanied by significant pallor and cyanosis. If arterial injection occurs, the physician should immediately apply ice and attempt to dilute the vessel with injections of normal saline. Procaine can be used to inactivate STS. Intravenous heparin and thrombolysis should be considered.

Ambulatory Phlebectomy

Ambulatory phlebectomy is an outpatient procedure used to remove varicose veins. This is a highly technical procedure which has been pioneered by dermatologists and requires additional training. A series of stab incisions are made along the course of the varicosity. Various hooks and clamps are used to remove the vein (Fig. 38-15). Sclerotherapy can follow for any remaining reticular veins.

Endovenous Ablation

Endovenous ablation should be considered in patients with greater saphenous incompetence and is rapidly replacing traditional vein stripping. Radiofrequency or laser (810 or 1320 nm) can be used to heat and damage the vein (Fig. 38-16). A catheter is placed under ultrasound guidance. Tumescent anesthesia allows the procedure to be performed painlessly, surrounds the vein and allows for greater contact between the catheter and vessel wall, and distends the skin away from the heat source and prevents cutaneous damage. The catheter is slowly withdrawn along the length of the vein, and the thermal injury leads to vessel occlusion.

LIPOSUCTION

Liposuction is used for the removal of local areas of adipose and to improve the patient's body contour. Liposuction is not a treatment for obesity and should not be used as a weight loss mechanism. The most common areas treated in women are the abdomen and thighs. Other frequently treated sites include the neck, jowls, knees, ankles, and breasts. Other conditions such as gynecomastia, buffalo hump, lipoma, lipodystrophy, and axillary hyperbidrosis are all conditions that can be treated by liposuction.

The current technique employed by dermatologists involves infiltrating the treated area with dilute anesthesia and aspirating the fat via cannulas attached to a vacuum. Tumescent anesthesia typically consists of 0.05% to 0.1% lidocaine with 1:1,000,000 epinephrine and sodium bicarbonate. The total safe concentration of lidocaine that can be used is 55 mg/kg.

Much discussion has been raised regarding the safety of liposuction. It is important to stress that the serious complications seen in liposuction are associated with general anesthesia, and not with procedures performed with local tumescent anesthesia. While there have been reports of deaths occurring during liposuction, no reports have occurred when patients were treated with turnescent anesthesia alone. Office-based turnescent liposuction performed by dermatologic surgeons is safe and has a lower complication rate than hospital-based procedures.

CHEMICAL PEELS

Superficial Peels

Peels are categorized by the level of injury they cause. Superficial peels cause wounding to the epidermis and may reach the papillary dermis. These peels are well tolerated by patients who have limited "down time" after treatment. Superficial peels are used in the treatment of photoaging, actinic keratoses, solar lentigenes, and pigmentary dyschromias. Given the limited nature of the injury induced by these peels, patients often need multiple treatments on a weekly or monthly basis to reach a desired result. However, patients need to understand that superficial peels cannot provide the improvement in wrinkles and deep furrows that may be possible with deeper injury peels.

Alpha-hydroxy acids (AHA) are naturally occurring agents found in foods, and glycolic and lactic acid are the

Table 38-3 Jessner's solution				
Resorcinol	14 g			
Salicyclic acid	14 g			
85% lactic acid	14 g			
95% ethanol qs ad	100 mL			

most commonly used for peeling. The depth of injury is determined by the pH, the concentration of the acid, the amount applied, and the length of treatment time. Glycolic acid, in concentrations up to 70%, is commonly used for melasma, acne, and photoaging. Following rapid application to the entire face, it must be neutralized with sodium bicatbonate or plain water. Glycolic acid has been used in combination with 5-FU for the treatment of actinic keratoses, a so-called "fluor-hydroxy pulse peel."

Salicylic acid, a beta-hydroxy acid, can be used in concentrations of 20% to 30% for the treatment of acne and mild photoaging. It is also used in combination with other agents as part of the Jesnner's solution. Following application, patients experience some mild stinging and discomfort. A whitening of the skin is noted after 5 min. Salicylic acid does not require neutralization, although cool compresses after application can soothe the skin.

Trichloroacetic acid (TCA) in concentrations of 10% to 35% is used extensively as a light peel. The agent is applied and erythema and a white frost are noted within 1 min. Repeated applications can be used to achieve a deeper peel. TCA does not require neutralization after application.

Jessner's solution combines resourcinol, salicylic acid, and lactic acid in ethanol (Table 38-3). This superficial peel has keratolytic activity and is commonly used for acne or hyperkeratotic lesions. It is self neutralizing and multiple applications can be performed to obtain a deeper injury.

Solid CO_2 (dry ice) has been used alone and in combination with TCA to obtain a deeper peel. It has been proposed as an effective treatment for acne scars and as a way to potentiate the effect of TCA to achieve a deeper peel.

Medium Depth Peel

Medium depth chemical peeling is defined as a controlled wound to the epidermis and deep papillary dermis, often with some extension into the upper reticular dermis. In contrast to the multiple treatments that are often performed with superficial peels, medium depth peels are generally done as a single procedure due to the more significant injury produced. These peels cause epidermal necrosis and significant dermal injury, which results in increased collagen production during the wound healing process over the next several months. Medium depth peels are indicated for the treatment of mild-to-moderate photodamage, rhytids, pigmentary dyschromias, actinic keratoses, solar lentigenes, and other epidermal growths. Lawrence et al demonstrated a similar efficacy with Jessner's/35% TCA medium depth peel as compared to 5-FU in the treatment of widespread facial actinic keratoses.

The classic medium depth peel is 50% TCA. However, it is generally not used as a single-agent peel due to the increased incidence of complications, namely scarring and dyspigmentation. Rather, combining 35% TCA with an initial application of another agent, such as Jessner's solution or glycolic

Fig. 38-17 Baker-Gordon phenol peel, white frosting following application. (Courtesy of Richard G Glogau, MD)

Table 38-4 Baker-Gordon formula

Croton oil	3 drops			

acid, can produce a medium depth injury without the complication associated with the higher concentration of TCA alone. As a result of the damage to the epidermis produced with the initial peel, the TCA is able to penetrate deeper and produce a more significant and even result.

Deep Peel

Deep chemical peels are defined as an injury down to the mid-reticular dermis. These peels are indicated for patients with moderate-to-severe photodamage and advanced rhytids. These peels produce significant injury and patients have an extended period of healing following treatment.

Baker-Gordon formula phenol peel is the traditional deep peel (Fig. 38-17). Undiluted 88% phenol does not produce a deep or consistent injury because it causes complete coagulation of epidermal keratin proteins, thus blocking further penetration. The Baker-Gordon formula (Table 38-4) reduces the concentration of phenol to 55%; the croton oil acts as a keratolytic and potentiates the depth of penetration of the phenol. Cardiac monitoring is required since phenol can produce arrhythmias. Intravenous fluids are given before and during the peel to limit the serum concentrations of phenol. In addition, the face is divided into smaller cosmetic units which are treated individually. An approximately 15-min wait is required between treating each subunit, spreading the entire procedure over 1 to 2 h, and further limiting the systemic concentration of phenol. Following application, occlusive tape can be applied if a deeper wound is desired.
