Epidemiology

Worldwide, oesophageal cancer, including cancer of the gastro-oesophageal junction (GEJ), is the sixth leading cause of death from cancer [1]. The vast majority of oesophageal cancers occur as either squamous cell carcinoma (SCC) in the middle or upper third of the oesophagus or as adenocarcinoma in the distal third or at the gastro-oesophageal junction, with other tumour types occurring only very rarely. Epidemiologic data show that the incidence of oesophageal cancer varies considerably from one country to another and often within a single country. The geographic diversity of oesophageal cancer worldwide, of which over 70% are SCC, underscores the multifactorial aetiology of this group of diseases. The highest rates are found in southern and eastern Africa and eastern Asia. An 'oesophageal cancer belt' extends from northeast China to the Middle East, where more than 90% of cases are SCC [2]. In Western industrialized countries, however, there has been a slight decline in SCC over the past three decades, while a dramatic rise in adenocarcinoma has been observed. Overall incidence of oesophageal adenocarcinoma is highest in white men over the age of 60. Mortality rates are very similar to incidence rates due to the relatively late stage of diagnosis and the poor efficacy of treatment with a survival rate at five years below 10%.

The pathogenesis of oesophageal cancer remains unclear. Data from animal studies suggest that damage from factors such as smoking or gastro-oesophageal reflux, which cause inflammation, oesophagitis, and increased cell turnover, may initiate the carcinogenic process. SCC most commonly develops in patients with a long-standing history of alcohol and/or tobacco consumption, whereas adenocarcinoma virtually always arises against a background of Barrett mucosa in the oesophagus (Table 36.1). Familial aggregation of both squamous cell as well as adenocarcinoma has been described, but the extent to which hereditary factors are involved in the development of oesophageal cancer is unclear [1, 2].

Squamous cell carcinoma: molecular biology and pathology

Definition

SCC of the oesophagus is a malignant epithelial tumour with squamous cell differentiation, which is defined as the penetration of neoplastic squamous epithelium through the epithelial basement membrane and extension into the lamina propria or deeper tissue layers. Oesophageal SCC is located predominantly in the middle and the upper third of the oesophagus and develops in flat cells that line the oesophagus.

Pathogenesis

Any factor that causes chronic irritation and inflammation of the oesophageal mucosa appears to increase the incidence of SCC. The two major risk factors for SCC are tobacco and alcohol (Table 36.1). Recurrent thermal injury to the oesophageal mucosa caused by the consumption of large amounts of hot beverages has also been consistently speculated to be a risk factor for SCC. Other causes of chronic oesophageal irritation include achalasia and oesophageal diverticuli, in which food is retained and decomposed by bacteria, releasing various chemical irritants. Genetic predisposition is found in non-epidermolytic palmoplantar keratoderma, or tylosis, a rare autosomal dominant disorder defined by a genetic abnormality at chromosome 17q25. Tylosis is characterized by hyperkeratosis of the palms and soles, as well as by thickening of the oral mucosa. In affected families, it confers up to a 95% risk of SCC of the oesophagus by the age of 70. Low socio-economic status is also linked to a higher risk of SCC of the oesophagus. Finally, several dietary factors have been associated with SCC, such as foods containing N-nitroso compounds and red meat [3, 4].

Histology

Oesophageal SCC is thought to develop through a multistep process, which involves basal cell hyperplasia, intraepithelial neoplasia (dysplasia and carcinoma in situ), and finally invasive carcinoma (see Figure 36.1). These tumours frequently present as fungating, ulcerating, or infiltrating lesions in the oesophageal epithelium. The fungating pattern is characterized by a predominantly exophytic growth, whereas in the ulcerative and infiltrating pattern the tumour growth is predominantly intramural, with a central ulceration and elevated ulcer edges. An infiltrating pattern of the cancer will only cause a small mucosal defect.

Basal cell hyperplasia

The basal layer is the deepest layer of the epidermis, containing basal cells. Basal cells divide continuously, forming new keratinocytes, replacing the old ones that are shed from the surface. Basal cell hyperplasia is diagnosed when the basal zone thickness is

greater than 15% of the total epithelial thickness, without elongation of lamina propria papillae.

Intraepithelial neoplasia

Intraepithelial neoplasia includes both architectural and cytological abnormalities. The architectural abnormality is characterized by a disorganization of the epithelium and loss of normal cell polarity. Cytologically, the cells exhibit irregular and hyperchromatic nuclei, an increase in nuclear/cytoplasmic ratio, and increased mitotic activity. Dysplasia is usually graded as low- or high-grade dysplasia. In carcinoma in situ, the atypical cells are present throughout the full thickness of the epithelium without invasion.

Invasive SCC

Neoplastic squamous cells are present and invade through the basement membrane. A mix of undifferentiated or primitive basal cells, large flat squamous cells, and keratinized foci is often observed. Tumour clusters may be found distant from the main mass due to lymphatic spread through the submucosa. The tumour cells often exhibit keratinization and have intercellular bridges. Cytologically, the cells have enlarged nuclei, multiple and enlarged nucleoli, and loss of nuclear polarity in cell clusters. Variants of SCC are basaloid SCC, verrucous carcinoma, and spindle cell carcinoma [4]. Immunohistochemical markers that are often used in the diagnosis of SCC are p63 and cytokeratin 5/6.

Molecular biology

Genetic changes associated with the development of oesophageal SCC include activation of oncogenes (e.g., cyclin D1, epidermal growth factor receptor (EGFR)) and inactivation of several tumour suppressor genes (e.g., p53, p16, retinoblastoma (Rb)). Loss of heterozygosity (LOH) on chromosome 17q25 has been linked with tylosis.

Proto-oncogenes

Cyclin D1

Gene amplification and the subsequent over-expression of cyclin D1 were commonly demonstrated in cell lines from oesophageal SCC. The product of cyclin D1 gene forms a complex with cyclin-dependent protein kinase (CDK) that governs a key in the cell cycle G1/S transition. Amplification of the gene has potential for growth advantage and enhances tumourigenesis.

EGFR

The ErbB family comprises four structurally related receptor tyrosine kinases, which are HER1 (EGFR, ErbB1), HER2 (Neu, ErbB2), HER3 (ErbB3), and HER4 (ErbB4). EGFR is expressed in many SCC cell lines and tumours [5]. Signal transduction by the EGFR induces tumour cell proliferation, migration, inhibition of apoptosis and angiogenesis (see Figure 36.2). EGFR has also been described as a prognostic marker in several tumours, including oesophageal cancer [6].

Tumour suppressor genes

p53

The p53 mutation is the most common genetic alteration in human cancers and the most frequently studied genetic alteration in oesophageal SCC. The p53 tumour suppressor gene, located on the short arm of chromosome 17, appears to have an important effect on cellular growth control. The p53 gene product is known to regulate cell growth and proliferation. The wild-type p53 protein suppresses cell growth by controlling the G1 checkpoint. The wild-type p53 protein also has several additional physiologic functions, including control of the G2 cell cycle checkpoint and mediation of apoptosis.

Fig. 36.2 EGFR signalling pathway. EGF and TGFα binding to EGFR typically promote cell survival, growth, and differentiation via the activation of several integrated signalling pathways.

p16

Methylation of the p16 gene is common in oesophageal SCC, and tends to increase in prevalence in mucosal foci as the histological severity of the disease increases. Gene methylation means the addition of methyl groups to cytosines in CpG islands. Methylation of these CpG islands has been reported to be a critical mechanism for the inactivation and silencing of several genes including transcription factors and genes involved in apoptosis, which promotes the development of cancers, including oesophageal squamous cell carcinogenesis. p16, acting as a cyclin-dependent kinase inhibitor, binds to and inhibits the activity of CDK4 and CDK6 and arrests the cell cycle in the G1/S phase in a p53-dependent pathway.

Rb

The LOH at the Rb locus is frequently detected in oesophageal SCC. LOH at the Rb locus causes a reduced expression of Rb protein (pRb). The retinoblastoma gene product controls cell proliferation through regulation of the cell cycle at the G1/S-phase transition. The pRb is bound to transcription factor E2F during the G1 phase. However, when pRb is phosphorylated by the cyclin-dependent kinase complexes, E2F is released, and the cell can initiate DNA synthesis.

Adenocarcinoma

Definition

Adenocarcinoma is a malignant epithelial tumour of the oesophagus with glandular differentiation arising predominantly from Barrett mucosa in the lower third of the oesophagus. Infrequently, adenocarcinoma originates from heterotopic gastric mucosa in the upper oesophagus, or from mucosal and submucosal glands.

Pathogenesis

Most adenocarcinomas arise from a region of Barrett metaplasia (Table 36.1). Barrett oesophagus, which is most commonly attributable to gastro-oesophageal reflux disease, occurs as an adaptive response to injury from refluxed acid and bile, as intestinal columnar epithelium is protected by mucus secretion (see Figure 36.3). The adenocarcinoma incidence increase may also be related to the Western obesity epidemic, either through direct physical effects increasing reflux or indirectly through a metabolic syndrome. Recently, a genome-wide association study in patients with Barrett oesophagus found evidence that SNP alleles predisposing to obesity also increased risk for Barrett oesophagus [7]. Adenocarcinoma is more frequently seen in males. The reasons for a male preponderance are unclear but an increased incidence in postmenopausal women raises questions about hormones and iron status.

Histology

Adenocarcinoma arises through a Barrett metaplasia/dysplasia sequence. Barrett metaplasia refers to a condition in which the normal stratified squamous mucosa is replaced by columnar-lined epithelium that extends upward from the GEJ. The condition is an acquired process that develops in response to an oesophageal mucosal injury that heals in the setting of the inflammatory stimulus of continued gastro-oesophageal reflux (Figure 36.4A). Barrett oesophagus may progress to dysplasia (Figure 36.4B and 36.4C) and adenocarcinoma (Figure 36.4D). The degree of dysplasia is determined by evaluating the architecture (relationship of glands and lamina propria), the cytology (nuclear and cytoplasmic features), and degree of surface maturation (comparison of nuclear size within crypts to nuclear size at the mucosal surface), and interpreting these findings in conjunction with the amount of background inflammation. A revised Vienna classification system is frequently used to score the degree of dysplasia (Table 36.2): (1) negative for neoplasia/dysplasia; (2) indefinite for neoplasia/dysplasia; (3) low-grade dysplasia; and (4) high-grade dysplasia.

Negative for neoplasia/dysplasia

This includes metaplastic epithelium showing reactive/regenerative changes. The nuclei may be slightly enlarged, hyperchromatic, with
Fig. 36.3 Barrett oesophagus.
Fig. 36.4 Histopathology of the oesophagus. (A) Barrett metaplasia. (B) Low-grade dysplasia—this type of dysplasia more commonly shows an 'adenomatous' cytological appearance, resembling low-grade tubular adenomata of the large bowel, where nuclei are elongated, slightly enlarged and hyperchromatic with inconspicuous nucleoli. There may be mild pleomorphism, mucin depletion, mild loss of polarity, nuclear crowding, and stratification of nuclei up to three-quarters of the height of the cell, but not touching the luminal surface. (C) High grade dysplasia—the cytologic changes are severe with markedly enlarged nuclei at the surface, pronounced pleomorphism, and at least focal loss of nuclear polarity. Surface maturation is lost. Mild to marked architectural distortion is a frequent finding, with crowded glands, loss of lamina propria, focal budding, and/or cribriform glands. (D) Adenocarcinoma—invasive adenocarcinoma is usually well to moderately differentiated cancer, with the malignant cells producing mucin and sometimes with foci of squamous or endocrine differentiation. Adjacent Barrett mucosa with high-grade dysplasia may be present and rarely signet-ring cells or papillary structures are observed. Variants of adenocarcinoma are (1) adenoacanthoma, (2) mucoepidermoid carcinoma, and (3) adenoid cystic carcinoma [4]. Immunohistochemical markers used for adenocarcinoma are periodic acid staining (PAS) and cytokeratin 7 and 20. PAS staining is based on the presence of neutral mucins in adenocarcinomas.
Images reproduced courtesy of Prof. Dr. Xavier Sagaert, Department of Pathology, University Hospital Leuven, Belgium.

smooth nuclear membranes, prominent nucleoli, and eosinophilic cytoplasm. There may be some stratification of the nuclei at the base. Neutrophils may also be present. Regenerative changes can be more pronounced at the squamo-columnar junction; therefore, the threshold for making a diagnosis of low grade dysplasia should be raised at this site.

Indefinite for neoplasia/dysplasia

This category is applied to biopsies where changes cannot be definitively described as reactive or neoplastic. It is most often used in the presence of pronounced inflammation or the loss of surface epithelium. Cytologic atypia characterized by hyperchromasia, overlapping nuclei, irregular nuclear borders, and nuclear stratification can be seen in the deep glands or the sides of villiform structures while the surface epithelium is free of atypia. The architecture should be largely normal with, at the most, minimal gland crowding. Surface maturation is present.

Molecular Biology

Although a clearly defined sequence of genetic alterations leading to adenocarcinoma has not been defined, several changes in gene structure, gene expression, and protein structure are associated with the progression of Barrett oesophagus to adenocarcinoma. An accumulation of abnormalities has been identified in a wide range of genes that regulate proliferation, apoptosis, invasion, metastasis, angiogenesis, and growth and cell cycle regulation. Alterations in tumour suppressor genes, including p53, are early events in the metaplasia–dysplasia–adenocarcinoma sequence, followed by loss of cell cycle checkpoints. The activation of proto-oncogenes and inactivation of tumour suppressor genes as the result of genetic instability lead to cumulative genetic errors and thereby the generation of multiple clones of transformed cells, which form the key genetic foci contributing to tumour development.

Proto-oncogenes

EGFR

Expression of the EGFR increases as Barrett oesophagus progresses to adenocarcinoma. The over-expression of erbB-2 is usually noted in adenocarcinoma but only rarely in SCC. ErbB-2 is located at chromosome 7p12-13, a frequently amplified region in oesophageal SCC and adenocarcinomas. TGFα binds to EGFR and stimulates cell division. Amplification of the TGFα gene at chromosome 2p13 has been found in the progression of oesophageal adenocarcinoma. In Barrett tissue, TGFα has been found to activate vascular endothelial growth factor (VEGF), which plays a role in the vascularization of adenocarcinomas. Expression of VEGF is indeed increased in Barrett adenocarcinomas.

bFGF

bFGF expression levels are significantly increased in Barrett adenocarcinomas and dysplastic tissues as compared to normal oesophageal mucosa and metaplasia. The fibroblast growth factors are

Table 36.2 Vienna classification system of gastrointestinal epithelial neoplasia

Category		Histology
Negative for dysplasia	A	Normal with well-spaced glands
	C	Regular nuclei, smooth membranes
	M	Complete
Indefinite for dysplasia	A	Normal to mild distortion, often inflamed
	C	Hyperchromasia, overlapping nuclei, irregular nuclei borders
	M	Complete when intact surface epithelium present
Low-grade dysplasia	A	Normal to mild distortion, gland crowding
	C	Minimal pleomorphism, maintained polarity, increased mitotic activity
	M	Minimal to none
High-grade dysplasia	A	Mild to marked distortion, crowded and budding glands
	C	Loss of polarity, markedly enlarged nuclei, prominent pleomorphism
	M	None

important pro-angiogenic factors with the capability to regulate growth and differentiation of various cell types.

Tumour suppressor genes

p53

p53 is mutated in more than 50% of oesophageal adenocarcinomas [7]. p53 protein over-expression is reported early in the transformation of Barrett oesophagus to adenocarcinoma and increases with histologic progression. Therefore, p53 immunostaining is often used in the pathology lab to detect dysplasia in Barrett oesophagus.

Surgical management

Clinical presentation

Signs and Symptoms

Both adenocarcinoma and SCC have similar clinical presentations except that adenocarcinoma arises much more commonly in the distal oesophagus or at the GEJ. Early-stage oesophageal cancer has no typical symptoms. Difficult transit through the oesophageal tube of harder ingredients (e.g., French fries or bread crusts), which can be overcome by the patient with careful chewing or frequent drinking, may precede outright dysphagia. Patients may also notice retrosternal discomfort or a burning sensation. Among patients with locally advanced cancer, obstruction of the oesophagus by the tumour causes progressive solid food dysphagia often accompanied by weight loss. Dysphagia indicates that the oesophageal lumen has been reduced by at least 50–75% of its normal diameter and that about two-thirds of the circumference of the oesophageal wall is involved. Regurgitation of food uncontaminated by gastric secretions can also occur in patients with advanced disease. Hoarseness may arise if the recurrent laryngeal nerve is invaded or due to chronic aspiration. Ultimately, oesophageal obstruction becomes complete for both solid food and fluids.

Chronic gastrointestinal blood loss from oesophageal cancer is common and may result in iron deficiency anaemia. However, patients seldom notice melena, haematemesis or blood in regurgitated food. Similarly, acute upper gastrointestinal bleeding is rare and is a result of tumour erosion into the aorta or pulmonary or bronchial arteries. Tracheo-bronchial fistulas are a late complication of oesophageal cancer. The fistulas are caused by direct invasion through the oesophageal wall and into the main stem bronchus. Such patients often present with intractable coughing or frequent pneumonias.

Clinical examination

Clinical examination is usually normal in localized disease, although supraclavicular or neck lymph nodes can be present in more advanced disease. Obviously, thorough clinical examination should be performed to exclude metastatic disease (e.g., malignant pleural effusion or ascites) or concurrent liver disease, since many patients have a history of alcohol abuse.

Diagnosis and staging

Diagnosis

Timely diagnosis of oesophageal cancer is hampered by the usually late occurrence of tumour-related symptoms. Most early oesophageal cancers are detected serendipitously or during screening for or surveillance of Barrett oesophagus. Patients with more advanced disease are often symptomatic for two to four months before seeking professional help. The diagnostic algorithm for oesophageal cancer includes establishing the definite diagnosis as well as evaluation of oncological and functional operability.

Initially, existence of a clinically suspected carcinoma should be either confirmed or ruled out. Previously, contrast medium swallow studies were most commonly applied for this purpose, but this has been largely replaced with endoscopy. A 2009 survey among surgeons regularly performing oesophagectomy showed that endoscopy and barium oesophagography are routinely used by 98% and 51% of surgeons, respectively [8].

Nowadays, patients with suggestive symptoms should preferably undergo endoscopy with biopsies. In addition to achieving a biopsy, the endoscopist should document tumour location relative to both the teeth and the GEJ, tumour length, extent of circumferential involvement, degree of obstruction, and any evidence of Barrett oesophagus to assist with treatment planning.

Gastro-oesophageal junction adenocarcinoma

A specific problem is the diagnosis, and especially the definition, of gastro-oesophageal junction tumours (usually adenocarcinoma). Because tumours originating at the GEJ are often differently defined and classified by surgeons, endoscopists, and pathologists alike, significant debate on the optimal multimodality treatment of these tumours persists.

According to the seventh-edition TNM staging system of the American Joint Committee on Cancer/International Union Against Cancer (AJCC/UICC) for oesophageal and gastric cancer, tumours whose midpoint is in the lower thoracic oesophagus, gastro-oesophageal junction, or within the proximal 5 cm of the stomach that extends into the gastro-oesophageal junction or oesophagus are classified as adenocarcinoma of the oesophagus for the purposes of staging [9]. These tumours are staged (and consequently treated) as oesophageal rather than as gastric adenocarcinomas. All other tumours, i.e. with a midpoint in the stomach lying more than 5 cm from the gastro-oesophageal junction or within 5 cm of the gastro-oesophageal junction but without extension into the oesophagus, are staged (and probably treated) as gastric cancers. This approach remains a subject of debate.

Siewert classified adenocarcinoma of the gastro-oesophageal junction in 1987 into three distinct types, based purely on the anatomic location of the epicentre of the tumour or the location of the tumour mass [10]. According to this classification, GEJ adenocarcinomas encompass all tumours with an epicentre within 5 cm proximal or distal to the anatomical Z-line, the 'squamo-columnar junction' visible as the transition between the reddish columnar epithelium lining the gastric cardia and the pale squamous epithelium lining the oesophagus.

Siewert Type I adenocarcinoma

If the epicentre of the tumour or more than 66% of the tumour mass is located more than 1 cm above the anatomic GEJ, then the tumour is classified as an adenocarcinoma of the distal oesophagus, type I. According to Siewert, these should be considered as typical adenocarcinomas of the distal oesophagus that infiltrate the gastro-oesophageal junction from above. Siewert type I tumours also have epidemiologic and histological characteristics that are similar to distal thoracic oesophageal adenocarcinomas, including a strong male predominance, association with a history of reflux symptoms, and a predominance of intestinal-type histology, having

arisen from Barrett metaplasia secondary to gastro-oesophageal reflux. In general, type I cancers more frequently involve lymph nodes in the upper mediastinum (tracheal bifurcation and above).

Siewert Type II adenocarcinoma

If the epicentre of the tumour or tumour mass is located within 1 cm proximal and 2 cm distal to the anatomic GEJ, it is classified as type II. These could be considered as 'true' gastro-oesophageal junction adenocarcinomas, arising from the cardiac epithelium or short segments with intestinal metaplasia at the gastro-oesophageal junction. There is increasing evidence to suggest that Siewert type II tumours have two distinct aetiologies, some being oesophageal adenocarcinomas probably arising from Barrett oesophagus, and others gastric adenocarcinomas caused by Helicobacter pylori infection and atrophic gastritis (as with type III tumours).

Siewert Type III adenocarcinoma

If the epicentre of the tumour or more than 66% of the tumour mass is located more than 2 cm below the anatomic gastro-oesophageal junction, the tumour is classified as type III. Type III tumours resemble distal (subcardiac) gastric cancers, with a similar proportion of diffuse and intestinal histologic types and no association with reflux, which infiltrate the gastro-oesophageal junction from below. They arise from the gastric mucosa, and their origin might be associated with Helicobacter pylori and atrophic gastritis.

Staging

After diagnosis is confirmed, pretreatment staging should be initiated (see Figure 36.5). The questions to be addressed are the potential resectability of the primary tumour with its locoregional lymphatic drainage as well as the presence of distant metastases.

Endoscopic ultrasonography (EUS), computed tomography (CT), and positron emission tomography (PET) are currently the procedures of choice.

A sophisticated diagnostic workup and staging must be performed in order to allow for an accurate treatment choice. Oesophageal cancer patients are grouped in different stages depending on tumour location, grade and histological type in combination with the tumoural extension according to the TNM principle. The staging system can be accessed at the website of the American Cancer Society [11].

While the TNM classification is essentially the same for adenocarcinoma and SCC, one of the major changes between the 2002 (6th) and the 2010 (7th) editions was the development of separate stage groupings according to histology [11]. This change was based upon an analysis of worldwide data on 4627 patients with cancer of the oesophagus or gastro-oesophageal junction who underwent surgery alone; this showed that among patients with lymph-node-negative tumours, prognosis was dependent on T-classification as well as histology, grade, and tumour location [12]. While the new AJCC/UICC staging system provides a better separation of prognostic groups for both histologies as determined by the TNM categories at the time of initial diagnosis, it was based on pTNM data from patients who were treated by oesophagectomy alone, without induction chemotherapy and/or radiotherapy. As a result, its prognostic utility in patients who receive multimodality therapy is unclear [12].

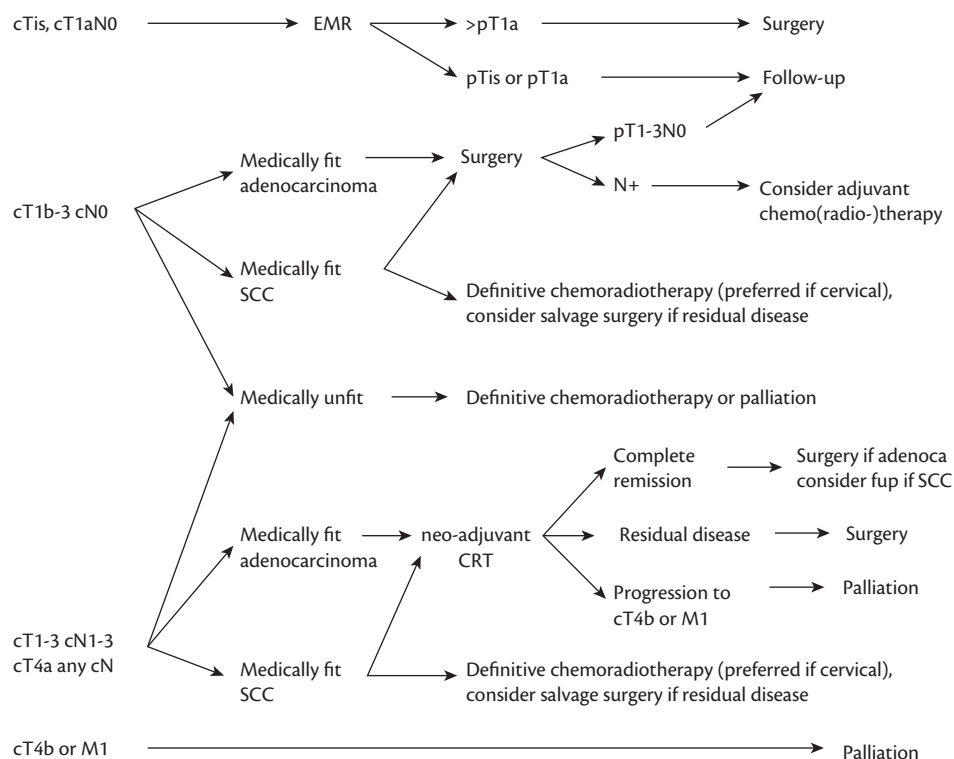
Stage is the most important factor in prognosis and choice of treatment and thus reliable non-invasive methods for accurate staging are very important. Staging usually begins with a CT scan of the thorax and abdomen to evaluate for the presence of metastatic


Fig. 36.5 Proposed treatment flow for oesophageal cancer.

disease. Patients without evidence of metastatic disease undergo EUS, which uses a high-frequency ultrasound transducer to provide detailed images of oesophageal masses and their relationship with the five-layered structure of the oesophageal wall. EUS allows assessment of both perigastric and mediastinal lymph nodes, which can potentially be sampled during the evaluation with a fine needle aspiration biopsy if the result would impact treatment decisions. PET and integrated PET-CT scans are useful to detect metastatic disease in patients who are otherwise believed to be surgical candidates after routine staging with conventional contrast-enhanced CT. The role of staging laparoscopy is controversial, and there is no consensus on this issue from expert groups.

Modalities

Oesophagography

Barium studies are well established in the diagnosis of oesophageal disorders, including carcinoma of the oesophagus and the GEJ. In general, a double-contrast examination is preferred to a single-contrast study. Barium swallow is considered safe, easy to perform, readily available, and inexpensive. Barium studies have a low sensitivity for early tumoral lesions and have a moderate positive predictive value but can be useful in the determination of the relationship between the tumour and the proximal sphincter (cricoid muscle).

Endoscopy

The role of endoscopy, consisting of upper endoscopy and endoscopic ultrasound, in diagnosis and staging of oesophageal cancer is crucial. Obviously, standard endoscopy with biopsies provides histological confirmation of the diagnosis. EUS for T and N staging has been well studied and is indicated to assess local disease extent in the absence of metastasis. Conventional EUS with a 7.5–12 MHz probe is able to visualize five oesophageal layers but does not discriminate between T1a and T1b disease. In general, the accuracy of EUS for T staging is reported to be 89% and this increases with increasing disease stage, thereby outperforming CT scan [13, 14].

In the era of neoadjuvant therapy, N staging often determines preoperative management. EUS characteristics suggestive of nodal disease include a diameter of more than 10 mm, a hypoechoic, homogeneous appearance, a round shape, and sharp demarcation. If all these features are present, the lymph node is very likely to be malignant [15]. However, all four features are only simultaneously present in 25% of malignant lymph nodes. In general, the accuracy of EUS for lymph node metastasis ranges between 64% and 90% [15]. It should be noted that specificity can affect patient management considerably: in a study including 214 patients, EUS was correct in only 64.5% of patients to predict final N staging, with a very good sensitivity (93.8%) but a poor specificity of 20%. Based on the N stage, 32% of the patients who underwent primary surgery should have received neoadjuvant chemoradiotherapy and 36% of the patient staged as N1 would have been wrongly assigned to neoadjuvant chemoradiotherapy [16]. Fine needle aspiration significantly helps to improve lymph node staging and increases specificity to more than 90% and should be considered mandatory if technically possible [17].

CT imaging

The penetration depth of EUS is limited to approximately 5 cm. Therefore, CT is generally added to the pretreatment workup in an effort to improve detection of metastases in distant lymph nodes and other organs. According to a recent meta-analysis, CT scans of the chest show a reduced sensitivity for detecting regional lymph-node metastases (0.50, 95% CI 0.41–0.60) compared with EUS [15]. However, the specificity of CT (0.83, 95% CI 0.77–0.89) is superior. Regarding malignant abdominal lymph nodes, the sensitivity is 0.42 (95% CI 0.29–0.54) with a specificity of 0.93 [95% CI 0.86–1.00]. As in many other organs, sensitivity of CT is hampered by its inevitable reliance on nodal size and shape as a diagnostic criterion. Obviously, metastases can be found in subcentimetric lymph nodes. Even if enlarged lymph nodes are visible, CT images do not always enable a distinction between enlargement due to metastatic spread or due to inflammation.

PET and PET-CT imaging

PET allows accurate non-invasive molecular characterisation of tissues, thereby adding a complement to the structural information on conventional imaging. Making use of the increased glucose metabolism now recognized as a key feature of a great range of malignancies, PET imaging with the glucose analogue 2-^{18}F-fluoro-2-deoxy-D-glucose (FDG) allows a better distinction between malignant and benign tissues [18]. SCC are typically strongly FDG-avid; in adenocarcinomas this is usually lower with ~25% of tumours that are not FDG-avid, mainly tumours with poor differentiation, diffuse growth pattern, or high mucus content [19].

Modern PET cameras in use for oncological imaging are typically hybrid devices that combine a PET camera with a CT resulting in a fusion dataset. FGD-PET/CT is widely accepted for TNM determination in oesophageal cancer. For the primary tumour, FGD-PET/CT can help to determine the longitudinal extent of the tumour, which can be useful for radiation treatment planning. For detection of regional lymph node involvement, a recent meta-analysis showed that EUS has a better sensitivity (80%) than CT or FDG-PET (50% and 57%, respectively), but the specificity of FDG-PET and CT is higher (83% and 85%, respectively) than that of EUS (70%) [15]. The main advantages of FDG-PET are the detection of normal-size lymph nodes with tumoural involvement and the fact that PET can detect malignant lymph nodes in areas that are not assessed with EUS. In a recent meta-analysis, for the detection of distant metastases FDG-PET showed a higher sensitivity than CT (71% versus 52%) with a comparable specificity (93% versus 91%), leading to detection of unsuspected M1 stage in up to 20% of patients [20].

The use of FDG-PET/CT leads to changes in stage in up to 40% of patients, and results in clinical management changes in up to one-third of patients [21]. Incorporating FDG-PET/CT leads to a better selection of patients with poor long-term prognosis as measured by five-year overall survival. In 5–10% of patients synchronous primary tumours can be detected [22].

Evolving role of surgery

Resection is generally considered integral to achieving cure in patients with oesophageal cancer. In very early stages, i.e. in cancers limited to the mucosal layer, endoscopic resection is an accepted alternative to surgery [23, 24]. In intermediate stages (T1b and T2 categories), primary surgical resection undoubtedly remains the treatment of choice. In locally advanced categories (T3 and T4a), surgery alone has shown rather disappointing survival rates.

Consequently, surgery is usually performed as part of a multimodal treatment strategy and commonly follows neoadjuvant chemoradiotherapy (CRT). The landmark paper by Herskovic was the first to demonstrate that definite CRT could result in survival rates comparable to what is achieved with surgery [25]. Consequently, some institutions prefer this approach, especially in SCC, to avoid the high morbidity and mortality associated with surgery in such patients. However, in a study from the linked Surveillance, Epidemiology and End Results (SEER)–Medicare database, five-year survival rates for patients with stages I–III oesophageal cancer treated with and without surgery were 28% and 10%, respectively [26]. Obviously, these data must be interpreted cautiously. The longer survival in the surgically treated patients could represent selection bias in that younger and healthier patients may have been selected to undergo more aggressive, multimodality treatment with surgery. Evidently, in patients with potentially operable cancer who are unfit for major surgery owing to an impaired functional status, definitive CRT is the procedure of choice. In cases of advanced disease or distant metastases palliative measures are indicated.

Endoluminal therapy

The first choice treatment for early neoplastic oesophageal lesions has shifted from surgery to endoluminal therapy over the last decade. In well-selected patients with well to moderately differentiated mucosal cancer without signs of lymphovascular invasion on histology, endoscopic resection (ER) has an excellent long-term outcome and survival, comparable to surgery [23, 24]. The rationale for this approach originates from the inherent morbidity and mortality of surgery on the one hand, and the low risk of nodal involvement in T1a cancers. The prevalence of nodal disease in mucosal cancer is estimated to be 0.7% and 1.4% in adenocarcinoma and SCC, respectively [27]. Unfortunately, conventional EUS is not suited for differentiating between T1a and T1b disease. High-frequency EUS probes (12–30 MHz) permit viewing a more detailed architecture, although several studies have shown that the accuracy for T staging in early cancer is insufficient in comparison to staging ER, with a sensitivity and specificity for diagnosing T1a disease of 62–100% and 65–94%, respectively [27]. In addition, a recent study showed that if a lesion looks endoscopically amenable for endoscopic resection, a staging ER can be performed, providing a final pathological staging. A study on high-resolution endoscopy compared the endoscopic appearance of early lesions to high-frequency EUS in 100 patients with early oesophageal neoplasia for predicting submucosal invasion. The accuracy was not different for high-resolution endoscopy or high-frequency EUS (83.4% and 79.6%, respectively) [28].

Endoscopic resection is the basis of proper risk stratification and patient selection as it allows the assessment of the histopathological prerequisites for a curative treatment. Only lesions limited to the mucosa that are well- to moderately-differentiated and without signs of lymphovascular infiltration can be considered as cured after ER, with a good oncological outcome, comparable to surgery [24, 27, 29]. However, in particular in Barrett disease, metachronous disease can occur in up to 30% of patients. Therefore, the preferred strategy in patients with a long enough life expectancy is to provide additional ablation with radiofrequency ablation (RFA) [30]. This is a recently introduced new ablative therapy for Barrett oesophagus during which radiofrequency energy is delivered through a balloon-based system for circumferential ablation

or with a cap-electrode attached to the tip of an endoscope for focal ablation. The generated heat will destroy remaining dysplastic and non-dysplastic epithelium with a high success rate [31]. It has to be emphasized that RFA is only indicated to ablate flat dysplasia and not for ablation of mucosal cancer [30, 32]. Pre-ER biopsies insufficiently predict final staging after ER, with upgrading of 20% of lesions with only high- or low-grade dysplasia on biopsy to a carcinoma after ER [33]. In the era of RFA it is therefore crucial to resect any small visible lesion for proper histological assessment and patient selection.

Principles of surgical treatment

The first direct transthoracic oesophagectomy for cancer was performed by Franz Thorek in 1913 in New York [34]. He carried out a left thoracic subtotal resection of the oesophagus for a SCC of the middle third in a 67-year-old patient. The patient subsequently survived for 13 years and was fed orally via an external rubber tube connecting the cervical oesophagus with the stomach.

It took another two decades to finally accomplish a successful oesophagectomy with an intrathoracic oesophagogastrostomy; Osawa has been given the credit for this pioneering success [35]. With the further improvements of thoracic anaesthesia and surgery, oesophagectomy became the mainstay of therapy for operable cancer of the oesophagus and remains so today.

The surgical treatment strategy of oesophageal carcinoma is complex and the long-term outcome of surgical therapy is often disappointing. A malignancy arising from the oesophagus may easily invade the adjacent organs, which makes the tumour surgically unresectable. Additionally, lymphatic dissemination is an early event and has a negative influence on survival. Lymph node metastases are found in less than 5% of intramucosal tumours, but in as many as 30–40% of submucosal tumours [36]. Furthermore, the oesophageal wall is characterized by an extensive submucosal lymphatic plexus, which supplies a drainage route for early dissemination and gives rise to jump-metastases (i.e. lymph nodes adjacent to the primary tumour are not affected, but more distantly located lymph nodes contain metastases) [37]. As a result, transmural tumours show lymph node involvement in over 80% and the number of involved nodes increases with the volume of the tumour.

Further adding to the complexity are the tumours of the GEJ which are classified by some as gastric cancer by others as oesophageal cancer. This explains in part the continuing controversy as to which strategy to follow when it comes to surgical approach and surgical techniques.

It is generally accepted that surgical resection should only be performed with curative intent. Resection is ill advised when macroscopically incomplete, because invasion of adjacent structures and/or non-resectable metastases are to be expected. Absolute contraindications for oesophagectomy include local tumour invasion of non-resectable neighbouring structures (T4b), carcinomatosis peritonei, haematogenous parenchymatous metastases, and non-resectable metastatic lymph nodes.

The pattern of lymphatic dissemination is difficult to predict, but carcinomas of the proximal and middle thirds of the oesophagus preferably metastasize to the cervical region, whereas more distal-lying tumours and tumours of the gastro-oesophageal junction more commonly metastasize to the lymph nodes around the celiac trunk. Resectable metastatic lymph nodes in the region of the primary tumour, including the celiac trunk and its trifurcation for

distal third tumours and cervical nodes for middle and proximal tumours, are not necessarily a contraindication for surgery. The presence of such lymph node metastases, however, has a negative influence on survival, even following extensive lymphadenectomy.

Macroscopic as well as microscopic completeness (R0) is the ultimate goal of oesophagectomy for cancer. Consequently, optimal preoperative staging is of paramount importance as well as individual case presentation and discussion at a multidisciplinary tumour board.

Before embarking on such major surgery, careful evaluation of medical operability is equally important. Indeed, many patients present with a history of alcohol and tobacco abuses requiring careful evaluation of cardiovascular, pulmonary, and liver function. An even more careful assessment of the operability of the older patient is essential when an operation of such magnitude is considered. An advanced age, in and of itself, is however not a contraindication for extensive surgical procedures for oesophageal carcinoma [38, 39].

The early-stage lymphatic dissemination as well as completeness of tumoural resection pose challenges for radical surgical treatment and are still a matter of debate. The concept of extensive en bloc resections was initially reported in 1963, but its associated mortality of more than 20% in that original report discouraged general acceptance [40]. Skinner and Akiyama reintroduced the concept of en bloc resection combined with extensive lymphadenectomy [41, 42]. Ultimately, they were able to reduce operative mortality to 5%, with five-year survival rates of 18 and 42%, respectively.

The radical en bloc resection, as opposed to the standard resection, aims at performing a wide as possible peritumoural with an en bloc lymph-node resection of the middle and distal thirds of the posterior mediastinum.

The two-field lymph node dissection incorporates, besides a wide local excision of the primary tumour, a lymphadenectomy of the entire posterior mediastinum, including the subcarinal nodes and up to the nodes along the left recurrent nerve and the brachiocephalic trunk. In the abdomen it includes the lymph nodes along the celiac trunk, common hepatic and splenic arteries, as well as the lymph nodes along the lesser gastric curvature and in the lesser omentum (the so-called DII lymphadenectomy).

The three-field lymph node dissection. The pattern of lymphatic dissemination is not restricted to the thorax and abdomen. About 20% of the patients with a distal tumour present with metastasis in the cervical region [36, 37]. In this operation, besides the already mentioned removal of thoracic and abdominal nodes, the cervical field includes the para-oesophageal nodes and the nodes lateral to the carotid vessel as well as the supraclavicular nodes.

These considerations on radicality of resection and extent of lymphadenectomy are the rationale to justify a transthoracic approach as opposed to the transhiatal approach for which the rationale is merely based on an effort to decrease perioperative morbidity and possibly postoperative mortality.

Techniques

Transhiatal oesophagectomy

The transhiatal oesophagectomy without thoracotomy has a number of practical advantages, i.e. a short operative duration, probably lower incidence of pulmonary complications and the avoidance of post-thoracotomy pain [43]. The method is particularly applicable to tumours of the distal oesophagus and GEJ where, via a surgically widened hiatus, the lower mediastinum can be approached. The organ for reconstruction is preferably the stomach, which is anastomosed to the remaining cervical oesophagus via the oesophageal bed (the so-called pre-vertebral route) or via the retrosternal route.

Transthoracic oesophagectomy

Oesophageal tumours situated in the proximal and middle thirds of the intrathoracic oesophagus are probably best approached via the right thoracic cavity. In contrast, distal tumours and tumours of the gastro-oesophageal junction may be better approached from the left side. The most commonly used transthoracic approaches are the Ivor Lewis (two-hole) and Mc Keown (three-hole) right thoracic approach and the left-sided approach through a left thoracophrenotomy [44–47].

Minimally invasive oesophagectomy (MIE)

In an effort to limit the physiologic stress of oesophagectomy while preserving the principle of en bloc resection, a minimally invasive approach to oesophageal resection allowing the same type of resection compared to the transthoracic approach has been developed [48]. The best indications for MIE are Barrett high-grade dysplasia or small tumours (T1a or T1b without suspicious nodes) although it is also increasingly used for more advanced cancers [49, 50].

Surgical Results

Over the years, controversy remained as to the radicality of resection and extent of lymphadenectomy. Those who believe that lymph node involvement equals systemic disease will advocate a simple resection and reconstruction typically through a transhiatal approach. Others believe that the natural course of the disease may be influenced by radical oesophagectomy and extensive (two- or three-field) lymphadenectomy. Although several publications both from Japan and from the West seem to indicate a benefit in favour of the more radical approach, definitive proof is lacking. More radical resections seem to result in overall survival rates between 35% and 50%, as shown in Table 36.3, whereas standard resection has five-year survival rates between 15% and 20%, as shown in Table 36.4, but these non-randomized data might have been influenced by selection bias [51–60].

But perhaps an even more important finding is the influence of hospital volume indicating a potential beneficial effect of centralization of oesophagectomy as suggested by an increasing number

Table 36.3 Survival after radical surgery

Author	N pat.	Three-year survival	Five-year survival
Ando et al. [51]	419	52%	40%
Akiyama et al. [42]	913	52.6%	42.4%
Isono et al. [52]	1740	42%	34.3%
Lerut, Nafteux et al. [53]	174	55%	42%
Collard et al. [54]	235 R0	65%	49%
	324 R0-2	50%	35%
Hagen et al. [55]	100	60%	52%
Altorki N et al. [56]	111	52%	40%

Collard et al. [54]	98	30%
Hagen et al. [55]	32	26%
Altorki NK et al. [59]	33	34.5% (4-year)

of publications [61, 62]. From these data, it must be clear that the results as obtained today in centres of experience with primary surgery are to be seen as the gold standard to which all other therapeutic options, and in particular the multimodality therapies, should be compared. In all trials, no standard quality criteria for the surgical arm have been determined. Not surprisingly, the mean Jadad quality score in different prospective randomized trials is rather low (2.1 on the scale of 5 points) [63, 64].

Surgical Complications

As for any other major surgical intervention, postoperative complications occur frequently after oesophagectomy. Postoperative morbidity, often major morbidity, is seen in up to 30% to 50% [65]. These complications can be divided in medical complications (e.g., cardiac arrhythmias, pulmonary infections, renal insufficiency, CVA, etc.) and surgical complications (e.g., anastomotic leak, chyle leak, and wound infection). A correlation between complications and early recurrence and its timing has been reported [65]. Achieving oesophagectomy without postoperative complications, therefore, is of utmost importance for oncologic reasons, underscoring the need to have this type of surgery performed in centres of experience.

Anastomostic Complications

Anastomotic complications are considered to be the Achilles heel of oesophageal surgery, in particular anastomotic leaks. The incidence of anastomotic leaks reported in literature is between 0% and 50%. However, recent studies have demonstrated that the incidence of leakage after cervical anastomosis can be kept well below 5% [66]. Orringer et al. and Collard et al. introduced the concept of a semi-mechanical side-to-side anastomosis. The authors claim that with this technique there is a significant reduction both in early anastomotic leaks and late strictures [67, 68].

Anastomotic strictures occur in approximately 15% to 30% of the patients. Early postoperative endoscopy in order to monitor healing, followed when necessary by early dilatations may reduce the incidence of benign strictures [69, 70].

Pulmonary complications

Pulmonary infections are the most important cause of early postoperative mortality [71]. Because of the high incidence in pulmonary complications after an oesophagectomy, transhiatal oesophagectomy was reintroduced in the 1970s [72]. A large randomized trial confirmed the short-term advantage of the transhiatal technique [57]. Similar results have been obtained in a randomized trial comparing MIE versus open oesophagectomy with 34% versus 12% pulmonary infections, respectively [73].

Chylothorax

The incidence of chylothorax following oesophagectomy is 1–4% and the management is still controversial. There is a place for short conservative treatment, which consists of drainage of the pleural cavity. Suspending enteral feeding and starting total parenteral nutrition can dramatically reduce the production of chyle. Failure of reduction within three to five days in the chyle output to less than 1 litre per 24 hours is an indication for surgery [74]. Postoperative identification of the site of leakage is facilitated by administering enteral lipids. Thoracoscopic ligation is technically feasible and in skilled hands is preferred over thoracotomy [75]. Percutaneous CT-guided embolization is another way to stop chyle leaks [76].

Vocal cord paralysis

Vocal cord paralysis is a well-known complication, causing hoarseness, dysphagia, weight loss, aspiration, dyspnoea, and pneumonia [77]. Dissection alongside both recurrent nerves may cause damage followed by a temporary or definitive vocal cord paralysis. Besides aspiration during eating and drinking, patients with vocal cord paralysis may also be at risk of reflux-induced aspiration and subsequent pneumonia. Because of these potentially life-threatening consequences, a number of authors advocate the early and aggressive treatment of vocal cord paralysis that does not recover within a few weeks of surgery. Teflon injection of the vocal cord is an easy and safe procedure resulting in substantial improvement of phonation and swallowing in the majority of patients [78]. Another technique reported to be successful is the use of silicone elastomere [79].

Reflux oesophagitis

Despite a significant reduction of acid output related to truncal vagotomy, persistent acid secretion has been reported, originating from an autonomous acid secretion in the gastric antrum cells [80]. Consequently, a substantial number of patients will suffer from reflux symptoms. There is a significantly higher incidence of reflux oesophagitis in patients with an intrathoracic anastomosis than in patients with a cervical anastomosis [81]. Gutschow et al reported that 38% of patients had reflux in the remnant oesophagus at three years or more after oesophagectomy [82]. In more recent years, the introduction of potent anti-acid medication (i.e. proton pump inhibitors) has probably resulted in a major decrease of reflux-related problems, although objective data are not available in the literature.

Gastric-emptying-related problems

Vagal denervation can result in chronic dysmotility of the gastric remnant and an outlet dysfunction of the pylorus, which may cause delayed emptying. This may induce a wide spectrum of symptoms: early satiety, postprandial fullness, heartburn, high dysphagia, aspiration, and pneumonia. The addition of a gastric drainage procedure has been advocated. However, the need for such drainage procedure has been criticized as being harmful because of pyloroplasty-related technical complications (leaks), dumping, and biliary reflux. The largest randomized study has been performed by Fok et al, with a meticulous analysis of eating abilities and gastric emptying function [83]. In this study, the whole stomach had

been used for reconstruction in all patients. From this study, gastric drainage procedures are recommended when using the whole stomach.

Gastric outlet obstruction

Irrespective of whether or not a pyloric drainage procedure has been performed, a number of patients may suffer from gastric outlet obstruction. Balloon dilatation of the pylorus can be an effective procedure to solve this problem. Bemelman et al. reported a successful outcome with balloon dilatation in six out of 18 patients [84]. An alternative is to administer erythromycin. Erythromycin is a motilin agonist and has been demonstrated to improve gastric emptying in normal subjects and in patients with diabetic gastroparesis or post-vagotomy gastroparesis [85]. More recently, botox injection into the pylorus has been successfully used [86].

Intestinal metaplasia in the oesophageal remnant

The ablation of the lower oesophageal sphincter mechanism and the vagotomy-induced pyloric dysfunction with possible enterogastric biliary reflux are of increasing concern in relation to the risk of development of Barrett metaplasia, especially in long-term survivors. In a series of 39 patients, Oberg et al. noticed a 47% prevalence of metaplastic columnar mucosa within the cervical oesophagus [87]. It is currently unknown whether these patients have the same risk of developing adenocarcinoma as is seen in the classic reflux-induced Barrett population [88].

Dumping, diarrhoea

After oesophagectomy followed by gastroplasty, many patients complain of dumping symptoms, with a reported incidence of between 10% and 50% [89, 90]. Diarrhoea, abdominal cramps, nausea, dizziness, postprandial sweating, and hypotension are the main complaints [91]. An effective relief of dumping symptoms can be achieved with dietary modifications to minimize the ingestion of simple carbohydrates and to exclude fluid intake during the ingestion of the solid portion of a meal. More severely affected patients may respond to agents such as pectin and guar, which increase the viscosity of the intraluminal contents, or to drugs such as the glucosidase inhibitor acarbose, which decreases the rapid absorption of glucose, or native somatostatin or the somatostatin analogue octreotide, which alter gut transit and inhibit the release of vasoactive mediators into the bloodstream [92].

Quality of life after operation

The nature of the operation, transhiatal versus transthoracic, or the position of the proximal anastomosis, high thoracic versus cervical, has only a limited effect on quality of life. Gastro-oesophageal reflux and dumping syndrome are encountered in more than half of the patients. 20–25% of patients also encounter stenosis of the proximal anastomosis. An anastomosis at the cervical level has a significantly lower chance of symptomatic reflux than one lying within the thorax, but has a higher chance of suture-line leakage and benign stricturing [93]. Global quality scores reveal a significant decrease in physical and role functional scales and an increase in fatigue, nausea, pain, dyspnoea, deglutition, and gastrointestinal symptoms in the initial postoperative phase. However, a gradual improvement is noticed over time, and one year after resection, patients not suffering from tumour recurrence consider their quality of life comparable to that of their predisease state. Ten years after surgery, two-thirds of surviving patients appear to maintain satisfactory ability for solid-food ingestion [93].

Radiotherapy (RT)

When radiation is used with curative intent in the treatment for oesophageal cancer, either alone or in combination with surgery and/or chemotherapy, the radiation volume should encompass the detectable tumour and the anatomic areas at risk for metastatic spread. In oesophageal cancer it is hard to determine these areas for the individual tumour. Moreover, the areas at risk are very large and this implies that if all areas at risk need to be covered, large radiation volumes are necessary.

Guidelines for selection of target volumes

According to the International Commission on Radiation Units and Measurements (ICRU) 50 guidelines, radiation oncologists use three different target volumes for radiotherapy planning: (1) gross tumour volume (GTV): gross extent of the malignancy as determined by all available means; (2) clinical target volume (CTV): GTV together with areas of possible subclinical microscopic disease; (3) planning target volume (PTV): CTV plus a margin to ensure that the CTV receives the prescribed dose [94].

When delineating the target volumes for oesophageal cancer, the radiation oncologist should make sure that the clinical target volume adequately encompasses all gross disease (whether primary tumour or macroscopically invaded lymph nodes) as well as lymph node areas at risk. Due to the anatomy of the oesophagus this will inevitably lead to large radiation volumes. Many of these more distant nodes are only microscopically invaded and the total dose given to these regions at risk does not need to be as high as the dose needed to treat macroscopic disease. The use of shrinking volumes is a logical approach to eliminate distant microscopically invaded lymphatics and nodes from the irradiated volume while limiting toxicity.

Delineation of the GTV

The GTV is delineated on planning CT, taking all clinical, endoscopic, and radiological information into account. FDG-PET/CT can play an important role in the planning of RT. The high-dose volume should be extended to include lymph nodes that are PET-positive without suspicion on CT or EUS [95]. The FDG uptake in the primary tumour can also be useful in the delineation of the primary tumour, with good correlation between PET-based length and pathological specimens [95]. Use of FDG-PET has been shown to reduce inter-observer variability with reduction of geographical miss of gross tumour. The dose distribution in normal tissue will change in a large majority of cases compared to CT-only planning, with a reduction of dose to the heart and lungs [96].

CTV margins around the primary tumour

Oesophageal cancer is notorious for its ability to spread intramurally distant from the main lesion. Oesophageal cancer can spread longitudinally and radially. Longitudinal spread occurs in both distal and proximal directions along the intramural lymphatic network and perineural spaces, with intramural localizations up to 5–6 cm from the primary tumour. In a study of 393 patients with SCC in the thoracic oesophagus, 60 were found by histological examination to have intramural metastasis [97].

The CTV should probably include 4–5 cm margins beyond the macroscopic tumour extent in the anterio-caudal direction and less (1.5–2.0 cm) horizontally around the GTV [98]. For adenocarcinoma of the lower third of the oesophagus and GEJ, the caudal extension of the CTV includes a 3–4 cm margin of gastric cardia below the lower border of GTV [99].

Elective nodal CTV

The oesophagus has a dual longitudinal interconnecting system of lymphatics in the lamina propria and the other in the muscularis mucosae. As a result of this system, lymph fluid can travel over the entire length of the oesophagus before draining into the lymph nodes [100]. Although upper oesophageal tumours spread mainly to the cervical and supraclavicular regions, involvement of the celiac nodes can occur in 10–30% of these tumours. The opposite is also true: involvement of the supraclavicular nodes can occur in 10–30% of patients with lower oesophageal tumours [100].

It is generally accepted that lymph node regions with a probability of 15–20% or more to be microscopically invaded should be included in the CTV. This would mean that the celiac trunk nodes do not need to be included in the CTV for all tumours of the upper and middle oesophagus. However, most cases referred for radiation have an advanced stage at diagnosis and are referred for preoperative, i.e. neoadjuvant, treatment. So the estimated percentage of involved nodes deduced from surgical series is probably lower than the probability among those patients referred for radiotherapy.

A recent meta-analysis pooled results from 45 observational studies with a total of 18,415 oesophageal carcinoma patients, > 90% with SCC [101]. The pooled estimates of lymph node metastasis rate in upper, middle, and lower thoracic oesophageal cancer were 30.7%, 16.8%, and 11.0% cervical; 42.0%, 21.1%, and 10.5% upper mediastinal; 12.9%, 28.1%, and 19.6% middle mediastinal; 2.6%, 7.8%, and 23.0% lower mediastinal; and 9%, 21.4%, and 39.9% abdominal, respectively. Lymph node metastases were most frequent in the paratracheal (31.7%) and perigastric (30.0%) lymph node areas, suggesting that these should always be included in the CTV [101].

For upper oesophageal cancer, cervical and upper mediastinal nodes should probably be included in the CTV, especially the supraclavicular, upper thoracic paraoesophageal, and thoracic paratracheal lymph nodes. Tumours located in the mid-oesophagus can skip not only up to the cervical lymph nodes, but also down to the abdomen. Thus, the CTV should include cervical, upper, middle mediastinal and abdominal portions, especially thoracic paratracheal, subcarinal, middle thoracic paraoesophageal, and lymph node stations around the cardia and the left gastric artery. As to the lower oesophagus, the CTV should cover the middle, lower mediastinal, and abdominal regions, especially including the lower thoracic paraoesophageal lymph nodes and the stations around the cardia, greater and lesser curvature, and the left gastric artery [101].

Regarding gastro-oesophageal junction adenocarcinoma, the European Organization for Research and Treatment of Cancer (EORTC) developed expert guidelines for target volume delineation in 2009. They advocate including the para-oesophageal lymph nodes in the lower thorax, the supra-diaphragmatic lymph nodes, the lymph nodes in the oesophageal hiatus of the diaphragm, the infra-diaphragmatic lymph nodes, those along the left gastric artery and around the celiac artery, as well as the right and left paracardial lymph nodes in all cases. For Siewert type I tumours, i.e. distal oesophageal tumours, the posterior mediastinal lymph nodes should also be included. In Siewert type II tumours, the lymph nodes along the lesser curvature, the short gastric vessels and the proximal splenic artery should be incorporated into the CTV. Siewert type III tumours should be delineated as gastric tumours and the CTV should at the very least include the lymph nodes along the lesser curvature, the short gastric vessels and the proximal as well as distal splenic artery, and the lymph nodes at the splenic hilum [99].

Techniques

The thoracic and upper abdominal region is a complex site for radiotherapy, because normal (e.g., lungs, heart, and spinal cord) and tumoural structures generally lie in close proximity to each other. The introduction of conformal radiotherapy with three-dimensional treatment planning (3D-RT) on CT scans signified a first major improvement over conventional two-dimensional radiotherapy (2D-RT), where the treatment portals are based on a radiographic simulation film. Forward treatment planning is employed for both 2D-RT and 3D-RT, which essentially consists of the radiation oncologist designing the RT fields and the radiation physicist generating an optimized dose distribution. In contrast, inverse treatment planning is employed with intensity-modulated radiotherapy (IMRT) and consists of identifying the target volumes and organs at risk on the planning CT. The dose to the tumour is specified, as well as the maximum acceptable doses to adjacent normal structures, and the physicist uses that information to produce the optimal plan, i.e. one that ensures target coverage by the prescribed radiation dose while reducing doses to the organs at risk. It may be expected that treatment with IMRT will result in fewer side effects [102].

Close patient monitoring and aggressive supportive care are essential during radiation treatment. Management of acute toxicities is necessary to avoid treatment interruptions or dose reductions. Anti-emetics should be given on a prophylactic basis when appropriate. Antacid and antidiarrhoeal medications may be prescribed when needed. If the caloric intake is inadequate, oral and/or enteral nutrition should be considered. Feeding jejunostomies or nasogastric feeding tubes may be placed if clinically indicated. Adequate enteral and/or intravenous hydration is necessary throughout CRT and early recovery.

Dose and fractionation schedules

Total radiation dose and daily fraction size are obviously important determinants for locoregional tumour control as well as acute and late toxicity. Definitive radiation therapy (i.e. without further surgery) requires a total dose of at least 59.4 to 66.6 Gy in daily fractions of 1.8 to 2.0 Gy. Smaller daily fractions (i.e. 1.8 instead of 2.0 Gy) potentially reduce the likelihood of late toxicity [98, 103].

The optimal radiation dose and fractionation schedule for pre- or postoperative radiotherapy has never been prospectively defined, although a total dose of at least 45.0 to 50.4 Gy is usually administered in 25 to 28 daily fractions of 1.8 Gy, five days per week, with adequate locoregional control and acceptable toxicity [98, 103].

Dose constraints for organs at risk

The complete volumes of the lungs, the liver, the kidneys, and the heart have to be delineated. Spinal cord must be outlined along the whole volume interested by the beams plus 2 cm above or below this volume.

Every effort should be made to keep the lung volume and doses to a minimum. Normal lung (>2 cm outside the target volume) should never receive more than 40 Gy. To reduce the incidence of postoperative pulmonary complications, a possible guideline is to limit the proportion of total lung receiving 20 Gy or more to 20% (V20 <20%) and 10 Gy or more to 40% (V10 <40%). Furthermore, the combined lung volume receiving less than 5 Gy should be higher than 2300 cc [98].

Further attention should be devoted to reduce unnecessary dose to other normal structures [98]. The maximal spinal cord dose must not exceed a total dose of 45 Gy. In case of combined modality treatment with concomitant chemotherapy this dose should probably be lowered. The whole heart must not have more than 30% exposed to a total dose of 40–50 Gy and not more than 50% exposed to a total dose of 25 Gy. Special effort should be made to keep the left ventricle doses to a minimum. At least 70% of one physiologically functioning kidney should receive a total dose of less than 20 Gy (V20 <60–70%). For the contralateral kidney, the volume exposed to more than 20 Gy has to be less than 30% (V20 <30%). Overall, not more than 50% of the combined functional renal volume should receive more than 20 Gy. Caution is required if the treatment is combined with chemotherapy, as there are no reports of the effect of concomitant treatment on renal function. The liver must not have more than 30% of its volume exposed to more than 30 Gy (V30 <30%). However, it is recognized that these guidelines may be exceeded as needed to achieve other important planning goals [98].

Brachytherapy

Brachytherapy permits treatment of a localized area of the oesophagus to high radiation doses with relative sparing of surrounding structures. This technique may be used alone or in combination with external beam radiotherapy with or without chemotherapy.

Brachytherapy involves intraluminal placement of a radioactive source into the oesophagus with a nasogastric applicator. With the introduction of small sources like Iridium-192 into afterloading brachytherapy, treatment of advanced obstructive tumours became possible using applicators with a small diameter (down to 1.7 mm).

For patient comfort, high dose rate (HDR) brachytherapy is common practice, although there is also some experience with low dose rate (LDR) brachytherapy. Modern HDR equipment delivers radiation much faster than 0.2 Gy/minute, permitting the delivery of a planned dose within minutes. Since HDR delivers a high dose of radiotherapy in a short period of time, fractionation is necessary; typically two to four fractions are administered for treatment of oesophageal cancer.

Total dose, fractionation, and overall treatment time of radiotherapy depend on the intent of treatment. For treatment with curative intent, a dose of 50–60 Gy (2 Gy per fraction) by external beam radiotherapy is followed by one or two brachytherapy applications with 5 to 6 Gy (HDR). The total dose for brachytherapy alone in a palliative setting is 15–25 Gy given in three to four HDR brachytherapy applications (4-6 Gy per fraction).

Brachytherapy alone is a palliative modality and results in a local control rate of 25–35% and a median survival of approximately five months. In the randomized trial from Sur et al., no significant difference was seen in local control or survival with high-dose brachytherapy compared with external beam [104].

Regarding combined modality treatment, no randomized data are available and results from retrospective analyses are mixed. The Radiation Therapy Oncology Group (RTOG) 92-07 trial prospectively combined CRT (5-FU and cisplatin with 50 Gy of external beam radiotherapy) with an intraluminal brachytherapy boost (20 Gy LDR or 15 Gy HDR) in 75 patients [105]. The HDR boost dose was reduced to 10 Gy after an interim analysis suggested high levels of treatment-related toxicity. Local failure was 27%, and acute toxicity included 58% of patients with grade 3 toxicity, 26% with grade 4, and 8% with grade 5. The cumulative incidence of fistula was 18% per year, and the crude incidence was 14%. Therefore, the benefit of adding intraluminal brachytherapy to curative radiotherapy, although theoretically interesting, remains unclear.

Medical management

Chemotherapy

Although there is a clear role for chemotherapy in oesophageal cancer, many studies have shortcomings. The strategy can be grouped into different potential indications: (1) peri-operative chemotherapy in resectable gastro-oesophageal junction adenocarcinoma, based on studies in gastric cancer, including gastro-oesophageal adenocarcinoma; (2) post-operative chemotherapy in gastro-oesophageal junction adenocarcinoma, also based on studies in gastric cancer, including gastro-oesophageal adenocarcinoma; (3) combined strategy with radiotherapy in the neoadjuvant treatment; (4) combined strategy with radiotherapy in the post-operative treatment of gastro-oesophageal junction adenocarcinoma based on studies in gastric cancer, including gastro-oesophageal adenocarcinoma; (5) metastatic squamous cell adenocarcinoma; and (6) metastatic adenocarcinoma. There is no evidence-based role as single modality for chemotherapy in the preoperative or post-operative treatment setting of SCC [106–108].

Amongst the shortcomings of published trials are the simultaneous inclusion of SCC and adenocarcinoma in many combined modality trials of locally advanced disease and in some trials in metastatic disease, the inclusion of locally advanced and metastatic disease, the heterogeneity of the chemotherapy and CRT regimens, and the relatively small sample size of many trials, with resulting weak statistical hypotheses.

Although there is no single standard regimen in combination regimens with radiotherapy, most modern studies and recommendations include combinations of two classic cytotoxic agents [109]. In combination with radiotherapy, the most frequently recommended regimens include a fluoropyrimidine/platinum based combination (often 5-FU and cisplatin). Recently, however, the combination of carboplatin and paclitaxel seems to be an excellent alternative with limited toxicity in combination with radiotherapy as demonstrated by Dutch investigators in the CROSS trial [110]. Potential valid alternatives to these cytotoxics include oxaliplatin, irinotecan, docetaxel, and capecitabine in different combinations, although these combinations have been evaluated less extensively in adequate phase III studies.

In patients with metastatic SCC, the number of high-quality randomized phase III studies remains limited. Often a combination of a fluoropyrimidine (5-FU or capecitabine) and a platinum (cisplatin or oxaliplatin) is proposed. There are, however, also limited data suggesting some activity of the taxanes (docetaxel and paclitaxel) and irinotecan.

Metastatic GEJ adenocarcinoma has been studied more extensively, since most of these patients are treated similar to patients

with metastatic adenocarcinoma of the stomach in a large number of well performed phase II trials (see Chapter on Gastric cancer). The evidence is, however, growing that there may be clear molecular differences between gastro-oesophageal junction adenocarcinoma and gastric adenocarcinoma (e.g., higher HER2 positivity rate in GEJ cancer and potentially different benefit from bevacizumab in Western patients) [111]. Although oesophageal adenocarcinoma is often treated in the same way as GEJ adenocarcinoma, it has never been demonstrated that these patients derive a similar benefit from chemotherapy. The regimens in metastatic adenocarcinoma often include a doublet and sometimes a triplet: the doublet often consists of a fluoropyrimidine (5-FU, capecitabine or S1) and a platinum (cisplatin or oxaliplatin). The triplets include these drugs added with docetaxel or epirubicin. The data on epirubicin are controversial and there is wide geographic difference in the addition of epirubicin to a fluoropyrimidine/platinum backbone. The taxanes docetaxel and paclitaxel and irinotecan are alternatives in first-line combinations or are options in second-line chemotherapy for patients with metastatic disease [112].

Targeted agents

There is ongoing activity on the unravelling of the molecular targets and pathways playing a role in SCC and adenocarcinoma and on the evaluation of novel targeted agents, especially in adenocarcinoma: trastuzumab has been approved for HER2 positive metastatic GEJ and gastric adenocarcinoma [111]. Trastuzumab is now also under investigation in peri-operative chemotherapy studies and in preoperative CRT regimens. Amongst the other agents under investigation, mainly in metastatic adenocarcinoma (in part because adenocarcinomas are more frequent in developed countries that have the ability to perform clinical trials), the new HER2 blockers TDM-1 and pertuzumab, the EGFR and HER2 tyrosine kinase inhibitor lapatinib, the angiogenesis inhibitors bevacizumab and ramucirimab, the cMET inhibitors (antibodies and tyrosine kinase inhibitors), mTOR inhibitors, and fibroblast growth factor receptor inhibitors are of research interest. Disappointing results were reported recently on the anti-EGFR antibodies cetuximab and panitumumab in metastatic adenocarcinoma of the stomach and GEJ [113, 114]. However, further evaluation is ongoing in SCC of the oesophagus in combination with chemotherapy, analogous to SCC of the head and neck region.

Multidisciplinary management

Surgery remains the standard treatment for early stage oesophageal cancer, with good overall survival rates (Table 36.3). Still, its utility as a monotherapy has been rightly challenged, especially in more advanced disease [115]. Data from contemporary surgical series in those patients are relatively disappointing (Table 36.4), even in high-volume centres. In an analysis of 4627 patients with oesophageal cancer who were treated with surgery alone without adjuvant or neoadjuvant therapy, five-year survival rates were <50% for all disease stages except stage I, and they were 15% for any patient with node-positive disease [116]. Consequently, neoadjuvant (preoperative), adjuvant (post-operative), and non-operative strategies aimed at improving survival in patients with apparently localized disease have been developed.

(Chemo-)radiotherapy alone

Definitive radiotherapy

Before the seminal paper by Herskovic et al., radiotherapy alone was sometimes performed in patients without distant metastases who were medically or surgically inoperable. Results were generally disappointing: in a meta-analysis of 49 historical series involving more than 8400 patients treated with radiotherapy alone, survival rates at one, two, and five years were only 18%, 8%, and 6%, respectively [117]. However, it should be noted that with modern radiotherapy and staging techniques, better results can be achieved. In a more recent retrospective analysis of 101 patients (only 11 adenocarcinomas) treated between 1985 to 1994, definitive radiotherapy was associated with a five-year survival rate up to 21% [118]. In that analysis, survival was better for adenocarcinoma than for SCC, though not statistically significantly. The only significant prognostic factor was the use of diagnostic CT scanning (42% versus 13% five-year survival with or without CT scanning, respectively, p = 0.01), which was associated with an increase in field size. This suggests that older, more unsatisfactory outcomes with definitive radiotherapy could be related to inadequate staging and patient selection, as well as outdated radiation techniques.

The potential of modern radiation techniques can be illustrated by a Chinese randomized trial in which surgery was compared to radiotherapy alone in 269 patients with oesophageal SCC [119]. Obviously, the quality of the surgery cannot be assessed, but lymph node dissection appears to have been limited. In the radiotherapy group, patients received a rather high total dose of 68.4 to 71.0 Gy without concomitant chemotherapy. The five-year overall survival rate was 36.9% in the surgery group versus 34.7% in the radiotherapy group, without statistical difference between the two groups. Obviously, such results cannot be extrapolated to patients with adenocarcinoma.

Still, the role for definitive radiotherapy alone appears limited, and concomitant chemotherapy should be prescribed whenever possible.

Definitive CRT

Theoretically, concurrent CRT should permit maximal tumour control through (1) higher locoregional control because of the additive, so-called radiosensitizing, effect of the chemotherapy on radiotherapy; (2) higher systemic control since the chemotherapy potentially reduces (micro-) metastatic disease.

As mentioned before, the seminal Herskovic paper was the landmark RTOG 85-01 trial, comparing radiotherapy alone (64 Gy in 32 fractions over 6.5 weeks) versus radiotherapy (50 Gy in 25 fractions over five weeks) with concurrent CRT (two cycles of 5-FU plus cisplatin) in patients with thoracic oesophageal cancer [25]. The CRT group received two additional chemotherapy courses, three weeks apart, after RT. Surgery was not part of the treatment schedule. It should be noted that the overall majority of patients (>90%) had SCC. The trial was stopped after the accumulated results in 121 patients demonstrated a significant advantage for survival in the patients who received CRT. In the radiotherapy group, two-year survival rate was 10%; the concomitant CRT group had a two-year survival rate of 38% (p <0.001). The patients who received combined treatment had significantly fewer local and distant recurrences. Severe toxicity was higher in the combined treatment arm (44% versus 25%). The trial was updated in 1999, confirming the important survival advantage of concomitant

chemotherapy: five-year survival with CRT was 26% versus 0% with RT alone [120]. Persistence of disease was the most common mode of treatment failure; however, it was less common in the groups receiving combined therapy (26%) than in the group treated with radiotherapy only (37%). There were no significant differences in severe late toxic effects between the groups.

In order to assess the optimal radiation dose in definitive CRT, the RTOG 94–05 trial compared a total dose of 50.4 versus 64.5 Gy (in daily 1.8 Gy fractions), both given in combination with cisplatin and 5-FU [121]. The higher radiation dose failed to show superiority compared to the lower dose with regards to local tumour control, overall survival, and relapse-free survival. On the other hand, acute adverse effects and treatment-associated deaths were significantly more common with the higher dose. Therefore, the regimen from RTOG 85–01 is still regarded as a reference regimen [25]. In many experienced centres, variations of this protocol have been developed and higher radiation doses are applied as a boost to smaller target volumes.

Combined approaches

Preoperative CRT

The often disappointing results with surgery alone and the apparent success and feasibility of definitive CRT have provided the motivation for the evaluation of combining CRT with surgery in an effort to further improve survival. Consequently, neoadjuvant CRT has been the most commonly investigated approach in the treatment of resectable oesophageal cancer in recent years.

At least nine trials compared surgery alone to some sort of preoperative CRT schedule for patients with potentially resectable oesophageal cancer [110, 122–129]. The most recent and largest meta-analysis included 1932 patients from 13 randomized trials [109]. The hazard ratio (HR) for the reduction of the overall mortality was 0.78 in favour of CRT (p = 0.002), resulting in an absolute two-year survival benefit of 8.7%. The benefit for patients with oesophageal SCC and patients with oesophageal adenocarcinoma was comparable.

Preoperative CRT increases the post-operative morbidity and mortality, according to some, but not all, studies. Three meta-analyses report on significantly increased post-operative morbidity and mortality following preoperative CRT [130–132]. However, the post-operative mortality was not increased when studies with dose per fraction above 2 Gy were not included [130].

The potential deleterious effects of preoperative CRT are only partly understood. Radiation in higher doses causes a disruption of the alveolar diffusion capacity and thereby deteriorates the pulmonary gas exchange. As a consequence, post-operative respiratory insufficiency occurs more often in irradiated patients [133]. Therefore, as emphasized above, current concepts of preoperative radiation treatment confine the target volumes to a necessary extent, limiting especially the exposure of the lungs. In this context, currently available techniques of intensity-modulated radiation treatment planning may have additional benefit.

The recently published CROSS trial is a prospective randomized controlled trial comparing surgery alone with neoadjuvant CRT followed by surgery [110]. It is the largest study investigating preoperative CRT in oesophageal cancer. Dutch investigators randomly assigned 363 patients with potentially resectable cancer (24% SCC, 76% adenocarcinoma) of the oesophagus or the gastro-oesophageal junction (in 11% of cases) to preoperative radiotherapy of 41.4 Gy over five weeks with weekly paclitaxel plus carboplatin or surgery alone. Preoperative CRT was well tolerated, with grade 3 or worse hematologic toxicity in 7%, and grade 3 or higher non-hematologic toxicity in <13%; there were also no differences in post-operative morbidity or mortality between the two groups. The complete (R0) resection rate was higher with CRT (92% versus 69%, p < 0.001), and 29% of those treated with CRT had a pathological complete remission (pCR). At a median follow-up of 32 months, median overall survival was significantly better with preoperative CRT (three-year survival rate 58% versus 44%, p = 0.003). Therefore, CROSS certainly defines the new standard of care for advanced (T3-4 or N+) disease.

In less advanced disease, upfront surgery will remain the standard of care, and preoperative CRT appears to add little. A French randomized trial by the Fédération Francophone de Cancérologie Digestive (FFCD) tried to assess whether preoperative CRT improves outcomes for patients with localized (stages I or II) oesophageal cancer [129]. In the FFCD 9901 trial, 195 patients were randomized from 2000 to 2009: 98 were assigned to surgery alone and 97 to neoadjuvant CRT, consisting of a dose to 45 Gy in 25 daily fractions of 1.8 Gy with 2 courses of concomitant chemotherapy (5-FU and cisplatin). After a median follow-up of 5.7 years, median overall survival was 43.8 months in the surgery group versus 31.8 months (p = 0.66) in the combined modality arm. Post-operative mortality rates were 1.1% in the surgery group versus 7.3% in the CRT group (p = 0.054), respectively. These data strongly suggest that neoadjuvant CRT does not improve overall survival but enhances post-operative mortality rate with this regimen for patients with early oesophageal cancer compared with surgery alone.

A consistent finding in many studies is that response to preoperative CRT, particularly the absence of residual disease in the surgical specimen, is an indication of better disease-free and overall survival. In a comprehensive literature review of 22 studies in which patients with oesophageal or gastro-oesophageal junction cancer underwent oesophagectomy after neoadjuvant CRT, patients with a pCR were two- to three-fold more likely to survive as were those with residual disease in the oesophagectomy specimen [134]. Overall survival for patients with pCR was 93.1%, 75.0%, and 50.0% at 2, 3, and 5 years, respectively, whereas it was 36.8%, 29.0%, and 22.6% for patients with residual tumour (p < 0.025).

These results provide the rationale for intensification of preoperative treatment. Apparently, escalation of the radiation dose will not be the answer [121]. Perhaps intensification of the chemotherapy schedule could further improve results. Several groups have reported their experience with sequential induction chemotherapy followed by CRT. Encouraging as some of these results might be, it should be noted that no randomized trial to date has compared sequential induction chemotherapy followed by CRT to standard CRT. Moreover, it remains to be seen whether the added toxicity of any of these approaches is balanced by substantial survival gains.

Preoperative chemotherapy

Multiple randomized trials have evaluated the benefit of chemotherapy administered prior to surgery. A survival benefit for neoadjuvant chemotherapy relative to surgery alone was shown in the recent meta-analysis on neoadjuvant treatments, including nine randomized comparisons (n = 1981) of neoadjuvant chemotherapy versus surgery alone for oesophageal or gastro-oesophageal

junction cancer [109]. The HR for all-cause mortality for neoadjuvant chemotherapy was 0.87 (95% CI 0.70–0.88), and this translated into an absolute survival benefit at two years of 5.1% and a number needed to treat to prevent one death of 19. The potential benefit of neoadjuvant chemotherapy was not offset by a higher post-operative mortality. The HR for SCC was 0.92 (0.81–1.04; p = 0.18) and for adenocarcinoma it was 0.83 (0.71–0.95; p = 0.01).

Preoperative chemotherapy or chemoradiotherapy?

Only one published trial, the German POET trial, directly compared preoperative CRT to neoadjuvant chemotherapy alone followed by surgery [135]. A total of 119 patients with locally advanced adenocarcinoma of the lower oesophagus or gastric cardia were randomly allocated to one of two treatment groups: induction chemotherapy (15 weeks of cisplatin plus 5-FU) followed by surgery; or chemotherapy (12 weeks of identical chemotherapy) followed by low-dose radiotherapy (30.0 Gy in 15 daily fractions of 2.0 Gy) concurrent with cisplatin and etoposide, followed by surgery. The study was prematurely closed due to low accrual. Although consequently underpowered, patients in the radiotherapy arm had a significantly higher probability of showing pCR (15.6% versus 2.0%) at resection. Preoperative radiotherapy improved three-year survival rate from 27.7% to 47.4% (p = 0.07]. Post-operative mortality was non-significantly increased in the CRT group (10.2% versus 3.8%; p = 0.26). Considering the importance of achieving pCR, these results demonstrate that radiotherapy is an indispensable component of the neoadjuvant treatment schedule for adenocarcinoma of the lower oesophagus and gastro-oesophageal junction. Whether these results can be extrapolated to SCC of the thoracic oesophagus is uncertain, but results from the CROSS trial strongly suggest that the benefit in those patients might be even larger [110].

The Sjoquist meta-analysis showed HR for all-cause mortality was 0.77 in favour of CRT compared to chemotherapy alone, but this was not statistically significant [109].

A randomized trial, the TOPGEAR trial, has been initiated to directly compare preoperative chemotherapy alone (consisting of epirubicin, cisplatin, and 5-FU [ECF]) versus CRT (two cycles of ECF followed by concurrent fluoropyrimidine-based CRT) in patients with resectable adenocarcinoma of the stomach and gastro-oesophageal junction. Both groups will receive three further cycles of ECF post-operatively.

Response assessment after neoadjuvant therapy

The early evaluation of response to neoadjuvant therapy (chemotherapy alone or CRT) has been extensively studied for oesophageal carcinoma. The therapy-induced reduction in FDG uptake is more pronounced than the morphological changes and precedes them by several weeks [136]. Patients with more pronounced reduction in uptake ('metabolic responders') have a better outcome than patients without or with a less pronounced reduction in FDG uptake ('metabolic non-responders'). For example, in one study the three-year survival rate was 70% versus 35%, respectively [137, 138]. In one prospective study (the Municon trial), after two weeks of initial cisplatin-based induction therapy metabolic non-responders were treated with immediate surgery whereas metabolic responders received a full course of neoadjuvant chemotherapy before surgery [139]. Compared to metabolic non-responders, the metabolic responders had a better median event-free survival (29.7 months versus not reached) and overall survival (14.1 and

25.8 months). In a follow-up study, the Municon II trial, metabolic non-responders after 14 days of chemotherapy were treated with salvage CRT whereas metabolic responders were treated with only chemotherapy, with surgery at the end of treatment in both groups [140]. The outcome in the metabolic non-responder group was significantly worse than in the metabolic responders, despite the more intense treatment. In other studies, early response prediction with FDG-PET was less accurate, with sensitivity and specificity of 70% in a recent meta-analysis, so that routine clinical adoption of PET-based treatment decisions is not warranted, and should only be done within the scope of prospective clinical trials [141]. In the US, a trial of PET-directed neoadjuvant therapy (NCT01333033) is being performed, in which metabolic non-responders will have their induction chemotherapy changed to a different regimen during radiation.

Is surgery still necessary?

Clearly, neoadjuvant treatment with chemotherapy and especially CRT improves survival in advanced, but not early-stage, oesophageal cancer. Particularly striking is the large percentage of patients with pCR in modern series (e.g., up to 30% in the recent CROSS trial [110]). Similarly remarkable is the observation that with modern definitive CRT series long-term overall survival rates can be achieved that are quite high, up to 30–40% [121, 142]. This raises the interesting question as to whether surgery is still always necessary and if concomitant CRT might not one day become the standard of care in selected patients [143].

Historical, non-randomized results from the 1992–1994 Patterns of Care study and the 1988–2006 SEER regional database suggest a survival benefit for post-CRT oesophagectomy [144, 145]. In addition, locoregional disease persistence is not uncommon in older series on CRT without surgery [25].

At least two randomized trials directly comparing CRT alone to CRT followed by surgery have failed to demonstrate better survival, although both show better locoregional control and a lesser need for palliative procedures when surgery is a component of multimodality treatment. It should be noted that the patient populations in both were either exclusively or predominantly SCC.

Stahl et al. randomly allocated 172 patients with locally advanced SCC of the oesophagus to either induction chemotherapy (3 cycles of 5-FU, leucovorin, etoposide, and cisplatin) followed by CRT (total dose to 40.0 Gy with cisplatin plus etoposide) followed by surgery or the same induction chemotherapy followed by CRT (at least 65.0 Gy with cisplatin plus etoposide) without surgery [146]. Treatment-related mortality was higher in the trimodality arm (12.8% versus 3.5%). After a median follow-up time of six years, the surgically treated patients had significantly better local control (two-year local progression-free survival 64% versus 41%; p = 0.003), but this did not translate into significantly better overall survival at three (31% versus 24%) or five (28% versus 17%) years. In comparison to other trials using concomitant CRT alone or followed by surgery, radiotherapy doses and the intensity of chemotherapy were low. This may in part explain the lower survival rate in the non-surgically treated patients when compared to the results of RTOG 85-01 [25].

In the French FFCD 9102 trial, 444 patients with potentially resectable (cT3N0-1) thoracic oesophageal SCC (89%) or adenocarcinoma (11%) received two cycles of 5-FU and cisplatin and either conventional (46 Gy in 4.5 weeks) or split-course (15 Gy,

days 1 to 5 and 22 to 26) concomitant radiotherapy [147]. Patients with response and no contraindication to either treatment were randomly assigned to surgery or continuation of CRT (three more cycles of 5-FU/cisplatin and either conventional (20 Gy) or split-course (15 Gy) radiotherapy). Two-year survival rate was 34% in the surgery group versus 40% in the CRT group (p = 0.44). Two-year local control rate was 66.4% in the surgical arm compared with 57.0% in the CRT arm, and stents were less required in the surgical arm (5% versus 32%, p <0.001). Again, the initial (three-months) mortality rate was 9.3% in the surgical arm compared with 0.8% in the CRT arm (p = 0.002).

In conclusion, although no significant survival advantage of surgical treatment was proven in these studies, there is a significant advantage for locoregional control in favour of surgical treatment. Therefore, surgical resection should be recommended in patients without contraindications and willing to take the risk of post-operative morbidity and mortality, particularly in adenocarcinoma patients since there are few data on non-surgical management and the rate of pCR is relatively low for adenocarcinoma as compared to SCC. Until now, there are scarce data on the efficacy of definitive CRT in oesophageal adenocarcinoma. Therefore, CRT alone is not a proven and established alternative to surgery. For patients with SCC who have an endoscopic complete response, non-operative management is an option balancing the risks of surgical mortality versus improved locoregional control.

Adjuvant therapies

Clearly, patients with cT3-4a and/or clinically node-positive oesophageal or gastro-oesophageal junction cancer should ideally be offered induction therapy with chemotherapy or CRT before surgical resection. Still, some patients will go immediately to surgery, usually because the extent of the disease was underestimated on preoperative EUS or imaging. For patients who are found to have advanced disease after surgery alone, the addition of post-operative, additional therapy (chemotherapy with or without radiotherapy) should be considered in an effort to improve outcome.

Adjuvant chemotherapy

Since trials of post-operative chemotherapy in oesophageal cancer did not show any benefit and suffered from many short-comings, post-operative chemotherapy in SCC cannot be recommended routinely. The data in GEJ adenocarcinoma are, however, more difficult to interpret, since the trials of post-operative chemotherapy usually include both gastric as well as GEJ adenocarcinoma. Most individual trials in Western patients did not show benefit, while the trials in Asia with adjuvant chemotherapy (predominantly S1) in mainly gastric adenocarcinoma showed benefit. A few relatively small combined analyses showed conflicting results. A large meta-analysis on adjuvant chemotherapy in adenocarcinoma based on individual patient data, however, showed a statistically significant and relevant benefit in favour of post-operative chemotherapy compared to surgery alone [148]. In that analysis from 17 trials (3838 patients) with a median follow-up exceeding seven years, adjuvant chemotherapy was associated with a statistically significant benefit in terms of overall survival (HR 0.82; p <0.001) and disease-free survival (HR 0.82; p < 0.001). Five-year overall survival increased from 49.6% to 55.3% with chemotherapy. The authors concluded that, post-operative adjuvant chemotherapy based on fluorouracil regimens was associated with reduced risk of death compared with surgery alone [148]. Since this is a meta-analysis, and since numerically the benefit remains smaller than that of perioperative chemotherapy and of post-operative chemoradiotherapy in GEJ and gastric adenocarcinoma, the level of recommendation of post-operative CRT remains lower and this option is only recommended in patients with high-risk tumours who were not offered a preoperative treatment and who are not good candidates for post-operative CRT.

Adjuvant chemoradiotherapy

For patients with node-positive adenocarcinoma of the GEJ, post-operative CRT is a well-established approach. The large Intergroup trial (INT-0116) by Macdonald et al. is undoubtedly the most important study in that respect [149]. A total of 556 patients with pT1-4 pN0-1 resected adenocarcinoma of the stomach (80%) or gastro-oesophageal junction (20%) were randomly assigned to active surveillance or post-operative CRT (one cycle of 5-FU with leucovorin (LV), followed by 45 Gy in 25 fractions of 1.8 Gy with 5-FU and LV during the first and last week, followed by two more cycles of 5-FU/LV) or surgery alone. The median overall survival in the surgery-only group was 27 months, as compared with 36 months in the CRT group (p = 0.005), although only 64% of patients could finish the combined modality arm as planned. Patients with gastro-oesophageal junction adenocarcinoma appeared to derive the same benefit as those with non-cardia gastric cancer.

Fuchs et al. tried to improve on the INT-0116 trial by prescribing ECF (epirubicin, cisplatin, and 5-FU) instead of 5-FU/LV before and after radiotherapy to 45 Gy with concomitant 5-FU [150]. They included 546 patients with resected gastric or gastro-oesophageal junction adenocarcinoma, but median disease-free survival was nearly identical (30 months in the 5-FU/LV group versus 28 months in the ECF group) in both arms.

In the current Dutch CRITICS trial, all patients will receive induction chemotherapy followed by surgery and randomization to post-operative chemotherapy versus CRT.

For other patients, particularly those with an oesophageal SCC, the optimal approach is uncertain. Some uncontrolled trials and retrospective comparisons of patients treated with and without CRT suggest potential benefit for post-operative CRT. However, others do not, and there are no randomized trials proving benefit as compared to surgery alone, or indeed post-operative chemotherapy [151].

Palliative treatment

Palliative systemic therapy

The prognosis of patients with metastatic oesophageal cancer remains very poor. It has been shown that patients in good condition and with good organ function treated with chemotherapy may derive a survival benefit from chemotherapy combinations, which remains, however, modest: the median survival of patients treated with best supportive care (BSC) is usually around three to four months, while with BSC plus chemotherapy it is around nine to 12 months. The development of regimens for therapy in oesophageal cancer is impeded, in part, by two histologies (squamous cell and adenocarcinoma) as well as the relatively small number of patients fit for clinical trials in developed countries.

Adenocarcinoma patients with advanced oesophageal adenocarcinoma or gastro-oesophageal adenocarcinoma are typically included in gastric cancer trials. For that reason, more extensive discussion of treatment options can be found in the text and tables dedicated to that disease (see Chapter on 'Gastric cancer'). For squamous cell cancers, regimens are typically selected that are used in squamous cell cancer of the lung or head and neck cancer, such as platinum compounds and taxanes, or regimens from trials which included both oesophageal histologies. An exhaustive search of clinical trial registries in late 2013 revealed no large trials of systemic therapies alone for oesophageal squamous cell cancers. In general, doublet therapy is preferred in first-line treatment, with second-line treatments comprising those drugs/classes not previously used. For example, a patient treated initially with capecitabine/oxaliplatin (± epirubicin) should subsequently receive a single-agent taxane, such as docetaxel.

The ECF (epirubicin, cisplatin, infusional 5-FU) and DCF (docetaxel, cisplatin, infusional 5-FU) combinations are considered standard regimens for first-line treatment in Western countries [152, 153]. In Japan, there is a significant benefit for the oral fluoropyrimidine S1 plus cisplatin over S1 alone in terms of response survival [154]. Therefore, S-1 plus cisplatin is the Japanese standard chemotherapy.

In the UK in particular, the REAL-2 phase III study in advanced gastric cancer were assigned to three weekly cycles of epirubicin plus cisplatin and either capecitabine or infusional 5-FU, or epirubicin plus oxaliplatin and either capecitabine or infusional 5-FU [155]. Based on the data from this study, and on clinical experience, oxaliplatin and capecitabine are frequently substituted in place of cisplatin and parenteral 5-FU in metastatic oesophageal cancer.

For HER2 positive metastatic gastro-oesophageal cancers, the benefits from trastuzumab apply from the ToGA trial, in which HER2 positivity more often found in gastro-oesophageal cancers than body of stomach (33.2 versus 20.9%) [156]. With trastuzumab combined with cisplatin plus either capecitabine or 5-FU, the median overall survival was 13.8 months (95% CI 12-16) in those assigned to trastuzumab plus chemotherapy compared with 11.1 months [10, 12, 13] in those assigned to chemotherapy alone (hazard ratio 0.74; 95% CI 0.60–0.91; p = 0.0046).

Explorations of the VEGF agent (bevacizumab) and the EGFR agents (panitumumab and cetuximab) combined with chemotherapy in gastrointestinal cancer have failed to show benefit (bevacizumab in combination with chemotherapy as first-line therapy in advanced gastric cancer; a randomized double-blind placebo-controlled phase III study [157 - 159].

For refractory or second-line therapies, active single agents are frequently used if not already given in first-line treatment. Ramucirumab, a monoclonal antibody VEGFR-2 antagonist, has been compared to BSC alone in this setting for gastro-oesophageal cancers (ramucirumab monotherapy for previously treated advanced gastric or gastro-oesophageal junction adenocarcinoma (REGARD: an international, randomized, multicentre, placebo-controlled, phase III trial) [160]. Median overall survival was 5.2 months in patients in the ramucirumab group and 3.8 months in those in the placebo group (hazard ratio 0.776, 95% CI 0.603–0.998; p = 0.047). This drug is likely to be approved in many countries, as a non-chemotherapy approach for this patient population.

Palliative local therapy

Dysphagia is undoubtedly the most important symptom in patients with advanced oesophageal cancer. Palliative resection is nowadays only seldom considered, and should probably be avoided. Endoscopic interventions include dilatation, laser therapy, endoscopic mucosal resection, and placement of self-expanding metal or plastic stents.

In a pivotal randomized trial by Homs et al., 209 patients with dysphagia from inoperable oesophageal carcinoma were assigned to metal stent placement or single-dose (12 Gy) HDR brachytherapy [161]. Dysphagia improved more rapidly after stent placement than after brachytherapy, but long-term relief of dysphagia was better after brachytherapy. Stent placement also had more complications than brachytherapy (33% versus 21%, p = 0.02), which was mainly due to an increased incidence of late haemorrhage. Quality-of-life scores were also in favour of brachytherapy. However, both groups did not significantly differ for persistent or recurrent dysphagia, or for median survival.

For patients with complete oesophageal obstruction, surgical or radiologic placement of jejunostomy or gastrostomy tubes may be necessary to provide adequate hydration and nutrition.

CHAPTER 37

Gastric cancer

Hideaki Bando, Takahiro Kinoshita, Yasutoshi Kuboki, Atsushi Ohtsu, and Kohei Shitara

Epidemiology

Gastric cancer is a malignant epithelial neoplasia which remains a common cause of cancer death worldwide, despite the recent steady decline in both the incidence and mortality of the disease. Several risk factors for gastric cancer have been reported. It has been suggested that *Helicobactor pylori* infection and diets containing N-nitroso compounds and salty foods may play important roles in the pathogenesis of this cancer. Several precancerous conditions (chronic gastritis and intestinal metaplasia) and precancerous lesions (adenoma and dysplasia) have been described in the stomach. Gastric adenocarcinoma has been morphologically classified into two types by Lauren (intestinal type and diffuse type) and by Nakamura (differentiated type and undifferentiated type). It has been shown that while the intestinal type adenocarcinoma predominates in high-risk areas, the diffuse type of gastric cancer is less likely to be related to environmental influences. According to the WHO classification, gastric adenocarcinoma can be subclassified into five subtypes: (1) tubular, (2) papillary, (3) poorly differentiated, (4) mucinous, and (5) mixed. Some morphological features are associated with genetic alterations with characteristic pattern of tumour spread and clinicopathological features. Hereditary diffuse gastric cancer, which is an autosomal-dominant cancer susceptibility syndrome having germline E-cadherin gene mutations, is characterized by the presence of multiple signet-ring cell carcinomas in the stomach.

Stomach cancer has been reported to be among the most frequently diagnosed malignancies in the world and remains the leading cause of cancer death worldwide. The incidence is high in eastern Asian countries such as Japan, China, and Korea, as well as Eastern Europe and Central and Latin America. North America, northern Europe and most countries in Africa and Southeast Asia represent areas of low incidence. There has been a steady decline in both the incidence and mortality of gastric carcinoma in the last three decades. The male–female ratio is 2:1, and the incidence of gastric cancer increases with age.

The major factors considered to be involved in the pathogenesis of gastric cancer have been classified into the following three categories: (1) environmental factors, (2) host factors, and (3) genetic factors. Environmental and host factors are thought to be the most important for intestinal-type gastric cancer, since families migrating from high-risk to low-risk areas acquire the level of risk that prevails in the new area [1]. Among the environmental factors, diet including smoked and salted foods and pickled vegetables appears to be the most significant [2]. The presence of N-nitroso compounds and benzopyrene in the diet may play an important role in gastric carcinogenesis [3]. In addition to the diet, *H. pylori* infection, which commonly takes place in early childhood and persists throughout adult life causing chronic atrophic gastritis, is important as a host factor [4, 5]. Inflammation induced by *H. pylori* causes chronic atrophic gastritis followed by intestinal metaplasia which is one of the precursor conditions prior to the development of gastric cancer.

Molecular biology of gastric cancer

There are two distinct types of gastric adenocarcinoma—intestinal (well-differentiated) and diffuse (undifferentiated)—which have distinct morphologic appearance, epidemiology, pathogenesis, and genetic profiles [6].

Intestinal-type cancers are causally related to *H. pylori*. While the infection usually starts in infancy or early childhood, there is a long latency period and cancers are typically clinically diagnosed four or more decades later [7]. During this period, a prolonged precancerous process takes place, represented by a cascade of events with the following well-characterized, sequential histopathologic stages: chronic active non-atrophic gastritis, multifocal atrophic gastritis, intestinal metaplasia, dysplasia (adenoma), and invasive carcinoma [8]. The manner in which environmental risk factors contribute to or influence the progression of *H. pylori*-induced gastric carcinogenesis is unclear.

Diffuse-type gastric cancers can also be induced by *H. pylori* infection, much as intestinal-type cancers. However, there are also prominent differences between these two variants. *H. pylori*-associated invasive intestinal-type cancers are characterized by a defined series of preneoplastic stages which are not seen in diffuse-type cancers. From an epidemiologic standpoint, both diffuse- and intestinal-type cancers have been decreasing in incidence in most countries, although the decline is more marked for intestinal-type cancers. Intestinal-type cancers are also more frequent in men and they are associated with a slightly better prognosis. Diffuse-type cancers are highly metastatic and characterized by rapid disease progression and a poorer prognosis than intestinal cancers. They also have a greater tendency to invade the gastric wall, sometimes extending to the lower oesophagus or to the duodenum. Occasionally, a broad region of the gastric wall or even the entire stomach is extensively infiltrated, resulting in a rigid thickened stomach, termed 'linitis plastica'. The main carcinogenic event in diffuse carcinomas is loss of expression of E-cadherin, a key cell surface protein for establishing intercellular connections and maintaining the organization of epithelial tissues [9].

Association between *Helicobacter pylori* infection and gastric cancer

The International Agency for Research on Cancer (IARC) has declared *H. pylori* to be a group I human carcinogen for gastric adenocarcinoma [10]. *H. pylori* can cause chronic active gastritis and atrophic gastritis, early steps in the carcinogenesis sequence. Furthermore, a number of studies in humans have demonstrated a clear association between *H. pylori* infection and gastric adenocarcinoma. The link has been demonstrated in both the intestinal and diffuse subtypes of gastric cancer. Two meta-analyses of cohort and case-control studies examining the relationship between *H. pylori* seropositivity and gastric cancer found that *H. pylori* infection was associated with a twofold increased risk for developing gastric adenocarcinoma [11, 12]. One of the largest prospective studies addressing *H. pylori* and cancer risk included 1526 Japanese patients, of whom 1246 had *H. pylori* infection [13]. Patients underwent endoscopy with biopsy at enrolment and then at one and three years. During a mean follow-up of 7.8 years, 36 patients developed gastric cancer (2.9%), all of whom were *H. pylori* infected. No uninfected patient developed cancer. Despite the clear association between *H. pylori* and gastric adenocarcinomas, only a minority of infected individuals will develop gastric cancer. Several hypotheses have been proposed to explain the role of *H. pylori* in carcinogenesis, although the exact mechanism is incompletely understood [14]. Initiation of the carcinogenesis process has been linked to oxidative stress brought about by inducible nitric oxide synthase (iNOS) which is produced by inflammatory cells responding to *H. pylori* infection. Nitric oxides are mutagenic and may induce abnormalities in the DNA of epithelial cells [3, 15]. Furthermore, two processes important in carcinogenesis are apoptosis (programmed cell death) and hyperproliferation. Following severe DNA damage, apoptosis occurs as a protective mechanism to prevent replication of mutated DNA. The mechanism by which *H. pylori* induces apoptosis is unclear. Proliferating cells may be resistant to apoptosis. This would upset the balance between cell growth and death, leading to hyperproliferation and the promotion of neoplasia. There is evidence of an increased amount of the anti-apoptosis protein, Bcl-2, in the setting of gastric dysplasia. Other reports have found that apoptosis may be due to plasminogen activator inhibitor (PAI)-2, the expression of which is increased by *H. pylori* and is increased in gastric cancer. An uncoupling of epithelial proliferation and apoptosis may be a strain-dependent phenomenon [16, 17].

In addition, certain polymorphisms in IL-1 beta and other cytokines may confer an increased susceptibility to non-cardia gastric adenocarcinoma caused by *H. pylori* by inducing a hypochlorhydric and atrophic response to *H. pylori* infection. An illustrative study compared IL-1 beta polymorphisms in 393 patients with gastric cancer compared with 430 controls. Two specific polymorphisms (IL-1B-31T and IL-1RN*2) were associated with low acid secretion and gastric atrophy. The authors concluded that 38% of *H. pylori*-related gastric cancer could be attributed to the presence of these alleles. IL-1 beta, a potent inhibitor of gastric acid secretion, is upregulated by the presence of *H. pylori* [18]. In addition, pro-inflammatory genotypes of tumour necrosis factor alpha (TNFα) and IL-10 were associated with more than a doubling of the risk of non-cardia gastric cancer. Carriage of multiple pro-inflammatory polymorphisms of IL-1 beta, IL-1 receptor antagonist, TNFα, and IL-10 conferred even greater risk. By contrast, these polymorphisms were not associated with an increased risk of oesophageal or gastric cardia cancers. These data suggest that gene polymorphisms influence cytokine expression, gastric inflammation, and risk for development of precancerous lesions in those infected with *H. pylori* [19].

Molecular biology of intestinal type cancer

Abnormalities in oncogenes, tumour suppressor genes, growth factors/receptors, cell cycle regulators, and epigenetic alterations have been identified. Some of these have been linked to *H. pylori* infection, while the relationship of many to *H. pylori* infection remains unresolved. Canonical oncogenic pathways such as E2F, RAS, p53, and Wnt/β-catenin signalling are also known to be deregulated with varying frequencies, suggesting a high degree of molecular heterogeneity.

Oncogenes, growth factors/receptors

Several oncogenes are over-expressed in various stages of gastric carcinogenesis, although none has consistently been shown to be present in any one particular stage.

KRAS/BRAF

The Ras–Raf–MEK–ERK–MAP kinase pathway plays a critical role in cell proliferation, and is frequently activated in cancer cells. Early involvement of KRAS mutations is suggested by their being found in invasive cancers, dysplasia, and intestinal metaplasia [20]. On the other hand, several studies have reported a low incidence of Ras gene mutation (codons 12, 13, and 61) in gastric carcinoma (roughly 0–10%). BRAF mutation is less common than Ras gene mutation. There seems to be no difference between Asian and Western gastric cancer [21].

EGFR

The epidermal growth factor receptor (EGFR) gene is located at chromosomal region 7p12 and encodes a 170-kDa transmembrane tyrosine kinase receptor. EGFR is activated by binding to its ligands such as epidermal growth factor or TGFα, resulting in homodimerization or heterodimerization with another member of the EGFR family. This receptor activation is followed by phosphorylation of specific tyrosine residues within the cytoplasmic tail, stimulating the downstream signalling pathway that regulates cell proliferation, migration, adhesion, differentiation, and survival. Gene amplification and/or protein over-expression of EGFR have been observed in a variety of solid tumours. The frequency of EGFR over-expression and/or amplification in gastric cancers has been variously reported to be 0–38% [22]. EGFR over-expression is associated with advanced gastric cancer, the presence of lymph node metastasis, a higher stage, and lymphatic invasion. The EGFR/MAPK pathway has also been shown to be activated in gastric carcinomas with microsatellite instability.

HER2

The proto-oncogene ERBB2 (also known as HER2) is a member of the ERBB/HER RTK family, additionally comprised of EGFR, HER3/ERBB3, and HER4/ERBB4 [23]. Upon extracellular ligand binding, these four receptors mediate normal cell proliferation and cell survival via two major signalling pathways: Ras-Raf-MAPK and PI3K/Akt/mTOR. Whereas EGFR and ERBB4 have known extracellular ligands and possess active tyrosine kinase domains, no direct high-affinity ligand has been identified for HER2 [24, 25].

Furthermore, ERBB3 binds several different ligands, but has little or no tyrosine kinase activity, and is possibly able only to weakly autophosphorylate [26]. HER2 is amplified or over-expressed in as many as 25% of gastric cancer cases. HER2 amplification or over-expression is most prevalent in intestinal gastric cancer (~30% HER2 positivity rate) and least prevalent in diffuse-type gastric cancer (~5% HER2 positivity rate). Assessment of HER2 positivity rates, therefore, depends entirely on the constituent population studied, and will be higher in areas where proximal gastric cancers prevail and less frequent where diffuse gastric cancers are common. HER2 mutations have been reported in breast cancer, lung cancer, and colorectal cancer. However, few reports are available on HER2 mutations in gastric cancer.

c-MET

c-MET is one of the tyrosine kinase receptors family, encoding a receptor for hepatocyte growth factor (HGF). Activation of c-MET by HGF and its signalling pathways is pivotal for cellular morphogenesis, regeneration, proliferation, migration, angiogenesis, and invasion. c-MET is expressed in a variety of normal epithelial and endothelial cells and mediates the biological activities of HGF [27, 28]. In vitro, highly virulent strains of *H. pylori* that make the effector protein CagA appear to modulate c-MET receptor signal transduction pathways, and this might influence cancer initiation and/or tumour progression [29]. c-MET over-expression and amplification have been reported in 18–82% of gastric carcinoma studied by immunofluorescence, immunohistochemistry (IHC), reverse transcription polymerase chain reaction (RT-PCR), Northern blot analysis and Southern blot analysis. However, MET mutation is quite low in gastric cancer.

Tumour suppressor genes

Approximately 50% of intestinal-type gastric cancers have alterations in genes that are thought to function as tumour suppressor genes, including TP53, TP73, APC (adenomatous polyposis coli), etc. [30].

TP53

The p53 gene (TP53) is an important regulator of the cell cycle, in particular at the point at which damaged cells must progress through cell cycle arrest and repair versus apoptosis [31]. Loss of TP53 expression by LOH or mutational inactivation is the most frequent genetic alteration in gastric cancer, occurring in over 60% of invasive tumours [32]. Abnormalities are also found in *H. pylori*-associated chronic gastritis, intestinal metaplasia, and dysplasia. p53 appears to be a key regulatory molecule in the response to microenvironmental chronic inflammatory stress. Furthermore, at least some data suggest that inactivation of p53 in gastric epithelial cells may reduce their ability to undergo apoptosis in response to injury caused by *H. pylori* [33].

TP73

LOH in TP73, a transcription factor related to TP53 that also functions as a tumour suppressor gene, can be detected in gastric carcinomas, and loss of expression has also been reported via epigenetic mechanisms (promoter methylation) in EBV-associated gastric cancers [34]. Over-expression of p73 and the oncogenic isoform DeltaNp73 suppresses p73 transcriptional and apoptotic activity in gastroepithelial cancer cells, and increases intracellular beta-catenin levels, an effect that is inhibited in the presence of wild-type but not mutant p53 [35].

APC

Mutations in the APC gene are identified in significantly more intestinal-type than diffuse-type gastric cancers. These mutations are also found in *H. pylori*-associated dysplasia and intestinal metaplasia. APC mutations modulate the Wnt/catenin signalling pathway [36, 37].

Cyclin E/CDKN1B

Cyclin E and cyclin-dependent kinase inhibitor 1B (CDKN1B) part in the G1/S transition. Cyclin E over-expression is a frequent event in gastric carcinomas, and it might be an indicator for malignant transformation of dysplasia, and/or tumour aggressiveness once an invasive cancer develops [38]. Decreased expression of cyclin-dependent kinase inhibitor 1B also correlates with an adverse prognosis in invasive gastric cancer. Furthermore, loss of CDKN1B expression increases susceptibility to gastric carcinogenesis in *H. pylori*-infected CDKN1B-knockout mice. The E2F family of transcription factors also plays a key role in the control of cell cycle progression, and over-expression of E2F-1 protein was confirmed in many of the gastric cancers [39].

Beta-catenin/Wnt signalling

Beta-catenin mutation is a frequent cause of Wnt pathway activation in gastric cancer [40]. Beta-catenin is important in mediating the E-cadherin-related cell adhesion and also in participating in Wnt signalling pathways. The Wnt signalling pathway regulates several processes during development, such as determination of cell fate, morphology, polarity, adhesion, and growth. Wnt signalling can be divided into canonical and non-canonical pathways. In the canonical pathway, Wnt signals (extracellular ligands, such as Wnt-1) stabilize beta-catenin, therefore activating gene transcription by interaction of beta-catenin with transcriptional factors. In gastric cancer tissues, in the expression of Wnt-1, beta-catenin has been found to be increased when compared to normal gastric tissue, and related to tumour size, tumour invasive depth, lymph node metastasis, pTNM stage, differentiation, and prognosis [41].

Epigenetic events

Epigenetic alterations such as DNA methylation of gene promoters can silence the expression of certain genes. At least some data suggest that aberrant promoter methylation may be closely associated with *H. pylori* infection and that higher methylation levels correlate with higher risk for invasive cancers [42]. Tumour suppressor genes such as CDKN2A, CDH1, MLH1, and RUNX3 are inactivated more frequently by aberrant DNA methylation than by mutations, indicating that gastric cancer is an epigenetic disease [43, 44]. In addition to methylation silencing of driver tumour suppressor genes, recent genome-wide analyses have revealed that hundreds of passenger genes are also methylated in gastric cancers. The fact that *H. pylori* infection induces epigenetic alterations provides the missing link between the causal role of *H. pylori* infection in gastric carcinogenesis and the deep involvement of epigenetic alterations in gastric cancers. It is currently speculated that infection by *H. pylori* induces H3K27me3 and removes RNA polymerase II at its target genes, and that these genes then become methylated [45]. Gastric cancer is a typical example of a disease in which infection, chronic inflammation, and epigenetic alterations are interconnected.

Genetic instability causes an accumulation of genetic alterations and participates in the early stage of gastric cancers. Cases in which two or more of five microsatellite loci show replication error are

considered to be showing high-frequency microsatellite instability (MSI-H), and those with only one locus showing replication error are considered to show low-frequency MSI (MSI-L). MSI-H is observed in only 4% of gastric carcinomas, in particular in the well-differentiated type in elderly patients [46]. The frequency of MSI-L is about 30% in primary gastric cancers, including early cancers. Some intestinal metaplasias and adenomas also show MSI-L, and these should be considered 'true precancerous lesions'. MSI-H is used as an indicator of HNPCC, which is caused by the germline mutation of mismatch repair genes, including hMLH1 and hMSH2. In sporadic gastric cancers with MSI-H, CpG island hypermethylation of hMLH1 is associated with loss of hMLH1 protein [47–49].

Diffuse-type cancer

Like intestinal-type cancers, diffuse-type gastric cancers can be induced by *H. pylori* infection. However, there are also prominent differences between these two variants. In most cases, this results from loss of expression of the cell adhesion protein E-cadherin. It has been reported that some of other signalling pathways or epigenetic events are important in diffuse-type gastric cancers.

E-cadherin

The main carcinogenic event in diffuse carcinomas is loss of expression of E-cadherin, a key cell surface protein for establishing intercellular connections and maintaining the organization of epithelial tissues. Biallelic inactivation of the gene encoding E-cadherin, CDH1, can occur through germline or somatic mutation, allelic imbalance events (e.g., loss of heterozygosity), or epigenetic silencing of gene transcription through aberrant methylation of the CDH1 promoter. Germline truncating mutations of the CDH1 gene, located on chromosome 16q22.1, were originally described in three Maori families from New Zealand that were predisposed to diffuse gastric cancer [50]. Subsequently germline mutations have been identified in many other kindreds worldwide. These mutations are not concentrated in a single hotspot, but rather evenly distributed along the gene in several different exons. The trigger and molecular mechanism by which the second allele of E-cadherin is inactivated appears to be diverse, and includes promoter hypermethylation, mutation, and loss of heterozygosity [51]. Abnormalities in CDH1 have also been linked to sporadic diffuse (and intestinal) carcinomas. Somatic mutations in the CDH1 gene are identified in 40–83% of sporadic diffuse-type gastric cancers, and promoter hypermethylation is also reported. Thus, the CDH1 gene appears to function as a tumour suppressor gene and its inactivation follows the classical 'two-hit' model [52, 53].

FGFR2

Fibroblast growth factors (FGFs) and their receptors are considered to be associated with multiple biological activities, including fundamental developmental pathways, cellular proliferation, differentiation, motility, and transforming activities. FGF signalling is also involved in many physiological roles in the adult organism, such as the regulation of angiogenesis and wound repair. FGF receptors (FGFRs) are expressed on many different cell types and regulate key cell behaviours of cancer cells. Emerging evidence has demonstrated that the deregulation of FGF signalling is frequently observed in various solid cancers and haematological malignancies. The K-sam gene was first identified and characterized as an amplified gene in the human gastric cancer cell line

KATO-III [54], and its product was later found to be identical to the bacteria-expressed kinase, or keratinocyte growth factor receptor, and FGF receptor 2 (FGFR2). FGFR2 mutations are reportedly rare in gastric cancers. On the other hand, FGFR2 amplification has been found in diffuse-type gastric cancer-derived cell lines and amplification was preferentially detected in diffuse-type gastric cancer. FGFR2 protein expression was positively correlated with scirrhous cancer, diffuse type, invasion depth, infiltration type, and poor prognosis [55].

c-MET

Frequent amplification of the c-Met gene in carcinogenesis and progression of scirrhous-type gastric cancers has been reported. With regard to the complex interaction between tumour cells and stromal cells, human HGF, whose receptor is a c-Met protein, may play an important role in progression and morphogenesis of gastric carcinoma. HGF is expressed by stromal fibroblasts and stimulates proliferation of gastric carcinoma cells which express c-Met protein [20].

IL-1a

IL-la, which is mainly produced by activated macrophages, mediates many of the local and systemic responses to infection and inflammation. IL-la activates T cells, B cells, and endothelial cells, increases number of neutrophilic cells, and affects the expression of various adhesion molecules. On fibroblasts, IL-la stimulates proliferation, prostaglandin production, and collagenase secretion.

IL-la may be involved in the multi-autocrine loops of the growth factor/cytokine system in gastric carcinoma. Therefore, there is a high possibility that IL-la produced by gastric carcinoma cells may act as a paracrine factor and cause stromal fibrosis and activation of the cytokine network. In fact, scirrhous gastric carcinomas characterized by productive fibrosis expressed IL-la mRNA at high levels. On the other hand, IL-la is well known to be produced by stromal cells, such as activated macrophages, fibroblasts, and vascular endothelial cells. IL-la secreted by the stromal cells could exert a great influence on cell proliferation, differentiation, and necrosis of gastric carcinoma in a paracrine manner [56].

Epigenetic events

In addition to CDH1, RAR-beta promoter hypermethylation was observed more frequently in diffuse-type gastric carcinoma than in other types. Moreover, hypermethylation of the CDH1 and RAR-beta promoters occurred concordantly. It was reported that retinoic acid induces expression of nm23- H1, which is known to reduce cell motility. Silencing of RAR-beta by promoter followed by hypermethylation-reduced nm23-H1 may occur frequently in carcinomas of the diffuse type [57].

Other oncogenic signalling pathway
Hedgehog pathway
Hedgehog (Hh) signalling plays an important role during embryonic development and differentiation, proliferation, and maintenance of adult tissues through the maintenance of stem cell population. Alterations in Hh signalling pathway activation are related to gastric cancers [58]. The expression of Hh ligands, Ptch1, Smo, and the three Gli transcription factors (Gli1, Gli2, and Gli3) has been related with more than two-thirds of primary gastric cancers and correlated with poorly differentiated and more aggressive tumours [59].

Notch pathway

The Notch signalling pathway is evolutionarily conserved and plays a role in many important and fundamental processes in cell and tissues such as proliferation, differentiation, apoptosis, cell fate determination, and maintenance of stem cells. Recently, an association between Notch signalling and progression of gastric cancer has been described. Three Notch receptors (Notch1–Notch3) and Notch ligand Jagged1 are expressed in human gastric cancer and the Notch signalling pathway is activated after infection with *H. pylori* in gastric cancer. Gastric cancer patients with Jagged1 expression in tumour tissues have more aggressive tumours and poor survival, suggesting an important role of this pathway in gastric cancer progression [60].

Transforming growth (TGF) factor-β pathway

Transforming growth factor (TGF) is a multifunctional cytokine that controls differentiation, apoptosis, cell growth, and immune reactions. TGF-β1, -β2, and -β3 are three isoforms of TGF-β that are present in mammals. In most types of cells, TGF-β is a potent growth inhibitor, so alterations on TGF-β signalling lead to tumour progression by the induction of angiogenesis, extracellular matrix accumulation, and immunosuppression.

Several studies have demonstrated that the over-expression of TGF-β in gastric cancer is correlated with lymph node metastasis and poor prognosis, as well as promotion of invasion and metastasis [60]. TGF-β induces RUNX3. RUNX3 interacts with FoxO3a/FKHRL1 to activate Bim and induce apoptosis. RUNX3 is expressed in glandular stomach epithelial cells; however, the loss of expression of this gene is associated with the progression, differentiation, metastasis, and poor prognosis of gastric cancer. *H. pylori* causes methylation of the RUNX3 gene and its loss of expression in gastric epithelial cells. Moreover, RUNX3 Smad4 inactivation has been documented in gastric cancer [62].

Cancer stem cells (CSCs)

Stem cells are functional units of growth that regenerate tissues and organs and play a role in tissue homoeostasis and repair after damage or loss. Stem cells have the unlimited ability to self-renew and the capacity to differentiate into several specialized cell types. Tumours may originate from a small subpopulation of CSCs that are able to maintain long-term tumour growth, tumour recurrence, and apoptosis and chemotherapy resistance. The results from some studies suggest that CD44, CD54, CD90, CD71, aldehyde dehydrogenase 1 (ALDH1), ATP-binding cassette subfamily B member 1 (ABCB1), ATP-binding cassette subfamily G member 2 (ABCG2), and CD133 etc. are potential biomarkers for gastric CSCs. Recent study has shown that expression of CD44, in particular that of a variant isoform (CD44v), contributes to reactive oxygen species (ROS) defence by promoting the synthesis of reduced glutathione (GSH), a primary intracellular antioxidant, namely that CD44v plays a role in the protection of CSCs from high levels of ROS in the tumour microenvironment [63]. In addition, some studies suggest that several signalling pathways, including Hedgehog and Wnt/beta-catenin, are essential for maintaining gastric CSCs [64, 65]. CSCs, which have already received great attention in the field of cancer research, are potential novel therapeutic targets in the treatment of gastric cancer.

Summary of the molecular biology of gastric cancers

In summary, gastric cancers that have epidemiologic and histologic distinction can also be distinguished by genomic and molecular analysis. As we improve our understanding of gastric cancer heterogeneity and its clinical consequences, our hope is to improve patient outcomes with improved prevention, screening and treatment options, using distinct biologic subtypes.

Pathology of gastric cancer: anatomy and histology of the stomach

The gastric wall consists of the mucosa, submucosa, muscularis propria, and serosa. The gastric mucosa lining the five regions of the stomach (cardia, fundus, corpus or body, antrum, and pylorus) measures 0.5–1.5 mm in thickness, and is composed of mucosal epithelium and a delicate stroma of connective tissue (lamina propria) occupying the space between the glands and the muscularis mucosae. Histologically, each mucosa is composed of surface foveolar epithelium and mucous secreting glands corresponding to the upper half and the lower half of the mucosa, respectively. The cardiac glands contain mucus-secreting cells. The fundic mucosa is characterized by the foveola representing one-fourth of the thickness mucosa, and straight fundic gland cells including chief cells, parietal cells, mucous neck cells, and endocrine cells. The chief cells produce pepsinogen I, and parietal cells produce acid and intrinsic factor, the latter of which binds to and facilitates the absorption of vitamin B12. Mucous neck cells are found at the junction of the gastric glands with the foveolar epithelial cells and produce a PAS-positive, diastase-resistant mucus. The antral mucosa and pyloric mucosa contain pyloric glands which are simple or branched tubules.

Most of the surface glandular cells express and secrete mucin that protects gastric epithelial cells from acid and proteinase secreted from chief and parietal cells. The mucin secreted by the foveolar epithelial cells is mainly PAS-positive neutral mucin, MUC1 and MUC5AC, and the glands secrete MUC6.

H. pylori infection and chronic gastritis

H. pylori infection

H. pylori infection is the most important predisposing factor for distal gastric carcinoma [4]. Patients with persistent *H. pylori* infection for prolonged periods of time exhibit typical phenotypic changes as chronic atrophic gastritis, focal intestinal metaplasia, and diffuse intestinal metaplasia and adenoma, which may be followed by the development of intestinal-type adenocarcinoma of the stomach. In *H.pylori*-positive subjects tested at least ten years prior to cancer diagnosis, the odds ratio was 5.9 (95% confidence interval 3.4–10.3) as compared to the non-infected population [5]. The cancer-preventive role of antibiotic therapy has been reported in patients free of atrophy or metaplasia. A randomized controlled trial study of 544 *H. pylori*-positive patients with early gastric cancer revealed a significant reduction in the recurrence rate of cancer in the group administrated eradication therapy after endoscopic resection [66].

Chronic atrophic gastritis

Chronic gastritis is pathologically divided into (1) chronic superficial gastritis and (2) chronic atrophic gastritis, based on the degree of inflammatory cell infiltration and presence of atrophy of the glandular epithelium. In chronic superficial gastritis, the inflammatory cell infiltration is limited to the foveolar epithelium, with no evidence of glandular atrophy. When the inflammatory cell

infiltration is associated with glandular atrophy, this condition is referred to as chronic atrophic gastritis. Persistent chronic atrophic gastritis causes atrophy of gastric mucosa showing cystic dilatation of the gastric glands and intestinal metaplasia where few inflammatory cells infiltrate.

Precancerous conditions and precancerous lesions

The precursors of gastric cancer have been divided into two categories: (1) precancerous conditions and (2) precancerous lesions [67]. Precancerous conditions are clinical entities associated with an increased risk of gastric cancer development, such as chronic atrophic gastritis, intestinal metaplasia, and chronic gastric ulcer, whereas precancerous lesions are pathological lesions that may show malignant transformation, such as dysplasia, adenoma, Menetrier's disease, hyperplastic polyp, and gastric stump. A list of precancerous conditions and lesions is given in Table 37.1.

Intestinal metaplasia

'Metaplasia' refers to the replacement of one type of adult tissue by another. Intestinal metaplasia of the stomach is morphologically and enzymatically defined as replacement of the antral or fundic gastric mucosa by glands resembling those of the intestine. Intestinal metaplasia has been classified into the complete type (small intestine) and incomplete (large intestine) type based on morphological, histochemical, and immunohistochemical studies. Complete metaplastic glands contain Paneth cells and exhibit sucrose trehalase, leucine aminopeptidase, and alkaline phosphatase activity, while incomplete metaplastic glands exhibit no histochemical evidence of trehalase or alkaline phosphatase activity. Incomplete-type intestinal metaplasia has drawn attention as a precursor for intestinal-type gastric cancer. P53 gene alterations and degree of DNA methylation have also been reported in the metaplastic glands [68, 69].

Adenoma, intraepithelial neoplasia/dysplasia

The term 'adenoma' is used to refer to a protruding neoplastic proliferative lesion by Western pathologists, whereas Japanese pathologists use the term to refer to all gross lesions that may be elevated, flat, or depressed. According to the WHO 2010 definition of dysplasia, dysplasia is an unequivocal lesion for neoplasia [70]. However, it is sometimes difficult to distinguish dysplasia from reactive or regenerative mucosal epithelium associated with active inflammation, especially in small biopsy samples. At least one of these three categories should be considered for the diagnosis of dysplasia/adenoma in gastric mucosal specimen. (1) Negative for intraepithelial

neoplasia/dysplasia—this category may include benign mucosal processes corresponding regenerative or metaplastic changes. (2) Indefinite for intraepithelial neoplasia/dysplasia—this is not a final diagnosis of the samples. (3) Intraepithelial neoplasia/dysplasia unequivocally comprising epithelial neoplasia characterized by cellular and structural abnormalities but no evidence of invasion.

Intraepithelial neoplasia/dysplasia has been classified low- or high-grade: (1) low-grade intraepithelial neoplasia/dysplasia is characterized by minimal structural abnormalities and mild to moderate cytologic atypia, including elongated but polarized nuclei and low to moderate mitoses. (2) High-grade intraepithelial neoplasia/dysplasia is characterized by both cytological abnormalities including a high nuclear/cytoplasm ratio with hyperchromatic nuclei and amphophilic nucleoli, and more prominent architectural disarray characterized by a high nuclear–cytoplasmic ratio, loss of nuclear polarity, and numerous mitoses. Lesions such as high-grade dysplasia/intraepiethelial neoplasia require medical management such as endoscopic mucosal resection (EMR) or rebiopsy to confirm the morphological grading.

Fundic gland polyps

Fundic gland polyps are neoplastic polypoid lesions of the stomach and may occur sporadically in patients with familial adenomatous polyposis (FAP) and in patients under long-term treatment with proton-pump inhibitors. Patients with FAP may develop dysplasia in the fundic gland polys; however, carcinoma is rare. Genetic alterations of the CTNNB1 (beta-catenin) and APC genes affecting the Wnt signalling pathway are observed. The detection of mutations of CTNNB1 and APC observed in the sporadic fundic gland polyps strongly support the contention that fundic-gland polyps are neoplastic.

Adenocarcinoma

Among the most common malignant tumours of the stomach is a gastric carcinoma, followed in frequency by lymphomas (4%), carcinoids (3%), and malignant stromal cell tumour (GIST) (2%). Gastric carcinomas are malignant epithelial neoplasms of the stomach including adenocarcinoma, adenosquamous carcinoma, carcinoma with lymphoid stroma (medullary carcinoma), hepatoid adenocarcinoma, squamous cell carcinoma, and undifferentiated carcinoma. The most frequent site of gastric adenocarcinoma is the lesser curvature of the antropyloric region. However, the incidence of upper gastric cancer has been reported as increasing in recent years.

Since gastric cancer has heterogeneous morphology and biology, there have been several classifications of gastric cancer. Gastric carcinoma is clinicopathologically classified on the basis of (1) macroscopic type, (2) depth of invasion, and 3) histologic subtype.

Macroscopic type

The macroscopic types of advanced gastric cancer are based on Borrmann's classification (see Figure 37.1) There are four types; type 1 (protruding type); type 2 (circumscribed excavating type); type 3 (ulcerated with infiltrating spread type); and type 4 (diffuse infiltrating without ulceration type). Each macroscopic type depends on the location of the tumours and the histological type. Type 1 and type 2 frequently occur in the antrum and correspond to the intestinal type. Type 4 is a scirrhous-type cancer that occurs in the antrum or fundus; type 4 has been termed 'linitis plastic'

Table 37.1 Precancerous conditions and lesions

Precancerous conditions	Chronic atrophic gastritis Intestinal metaplasia
Precancerous lesions	Dysplasia/adenoma
	Gastric polyps
	Hyperplastic polyp
	Fundic gland polyp
	Chronic gastric ulcer
	Ménétrier's disease
	Post-resection gastric stump

Type 1: protruding type
Type 2: circumscribed excavating type
Type 3: ulcerated with infiltrating spread type

Type 4: diffuse infiltrating without ulceration type

Fig. 37.1 Macroscopic type of gastric adenocarcinoma.

characterized by diffuse thickening and hardening of almost the entire gastric wall. This scirrhous-type cancer is often encountered in the younger age group and the male–female ratio is almost the same. The features of type 3 are intermediate between type 2 and type 4.

Depth of invasion

The tumour staging for the gastric carcinoma was based on the depth of invasion based on the classification proposed by the UICC (International Union Against Cancer); see Box 37.1. The T categorization is now identical to that for other gastrointestinal carcinomas such as those of oesophagus, duodenum, and colon.

Histological classification of gastric adenocarcinoma

Since the histological features of gastric carcinoma are markedly heterogeneous, there are several histological classifications for gastric adenocarcinomas. Figures 37.2 and 37.3 that show the representative histological subtypes of gastric adenocarcinoma based on the WHO classification, Lauren's classification, and Nakamura's classification.

WHO classification

The WHO histological classification is strictly descriptive for the morphology [70].The five main types of gastric adenocarcinoma are identified in the WHO classification according to the morphological patterns: (1) tubular, (2) papillary, (3) mucinous, (4) poorly differentiated, including signet-ring-cell carcinoma, and (5) mixed carcinomas (Figures 37.2 and 37.3).

1. Tubular adenocarcinoma is composed of dilated or branching tubules of disarrayed glandular structures. It can be classified

---

Box 37.1 Classification of depth of invasion in gastric cancer

Tis: Carcinoma in situ (intraepiethelial tumour without invasion of the lamina propria, high-grade dysplasia)
  T1: Tumour invades lamina propria, muscularis mucosae or submucosa.
  T1a: Tumour invades lamina propria or muscularis mucosae.
  T1b: Tumour invades submucosa.
  T2: Tumour invades the muscularis propria.
  T3: Tumour invades the subserosa.
  T4: Tumour perforates serosa or invades adjacent structures.
    T4a: Tumour perforates the serosa.
    T4b: Tumour invades adjacent structures.

---

into well-differentiated and moderately differentiated subtypes. Acinar and solid structures are also present in various amounts. Individual neoplastic cells are columnar, cuboidal, or flattened and show high nuclear/cytoplasmic ratio with various atypical nucleus.

2. Papillary adenocarcinoma is characterized by the presence of papillary or villous structures mainly composed of cuboidal to cylindrical tumour cells. This type is often associated with tubular structures (papillotubular adenocarcinoma). The degree of cellular atypia and mitotic index vary.

3. Poorly differentiated adenocarcinoma, including signet-ring-cell carcinoma, is composed of poorly cohesive carcinoma cells occurring as isolated cells or arranged in small clusters with few distinct glandular structures. Signet-ring cells are characterized by a central clear globoid droplet of cytoplasmic mucin with an eccentrically placed nucleus. This type of cancer cell is often observed in 'linitis plastica'-type tumours.

4. Mucinous adenocarcinoma is composed of cancer cells that are composed of either differentiated or poorly differentiated adenocarcinoma cells with large amounts of extracellular mucinous pools. The tumour shows more than 50% extracellular mucin area.

5. Mixed carcinoma displays a mixture of the differentiated glandular and poorly cohesive cancers in a single tumour.

6. Rare histological variants represent about 5% of all gastric cancers and include adenosquamous carcinoma, squamous cell carcinoma, hepatoid adenocarcinoma, carcinoma with lymphoid stroma (medullary carcinoma), choriocarcinoma, carcinosarcoma, and undifferentiated carcinoma.

Lauren classification and other classification

Lauren was the first to classify gastric cancer into two distinct morphological types, the intestinal type and diffuse type [6]. Tumours containing approximately equal amounts of intestinal and diffuse components are termed mixed.

Carcinoma of the intestinal type may arise from the metaplastic epithelium and show various degrees of differentiation from well-differentiated glandular structures to poorly differentiated solid cell nests. Carcinoma of this type preferentially metastasizes
Fig. 37.2 Histological classification of gastric adenocarcinoma. Intestinal type (Lauren [6])/differentiated type (Nakamura [71]). (A) Tubular adenocarcinoma; (B) papillary adenocarcinoma.

hematogenously to the liver. However, diffuse-type gastric cancer frequently occurs in the antropyloric region and body of the stomach and is composed of poorly cohesive cells with little or no gland formation, and preferentially metastasizes to the peritoneal cavity. The representative gastric cancer of diffuse-type cancer is known as 'linitis plastica', which is characterized by occurring predominantly in young females. Penetration of the serosa by carcinoma frequently results in peritoneal seeding. Bilateral massive involvement of the ovaries (Krukenberg tumour) can result from transperitoneal or hematogenous spread.

Nakamura categorized all gastric carcinomas into the differentiated or undifferentiated types, which vaguely correspond to the intestinal type and diffuse types classified by Lauren [71]. As Nakamura's classification is based on the different morphological structure of the tumour, the differentiated type is composed of well differentiated and moderately differentiated tubular adenocarcinoma and papillary adenocarcinoma, and the undifferentiated type represents poorly differentiated, signet-ring-cell, and mucinous carcinoma. However, some cases of poorly differentiated adenocarcinoma with solid growth could be differently classified as the intestinal type by Lauren's classification but as the undifferentiated type according to Nakamura's classification.

The TNM classification of malignant tumours by the UICC proposed the histopathological grading as G categories, which apply to all digestive system tumours except those of the liver (see Table 37.2).

Early gastric cancer

Based on the clinicopathological behaviour, 'early gastric cancer' is defined as an invasive carcinoma that is limited to the mucosa or the mucosa and submucosa regardless of the nodal status. Most cases of early gastric cancer show a low incidence of lymph node and distant metastasis; however, if left untreated, they progress over a few months to several years.

Early gastric cancers are classified endoscopically into the three following categories according to their macroscopic appearance, protruded (type 0-I), superficial (type 0-II) and excavated (type 0-III). The most predominant of these type, 0-II, is further subdivided elevated (0-IIa), flat (0-IIb), and depressed (0-IIc) lesions. The risk of deep and multifocal penetration of the submucosa or lymphatic invasion varies from case to case, so the surgical and endoscopic submucosal resection specimens must be pathologically examined in detail in order to select the most suitable treatment.

Tumour spread

Gastric cancer arises from the mucosa and spreads by direct extension to adjacent organs, metastasizes to lymph nodes or distant organs, or shows peritoneal dissemination. The presence of serosal
Fig. 37.3 Histological classification of gastric adenocarcinoma. Diffuse type (Lauren [6])/undifferentiated type (Nakamura [71]). (A) Signet-ring-cell carcinoma; (B) poorly differentiated adenocarcinoma.

Table 37.2 Histopathological grading of gastric cancers

GX	Grade of differentiation cannot be assessed
G1	Well differentiated
G2	Moderately differentiated
G3	Poorly differentiated
G4	Undifferentiated

spread is more common in tumours with infiltrative growth such as macroscopic type 3 and type 4 lesions than in the expanding growth type tumours, such as type 1 and type 2. The presence of mucosal (submucosal) lymph vessel infiltration is statistically associated with lymph node metastasis. Vascular invasion is also strongly associated with a high frequency of distant metastasis. The most frequent sites of metastasis from gastric carcinoma are the liver, peritoneum, and lung, followed by adrenal gland, ovary, and bone marrow.

Close association has been observed between the histological type and the sites of metastasis: intestinal-type carcinomas preferentially metastasize hematogenously to the liver, whereas diffuse-type carcinomas tend to be associated with peritoneal dissemination.

Molecular targets in gastric cancer

Recent advances in molecular biological techniques have clarified the presence of some molecular genetic alterations of gastric cancer. Table 37.3 shows a list of gene alterations in gastric cancer. Some of them are closely associated with the histological subtypes. While APC gene mutations and LOH, p53 gene mutation, KRAS gene mutations, and ErbB 2 gene amplification have been reported to occur more frequently in intestinal-type gastric cancer, RB1 loss of expression, FGFR2, K-SAM gene amplification are more frequently observed in diffuse-type gastric cancer. Cell adhesion molecule abnormalities have been reported in the poorly-cohesive-type gastric cancer. CDH-1 (E-cadherin) and CTNNB1 (βeta-catenin) gene alterations have been reported in both gastric cancer cell lines and human gastric cancer [72]. These findings are good examples of gene-morphological consistency, wherein dysruption of cell adhesion by gene mutations is frequently detected in poorly cohesive adenocarcinoma including signet-ring cell carcinoma.

Anti-c-erbB2 (HER2) antibody is now used as a molecular target therapy for c-erbB2 positive gastric cancer. HER2 testing is now recommended to all advanced and recurrent gastric cancer patients. Compared to the HER2 testing in breast cancer, more heterogenous HER2 expression has been reported in gastric cancer (Figure 37.4) [73]. In addition to ERBB2, some receptor type tyrosine-kinases, such as EGFR, FGFR2, c-MET, and VEGFR are drawing attention as new targets for therapy.

Whole exon analysis has been introduced recently as an advanced molecular technique and revealed new genetic profiles of many cancers including gastric cancer [74, 75]. However, so-called driver gene mutations have not been identified yet in gastric cancer.

Hereditary diffuse gastric cancer

Hereditary diffuse gastric cancer is an autosomal-dominant cancer-susceptibility syndrome that is characterized by

Table 37.3 Histological types and gene alterations

Gene	Alteration	Frequency
APC	LOH, Mutation	intestinal (30-40%) > diffuse (<2%)
DCC	LOH	intestinal (60%) > diffuse (<1%)
P53	LOH, Mutation	intestinal (25–40%) > diffuse (0-21%)
RB1	Reduced expression	diffuse (30%)
CDKN1B	Reduced expression	40–50%
CDH1	LOH, Mutation Reduced expression	diffuse (>50%)
CTNNB1	Mutation	17–27%
BLC2	Over-expression	diffuse (10–30%)
c-MYC	Over-expression	40–45%
Cyclin E	Over-expression	15–20%
KRAS	Mutation	intestinal (1-28%) > diffuse (<1%)
EGFR	Amplification Over-expression	30%
ERBB2	Amplification Over-expression	intestinal (15–25%) > diffuse (0–5%)
FGFR2	Amplification Over-expression	30%
MET	Amplification Over-expression	intestinal (7%) > diffuse (7%)

Abbreviation: LOH, loss of heterozygosity.

signet-ring-cell gastric cancer and lobular carcinoma of the breast. The genetic basis for this syndrome was discovered in 1998, and consisted of germline mutations of the E-cadherin (CDH-1) gene. The International Gastric Cancer Linkage Consortium (IGCLC) defined criteria for genetic analysis of the CHD-1 gene mutation to detect the hereditary diffuse gastric cancer syndrome. The age at onset of clinically significant diffuse gastric cancer varies even within families. The cancer is characterized morphologically by the presence of multifocal invasive lesions of signet-ring-cell carcinoma, with no mass lesion. Histological examination of the entire gastric mucosa is necessary before the absence of neoplasia can be claimed. Early invasive carcinoma is not restricted to any topographic region of the stomach. The signet-ring-cell carcinomas observed in asymptomatic CDH-1 mutation show absent or reduced E-cadherin staining.

Surgical management of gastric cancer

The current role of surgical therapy in the treatment of gastric cancer includes staging, resection with curative intent, and palliation or tumour reduction in patients with stage IV disease. Surgical treatment remains the best treatment modality for a potential cure. The primary goal of surgery is to accomplish complete removal with negative margins (R0 resection). The extent of prophylactic or curative lymph node dissection remains controversial, and the surgical strategy of lymph node dissection differs between the East (countries with a higher incidence, such as Japan or South Korea) and the West (countries with a lower incidence, such as the
Fig. 37.4 Heterogeneous expression of HER2 protein and gene amplification. (A) HER2 IHC; (B) HER2 ISH.

US). During the past decade, laparoscopic surgery has played an increasingly important role—not only in staging, but also in radical gastrectomy with lymph node dissection, especially in East Asian countries.

Extent of gastric resection in curative surgery: surgical margin

In surgery with curative intent, a sufficient resection margin should be ensured to determine the resection line. The length of the proximal margin recommended by the Japanese guideline according to cancer type is indicated below [76].

Advanced-stage cancer

In tumours with an expansive growth pattern, at least 3 cm is recommended for the proximal margin. In tumours with an infiltrative growth pattern, 5 cm is recommended. However, for tumours invading the oesophagus, a 5 cm proximal margin is not necessary. To ensure safe surgical margins, intraoperative frozen section examination is desirable.

Early-stage cancer

For T1 tumours, 2 cm is the recommended safety margin. When the border is unclear in superficial tumours, preoperative marking clips placed by gastroendoscopy may be helpful to confirm the resection line during the operation.

Type of gastric resection

The various types of gastric resection currently performed include: total gastrectomy, distal gastrectomy (subtotal gastrectomy), proximal gastrectomy, pylorus-preserving gastrectomy, and segmental gastrectomy or local gastrectomy.

If the tumour is located within the distal two-thirds of the stomach and an adequate proximal margin can be obtained, distal gastrectomy is preferred in Japan. If the tumour involves the upper third of the stomach, total gastrectomy is chosen. Although the same opinion is held outside Japan [77], total gastrectomy is generally accepted rather than subtotal gastrectomy in European countries for better local control [78]. There is controversy regarding whether splenectomy is mandatory in combination with total gastrectomy for the purpose of complete clearance of lymph nodes at the splenic hilum (at least 10 lymph nodes). A randomized controlled trial is currently ongoing in the Japan Clinical Oncology Group (JCOG) to estimate the impact of splenectomy on long-term survival [79]. In

general, pancreas-preserving total gastrectomy with splenectomy is considered for tumours located along the greater curvature of the upper stomach in Japan.

Function-preserving gastric resection has also become an important consideration in the treatment of early-stage gastric cancer. Some articles have reported that preservation of the pylorus, vagal nerve, and gastric reservoir significantly improves patients' gastrointestinal function and quality of life. Pylorus-preserving gastrectomy is performed for tumours located in the middle stomach, ensuring a margin of at least 4 cm from the pylorus. Proximal gastrectomy is performed for tumours located in the proximal third of the stomach, ensuring that more than half of the stomach can be preserved. At present, these procedures are only recommended for cT1N0 cancer. Local excision gastrectomy plays little role currently because of the progression of peroral endoscopic interventions. However, it is possible that the utility of local gastrectomy will be re-evaluated if innovative diagnostic technologies such as sentinel node diagnosis are developed.

Lymph node dissection

History in Japan

In the 1960s, Japanese surgeons established D2 lymphadenectomy, which includes systematic dissection of the perigastric nodes (first tier) and the nodes around the celiac artery and its branches (second tier). Early studies demonstrated that the five-year survival rate of patients with positive lymph node metastasis including the second-tier nodes ranged from 30% to 40% after D2 dissection [80]. No randomized clinical trials have compared D1 and D2 dissections in Japan, but since the aforementioned early studies were performed, D2 dissection has been recognized as standard surgery in Japan. Since the 1980s, more radical extended lymphadenectomy, namely extended para-aortic node dissection (D3 or PAND), has been performed in many high-volume centres for patients with positive nodes. However, a multi-institutional randomized trial conducted by the JCOG showed no survival benefits of D3 compared with D2, at least in patients with curable gastric cancer (JCOG 9501) [81]. In JCOG 9501, a total of 523 patients were randomized to either D2 lymphadenectomy or D3 (D2 + PAND) lymphadenectomy. The results demonstrated higher morbidity with D2 + PAND (28.1% versus 20.9%, P = 0.07); however, there was no difference in mortality (0.8% in both groups). There was also no difference in survival between the two groups, with five-year

survival rates of 70% and 69%, respectively (P = 0.85). Thus, to date, the Japanese guideline recommends that potentially curable gastric cancers should be treated by standard gastrectomy with D2 lymph node dissection, but for early-stage cancer, minimal lymph node dissection such as D1 or D1+ is recommended. The techniques of D2 dissection in open surgery are widespread. D2 dissection is performed not only in community hospitals in Japan, but also in Eastern countries such as South Korea and China. However, D3 dissection (D2 + PAND) is not routinely performed for prophylactic lymph node dissection in Japan.

Nodal station and lymphadenectomy definition in Japan

The lymph node stations surrounding the stomach have been precisely defined by the Japanese Gastric Cancer Association (JGCA) [82]. The JGCA previously divided these stations into four levels (first through fourth tier) based on analysis of the lymphatic flow from the stomach, and these designations were defined on the location of the primary tumour (i.e., upper third, middle third, and lower third) [83]. The anatomic definitions and numbering of the lymph node stations have remained constant during further revisions of the JGCA classification system. There have been several revisions, and in 2010 the JGCA abandoned the designation of nodal stations to more closely adopt and avoid confusion with the staging of the UICC/American Joint Committee on Cancer (AJCC). Lymph node stations 1 to 12 and 14v are defined as regional gastric lymph nodes (Table 37.4); metastasis to any other nodes is classified as M1. Nodal stations for D1 and D2 are now defined by the type of operation performed rather than the tumour location (Table 37.4).

D1 versus D2 studies in Western Countries

In contrast, in Western countries, most surgeons avoid extensive lymph node dissection as performed in Eastern countries; instead, D1 lymph node dissection (perigastric nodes only) is performed in the majority of institutions. This difference between Eastern and Western countries may exist for several reasons. First, the incidence of gastric cancer is much higher in Eastern countries; therefore, surgeons are more familiar with gastric cancer surgery and the surgical anatomy surrounding the stomach. It is unquestionable that the controversy regarding the extent of lymph node dissection stems from differences in the global epidemiology of gastric cancer. Second, Western general populations have higher body mass indices and more visceral adipose tissue, which may increase post-operative complications after intensive lymph node dissection around the pancreas. Third, proximal tumours, which tend to behave more aggressively, are less common in Japan than in the West.

In an attempt to clarify the effectiveness of D2 dissection established in Japan, two large European randomized controlled trials comparing D1 and D2 dissection were carried out in the 1990s (Table 37.5). In the UK, a multicentre randomized controlled trial (Medical Research Council (MRC) trial) which enrolled 400 patients was performed to compare D1 and D2 lymphadenectomy [84, 85]. The study showed significantly higher morbidity (46% versus 28%, P <0.001) and mortality (13% versus 6.5%, P = 0.04) in the D2 group. No difference in overall survival or disease-specific survival was observed between D1 and D2 lymph node dissection. This study was highly criticized because of the quality of lymph node dissection: the median number of retrieved lymph nodes was 13 in the D1 group and 17 in the D2 group. In addition, many Eastern surgeons pointed out that the mortality rate was unacceptably high, which

Table 37.4 Regional lymph node stations of the stomach

Number and definitions	
1	Right paracardial LNs
2	Left paracardial LNs
3a	Lessor curvature LNs along the branches of left gastric artery
3b	Lessor curvature LNs along the second branch and distal part of right gastric artery

was mainly caused by inappropriate distal pancreaticosplenectomy in D2 total gastrectomy. The second major European study was the Dutch Gastric Cancer trial (Dutch trial), in which 711 patients were randomized to either D2 or D1 lymph node dissection [86–88]. All surgeons were instructed by an expert from Japan, and all D2 lymph node dissections were supervised by a specialized surgeon. In spite of this setting, non-compliance was encountered in 36% of D1 and 51% of D2 dissections. Likewise, as in the MRC trial, the D2 arm showed higher morbidity (43% versus 25%, P <0.001) and mortality (10% versus 4%, P = 0.004). The survival data were reported for three separate time intervals. In the first two publications, there was no difference overall or disease-specific survival, with a reported 11-year overall survival rate of 35% in the D2 arm versus 30% in the D1 arm (P = 0.53). At that time, management of gastric cancer in the West was greatly influenced by these disappointing outcomes, and surgeons in the West became even more reluctant to perform D2 dissection. Many Japanese surgeons considered the results of these two trials to have an unacceptably high operative mortality

rate, which had likely masked any potential survival advantage. Perioperative mortality in the JCOG 9501 trial was 0.8%, and the five-year survival rate was 70%; in the European trials, however, the mortality rate was 4–6% and the five-year survival rate was 33–35%. However, the five-year results of the Dutch trial were published in 2010, indicating that there remains no significant difference in overall survival [89]. Interestingly, there was improved locoregional control in the D2 arm and improved gastric cancer mortality in the D2 arm (37% versus 48%, respectively; P = 0.01). Thus, in the West, the NCCN guidelines recommend that gastric cancer surgery should be performed by experienced surgeons in high-volume centres and should include removal of perigastric lymph nodes (D1) and those along the named vessels of the celiac axis (D2), with a goal of examining 15 or more lymph nodes. To avoid perioperative morbidity and mortality, the NCCN guideline also recommends modified D2 lymphadenectomy (without distal pancreatectomy or splenectomy), which is standard in the West [90]. The Italian Gastric Cancer Study Group recently published their randomized clinical trial comparing D1 and D2 gastrectomy in 267 patients treated at specialized hospitals and revealed that specialized centres may have lower rates of morbidity and mortality (12% versus 17.9% and 3% versus 2.2%, respectively) with D2 dissection, even in Western countries [91].

Study of D1 versus D3 in Asia

In the East, another randomized trial was performed in Taiwan comparing D1 and D3 lymphadenectomy in 211 patients, although it was a single-institution study involving three highly trained surgeons [92]. This study showed that the morbidity rate was higher in the D3 group (17.1% versus 7.3%, P = 0.012); however, no operative mortality was reported in either group. More lymph nodes were retrieved in the D3 group than in the D1 group (37.2 versus 19.4, respectively). The study demonstrated improved survival with D3 lymphadenectomy, although the difference was small (59.5% versus 53.6%, P = 0.041). This study suggests that in the hands of highly experienced surgeons, D3 lymphadenectomy is superior to D1 with low operative mortality.

Laparoscopic gastrectomy with lymph node dissection

Laparoscopic gastrectomy is now widely accepted in many communities, mainly in Japan and South Korea. When compared with open surgery, advantages regarding short-term outcomes, such as faster recovery, decreased blood loss, and less pain with minimal wounds, have been reported. Laparoscopic surgery for gastric cancer was launched in the early 1990s [93]. Its techniques, including meticulous lymph node dissection under a magnified endoscopic view and intracorporeal intestinal reconstruction, were subsequently developed in Eastern countries, especially in Japan. Laparoscopic surgery is currently regarded as the treatment of choice for early gastric cancer. The feasibility and safety of laparoscopic distal gastrectomy in the treatment of stage I gastric cancer have been proven by several prospective studies that investigated post-operative complications (JCOG 0703 and Korean Laparoscopic Gastrointestinal Surgery Study 01 trials [KLASS 01]) [94, 95]. However, laparoscopic distal gastrectomy is recognized as investigational treatment, not as a standard procedure, in the Japanese guideline because the oncological outcomes have not been clearly demonstrated in any prospective studies. At present, the long-term outcomes of laparoscopic distal gastrectomy in early-stage gastric cancer have been assessed in randomized clinical trials in Japan and South Korea (JCOG 0912 and KLASS 01 trials).

The majority of these studies have been performed in Japan and South Korea, where more patients present with early gastric cancer; applicability to Western countries, where patients present at more advanced stages, remains to be seen. The safety and oncologic validity of laparoscopic gastrectomy with D2 dissection for advanced gastric cancer are still being debated because of the technical difficulties of this procedure. Only one meta-analysis has reported on the comparison of laparoscopic gastrectomy with D2 dissection [96]. Although this report was based mostly on case-controlled studies, laparoscopic gastrectomy with D2 dissection resulted in a longer duration of operation by approximately one hour, reduced blood loss, fewer total post-operative complications, less pain, faster bowel function recovery, and shorter hospital stay, with similar numbers of harvested lymph nodes and a similar overall survival rate compared with open gastrectomy with D2 dissection.

Laparoscopic total gastrectomy was first reported in 1999 [97], but it is still considered to be a technically demanding procedure. Long-term follow-up data for validation of oncological outcomes are still lacking. Robotic gastrectomy is also currently performed by Japanese and Korean experts in laparoscopic surgery, but, again, conclusive data are lacking.

Non-curative surgery

Palliative surgery

Palliative gastric resection is performed to improve symptoms such as stenosis or haemorrhage due to tumour-related haemorrhage in patients with stage IV non-resectable gastric cancer. When the tumour is expected to be relatively easy to remove without risks, palliative resection is selected. When palliative resection seems difficult or the operation is risky, bypass surgery such as gastrojejunostomy may be elected to improve the patient's quality of life.

Reduction surgery

Gastrectomy as reduction surgery is performed in an attempt to decrease the tumour volume in patients with other non-curative factors, such as liver metastasis or peritoneal dissemination. The purpose of this surgery is to prolong survival time by reducing tumour volume; however, there is insufficient scientific evidence to support the effectiveness of this kind of surgery in patients with

gastric cancer. A randomized clinical trial is currently ongoing to compare reduction surgery and systemic chemotherapy with the cooperation of both Japan and South Korea (JCOG 0705/REGATTA).

Staging laparoscopy

Even current CT scan devices of the highest quality have limitations in the detection of metastases on peritoneal surfaces. Numerous studies have demonstrated the effectiveness of staging laparoscopy in the management of patients with gastric cancer. Laparoscopic inspection should include full inspection of peritoneal surfaces and the liver to detect metastases. Suspicious peritoneal lesions should undergo biopsy. In addition, peritoneal cytology using normal saline should be performed. Positive biopsy or peritoneal cytology results are considered indicative of the presence of metastatic disease.

Medical management of gastric cancer

In Japan or Korea, where screening is performed widely, early detection of gastric cancer is often possible. In other countries, most cases are diagnosed in advanced stage. Overall, gastric cancer is a fatal malignancy with the one of the worst five-year survival rates. According to data from the US National Cancer Institute Surveillance, Epidemiology and End Results (SEER) programme, the five-year survival for patients with gastric cancer was 22% [98]. Based on population-based cancer registries, the survival rate is higher in Japan than in other countries (approximately 50–60% versus 20–25%) [99, 100].

Treatment strategies for localized but advanced gastric cancer vary in different geographic regions. Primary gastrectomy with lymph node dissection followed by adjuvant chemotherapy is standard in Asian countries. Neoadjuvant chemotherapy and chemoradiotherapy is standard in Western countries. For patients with metastatic disease, cytotoxic chemotherapy is the most effective treatment modality to prolong survival and alleviate symptoms. The addition of targeted agents has also been recently investigated.

Adjuvant chemoradiotherapy

Between 1991 and 1998, the US Intergroup INT-0116 randomly assigned 556 patients with curatively resected gastric or EGJ adenocarcinoma (Stage IB–IV, M0) to surgery only and surgery plus post-operative chemoradiotherapy. Adjuvant treatment consisted of 45 Gy radiotherapy, with bolus fluorouracil (FU) plus leucovorin. One cycle of bolus FU plus leucovorin before chemoradiation and two cycles after chemoradiation were also given [101]. Median overall survival (OS) was significantly longer (36 versus 27 months) in the chemoradiotherapy group (P = 0.005). Benefits were maintained with ten-year median follow-up (the hazard ratio (HR) for OS 1.32; P = 0.0046) and no increases in late toxic effects were noted [102]. Current consensus guidelines in the US recommend post-operative chemoradiotherapy as a treatment option. However, this study has been criticized, mainly for the limited extent of the surgical procedure. Although D2 lymph node dissection was recommended, it was performed in only 10% of patients and 54% of patients underwent a limited lymph node dissection (D0), which could have undermined survival.

In Korea, additional data for chemoradiotherapy has been provided by the ARTIST trial. 458 patients with curatively resected gastric cancer by D2 lymph node dissection (Stage IB–IV, M0) were randomly assigned to six courses of post-operative capecitabine plus cisplatin (XP) or two courses of post-operative XP followed by chemoradiotherapy (45 Gy RT with concurrent daily capecitabine) and two additional courses of XP [103]. Compared to chemotherapy alone, the addition of RT to XP chemotherapy did not significantly improve the three-year disease-free survival (DFS) rate (78.2% versus 74.2%; p = 0.0862). For the patients with completely resected gastric cancer and a D2 lymph node dissection, the role of adjuvant radiotherapy is still unclear.

Key clinical trials of Adjuvant and Neoadjuvant therapy are briefly discussed in Table 37.6.

Neoadjuvant/perioperative chemotherapy

In contrast to the US, perioperative (preoperative plus post-operative) chemotherapy has become the main approach in European countries.

The British Medical Research Council (MRC) conducted the first well-powered phase III trial (MAGIC trial) that evaluated perioperative chemotherapy for patients with resectable gastroesophageal cancer. In this trial, 503 patients with potentially resectable gastric (74%), distal oesophageal (11%), or EGJ adenocarcinomas (15%) were randomly assigned to surgery alone or surgery plus perioperative chemotherapy. Chemotherapy consisted of three preoperative and three post-operative cycles of epirubicin, cisplatin, and infusional 5-fluorouracil (ECF) [104]. Although chemotherapy was well tolerated and fewer than 12% of all patients developed grade 3 or 4 toxic effects, only 104 (42%) completed all protocol treatment. The extent of lymph node dissection was determined by the surgeon's discretion, and the reported rates of D2 dissection were 41% in the perioperative-chemotherapy group and 40% in the surgery group. As compared with the surgery group, the perioperative-chemotherapy group showed a significantly better OS (HR 0.75; P = 0.009; five-year rate, 36.3% versus 23.0%) and progression-free survival (PFS) (HR 0.66; P<0.001).

In a more recent FNCLCC/FFCD trial, the benefit of perioperative chemotherapy (infusional FU plus cisplatin, every four weeks) was also shown in patients with potentially resectable adenocarcinoma of the stomach, EGJ, or the lower third of the oesophagus [105]. Patients undergoing perioperative chemotherapy showed a significantly better OS (HR 0.69; P = 0.02; five-year rate, 38% versus 24%) and a better DFS (HR 0.65; P = 0.003; five-year rate 34% versus 19%).

Based on these results, perioperative chemotherapy, particularly with ECF, in addition to D1 surgery has become the standard treatment in European countries.

Adjuvant chemotherapy

Although more than 30 randomized trials have compared adjuvant chemotherapy to surgery alone in curatively resected gastric cancer up to the present time, most studies were negative for OS. The reasons for these negative results were considered to be due to poor statistical power, inferior surgical techniques, and ineffective regimens. An individual patient-level meta-analysis of randomized control trials was performed by the GASTRIC (Global Advanced/Adjuvant Stomach Tumour Research International Collaboration) Group to quantify the potential benefit of chemotherapy after complete resection over surgery alone [106]. From 17 randomized controlled trials, 3838 patients were included in their analyses; they

Table 37.6 Results of pivotal Randomized Trials of Adjuvant and Neoadjuvant therapy for resected Gastric Cancer

Study	Stage	Treatment	No. of Patients	Three-year RFS (%)	Three-year survival (%)

[†]At 5 years.

RT, radiotherapy; XP, capecitabine plus cisplatin; ECF, epirubicin, cisplatin and infusional 5-fluorouracil; RFS, relapse-free survival.

concluded that adjuvant chemotherapy was associated with a statistically significant benefit in terms of OS (HR 0.82; P < 0.001) and DFS (HR 0.82; <0.001).

In Japan, the ACTS-GC trial evaluated the benefit of adjuvant treatment with S-1 monotherapy in patients with stage II or III gastric cancer who had undergone curative surgery with D2 lymphadenectomy. In this study, 1059 patients were randomly assigned to one year of S1 versus surgery alone [107]. Five-year OS and relapse-free survival (RFS) were significantly better with S-1 (five-year OS 71.7% versus 61.1%; HR 0.669 and five-year RFS 65.4% versus 53.1%; HR 0.653) [108]. In comparing the results among the ACTS-GC, INT-0116, and MAGIC trials, there are remarkable differences in survival rates: even the surgery alone group in the ACTS-GC trial resulted in remarkably higher rates than the treatment groups in other studies (INT-0116 (three-year); 50% versus 41%, and MAGIC trial (five-year); 36.3% versus 23.0% for the treatment and control groups, respectively) [109, 101].

The CLASSIC trial investigated the benefit of adjuvant therapy with capecitabine plus oxaliplatin. In this trial, 1035 patients with stage II–IIIB gastric cancer were randomly assigned to eight cycles of capecitabine plus oxaliplatin for six months or surgery alone after D2 gastrectomy [110]. The study was conducted in South Korea, China, and Taiwan. At a median follow-up of 34.2 months, chemotherapy was associated with a significant improvement in three-year DFS, which met its primary endpoint (74% versus 59%, HR 0.56, P<0.0001). In a subgroup analysis, three-year DFS benefits of capecitabine plus oxaliplatin were consistently shown for all disease stages (stage II, IIIa, and IIIb). Although a robust estimate of median OS is not yet available, the improvement of three-year OS was a borderline statistically significant (83% versus 78%, HR 0.72, P = 0.0493). Further follow-up is needed to confirm the impact in

OS and whether two-drug combinations in this study were better than monotherapy in future comparison with the results of ACTS-GC.

The results of these two studies strongly support that the use of post-operative chemotherapy after curative surgery with D2 lymph node dissection is standard treatment in Asia. The role of intensive perioperative chemotherapy or chemoradiation in patients who undergo D2 surgery remains undetermined.

Summary of medical management of gastric cancer

Gastrectomy with D2 lymph node dissection is the standard treatment for resectable gastric cancer in the East Asia. On the contrary, in Western countries, D2 lymph node dissection is considered a recommended standard procedure, but not uniformly performed. These facts might affect the geographical variations of the standard treatment and the survival rate.

In the US, D0 or D1 surgery plus fluorouracil-based post-operative chemoradiotherapy is a standard of care. In Europe, perioperative chemotherapy is established as a standard option for patients with resectable gastric cancer who have undergone curative surgery with limited lymph node dissection (D1). In eastern Asia, the results of two large trials support the use of post-operative chemotherapy after curative surgery with D2 lymph node dissection in patients with resectable gastric cancer.

Medical management for unresectable and metastatic gastric cancer

Chemotherapy for unresectable gastric cancer

The goals of chemotherapy in patients with advanced gastric cancer are to palliate symptoms and prolong survival. Even with

combination chemotherapy it is difficult to cure patients with metastatic gastric cancer. A number of small randomized trials and a meta-analysis provide evidence for the benefit of systemic chemotherapy as compared to supportive care alone for patients with advanced gastric cancer. In a meta-analysis of three trials comparing chemotherapy versus best supportive care, there was a significant benefit of chemotherapy in terms of overall survival (OS, HR 0.37), which translated into an improvement in median OS from 4.3 to 11 months. Effective cytotoxic agents for advanced gastric cancer include 5-fluorouracil (5-FU), oral fluoropyrimidines (S-1, capecitabine), platinum agents (cisplatin, oxaliplatin), taxanes (docetaxel, paclitaxel), irinotecan, and anthracyclines, with reported response rate as single agents ranging between 10% and 40%.

First-line chemotherapy for gastric cancer

Systemic chemotherapy is indicated to patients with good general status, sufficient organ function, and without significant comorbidity. Since efficacy of chemotherapy is still limited and the purpose of chemotherapy is to prolong the OS, the indication of chemotherapy for patients with poor performance status, organ dysfunction, and comorbidity should be discussed cautiously.

Combination chemotherapy regimens are the treatment of choice in clinical practice based on meta-analysis of several randomized trials which showed a modest but statistically significant survival benefit of combination chemotherapy when compared to single-agent therapy, where the HR for death was 0.82. First-line regimens have resulted in median PFS of four to six months and median OS of around ten to 13 months. Doublet chemotherapy is currently the standard in many Asian countries, with preferred regimens containing of a platinum compound, typically cisplatin, in combination with either infusion 5-FU or an oral fluoropyrimidines (S-1, capecitabine). In contrast, the ECF (epirubicin, cisplatin, infusional 5-FU) and DCF (or TCF, docetaxel, cisplatin, infusional 5-FU) combinations have regarded as standard regimens for first-line treatment in Western countries, primarily in Europe [111]. Oxaliplatin, a newer platinum agent is used in place of cisplatin in approved countries since at least comparable efficacy of oxaliplatin is reported in randomized studies.

Treatment regimens should be cautiously selected based on a patient's status. For example, cisplatin is contradicted to patients with severe renal dysfunction. The use of oral agents requires both patient sufficient compliance and gastrointestinal tract function. Patients with poor performance status might be a candidate for single-agent systemic chemotherapy or supportive care alone. The duration of chemotherapy for patients with advanced gastric cancer has not yet been specifically studied. In general, chemotherapies are given until the patient has progressive disease or unacceptable toxicities, although individualization is important based on each patient's tolerance and response to the treatment regimen, as well as the patient's preferences.

After the establishment of HER2 protein (human epidermal growth factor receptor type-2) as a new target of treatment for gastric cancer, HER2 positive gastric cancer has been treated with HER2 targeting therapy (i.e. trastuzumab). Patients with advanced gastric cancer should be screened for HER2 status. Detail of HER2 targeting treatment will be described later ('Targeting HER2').

Key clinical trials of cytotoxic chemotherapy are briefly discussed in Table 37.7.

OS, overall survival; PFS, progression-free survival: TTP, time-to progression: ORR, overall response rate.

In the V325 study, docetaxel plus cisplatin and 5-FU showed superior response rates, time to tumour progression, and survival in comparison with 5-FU and cisplatin [112]. Although DCF is approved by the US Food Drug Administration (FDA), a high incidence of febrile neutropenia is problematic. Various modifications of DCF have been evaluated in clinical trials.

The efficacy of the oral fluoropyrimidine derivative S-1 was shown in the Japanese phase III (JCOG 9912 trial) which evaluated non-inferiority of S-1 alone and superiority of irinotecan plus cisplatin over infusional 5-FU [113]. The response rate was higher with S1 than with 5-FU and median OS was 11.4 versus 12.3 months. The SPIRITS trial in Japan showed a significant benefit for combined S1 plus cisplatin over S1 alone in terms of both response rate and median survival [114]. Therefore, S-1 plus cisplatin is the Japanese standard chemotherapy. The FLAGS (First-Line Advanced Gastric Cancer Study) trial as a global phase III study did not show the superiority of S-1 plus cisplatin compared to infusional 5-FU plus cisplatin, although it showed a more favourable toxicity profile with S-1 plus cisplatin [115].

Capecitabine is another oral fluoropyrimidine. REAL-2 is a randomized phase III study in which 1002 patients with advanced gastric cancer were assigned, using a 2 x 2 factorial design, to three-weekly cycles of epirubicin plus cisplatin and either capecitabine or infusional 5-FU, or epirubicin plus oxaliplatin and either capecitabine or infusional 5-FU [109]. This study clearly showed non-inferiority of capecitabine to 5-FU and oxaliplatin to cisplatin. Oxaliplatin is associated with less neutropenia, anaemia, alopecia, and thromboembolic events than cisplatin. Sensory neuropathy and diarrhoea is more common with oxaliplatin. Similar results of non-inferiority of capecitabine to 5-FU were reported in another randomized trial (ML17032) which compared cisplatin plus either capecitabine or infusional 5-FU [116]. Based on these data, in clinical practice, many physicians select doublet combinations with either infusional 5-FU, capecitabine or S-1 combined with oxaliplatin (i.e. FOLFOX, XELOX, or S-1+oxaliplatin).

Second-line chemotherapy

For patients with an adequate performance status, utilization of other active agents not used in the first-line regimen is a reasonable option, either in combination or as serial single agents. At this time, there is no single standard approach for second-line therapy. Commonly used second-line agents after first-line 5-FU/fluoropyrimidines and platinum agents include irinotecan and taxanes. The survival benefit of second-line therapy was recently confirmed in randomized trials. In a Korean trial, patients with advanced gastric cancer and prior exposure to fluoropyrimidines and a platinum agent with good performance status were randomly assigned to best supportive care with or without chemotherapy (docetaxel or irinotecan). Second-line chemotherapy was associated with a significant improvement in median overall survival (5.3 versus 3.8 months) and patients were also significantly more likely to receive further salvage chemotherapy [117]. Similar survival befits with docetaxel compared with BSC was observed in another phase III trials in EU (COUGAR-02 [118]). Japanese trials (WJOG4407G) showed similar efficacy with weekly paclitaxel and irinotecan [119].

Recently, ramucirumab, an anti-vascular endothelial growth factor (VEGF) receptor antibody is reported to improve the prognosis of previously treated advanced gastric cancer. Detail of ramcirumab will be discussed below ('Targeting VEGF').

Biologic agents for gastric cancer

Targeting HER2

HER2 protein, also known as HER2/neu or ErbB2, is a transmembrane receptor with a molecular weight of 185 kDa, and its positivity is important for gastric cancer since HER2 positive patients are candidates for HER2 targeting agents. The HER family, after the activation of its receptor, enables transmission of the growth factor activation signal through the downstream signalling pathways, inducing cellular responses including cell proliferation, differentiation, and migration. Approximately 10–30% of gastric cancers over-express HER2, a similar percentage to that seen in breast cancer, although the definition of HER2 positivity is slightly different from that of breast cancer. HER2 status in gastric cancers is assessed in terms of HER2 protein expression by IHC and HER2 gene amplification by fluorescence in situ hybridization (FISH). HER2 expression is categorized into one of four levels (0, 1+, 2+, 3+) based upon a composite score that incorporates the intensity of staining and the percentage of cancer cells demonstrating that intensity. Patients with IHC +3 are considered to be HER2 positive. Patients with equivocal results (+2) should undergo FISH testing to confirm gene amplification. For interpretation of FISH, a HER2–CEP17 ratio of 2 or greater is considered to be HER2 amplified (FISH positive). HER2 positivity is more common in oesophagogastric cancer than distal gastric cancer. In addition, HER2 positivity is more common with intestinal-type than with diffuse-type gastric cancers.

Trastuzumab is an IgG1 monoclonal antibody against HER2 protein. Trastuzumab can specifically recognize the extracellular domain of HER2 and inhibit signalling. An antitumour activity of trastuzumab has also been reported and is due to antibody-depended cellular cytotoxicity.

The ToGA multiregional randomized trial was conducted to verify the clinical benefits of combination therapy with trastuzumab and standard chemotherapy (cisplatin and fluoropyrimidine (5-FU or capecitabine), FC) for patients with HER2-positive gastric cancers [120]. Among the samples screened, 22.1% were HER2 positive. The intestinal type exhibited a higher rate of HER2 positive than did the diffuse type (34% versus 6%); in addition, HER2 positivity was higher for adenocarcinoma of the oesophagogastric junction compared to gastric cancer (33.2% versus 20.9%). In the ToGA study, the median OS was significantly longer in the combination arm: 11.0 months for the FC arm versus 13.8 months for the FC + trastuzumab arm (HR 0.71, P = 0.0046). Both PFS and response rate were also significantly improved in the combination arm: 6.7 versus 5.5 months (HR 0.71, P = 0.0002) and 47.3% versus 34.5% (P = 0.0017), respectively. In the subset analysis of HER2 status, the effect of trastuzumab was more prominent for IHC2+/FISH+ or IHC3+ patients. The toxicities in the two arms were comparable, except that a higher number of trastuzumab-treated patients had grade 3 or 4 diarrhoea (9% versus 4%) and an asymptomatic decrease in left ventricular ejection fraction (5% versus 1%). From these results, for HER2-positive cases, trastuzumab showed a clear survival benefit, and the use of trastuzumab was approved in many countries. Additionally, results of retrospective subset analysis suggest that it is applicable for the group that is IHC2+/ IHC3+ and FISH positive. Controversy exists on whether to recommend trastuzumab in IHC 0-1+ cases that are FISH-positive. Randomized studies of several new agents (lapatinib, trastuzumab/emtansine and pertuzumab) are currently ongoing.

Targeting VEGF

The VEGF pathway is reported to play a role in tumour growth and is associated with poor prognosis in patients with several types of malignancies. The anti-VEGF monoclonal antibody has proven efficacy in several types of malignancies such as colon cancer, lung cancer, renal cancer, and ovarian cancer.

Ramucirumab is a fully humanized monoclonal antibody of VEGF receptor 2 (VEGFR-2). The REGARD trial was conducted in 30 countries to compare ramucirumab and best supportive care (BSC) with placebo as second-line treatment (following disease progression on first-line platinum or fluoropyrimidine-containing combination therapy) in a total of 355 patients [121]. The ramucirumab arm was associated with longer OS (5.2 versus 3.8 months; HR = 0.776; P = 0.04) and prolonged PFS.

Palliative care

The majority of patients with advanced gastric cancer will require palliative treatment at some point in the course of their disease. To alleviate tumour-related symptoms is an important aspect of treatment for advanced gastric cancer. For patients with poor performance status or patients who cannot tolerate intensive chemotherapy, supportive care alone is an appropriate treatment. Assessment of severity of the disease-related symptoms is essential to initiate appropriate palliative interventions that will prevent and relieve symptoms. Treatment options used for palliation of symptoms in patients with advanced gastric cancer include: gastrojejunostomy, endoscopic placement of a self-expandable metallic stent for gastric stenosis or obstruction; and pain control with pain medications and radiotherapy (especially for bone metastasis).

Rectal cancer and systemic therapy of colorectal cancer

Regina Beets-Tan, Bengt Glimelius, and Lars Påhlman

Introduction to rectal cancer

Approximately every third colorectal cancer (CRC) starts in the rectum. There is no clear demarcation border between rectum and colon although the likely most used definition is that cancers starting up to 15 cm above the anal verge are referred to as rectal cancers. The great majority of CRC are adenocarcinoma and there are great similarities in many aspects between the two anatomical regions. Therefore, in order to avoid overlap, the epidemiology, risk factors, molecular genetics, inherited syndromes, pathology and screening are described in the chapter on colon cancer, whereas staging, follow-up, and treatment of metastatic disease are dealt with in this chapter on rectal cancer.

Surgical removal of all known disease is basically the only therapy that can cure a patient with CRC. The exception is small rectal cancers that can either be treated with endoluminal contact radiotherapy/brachytherapy or that are sufficiently sensitive to chemoradiotherapy.

The cured fraction can be slightly elevated by additional pre- or post-operative radiotherapy and/or post-operative chemotherapy. Surgery is not always possible, either because the disease cannot be resected (inextirpable primary or multiple secondaries), or for general reasons (very high age or severe concomitant diseases). Today, approximately 40% of the patients with rectal cancer are left with palliative treatments, either primarily or because of a recurrence later during the course of the disease. The treatment armamentarium has markedly expanded during the past decade, partly because of significant increased knowledge about the genetic pathways of CRC development. This has resulted in improved overall survival, although the survival gains have been rather modest.

For an explanation of the epidemiology, molecular biology, and pathology of rectal cancer, please refer to Chapter 39.

Surgical management of rectal cancer

Diagnosis and staging of colorectal cancer

CRC is presently staged according to TNM7 from 2010 [1]. A new version of TNM is presented every five to ten years based on new knowledge. There are presently controversies as to the best version, and some countries use TNM5, mainly because of concerns about stage migration caused by different criteria for lymph node metastases [2]. The major criteria for staging colorectal cancer can be found on the website of the American Cancer Society [3].

Most patients with rectal cancer have some type of symptoms like bleeding, without or with anaemia, mucous discharge, or changes in bowel habits. Pain may be a sign of a large tumour growing outside the bowel wall into the pelvic sidewall, and weight loss a sign of distant metastases. Some villous adenomas have a profound mucous production leading to symptoms of diarrhoea and problems with major discharge with decreased serum potassium and sodium.

Once there is a suspicion of a rectal adenoma or malignancy, endoscopy should be performed. The whole rectum can, without any problem, be examined with a flexible sigmoidoscope and is preferable. However, when measuring the distance from the anal verge to the tumour it is more accurate to use a rigid rectoscope. Biopsies taken with a flexible sigmoidoscope are often too small and for this reason it is also preferable to change to a rigid rectoscope to take larger biopsies for diagnosis. Small polyps, less than 1 cm, are rarely malignant but the larger the polyp the higher the risk of malignancy. Adenomas larger than 2.5 cm have malignant transformation in about 25% [4]. Sometimes it is difficult to distinguish whether or not large villous adenomas are malignant.

A digital examination is of outmost importance to evaluate whether or not the tumour is fixed to the wall, tethered to the surrounding fat, or is an early tumour confined to the bowel wall [5]. The relation to the pelvic floor and the puborectal sling gives important information as to whether a sphincter-preserving procedure can be carried out or if the patient requires an abdominoperineal resection [5]. Based on the digital examination, endorectal ultrasonography (ERUS) for an early lesion will disclose whether the tumour is growing into or through muscularis propria [6]. If the tumour is more advanced, the mesorectal fascia (MRF) is of greatest interest and a magnetic resonance imaging (MRI) investigation is essential [7, 8].

Preoperatively, a 'clean colon' examination has to be done to rule out whether synchronous lesions are present. Preferably this is done with colonoscopy, but computed tomography (CT) colonography is also used [9]. Moreover, the liver and lungs have to be examined to disclose distant metastatic disease. This is done with CT of thorax and abdomen; in cases of equivocal CT findings PET/CT may give more information.

See Chapter 30 'Population cancer screening' for a discussion of screening in colorectal cancer.

Imaging of rectal cancer

Introduction to imaging of rectal cancer

The treatment of rectal cancer had been plagued by high local recurrence rates until the role of a good surgical technique and additional

(chemo)radiotherapy ((C)RT) was fully appreciated. (C)RT is more effective when given before, rather than after the resection [10–12]. Previously, decisions on post-operative treatment were based on the risk assessment for recurrence through histological evaluation of the surgical specimen. Decisions on preoperative treatment must be based on risk assessment through clinical evaluation and imaging. Although modern CT techniques can provide information for locoregional and distant staging, ERUS and MRI are the two best imaging methods for rectal cancer local staging and recommended as part of standard workup. The radiologist's role in the multidisciplinary management has become crucial. In addition to a reliable prediction of certain risk factors for local recurrence, the imaging findings will have clinical consequences and dictate both treatment strategy and treatment details such as surgical approach and radiotherapy volumes.

Risk factors for local recurrence

Histopathological risk factors for local and distant recurrence are T stage, N stage, distance of the tumour to the circumferential resection margin (CRM), perineural invasion, lymph and blood vessel invasion, and grade [13–15]. It is unrealistic to expect 100% accuracy from any imaging technology in predicting the histological classification; imaging is, however, helpful in predicting risks for recurrence with volume and relation to anatomical structures as main prognostic variables.

Tumour stage

Since the mid-1980s ERUS has been used to assess tumour growth into the bowel [16, 17]. It is superior to all other imaging techniques in visualizing all layers of the rectal wall, with three hyperechoic and two hypoechoic bands, corresponding to the anatomic layers and the interfaces between them. It is generally considered that ERUS is good in imaging smaller tumours. For large lesions, ERUS can identify ingrowth in surrounding structures that are within the field of view such as vagina, prostate, and seminal vesicles. Difficulties of ERUS arise with tumours located high in the rectum and stenosing tumours that are beyond the reach of the endosonography probe. The overall limited field of view provides insufficient anatomical information on the posterior extent of the tumour into the mesorectal fascia and pelvic wall.

The distinction between a T2 and a T3 tumour is usually straightforward histologically. This does not always easily transfer to staging through imaging. Although imaging may provide accurate information on the size of the tumour, both MRI and ERUS will have difficulties in predicting the exact microscopic relationship to a histological interface. Reports have shown MRI accuracies for T staging varying between 65% and 86%. MRI is accurate for identifying large T3 and T4 tumours with sensitivities for prediction of T3 varying between 80% and 86% and specificities between 71% and 76%. MRI is the technique of preference to map the tumour and, in contrast to ERUS, anatomical information from MRI is less subject to interobserver variations [18]. Most staging failures with MRI occur in the differentiation of tumours at the interface of rectal wall layers, i.e. the distinction between T1 and T2 lesions and between T2 and borderline T3 lesions. A T1 tumour cannot be reliably distinguished from T2 because the submucosal layer is generally not visualized on MRI. MRI has difficulties in determining lesions on the border of T2 and T3 if the tumour shows spiculations corresponding with desmoplastic reaction. In a large

European study (MERCURY), MRI was accurate in predicting the extramural depth of tumour ingrowth in the mesorectum, a prognostic factor that is not part of the TNM staging system.

Mesorectal fascia (MRF)

The importance of the involvement of the MRF as a prognostic factor has been recognized and confirmed in the past 20 years [14]. The ideal plane of resection in a total mesorectal excision (TME) is just outside MRF, and a positive CRM can be the result of inadequate TME surgery. An involved MRF is defined as a closest distance of ≤ 1 mm between tumour and the MRF, as this represents an important prognostic cut-off point.

While a positive CRM is a problem of surgical technique, an involved MRF is a matter of preoperative identification of the advanced tumours for an adequate preoperative treatment. These patients should be identified with MRI. Furthermore, regardless of the preoperative treatment, it is important for the surgeon to know the exact anatomical relation of the tumour to the MRF and surrounding structures in order to obtain a complete resection.

Many single-centre studies have shown that MRI is highly accurate for the prediction of an involved MRF [18–20]. Because of the accurate depiction of the tumour mass in relation to the MRF it is often said that with MRI 'what you see is what you get' (Figure 38.1).

A systematic review confirms the high performance of MRI, showing sensitivities between 60% and 88% and specificities between 73% and 100% [7]. The MERCURY study [8] showed a sensitivity of 59% and specificity of 92%. Centres can report a decrease in the number of positive margins after the incorporation of MRI and discussion of all rectal cancer patients in multidisciplinary meetings [21, 22].

Nodal stage

Identifying nodal disease with imaging remains difficult because using size criteria alone results in only moderate accuracy. Lymph nodes with a diameter of ≥10 mm are invariably malignant, but the majority of involved nodes are smaller than 5 mm [23]. In addition to size, with 5 mm as the cut-off, ERUS also uses roundness, border irregularity, and hypoechoic nature as criteria for malignancy. For MRI the same criteria of roundness and border irregularity are used, and heterogeneous signals provide additional accuracy over size alone [24, 25]. This can be of help in evaluating nodes that are larger than 5 mm, but characterization of smaller nodes is not reliable. The difficulties in nodal staging with the standard imaging methods are illustrated by a multicentre report in which cT3N0 tumours, staged with ERUS or MRI were node positive at histology in 22%, despite preoperative CRT [26].

MRI techniques are continuously improving, and with modern machines, new sequences, and lymph-node-specific MR contrast agents the accuracy will improve. An example is ultrasmall superparamagnetic particles of iron oxide (USPIO) that showed higher accuracy for lymph node characterization in prostate and rectal cancer [27]. USPIO is not available for regular use because it is not FDA approved.

How does one work in practice with a suboptimal accuracy of preoperative lymph node imaging? One approach is to rely on imaging information on nodal status only when the tumour is associated with round large nodes (>5 mm) that are irregular in border and/or heterogeneous in signal or echogenicity. Whenever these criteria for node positivity are absent on ERUS or MRI, information on nodal
Fig. 38.1 (A) A sagittal MR image of a male patient with a high rectal tumour (black arrow) confined to the bowel wall. MRI visualizes a resectable tumour at distance from the TME resection plane. (B) An axial MR image of a female patient with a T4 rectal tumour, invading the cervix anteriorly (white arrow). Laterodorsal on the left side the tumour threatens but does not invade the mesorectal fascia (white arrow head).

status is not reliable. Another approach is to disregard the imaging data on nodal status and give preoperative treatment in most patients according to T (sub)stage, accepting over-treatment rather than under-treatment. A third approach is to take into account the prevalence of nodal metastases according to T (sub)stage and give neoadjuvant therapy for T3NX lesions, regardless of nodal imaging results, but not for T2 (or T3a/b) N0 lesions [26]. It can be argued that the small volume nodal disease that is easily missed by imaging is prognostically less important for local recurrence and may be controlled by good TME surgery [28]. Although there are no real data to support or refute any of the above approaches, the most practical strategy seems to be to use the information on lymph node staging in the preoperative decision making, keeping in mind the suboptimal accuracy. Erring on the safe side, large tumours or tumours extending deep into the subserosa or close to MRF can be treated preoperatively irrespective of the nodal status.

Restaging after chemoradiotherapy

For rectal tumours that respond well to preoperative CRT, restaging by MRI is useful but only if the surgeon will act upon the imaging findings. If the latter is the case, the surgeon needs to know whether the tumour has regressed from an anticipated involved resection plane, so a less extensive resection can be considered. Accurate restaging is becoming more relevant nowadays with discussions on organ-saving treatment.

Tumour regression from the MRF

Literature shows consistent results on the performance of MRI for assessment of tumour regression from the MRF. The overall accuracy for prediction of MRF involvement after (C)RT is around 80% with NPVs up to 90% [29, 30]. The high NPV is at the expense of 50% positive predictive value (PPV), mainly due to the difficulties in interpretation of fibrosis. A fibrotic thickening of the MRF is in 50% associated with viable small clusters of tumour in the fibrosis. To be on the safe side and prevent under-treatment a high false positivity is more acceptable than a high false negativity.

Tumour and nodal downstaging

The same difficulties in interpreting fibrosis also occur with a fibrotic tumour bed after irradiation. If morphological MRI only is used, it leads to inaccurate assessment of tumour downstaging

and over-estimation of tumour remnant. If morphologic MR features and MR volumetric changes of the tumour are combined, the assessment of an ypT0-2 tumour can increase the accuracy from 78% to 87% [31, 32]. PPV in these studies increases to 94%. One should bear in mind, however, that a learning curve exists. A general radiologist who has no previous training in pelvic MRI reaches the level of an expert reader after 60 to 80 MRIs.

Crucial in the selection of organ-saving treatment is the identification of node negativity. Up to 45% of visible nodes disappear and another 40% decrease in size (unpublished data). Sterilization of nodes is reported in a significant proportion after (C)RT. Restaging the nodes with MRI is more accurate than with ERUS [26]. MRI studies from recent years have reported accuracies of 67–90% and negative predictive values (NPVs) of 83–93% for MR nodal staging after (C)RT. Accepting some false positives, patients with sterilized nodes can be reliably identified on standard MRI.

Future perspectives and conclusions

The most promising development is the non-invasive assessment of imaging biomarkers by metabolic and functional imaging. FDG-PET/CT is promising for assessment of response during and after CRT. MRI is evolving as a competitive alternative because of its versatility and higher cost-efficiency. In addition to detailed information on morphology, MRI provides information on tumour heterogeneity by evaluating local tumour perfusion (dynamic contrast enhanced MRI) and diffusional capacity (diffusion weighted MRI) [33]. The introduction of new hybrid MR/PET machines in clinics will speed up the availability of a fast and accurate whole body staging process. Image reconstruction technology also evolves rapidly by automatically reconstructing and calculating complex quantification data.

In the multidisciplinary treatment of rectal cancer there is an increased demand for accurate selection of patients for individual tailoring of treatment, both at primary staging and at restaging after preoperative treatment. MRI has a prominent role in this decision-making strategy. While ERUS remains the most cost-efficient method in the workup of small superficial tumours, MRI is the preferred modality to assess the extent of large tumours. Nodal staging is at present not sufficiently reliable, although slightly more accurate in the restaging setting. Restaging MRI after (C)RT

is useful, if alteration of treatment plan is considered. MRI can evaluate tumour downsizing and downstaging and can predict tumour regression from the planned surgical resection plane.

Principles of surgery

Management of rectal polyps

It is essential to evaluate the histopathological features of polyps in the rectum. Hyperplastic polyps can most often be ignored whereas adenomas have to be followed up. If there are several hyperplastic polyps (more than five) in the rectum, many claim that the whole colon has to be investigated, to secure that no malignancy further proximally is present [34]. There is no good study that shows that proximal neoplasms are found more often if several hyperplastic polyps are seen during sigmoidoscopy than if no pathology is detected. If adenomas are found, the whole colon must be examined to detect proximal tumours. If there are numerous adenomas, familiar adenomatous polyposis (FAP) must be suspected and the family history should be explored. Patients with FAP should be screened for mutations in the APC gene and based upon that mutation it is possible to screen the whole family with a simple blood test.

The majority of the polyps and adenomas can be handled by endoscopic removal. Sessile adenomas with a broad base (more than 1 cm) should preferably be removed with a TEM (transanal endoscopic microsurgery) technique [35]. Very experienced endoscopists can remove such an adenoma with the EMR (endoscopic mucosa resection) technique [36]. With TEM, a full thickness biopsy into the fat can be done. It is then possible to evaluate how deep a cancer has grown.

Management of rectal cancers

The gold standard treatment for rectal cancer is resection of the diseased bowel segment. The technique in the upper and middle rectum is exactly the same whether or not a sphincter-preserving procedure or an abdominoperineal excision is carried out. However, in small tumours confined to the mucosa or bowel wall, a local excision preferably with the TEM technique can be considered.

Preoperative preparation

The distance from the anal verge to the tumour and the relation to the pelvic floor and the puborectal sling are the landmarks for the decision as to whether or not a sphincter-preserving procedure can be carried out. With this information together with the preoperative MRI it is possible to evaluate if the tumour can be radically (R0) resected without a stoma. This is especially important in low-lying tumours if an intersphincteric procedure is planned. Preoperative bowel preparation is important, particularly if a sphincter-preserving procedure is to be carried out, since the majority of these patients today will have a functioning ileostomy and the bowel should be empty during the healing period of the anastomosis [37, 38]. If an abdominoperineal excision is planned, an enema to empty the left colon is sufficient. The day before surgery it is important to mark the stoma site. The patient should have prophylactic antibiotic cover before surgery [39] and prophylaxis for venous thromboembolism. The thrombosis prophylaxis should be longer than the hospital stay, preferably until one month after surgery, since longer prophylaxis than eight to ten days reduces the thrombosis risk even further without causing more adverse effects [40].

Surgical technique

There should be no difference in the procedure whether the operation is carried out as open surgery or laparoscopically, but both approaches must follow the TME technique (Figure 38.2) [41]. In the open technique, it is most often easier to start to mobilize the sigmoid from the left side and identify the ureter and also the hypogastric nerves and enter the correct plane under the sigmoid colon. Having carried out the same procedure on the right side, the vessels to the rectum can be divided. If working laparoscopically, most surgeons prefer to start on the right side, but the mobilization
Fig. 38.2 (A) Surgical specimen after a low anterior resection for a rectal cancer using the TME-technique with dissection outside the mesorectal fascia (shining on the picture). (B) Surgical specimen after an abdominal excision where the abdominal dissection was stopped appropriately prior to the perineal dissection to avoid coning. (C) Coning into the puborectal muscle creating a waist was done, increasing the risk of a non-radical resection.

in the abdomen, control of the nerves, and vessel ligation are identical. Some prefer a 'high tie' division of the vessels, which means that the inferior mesenteric artery is divided flush to the aorta. 'Low tie' indicates that the first branch of the inferior mesenteric artery, arteria rectalis superior, is divided. It has been debated whether a 'low tie' will change the cancer outcome. However, cancer positive lymph nodes in that short distance, from the aorta to the first division of the inferior mesenteric artery (1–2 cm), indicate disseminated disease beyond any chance of surgical cure and therefore most surgeons divide the vessel dependent upon what is needed for the surgery [42]. If a low anterior resection is planned, it is often convenient to do a 'high tie' in order to have sufficient bowel length to reach down, but when an abdominoperineal excision is planned, where the sigmoid colon is taken out as a stoma, a 'low tie' is enough.

Once the vessels have been divided and the hypogastric nerves identified, the non-vascular plane dorsally around the MRF is identified and followed down into the pelvis. Most often it is easy to do this posteriorly first and then go laterally on both sides. Anteriorly, in men, part of the bladder peritoneum should be included in the resection. The vesicles are identified and it is often easy to find the correct plane anterior to the Denonvilliers' fascia. In women, the posterior fornix of the vagina should be identified in a similar way but this is often more difficult with some bleeding from veins. Once the anterior or posterior plane is released, the lateral part of the dissection will continue. Care has to be taken not to destroy the nerves going to the prostate and the vessels to the top of the vagina. This area has been called the 'lateral ligaments' but they are nerves and should not be divided. However, in approximately 10% a mid-rectal artery is also running in this structure, which can be easily handled with care. There should not be any sexual disturbances after a rectal cancer dissection provided that the nerves are moved aside [43]. If the tumour grows into the nerves, they of course must be sacrificed.

If an anterior resection is planned, the dissection will continue down to the top of the pelvic floor. The rectum is then divided below the tumour with a straight stapler. Before this, an enema to wash out the rectal stump is advisable since data support that this decreases the risk of local recurrence [44]. The question is whether it is necessary to go down to the pelvic floor in all rectal cancer patients when a sphincter-preserving procedure is planned. Often it is easier to do a TME. But in cancers in the upper rectum, particularly in females, one can stop the dissection below the tumour if the division is done at least 5 cm distally of the tumour. The 5 cm rule is essential in high rectal cancers in order to remove all potential tumour deposits in the mesorectum [45], but in low rectal cancers one can accept a lesser margin provided that a TME is done [46]. In the bowel wall, a 1 cm margin is enough if a sphincter-preserving procedure is carried out [47].

If an abdominoperineal excision is planned, the abdominal dissection should be stopped at the level of the top of the vagina or the seminal vesicles. Otherwise there is a risk of coning into the puborectal muscle and creating a wrist on the specimen with a high risk of positive CRM (Figure 38.2). By stopping the abdominal phase in this area it is possible to go from below outside the sphincters, follow the levator muscles, and come to the abdominal resection plane without coning. The risk of CRM positivity and consequently a local recurrence will then be less. The perineal part of the procedure can be done in patients in lithotomy or prone position [48]. Most surgeons advocate the prone position mainly because it is then easier to teach others how to do it.

Open or laparoscopic surgery

There is still a debate as to whether rectal cancer surgery should be carried out laparoscopically or not. Data from a randomized trial indicates that both the short-term and long-term results are the same [49–52]. A new trend is to do these operations with robotics [53]. One randomized trial is finished, the ROLARR-trial, and preliminary data are awaited in the Fall 2015 [54]. A completely new way to perform the mesorectal excision is to do it from below. Several reports have found this feasible, but new complications have been seen, like the risk of ureteral damage if the dissection goes too lateral [55, 56].

Results of surgery for rectal cancers

Important endpoints after rectal cancer surgery are the immediate complication rate, i.e. post-operative mortality and morbidity, local recurrence rate, and cancer-specific survival. CRM positivity is a good surrogate endpoint for both local recurrence and cancer-specific survival [14].

Overall post-operative mortality in the Western world should not be more than 1–2% since rectal cancer surgery is elective [57]. The mortality will increase in an elderly population with more comorbidity but should on average be below 2%. The post-operative morbidity is more complex. If all types of complications are counted, approximately 35% of the patients will have a complication [57]. These could be anything from serious wound infections, perineal wound infections, deep vein thrombosis, and pulmonary embolism to more superficial problems such as urinary infection and pneumonia. A dreadful complication is an anastomotic leakage, which has been described in 10% to 25% [58]. A randomized trial showed that a diverting ileostomy decreases the frequency and the consequences of a leakage after an anterior resection; despite a covering ileostomy, approximately 10% will have a leakage [58].

The local recurrence rate has historically been high with reported figures of 30–50% [59]. With the TME technique this has been diminished and with selective use of appropriate radiotherapy the local recurrence rate in the population who undergo radical surgery should not be higher than 5–10% [60, 61].

Survival has also improved and, in many Western countries, a relative survival above 60% is possible to reach [57, 62]. The most likely reasons for this improvement are the efforts to decrease rectal cancer local recurrence rates by better staging, improved surgery, and incorporation of (C)RT.

Role of radiotherapy

Introduction to the role of radiotherapy

Improved surgery is likely responsible for about half of the reduction in local recurrence rates in population-based materials from 30% to 50% a few decades ago down to about 5% to 10%, and the addition of RT is likely responsible for the other half. The different surgical approaches have not been subject to randomized studies, whereas additional RT has. The studies collectively show that pre-operative RT is more efficient than post-operative RT, even when given with concomitant chemotherapy (CRT), and reduces the risk of local recurrence by slightly more than half (see Table 38.1) [63, 64]. The relative effect of RT is higher the lower the absolute risk of local recurrence after surgery alone, i.e. RT is relatively more effective with better surgery. This may be because improved surgery

Table 38.1 Major randomized radiotherapy trials in primary rectal cancer[1]

Study	Inclusion time	No of patients	Treatments			Patient group[3]	Radiation technique[4]	Increased death	Local recurrence (%)			Increased survival	Comments
pre-TME era			Surgery alone	Preop (C)RT	Postop (C)RT				Surgery alone	Preop RT + surgery	Postop RT		
Uppsala [11]	1980–1985	471	-	5,1 x 5[2]	2 x 30	Intermediate	3D-CRT	No	-	13*[5]	22	No	Preop 5 Gy x 5 is better than post-op RT (60 Gy). Increased risk of late complications after post-op RT
Stockholm I [282]	1980–1987	849	Yes	5 x 5		Intermediate	AP-PA	Yes	28	14**	-	No	Increased post-op death (8% versus 2%), large target, suboptimal technique, decreased local recurrence risk. Increased risk late complications.
SRCT [67, 70]	1987–1990	1110	Yes	5 x 5		Intermediate	3D-CRT	No	27	12***	-	Yes	Decreased local recurrence risk, no increased acute toxicity, some late toxicity after 10–15 years.
Stockholm II [283]	1987–1993	557	Yes	5 x 5		Intermediate	3D-RT	Yes?	25	12***	-	(Yes)	Overlaps to a large part SRCT, simplified radiation technique, tendency to increased post-op mortality (4% versus 1%). Lower local recurrence risk, increased survival as in SRCT. Increased risk late complications.
Post-TME era													
TME [68, 72]	1996–1999	1861	Yes	5 x 5		Intermediate	3D-CRT	No	11	5***		No	No increased post-op mortality. Decreased local recurrence risk even with TME, no improved survival, some risk for increased late complications after five to ten years.
MRC-CR07 [69]	1998–2005	1350	-	5 x 5	CRT if CRM+	Intermediate	3D-CRT	No		5**	11	Yes	Preop 5 Gy x 5 better than post-op CRT if CRM+, marginally increased survival. No increase in late complications (3–5 years).
Polish [74]	1999–2002	312	-	5 x 5 CRT		Intermediate (low)	3D-CRT	No		11 16		No	First study that shows less risk of acute toxicity from 5 x 5 compared with preop CRT, no difference local recurrence and survival or late complications (three to five years).
TROG [284]		326	-	5 x 5 CRT		Intermediate	3D-CRT	No		7 4		No	Same design as the Polish study, same results.
EORTC 22921 [78]	1993–2003	1011	-	RT CRT	RT CRT	Intermediate	3D-CRT	No		15 8		No	2 x 2 design, chemotherapy in addition to RT (CRT) gives fewer local recurrences than RT alone, increased toxicity, no increased survival

(continued)

Table 38.1 Continued

Study	Years	No.		Arm 1	Arm 2	Inclusion	RT type			Recurrence		Survival	Comment
FFCD 9203 [77]	1993–2003	742	-	RT CRT		Intermediate	3D-CRT	No		17 10		No	Preop CRT results in fewer local recurrences than preop RT, increased toxicity, no survival difference
LARCS [79]	1998–2003	207	-	RT CRT		Locally advanced (ugly)	3D-CRT	No		33 18*		Yes	The only study in ugly rectal cancers, preop CRT gives better local control and better disease and cancer specific survival, tendency better survival (66% versus 53% after five years). Increased acute and possibly late toxicity from CRT.
AIO-94 [10, 285]	1995–2002	823	-	CRT	CRT	Intermediate	3D-CRT	No		6**	13	No	Preop CRT is less toxic and gives fewer local recurrences than post-op CRT, no difference in survival

[1]Only large studies of relevance for present treatment recommendations are included.

[2]5 x 5 means 5 Gy daily for five days during one week. CRT means chemoradiotherapy with 1.8–2 Gy daily to 45–50.4 Gy. RT means the same radiotherapy as in the CRT arm without chemotherapy.

[3]Inclusion criteria in the studies. In the early studies patients who had a resectable tumour, excluding the polyp cancers, were included. In later studies, intermediate (bad) tumours were included except in LARCS that included 'non-resectable' (ugly) tumours.

[4]3D-CRT means 3D-conformed radiotherapy, three or four beams with blocking of normal tissues that did not contain tumour cells. 3D-RT (in the Stockholm II study) means four beams but no blocking. AP-PA means anterior posterior beams with no blocking, meaning high radiation doses to large normal tissue volumes.

[5]* P <0.05, ** P <0.01, *** P <0.001. Only statistically significant values have been presented.

results in leaving fewer and smaller tumour deposits behind, which can then be more easily eradicated by the RT covering a larger tissue volume than has been surgically removed. The relation between the risk of local recurrence after surgery alone versus after preoperative RT and surgery is illustrated in Figure 38.3. There is a gain from preoperative RT even in early tumours operated on by the best surgeons, but the number of patients needed to treat to prevent one local recurrence becomes too high considering the adverse effects from the RT.

The importance of local control in rectal cancer

Radical removal of the primary rectal cancer and no local recurrence are prerequisites for cure, although secondary surgery and/or CRT can salvage occasional local recurrences. Avoidance of persistent or recurrent tumour in the pelvis is important, even if cure cannot be achieved, since uncontrolled pelvic growth is usually associated with severe, disabling symptoms.

Thus, an important aim is to treat so that the risk of residual disease in the pelvis is very low or preferably less than about 5% in the population in which locally curative treatment is intended. This should be possible in all but the few (≤5%) who present with a fixed tumour growing into a non-readily resectable organ (less than half of those with clinical stage T4 (cT4)). At the same time,

as little acute and late morbidity as possible should be aimed at. Surgery, particularly if extensive, may give substantial morbidity, and additional treatments like RT or CRT, whether given pre- or post-operatively, increase morbidity. Thus, the additional treatments should be given selectively, i.e. when they benefit sufficiently many.

Tumours with distal extension to 15 cm or less (as measured by rigid sigmoidoscopy) from the anal margin are classified as rectal. Whether this 15 cm limit is the best for choosing a 'rectal cancer strategy' or a 'colon cancer strategy' is open to discussion. Others prefer to separate colon and rectal cancers at the peritoneal reflection, or about 9–12 cm from the anal verge. The localization of the tumour in relation to adjacent organs and structures and, thus, the distance from the anal verge are important for outcome and treatment. Cancers between 10 cm and 15 cm are best discussed as rectal cancers since RT is an important component of therapy to decrease the risk of local failure, even if less often than for lower rectal cancers (0–10 cm) [57].

From a practical point of view, rectal cancers can be divided into three groups, early (cT1–2, some cT3, where c indicates clinical), intermediate (most cT3–, some cT4) and locally advanced (some cT3, most cT4). Other factors than cT-stage, such as tumour height, closeness to the MRF (potentially the CRM; preoperatively, the term MRF is better than CRM, since the CRM cannot be defined until after surgery [65]), nodal (cN) stage, and extramural vascular invasion are also relevant. It is at present not possible to provide a precise description of which T and N substages belong to these groups. The terms 'favourable or early or good', 'intermediate or bad', and 'locally advanced or ugly' are used for categorizing the rectal cancers into these clinical subgroups (Figure 38.4). In clinical practice and in many recent studies, the term 'locally advanced' has been commonly used for the 'intermediate/bad' group, but is best reserved for the truly 'locally advanced/ugly' tumours [63].

Differences in treatment strategy in the world

There is a difference in how lateral lymph node metastases outside the mesorectum, frequently seen in intermediate/locally advanced tumours below the peritoneal reflection, are managed. Surgical removal of these nodes has been the preferred option in Asia, whereas the rest of the world has explored the value of radiation in addition to surgery for the primary, to kill the tumour deposits. Both extensive surgery (i.e. more than TME) and additional RT increase morbidity. There are no randomized studies that compare the two strategies. Comparisons between trials reveal that the results are equally good at specialized centres, although patient selection precludes firm conclusions. In clinical practice, it is more efficient to 'remove' subclinical cancer deposits using radiation rather than surgery unless it is dissected in a surgical plane. This is not possible outside the MRF. The resultant morbidity is very different although the impact of this on patient well-being differs between cultures.

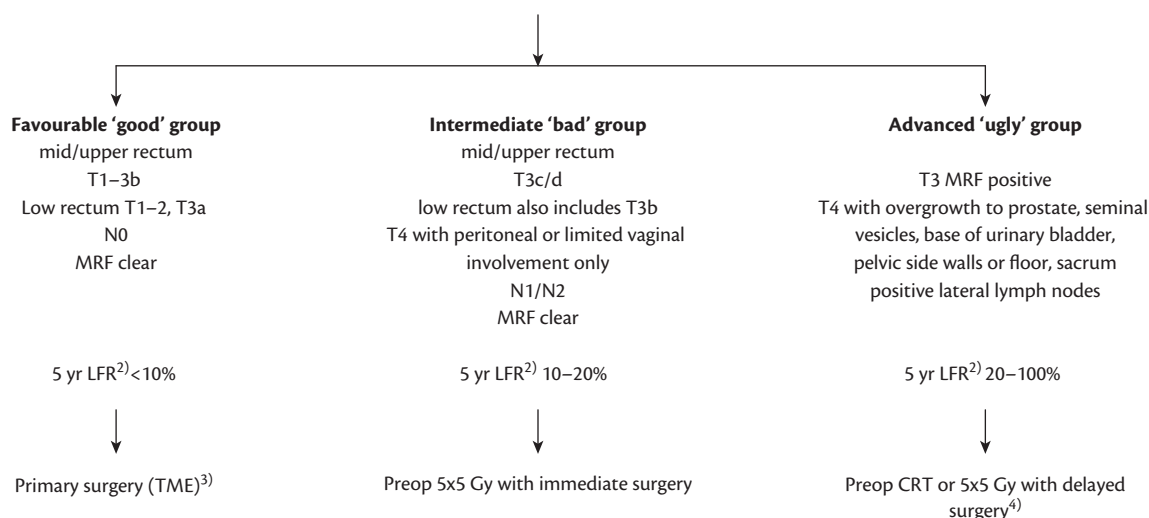
In the Western world, preoperative RT has been mainly explored in Europe, whereas post-operative RT has been explored in the US. A few small studies have indicated that post-operative CRT was better than post-operative RT in preventing local recurrence and that treatment was more effective than no additional treatment. Based upon this, a National Cancer Institute (NCI) report in 1991 stated that post-operative CRT should be standard treatment in rectal cancer stages II and III [66].
Fig. 38.3 Local recurrence risk after preoperative RT and surgery in relation to surgery alone (solid line from origin at a 45-degree angle) for primary rectal cancer. The symbols around the downwards convex line are from randomized studies where preoperative RT with surgery was compared with surgery alone. The results from studies after 2001 also fit along this line. The vertical bars illustrate the difference in local recurrence-risk between non-irradiated and irradiated groups. The solid line to the left illustrates an early (good) tumour where the local recurrence-risk is decreased from about 4% to about 1%. The dotted line in the middle illustrates a tumour belonging to the intermediate (bad) group where the local recurrence-risk is decreased from approximately 10% to 3%. The hatched line to the right illustrates the decrease in locally advanced (ugly) tumours where the decrease can be from some 30% down to 15%. The relative difference is about 70% in early tumours and about 50% in locally advanced tumours. The absolute difference should be put in relation to the problems that local recurrences give raise to in terms of morbidity and mortality and the late adverse effects RT can cause.


Fig. 38.4 Subgrouping of localized rectal cancer assessed by MRI and recommended primary treatment.

[1]The algorithm does not primarily address the risk of systemic disease, although this risk also increases with the presence of many of the risk factors, however, not necessarily parallel to the local failure rate (LFR). The algorithm is also 'too simplified' in that other factors like size of the mesorectum, anterior or posterior location, extramural vascular invasion (EMVI+) are relevant. Note that the distinction between subgroups is not between T2 and T3 and between T3 and T4 but rather within T3.

[2]Calculated in the group of patients planned for surgery, i.e. irrespective of the surgical outcome. The figures are valid if the surgeon is an experienced rectal cancer surgeon and no pre-treatment is given.

[3]A local procedure is possible in a few patients (chiefly pT1, sm1(2), N0). This group is in the text referred to as 'very favourable'.

[4]CRT means chemoradiotherapy to 45–50.4 Gy in 1.8–2 Gy fractions with 5-fluorouracil (capecitabine). 5 x 5 Gy in one week with delayed surgery is used in patients not fit for CRT.

In Europe, in contrast, large randomized trials compared surgery alone versus preoperative RT and surgery. These studies showed that, particularly if short-course RT was used, i.e. the Swedish 5 x 5 Gy schedule in one week with immediate surgery, there was a relative reduction in local failure rates of 50–60% [67–69]. Long-term follow-up of the trials have shown that the recurrences are prevented, not just delayed [70–72]. Based upon these results, preoperative RT was recommended early on as routine therapy in many countries, but not until quite recently in most countries.

Pre- or post-operative RT—short- or long-course RT—RT with or without chemotherapy—sphincter preservation?

For about two decades, several research questions have dominated the arena: (1) should the RT be given before or after surgery; (2) should it be long-course or short-course; and (3) should the long-course RT be given alone or with chemotherapy? In Europe researchers were not convinced of the advantages of concomitant chemotherapy, as stated in the US documents. In addition, (4) sphincter-preserving surgery was considered important, and whether this could be increased after preoperative (C)RT was debated extensively, and subject to trials.

Pre- or post-operative RT?

Multiple randomized trials have shown that preoperative RT is more effective than post-operative RT, whether the RT is given alone or with chemotherapy [10–12]. It is also less toxic. Most of the world has now accepted that additional (C)RT in rectal cancer should be given before rather than after surgery. An analysis of data from all randomized studies also indicated that preoperative RT is more dose-efficient than post-operative RT [73], i.e. a lower radiation dose is needed to give the same effect.

Short- or long-course RT?

The question of whether a short-course (5 x 5 Gy) schedule in one week or a long-course conventionally fractionated RT (1.8–2.0 Gy x 25–28 in five to six weeks) in the intermediate (bad) risk group is not yet settled. Two randomized trials including 316 and 326 patients, respectively, could not find any difference in local recurrence rates, disease-free survival (DFS) and overall survival (OS) between the groups randomized to short-course RT or long-course CRT (Table 38.1) [74, 75].

Differences between and potential advantages of the two schedules are given in Table 38.2. The short-course schedule has gained much popularity in the northern European countries where the trials have been performed. Many concerns have been expressed about the long-term consequences of hypofractionated (giving fraction doses above 2 Gy) RT. There is considerable evidence that the short-course schedule results in long-term morbidity, and the scale of that morbidity is well known [76]. The long-term morbidity of CRT whether given pre- or post-operatively has not been studied systematically, with the result that the extent of late morbidity is not known. Both options, short-course 5 x 5 Gy and long-course CRT, are considered valid in the intermediate group of rectal cancers [63], although the short-course schedule is much less resource demanding and has less acute toxicity.

RT without or with chemotherapy?

If long-course RT is combined with 5-FU-based chemotherapy, local control is improved (9% versus 17% in the intermediate group and 18% versus 33% in the locally advanced group) based upon the results of three randomized studies [77–79]. A significant survival gain was only seen in the trial including locally advanced cancers [79, 80]. Whenever a patient with a locally advanced rectal cancer receives preoperative treatment, CRT should be used unless the patient cannot tolerate this treatment. It should, however, be

Table 38.2 Main differences between and potential advantages of short-course and long-course preoperative radiotherapy in intermediate (bad) rectal cancers[1]

	Short course	Long course
Total (physical) radiation dose	25 Gy	45–50.4 Gy
Fraction size/number of fractions	5 Gy/5	1.8–2 Gy/23–28
Radiation duration	1 week	4.5–5.5 weeks
BED[2], acute effects	37.5 Gy	37.5–44.4 Gy
BED[2], late effects	66.7	72–84 Gy
Overall treatment time	About 10 days	10–14 weeks
Demands of radiation resources	Planning + 5 fractions	Planning + 23–28 fractions
Concomitant chemotherapy[3]	No	Yes
Acute toxicity	Minimal	More
Late toxicity	Present, limited in the "bad" group	Present, but not extensively studies. Anticipated higher than after short course
Down-sizing/ Down-staging	No[4]	Yes[5]

[1]In locally advanced (ugly) tumours, long-course CRT is the evidence-based and preferred option although short-course RT with a delay to surgery is an option if CRT is not tolerated because of high age or co-morbidity.

[2]Biologically effective dose according to the time-corrected linear quadratic model. Major uncertainties exist in the relative biological efficacy of the fractionation schedules concerning particularly the acute (antitumour) effects. The parameters selected for the acute effects were those used in the meta-analyses from 2001 [12], even if they can be criticized and probably are incorrect. For late effects, an α/β of 3 Gy with no time correction is used. The important message is that the anticipated antitumour effects do not differ substantially and that late toxicity is at least not higher using short-course RT.

[3]Improves local control with long-course RT, increases acute toxicity and probably also late toxicity. Should not be given with short-course RT.

[4]Seen after short-course RT with delayed surgery.

[5]Not relevant in these intermediate tumours (unless organ-preservation is aimed at), however, relevant in locally advanced (ugly) tumours.

recognized that the gains from the chemotherapy addition are limited and come at a rather high price in terms of more acute toxicity (grade 3–4 gastrointestinal toxicity of about 15%) and potentially also more late toxicity.

Sphincter preservation, organ preservation

Trials, again chiefly run in Europe, have explored whether long-course CRT with a delay of four to eight weeks before surgery could increase sphincter preservation rates, whereas others took it for granted that this was the case. The trials have shown that this effect did not occur to any meaningful extent [81, 82]. It is possible that better restaging of the tumour using MRI after long-course CRT could have influenced the possibilities of performing sphincter-preserving surgery. Hopes about improved chances of sphincter preservation influenced routines in many countries, particularly in southern Europe, Germany, and the US. At present, hopes about organ preservation influence treatment decisions.

Risk-adapted treatment

Very favourable rectal cancer

In the earliest, most favourable cases, chiefly the malignant polyps (Haggitt 1–3, T1 sm1(-2)N0), a local procedure (e.g., using the TEM technique) is appropriate [83]. The resection should be radical (R0) without signs of vessel invasion or poor differentiation. If this is not the case or if the tumour infiltrates deeper into the submucosa (Haggit 4, T1 sm(2-)3) or is a T2 tumour, the risk of recurrence is too high (≥10%) and the patient should have post-operative CRT or, more safely, be recommended major (TME) surgery. If the cancer is biopsy verified, presurgery CRT is preferred if the intent is to perform a local procedure. As an alternative to local surgery, alone or with (preoperative) CRT, local RT (brachytherapy or contact X-ray therapy [Papillon technique]) can be used. Experience of these treatments is limited outside specialized centres [84] and more prospective studies are required before they can become part of clinical routines.

Early 'good' rectal cancers

In the early favourable cases (cT1-2, some early cT3a(-b)N0(1) and clear MRF (MRF–) according to MRI, 'good' group) above the levator muscle plane, surgery alone, using the TME technique is appropriate, since the risk of local failure is low [63]. Although the randomized trials using short-course RT have shown that this treatment even further reduces local recurrence rates (from 5–10% to 2–5%) [61–63], surgery alone is recommended since the addition of preoperative RT results in over-treatment of too many individuals [63]. The balance between the reduction in local recurrence rates and long-term morbidity is intricate (Figure 38.4).

Intermediate 'bad' rectal cancers

In the intermediate 'bad' group (most cT3 (cT3(b)c+, MRF– according to MRI), some cT4 (e.g., limited vaginal or peritoneal involvement only), preoperative RT is recommended, since this reduces local recurrence rates. Even in the absence of signs of extramural growth on ERUS or MRI (cT2) in very low tumours (0–5 cm), preoperative RT may be indicated because the distance to the MRF is very small. Twenty-five Gy delivered during one week followed by immediate surgery (<10 days from the first radiation fraction) is convenient and of low toxicity [67–69]. Trials have shown that the risk of local failure in the randomized population has been reduced by 50–70% versus surgery alone (Table 38.1). A more demanding, but not proven to be more effective, alternative is 46–50.4 Gy, 1.8–2 Gy/fraction with 5-FU (bolus, continuous infusion or oral) [63]. Two European trials [77, 78] showed that the addition of 5-FUFA improves local control with reduced local failure rates after five years. These were 16–17% in the preoperative RT arms alone and 8–10% in the CRT arms. In the EORTC trial, the same reduction was seen irrespective of whether the chemotherapy was administered concomitantly or post-operatively. Two trials (Polish, TROG 01.04) have compared preoperative 5 x 5 Gy and preoperative CRT (5-FUFA + 50.4 Gy) without detecting any difference in local recurrence rates, DFS and OS [74, 75]. In the MRC-CR07 trial, preoperative 5 x 5 Gy was compared with post-operative CRT if CRM was positive. Local recurrence rates (5% versus 17%, P<0.001) and DFS (hazard ratio (HR) 0.76, P = 0.01) favoured the preoperative arm whereas OS did not differ significantly (HR 0.91, P = 0.04) [69].

Locally advanced 'ugly' rectal cancers

In the locally advanced, sometimes non-resectable cases (cT3 MRF+, cT4 with overgrowth to other organs), preoperative CRT, 50.4 Gy, 1.8 Gy/fraction with concomitant 5-FU-based therapy should be used [63, 79] followed by radical surgery six to eight weeks later. In the Nordic randomized trial (cT4NXM0), local control was significantly better after five years in the CRT arm (50 Gy + bolus 5-FUFA) than in the RT-only arm (50 Gy) (82% versus 67%, P = 0.03). In addition, DFS and cancer-specific survival were better in the combined modality arm, whereas OS did not significantly differ (66% versus 53% at five years, P = 0.09) [79].

In very old patients (≥80–85 years) and in patients not fit for CRT, 5 x 5Gy with a delay of approximately eight weeks before surgery is an alternative option, after favourable reports from several centres [85–87].

What chemoradiation schedule? Targeted drugs?

Standard preoperative CRT means a dose of 46–50.4 Gy together with 5-FU given either as bolus injections together with leucovorin six to ten times during the radiation (as in the trials proving that CRT provides better local control than RT alone) [77–80], prolonged continuous infusion (likely better than bolus) or oral capecitabine [88]. Combinations of 5-FU or other antifolates with other cytotoxics like oxaliplatin or irinotecan or targeted biological drugs have been extensively explored in phase I–II trials, which have claimed more favourable results (more downsizing, higher pathological complete remission (pCR) rates), but also more acute toxicity. Several comparative randomized trials using oxaliplatin have been performed. Mature data are reported from one of the studies, the German AIO-04 trial [89]. The trial included 1265 patients belonging to what here is named intermediate rectal cancers (in the article locally advanced). At three years, DFS in the investigational arm receiving preoperative CRT with infused 5-FU and oxaliplatin and postoperatively likewise infused 5-FUFA with oxaliplatin was 76% compared with 71% (HR 0.79, P = 0.03) in the control arm receiving 5-FU only. The 5-FU-schedules, however, varied between the two arms. Local and distant recurrences did not significantly differ between arms, although a slight advantage for the experimental arm may be present. It is too early to consider the addition of oxaliplatin as a new reference treatment, at least for the cancer stages included in the trial (chiefly cT3). The initial results of the other studies are not favourable, although pCR rates may be slightly increased [90, 91], and these combinations are thus still experimental. Nor are the initial results of adding targeted drugs like cetuximab, panitumumab, or bevacizumab favourable. When cetuximab was added to neoadjuvant oxaliplatin–capecitabine and preoperative CRT in the randomized phase II EXPERT-C trial, more radiological responses were seen in the cetuximab arm (89% versus 72%, P = 0.003) in the KRAS wild-type population (N = 90) [92]. OS was also improved (96% versus 81% at three years, P = 0.04, which was, however, not significantly at five years (84% and 72%), P = 0.20 [93]).

Post-operative chemoradiotherapy

Post-operative CRT (about 50.4–54 Gy, 1.8–2.0Gy/fraction) with concomitant 5-FU-based chemotherapy is no longer recommended, but could be used in patients with positive CRM, perforation in the tumour area, or in other cases with high risk of local recurrence if preoperative RT was not given. The strategy of giving post-operative CRT to CRM+ tumours was, however, inferior to giving preoperative 5 x 5 Gy to all [68].

Organ preservation

Apart from the earliest tumours that can be treated with local surgery or local RT, as previously described, it has become increasingly popular to first deliver CRT, restage the tumour and, if it has disappeared completely at palpation, endoscopy, and MRI (complete clinical remission, cCR) to postpone surgery (organ preservation) [94, 95]. If there are questions as to whether the tumour has completely disappeared, an excision biopsy of the previous tumour area can be carried out [92, 94]. If no viable tumour cells are found, no further therapy is delivered and the patient is monitored closely for at least five years. It is then assumed that potential lymph node metastases have been eradicated parallel with the excellent response of the primary tumour. Although this may undoubtedly occur in some patients, this strategy has not been subject to properly controlled prospective studies. It is likely that this excellent response will not be frequently seen in the intermediate and locally advanced cases [95], except if the tumour is small and located at the sphincter or levator plane, but rather only in the early cases. The advantages, no major surgery and no rectal excision if the tumour is very low, are apparent for certain individuals who run a high risk from surgery or who cannot accept a stoma. However, the disadvantages for many others are seldom discussed. In most patients with an early 'good' rectal cancer, a low anterior resection alone is the preferred therapeutic option. Cure rates are high and morbidity is only a result of the surgery, although this may be problematic with long-term bowel dysfunction for some patients (low anterior resection syndrome, LARS [99]). If these patients are instead treated with the aim of organ preservation, all will receive CRT with its acute morbidity. Those responding well clinically (cCR) could then be cared for with a watch-and-wait policy. These are the patients who have a potential benefit from this approach, although they would all suffer from the long-term toxicity that can be seen after CRT. If the tumour is located in the lower rectum, at least part of the sphincters must be included in the irradiated volume, and poor anal function can be a result. For those not responding well or those recurring during follow-up, major surgery is required. These patients will thus suffer the morbidity inherent in both CRT and surgery. No study has so far had a prospective design so it is not possible to estimate the proportion of patients who do not require major surgery [97].

Evaluation of response after preoperative (chemo) radiotherapy

Since the response to preoperative CRT influences prognosis [98] and thus subsequent therapy, attempts clinically and pathologically to restage the tumours have been made. The increasing experience in evaluating tumour response by repeat MRI is described in the previous section. Using FDG-PET, decrease in uptake can also be seen [100, 101]. At present, knowledge about the relevance of these changes is too uncertain to modify the extent of surgery.

Several systems for pathological tumour regression grading have been used. The best approach as regards reproducibility, prognostic information, etc. is not yet known. The tumours should at least be graded into three groups, complete response (pCR), some (potentially in the future good, moderate, and poor) response and no

response. The proportion of pCRs is influenced by the intensity of dissection. Standardization of the dissection is required before pCR rates can be used as a valid endpoint.

Radiation therapy volumes and doses

Whenever RT is indicated to lower the risk of local failure in the 'intermediate/bad' group or to cause downsizing to allow radical surgery in 'locally advanced/ugly' tumours, the primary tumour with mesorectum and lymph nodes outside the mesorectum at risk of containing tumour cells more than exceptionally should be irradiated. In the 'early/good' group before or after a local procedure, only mesorectal nodes are at sufficient risk to be involved. The appropriate dose to subclinical disease is not precisely known, but with 5-FU chemotherapy should be at least 45 Gy in 1.8–2 Gy fractions. The relative reduction in local failure rates is then in the order of 50–60%, and subsequently there is room for improvement. A boost of about 4–6 Gy in 2–4 fractions to the primary tumour can be given.

The entire mesorectum is at risk of having tumour deposits, often in the mesorectal lymph nodes, in all tumours except the very earliest (T1 sm1–2) and should be included in the clinical target volume (CTV). An exception is high tumours where it is sufficient to include the 4–5 cm distal to the tumour. Besides the mesorectal nodes, the presacral nodes along aa rectales superiores up to the level of S1–2 (if presacral nodes are radiologically involved, the upper border should be even higher). Local recurrences above S1–2 are seldom seen [102, 103]. The lateral nodes along aa rectales inferiores and aa obturatorii and the internal iliac nodes up to the bifurcation from aa iliac communes should be included in tumours below the peritoneal reflection, i.e. up to about 9–12 cm from the anal verge [104]. The risk of lateral node involvement in the Western world is not properly known, but studies from Asia show that these lymph nodes are rarely involved in low-mid-rectal pT1-2 tumours and in high tumours irrespective of T stage [105]. External iliac nodes should only be included if an anterior organ like the urinary bladder, prostate, or female sexual organs is involved. The medial inguinal nodes need only to be prophylactically irradiated when the tumour grows below the dentate line [106]. When lymph nodes are metastatic so that this can be seen on imaging, there is a risk of aberrant spread, and CTV can be enlarged to include other nodal stations than those described.

Fossae ischiorectales should only be included when the levator muscles and the internal and external sphincters are involved, since the fascia inside the levators is a strong barrier to tumour cell penetration [107].

Late toxicity from rectal cancer radiotherapy

The prevention of local failures, with the severe morbidity they may have, must be weighed against the morbidity from (C)RT that all treated patients can develop. Studies have tried to estimate what minimal absolute gain should be present for patients to prefer RT alone. These studies are difficult to interpret, although many patients accept an absolute 3% difference for the known morbidity risks of RT [108].

From the randomized trials, we have good evidence of morbidity after 5 x 5 Gy [76]. Increased risks of poor anal and sexual function, small bowel toxicity with obstruction, and secondary malignancies have been reported. These are increased roughly between 50–100%. For example, if the risk of any anal incontinence is 40% after surgery alone, it is about 60% after RT + surgery. If more severe incontinence problems are seen after 8%, it is increased to about 12%. Late bowel obstruction was seen in 6% after surgery alone and in 8–10% after combined therapy. Finally, the risk of second malignancy after a follow-up between 14 to 20 years was 9% versus 4% (relative risk 1.85 (95% confidence interval (CI) 1.23–2.78) in two Swedish studies [109]. No increased risk of secondary malignancies was seen in the Dutch TME-study [110]. With these figures in mind for those who survive at least eight to ten years, an absolute reduction in the risk of a local failure of approximately 5% motivates the recommendation to irradiate (Figure 38.3). Importantly, the RT given today will mean less late toxicity than that seen in the follow-up studies of the RT delivered during the 1980s and 1990s.

An important question as yet unresolved is the late toxicity from 5 x 5 Gy compared with the toxicity seen after 46–50 Gy in 25–28 fractions, usually administered with 5-FU. We know the long-term morbidity from 5 x 5 Gy up to at least ten years follow-up (with yesterday's techniques) from studies including thousands of patients. We do not have this knowledge from CRT. The Polish [74] and MRC-CR07 trials [69] have reported late toxicity after four years of follow-up, without being able to detect any differences between 5 x 5 Gy and CRT to 46–50 Gy. The short-course schedule uses a high fraction size of 5 Gy, compared with 1.8–2.0 Gy, whereas the total dose is less (25 Gy compared to 46–50 Gy). Both the fraction size and the total dose are relevant. The relationship between total dose, fraction size, and late toxicity is, however, complex (Table 38.2).

Another yet unresolved question is whether the addition of 5-FU, or in the future other drugs, increases late toxicity [111]. In one of the two randomized trials in the intermediate risk group [77, 78], the addition of 5-FU affected global QoL, social functioning and diarrhoea negatively. Almost 60% of the patients suffered faecal incontinence, impairing their social life [112]. In the trial in locally advanced/ugly cancers, more patients had stoma or poor anal function in the CRT group than in the RT group (89% versus 70%, P = 0.046) [113], but no differences in QoL were seen after four to eight years [114]. Whether this means that the chemotherapy addition results in more late toxicity or if this difference reflects survival of patients with more advanced tumours in the CRT group cannot be deduced.

Medical management

Adjuvant chemotherapy

In colon cancer there is high scientific evidence for significant gains in both DFS and OS from adjuvant biochemically modulated 5-FU or capecitabine. The addition of oxaliplatin further improves DFS and possibly OS [115]. The relative reduction in recurrences by fluoropyrimidines in stage III is in the order of 30–35% and a further 15–20% by the addition of oxaliplatin, resulting in an overall relative reduction of 40–45%. Based on these results, adjuvant systemic chemotherapy is standard treatment in colon cancer stage III and in stage II if the risk of recurrence is high.

In rectal cancer, the scientific evidence for convincing gains in DFS and OS from adjuvant chemotherapy is much less. The large adjuvant trials have included comparatively few patients with rectal cancer or have focused on colon cancer alone. The trials evaluating the value of oxaliplatin have so far only included colon cancer patients. Most patients with rectal cancer have also received locoregional treatment with pre- or post-operative RT or CRT, whereas this is not done in colon cancer. This more complex treatment

scenario and the evolvement over time of the local treatment strategies (better surgery and more often RT or CRT) have made the effects of adjuvant chemotherapy in rectal cancer more difficult to evaluate. The low level of scientific evidence for benefit from adjuvant chemotherapy in rectal cancer is acknowledged in authoritative treatment guidelines and by expert groups that still often conclude that such treatment should be considered based on the principles used for colon cancer [63, 116].

A Cochrane report [117], based on 21 clinical trials including 9221 patients treated over several decades, during which locoregional treatment has undergone considerable changes, concluded that statistically significant gains are present in both DFS and OS (Table 38.3). Based on this report, it is possible to conclude that adjuvant treatment for rectal cancer could be given as it is for colon cancer. A systematic review, however, concluded that adjuvant chemotherapy after surgery for rectal cancer following RT or CRT is not 'evidence-based' [118]. The trial data were then divided based on whether surgery was the only locoregional treatment or was accompanied by pre- or post-operative RT or CRT. Based upon the report of a few randomized studies in 2014 and 2015, two additional meta-analyses, one of which was based on individual patient data, have been published in 2015 [119, 120]. They both reach the conclusion that there is no evidence of benefit from adjuvant chemotherapy in patients who preoperatively received RT/CRT. The trial results are summarized in Table 38.3.

Adjuvant chemotherapy following surgery alone

This treatment setting, in most cases not relevant today in the Western world, except for the early stages, has mostly been studied in Japan. The trials, in total including more than 2000 rectal cancer patients, showed statistically significant benefit in DFS and/or OS with risk reductions in the 15–30% range from adjuvant oral UFT (uracil/tegafur) or carmofur, sometimes together with mitomycin C [121–125]. Similar observations were also observed in two Western world trials, including the QUASAR trial, which explored the value of adjuvant 5-FUFA in patients with colon or rectal cancer where the benefit of adjuvant chemotherapy was considered uncertain [125].

Of 3239 patients in the QUASAR trial, 984 had rectal cancer. In this group, OS at five years was 78% in the group randomized to 5-FUFA compared with 74% in the control group (HR 0.77, P = 0.05). Subgroup analyses with patients divided into those with surgery alone (N = 549) or pre- (N = 198) or post-operative RT (N = 201) did not show significant heterogeneity between the groups. The groups were too small to show statistically significant differences but all showed point estimates indicating benefit from adjuvant chemotherapy.

Adjuvant chemotherapy following surgery and post-operative RT or CRT

Four moderately sized trials showed no benefit in DFS or OS from adjuvant 5-FU for six to 12 months [126–129]. This treatment setting was also part of the QUASAR trial [125].

Adjuvant chemotherapy following preoperative RT or CRT and surgery

This was investigated in the 2 x 2 factorially designed EORTC 22921 trial. In total, 1011 patients were randomized to preoperative RT or CRT and to post-operative adjuvant 5-FUFA for three months or observation [78]. Adjuvant chemotherapy tended to provide benefit in DFS and OS following preoperative RT or CRT, but the differences were not statistically significant. However, in patients given adjuvant chemotherapy, the local recurrence rate was reduced from 17% to 9% (P = 0.002). In an update of the trial after 10 years [130], there was still a gain from adjuvant chemotherapy in the risk of local recurrences (22% versus 12–15%) but no difference in DFS and OS. In the QUASAR trial, an obvious trend to benefit from adjuvant chemotherapy was seen among the 198 patients who had preoperative RT [125].

The Dutch/Swedish PROCTOR/SCRIPT trial randomized patients following short-course RT and immediate surgery or long-course CRT to six months of 5-FU/leucovorin (PROCTOR) or capecitabine (SCRIPT) or observation only, and the UK Chronicle trial randomized patients after preoperative CRT to observation or adjuvant capecitabine and oxaliplatin [131, 132]. Both trials closed patient inclusion prematurely due to poor recruitment. None of the studies reveal any significant gains in OS or DFS however, the trials lack statistical power to exclude meaningful gains. In an Italian trial [133], 635 patients were randomized to 4.5 months of adjuvant 5-FUFA or observation alone after preoperative CRT. No differences in OS, DFS, distant metastasis rates or local recurrence rates were detected.

Adding 5-FU-based adjuvant chemotherapy after surgery alone thus seems to provide meaningful benefit in terms of OS and DFS, and perhaps also local recurrence rate. This is in correspondence with colon cancer. From a clinical practice point of view, however, this has limited relevance since probably very few patients today with more advanced rectal cancer up to the level of about 10 cm have surgery without preoperative (C)RT. This knowledge is of use when a patient has been operated on without prior (C)RT based on favourable clinical and radiology findings at staging, but with high-risk features in the histopathology report. It is then reasonable to consider adjuvant chemotherapy as an alternative to post-operative CRT, since it may provide both improved local and systemic control. It is acknowledged, however, that these data are not strong, particularly not for the use of an oxaliplatin–fluoropyrimidine combination where no mature trial data exist. If the local recurrence risk is high (e.g., non-radical surgery (R1+R2 or CRM+), CRT are more relevant than if the risk criteria indicate higher risk of systemic relapse (e.g., N2 or EMVI+). However, a beneficial effect from adjuvant chemotherapy on local recurrences is also supported by pooled analyses of several trials [134, 135], but pooling of data from different trials may easily introduce bias.

The overall picture gets complicated when preoperative CRT has been used. For such therapy given post-operatively, most data show that adjuvant chemotherapy provides no major benefit [136, 137]. Most data indicate that when preoperative (C)RT has been given, the benefit from adding adjuvant chemotherapy is likely also very small or absent, with the QUASAR trial as an exception [119, 120]. By adding preoperative (C)RT, which has an obvious effect on small tumour deposits locoregionally, as indicated by reduced local recurrence rates, the effect from adjuvant chemotherapy is in some way reduced. The chemotherapy added to RT could theoretically have an adjuvant systemic effect although this is unlikely considering the lack of benefit in OS and DFS from preoperative CRT compared with RT alone [74–78] and the low total systemic exposure to chemotherapy compared with conventional adjuvant chemotherapy.

Table 38.3 Major randomized clinical trials and summary of recent meta-analyses on the role of systemic adjuvant chemotherapy after locoregional treatment of rectal cancer for cure

Locoregional treatment	Study/reference	No of pts	Stages, treatments	Results	Comments
Surgery alone	Sakamoto/Japanese meta-analysis [123]	2310 from 3 old trials	Stages I–III, 5-FU, UFT or carmofur 6 m, mitoC 6 m added in two trials	HR for OS 0.86 (P = 0.049), for DFS 0.77 (P = 0.0003)	No gain in colon cancer (n = 2380)
	JSCCR/Japanese meta-analysis [124]	2385 from 3 trials	Stages I–III, UFT or carmofur 12 m, mitoC 6 m	HR for OS 0.92 (P = 0.04), for DFS 0.83 (NS)	2 trials probably included in [111]
	Sakamoto/Japanese meta-analysis [121]	2091 from 5 trials	Stages I–III, UFT or carmofur 12–24 m, mitoC 6 m added in three trials	HR for OS 0.82 (P = 0.02), for DFS 0.73 (P < 0.0001) and for LRFS 0.68 (P = 0.003)	Some trials overlapping with [111] and [112]
	NSAS-CC [122]	274	Stage III, UFT 12 m	HR for OS 0.60 (P = 0.034), for DFS 0.66 (P = 0.033)	Included in [112] updated results. No gain in colon cancer (n = 334), HR 0.82, P = 0.4).
	Nordic trials [286]	691	Stages II–III, 5-FU (various) 4–12 m	OS at 5 y 73% versus 81% for AC in stage II (P = 0.09) and 51% versus 48% for AC in stage III (P = 0.91)	A gain was seen in colon cancer stage III (n = 708, OS at 5 y 48 versus 55%, P = 0.15)
	NSABP-R01 [287]	371	Stage II–III, 5-FU, semustine and vincristine	OS and DFS improved (43% versus 53% for AC at 5 y, P = 0.05 and 30% versus 42% for AC, 0.006, respectively	Postop RT alone had no effect on OS or DFS
	QUASAR uncertain [125]	549	Stage II, III, 5-FU 6 m	HR for OS approx 0.85 (NS), for DFS approx 0.75 (NS)	Subgroup analysis. In all 948 RC patients included HR for OS was 0.77 (95% CI 0.54–1.00), for DFS 0.68 (0.4–0.96). 86% of all pts included had stage II
Surgery and post-op RT/ CRT	Hellenic Group [126]	220	Stage II, III, post-op CRT w/ wo 5-FUFA four cycles	AC NS improved DFS at 5 y from 68 to 70% and OS from 73 to 77%	
	Cafiero et al [129]	218	Stage II, III, post-op RT w/ wo 5-FU/Leva 6 m	HR for OS 1.04 (P = 0.9), for DFS 1.12 (P = 0.6)	Low compliance with adjuvant chemotherapy, NS improvement in compliant pts
	Dutch group [128]	299	Stage II, III, post-op RT w/ wo 5-FU/Leva 12 m	HR for OS approx 0.95, for DFS approx 0.90 (NS)	Approx 75% of pts had at least 6 m treatment. Significant effect seen in colon cancer in the same trial
	ECOG Est 4276 [126]	237	Stages II–III, post-op RT, CT or CRT	5-yr OS RT 46%, CT 47%, CRT, 50% (NS)	Abstract only
	QUASAR uncertain [125]	201	Stage II, III, post-op RT w/ wo 5-FU 6 m	HR for OS approx 0.80 (NS), for DFS approx 0.65 (NS)	See comment on QUASAR above
Preop RT and surgery	EORTC 22921 [78]	505	cT3, T4, preop RT w/wo 5-FU 3 m	HR for OS for AC versus no AC 0.85 (0.68–1.04) and for DFS 0.87 (0.72–1.04). LR at 5 y was 17 and 10% in the RT and RT/ AC groups, respectively	Represents 2 of the 4 arms in this trial. Results not separated for preop RT and CRT (see below) groups. 27% of pts scheduled for AC never started. Difference in LR between preop RT only and the other 3 groups, P = 0.002
	QUASAR uncertain [125]	198	Stage II, III, 5-FU 6 m	HR for OS and DSF approx 0.55 (NS)	See comment on QUASAR above
	PROCTOR/SCRIPT [131]	470	Stage II, III, preop RT (5x5) or CRT 5-FU (PROCTOR), Cap (SCRIPT) 6 m	OS at 5 y 79% versus 80% for AC (HR 0.93 (0.60–1.39), DFS HR 0.80 (0.60–1.07, P = 0.13). No diff in LR	61 patients had preop CRT, 376 preop RT, prematurely broken

(continued)

Table 38.3 Continued

Preop CRT and surgery	EORTC 22921 [78, 130] l	506	cT3, T4, 5-FU 3 m post-op	See above. LR was 9% and 8% in the CRT and CRT/AC groups, resp	See above. Long-term follow-up after 10 years did not alter the results
	Italian Group [133]	655	Fixed/tethered RC. 5-FU 4.5 m post-op	OS 69% for CRT only and 68% when AC added (NS). No difference in DFS or LR	28% never started AC
	Chronicle [132]	113	Preop CRT, Xelox 4.5 m	OS 3 y, 89% versus 88%. (HR 1.18), DFS 78% versus 71%, HR 0.80 (0.38–1.69)	Prematurely closed, 93% started AC, 48% completed 6 cycles
	Individual meta-analysis [119]	1196 from 4 trials	Preop RT or CRT	OS HR 0.97 (0.81–1.17), distant rec, HR 0.94 (0.78–1.14)	Overall no gain. In tumors 10–15 cm, DFS HR 0.59 (0.40-0.85, P = 0.005)
	Systematic Overview [120]	2431 in 5 trials	Preop CRT/RT versus observation	OS HR 0.94 (0.81–1.09), DFS 0.93 (0.81–1.06)	
		2710 in 4 trials	Preop CRT with or without oxaliplatin, AC±oxaliplatin	DFS HR 0.84 (0.66–1.06, P = 0.15)	3 trials short follow-up, 1 trial published [89] sign gain in DFS and OS. Not the same 5-FU in controls and experimental group
All	Cochrane analysis [108]	9221 from 21 trials	All stages, all treatments, all settings	HR for OS 0.88 (0.76–0.91), for DFS 0.75 (0.68–0.83)	Great heterogeneity between trials running during several decades

Abbreviations: preop, preoperative; Postop, post-operative; AC, systemic adjuvant chemotherapy; RT, radiotherapy; CRT, chemoradiotherapy; pts, patients; UFT, uracil-tegafur; carmofur, 1-hexylcarmobyl-5-fluorouracil; m, months; HR, hazard ratio; OS, overall survival; DFS, disease free survival; LRFS, local relapse-free survival; JSCCR, Japanese Society for Cancer of the Colon and Rectum; HCFU, 1-hexylcarbomoyl-5-fluorouracil; NS, not statistically significant; 5-FU, 5-fluorouracil (modulated with folinic acid in most trials); mitoC, mitomycin C; y, year; w/wo, with or without; Leva, levamisole; approx., approximately; CI, confidence interval; resp, respectively.

Source: data from Hoirup Petersen S et al., Post-operative adjuvant chemotherapy in rectal cancer operated for cure, *Cochrane Database of Systematic Reviews*, Issue 3, Art. No.: CD004078, Copyright © 2012 The Cochrane Collaboration. Published by John Wiley & Sons, Ltd.

One possibility is a lower sensitivity of rectal cancer compared with colon cancer in the adjuvant setting based on differences in tumour biology. Similar activity of chemotherapy in terms of tumour response rates and benefit in PFS and OS in metastatic CRC argue against this possibility. However, colon cancer differs from rectal cancer in several aspects relevant to tumour biology, and although such differences may not materialize when metastatic, they may be important in putative tumour 'stem cells', responsible for establishment and growth of metastasis in different organs.

Yet another explanation to the small or absent effect from adjuvant chemotherapy in rectal cancer treated with preoperative CRT would be the timing of adjuvant chemotherapy, i.e. that adjuvant chemotherapy starts later than in colon cancer due to the time spent on CRT and waiting for surgery and/or post-operative complications. In colon cancer the efficacy of adjuvant chemotherapy is attenuated by time of start after surgery [138].

Starting with the systemic rather than the locoregional treatment in rectal cancer could approach the relevance of the timing effect. Apparently favourable findings in the EXPERT(-C) trials, where four cycles of XELOX were given prior to CRT, indicate that this approach may be beneficial [92, 139]. This approach seems feasible and well tolerated [139, 140], and is being investigated in the RAPIDO trial in which patients with poor-prognosis rectal cancer are randomized to conventional CRT followed by surgery and optional adjuvant chemotherapy or short-course RT followed immediately by neoadjuvant chemotherapy (six cycles of XELOX) and surgery [141].

Subgroup analyses of the EORTC 22921 trial have indicated that patients with tumour downsizing from cT_{3-4} to pT_{0-2} compared with those with tumours remaining as pT_{3-4} following (C)RT had better prognosis but also showed benefit from adjuvant chemotherapy [142]. However, this effect seemed restricted to preoperative RT and not to CRT, and was not related to nodal status after treatment. Additional methodological problems with the subgroup analysis are present [118]. Thus, although response to neoadjuvant CRT provides prognostic information in rectal cancer, it cannot, based on current knowledge, be used to predict the efficacy of adjuvant chemotherapy.

Follow-up

The rationale for follow-up of patients after rectal cancer surgery is to find metachronous tumours for quality control and audit.

Metachronous metastases and new primary colorectal tumours

The most common places for a recurrence are the liver or the lungs. Therefore follow-up programmes include scanning of these organs, potentially allowing radical metastasectomy if recurrence occurs. Preoperatively, the liver and the lungs are scanned, preferably with CT. Post-operatively the patient should be investigated with the same type of scan so that it is possible to compare the findings. There is a debate as to how often patients should be scanned. In many centres worldwide patients are seen every sixth month or sometimes even more often during the first years, but the literature is very scarce and there is no data to support intense follow-up. The COLOFOL trial randomized 2500 patients with stages II and III CRC to intensive follow-up (every sixth month the first two years and then a three-year follow-up) or a 'standard' follow-up (one and three years after surgery). In both groups, scanning of the liver and lungs and a CEA value were done. Follow-up is ongoing. The primary endpoint is survival [143].

Between 3–4% of patients who have had CRC will later have another colorectal tumour [144]. Therefore, a follow-up programme with colonoscopies has been recommended. Again, no consensus about the frequency exists. Based upon a Danish trial, where 600 patients were randomized to colonoscopy every year or every fifth year it is sufficient to investigate most patients every fifth year [145].

Quality control

Since rectal cancer surgery is a major procedure with many complications, it behooves patients to be seen post-operatively. In many countries nurse practitioners perform this in cooperation with the surgeon [146]. An enterostomal therapy nurse is essential for all patients with a stoma. The patient has to be checked by the operating surgeon some weeks after discharge to disclose problems which can hopefully then be corrected. Based upon that follow-up visit it might be necessary to see the patient several times, if post-operative complications persist. Once the post-operative period is over a follow-up programme for metachronous metastases should be followed, as outlined previously.

Audit

Another important aim is to use follow-up as an audit for the department. It is important that all departments handling rectal cancer patients are aware of their results concerning both early and late complications and oncology outcome, and can break down the data on the individual surgeons. A good audit system allows changing procedures and improving the results [147].

Treatment of metastatic disease

In colon and rectum cancer, about 20% of the patients in Western populations have synchronous metastases, and another 20% will later develop metastases. The most common site is the liver, but lung metastases are also frequent, particularly if the primary is in the rectum. If the disease is metastatic, the primary tumour site is less important since it has not been possible to detect any clinically relevant differences in tumour behaviour or response to medical therapy. The primary tumour site is of relevance in synchronous disease if surgery of the primary, for cure or for palliation, is planned.

During the past 20–25 years scientific activities in metastatic CRC (mCRC) have markedly increased. Definite improvements have also been seen. Although one may question whether the gains achieved have been sufficient in proportion to the efforts, the gains have markedly influenced clinical routines. In spite of the apparently marked progress in medical treatments of mCRC, surgical removal of all known disease is in practice the only therapy that can cure a patient with mCRC. Alternatives to surgical removal of metastases, if technically possible and the tumour is biologically sound, are radiofrequency ablation (RFA), other invasive ablative procedures, and stereotactic body radiotherapy (SBRT). Progress in medical oncology has, however, contributed to potential cure for some patients with mCRC.

Advances in systemic treatment of patients with metastatic colorectal cancer

In the absence of tumour-controlling treatments, the prognosis for patients with mCRC is poor with, on a population level, a median survival of less than six months and a very low probability of surviving beyond one or two years. Median survival in most recent trials is at least three times longer than it was two decades ago. The impression is also that these patients mostly do well during those extra months. This impression has been substantiated in trials where quality of life (QoL) estimations have been performed. A number of small steps have been taken, together resulting in median survival of patients included in trials being prolonged from about six to eight months to about 24 months or even slightly longer if molecular selection is done (Table 38.4).

Survival in population-based materials of patients with newly diagnosed stage IV CRC is presently about one year [148]. The discrepancy between survival of about one year in the entire population and above two years in the most recent trials clearly indicates that patients included in trials are selected [149]. It is important to focus on reasons for this selection and develop treatments that not only benefit the fittest patients.

Balancing gains and costs

The effects of chemotherapy on objective response rates (RRs), progression-free survival (PFS), OS and QoL are well documented in mCRC. Most gains with high statistical significance have been shown in individual trials or in meta-analyses of the trials [150, 151]. More toxicity and higher economic costs have accompanied each improvement in treatment results. The cost increase is particularly true for the development that has taken place in the past decade. The overall gains in terms of longer PFS and OS, and

Table 38.4 Chemotherapy in advanced colorectal cancer, development with time

Decade	Median survival	Action taken
1970	4–5 months	Supportive care, unselected patients
1980	6–7 months	Supportive care, trial patients
	10–12 months	5-FU/folinic acid (FA), trial patients
1990	12–14 months	5-FUFA, good performance trial patients
	14–15 months	5-FUFA + new drug[1], good performance trial patients
2000	15–17 months	5-FUFA + new drug, first- and second-line treatment
	18–20 months	5-FUFA + new drug, sequential treatments, local methods (chiefly surgery)
	20–22 months	5-FUFA + new drug, sequential treatments, local methods + targeted drugs[2], good performance trials patients
2010	22–26+ months	5-FUFA + new drug, sequential treatments, local methods + targeted drugs used in subgroups potentially benefiting from therapy, very good performance trials patients that could potentially be resected
2015	26–30+	Everything above, triplet+beva or doublet +EGFR in RAS wild-type tumours

Patient selection and better treatments are most important for this prolongation in median survival.

Follow-up routines are also of importance. About 2–4 months may be explained by earlier diagnosis of metastases in recent compared with older patient series.

[1] irinotecan or oxaliplatin

[2] bevacizumab, cetuximab, or panitumumab

QoL improvements of palliative chemotherapy in mCRC are sufficiently large to merit such changes being made to routine therapy [152]. What may need further discussion is whether all incremental gains are sufficiently large in relation to toxicity, other inconveniences, and costs to qualify as routine therapy. Since trial methodology has improved, including recognition to perform large trials, there is danger that 'too small' gains are proven to have statistical significance.

Most clinicians agree that statistical significance does not necessarily indicate clinical relevance. Still, this conclusion is controversial. There is no consensus on whether a minimum size of any gain, in relation to toxicity, inconvenience, and other costs, in fact exists. Further, there is no consensus as to the most relevant parameter for treatment efficacy. Most importance is given to OS, although PFS has replaced OS as primary endpoint in most clinical trials, at least in the first-line situation [153]. Of great relevance is also the individual patient's judgement of whether a particular gain is sufficient to accept therapy in the light of anticipated treatment burden. However, research and clinical experience have shown that patients generally also want to be treated for small gains [154], and sometimes for gains too small for doctors or healthcare providers to accept. Many patients facing the outcome of progressive cancer accept very short survival prolongation or limited probabilities of symptom relief, even at the cost of considerable toxicity.

Costs have increased substantially on anticancer drug budgets, and mCRC is no exception [155]. The number of studies of costs in patients with mCRC is limited [152, 156], and, although there may be claims that one treatment is cost-effective in comparison with other treatments, it is difficult to draw firm conclusions. Some of the recent development seen in mCRC is very close to or above the limit of what may be acceptable, at least in healthcare systems that have the ambition to offer equality to all individuals. This is also reflected in, for example, the guidelines published by the National Institute for Health and Clinical Excellence (NICE) [152, 157].

Necessity of continuous good supportive care

Even if the death of many patients with mCRC has been postponed by several months or years, the ultimate fate is clear from the very beginning for the majority of them. This knowledge and the fear of problematic symptoms later in the course of the disease may be a burden to the patients, their relatives, and close friends. Even if the palliative treatments appear to function well, with tumour regressions and limited toxicity, there is need for continuous support. This need increases when fewer treatments with sufficient probability to work remain. The requirements of palliative care when death is approaching are likely the same whether they occur a few months or a few years after the diagnosis of incurable disease.

Chemotherapy can prolong life and improve the well-being of patients with metastatic colorectal cancer

Until the late 1980s there was no evidence that treatment had any meaningful influence on the well-being of many patients. Single patients had short-lived benefit from being treated, but the impression was that it did not prolong survival [158]. In 1989, two randomized trials comparing 5-FU alone, the mainstay of treatment for decades, with biochemically modulated 5-FU, reported prolonged survival (median about three months) and improved QoL by the combined regimen [159, 160]. A meta-analysis [150] and a systematic overview [161] of 11 trials, including overall 796 patients, reported that 5-FU-based treatment (systemic or regional administration) prolonged median survival by four to six months compared with a control group (no or delayed chemotherapy). Supportive evidence for survival gains also comes from trials in the second- and third-line situation after failure on previous regimens [162].

Trials randomizing between chemotherapy and no/delayed chemotherapy or comparing different schedules have shown that the QoL of individual patients can be improved by treatment, or at least remain stable even if the treatment may cause disabling toxicity [162, 163]. Using fluoropyrimidines alone, an objective response (complete and partial remission, CR + PR) and stationary disease (SD) with a duration exceeding four months to 5-FU-based therapy is usually associated with a favourable QoL outcome (Table 38.5). This is the same using combinations of drugs, which more frequently result in objective responses, although increased toxicity to the treatments may temporarily counterbalance this [164, 165]. A response to treatment is also an independent predictor of survival [166, 167], although this relation is not always strong, since survival prolongation is also seen in those with SD. The arbitrarily set criteria for an objective response (30% in the sum of the longest diameters using RECIST) [168] are not optimal for survival prediction [169]. Further, subsequent lines of therapy also influence OS.

The elderly and comorbid patients represent a therapeutic challenge. Even if age per se is not a prognostic factor in most of the trials [170, 171], the great majority of the elderly population is never evaluated for trial participation. Thus, selection among the elderly is extensive [162]. Many patients above an age of 75–80 years do not tolerate present treatments particularly well, even if they are in a very good shape at diagnosis of mCRC. However, there are exceptions and a reasonably high chronological age should not be an absolute contraindication to initiating therapy.

5-fluorouracil (5-FU), biochemically modulated 5-FU, oral fluoropyrimidines

Among the drugs tested for antineoplastic activity in mCRC, 5-FU is still the individually most active agent. During the 1990s, chemotherapy for mCRC using fluoropyrimidines evolved along several paths; potentiation of 5-FU bolus activity by biochemical modulators, particularly methotrexate and folinic acid (FA, leucovorin), protracted venous infusion of low daily doses, infusions during one or a few days of comparatively high 5-FU doses alone or modified by FA, and combinations of the alternatives. 5-FU likely acts differently depending upon schedule [172]. Biochemically modulated 5-FU results in more tumour regressions than 5-FU alone, at least when given as bolus injections. This has not been translated into considerable survival prolongation. Since toxicity is not substantially increased, biomodulated 5-FU is considered to be a better palliative treatment than 5-FU alone unless prolonged infusions (three days or longer) are given. There is at present no firm evidence showing that any of the modulated 5-FU regimens (Table 38.6) is superior to the others, although the 'infused' regimen is considered superior to bolus regimen, since it gives more tumour regressions, longer PFS, and less toxicity [173–175]. The comparator in those trials was the Mayo Clinic regimen. This regimen is, however, associated with a high degree of toxicity, and generally considered

Table 38.5 Relations between an objective response and quality of life changes (patient defined/independently categorized) to 5-FU-based chemotherapy alone (above) or in combination with irinotecan in advanced colorectal cancer (below)

Quality of life	Objective response		
	CR + PR + SD4	SD2+PD	All
Improved	38	4	42
Unchanged	8	4	12
Worse	4	60	64
All	50	68	118
	Objective response		
Quality of life	CR + PR + SD4	SD2+PD	All
Improved	61	8	69
Unchanged	54	7	61
Worse	26	12	38
All	141	27	168

Data are pooled from three Nordic trials run during the 1980s and 1990s where symptomatic patients were treated with 5-FU alone or biochemically modulated 5-FU, or from the Nordic 7 study where patients were treated with FUFA + irinotecan [152] (not all centres participated in the QoL substudies).

Abbreviations: CR, complete remission, PR, partial remission, SD4, stationary disease for at least 4 months, SD2, stationary disease between 2 and 4 months, PD, progressive disease. Using the comparably low-toxic single agent 5-FU, a response was in most patients associated with improved well-being, whereas this was not always the case with a more toxic treatment where particularly diarrhoea, fatigue, and hair loss at least temporarily resulted in poorer global quality of life. The lack of response was usually not associated with improved well-being.

Table 38.6 Palliative chemotherapy regimen in colorectal cancer: selection of 'evidence-based' treatment options

First and second line	
Fluoropyrimidines alone	
Bolus 5-FU+folinic acid (FA)	Mayo Clinic, Roswell-Park, Machover, Nordic FLv
Infused± FA	German AIO, Spanish TTD, Lokich
Hybrid bolus/infused+FA	deGramont (Lv5-FU2, several simplified variants)
Oral	Capecitabine, UFT+FA, S1
Raltitrexed	
Combinations of a fluoropyrimidine and another cytotoxic drug	
	5-FUFA + oxaliplatin (like FOLFOX 4-7, FLOX)
	5-FUFA + irinotecan (like Lv5-FU2-Iri, FOLFIRI, FLIRI)
	5-FUFA + oxaliplatin + irinotecan (FOLFOXIRI)
	Capecitabine + oxaliplatin (XELOX)
	Capecitabine + irinotecan (XELIRI)
	Lokich + Mitomycin C (seldom used any more)
Other combinations	Irinotecan and oxaliplatin (IROX) (inferior to fluoropyrimidine-combinations)
Combinations with targeted drugs	
	5-FUFA + bevacizumab
	Capecitabine + bevacizumab
	5-FUFA + irinotecan or oxaliplatin + bevacizumab
	Capecitabine + irinotecan or oxaliplatin + bevacizumab
	5-FUFA + irinotecan or oxaliplatin + cetuximab or panitumumab
	5-FUFA + irinotecan + aflibercept
	5-FUFA+irinotecan+oxaliplatin+bevacizumab
Third and fourth line	
EGFR-inhibitor	Cetuximab
	Panitumumab
	Irinotecan + cetuximab (or panitumumab)
Multikinase inhibitor	Regorafenib
Fluoropyrimidine	TAS102

Abbreviations: FA, folinic acid (leucovorin); 5-FU, 5-fluorouracil.

unacceptable as palliative treatment [176]. Other bolus schedules are better tolerated [177].

Several oral alternatives were also developed. Capecitabine is converted to 5-FU, preferentially in tumour tissue, by thymidine phosphorylase. Studies have shown that results are similar to intravenous 5-FUFA in metastatic disease [178]. UFT is composed of tegafur, a fluorouracil prodrug, and uracil that competes with 5-FU as a substrate for dihydropyrimidine dehydrogenase (DPD), responsible for 5-FU catabolism. Again the efficacy and safety profile of UFT + leucovorin is similar to 5-FUFA in mCRC. S1, a combination of tegafur, oteracil, and dihydroxypyrimidine, also has activity in mCRC [179]. Oral 5-FU prodrugs (best explored using capecitabine) can replace 5-FUFA in all lines of therapy since they are more convenient and have the same efficacy [180]. The level of toxicity is about the same, although the toxicity profiles are not identical.

New drugs and drug combinations

During the late 1990s, two other drugs were introduced in the treatment of mCRC. Oxaliplatin is a third-generation platinum that has low activity as single agent. However, when combined with 5-FUFA (or capecitabine) [181], it is superior to 5-FUFA alone. The lack of a clear OS benefit in the trials is likely obscured by crossover for salvage therapy. Although primarily tested with the bi-monthly de Gramont schedule [181], it has been combined with other infused regimen [182], bolus 5-FUFA [183], oral fluoropyrimidines [184], raltitrexed, and irinotecan. Oxaliplatin with capecitabine (XELOX) results in similar PFS and OS to infused 5-FUFA/oxaliplatin-combinations [184].

Irinotecan, CPT-11, is a topoisomerase I inhibitor which showed activity in patients who had failed 5-FUFA treatment. Irinotecan was superior to best supportive care (BSC) (OS median three months, P <0.001) and best estimated chemotherapy regimen

(Lv5FU2) (OS median two months, P = 0.04) in two randomized studies [162, 185]. The addition of irinotecan to infused 5-FUFA (48-hour bimonthly and weekly 24-hour) in first line gave more responses than 5-FUFA alone (about 40% versus 20%; P < 0.001), longer PFS and OS, median about two months [186, 187].

Combinations of either oxaliplatin or irinotecan with 5-FUFA have higher antitumour activity than 5-FUFA alone with more objective responses, longer PFS, and slightly prolonged OS. It also appears that the superiority is independent of the chosen 5-FUFA regimen, although one irinotecan/bolus 5-FUFA combination (IFL) was too toxic [187, 188]. IFL, at a reduced initial dose (rIFL), was inferior to bolus/infused 5-FUFA/oxaliplatin (FOLFOX-4) [189].

We have lived without knowledge of the best 5-FUFA schedule for the past decades. Presently, the best combination schedule is not known, although many consider either oxaliplatin or irinotecan with the de Gramont schedule (including several simplified variants) to be reference schedules (FOLFOX and FOLFIRI). Head-to-head comparisons between the many 5-FUFA/irinotecan or 5-FUFA/oxaliplatin combinations have hardly been done. The bolus FLIRI regimen resulted in the same PFS and OS and had the same toxicity as bolus/infused Lv5-FU2-Iri (FOLFIRI is a variant), but slightly lower RR (35% versus 49%, P <0.001) [190]. In a pooled analysis of six randomized studies of 3 494 patients comparing oxaliplatin with 5-FUFA (any FLOX/FOLFOX variant) or capecitabine, similar OS and PFS were found, whereas RRs were slightly lower using XELOX (odds ratio 0.85 (95% CI 0.74–0.97, P = 0.02)) [184]. The toxicity profiles differ between XELOX and 5-FUFA/oxaliplatin, but overall toxicity is similar [191]. As palliative treatments, a more convenient XELOX regimen can be used [184, 192, 193], whereas it has been argued that a 5-FUFA/oxaliplatin combination (like FOLFOX) should be used when tumour cell kill is to be maximized, as in the neo-adjuvant/adjuvant and conversion situations. The same can probably also be said about combinations of capecitabine and irinotecan (XELIRI) [194]. Initially, XELIRI gave rather too much unpredictable toxicity and shorter PFS, but more recent studies indicate that it is effective and tolerable [194–197]. The differences between the more convenient oral alternatives and the entirely intravenous schedules are small, and the alternatives can likely be used interchangeably for palliation according to patient and doctor preferences.

Both irinotecan and oxaliplatin add toxicity and cost to the 5-FUFA treatment. The toxicity profiles of irinotecan (preferentially diarrhoea, some alopecia) and oxaliplatin (preferentially paraesthesias) are entirely different, and it is not possible to state that one of the drug combinations can be favoured over the other. Several randomized phase II studies have compared the combinations (5-FUFA/IRI and 5-FUFA/OX, alone or with targeted drugs) without detecting any significant difference in efficacy [196, 198–200]. The regimen to choose must individually be evaluated and discussed with the patient.

Second-line treatment

After failure on one 5-FU-containing regimen, patients could respond to another 5-FU-based regimen. If the first regimen was bolus 5-FU, infused 5-FU was frequently used based upon the assumption that the antitumour activity was different [172]. It was not until irinotecan, with a different mode of action, appeared

that conclusive trials were performed. Irinotecan significantly prolonged survival in patients refractory to 5-FU when compared with either BSC [162] or bolus-infused 5-FU (Lv5FU2) [172]. These two randomized trials greatly influenced the use of several lines of chemotherapy in patients still in good shape in spite of failing one regimen. Slightly later, oxaliplatin with 5-FUFA (FOLFOX-4) showed superior activity to either drug alone following bolus IFL [201]. About 35–40% of the patients had symptom relief, compared with 10–15% in the control groups, and median PFS was prolonged from two to four months. Objective responses were seen in about 10% of the patients treated with FOLFOX-4 compared with 0–2% in those treated with Lv5-FU2 or oxaliplatin alone.

In a large MRC-FOCUS study, irinotecan alone after failure on 5-FUFA was slightly inferior to a combination of 5-FUFA with either irinotecan or oxaliplatin in second-line (RR 11% versus 16–23%, disease-control at 12 weeks (CR + PR + SD) 40% versus 57–60%, P < 0.005) [202]. In 491 patients failing on 5-FUFA, FOLFOX-4 resulted in more responses (28% versus 16%, P = 0.009) and longer PFS (6.2 versus 4.4 months, P = 0.009) than irinotecan alone, but OS was the same (median about 14 months) [203]. About half of the patients received the mandated third-line therapy. The trials show that it appears important to keep 5-FUFA in the second-line situation and that there is no major difference if an irinotecan or an oxaliplatin combination is used upfront.

Sequential treatment

Once it was established that a cytotoxic drug with another mode of action had activity after failure on a previous regimen and that combination chemotherapy was more efficient than 5-FUFA, sequential administration was explored. Trials have shown that OS is similar whether the first-line regimen is a 5-FUFA (capecitabine) combination with irinotecan or with oxaliplatin [196, 198, 200, 202]. The non-chosen combination is given in second line. OS has, in trials including patients in good performance and with no laboratory abnormalities precluding therapy, been up to 20–22 months using either of the two sequences. Objective responses can be expected in about 50% to the first-line combination and in 10–15% to the second-line combination. Median PFS in first line is eight to nine months and three to four months in second line. The toxicity profiles of the combinations are entirely different and it is up to the individual patient to prefer either sequence. Since oxaliplatin frequently causes disabling and persistent peripheral neurotoxicity, there is some rationale starting with an irinotecan combination since time to progression, and thus treatment duration, is much longer in first than in second line. The time to death, during which the patient potentially has to live with neuropathy, is then longer. Irinotecan combinations, however, result in alopecia more often than oxaliplatin combinations (about 60% versus 5%).

Single-agent fluoropyrimidine as initial treatment

Combinations of two cytotoxic drugs result in more toxicity than modulated 5-FU alone. Therefore, in order to postpone the occurrence of severe toxicity, several trials have started with 5-FUFA in first line and given combination chemotherapy in second and third lines as opposed to starting with one combination in first line and giving the other combination in second line. The largest of these trials (MRC FOCUS [202]) randomized 2135 patients to three strategies: A—single 5-FUFA, then single irinotecan; B—single 5-FUFA, then combination with FUFA/IRI or FUFA/OXA; C—combination

upfront, either FUFA/OXA or FUFA/IRI. Median OS was 14 months using strategy A, i.e. providing only single-agent therapy. It was between 15 and 17 months in strategies B and C whether the choice of first-line combination included irinotecan or oxaliplatin. There was no overall difference between strategies B and C, i.e. it is non-inferior to start with single-agent 5-FUFA provided the patients do not have an initially aggressive clinical course, prompting upfront combination therapy. Patients, who could be surgically resected, if sufficient tumour regression is obtained, should not initially receive fluoropyrimidine alone. Similar results were seen in a subsequent study in elderly and frail patients (FOCUS-2 [204], another UK study [205], the Dutch CAIRO-1 study (N = 820) [195], and the FFCD 2000-05 study (N = 410) [206]. A staged approach of initial single-agent treatment upgraded to combination after failure is thus not worse than upfront combination therapy in properly selected patients, but only initially less toxic, postponing more severe toxicity.

Triple combination as initial treatment

In situations where initially it may be important to induce responses as frequently as possible (e.g., in the liver conversion situation) all three active drugs (5-FU, irinotecan, and oxaliplatin) have been combined. In a randomized study including 244 patients, patients who received the triple combination FOLFOXIRI compared to the reference regimen FOLFIRI responded more frequently (66% versus 41%, P = 0.002), and had longer PFS (median 9.6 versus 6.9 months, P = 0.006) and OS (median 23 versus 17 months, P = 0.03) [207]. Toxicity was substantially increased (e.g., grade 3 to 4 neutropenia 50% versus 28%, P = 0.001). After long-term follow-up [208], an absolute benefit in OS of 7% (15% versus 8%) at five years was seen. In a follow-up study including 508 patients comparing the same regimen with the addition of the targeted drug bevacizumab, the triplet again was significantly superior (e.g. PFS median 12 versus 10 months, P = 0.003) [209]. A Greek study including 283 patients compared a slightly dose-reduced FOLFOXIRI with FOLFIRI and found similar results, albeit not statistically significant [210]. Chemotherapy triplets are not yet routine therapy in palliative treatment of patients with mCRC due to the much higher toxicity, but could be used if it important to induce tumour regressions as efficiently as possible, e.g. in the conversion situation and in a clearly symptomatic patient. In the conversion situation, a small randomized phase II study (OLIVIA, n=80) the triplet FOLFOXIRI + bevacizumab was superior to the doublet mFOLFOX-6 with bevacizumab [211].

Targeted drugs

Prior to around 2000, clinical development was concentrated on 'conventional' cytotoxic drugs, the fluoropyrimidines, irinotecan, and oxaliplatin. Different combinations of these drugs, including a triplet combination have been further explored since 2000. Further improvements in patient outcomes have been noted although most of the improvements were already being seen around 2000. During the past decade, most clinical research efforts have concentrated on the exploration of drugs targeting specific molecules associated with CRC cells. Knowledge about molecular events initiating or promoting cancer cell growth in general and CRC in particular had grown substantially during the previous decades.

The development in mCRC has concentrated on targeting vascular endothelial growth factor (VEGF) and the epidermal growth factor receptor (EGFR, HER-1). Clinical progress has been seen, and four monoclonal antibodies are approved for mCRC. Other molecular entities, also aiming at other targets, have been tested, so far without any major success. The improvements seen with the approved drugs bevacizumab and aflibercept, targeting VEGF, and cetuximab and panitumumab, targeting EGFR, as well as those that may be approved in the coming year, have been at best modest when explored in populations with tumours non-screened for certain molecular changes. The inability to identify subpopulations enriched for response has so far prevented substantial improvement. Exclusion of patients with tumours containing RAS mutations for treatment with EGFR inhibitors is an important exception.

Antiangiogenic drugs

Bevacizumab

Bevacizumab (Avastin®) is a recombinant, humanized monoclonal antibody against VEGF. In the pivotal trial, 813 patients received the bolus IFL regimen with placebo or bevacizumab (5 mg/kg) [212] (Table 38.7). Initially, a third arm with 5-FUFA + bevacizumab was included. Median OS and PFS increased and RRs were improved. The increased efficacy came at limited toxicity. Hypertension was seen in 22% of IFL+bevacizumab-treated patients compared to 8% with IFL+placebo. Bowel perforation was more common in bevacizumab-treated patients (1.5% versus 0.0%).

Supportive findings were reported from randomized phase II studies. A pooled analysis of patients (N = 490) from three studies showed statistically significant gains in RR and OS when bevacizumab was added to 5-FUFA [213]. Tolerability was the same in these studies preferably including patients older than 65 years. The efficacy of bevacizumab to either 5-FUFA or IFL in elderly patients (≥65 years) was separately shown in another analysis of the studies (OS 19.3 versus 14.3 months, HR = 0.70 (95% CI 0.55–.90, P = 0.006)). RRs did not differ (34% versus 29%, ns [214]). Patients randomized to capecitabine with bevacizumab had longer PFS, but not longer OS, than patients treated with capecitabine in another study [215] (Table 38.7). Mitomycin-C did not further improve the results.

The good tolerability of bevacizumab was subsequently confirmed in observational studies [216–219]. The risks of arterial events and bowel perforation are about 2% in patients fulfilling inclusion criteria for clinical trials.

In a subsequent first-line study, 1401 patients were randomly assigned to FOLFOX-4 or XELOX and bevacizumab/placebo in a 2 x 2 factorial design [220]. The primary endpoint, PFS, favoured bevacizumab (9.4 versus 8.0 months; HR 0.83, 95% CI 0.72–0.95, P = 0.002), but the effect was much smaller than in the IFL study [212]. RRs were identical (38%) and OS differed, although not significantly. The reasons for the much less impressive data have been speculated upon. FOLFOX-4 is more effective than IFL [189]. Oxaliplatin has cumulative toxicity that sooner or later requires discontinuation of the drug. Bevacizumab was then frequently also withdrawn, particularly in the placebo arm (71% versus 53%). Retrospective analyses of observational studies [216, 217] have indicated that prolonged exposure to bevacizumab may be beneficial, but such comparisons can be biased. Continuous treatment with bevacizumab after chemotherapy withdrawal either pre-planned or because of toxicity has been explored in a randomized TML trial in patients with metastatic colorectal cancer progressing up to three months after discontinuing first-line

Table 38.7 Benefit of bevacizumab or aflibercept targeting angiogenesis to chemotherapy in metastatic colorectal cancer, major studies only

[a] Two doses of bevacizumab were given, 5 mg/kg versus 10 mg/kg with no statistically significant difference; however, the 5 mg/kg dose was numerically better.

[b] Patients received bevacizumab in first line.

** = P < 0.01; *** = P < 0.001; beva = bevacizumab; afliber = aflibercept; ramu=ramucirumab.

bevacizumab plus chemotherapy who were randomly assigned to second-line chemotherapy with or without bevacizumab 2.5 mg/kg per week equivalent (either 5 mg/kg every two weeks or 7.5 mg/kg every three weeks, intravenously). The choice between oxaliplatin-based or irinotecan-based second-line chemotherapy depended on the first-line regimen (switch of chemotherapy) [221]. The primary endpoint, OS, was improved from 9.8 months for placebo to 11.2 months for bevacizumab, which has led to approval by agencies for so-called 'bevacizumab beyond progression' (see 'Aflibercept', below).

After failure on an irinotecan–5-FUFA combination, 829 patients were randomized to FOLFOX-4 with or without bevacizumab (10 mg/kg) [222]. The addition of bevacizumab resulted in improved RRs (23% versus 8%, P < 0.001), PFS (7.3 versus 4.7 months, P < 0.001) and OS (12.9 versus 10.8 months, P = 0.001). Bevacizumab thus improved outcomes together with an oxaliplatin combination in the second-line situation in a better way than it did in the first-line situation (Table 38.7). Bevacizumab alone had no activity (RR 3%, median PFS 2.7 months). When bevacizumab was added to combination chemotherapy in the second-line situation after failure on the other combination with bevacizumab, a small gain in PFS (5.7 versus 4.1 months, P < 0.001), and OS (11.2 versus 9.8 months, P < 0.01) was seen [223].

The effect of bevacizumab appears relatively better in combination with 'less effective chemotherapy' (fluoropyrimidine, IFL), but this statement is only based upon intertrial comparisons. No improved outcome was seen in a small Greek study (N = 222)

comparing 5-FUFAIri±bevacizumab given every third week (OS 22 versus 25 months, P = 0.13, similar RRs) [224]. No differences in outcomes were seen in a subgroup analysis of a German study where patients with KRAS-mutant tumours (N = 100) were randomized between FOLFIRI + cetuximab (EGFR-inhibitors are not active in these tumours, see 'EGFR inhibitors') and FOLFIRI + bevacizumab [225].

No predictive factors for efficacy have been identified. Hypertension during treatment has been suggested as relevant for long PFS and OS [226], but this is controversial [227]. There is an urgent need to understand the mechanism of action for bevacizumab and to identify predictive markers. Current data do not, for example, support efficacy in all regimens [228].

Aflibercept

After failure on an oxaliplatin combination in first-line, aflibercept (VEGF-trap, Zaltrap®), a recombinant human fusion protein that acts as a decay receptor preventing VEGF-A, VEGF-B, and PIGF from interacting with their receptors with FOLFIRI was superior to FOLFIRI alone [229]. Of the 1226 patients, 30% had received prior bevacizumab. Median OS was 13.5 months for FOLFIRI + aflibercept versus 12.1 months for FOLFIRI + placebo (HR 0.82 (0.71–0.97, P = 0.003). In addition, PFS (6.9 versus 4.7 months, HR 0.76, P < 0.001) and RR (20 versus 11%, P < 0.001) favoured aflibercept. Diarrhoea, fatigue, stomatitis, infection, hypertension, and neutropenia were among the toxicities seen more frequently in the aflibercept-treated group. As with bevacizumab, aflibercept has

also been approved for patients progressing on first-line antiangiogenic therapy.

EGFR inhibitors

Cetuximab

Cetuximab (Erbitux®) is a human-murine chimeric monoclonal antibody inhibiting EGFR. It was first explored in patients with chemotherapy refractory disease. Initially, the tumours should express EGFR immunohistochemically in at least some cells, but this was later found not to be necessary for a therapeutic effect. In the pivotal randomized phase II BOND-1 study [230], patients (N = 329) had failed treatment with irinotecan. The trial showed that this resistance could be overcome by adding cetuximab. RRs to the combination was 23% compared to 12% (P = 0.007) with cetuximab only. PFS was also significantly longer (median 4.1 versus 1.5 months, P <0.001), but not OS.

A randomized phase III study in 572 chemotherapy-refractory patients showed that cetuximab alone compared to BSC prolonged PFS (median 2.0 months, HR 0.68, P < 0.001) and OS (6.1 versus 4.6 months, HR 0.77, P = 0.005) [231]. Similar effects have been shown using the other EGFR-inhibiting antibody panitumumab (see 'Panitumumab') [232]. The predominant toxicity of EGFR inhibition is skin toxicity. Patients who get an acne-like rash of grade 2 or more have better RRs and longer survival. Further analyses have shown that the antitumour effects are restricted to patients with tumours with wild-type KRAS [233, 234]. In these studies, mutations were investigated in codon 12 and 13. The evidence is most solid for mutations in exon 2, codon 12, being by far most common (almost 80% of the approximately 40% who have a mutated KRAS). Mutations in codon 13 (almost 20%) do not necessarily indicate total resistance to EGFR inhibition [235]. More recent knowledge using both cetuximab and panitumumab has revealed that rarer KRAS mutations in exon 3 and 4 and NRAS mutations in exons 2–4 also confer resistance to EGFR inhibition [236, 237]. Altogether, between 55% and 60% of metastatic CRC carry a mutation in the RAS gene, and these patients should not be treated with an EGFR inhibitor.

Cetuximab has also been tested with combination chemotherapy in first-line treatment (Table 38.8). The CRYSTAL study [238–240] compared FOLFIRI with FOLFIRI + cetuximab in 1198 patients with EGFR-positive tumours. Retrospectively, the analyses were performed according to first KRAS mutation status and subsequently RAS mutation status, and all benefit from cetuximab was seen in the RAS wild-type group, constituting about half of the analysed population. In the wild-type group, OS (median 28.4 versus 20.2 months, HR 0.69, P = 0.002), PFS and RR (66% versus 39%, OR 3.1, P < 0.001) favoured cetuximab-treated patients. RAS mutation was not prognostic, whereas the presence of a BRAF V600E mutation was similar to other studies [241]. It was not established whether BRAF mutations were predictive for response to EGFR inhibition [240].

A beneficial effect from the addition of cetuximab was also seen in the randomized phase II study OPUS [242], but not in two more recently reported phase-III studies [243, 244] (Table 38.8). In the MRC-COIN study, 1630 patients received FOLFOX or XELOX with no overall benefit of the cetuximab addition in the KRAS wild-type population. A tendency to better results in cetuximab-treated patients was seen with FOLFOX but not with XELOX [243]. No beneficial effect was seen in the Nordic 7 study where the bolus Nordic FLOX regimen was used [244]. The reasons for the lack of efficacy from cetuximab in these two large studies are not known, although it has been speculated that oxaliplatin, bolus 5-FUFA, or capecitabine are not optimal partners for EGFR-inhibition, whereas irinotecan and infused 5-FUFA are. In a meta-analysis of 14 randomized trials (cetuximab and panitumumab), it was seen that the heterogeneity between first- and second-line trials was best explained by the fluoropyrimidine used [245].

Two large trials, FIRE-3 and C80405, comparing first-line cetuximab versus bevacizumab with combination chemotherapy have been reported in various stages of maturity and with some differing conclusions [246, 246]. The trials cannot be directly compared for many reasons, including the types and quantities of therapy beyond first progression, and planned surgery for resections of liver metastases in C80405, among others. In FIRE-3, there was no difference in RR (65% versus 59%, P = 0.18, PFS (10 months both groups), whereas a significant improvement in overall survival was seen (median 33 versus 25 months, HR 0.70, P = 0.006) in the RAS wild-type group. The survival gain was not shown in C80405. Importantly, in these trials, when only the patients with all RAS wild-type tumours were evaluated, overall survival in excess of 30 months was seen.

Panitumumab

Panitumumab (Vectibix®) is a human monoclonal antibody inhibiting EGFR. Compared to cetuximab, which is a chimeric antibody, it gives rise to fewer infusion-related allergic reactions. When the two antibodies were compared in a randomized study in third line (the ASPECCT study, N = 999), OS (median about ten months), PFS (median four months), and response rates (20–22%) were similar [248]. Toxicity was also similar, with the exception of infusion reactions, which were more common with cetuximab (1.8% versus 0.2%).

The results seen using panitumumab in first line together with FOLFOX [249] or in third line against BSC [235] appear similar to the results seen in the corresponding trials using cetuximab (Table 38.8). Panitumumab has also been explored in second line with FOLFIRI after failing FOLFOX (± bevacizumab) [250]. A statistically significant gain was seen in the primary endpoint PFS (median 5.9 versus 3.9 months, HR 0.73 (P = 0.004), RR (35% versus 10%, P <0.001)) but not in OS (14.5 versus 12.5 months, HR 0.85, P = 0.1) in patients with KRAS wild-type tumours.

Taken all evidence reported from clinical trials together, it is likely that cetuximab, being studied more extensively, and panitumumab have similar anti-tumour activity and that none of them has any efficacy in RAS-mutant tumours. It is also likely that BRAF-mutation indicates resistance to these inhibitors [251], meaning that only about one-third of the mCRC population is eligible for therapy. The effects from the drugs seen in the trials including patients with molecularly unselected tumours are then restricted to the wild-type population, meaning that the gains are potentially larger than reported from the old trials.

Antiangiogenic and anti-EGFR treatment in combination

Since both bevacizumab and cetuximab have efficacy with chemotherapy or, in the case of cetuximab, alone, it was a natural step to combine the two biological agents. This was explored in two first-line studies, the CAIRO-2 study [252] and the PACCE trial [253]. Both trials showed that the addition of an EGFR-inhibitor to chemotherapy with bevacizumab resulted in worse outcomes. The mechanism behind this negative interaction is not known.

Table 38.8 Benefit of EGFR-inhibitors to chemotherapy in metastatic colorectal cancer in the major studies

[1] Numerically, a benefit from cetuximab was seen using FOLFOX but not using XELOX.

** = P <0.01; *** = P <0.001.

When bevacizumab was added to irinotecan + cetuximab or to cetuximab alone in the randomized phase-II BOND-2 trial in chemotherapy refractory patients [254], apparently better results were seen than in the preceding BOND-1 trial [230]. The study included only 83 patients and the comparison was with a historical control, which is why the results are only hypothesis-generating.

Two small retrospective studies have reported that the addition of bevacizumab to irinotecan and cetuximab in patients resistant to other treatments, i.e. basically in fourth-line situations, results in apparently favourable results with several responses: PFS of about eight months and OS of 12 months [255, 256]. Although these results speak against the results of the two randomized first-line studies, they are intriguing, indicating that tumours previously exposed to chemotherapy may act differently than previously non-exposed tumours. They prompt further mechanistic studies of the activity of bevacizumab and EGFR inhibitors.

Regorafenib

Regorafenib is a small-molecule multikinase inhibitor that prolonged OS by median 1.4 months (from 5.0 to 6.4 months, HR 0.77 (95% CI 0.64–0.94), P = 0.005) in a trial including 760 patients who had failed all available standard therapy (fluoropyrimidine, oxaliplatin, irinotecan, bevacizumab, and an EGFR-inhibitor in KRAS wild-type tumours) [257]. Hand-foot skin reactions, fatigue, diarrhoea, hypertension, and rash or desquamation were common adverse events in relation to regorafenib.

TAS-102

TAS-102 is a novel nucleoside antitumor agent consisting of trifluridine and tipiracil hydrochloride. Trifluridine is the active component of TAS-102 and is directly incorporated into DNA. However, when trifluridine is taken orally it is largely degraded to an inactive form. Tiperacil hydrochloride prevents the degradation of trifluridine. In a large phase-III RECOURSE trial tested in a refractory population similar to the regorafenib study, TAS-102 prolonged overall survival compared to placebo (HR = 0.68); median overall survival was 7.1 months for TAS-102 and 5.3 months for placebo. TAS-102 also improved PFS compared to placebo (HR = 0.48), results comparable to regorafenib [258]. Neutropenia was the most common adverse event. This drug has been designated for fast-track approval in the US.

Ramucirumab

Ramucirumab is a human IgG1 monoclonal antibody that targets the extracellular domain of VEGFR-2, classifying it as an antiangiogenic agent. This drug has shown to be of benefit in second-line therapy in gastric and lung cancers, alone and with chemotherapy. Recently, data from the RAISE trial were presented in patients progressing on fluoropyrimidine, oxaliplatin, and bevacizumab who were randomize to FOLFIRI with or without ramucirumab [259]. The results were quite similar in the same setting as bevacizumab and aflibercept. In 1072 eligible patients who were randomized, the OS HR was 0.84 (95% CI: 0.73, 0.98; log-rank P = 0.0219). Median OS was 13.3 months for RAM versus 11.7 months for PBO. The PFS HR was 0.79 (95% CI: 0.70, 0.90; log-rank P = 0.0005). Median PFS with RAM was 5.7 months and 4.5 months for PBO. ORR was 13.4% RAM; 12.5% PBO (P = 0.6336). Significant toxicities included neutropenia, fatigue, hypertension, and diarrhoea.

Treatment intention

When deciding what treatment an individual patient with mCRC should receive of the many evidence-based options (Table 38.6), the treatment intention is of greatest relevance. At present, it is important to discuss this in the following terms: (1) neoadjuvant, (2) conversion, (3) immediate palliation, and (5) palliation.

Neoadjuvant

In this situation, the patient has one or a few metastases, possibly with a primary tumour that are technically all resectable. The primary aim of chemotherapy is to eradicate microscopic tumour cells to decrease the risk of recurrence after resection. The traditional way is to resect and give adjuvant chemotherapy. This has been explored in two small French trials (N = 278) that found a slight OS gain (HR 1.32 (95% CI 0.95–1.82, P = 0.1) using 5-FUFA [260]. The concept of early systemic treatment to kill subclinical disease, operate, and then give the rest of the chemotherapy afterwards was explored in the EPOC trial (N = 364) where six cycles of FOLFOX

were given preoperatively and six cycles post-operatively [261]. The primary endpoint DFS was improved (35.4% versus 28.1% at three years) in the randomized population; however, it was not statistically significant (HR = 0.79, P = 0.058). In the resected population, the gain was 9.2% units, P = 0.025. OS at five years was insignificantly improved (from 48% to 51% in all randomized patients, P = 0.3). Preoperative chemotherapy increased post-operative morbidity, but did not increase post-operative mortality in the study.

The presently best documented and likely most efficient treatment in this neoadjuvant situation is FOLFOX. As adjuvant treatment, an irinotecan combination is not sufficiently superior to 5-FUFA alone [262]. The addition of bevacizumab or cetuximab to FOLFOX does not improve outcome in colon cancer stage III and has presently no role as neoadjuvant therapy. When cetuximab was added to FOLFOX in the randomized New-EPOC trial including patients with resectable liver metastases (KRAS exon 2 wild-type tumours), shorter PFS was seen in the group treated with cetuximab [263]. The interpretation of the results has been much discussed.

Conversion

In this situation, the metastatic disease burden is limited, usually confined to the liver, but not (readily) resectable. It is then important both to cause tumour regression to allow surgery and to kill micrometastases, i.e. to maximize the chances for the patients to remain disease-free after potential resection. Macroscopic liver metastases generally contain 10^9–10^{10} tumour cells and subclinical foci may contain up to this number. Since CR to medical therapy in mCRC is rare and PR only means about one log of cell kill, the present therapy is far from being curative, even if subclinical foci are more likely to be eradicated than macroscopic disease. The regression of visible liver metastases has sometimes been impressive, and has indicated that liver surgery or an ablative procedure, removing remaining metastatic lesions, may potentially cure some. It is attractive to combine the best of local and systemic treatment, but the weakest component of this is the systemic treatment.

In retrospective analyses of multiple trials, correlation between response rates to chemotherapy and the proportion of patients who could be resected has been seen [264]. The most effective treatment (highest RR, longest PFS) in metastatic disease should thus be given. Since the many alternatives have frequently not been compared to each other, it is impossible to identify that regimen. In RAS wild-type tumours, one choice is FOLFIRI + cetuximab based upon the CRYSTAL study [239]. In the study, the differences in RR (57% versus 40%) and PFS (9.9 versus 8.4 months) between the chemotherapy doublet or the doublet with an antibody were among the largest seen in a phase III trial. This does not automatically mean that this treatment is the most effective in inducing responses, although it is presently a preferred option [116]. In RAS-mutant tumours, where an EGFR inhibitor has no role, FOLFOXIRI is likely the most active option [207], potentially in combination with bevacizuma [209, 211]. In both RAS wild-type and mutated tumours, a doublet without or with bevacizumab is likely not substantially inferior and all combinations are valid options.

Most experience with 'conversion' of liver metastases came initially from a French group at Hôpital Paul Brousse, Villejuif [265, 266], but was later reported from numerous sites and from large collaborative trials. In unselected groups of patients with mCRC, up to about 10% can presently have radical surgery. In groups of patients

with potentially resectable liver metastases only, as many as 20–50% have had secondary liver surgery [199, 267]. Patient selection, rather than more efficient treatment is responsible for these figures.

The distinction between resectable and non-resectable liver metastases is far from clear and probably interpreted differently at different hospitals. A common definition of non-resectable metastases is large size, poor location, multinodularity, and/or extrahepatic disease. A sufficiently large volume of the liver must remain after resection. None of these factors necessarily implies that surgery could not remove all tumour lesions without any pretreatment but they all indicate poor prognosis [267], and most teams likely hesitate to operate upfront even if some of those patients could have been long-term survivors after primary surgery. Patients operated upon for cure after conversion chemotherapy have a prognosis that is almost in line with those with less advanced disease having surgery alone, suggesting that their survival has been improved. However, the magnitude of the survival gain is not precisely known. Even if the magnitude of gain in the EPOC trial [261] was limited, disappointing to many, the study tells that combinations of local and systemic treatments are here to stay.

Preoperative chemotherapy increases toxicity at liver surgery and there is a wish to restrict the number of cycles before resection [267]. However, even if this is valid, the inability of present systemic treatments to eradicate all subclinical disease is what ultimately kills most patients. The balance between the number of cycles before resection, toxicity at surgery, and the possibility of curing as many as possible is not properly known. Since preoperative treatment is likely the most relevant part for OS, the number of cycles given should not be too few even if 'resectability' is rapidly achieved. Six to eight cycles of a fortnightly regimen before and four to six after is probably better than three to four before, although this statement is not universally agreed upon.

Immediate palliation

In these patients with progressive, usually symptomatic, disease, there is a need rapidly to induce antitumour activity, and tumour regression, without necessarily fulfilling criteria for an objective response. At the same time, treatment is palliative since the disease burden is too extensive to allow future surgery, even if good regression is seen, and excessive toxicity should be avoided. A prolonged time to progression and as long and as good a life as possible are the ultimate aims. A chemotherapy doublet (see Table 38.6 for examples), alone or with bevacizumab, is the currently preferred choice. In the light of the results of the FIRE-3 trial described above showing prolonged survival with the addition of cetuximab if the tumour was RAS wild-type, some would argue that an EGFR-inhibitor should be the preferred first-line treatment. In analogy, if the tumour is RAS-mutated, a triplet, alone or with bevacizumab, is an option since this treatment also prolongs PFS and OS. If starting with a doublet, it does not matter whether oxaliplatin or an irinotecan doublet is used for survival. Toxicity is important, and one has to choose between the risk of getting disturbing peripheral neuropathy, possibly for the rest of the patient's life, from the point of diagnosis or at a later time, and initial hair loss, which is seen more frequently after irinotecan. In the second-line situation, the other combination is used. If bevacizumab were not part of first-line treatment, it could then be added. In the third-line situation, an EGFR inhibitor can be used, alone or preferably with irinotecan, in KRAS wild-type tumours.

Palliation

In many patients with recently detected disseminated disease, no or only mild tumour-related symptoms are present. If, in addition, there are no signs of rapidly progressive disease, such as leucocytosis, thrombocytosis, or increased alkaline phosphatase, and the extent of disease and/or comorbidity precludes secondary surgery, an initial period of wait-and-see or fluoropyrimidines alone is a valid option. If no initial treatment is chosen, close monitoring is recommended. Clinical evaluation with simple laboratory tests every month and imaging every other month may be appropriate. A strategy to wait until symptoms or other signs of progression appear, with clinical evaluation every other month, may compromise OS, as was seen in a randomized trial [163]. In the trial, OS was almost median five months longer (14 versus nine months, P <0.02, N = 183) in the primary chemotherapy group. During this initial wait-and-see period, the patient could be eligible for 'window-of-opportunity' trials exploring new molecular compounds [268]. Otherwise, a fluoropyrimidine (5-FUFA or capecitabine) alone or with bevacizumab is indicated since this strategy postpones severe toxicity and does not compromise survival [195, 202]. When this treatment no longer controls disease, one of the doublets is given followed by the other after progression. In RAS wild-type tumours, an EGFR-inhibitor could be used in the fourth line and possibly regorafenib or TAS102 in the fifth and so far last evidence-based line.

Treatment interruptions, maintenance therapy

Breaks in the treatment should be utilized frequently whenever tumour growth is retarded. Several trials have shown that (toxic) chemotherapy holidays in one or another way in properly selected patients do not compromise OS [243, 244, 269–273]. A systematic review of 11 studies including 4854 patients concluded that 'intermittent strategies of delivering systemic treatment of mCRC do not result in a clinically significant reduction in OS compared with a continuous strategy of delivery, and should be part of an informed discussion of treatment options with patients with mCRC' [274]. Several details, such as the proper duration of the (intensive) chemotherapy phase, the duration of the interruption, and whether or not maintenance is of value, are still missing. The French GERCOR group randomized 620 patients to FOLFOX-4 continuously or FOLFOX-7 with oxaliplatin in a stop-and-go fashion [269]. OS was similar in the two groups (19 versus 21 months, ns). In a subsequent trial (OPTIMOX-2, N = 202), 5-FUFA was not used in the oxaliplatin-free periods [275]. Since OS tended to be worse in the stop-and-go group (median 19 versus 26 months, P = 0.055), it has been suggested that maintenance with 5-FUFA is better than a chemotherapy-free period. Whether targeted drugs have a role during the maintenance has been explored in trials. The Cairo3 trial [276] randomized 558 patients to either a maintenance group receiving capecitabine and bevacizumab or an observation group who had reached at least stable disease after six cycles of 3-weekly capecitabin, oxaliplatin and bevacizumab (CAPOX-B). Time to the primary endpoint, secondary progression (PFS2), was 11.7 months in the maintenance group and 8.5 months in the observation group (HR 0.67, P = 0.0001). Global quality of life did not deteriorate during maintenance treatment. A German study (AIO KRK 0207) has preliminarily reached similar results [277]. In the trial, bevacizumab alone was not inferior to a fluoropyrimidine with bevacizumab as maintenance treatment. OS was not improved.

Two trials have evaluated erlotinib, a small molecule against EGFR as maintenance treatment. In the GERCOR-DREAM study [278] including 452 patients PFS (4.9 months with bevacizumab alone and 5.9 months with bevacizumab/erlotinib (HR 0.77, P = 0.01). OS was also prolonged (median 22.1 months versus 24.9 months (HR 0.79, P = 0.04). In the other trial (Nordic ACT) [279] enrolling 249 patients median PFS was 4.2 months in the group of patients who received bevacizumab alone and 5.7 months in those receiving bevacizumab and erlotinib (HR 0.79, P = 0.2). Collectively, the trials show that interruptions in the administration of intensive chemotherapy should be used and indicate that if the breaks are filled with less intensive treatment, at least time to progression will be prolonged. The best maintenance treatment is not established.

Concluding remarks and remaining issues

The results of chemotherapy have improved substantially during the past several years. From being a treatment of unproven value, benefiting very few, during the 1980s, it is now a well-documented treatment prolonging survival, relieving, or postponing symptoms in many, and potentially curing a few if combined with local methods, particularly surgery. Median survival has been prolonged from about six months to above 22–24 months in some patient series (Table 38.4). Earlier detection of metastatic disease, generally because of routinely performed imaging with methods like spiral CT and MRI, detecting smaller lesions than possible before, is responsible for some of the longer survival seen. Selection of patients with more limited disease spread, for example only or predominantly liver metastases, is another important reason for the apparently much better results. Medical oncology is not solely responsible for the progress.

The extra months, or years, gained are generally good months in spite of the toxicity seen. Future improvements are probable using a multidisciplinary approach, together with the hope that new treatments, based upon recent tumour-biological knowledge, will eventually yield clinically meaningful effects. The exploration of new and better response predictors has highest priority. So far, only RAS mutation status is relevant for routine use prior to EGFR inhibition [280]. Besides likely predicting resistance to EGFR-inhibition, the presence of a BRAF-mutation also indicates poor survival, and it is possible that this should influence the choice of initial therapy, e.g. not to start with a fluoropyrimidine alone but rather with a doublet or rather give a triplet instead of a doublet. There are no trial data to guide in this decision. The lack of predictors is particularly critical for antiangiogenesis treatments. The gains seen so far with the 'biologics' have, however, been modest, sometimes minute. Trial designs other than performing large randomized studies to, hopefully, find those incremental gains must be explored. Target-driven small randomized phase-II studies and window trials are some examples [268, 281].

Multidisciplinary management of complex cases

For a general discussion of multidisciplinary management, see Chapter 39.

Patients presenting with an intermediate or locally advanced rectal cancer and synchronous metastases are particularly challenging cases, both if they are potentially curable should all disease ultimately be resected radically and if this is not possible, i.e. the intent is palliative from diagnosis. Two case presentations will illustrate the therapeutic dilemmas.

Case 1

A 69-year-old previously healthy man has noted blood in his stool for a few months. Minor problems with defecation. No weight loss. A 5 cm large rectal tumour 5 cm from the anal verge is discovered. Biopsies show infiltrating mucinous adenocarcinoma. Pelvic MRI reveals a cT3dN2 tumour, EMVI+, MRF+, i.e. locally advanced (ugly) requiring preoperative (C)RT to be resected with high probability of local control. CT of the thorax and abdomen shows three three to five large liver metastases, all in the right lobe. The liver metastases require a right-sided hepatectomy to be radically resected, even if they are diminished in size. The patient is potentially curable.

The greatest threat to this patient's life is the liver metastases. For this reason, initial combination therapy can be advocated. The primary tumour may also respond to systemic therapy, but radiation has a higher probability for response. Conventional CRT over five to sex weeks is an option, but the systemic chemotherapy component is then weak during those weeks and during the recovery period, i.e. up to ten weeks overall. Higher dose intensity of the systemic treatment can be achieved if 5 x 5 Gy is given, allowing full-dose chemotherapy from ten to 12 days later. The patient requires all modalities, and an attractive sequence is 5 x 5 Gy, combination chemotherapy, surgery of the liver metastases and the primary, and possibly more chemotherapy up to about six months in all if regression was seen during the induction phase.

Case 2

The same case as above. An MRI of the liver reveals eight additional small metastases involving all segments. There is thus no potential for cure and the situation is palliative. The liver metastases are still the greatest threat to the length of life, which is why upfront chemotherapy is the preferred option. The primary tumour does not require immediate intervention, and surgery without prior radiation and a delay is suboptimal. If the patient responds, the chemotherapy may continue. If the primary tumour does not become symptomatic, chemotherapy through the second and third lines may continue. If symptoms cannot be controlled by chemotherapy, local RT may be given, often controlling symptoms for six to eight months. Surgery for the primary may often not be needed, but should always be considered if it is expected to cause local problems not controlled by the non-surgical therapies. With the extent of liver metastases at diagnosis, liver surgery is not relevant even if a good response is seen.

CHAPTER 39

Colorectal cancer

Alex Boussioutas, Stephen B. Fox, Iris Nagtegaal, Alexander Heriot, Jonathan Knowles, Michael Michael, Sam Ngan, Kathryn Field, and John Zalcberg

Epidemiology of colorectal cancer

Colorectal cancer (CRC), which includes primary cancers of the colon and rectum, is the third most common cancer in men and second for women in the world, based on GLOBOCAN statistics current at 2012 [1]. This accounts for 1.36 million new cases of CRC per year and 694,000 deaths attributed to this disease.

When comparing developed regions and developing regions according to United Nations criteria, the age standardized rates (ASR) per 100,000 for incidence of CRC was 36.3 in males from developed regions and 13.6 from less developed regions. Female patterns were similar with 23.6 in developed regions and 9.8 in less developed regions. Particularly high incidence was found in Australia and New Zealand, Southern and Western Europe and North America. The incidence is higher in men than women (based on sex ratio of ASR of 1.4:1) [1].

The risk for developing CRC increases with age and there are suggestions that the distribution of incident cancers in the colorectum is becoming more proximal [2–4]. Age has been suggested as being a contributing factor to this observation [5] as well as female gender [6] and possible use of screening that may detect more lesions of the left colon. Recent observations of the prevalence of colon cancer from Surveillance, Epidemiology and End Results (SEER) Medicare data in the US show 67% were right-sided lesions [7] consistent with older studies. However, there has been a decline in incidence of CRC since the mid-1980s in the US; it has been suggested this may, in part, be the result of screening for CRC, particularly the emergence of endoscopic screening [8]. It is notable, however, that the decline in incidence commenced before the widespread implementation of endoscopic screening in the US, attesting to alternative explanations.

There has been a related reduction in mortality attributed to CRC in US over a similar time frame [9]. The survival at one year and five years after therapy for CRC is 83.2% and 64.3%, respectively [10]. This raises the issue of survivorship, which will be dealt with later in this chapter. Estimates of the prevalence of CRC survivors in the US in 2012 make this the second commonest cancer diagnosis among survivors, at 9% for males and 8% females [10].

Risk factors for CRC

Chronic inflammation/inflammatory bowel disease

Chronic inflammation plays a critical role in initiating, sustaining, and advancing tumour growth. Chronic inflammation alters the microenvironment by soluble mediators (cytokine networks) through recruitment of cells that stimulate tumour growth. The production of reactive oxygen and nitrogen species by inflammatory cells can cause DNA damage in epithelial cells, which may lead to activation of oncogenes and inactivation of tumour suppressor genes. Indeed, these oxygen forms reduce expression and activity of mismatch repair proteins including MLH1, MSH2, and MSH6 by direct enzyme damage, transcription factor displacement, or up-regulation of DNA methyltransferase. Structural DNA damage, such as strand breaks and cross-links can lead to chromosomal instability. In addition, increased methylation and aberrant microRNA expression are present in chronic inflammatory conditions. Inflammation can also supply bioactive molecules to the tumour microenvironment. In addition to local effects, increasing evidence suggests that the presence of chronic inflammation can cause genotoxicity affecting mainly leucocytes that might decrease antitumour responses. Several genetic and epigenetic changes in epithelial cells have been described in ulcerative colitis that might be responsible for colon carcinogenesis. Early events in colitis-associated cancer often involve microsatellite instability (MSI) and p53 mutations, which are already present in non-dysplastic, chronically inflamed tissue. Accelerated colon aging has been suggested as one of the main contributions to the increased cancer risk in patients with ulcerative colitis, based on premature telomere shortening and increased age-related CpG island methylation.

Thus, both ulcerative colitis and Crohn's disease are a significant risk factor for the development of CRC, after inherited syndromes like Familial Adenomatous Polyposis (FAP) and Lynch syndrome with a relative risk of 19x and 18x, respectively. For ulcerative colitis there are cumulative probabilities of 8% at 20 years, and 18% at 30 years (without surveillance or chemoprophylaxis) and for Crohn's disease there is a cumulative risk for CRC of ~7% at 20 years and these tend to be related to the degree of colonic involvement. Although rare, after continued inflammation, pouch-related carcinomas occur in patients with inflammatory bowel disease. The tumours that develop are more likely to be well-differentiated adenocarcinomas of mucinous or signet-ring-cell type compared with sporadic CRC and may demonstrate differences in molecular characteristics.

Radiation

Radiation-induced neoplasia is a well-recognized effect of either sunlight, ionizing or particulate radiation. Different tissues react

differently to these types of radiation and despite the severe acute effects of radiation, the gastrointestinal tract is fairly resistant to radiation-induced neoplasia as shown by the rare secondary tumours that develop after treatment of prostate, cervix and bladder.

Diet and lifestyle

There is a burgeoning literature on the association of diet and dietary components with risk of developing CRC. The role of diet as a contributory factor to the development of CRC has been estimated to be as high as 50% of sporadic CRC [11, 13].

Burkitt reported the association with fibre intake in 1971, attributing the observation of lower incidence in Africans to their high-fibre diet [12]. Since that time, there have been multiple studies that have investigated the effect of dietary fibre on incidence of CRC. Case control studies have suggested a mild protective effect [13, 14] but the results from cohort studies have been mixed [15–17] with reports of confounding due to lifestyle and non-fibre food groups [18] that were not incorporated in the earlier study designs. It has been suggested that the protective effect of dietary fibre may be due to specific subtypes of fibre such as cereal fibre [19] and may explain some of the mixed results in other studies that grouped all types of fibre.

Red meat or processed meat consumption and the fat content of diets have been associated with the risk of developing CRC [20–23]. Willet et al. reported that a diet high in animal fat was particularly associated with increased risk of CRC [23]. The initial positive associations between these diets and CRC risk have been brought into question and the magnitude of the risk is also questionable based on other prospective studies and large meta-analyses [24–26].

There are several hypotheses linking a diet high in animal fat and risk of CRC. One mechanistic link involves increased exposure of the colon to bile acids, which acts as a mutagen or carcinogen [27–29]. There are reports of increased levels of excreted bile acids in populations that are at increased risk of CRC [30, 31]. One of the prevailing theories is that bacterial flora may produce carcinogens from animal fat or bile acids in the colon [32]. There have also been suggestions of bacterial or viral effects that may contribute to the risk of CRC through multiple mechanisms but involving inflammation of the epithelium [33].

Lifestyle often confounds analysis of studies investigating diet and CRC risk. There have been attempts to clarify the role of lifestyle in the risk for CRC. A recent large prospective cohort trial in Denmark addressed this issue and suggested adherence to recommendations for physical activity, waist circumference, smoking, alcohol intake, and diet may reduce the risk of CRC by up to 23% [34]. This is compelling data that a significant proportion of CRC risk can be modified by lifestyle measures.

On the balance of evidence it would appear that lifestyle and certain dietary modification may be beneficial in reducing the risk of CRC, but the degree of benefit remains to be determined. Given the negligible health risks of such positive lifestyle changes, it makes practical sense for health professionals to advocate these changes for those deemed to be at risk of CRC. The data on specific diets remains inconclusive, particularly with respect to red meat and dietary fibre. However, a number of studies and at least one large meta-analysis have suggested Vitamin D intake and blood 25(OH)D levels were inversely associated with the risk of CRC [35]. The VITamin D and OmegA-3 TriaL (VITAL) is an ongoing randomized clinical trial in 25,875 US men and women investigating whether taking daily dietary supplements of vitamin D3 (2000 IU) or omega-3 fatty acids (Omacor® fish oil, 1 g) reduces the risk of developing cancer, heart disease, and stroke in people who do not have a prior history of these illnesses (NLM Identifier NCT01169259).

Post-cholecystectomy

Another link to the role of bile acids and CRC comes from observational data suggesting an association of cholecystectomy and risk of developing CRC [36]. Two meta-analyses of predominantly case-control studies suggested an increased risk of CRC in the proximal colon [37, 38] and both raised concerns about the quality of the data.

A relatively recent study from Sweden suggested a higher-than-expected incidence of proximal CRC and proximal carcinoids [39]. A concern with these data was raised in earlier studies suggesting that there was more enriched risk after 15 years post-cholecystectomy [37]. The Swedish study measured potential latency and found the majority of cases of CRC occurred earlier than 15 years, which is contrary to earlier studies. They concluded that the risk of CRC post-cholecystectomy is low.

Diabetes, obesity, and insulin resistance

There is consistent evidence of an association of obesity [40, 41] and type II diabetes mellitus and risk of CRC [42–44]. Early studies were small and difficult to interpret the risk of type II diabetes mellitus in the context of confounders such as BMI and physical inactivity [45, 46].

Prospective studies showed an independent association between type II diabetes mellitus and onset of CRC in men and women [44, 47]. Other studies have found the same trend in increased risk in both males and females, but the result did not reach statistical significance in women [48]. In an analysis of the Nurses Health Study, adult onset type II diabetes mellitus was also found to be a risk factor for the development of CRC [49] with a multivariate adjusted relative risk of 1.30 (95% CI 1.20–1.40). This relative risk is consistent with the risk for men. A Japanese prospective cohort study of more than 90,000 individuals also made an association of diabetes mellitus and colon cancer with an adjusted relative risk of 1.36 (95% CI 1.00–1.85). However, when they excluded diagnoses of colon cancer within five years, which may have antedated the diagnosis of diabetes mellitus, the risk for CRC was not significant 1.14 (95% CI 0.74–1.75) [50].

There are a number of hypotheses posed for the mechanism of type II diabetes mellitus accounting for an increased risk of CRC. There is data suggesting a causal role of hyperinsulinaemia and insulin-like growth factors (IGF) in colorectal carcinogenesis. Colorectal cancer cells are found to express insulin and IGF-1 receptors [51, 52] and there is animal data implicating insulin as a promoter of growth of aberrant crypt foci which are thought to be the earliest precursor lesion of CRC [53]. Indeed, high endogenous insulin has been suggested as a risk factor for CRC when levels of C-peptide are measured in high-risk populations [54, 55].

There is a suggestion that exogenous insulin therapy may also lead to higher risk of CRC [56] although data are conflicting, with the association of type II diabetes probably accounting for the excess risk rather than insulin therapy [48].

As yet, screening guidelines have not specifically targeted individuals with diabetes mellitus for more intensive screening interventions, but this may be a consideration in populations with endemic obesity and increasing prevalence of type II diabetes mellitus.

Cigarette smoking

A meta-analysis of observational data [57] has found those individuals that have ever smoked have a relative risk of 1.18 (95% CI 1.11–1.25) of developing CRC over those individuals who have never smoked. This study found an equally significant increase in mortality from CRC in smokers. Previous studies also made the association between cigarette smoking and CRC incidence [58].

Alcohol

The association between alcohol consumption and CRC risk has been made in a number of studies. A recent meta-analysis summarizes the potential risk for moderate to heavy consumers up to a relative risk (RR) of 1.52; 95% CI 1.27–1.81 for persons consuming more than four standard drinks per day [59]. In support of no association with low alcohol intake, a study investigating consumption of up to 30 g alcohol per day (one standard drink) in the UK Dietary Cohort Consortium found no association with CRC [60]. There are ongoing studies investigating the potential beneficial role of specific types of alcoholic beverages and the risk of CRC. Red wine has been postulated to lower the risk of CRC due to its content of polyphenols but this work needs further study.

Ureterocolic anastomosis

The practice of ureterosigmoidostomy has been reported to increase the risk of CRC at the anastomosis. This is an uncommon complication of an uncommon procedure and has a long latency [61–63].

Genetic risk factors

There are a number of dominant and recessively inherited predispositions for CRC. These will be covered in the section 'Molecular biology'.

Screening for CRC

There are now well-established guidelines that address screening issues for patients deemed at average or population-level risk and those at high risk due to high penetrance genetic syndromes through many gastroenterological associations (the American Gastroenterological Association, the British Society of Gastroenterologists, and Australian National Health and Medical Research Council are some examples).

As mentioned earlier, the incidence of CRC in the US has been declining over the last three decades [9, 64]. Screening has been determined as a factor accounting for up to 50% of the decreasing incidence using microsimulation modelling methods, particularly with the removal of adenomatous polyps [64]. Screening may also have contributed to the reduction in mortality due to earlier diagnosis and management of CRC.

Risk factors that are considered in the allocation of appropriate screening recommendations include: (1) genetic risk such as Lynch syndrome or FAP mutation carriers; (2) personal history of colorectal carcinoma or adenomatous polyps of the colon; (3) inflammatory bowel disease with colonic involvement for over eight years;

(4) family history of CRC but not meeting criteria for a diagnosis of a known genetic syndrome; and (5) demographic and clinical risk factors that are known to attribute higher risk for CRC. These have included race/ethnicity in the US, where black persons have highest incidence and mortality from CRC [65].

While recommendations vary slightly according to country, average risk persons are advised to consider a number of options for screening strategies as outlined in greater detail in Chapter 30, 'Population cancer screening':

1. Faecal immunochemical test (FIT) which has largely replaced the guaiac-based faecal occult blood test (gFOBT) annually or biennially.

2. Faecal DNA testing.

3. Flexible sigmoidoscopy.

4. Colonoscopy.

5. CT colonography (although this is not widely adopted yet).

Chemoprevention of CRC

Aspirin and NSAIDs

Epidemiological associations of a negative correlation with CRC incidence and regular use of aspirin [66, 67] stimulated significant research into its use as a potential chemoprevention agent.

These initial studies led to intervention studies into aspirin as a chemoprevention for CRC. A systematic review of the literature prepared for the US Preventive Services Taskforce [68] suggested regular aspirin use reduces the incidence of CRC with a pooled relative risk reduction of 22%, especially with longer duration of therapy and at relatively high dosage. The study did acknowledge the potential harms of aspirin when given at dosage above 200 mg/day with an approximate gastrointestinal bleed rate of 2.69% per year. This study acknowledged a discrepancy in data from randomized controlled studies that did not show as significant an effect as observational studies.

Another meta-analysis of radiochemotherapy (RCT) data suggested the effect of aspirin was seen in the first 12 months after the intervention [69]. There have also been mixed effects on the incidence of colonic adenoma with studies suggesting a reduction in incidence of new adenomas in patients with a prior CRC or adenoma that was treated with regular aspirin [70, 71].

Follow-up data from British-led intervention trials of aspirin have been analysed suggesting a reduction in the incidence of CRC of approximately 24% in patients taking aspirin [72]. This also led to improved prognosis.

A randomized control trial of daily aspirin in Lynch syndrome patients has shown a reduction in incidence of CRC after a treatment period of at least two years' duration [73]. The initial analysis of this data did not show a significant difference at one year [74]. A peculiarity of this data was that there was no difference in the incidence of adenomas between the control group and treatment group during the follow-up period.

Studies have also shown that NSAID drugs reduce the burden of colorectal adenomas in familial adenomatous polyposis (FAP) patients, with sulindac being the best studied, showing up to 40% reduction in polyp burden [75–77]. Although there is benefit from COX2 selective inhibitors, their potential cardiovascular toxicity at

high dose has caused concern. Generally, NSAID drugs are advocated to delay definitive colectomy in FAP patients but do not replace prophylactic surgery [78].

Molecular biology and pathology of CRC

Molecular biology

Genomic integrity in normal cells is maintained by a comprehensive array of DNA repair machinery. However, mutations in genes coding for elements in the different repair pathways leads to genomic instability, the 'mutator' phenotype, which facilitates the development of cancers. There are three main molecular pathways [79–80] leading to genomic instability in CRC development. First, the conventional adenoma-carcinoma sequence characterized by chromosomal instability (CIN), as reported by Vogelstein et al. [81] which accounts for ~60% of colorectal carcinoma. Second, defects in DNA repair that accounts for ~5% and lead to the microsatellite instability pathway (as seen in the prototypical HNPCC/Lynch syndrome) and third, aberrant DNA methylation that leads to the so-called CpG island methylated phenotype (CIMP+), which accounts for the remaining ~35% [82–84]. Since there is no consensus on the precise criteria of these pathways they are not mutually exclusive.

Chromosomal instability (CIN)

This is characterized by large and frequent changes in chromosomal copy number and structure that result in inactivation of tumour suppressor genes (the so-called suppressor pathway) [85]. The tumour karyotype is complex with numerous chromosomal gains and losses that differ between tumour cells. The definition of CIN has not been standardized, with many different methodologies and criteria being used such as karyotyping, FISH, LOH, array CGH, and more recently next-generation sequencing. Indeed, some authors have suggested that there are sub-categories within CIN with low and high subtypes that may be prognostic [86, 87].

There are many proposed mechanisms that could be responsible for the CIN phenotype [85]. See Figure 39.1. The aneuploidy could result from chromosomal segregation disorders from perturbations in the spindle assembly that control the mitotic checkpoint or centrosomes and anchor the microtubules [88–91]. Other potential causes of CIN include telomere dysfunction through shortening, resulting in repetitive breakage–fusion–bridge cycles, amplification of DNA sequences genomic alteration [92] and abnormalities in the DNA damage response [93]. All these processes, therefore, lead to unbalanced structural rearrangements leading to the numerous mutations in CRC demonstrating CIN; however, only a small proportion will be driver mutations, with the majority being passenger mutations [94].

DNA-repair abnormalities

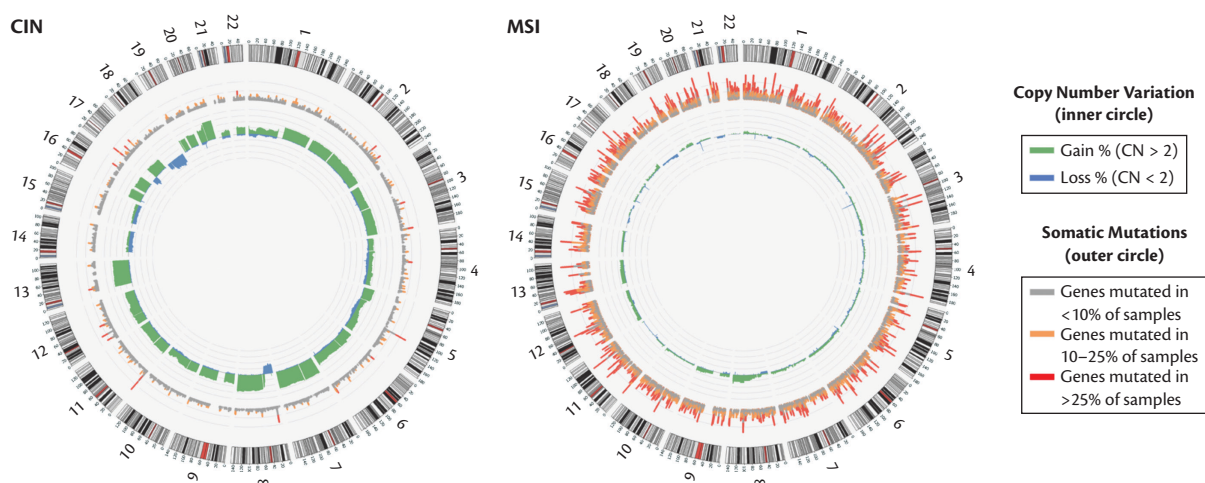
Cells have developed a vast array of different mechanisms of DNA repair to ensure genomic integrity [90, 95]. Indeed, ~30% of the genes in the human genome encode for proteins that regulate DNA fidelity [96]. One such DNA repair apparatus is the mismatch repair pathway, which removes replication errors in a strand-specific manner, to remove mismatched nucleotides from the newly replicated strand of DNA. The major proteins involved in this process are MLH1, MSH2, MSH6, PMS2, which form functional heterodimers [97, 98]. Mutations in these genes lead to loss of function leading to strand slippage or looping in repetitive regions present in introns, untranslated terminal regions, and the coding exons throughout the genome [98]. This results in increases in sequence length in daughter cells during DNA synthesis or shortening if there is slippage during DNA replication. This can be assessed in the pathology laboratory using MSI testing (see Figure 39.2) [99, 100]. The degree of MSI can be categorized as high MSI (MSI-H) when two or more panel markers are involved, low MSI (MSI-L) if only one marker is involved, and microsatellite stable (MSS) if none [101, 102]. The value of a MSI-L category remains questionable [84] since the clinical presentation of MSI-L tumours has yet to be fully determined.


Fig. 39.1 CIRCOS plot demonstrating inherent difference between the two broad molecular subtypes of CRC: MSI-H and CIN. While CIN tumours are characterized by genome-wide copy number aberrations, MSI-H tumours remain largely chromosomally stable (inner circles represent the proportion of tumours with copy number gain/loss at a given chromosomal location). Conversely, MSI-H tumours exhibit elevated number of non-synonymous mutations (both single nucleotide polymorphisms and indels, especially around simple sequence repeats), when compared to CIN tumours (outer circle represents proportion of samples with a non-synonymous mutation at a given gene).
Figure kindly provided with the permission of Dr D Mouradov and Dr Seiber.

Since there are repetitive sequences in a number of oncogenes including growth factor receptors (EGFR, TGFβ type II), cell cycle and apoptosis (BAX, caspase-5), and DNA repair (CHK1, MLH3, MSH3) subsequent alterations in these genes lead to further accumulation of genetic changes [96].

The preferred test for MMR deficiency is the combination of MSI testing with immunohistochemistry to MMR proteins (see Figure 39.3), since this can identify the likely candidate gene for subsequent germline testing which testing for MSI cannot. MLH1 methylation can be responsible for aberrant MLH1 staining and

MSI (~15% of all MSI tumours and >80% of sporadic MSI CRCs) with similar morphology as the other MSI tumours and a good prognosis [102, 103].

A further DNA repair pathway mechanism of CRC development results from mutation in the Mut Y homolog (MUTYH) gene (see section on MUTYH below).

Aberrant DNA methylation

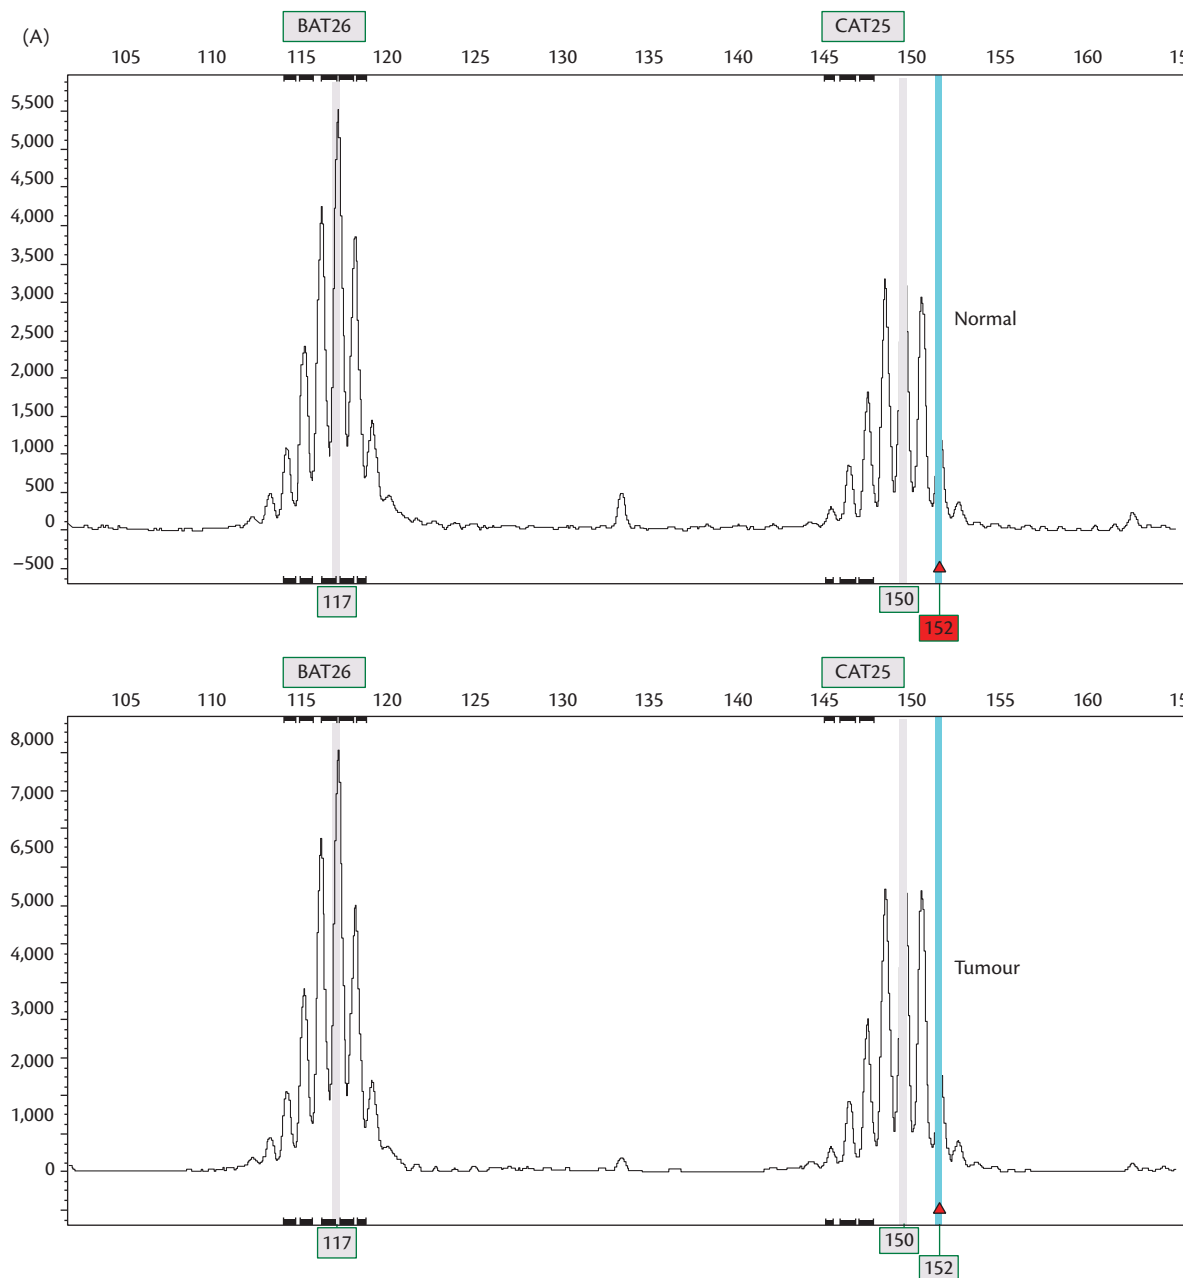
DNA methylation is more frequent in tumorigenesis than DNA mutation [104]. Although aberrant methylation occurs throughout


Fig. 39.2 Microsatellite electropherograms following multiplex PCR amplification of fluoresceinated microsatellite markers from a microsatellite stable (A) and unstable (B) CRC. Normal and tumour DNA product from the same individual are amplified for each microsatellite marker and the product lengths are compared to determine MSI status. Amplification normally gives rise to a central peak plus a Gaussian distribution of stuttering peaks from slippage of the polymerase during the amplification reaction. The appearance of additional shorter peaks from shortening of the repeats occurs in the tumour cells. Residual normal peaks are often present in the tumour electropherogram due to contamination of non-neoplastic cells within the tumour sample.
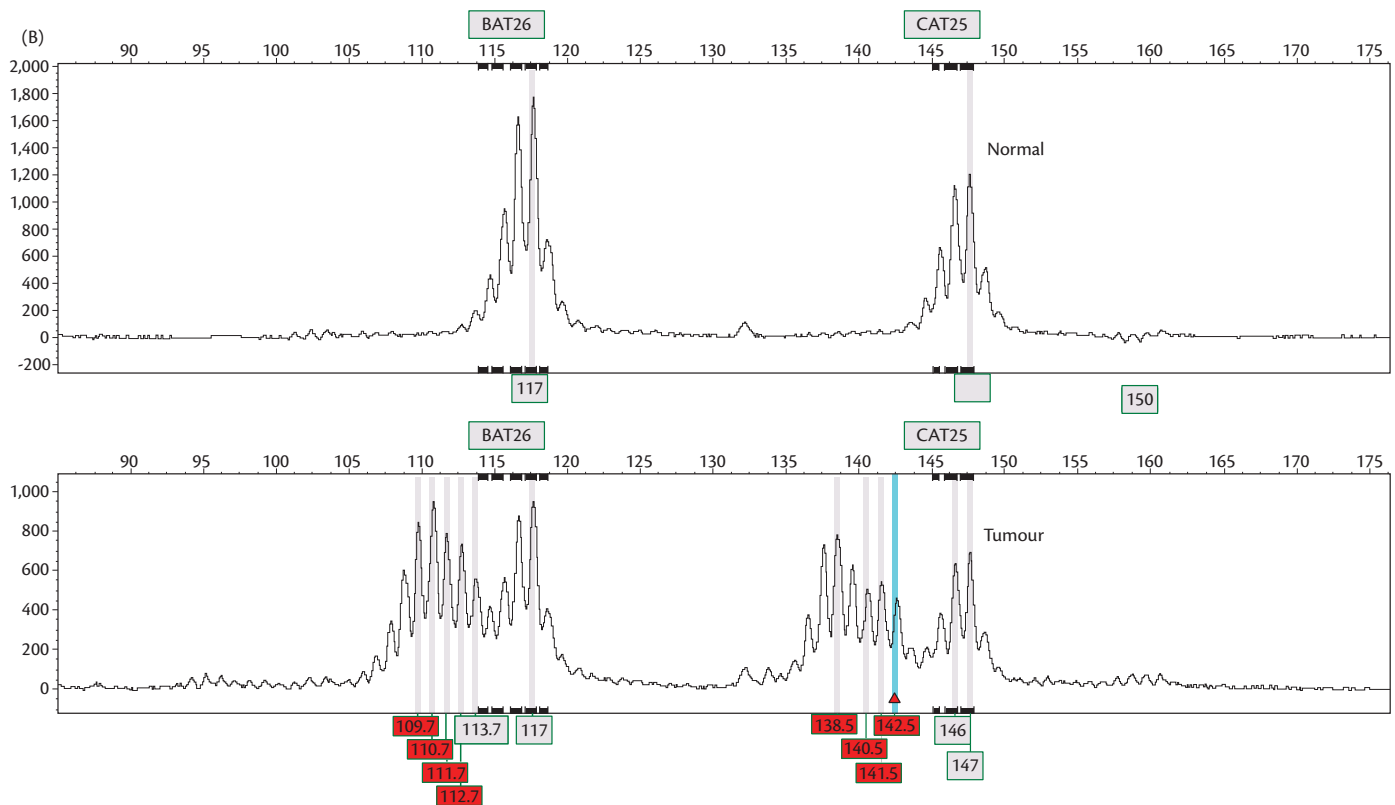

Fig. 39.2 Continued

the genome, methylation that leads to transcriptional silencing occurs preferentially at CpG islands present in up to 60% of the 5' promoter region. There is a group of ~35% CRCs that become aberrantly and extensively methylated that have been termed CpG island methylator phenotype (CIMP) [84, 105]. Methylation appears to occur early in CRC development as it is identified in adenomas [106–110]. The precise definition of this group is unclear with different classification schemes using different markers for CIMP [105]. It is also unclear whether such CRC are a true molecular subtype or represent the end of a spectrum of methylation.

Nevertheless, there are data to suggest that there are qualitative as well as quantitative differences within CIMP that are determined by the molecular pathway of tumourigenesis, either the traditional adenoma-carcinoma or serrated adenoma-carcinoma [84, 111–113]. Thus, CIMP1 is predominantly associated with methylation of multiple genes including MLH1 through the increased susceptibility to methylation from a BRAF mutation, which results in MSI. CIMP2, another category, is characterized by KRAS and is associated with methylation of a restricted number of genes including the DNA repair gene, O-6-methylguanine DNA methyltransferase (MGMT) that results in base excision and repair defects leading to the observed chromosomal instability and LOH; these are MSI-low. The third CIMP negative category is rarely methylated but demonstrates p53 mutation [114]. The CIMP1 and CIMP2 categories are proposed to arise from an alternative serrated adenoma pathway. The BRAF serrated pathway is better defined than the KRAS mediated pathway.

Key genes involved in CRC

In CRC, the presence of repeating molecular aberrations in copy number, expression profile, methylation patterns, and mutations support a common underlying biology. Several pathways are central to CRC carcinogenesis, the Wnt signalling pathways being the most important [115]. The tumour suppressor gene APC is frequently mutated, in a minority of cases beta catenin is mutated, and in rare cases, functional analogues of APC like AXIN 1 and 2, and NKD1 are the first step towards CRC. Consecutive steps towards tumour development are the inactivation of additional tumour suppression genes in the p53 and TGFβ pathways. Activation of oncogenes such as KRAS, BRAF, and PI3CKA are necessary for the development of the tumour. When DNA repair defects are the initial step for carcinogenesis, the sequence of events can be modified and frequencies of affected genes are different. Recent data from massive parallel sequencing demonstrate that by including these commonly affected genes and pathways a total number of 24 genes are repeatedly mutated in CRC [116] but the frequency may differ between primary and metastases [117].

Inherited aspects of colorectal carcinoma

Approximately 25% of all colorectal carcinoma is estimated to have an hereditary element (see Figure 39.4). The major CRC genetic syndromes that account for ~5% of the hereditary effect and include FAP, attenuated FAP (AFAP), MUTYH-associated polyposis (MAP), and Lynch syndrome (hereditary nonpolyposis CRC, HNPCC) [118]. Rarer syndromes include hamartomatous polyposis conditions (Peutz–Jeghers syndrome (PJS), juvenile polyposis syndrome (JPS), and others) [119–121] and hyperplastic polyposis [122]; they contribute a further small proportion of cases together with a number of genetic syndromes including Li–Fraumeni (p53) [123] and Bloom's (BLM) [124] that are associated with multiple tumour types and sites, including the colon. Additionally, familial CRCs that do not meet the clinical criteria for a diagnosis of known
Fig. 39.3 Mismatch repair immunohistochemistry. Immunohistochemistry for MSH6. One of the mismatch repair proteins, showing the loss of staining for protein in the tumour cells (large arrow) with retention of expression in the non-neoplastic elements including normal intestinal crypts, stromal cells (thin arrow) and lymphocytes.

hereditary CRC syndromes have up to a sixfold increased risk that is dependent on the age and number of affected family members. A component of this increased risk is likely to be due to a number of low-penetrance risk genes that account for ~10% of the familial association have been identified using genome wide association studies [125, 126] which might also act as modifiers of other more penetrant genes.

Major hereditary syndromes
Familial adenomatous polyposis (FAP)

FAP is an autosomal dominantly transmitted disease caused by a mutation of the APC gene located on 5q21, which is a negative regulator of the Wnt pathway [127–129]. Most mutations are nonsense type, leading to the formation of a truncated protein. FAP is characterized by up to thousands of adenomatous polyps in the large intestine that develop in childhood and inevitably transform to CRC by 40 years of age [130]. However, there are FAP variants

that depend on the region and the type of mutation (i.e. frameshift mutation versus missense mutation) in the APC gene. These include (1) attenuated FAP, a variant that has a later presentation with polyps that are fewer in number compared with conventional FAP (up to 100 polyps), and a lower (~70%) lifetime risk of CRC [131]; (2) Gardner's syndrome, in which individuals also develop extracolonic tumours including upper GI polyps, small intestinal tumours, desmoid tumours, osteomas, and cysts; and (3) one form of Turcot's syndrome in which patients develop CRC and medulloblastoma [132–134]. Thus, for example, a mutation between codons 1250–1464 is associated with usual-type FAP whereas mutations at the 3' end are associated with desmoid tumours [130, 133].

MUTYH

MUTYH is located on chromosome 1p, and encodes a protein of the DNA base excision repair (BER) pathway, mutations of which predispose to the development of CRC [135]. The BER system is responsible for repairing one of the most stable deleterious products of oxidative DNA damage, that of 8-oxo-7,8-dihydro-2-deoxyguanosine. Formation of such damaged DNA predisposes to point mutations particularly increased G:C to T:A transversions [135], but even though the genomic instability effects individual base pairs the tumours demonstrate CIN [136]. MUTYH polyposis is autosomal recessive and is associated with variable adenomatous polyposis from only a few to several hundred that can mimic FAP; it has a significant increase in susceptibility to CRC that approaches 100% by the age of 60 years [137–139]. Two common variants have been reported—Tyr165Cys and Gly382Asp, which account for ~80% of cases. Affected individuals also have an increased incidence of developing other tumour types [135].

Lynch syndrome

Lynch syndrome is an autosomally dominant disease characterized by colorectal, endometrial, ureteric, gastric, ovarian, biliary, urinary tract, small bowel, brain, and pancreatic carcinomas that result from germline inactivation of DNA mismatch repair genes (see Chapter 31, 'Familial cancer syndromes and genetic counselling'). Lynch syndrome is largely (~80%) due to mutations in

- Sporadic
- Familial
- Lynch syndrome
- FAP/AFAP
- MUTYH
- Peutz–Jeghers
- Juvenile polyposis
- Serrated polyposis
- Li-Fraumeni
- Bloom
- Others
Fig. 39.4 Frequencies of hereditary CRC. The majority of CRC have a sporadic origin (75%), 15% of cases have an increased risk of CRC (familial CRC), but no defined underlying gene mutation. The remaining 10% of cases originate from patients with a known hereditary cancer syndrome, of which Lynch syndrome is the most frequent (5%).

MLH1 and MSH2 with alterations in MSH6 (10%), PMS2, and MLH3 accounting for the remainder. A rare germline deletion in TACSTD1, resulting in TACSTD1/MSH2 fusion transcripts generation with epigenetic inactivation of the corresponding MSH2 allele, also causes Lynch syndrome. The overall lifetime risk of CRC is 80%, but risks vary depending on the gene affected (e.g., PMS2 has only a 15–20% risk for CRC). Although mutations can be identified spanning these genes, founder mutations have been identified, accounting for up to 10% of all Lynch syndrome patients. Variants of Lynch syndrome include (1) Turcot syndrome, the result of mutation in the mismatch repair genes hMLH1 or hPMS2 characterized by CRC and glioblastoma and (2) Muir–Torre syndrome, which results from mutations in MLH1 and MSH2 and is characterized by the presence of sebaceous gland neoplasms and visceral malignancies, usually CRC. Screening for Lynch syndrome includes using immunohistochemistry for MMR proteins on CRC or endometrial carcinomas (other Lynch-associated tumours have low specificity and sensitivity) for absence of staining and MSI [100]. Since absent staining of MLH1 protein might be due to methylation, BRAF mutation status by mutational analysis or use of mutation-specific antibodies may be required. If negative, directed germline mutation analysis can be performed; in the future, clinical massive parallel sequencing may alter this testing algorithm.

Hamartomatous polyposis syndromes
Peutz–Jeghers syndrome
Peutz-Jeghers syndrome is an autosomal dominant disorder that presents in childhood, characterized by mucocutaneous pigmented lesions around and within the mouth, and hamartomatous polyps in the gastrointestinal tract, particularly the small bowel [121]. Most patients have a germline truncation or missense mutation in the tumour suppressor STK11 gene, located at 19p13.3 that encodes a serine threonine kinase (STK) protein [140], although other genes may be implicated (e.g., MYH11 [141]). Mutation results in tumour suppressor activity as LKB1-AMPK signalling negatively regulates the mTOR pathway [142]. Activation of mTOR signalling leads to hamartoma formation, which predisposes to a number of malignancies in the gastrointestinal tract and other organs including pancreatic, lung, breast, uterine, ovarian, and testicular tumours [143, 144].

Juvenile polyposis
Juvenile polyposis is rare and has three main subtypes comprising juvenile polyposis of infancy, juvenile polyposis of the colon, and generalized juvenile polyposis, all of which have different modes of presentation [119, 120]. Patients with juvenile polyposis of infancy have no family history and present with diffuse gastrointestinal polyposis that is associated with macrocephaly, digital clubbing, and hypotonia. Individuals usually die from non-neoplastic complications of the condition such as haemorrhage, malnutrition, or and intussusception before the age of 2 years.

Juvenile polyposis of the colon and generalized juvenile polyposis usually present by the age of 10 with acute or chronic gastrointestinal haemorrhage, anaemia, and polyps that can number in the hundreds. Patients have a cumulative life-time risk for CRC of 39–68% and an increased risk of other intestinal tumours, dependent on the location of the polyps. They are associated in 50–60% with an inherited or new mutation (usually point mutations or small deletions but also large deletions in 5–15%) in SMAD4 and BMPR1A. Mutations of PTEN, the gene responsible for Cowden syndrome, have also been reported, and some individuals with

SMAD4 germline mutations have hereditary haemorrhagic telangiectasia [145]. All these genes encode proteins in the TGFβ signalling pathway and thus might represent be a spectrum of phenotypes.

Mixed polyposis syndrome
Mixed polyposis syndrome is a relatively recent recognized entity, without any clear definition, caused by a mutation in BMPR1A and thus, might be part of the spectrum of TGFβ-pathway-associated polyposes. This mutation shows an autosomal dominant inheritance and carriers have an increased risk of CRC [146, 147] on a background of adenomas and hyperplastic and juvenile polyps.

Others
Polyps closely resembling juvenile polyps are found in other conditions such as Cowden disease, an autosomal dominant condition of the phosphatase and tensin homolog (PTEN) gene or rarely SDHB. However, although polyps are identified in the gastrointestinal tract in ~80% there is no apparent cancer risk [121]. Bannayan–Riley–Ruvalcaba syndrome, characterized by juvenile polyps, mental retardation, macrocephaly, lipomatosis, haemangiomas, and genital pigmentation was originally thought to be a distinct entity but also harbour a PTEN mutation in 60% of individuals. Thus, an aggregate term of PTEN hamartoma syndrome has been suggested [148], the phenotypic differences being due to ascertainment bias. Cronkhite–Canada syndrome is a further gastrointestinal polyposis of unknown aetiology but is non-hereditary [149].

Hyperplastic polyposis syndrome
Hereditary non-polyposis colon cancer/hyperplastic polyposis is a rare condition defined by arbitrary criteria that are likely to represent a spectrum of conditions. They are characterized by the WHO as having (1) at least five histologically diagnosed hyperplastic polyps proximal to the sigmoid colon of which two are greater than 10 mm in diameter; (2) any number of hyperplastic polyps occurring proximal to the sigmoid colon in an individual who has a first-degree relative with hyperplastic polyposis; or (3) more than 30 hyperplastic polyps of any size, but distributed throughout the colon [150–152]. Individuals develop CRC (baseline 25–37% of patients [150, 153]) on a background of hyperplastic polyps, other serrated adenomas, and even traditional adenomas. The molecular genetics of this condition(s) is unknown.

Pathology of colorectal carcinoma
Precursor lesions of CRC

Aberrant crypt foci (ACF)
ACF are microscopic mucosal abnormalities [154], some of which may be precursors to CRC [155]. ACF are most frequent in the rectum, descending and sigmoid colon and microscopically have the morphology of dysplastic microadenomas (single crypt adenomas) or hyperplastic crypts with or without a serrated luminal pattern. Although reported in FAP and sporadic CRC they are also identified in ~40% of patients with benign colonic diseases such as diverticular disease, rectal prolapse, and volvulus [155]. The number of ACF increases with age and correlate with the presence of adenomas. The adenomas that form from ACF in the context of FAP have APC mutations, whereas those in the sporadic setting harbour KRAS mutations (and lack of methylation). The non-dysplastic ACF might be precursors of CRC through the alternate serrated

adenoma pathway associated with BRAF and occasionally KRAS mutations [156, 157].

Adenomas

These are largely polypoid neoplasms characterized by dysplastic large intestinal-type epithelium, although some show a flat or sessile configuration. They can show a tubular, villous, or mixed architecture and most are <10mm. Villous adenomas >10mm with severe dysplasia are associated with synchronous or metachronous carcinoma associated with the CIN pathway. The pathology is similar whether the patient has FAP or its variants, with MUTYH-associated polyposis or sporadic. KRAS rather than BRAF mutations are associated with adenomas.

Serrated polyps

Serrated polyps [84, 113] are a heterogeneous collection of lesions characterized by serrated epithelium and account for a ~40% of colorectal polyps. There are many forms, some forms of which, through genetic and epigenetic changes akin to the traditional adenoma-carcinoma sequence, progress along a 'serrated pathway' as an alternate mechanism of CRC development.

Hamartomatous polyps

These are malformations of the mucosa, lamina propria, and sometimes muscularis propria that form a polyp. They have varied morphologies depending on the underlying pathogenesis but include polyps with a central smooth muscle core that arborizes and is covered by mucosa with a villous pattern, as in Peutz–Jegher, to simple tags and mixtures of connective tissue with oedematous stroma, cystic gland formation, variable inflammation, lobulation, and branching.

Colorectal carcinoma

The histological biopsy forms the basis for therapeutic decisions for the patient and, for rectal cancer, is a requirement for the commencement of neoadjuvant therapy. After surgery, pathological evaluation [158] of the characteristics of the primary tumour, the presence of lymph node metastases, and the evaluation of treatment (surgery and neoadjuvant therapy) form the basis for subsequent adjuvant therapy. Primary tumour characteristics that are suggestive of hereditary cancer syndromes might necessitate additional testing, such as MSI testing and MMR immunohistochemistry. In case of advanced or metastatic disease, additional molecular testing can be performed in order to test suitability for targeted therapies (e.g., RAS testing) [159].

The macroscopic appearances of CRC are varied with tumours having an appearance that is endophytic, exophytic, or annular with or without ulceration or a combination; a rare form of diffuse infiltration has also been described. The presence of carcinoma is defined as invasion through the muscularis mucosa to the submucosa. Histological classification follows the World Health Organization. There are also other non-epithelial tumour types, which might be encountered in the colon and rectum: lymphomas, sarcomas, and melanomas [160].

Particular histological tumour types are associated with particular molecular characteristics. For example MSI-H tumours, whether Lynch or sporadic, tend to be well circumscribed, proximally located, and demonstrate two patterns: (1) well-differentiated mucinous and (2) poorly-differentiated with tumour-infiltrating lymphocytes, a Crohn's-like reaction (also classified as medullary carcinoma), which despite their poor differentiation have a good prognosis.

Location

The majority of CRCs are located in the distal colon and rectum, although the frequencies at different sites depend on the underlying molecular genetics. Thus, tumours demonstrating MSI or CIMP are generally right-sided (caecum, ascending and transverse colon) whereas CIMP-positive and MSS cancers occur on right and left; MSS without CIMP are located mainly in the left colon. Although location has been used to aid classification of the underlying pathogenesis of CRC, recent data suggests that non-MSI tumours are similar irrespective of their origin, whereas a continuum model may apply for MSI tumours as frequencies of CIMP, MSI, and BRAF mutation increase in a linear manner distal to proximal [161].

Pathologic prognostic markers

Stage

The staging system of choice is the TNM or AJCC classification [162, 163]. The three pillars of this system are depth of **T**umour penetration (TNM I and II), presence of lymph **N**ode metastases (TNM III) and distant **M**etastases (TNM IV). This system can adequately predict local recurrence, distant metastases, and survival rates, although stage II patients do show a large variation in prognosis. A special high-risk stage II group has been defined, characterized by the presence of perforation, T4, obstruction, less than ten examined lymph nodes, extramural vascular invasion, or poor differentiation [164].

Lymph node burden

One of the most important factors in patients' prognosis is the presence of nodal metastases. Approximately ~70% of the patients with no lymph node metastases are alive five years after surgery, while those with metastases have a five-year survival rate of 40%. Standard guidelines are provided for the number and location of the examined lymph nodes, but ideally 12 lymph nodes should be examined before a patient can be classified as N0. Nevertheless, in daily practice, even 12 lymph nodes can be challenging to acquire, as the number of nodes is influenced by preoperative radiotherapy and in the type of resection performed, as well as variation between patients [165]. Differences in the quality of pathological examination using a combination of visual inspection, palpation, and dissection is another important factor determining the yield of lymph nodes isolated from the perirectal fat.

Early CRC cancer

With the widespread introduction of population screening for CRC, the number of early CRCs is expected to increase from the ~25% that currently present with early disease (stage I). Local excision is an attractive option for early disease in both colon and rectal cancer, since it is associated with considerably less surgery-related morbidity and almost no post-operative mortality compared with colectomy and total mesorectal excision (TME) (mortality rates of 1.9–6.5% (rectum) and 3.2–9.8% (colon) have been reported). Patient selection through careful histological analysis of local excision specimens can be very useful to avoid over- and under-treatment. Several pathologic features of the primary tumour have been associated with presence of LNM, such as poor

differentiation, tumour budding, presence of lymphatic or vascular invasion, and submucosal invasion depth.

Histological prognostic factors

Mucinous carcinomas have a slightly poorer prognosis than adenocarcinomas, mainly from presentation at advanced stage. Signet-ring-cell carcinomas, as well as mucinous carcinomas with signet ring cells, are associated with poor prognosis. In contrast, medullary carcinomas have a very good prognosis. Histological grading of cancer though the assessment of tumour differentiation is used as a surrogate for tumour aggressiveness. There are a variety of systems [166] but the majority of studies use a two-tiered stratification. Growth pattern is another feature that has prognostic value in CRC. The circumscript/pushing configuration is associated with a good prognosis, while diffuse infiltration is associated with a poor prognosis [167]. A closely-associated feature is the presence of tumour budding [168], where tumour cells at the invasive front of CRC detach into single cells or clusters of up to five cells. The presence of budding is associated with lymph node metastases and metastatic disease. Other histological features that have prognostic relevance are (1) lymphatic invasion (tumour cells in the submucosal lymphatic vessels), which is mainly related to the risk of lymph node metastases; (2) extramural vascular invasion (tumour cells in the subserosal blood vessels), which is associated with the development of blood-borne distant metastases; and (3) perineural invasion (tumour cells in and around nerves), which is associated with local as well as distant recurrence [169].

Tumour regression grading after neoadjuvant therapy

Various methods have been developed to grade tumour regression to assess neoadjuvant treatment, and although using differing criteria, each generally show increased regression is associated with a prolonged survival. However, the lack of standardization of grading together with inter- and intra-observer variation make regression grading a less reliable indication of tumour response such that other factors, such as circumferential radial margin involvement, are more important [170]. Nevertheless, although response grading is of some utility, the main purpose of neoadjuvant therapy is downstaging of the tumour, facilitating surgical excision.

Other prognostic markers

Despite the numerous publications about prognostic markers in CRC, few are used in practice such as an inflammatory infiltrate in and around the tumour [171]. Recent developments have standardized this analysis in the Immunoscore® [172], which is currently under investigation in a multicentre study. There is consistent evidence for the favourable prognosis of MSI tumours [80] whereas BRAF mutation is associated with a poor prognosis [173].

Predictive markers

The presence of MSI has previously been considered a contraindication for 5-FU-based therapy, although again conflicting studies have been published. In a meta-analysis [174] no clear conclusion could be drawn about the effects of MSI on 5-FU response, due to significant inter-study heterogeneity. However, with the relative good prognosis of these tumours, the potential for beneficial effects is small. For targeted therapy, the predictive marker is KRAS mutation. In the presence of an activating KRAS mutation, inhibition of the EGF receptor does not have the desired effect on tumour cells and thus there is no indication for this therapy. It is expected that the increased use of targeted drugs will lead to the identification of additional predictive markers.

Surgical management

Surgery is the mainstay of treatment for colon cancer. If a patient is fit enough to undergo surgery, resection of the primary tumour with excision of the draining lymph nodes provides the only option for cure, with around two-thirds of the patients disease-free at five years [175], and recurrence after this time is rare. The introduction of laparoscopic colorectal surgery over the last decade has reduced the traumatic impact of surgical resection, improving patient recovery. Advanced colonoscopic techniques such as endoscopic mucosal resection have facilitated removal of adenomas that would previously have required surgical resection. These are being identified more frequently with the advent of national bowel cancer screening programs.

Survival rates following surgery remained static for some time, but the introduction of adjuvant chemotherapy has resulted in an improvement in survival and a reduction in the development of metastatic disease. The surgical approach to metastatic disease, either metachronous or synchronous, has evolved to become increasingly proactive. Resection of liver, lung, and peritoneal metastases can be curative and improve survival outcomes. The increased survival of patients with stage IV disease through improvements in chemotherapy has also led to an increased role for surgery to control palliative symptoms.

Diagnosis

Colonoscopy is the gold standard diagnostic test for colon cancer, with a sensitivity of 95% [176]. Cancers can be visually assessed and biopsied to provide tissue for histological diagnosis. Histology may be inconclusive due to sampling of tumour slough and inflammation or if a malignant core is surrounded by adenoma. If further biopsies are inconclusive or the lesion is not reachable endoscopically, it should be considered to be malignant. CT pneumocolonography provides a diagnostic alternative to endoscopy. The sensitivity for cancers is equal to that of colonoscopy [176]; however, identified abnormalities need endoscopic evaluation.

With the increase in minimally invasive surgery, lesions should be marked at their distal border with Indian or carbon particle suspension 'ink'. Lesions impassable with an endoscope are at risk of obstruction and early surgery or colonic stenting should be considered. If there is an impassable lesion, the remainder of the colon should be examined for synchronous lesions by CT pneumocolonography.

Preoperative staging

This aims to identify metastatic spread and local invasion. The mainstay of staging in colonic cancer is high-resolution CT scanning. This should include the chest, abdomen, and pelvis. The two commonest sites of haematogenous spread are to the liver and the lungs. Incidental liver lesions may cause diagnostic uncertainty and further imaging with ultrasound or MRI may be required. FDG-PET scanning is being used more frequently, as it has a higher sensitivity for recurrent and metastatic disease than CT [177]. It can also help differentiate between benign and malignant lesions seen on standard CT. In patients with metastatic disease being considered for curative resection, it may identify otherwise occult metastases.

Identification of locally advanced disease allows planning of en-bloc resection of the invaded organ along with the primary tumour, if the patient is fit enough. In colon cancer, the proximity of the small bowel and the mobility of the colon make the use of neoadjuvant chemoradiotherapy mostly impractical.

Preoperative assessment

Prior to elective cancer resection there is a window to investigate the patient's general health. The stress of abdominal surgery places the patient at risk of ischaemic vascular events, thromboembolism, and hypostatic and invasive-line-related infections. Preoperative assessment aims to find unidentified or undertreated medical conditions and assess the likelihood of surviving the procedure. This is usually started with a pre-anaesthetic assessment and may then be aided by a number of objective measures of patient 'fitness'.

Ischaemic and valvular heart disease, respiratory conditions, hypertension, and diabetes mellitus should be optimally medically managed prior to surgery. Medical conditions such as cardiac ischaemia, which would normally require intervention, should be treated and surgery delayed to allow this [178].

An objective measure of risk can be gained with scores such as the acute physiology and chronic health evaluation score or physiological testing such as cardio-pulmonary exercise testing. These can help to identify patients who require more aggressive and invasive perioperative care [179]. They can also identify patients in whom surgery has a high risk of complications or death. If patients are found to have poor performance with physiological testing, then preoperative optimization of haematinics, nutrition, and exercise programmes may improve their outcome [180].

The multidisciplinary team

Once diagnostic, staging, and preoperative assessment have taken place, cases should be presented to a CRC multidisciplinary team. These groups review the radiology and histology, ensuring quality control and allowing a consensus opinion on the appropriate management of individual cases.

Perioperative care

Colonic cancer surgery has led the way in the healthcare trend towards early mobilization and reduced inpatient stay. The work by Kehlet [181] in open intestinal surgery has become the cornerstone of enhanced recovery programmes. These are often combined with the reduced surgical stress of minimally invasive techniques to facilitate early discharge.

Perioperative care should start prior to admission. Consent is best gained away from the stress of the surgical environment. Patients can meet stoma therapists, nurse specialists, and enhanced recovery coordinators prior to their stay. Education on thromboembolic prevention, physiotherapy, and pain control can be provided. Bowel preparation and preoperative nutritional supplements can all be taken at home prior to admission. In most cases, it is safe for patients to be admitted on the morning of surgery [182].

Enhanced recovery tries to facilitate the normal return of gut and motor function. This combines early feeding and mobilization with reduced opiates and nauseating anaesthetic agents. Pain control with local or regional anaesthetic blocks and non-steroidal anti-inflammatories are combined to reduce opiates. Tubes which reduce mobility such as abdominal drains, nasogastric and urinary catheters are avoided or used for short periods. Intravenous fluid replacement is 'targeted' [183] intraoperatively and in the post-operative period replaced at maintenance volumes only, until full oral nutrition has returned. Enteral nutrition is encouraged from day one in the post-operative period.

Thromboprophylaxis is particularly important in patients with a cancer diagnosis and undergoing abdominal surgery. Anti-thromboembolism stockings, pneumatic compression devices, and early low-molecular-weight heparin should all be utilized if possible, aided by early return to mobility.

Surgical techniques

Colonic resection

The underlying principle of surgery for colon cancer is resection of the bowel where the tumour has originated along with the lymph nodes draining that area. The two ends of bowel are then joined together with an anastomosis to restore bowel 'continuity'. Lymph node involvement is usually unknown until the resected specimen is reviewed by the pathologist. Hence, the extent of resection is determined by the lymphatic anatomy of the colon. Lymphatic colonic drainage channels follow the arterial blood supply. By ligating and dividing the relevant artery close to its origin, 'high ligation', removal of the draining lymph nodes is ensured. Turnbull proposed a 'no-touch technique' [184], where ligation of the feeding vessels is undertaken prior to mobilization of the tumour, reducing tumour spread. In fact, this was a surrogate for 'proper' high arterial ligation and adequate resection of the lymph node containing colonic mesentery. See Figure 39.5.

Division of the artery will define an area of colon which will become ischaemic. This should contain the tumour and margins of 'normal' colon of at least 5 cm proximally and distally. The two ends of intestine should have adequate blood supply from the adjacent arterial vessels via the marginal artery to allow healing. The marginal artery runs around the length of the colon and is supplied by branches of both the superior mesenteric and inferior mesenteric arteries. The blood flow in this artery is determined by the distance from the feeding vessel and the quality of those vessels. This is affected by factors such as atherosclerosis, hypotension, vasoconstriction, and cardiac output. The quality of blood flow in the marginal artery can be demonstrated by pulsatile flow on division of the vessel [185]. If the blood supply is poor, further resection of colon may be required. Other factors influencing anastomotic healing include tension across the anastomosis, radiotherapy, or bowel disease. Healing is also influenced by global patient factors such as poor nutrition, immunosuppression, and concurrent illness. Despite this, most colonic surgery can be anastomosed safely. In obstructed or severely malnourished patients a de-functioning or temporary-end ileostomy can be life-saving. In most cases, the risk of anastomotic leaks is not enough to warrant their formation.

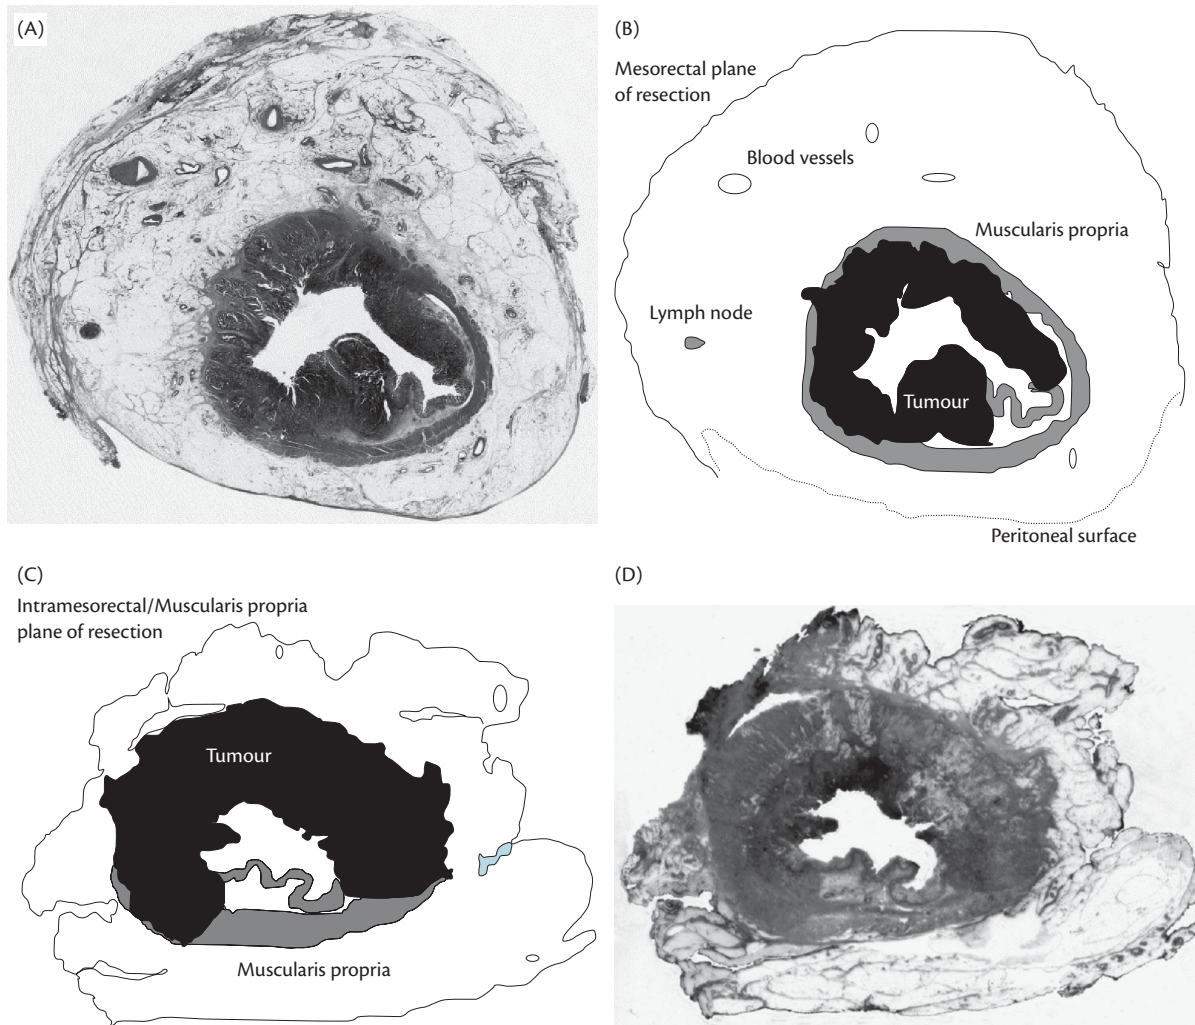
When performing a right hemicolectomy, the ileocolic artery is high ligated, along with the right colic artery which is present in 10% of patients. This resection will allow removal of caecal, ascending colon, and hepatic flexure tumours. For tumours of the descending and sigmoid colon high ligation of the inferior mesenteric artery is performed as part of a left hemicolectomy or high anterior resection. Tumours of the transverse colon are predominantly supplied by the middle colic artery but may include supply from the ileocolic vessels. These tumours are removed with an


Fig. 39.5 Quality of surgery and relation to the circumferential resection margin. (A)–(B) Good quality of surgery, the plane of resection is on the mesorectal fascia, the CRM is free. (C)–(D) The plane of surgery is on the muscularis propria, the CRM is threatened.

extended right hemicolectomy, where ligation of the middle colic is added to that of the ileocolic artery. Transverse colon resections are rarely performed as they may compromise the oncological resection and have been associated with a higher anastomotic leak rate [186].

The steps required to undertake a colonic resection remain fairly constant. The right and left colon are retroperitoneal with their vessel containing mesentery draped over the retroperitoneal structures, whilst the transverse and sigmoid colon are freely mobile on their respective mesenteries. The right and left colon are mobilized by division of their peritoneal attachments. Once mobilized, the supplying vascular pedicle is divided high and the mesentery divided up to the points on the bowel appropriate for the resection. After resection, the bowel is usually reanastomosed using one of a number of configurations. These include end-to-end, end-to-side, and side-to-side anastomoses, all of which can be performed using hand-sewn or stapled techniques.

Treatment of splenic flexure tumours

The surgical management of tumours near the splenic flexure remains difficult. This area is a watershed between the middle colic and left colic artery and branches of both will supply most of these tumours. If the inferior mesenteric artery is taken high then the whole of the left colon needs to be resected unless one relies on marginal artery supply to maintain the remaining left colon. The alternative is to perform an extended right hemicolectomy and anastomose the ileum to the left colon. This doesn't take as much of the left-sided lymphatic drainage but replaces poorly vascularized left colon with ileum to form an anastomosis. There remains no good evidence to favour one approach, and surgeons commonly make the decision based on the position of the tumour intraoperatively.

Laparoscopic colonic resection

The advent of laparoscopic or minimally invasive approaches has been the major change in surgery for CRC over the last ten years. There remains a spectrum of uptake for these techniques. The fundamental steps and principles of colonic resection are the same as for open surgery but are performed via small incisions in the abdominal wall through which 5 mm or 10 mm 'ports' are inserted. The laparoscopic instruments are then inserted through

these ports. Division of the mesentery can be undertaken intra- or extra-corporally. The bowel division and subsequent anastomosis may also be undertaken intra- or extra-corporally, the mobilized specimen being delivered through a small incision using a wound protector to minimize wound or port site implantation. The end result is the same operation as an open resection but with a reduction in iatrogenic trauma to the patient.

Initially, there were concerns of an inferior oncological outcome for laparoscopic resection as well as fears of implantation of tumour cells at port sites. A number of multicentre randomized trials of laparoscopic versus open resection for colon cancer were completed and published early in the millennium. These include the CLASSIC [187], COST [188], and COLOR [189] trials. These have demonstrated oncological equivalence and no significant risk of port site metastasis. Patient recovery is quicker following laparoscopic resection as measured by reduction in analgesic requirements and reduced time to bowel function. There is also a reduction in length of inpatient stay, increased by combining minimally invasive surgery with enhanced recovery programmes. There is a learning curve for attaining laparoscopic skills and laparoscopic colonic resection. Even in experienced hands there remain limits on what is possible. Conversion rates to open surgery are around 10%, and relative contraindications such as previous laparotomy, emergency cases, or bowel obstruction make laparoscopic surgery challenging. For the majority of elective colonic resections a laparoscopic approach should be considered the approach of choice.

Colonic cancer and inflammatory bowel disease

Colitis due to Crohn's disease and ulcerative colitis predisposes to the development of colonic cancer. In patients with pancolitis who develop an adenocarcinoma or area of dysplasia there may be a field change in the colon. These patients have a high risk of further tumours or dysplasia developing or already being present. In this situation it is safest to remove the whole colon and rectum [190]. In ulcerative colitis the patient can be left with either an end ileostomy or a restorative ileoanal pouch.

If the patient has segmental colitis then a balance needs to be struck between segmental resection and colectomy. In patients with mild, burnt-out, or very limited disease it may be possible to perform a standard segmental resection. Prior to this, careful evaluation of patients' symptoms and endoscopic evaluation of the mucosa is essential. Patients with limited disease but troublesome urgency and frequency will have a poor functional result with a segmental resection. For these patients an end stoma or pouch may well give a better quality of life.

Colonic cancer and polyposis or HNPCC

Patients with familial adenomatous polyposis coli should be managed in specialist centres. Following a period of endoscopic surveillance started in their late teens, they should have a colectomy and pouch or ileoanal anastomosis formed in their twenties prophylactically.

Patients with hereditary non-polyposis coli are best treated with a subtotal colectomy and ileorectal or ileosigmoid anastomosis [191]. The remainder of the colon should then be regularly examined with flexible sigmoidoscopy to prevent metachronous disease developing.

Colon cancer presenting as an emergency

Undergoing emergency surgery for colonic cancer is an independent poor prognostic factor [192]. In patients with malignant perforation the aim should be to treat the emergency expediently to reduce peritoneal contamination time. The aim should be to allow the patient to receive adjuvant chemotherapy, if required, soon after surgery to improve its efficacy. It may be more sensible to perform a Hartmann's, removing the attendant risks of anastomotic leak and reducing operative time. This can be reversed once the patient has completed chemotherapy.

Patients presenting with obstructing tumours may be treated with surgery or stenting. Right-sided tumours should be treated with a right hemicolectomy. Although this is considered a low-morbidity procedure, the complications rates are higher than the elective setting, with anastomotic leak rates as high as 10% and a mortality of 17% [193]. In patients who are unfit for surgery or are palliative, stenting provides an alternative treatment [194]. The use of stenting in patients who have metastatic disease or as a bridge to surgery in obstruction is still being evaluated with prospective trials, but has been shown to be safe in retrospective studies [195]. Stents should be placed using a combination of endoscopy and radiological guidance. Results are best when stents are placed in short left-sided strictures. In acute obstruction, delay waiting for stenting must be avoided as there is a risk of perforation and caecal ischaemia. If stenting is not available or appropriate then emergency resection should be undertaken. If the caecum is not viable then a subtotal colectomy should be performed. This is a safe operation but an ileorectal anastomosis as a single or two-stage operation can lead to troublesome loose motions and nocturnal call to stool. If the remainder of the colon is viable, a Hartmann's or segmental resection can be used. Studies have shown that segmental resection and primary anastomosis is a safe operation in the emergency setting [196].

Treatment of polyp or early cancers

Improvements in endoscopic polypectomy techniques have allowed bigger polyps to be excised. Early cancers or 'polyp' cancers (stage 1 or T1/T2) are being found more commonly in these resected polyps. Early cancers that have not already been excised at colonoscopy should be treated with standard resection techniques.

Colonic adenomas are polyps with areas of cellular dysplasia. They have a risk of malignancy broadly related to size, with polyps smaller than 1 cm having less than a 1% chance of containing a malignant focus [197]. All polyps larger than 1 cm and those with suspicious features should be tattooed prior to polypectomy or tattooed and biopsied if not excisable. Polypectomy can be performed using endoscopic mucosal resection, where the polyp is lifted away from the submucosa with saline/gelatine or hyaluronate solution. The polyp is then excised with a diathermy snare. Endoscopic submucosal dissection is a modification using an endoscopic diathermy knife to resect the lesion en bloc, which can reduce recurrence [198, 199].

Resected polyp cancers cannot be fully staged. To determine if further resection is required, features that increase the risk of lymph node spread or local recurrence are identified. If the polyp cancer is incompletely excised or within 1–2 mm of the diathermy margin, further excision should be undertaken. The risk of spread or invasion is also related to the levels of invasion towards the base of the polyp: see Haggitt [200] for stalked and Kikuchi [201] for flat polyps. If the patient is unfit for surgery, then endoscopic surveillance

Table 39.1 Risk factors for lymph node positivity in early CRCs [200]: high-grade, lymphovascular invasion, budding, cribriform cellular pattern

Risk factors	Lymph node metastasis	Micromets in 'negative' node
0	0.7%	6.8%
1	27%	14.3%
>2	36%	16.7%

can be used. Features which suggest more aggressive cancer types with a greater likelihood of metastasis are high grade, lymphovascular invasion, budding, and cribriform cellular pattern, which are shown in Table 39.1.

Liver and lung metastasis

There has been a change in the philosophy of metastatic colon cancer management over the last 20 years. The two most common sites of metastasis, liver and lungs, can now be treated curatively with resection. Improvements in imaging have allowed metastases to be identified earlier and improvements in surgical technique and haemostatic technology have reduced the physiological insult of the surgery. Liver resection has now become the standard of care for hepatic metastasis, with five-year disease free survival of 26–34% [202]. Whilst hepatic resection was initially limited to one to three metastatic deposits, the indications for resection are now much broader. Hepatic resection can be considered if the metastatic disease can be resected with clear margins, leaving enough functional liver—around 30%—for survival. Factors such as the volume of metastatic disease and time of recurrence are predictive of long-term outcome [203].

Patients who present with liver metastasis and a primary colon tumour may undergo synchronous resection or have their liver metastasis resected in a separate operation. Synchronous resection is usually reserved for patients having a simple colonic resection and a simple liver resection. The morbidity with simultaneous resection can be significantly increased, with higher rates of anastomotic leaks making complex resections unsafe [204].

Strategies have also developed to address initially unresectable hepatic disease. Chemotherapy may downstage unresectable disease to resectable disease. A recent European Organisation for Research and Treatment of Cancer (EORTC) randomized trial has demonstrated the benefit in progression-free survival of preoperative chemotherapy in the majority of resectable cases [205]. Lack of adequate functional liver post resection can be addressed by staged liver resection. This can be combined with portal vein embolization to generate hypertrophy of one side of the liver, increasing residual liver volume. Even unresectable liver deposits can be controlled by radiofrequency or microwave ablation.

Pulmonary resection of colorectal metastatic disease is a more recent development but has also demonstrated survival benefits. This has been facilitated by the advent of improved imaging and surveillance leading to higher detection rates and the use of minimally invasive thoracoscopic techniques, reducing the morbidity of pulmonary resection [206].

Peritoneal disease

Up to 10% of colon cancer cases have peritoneal spread at the time of presentation, and its treatment remains one of the challenges in colon cancer management. Cytoreductive surgery and perioperative intraperitoneal hyperthermic chemotherapy (HIPEC) has provided a treatment option for these patients [207]. The principle is to surgically resect the macroscopic peritoneal disease leaving microscopic or minimal visible disease only. Heated intraperitoneal chemotherapy, either oxaliplatin or mitomycin C, is then added to the abdominal cavity to control any remaining malignant cells. Patient selection is important as the surgery can be extensive, involving resection of a number of organs and stripping of large areas of peritoneum. It is usually reserved for patients with good performance status and low volumes of disease. A single randomized trial demonstrated a survival advantage, with a median survival of 22 months [208]. This data is being increasingly supported by large cohort studies [209].

Results of surgery and treatment for colon cancer

Elective colon cancer surgery is considered to have a low mortality and morbidity, with good postoperative quality of life. Results from large prospective multicentre trials show mortality figures of 1–4%, and morbidity of 1–20% [210, 211]. The surgery still has significant risks of adverse events. This is in part because even very elderly patients and those with multiple comorbidities will be offered surgical treatment. The quality of life following surgery is excellent, even in older populations, often with scores as good as or better than before surgery [212].

The results of colon cancer treatment have been improving steadily over the last 30 years, with 22% five-year survival for colon cancer in 1971–1975 compared with 51% in 2001–2006 [213]. Outcomes in the UK are not as good as for those with equivalent disease in the rest of Western Europe. The reasons for this remain poorly understood [214, 215]. The main determinant of survival is still cancer stage (Table 39.2); other independent poor prognostic features include presentation as an emergency and poor socioeconomic groups [216], and cancer features associated with more aggressive phenotypes such as lymphovascular and perineural invasion, tumour budding, mucinous, and poorly differentiated cell types.

Table 39.2 Percentage of cases and five-year relative survival (%) by stage at diagnosis, CRC patients diagnosed 1996–2002, England [213]

AJCC/Dukes' stage	Percentage of cases	Five-year survival
Stage 1/A	8.7%	93.2%
Stage 2/B	24.2%	77%
Stage 3/C	23.6%	47.7%
Stage 4/D	9.2%	6.6%

Medical management of early-stage disease

See Chapter 38 for the management of stage IV disease. Approximately 70–80% of newly diagnosed cases of CRC undergo curative resection; however, 40% of these develop incurable recurrent disease due to undetected micrometastases [217, 218]. Patients with stage III (A (T1, 2N1M0), B (T3, 4N1M0), C (T x N2M0) or Dukes' C) disease have a five-year survival rate from 83% to 44%, respectively, with three-year disease-free survival (DFS) ranging from 45% to 52%. Those with stage II (A (T3N0M0) or B (T4N0M0)) colon cancer after surgical resection have a five-year survival rate of 45–60% and 64–75%, respectively [217, 219]. The inability to cure all such patients is a direct consequence of residual occult disease.

Adjuvant chemotherapy is offered to such high-risk patients with the aim of decreasing relapse and improving overall survival (OS) by attempting to eliminate microscopic residual disease. It is offered where the benefits outweigh the risks from chemotherapy-related toxicities. Adjuvant therapy has been offered to patients with stage III disease as standard therapy for over two decades [220], a practice strongly reinforced by two recent meta-analyses [221, 222].

In the case of patients with stage II disease, the role of adjuvant therapy is controversial given the difficulty in identifying patients at the highest of risk who would benefit the most from adjuvant therapy [223]. The recognized clinical/pathological poor prognostic markers for patients with stage II disease include (1) poorly differentiated histology [224], obstruction or perforation at presentation [225], lymphovascular invasion [226]; (2) fewer than 12 lymph nodes retrieved during primary resection [225, 227, 228]; and (3) tumoural stage, including T4 disease (with invasion into adjacent organs) [224, 229]. From the SEER database, it was observed that the five-year OS rates between T3N0 and T4N0 patients was 87.5%±0.4% versus 71.5%±0.8% and between T4a (penetration through visceral peritoneum) and T4b (penetration of other organs or structures) 79.6%±1% versus 58.4%±1.3%, respectively [229]. These high-risk factors have not been evaluated in prospective trials in which such patients were randomized to treatment versus no treatment [230].

Adjuvant chemotherapy for stage III disease (T1–4, N1–2M0)

Adjuvant chemotherapy has been the standard of care for stage III disease for the last two decades. Initial efforts concentrated on the evaluation of 5-fluorouracil (5-FU)-based regimens and 5FU biochemical modulation. With the advances in the treatment of metastatic disease including oral 5-FU prodrugs, oxaliplatin, irinotecan, and the biologicals (including EGFR and anti-vascular endothelial growth factor (VEGF) monoclonal antibodies), these agents have also been evaluated and—in some cases—are now standard of care in patients with stage III disease. These new agents either provided a more favourable administration or toxicity profile (as in the case of the oral 5-FU prodrugs) or increase in DFS or OS (in the case of oxaliplatin).

During this time, three-year DFS rate has been validated as an appropriate endpoint for adjuvant trials given its strong correlation with five-year OS (correlation coefficient 0.86, HR = 0.91) [231]. On a subsequent analysis of six additional phase III trials, the two- or three-year DFS HRs were highly predictive of five- and six-year OS

HRs in stage III, but not stage II patients. In all patients, the DFS/OS association is stronger for six-year OS; thus at least six years' follow-up was recommended to assess OS benefit [232]. However, extended survival after recurrence reduces the association between treatment effects on thee-year DFS and five-year OS, particularly in stage II patients [233]. In modern adjuvant trials, six or seven years may now be required to demonstrate OS improvements [233].

5-FU-based therapy

The major advances in adjuvant chemotherapy for resected CRC were made in the early 1990s, with the biochemical modulation of 5-FU with either levamisole (Lev) or LV. Two recent meta-analyses have shown that the reduction in mortality by modulation of 5-FU by LV or Lev (29%, P < 0.007; 22%, P < 0.01, respectively) was significantly larger than that for unmodulated 5-FU (6%, P < 0.11) [221, 222].

The NCCTG study demonstrated the benefit of 5-FU-Lev relative to observation or Lev alone in reducing tumour recurrence and improving OS in patients with Dukes' C disease [234]. The IMPACT, NSABP-C03, and NCCTG trials have all demonstrated the advantage of 5-FU-LV relative to their respective control arms [235–237]. Since then, several large multicentre randomized trials have been performed to define the optimal 5-FU-based regimen: that is, the combination with high- or low-dose LV (HDLV, LDLV, respectively) and/or Lev in patients with stage III colon cancer. One of the largest was the Intergroup-0089 trial, a four-arm trial involving 3760 patients with high-risk stage II/III disease [238]. The other large trial, the QUASAR study, evaluated the role of Lev (versus placebo) and LV dose (175 mg versus 25 mg) in stage I–III CRC [239–240]. These large studies demonstrated the following: (1) 5-FU/HDLV is equivalent to 5-FU/LDLV at least as administered in the daily by 5, four-weekly regimen; (2) the weekly regimen of 5-FU-LV is equivalent but less toxic compared with a four-weekly regimen; (3) the addition of Lev provided no additional survival benefit [237–241]; and (4) the efficacy of adjuvant chemotherapy for 12 months provided no further benefit compared with six months.

The efficacy of 5-FU-LV or -Lev in the adjuvant setting has been evaluated specifically in terms of the elderly with stage III disease [242–244]. The lack of significant interaction between age and treatment efficacy has been demonstrated by the results of a meta-analysis (seven trials involving 3351 patients) [242], a population analysis using NCI SEER and the US Medicare database [243], and a prospective analysis of 85,934 patients from 1990 to 2002 [244].

Oral 5-FU prodrugs

The most widely available is capecitabine, a prodrug that undergoes final conversion to 5-FU through tumoural thymidine phosphorylase. In terms of adjuvant therapy, capecitabine (24 weeks, 1250 mg/m^2 twice daily, day 1–14, one week rest) was compared to the six-months' bolus 5-FU-LV as adjuvant therapy for stage III colon cancer in the randomized phase III X-ACT trial [245]. The DFS (primary study endpoint) in the capecitabine arm was at least equivalent to that in the 5-FU-LV arm (HR = 086, P = 0.04); the upper limit of the HR was significantly (P < 0.001) below the predefined margins for non-inferiority. Capecitabine was also associated with significantly fewer 5-FU-related grade 3/4 adverse events (AEs; P < 0.001) and fewer adverse-event (AE)-related hospital admissions. Pharmacoeconomic analyses performed in several countries showed that the savings in direct costs (drug administration and AE-related costs) associated with capecitabine versus

5-FU-LV offset the drug acquisition costs [245]. A follow-up report with a median follow-up of 6.9 years again confirmed these earlier results with regards to DFS [246].

Oxaliplatin and 5-FU or capecitabine

The efficacy of oxaliplatin plus 5-FU in the adjuvant setting was demonstrated by two pivotal trials: the MOSAIC [247] and the NSABP C07 trials. In the MOSAIC trial, 2246 patients who had stage II or III colon cancer were randomized to receive a combined bolus and infusional 5-FU regimen (LV5-FU2) alone or with oxaliplatin (FOLFOX4) for six months. The primary endpoint was 3-year DFS [247]. A total of 1123 patients were randomly assigned to each group. The rate of DFS at three years was 78.2% in the group given FOLFOX4 versus 72.9% in the LV5-FU2 group (P = 0.002). In the group given FOLFOX4, the incidence of grade 3 sensory neuropathy was 12.4% during treatment, decreasing to 1.1% at one year of follow-up [247].

With longer follow-up, the final results of the study, including six-year OS and five-year updated DFS were reported [248]. The five-year DFS rates were 73.3% and 67.4% in the FOLFOX4 and LV5-FU2 groups, respectively (HR = 0.80; P = 0.003). Six-year OS rates were 78.5% and 76.0% in the FOLFOX4 versus LV5-FU2 groups, respectively (HR = 0.84; P = 0.046). The corresponding six-year OS rates for patients with stage III disease were 72.9% and 68.7%, respectively (HR = 0.80; P = 0.023). Of note was that no difference in OS was seen in the stage II population [248].

In the NSABP C07 trial, 2492 patients with stage II and III colon cancer were randomly assigned to either 5-FU 500 mg/m^2 bolus weekly for six weeks plus LV 500 mg/m^2 IV weekly for six weeks during each eight-week cycle (Roswell Park regimen) for three cycles (5-FU-LV), or the same 5-FU-LV regimen with oxaliplatin 85 mg/m^2 IV administered on weeks 1, 3, and 5 of each eight-week cycle for three cycles (FLOX) [249]. The DFS hazard ratio (FLOX versus 5-FU-LV) was 0.80 (P <0.004). The four-year DFS rates were 67.0% for 5-FU-LV and 73.2% for FLOX, respectively. In terms of stage II and III patients: for stage II the four-year DFS was 81% versus 84.2%, and stage III 61.1% versus 68.9% for 5-FU-LV and FLOX, respectively [249].

A subsequent trial compared capecitabine plus oxaliplatin (XELOX; oxaliplatin 130 mg/m^2 on day 1 plus capecitabine 1000 mg/m^2 twice daily on days 1 to 14, every three weeks for 24 weeks) with bolus 5-FU-LV (Mayo Clinic for 24 weeks or Roswell Park for 32 weeks) as adjuvant therapy for patients with stage III colon cancer [250]. The primary study endpoint was DFS. After 57 months of follow-up, the three-year DFS rate was 70.9% with XELOX and 66.5% with 5-FU-LV (HR = 0.80, P = 0.0045). The HR for OS for XELOX compared to 5-FU-LV was 0.87 (P = 0.1486). The five-year OS for XELOX and 5-FU-LV were 77.6% and 74.2%, respectively. It was thus concluded that the addition of oxaliplatin to capecitabine improves DFS in patients with stage III colon cancer. XELOX is thus considered an additional adjuvant treatment option for these patients [250].

The efficacy of adjuvant oxaliplatin therapy has also been confirmed, albeit inconsistently, in the elderly. Subgroup analyses of DFS of the NO1968 trial comparing XELOX to 5-FU-LV, demonstrated reduced risk of recurrence in all subgroups receiving oxaliplatin including patients <65 years of age and those ≥65 years of age; however, in the latter group the trend was not significant [250]. A post hoc analysis of the effect of oxaliplatin in the NSABP

CO7 trials did vary by age for OS (younger than age 70 versus 70+, interaction P = 0.039), with a similar trend for DFS (interaction P = 0.073). Oxaliplatin significantly improved OS in patients younger than age 70 (HR, 0.80; P = 0.013), but no positive effect was evident in older patients [251].

An analysis of the ACCENT database, derived from six phase III adjuvant trials comparing IV 5-FU to combinations with irinotecan, oxaliplatin, or oral FU in stage II/III colon cancer, evaluated data from 10,499 patients younger than 70 and 2170 patients ≥70 years. OS, DFS, and TTR were not significantly improved for those patients older than 70 years of age in the experimental versus control arms. The interaction between age and treatment was statistically significant for all endpoints (P = 0.01 for OS, DFS, and TTR) [252]. A further analysis evaluated the benefit of the oxaliplatin combination in patients above and below 70 years of age (overall, 3742 patients; 614 ≥ 70 years of age) from four clinical trials in the adjuvant and metastatic setting [253]. OS and DFS rates did not differ by age, though data from patients older than 80 was sparse [253].

Irinotecan and 5-FU

Despite the activity of irinotecan in the treatment of advanced CRC, randomized phase III trials in the adjuvant setting (including CALGB 89803, PETACC3, ACCORD 2 trials) have failed to demonstrate an added benefit relative to 5-FU-LV alone [254–256]. Further trials evaluating this agent in this setting have not progressed.

Biological agents and combination chemotherapy

In the metastatic setting the antiangiogenic agent, bevacizumab, a monoclonal antibody to VEGF, and the anti-EGFR monoclonal antibodies cetuximab and panitumumab have shown added benefit when added to conventional chemotherapy backbones, whether oxaliplatin- or irinotecan-based or 5-FU-LV [257]. However, recent phase III trials in the adjuvant setting have demonstrated that these biological agents provide no additional benefit and may actually be detrimental when added to a chemotherapy backbone, usually oxaliplatin-5-FU.

In the case of bevacizumab, the NSABP C08 [258] and the AVANT trials [259] have shown no additional benefit. In the former trial, 2672 patients with stage II/III disease were randomized to mFOL-FOX6 for six months versus the same regimen with 12 months of bevacizumab. The primary endpoint of three-year DFS was 75.5% versus 77.4% for the control and experimental arms, respectively (HR = 0.89, P = 0.15). There was a transient effect of bevacizumab during treatment whereby the impact on DFS was significant before versus after a 15-month landmark: HR = 0.61 (P < 0.001) and HR = 1.22 (P = 0.076), respectively [258]. The reason for this transient benefit of bevacizumab is unclear [258, 260].

The lack of benefit with bevacizumab was, however, confirmed by the AVANT trial, in which high-risk stage II/III patients were randomized to FOLFOX4 for six months ± bevacizumab for 48 weeks or XELOX for six months ± bevacizumab for 48 weeks [259]. The addition of bevacizumab did not prolong DFS or OS in stage III patients, with efficacy favouring the chemotherapy-alone arm [259]. Two other large relevant trials are yet to be reported. These include the QUASAR 2 study, randomizing patients to capecitabine ± bevacizumab, and ECOG E5202 [260].

In terms of cetuximab, the NCCTG-N0147 trial randomized patients with stage III KRAS wild-type disease to six month of mFOLFOX6 ± cetuximab [261]. Three-year DFS for mFOLFOX6

alone was 74.6% versus 71.5% with the addition of cetuximab (HR = 1.21; P = 0.08), with no significant benefit in any subgroups assessed [260]. The PETTAC8 trial was of similar design: a pre-specified interim analysis did not support a benefit in DFS for patients given cetuximab plus FOLFOX-4 compared with patients treated with FOLFOX-4 alone. The FoxTROT trial evaluating FOLFOX or XELOX ± panitumumab is yet to be reported [262].

The mechanisms for this lack of synergy with chemotherapy and the biological agents in this setting as compared to advanced disease are not clear but may be explained by the induction of compensatory/alternate mechanisms and pro-survival pathway activation by VEGF or EGFR inhibition, which have been discussed elsewhere [263].

Adjuvant therapy of patients with resected stage II colon cancer

The case for and against

In the case of patients with stage II disease the role of adjuvant therapy is controversial given the difficulty in identifying patients at the highest risk who would benefit the most from adjuvant therapy whilst avoiding potential toxicity in patients who would not benefit [223].

The efficacy of systemic adjuvant chemotherapy for patients with stage II cancer has still not been confirmed. A pooled analysis of 1016 patients with B2 colon cancer from the IMPACT trial, in which patients were randomized to 5-FU-LV versus observation, found chemotherapy did not provide a significant advantage in terms of event-free survival (EFS) (82% versus 80%, respectively) or OS (76% versus 73%, respectively) after a median follow-up of 5.75 years [264]. However, in contrast, when the results from the NSABP C01–4 trials were pooled to compare the efficacy of chemotherapy in 1565 patients with Dukes' B relative to Dukes' C disease, regardless of stage, there was a reduction in mortality, DFS, and recurrence after chemotherapy. The reduction for Dukes' B was of a similar magnitude to that seen for Dukes' C disease [265].

The large phase III QUASAR trial randomized 6668 patients with resected stage II and III colon cancer to 5-FU (370 mg/m^2) with HD (175 mg) or LD (25 mg), LV and either Lev or placebo. The primary outcome was all-cause mortality [239–240]. Overall, 28% of the patients entered had stage B (or stage II) disease, selected for high risk features, such as T4, obstruction, and perforation. The relative risk of recurrence for colon cancer was reduced with an HR of 0.78 (P = 0.004), and the relative risk for cancer-related death was also reduced, HR = 0.84 (P = 0.06). Treatment efficacy did not differ significantly by tumour site, stage, sex, age, or chemotherapy schedule [239–240].

In terms of modern combination therapy there is relevant data from the MOSAIC and the NSABP C07 trials in patients with stage II disease. In terms of the MOSAIC trial, 899 patients with stage II disease were randomized between LV5U2 versus oxaliplatin-LV5U2. With a median follow-up of 6.8 years: five-year DFS was 79.9% versus 83.7% (HR = 0.84, P = 0.258) and the six-year OS 86.8% versus 86.9% (P = 0.986), respectively [248]. For the NSABP CO7 trial, 29% overall had resected stage II disease; the four-year DFS was 81% versus 84.2% in favour of FLOX [249].

A recent Cochrane analysis considered all randomized trials or meta-analyses containing data on stage II colon cancer patients undergoing adjuvant therapy versus surgery alone; overall 8642 patients were considered [262]. In terms of the effect of adjuvant therapy on stage II colon cancer, the pooled relative risk ratio for OS was 0.96 (95% CI 0.88–1.05), and for DFS 0.83 (95% CI 0.75–0.92). Hence the benefit was in terms of DFS only. The authors concluded that it was reasonable to discuss the benefits of adjuvant systemic chemotherapy with those stage II patients who have high-risk features. The comorbidities and likelihood of tolerating adjuvant systemic chemotherapy should be considered as well [266].

Identifying high-risk stage II patients

Given the modest benefit for adjuvant therapy in patients with resected stage II disease, there is thus an urgent need to better characterize high-risk patients who would gain the greatest benefit. At present, the identifiers of high risk relate to the tumour as well as clinical factors, albeit inconsistently [223]. Considerable effort has been directed to identify molecular prognostic and predictive factors; however, as expected, there is considerable heterogeneity in terms of the cohorts evaluated, prospective versus retrospective analyses, and analytical methodology.

The markers evaluated thus far include aneuploidy/tetraploidy DNA, 18q allelic loss, as well as microsatellite status (MS), p53, KRAS, BRAF, and thymidylate synthase [230, 277–270]. A detailed review of these molecular factors with regard to stage II disease has been published recently [271]. These factors, however, may not be mutually exclusive: for example, the molecular analysis of the PETACC-3 study found that in stage II–III colon cancer, KRAS mutation status did not have major prognostic value, but BRAF was prognostic for OS in MS-L/MSS tumours [268].

Microsatellite instability (MSI)

The assessment of MSI, which serves as a marker for DNA mismatch repair (MMR) system function, has emerged as a useful tool for risk stratification of patients with stage II colon cancer. It seems clear, from retrospective studies and meta-analyses, that patients with stage II and III tumours classified as MSI-H (or defective MMR (dMMR)) have a better prognosis, independent of adjuvant therapy, relative to MSS tumours [272–274].

Whilst the prognostic importance of MSI has been confirmed, however, its importance in predicting response to adjuvant chemotherapy is unclear [267]. It appears that patients with dMMR do not benefit from adjuvant 5-FU therapy [275, 276]. The largest study involved 457 patients who were previously randomized to 5-FU-based therapy adjuvant therapy (n = 229) versus no post-surgical treatment (n = 228) [276]. Overall, 70 (15%) of 457 patients exhibited dMMR. Adjuvant therapy significantly improved DFS (HR = 0.67; P = 0.02) in patients with preserved MMR tumours. Patients with dMMR tumours receiving 5-FU had no improvement in DFS (HR = 1.10; P = 0.85) compared to surgery alone. A parallel analysis of a pooled data set of 1027 patients confirmed these findings [276].

The data thus far support MMR status assessment for patients being considered for 5-FU therapy alone. Based on the body of current data, with the caveat that MSI status is still to be validated prospectively as a predictive biomarker, the current NCCN guidelines recommend that where adjuvant therapy is being considered in patients with stage II disease, MSI status must be assessed; those with MSI-H tumours should not be offered 5-FU-based therapy [225, 260].

It is unclear whether this also applies to oxaliplatin-5-FU adjuvant regimens. A recent study investigated the clinical

implication of MSI-H/dMMR and p53 expression in resected colon cancer patients who received post-operative FOLFOX therapy [277]. Overall, in 135 patients there were 13 (9.6%) patients with stage II disease and 108 (80%) patients with stage III. MMR status was not significantly associated with DFS or OS in patients receiving adjuvant FOLFOX. It was concluded, albeit in this small heterogeneous study, that adding oxaliplatin to adjuvant chemotherapy may overcome the negative impact of 5-FU on colon cancers with MSI-H/dMMR [277].

18q allelic imbalance (18qAI)

The chromosome 18q contains the tumour suppressor genes deleted in colon cancer (DCC) and the SMAD4 gene, which are lost in the oncogenic development of CRC [278]. The allelic loss of 18q is manifested as a loss of heterozygosity (LOH). The 18qLOH or 18 allelic imbalance (18qAI) have been correlated with a poorer prognosis in patients with stage II and III disease, albeit inconsistently [279, 280].

In a landmark study, LOH from chromosomes 18q, 17p, and 8p, cellular levels of p53 and p21 (WAF1/CIP1) proteins, TGF-beta1 type II receptor gene mutation, and MSI status were analysed in 460 patients with stage III and high-risk stage II colon cancer who had been treated with 5-FU-based therapy [280]. Among patients with MSS stage III cancer, five-year OS after 5-FU-based chemotherapy was 74% in those whose cancer retained 18q alleles and 50% in those with 18q LOH (RR for death with 18q LOH was 2.75; P = 0.006). The five-year OS among patients whose cancer had MSI-H was 74% in the presence of a mutated gene for the TGF-beta1 type II receptor and 46% if the tumour did not have this mutation (RR of death, 2.90; P = 0.03). It was concluded in this retrospective study that retention of 18q alleles in MSS cancers and TGF-beta1 type II receptor gene mutation in cancers with high levels of MSI-H point to a favourable outcome with 5-FU-based regimens for stage III colon cancer [280].

The recently closed ECOG E5202 study is also relevant in this regard. It assigned stage II patients, stratified by MSI status and 18q allele imbalance, to observation for low-risk patients (MSS or MSI-L with retention of 18q or MSI-H) and high-risk patients (MSS/18qLOH or MSI-L/18qLOH) to FOLFOX4 +/ bevacizumab. It was closed early following the reports of the AVANT and NSABP C08 trials that demonstrated the lack of benefit of bevacizumab in the adjuvant setting [260].

Gene expression approaches

Quantitative gene expression assays have been evaluated to assess recurrence risk, though with less utility for the benefits from chemotherapy in patients with stage II disease. There are at present two commercially available gene expression classifiers (ColoPrint® and Oncotype DX®) that have been developed and are being subsequently validated prognostically to classify patients with early-stage colon cancer at high risk of relapse, rather than to determine their predictive ability in terms of outcomes from adjuvant chemotherapy [281, 282]. Others have also been reported and are being validated [283, 284].

ColoPrint® is an 18-gene prognostic classifier that was developed to predict disease relapse in patients with early-stage CRC. It was derived from fresh frozen tumour tissue from 188 patients with stage I to IV CRC undergoing surgery, whereby the majority (83.6%) did not receive adjuvant chemotherapy, and were analysed using Agilent 44K oligonucleotide arrays [281]. The classifier components were identified for their association with five-year distant metastasis-free survival. The classifier was validated on an independent set of 206 samples from patients with stages I–III CRC, whereby the signature classified 60% of patients as low risk and 40% as high risk. Five-year relapse-free survival (RFS) rates were 87.6% and 67.2% for low- and high-risk patients, respectively, with a HR of 2.5 (P = 0.005). In a multivariate analysis, including pathological stage and MSI status, the signature remained one of the most significant prognostic factors, with a HR of 2.69 (P = 0.003). In patients with stage II CRC, the signature had an HR of 3.34 (P = 0.017). Thus, ColoPrint® significantly improved the prognostic accuracy of pathologic factors and MSI in patients with stage II and III CRC and may identify patients with stage II disease who may be managed without chemotherapy [281].

ColoPrint® has subsequently been validated in an independent dataset, comprising of 320 stage II patients, 227 of which were T3/MSS [285]. In the analysis of all stage II patients, ColoPrint® classified two-thirds of stage II patients as being at lower risk. The three-year RFS was 91% for low risk and 74% for patients at higher risk, HR of 2.9 (P = 0.001). Standard poor prognostic clinicopathological parameters did not predict a differential outcome for high-risk patients (P <0.20). In the subgroup of patients with T3 and MSS phenotype, ColoPrint® classified 61% of patients at lower risk with a three-year RFS of 91% and 39% of patients at higher risk with a three-year RFS of 73% (P = 0.002) [285].

The second type of commercial assay is the Oncotype DX®. It was developed to quantify the risk of recurrence, as well as the likelihood of differential treatment benefit, of 5-FU/LV adjuvant chemotherapy for patients with resected stage II and III disease [282]. Fixed, paraffin-embedded tumour blocks were analysed from 1086 patients with stage II or III colon cancer treated as part of the NSABP C-01, -02, -04, and -06 trials. In its final development, the assay comprised of an 18-gene panel that included seven genes for RFS prognosis in colon cancer to yield a prognostic recurrence score (RS), six genes to predict response to 5-FU/LV chemotherapy to yield a predictive treatment score (TS), and five reference genes. Subsequent algorithms were developed to identify groups of patients with low, intermediate, and high likelihood of recurrence and benefit from 5-FU/LV [282].

Oncotype DX® has been subsequently validated in the stage II CRC dataset from the QUASAR study [273]. RNA was extracted from fixed paraffin-embedded primary colon tumour blocks from 1436 patients. Both RS and TS were calculated from gene expression levels of the 13 cancer-related genes described previously. The risk of recurrence was significantly associated with RS: recurrence risks at 3 years were 12%, 18%, and 22% for predefined low-, intermediate-, and high-recurrence risk groups, respectively. T stage (HR 1.94; P <0.001) and MMR status (HR 0.31; P <0.001) were the strongest histopathologic prognostic factors. There was no trend for increased benefit from chemotherapy at higher RS (P = 0.95). It was concluded that this continuous 12-gene RS provided prognostic value that complements T stage and MMR. The TS was not predictive of chemotherapy benefit [273]. The Oncotype DX® assay has also been validated in the dataset derived from the PETACC-3 trial [284].

In conclusion, adjuvant therapy is recommended for patients with resected stage III colon cancer. Patients, based on fitness and preference, with completely resected stage III cancer should be offered six months of adjuvant chemotherapy, which optimally should start within eight weeks of surgery. The optimal regimen is oxaliplatin in combination with 5-FU-LV or capecitabine, based on

relevant consideration of the therapeutic ratio, especially in regard to neurotoxicity. Patients not considered suitable for oxaliplatin should be offered 5-FU-LV (weekly bolus, or Roswell Park regimen, or LV5-FU2 bolus-infusional regimen) or capecitabine [230]. Patient compliance in terms of cumulative toxicity and the differing toxicity profile for capecitabine must be carefully considered. Current trials are now investigating the optimal length of therapy, i.e. three versus six months (IDEA trial, multinational intergroup trial) and the SCOT (Short Course Oncology Therapy), a study of adjuvant chemotherapy in colorectal cancer by the CACTUS and QUASAR 3 Groups, and the additional benefit of the EGFR monoclonal antibody panitumumab (the FOxTROT trial), which is also testing the role of neoadjuvant therapy [263].

In terms of patients with resected stage II disease, adjuvant chemotherapy may be discussed with patients at high risk of disease relapse, based upon clinicopathological factors discussed above and whilst considering the patients' comorbidities, age, as well as the risk of therapy-related adverse events. MSI status must be assessed for those patients being considered for adjuvant therapy, and those with an MSI-H tumour should not be offered 5-FU-based therapy alone [225, 260]. The utility of oxaliplatin-based therapy in this setting is controversial, given the marginal benefit and greater risk of toxicity. Where available, commercial gene expression classifiers may also be considered to further classify patients based on risk of relapse. However, at his stage they cannot predict which patients are likely to respond to therapy.

Radiotherapy for colon cancer

In contrast to rectal cancer, the role of adjuvant radiotherapy is not well established in the management of colon cancer. The colon is a much longer structure than the rectum. It begins with the caecum in the right iliac fossa, and continues as the ascending colon in the retroperitoneal region on the right side of abdomen. It then becomes the transverse colon with its mesentery attached to the posterior abdominal wall, running from the right side to the left side of the abdomen. It runs further as the descending colon in the retroperitoneal position on the left side of the abdomen, and then as the sigmoid colon with its mesentery in the lower abdomen.

Colon cancer may recur locally in several different ways: anastomotic recurrence, tumour bed recurrence, and nodal recurrence [286]. The risk of local recurrence is, however, lower compared with rectal cancer. Anastomotic recurrence is not common, possibly because, at surgery, wide proximal and distal resection margins are achievable in most situations. The extent of proximal and distal resection margins is determined not only by the tumour extent, but also by the amount of vascular supply of the colon that is resected during clearance of the lymphatic drainage.

The risk of tumour bed recurrence varies for different parts of the colon. The high-risk portion is the immobile part of the colon in the retroperitoneal position—the ascending colon and the descending colon. The risk is particularly high when the tumour involves the posterolateral wall of the colon where the serosa is lacking. The low-risk portion is the mobile part of the colon with complete peritoneal covering attached to the posterior abdominal wall with its mesentery, the transverse colon, and the sigmoid colon. Wide circumferential margins are achievable in these areas. The risk of local recurrence also depends on whether the adjacent organs, when invaded by the tumour, can be sacrificed for an extended resection.

Adjuvant radiotherapy was found to decrease local recurrence for locally advanced tumours [287]. It was found to be beneficial for patients with T4 lesions, tumours associated with abscess or fistula formation, and residual local disease after subtotal resection [288]. It was also found in a retrospective study that post-operative radiotherapy decreased the risk of local recurrence in patients with T3–4 tumours of the caecum, ascending colon, or descending colon [289].

In view of the high risk of local recurrence in the autopsy and reoperation series, a randomized controlled study was performed to evaluate the benefit of adjuvant radiation in addition to adjuvant chemotherapy after complete resection of the colon cancer [290]. Patients suitable for the Intergroup Protocol 0130 were those with resected colon cancer where there was tumour adherence or invasion to the surrounding structures and with T3N1 or T3N2 tumours of the ascending or descending colon. The experimental arm included treatment with radiation to a total dose of 45 to 50.4 Gy in 1.8 Gy per fraction, in addition to adjuvant chemotherapy consisting of 5-FU and levamisole. This study was terminated because of slow accrual after the enrolment of 222 patients, which was less than a third of the accrual target. Data from assessable patients (n = 187) showed that patients who received chemotherapy or chemoradiation had similar overall survival and disease-free survival rates. Toxicity was higher among chemoradiation patients. These results, however, must be interpreted with caution because of the high number of ineligible patients and the limited power of the study to detect potentially meaningful differences.

Several deficiencies in the study methodology were subsequently identified. Radio-opaque surgical clips for guiding the radiation field were used only in a minor proportion of patients. Preoperative imaging was not available for most patients. The completeness of the resection could not be confirmed because of the lack of information about the radial margins. It highlights the importance of close cooperation among surgeons, radiation and medical oncologists, pathologists, and radiologists in selection of patients for adjuvant radiotherapy.

In order to evaluate the area at risk for adjuvant radiotherapy planning, availability of a preoperative CT scan, operation notes, and pathology report are essential. In addition, surgeons can assist in localization of the tumour bed by inserting radio-opaque surgical clips at the time of surgery. Accurate localization of the tumour bed improves tumour control by reducing the risk of marginal miss. It also limits unnecessary radiation exposure to the nearby critical structures at low risk for involvement.

The organs that limit radiation dose vary according to the location of the colon cancer. These organs include small intestine, liver, kidneys, spinal cord, urinary bladder, and gynaecological structures. Improvement of radiotherapy technique allows treatment to be delivered safely. Radiation side effects have been significantly reduced with conformal radiotherapy and intensity-modulated radiation therapy (IMRT).

Adjuvant chemoradiation is to be considered for selected patients with T4 disease penetrating to a fixed structure or for patients with recurrent disease. Preoperative chemoradiation is also a consideration for patients with clinical T4 or recurrent disease to increase the chance of complete resection. In addition, highly selected cases of T3 cancers on the posterolateral wall of the ascending and descending colon, where wide resection margins cannot be achieved, are to be considered. The common dose regimen for adjuvant chemoradiation is 45–50.4 Gy in 1.8 Gy per fraction over 5–5.5 weeks with

concurrent infusion chemotherapy 5-FU. The radiotherapy target volume includes the primary tumour bed with a margin. There is no evidence that enlarging the radiotherapy target volume to include the regional lymph nodes improves outcomes [287]. Radiation can also be delivered intraoperatively in specialized centres after resection of the colon cancer [291]. Intraoperative radiation therapy (IORT) is a highly conformal form of radiotherapy. Special equipment and dedicated operation theatres are necessary for this procedure. Two forms of IORT are available. One form of delivery is with electrons from a dedicated linear accelerator located in a shielded theatre. IORT can also be delivered by brachytherapy with the flap technique. Brachytherapy is a form of radiotherapy where a radiation source is placed inside or next to the area requiring treatment. The radiation target volume is tailored according to the area at risk at the time of surgery. Side effects are kept to a minimum by displacing normal organs away from the radiation field during treatment. In addition, lead shields are used to protect tissue close to the radiation target. The effective depth of radiation is approximately 1 cm. It is reserved for situations where a wide circumferential resection margin is not achievable. In order to select suitable cases for IORT, thorough preoperative workup is necessary.

Whole abdominal radiation therapy (WART) has also been attempted to reduce the risk of intra-abdominal recurrence. A pilot clinical study of WART was performed in patients with locally advanced colon cancer, in view of the high incidence of peritoneal metastasis in this group of patients [292]. The inclusion criteria of the Southwest Oncology Group study were patients with completely resected T3Nl–2M0 colon cancer. Infusion chemotherapy 5-FU was administered with concomitant 30 Gy of WART in 1 Gy per fraction. An additional 16 Gy boost to the tumour bed was administered in 1.6 Gy per fraction. There were no treatment-related fatalities but 17% of patients had severe toxicity and 7% had life-threatening toxicity of any kind. Its efficacy has not been confirmed in randomized studies.

Radiation therapy for liver metastasis

In a selected group of patients, resection of liver metastasis provides long-term tumour control and improved survival [293]. Recently, high-dose radiotherapy has been used to eradicate liver metastasis; this is a treatment option available in specialized centres. Technological improvements in radiation delivery have allowed liver irradiation to be delivered safely up to doses of 90 Gy in 1.5 Gy per fractions [294].

Stereotactic body radiotherapy (SBRT) is an emerging technique employed in the treatment of liver metastasis. It delivers high doses of radiation to the liver metastasis with multiple fields, resulting in highly conformal dose gradients that can spare normal structures from high risk of toxicity. High accuracy and precision of treatment is ensured by use of image-guided radiotherapy at every treatment course (usually one to six treatments). Insertion of radio-opaque markers in the liver can facilitate localization of the metastasis at every treatment. 4-dimensional CT imaging is used in planning the position of the metastasis during different phases of the respiratory cycle. Accordingly, internal motion of the lesion can be accounted for in the radiotherapy plan. Various methods to control respiratory motion are used. Abdominal compression is used to reduce abdominal movement during the respiratory cycle. Active or voluntary breathholding during simulation and treatment

allows treatment to be delivered at either an inhale or exhale phase of breathing. Gated radiotherapy can be performed by obtaining a respiratory signal or position of the tumour by use of either an internal or external fiducial marker. These methods allow smaller margins to be used in radiotherapy delivery and hence reduce rates of normal tissue toxicity while obtaining ablative doses of radiotherapy to the tumour.

In a multi-institutional phase I/II study, patients with one to three hepatic lesions and maximum individual tumour diameters less than 6 cm were included. Radiation dose was escalated from 36 Gy to 60 Gy, in three fractions, in increments of 6 Gy, during phase I study. The phase II dose was 60 Gy in three fractions. Thirteen patients were treated to a dose less than 60 Gy, and 36 patients received 60 Gy. Forty-seven patients with 63 lesions were treated. Grade 3 or higher toxicity was 2%. Actuarial in-field local control rates at one and two years after SBRT were 95% and 92%, respectively. Among lesions with maximal diameter of 3 cm or less, two-year local control was 100%. Median survival was 20.5 months [295].

A different approach is individualizing total radiation dose according to the normal tissue tolerance of the liver. In a phase I study, 68 patients with inoperable liver metastases were treated with individualized SBRT. Median radiation dose was 41.8 Gy (range 27.7 to 60 Gy) in six fractions over two weeks. Median tumour volume was 75.2 ml (range 1.19 to 3,090 ml). Two grade 3 liver toxicity enzyme changes occurred, but no radiation-induced liver disease or other grade 3 or higher liver toxicity. The one-year local control rate was 71% (95 CI, 58% to 85%) [296].

New treatment strategies are being explored. A dose-escalating phase I study is being performed to investigate the maximum tolerated dose of single-fraction SBRT (NCT01162278). A phase I/II trial combines liver SBRT with sorafenib (NCT00892424). Proton beam SBRT is being investigated in treating liver metastasis (NCT01239381). Proton beam radiation uses tiny particles to deliver radiation to tumours. A phase II with individualized SBRT for liver tumours is being conducted with patients who have had previous liver treatment (NCT01522937). The development of SBRT for liver metastasis has been promising. Conformal external beam radiotherapy can be considered in highly selected cases or in the setting of a clinical trial but it should not be used indiscriminately in patients who are potentially surgically resectable.

Multidisciplinary care of early stage colon cancer

Introduction to multidisciplinary care

As management strategies for colon cancer become increasingly refined and personalized medicine becomes the rule rather than the exception, complexity arises when optimizing the treatment for individuals. The treatment of colon cancer has evolved over the last several decades from what was originally primarily a surgical disease, to one where it is expected that doctors and allied health professionals from several disciplines will be involved in patient management from the outset. A multidisciplinary approach is essential from the point of diagnosis, through treatment, and beyond. While the role of multidisciplinary involvement is most obvious in challenging and complex scenarios, every patient in fact requires expertise from several medical and allied health disciplines—a biopsychosocial approach for optimal outcomes

after the diagnosis of colon cancer. Many (over 60%) are cured from their colon cancer, and thus surveillance and survivorship issues are particularly pertinent in the setting of colon cancer.

This section will outline the multidisciplinary nature of early-stage colon cancer care. As several aspects of such care are addressed in other chapters within this textbook, a general overview will be presented in these circumstances.

Role of multidisciplinary meetings and team management—consensus and controversies

Multidisciplinary team meetings and strategies have been implemented in many cancer centres throughout the world. Multiple doctors are involved in an individual's care; a prior UK study of 50 cancer patients found that within the first year of diagnosis, patients saw an average of 28 doctors [297]. Clearly, communication between these doctors is of critical importance. A multidisciplinary approach can help to streamline a patient's personal navigation through the system of colonoscopies, blood work, radiological investigation, surgery with or without perioperative chemotherapy or radiotherapy, stomal care, and timely post-operative oncological review, and appropriate follow-up. Aside from the 'physical' aspects of multidisciplinary care, the involvement of a multidisciplinary team can also identify potential psychosocial or comorbidity-related issues which may need to be considered and addressed during the patient's care. Finally and most importantly, discussion in a multidisciplinary context may help to identify patients who are suitable for clinical trials [298].

A more formalized approach to multidisciplinary care, including multidisciplinary team meetings, documentation, and care planning, is a concept increasingly embraced worldwide. The UK National Institute for Health and Clinical Excellence (NICE) guidelines recommend that patients with CRC should be treated by a multidisciplinary team [299]. Effective, coordinated, universal multidisciplinary care, although desirable, is not as prevalent in some centres as others [300].

The literature regarding the effectiveness of a formalized multidisciplinary approach is largely supportive [301], but while this is certainly felt to improve timeliness of referral, communication between specialists, and quality of patient care, it has been more difficult to demonstrate objective evidence that the multidisciplinary team improves patient outcome, especially in the context of changing and improving proposed therapies. An international literature review in 2010 of 21 studies investigating the impact of multidisciplinary care on patient survival could not demonstrate a positive relationship between the two, largely due to significant heterogeneity in the definition of multidisciplinary care, but noted that 12 of the studies did report a statistically significant association between multidisciplinary care and patient survival [302]. Specifically for CRC, a single-centre study from China comparing outcomes before and after the introduction of an MDT concluded that MDT discussion was an independent variable associated with improved overall survival [303]. Similarly, a single-surgeon audit from the UK of cases before and after the implementation of an MDT meeting reported a significant association between MDT status and survival, as well as a prognostic indicator of chemotherapy prescription [304].

Where possible, all patients with newly diagnosed CRC should be discussed and managed in a formalized multidisciplinary setting, while nevertheless recognizing that hospitals and centres may have differing capacities for multidisciplinary care depending on location and resources. A good outline of the 'ideal' MDT system is provided in the NICE guidelines.

Multidisciplinary management of colon cancer in special groups

Elderly patients

The current consensus is that the management of older cancer patients needs to be multidisciplinary—and ideally involves a geriatrician, where possible, as well as the patient's community doctor. A formalized comprehensive geriatric assessment is ideal, but may be resource intensive [305, 306]. Even without the resources to implement a comprehensive geriatric assessment, the role of social work, physiotherapy, and occupational therapy practitioners is clearly of value when assessing the ability of an older person to live well in the community. A decision about adjuvant chemotherapy must be made with this in mind, being aware that the balance between recurrence risk and quality of life is perhaps a more delicate one in the very old.

Young patients

Two to three percent of CRC is diagnosed in individuals less than 40 years of age. A diagnosis of any malignancy in a young person is associated with specific issues—in particular fertility and the possibility of a genetic cause or familial cancer. Concurrent illness such as inflammatory bowel disease, known to be associated with increased risk of CRC, may be present and need treatment, usually by a gastroenterologist. Concomitant immunosuppressive drugs used to treat inflammatory bowel disease may increase the risk of chemotherapy-associated myelosuppression. Additionally, many young people are working rather than retired at the time of diagnosis—thus the need for social work involvement with respect to the economic consequences of being away from the workplace during treatment. Disability-adjusted life years are rarely accounted for when considering the cost of CRC to the community, but are pertinent in this patient group.

There is ongoing dissent in the literature regarding whether young age at diagnosis is a poor prognostic factor itself in CRC. One American study utilizing a prospective clinical database concluded that patients under 40 did not have inferior DFS, but were more likely to have higher surgical lymph node yield and receive adjuvant chemotherapy; the authors postulated that more aggressive management may result in similar survival outcomes [307]. A UK retrospective review of young patients found that although no differences in survival overall was seen, younger patients had a higher rate of T4 disease and vascular invasion, both of which led to inferior outcomes [308]. A study from Scotland reported on ten-year survival outcomes for over 2000 patients, concluding that young age did not have an adverse impact on cancer-specific survival [309]. A Canadian retrospective study over 20 years, however, concluded that young patients with early-stage CRC had survival outcomes inferior to expectation [310]. Similarly, a Taiwanese study found inferior survival outcomes in young patients with CRC [311]. It may be stage at diagnosis rather than age itself that may contribute to what may appear to be worse overall outcomes in young patients with CRC.

Fertility may be affected by surgery, radiotherapy, and chemotherapy. While radiotherapy is generally not a consideration for early-stage colon cancer, chemotherapy in many cases will

be considered in particular in a young person where much is at stake. The implications of fluoropyrimidines on gonadal function are thought to be minimal; however, oxaliplatin may be moderately gonadotoxic [312, 313]. Pregnancy should be avoided during chemotherapy and for several months afterwards. In male patients who are considering having children, the option of sperm collection and storage prior to chemotherapy must be discussed. In female patients, there are several options to consider for oocyte or ovarian preservation [312–314]. Expedited referral to a fertility expert is essential if fertility preservation is desired in young women diagnosed with CRC. The timing of fertility preservation techniques must be balanced with the need to commence adjuvant chemotherapy ideally within six to eight weeks of surgery.

Role of allied health teams and lifestyle factors in multidisciplinary management

Nurse practitioner

With the advent of screening faecal occult blood tests, and the universal recognition that CRC screening reduces mortality from the disease, comes the ever-increasing need for endoscopists to perform diagnostic lower gastrointestinal endoscopy. To this end, nurse practitioners have been involved in some centres for several years [315, 316]. A more recent randomized controlled trial comparing screening colonoscopy performed by nurse practitioners (n = 50) or gastroenterologists (n = 100) found that the nurse practitioner group were as safe and accurate as the gastroenterologist group [317]. The use of nurse practitioners for this purpose has been advocated by many as a way of safely, efficiently, and effectively addressing the need for endoscopic services [318]. Nurse practitioners are also involved in follow-up clinics after CRC diagnosis in some centres, again addressing the demand for timely and appropriate follow-up methods given the high prevalence of survivors [319]. Since the advent of capecitabine, an oral 5-FU analogue, for the management of both early-stage and metastatic CRC, nurse-led hospital and home-based care has been shown to be effective in monitoring and delivering oral chemotherapy safely [320, 321].

Stomal therapist

Depending on the type of bowel surgery required, a temporary or permanent stoma may be necessary for individuals undergoing resection of colon or rectal cancer. A stoma may have significant adverse effects on patient quality of life and body image [322, 323], although an earlier Cochrane review did not conclude firmly that quality of life with a stoma was significantly inferior [324]. Where possible, preoperative assessment and education by a stomal therapist is ideal. A study across 12 colorectal surgical units in Spain showed that patients who did see a therapist preoperatively had significantly less stoma complications and anxiety than those who did not [325]. Ongoing physical and psychological support from a stomal therapist while a stoma is present is appropriate.

Dietetics

Weight loss is significantly associated with decreased survival in colon cancer. Conversely, obesity places a person at increased risk of not only developing CRC but also having inferior outcomes [326–332]. The role of a dietician in the management of early-stage colon cancer is important at three steps: the acute phase of perioperative care and surgical recovery, the medium-term phase during adjuvant chemotherapy treatment, and the longer-term phase of healthy eating to maintain a healthy weight range. In the metastatic setting, managing cancer-related cachexia also requires the expertise of a dietician.

To demonstrate a positive association between particular dietary constituents and cancer incidence requires large cohort studies over long periods of time, and definitive evidence may remain elusive. Meat consumption, in particular processed meats, has been associated with increased risk of colon cancer in one meta-analysis [331]. A high-fibre diet was shown to be protective in the EPIC prospective cohort study, involving over 510,000 people [332]. A prospective observational study of over 1000 patients enrolled in an adjuvant stage III colon cancer trial found that a Western-pattern diet was associated with higher recurrence and mortality compared with a prudent dietary pattern, as has low levels of vitamin D [333]. It is important to be aware of these and other similar studies, in order comprehensively to advise patients on strategies to reduce their risk of CRC development and recurrence.

Exercise

Exercise is protective against the development of colon cancer [334]. Greater levels of exercise both pre- and post-diagnosis of CRC have been positively associated with improved survival in several observational studies. The Melbourne Collaborative Cohort Study, involving over 41,000 Australians, found that of the 528 people diagnosed with CRC over the follow-up period, those who exercised regularly had significantly improved disease-specific survival, in particular for stage II–III cancers, where the HR for DFS was 0.49 (P = 0.01) [335]. This finding, if related to a new anti-cancer agent, would be practice-changing if confirmed in a prospective study, which is understandably difficult to achieve in an intervention such as exercise, although intervention trials are underway. Nevertheless, exercising more and maintaining a healthy body weight are most likely the two most influential lifestyle modifications an individual can address in order to reduce their lifetime risk of CRC; and at least in the case of exercise, to reduce the risk of recurrence and death from their disease.

An oncologist, surgeon, or family practitioner alone can only partly influence an individual's decision to address issues such as weight loss and exercise, Similarly to the anti-smoking message and campaign, a multidisciplinary approach will surely be required to help effect the increasing body of evidence regarding the adverse effects of obesity and lack of exercise in the risk of CRC and other malignancies. A team effort, including government and non-government as well as doctors, dieticians, physiotherapists, and exercise physiologists will be required. Importantly, strategies are needed for the purposes of prevention as well as post-diagnosis health and, as such, addressing these risk factors is a large-scale effort and extends well beyond the individual and into the realms of public health and health policy.

Surveillance and follow-up—a multidisciplinary pathway

The aim of surveillance after curative-intent treatment of early-stage colon cancer is to improve survival by detecting early (curable) recurrence or small-volume asymptomatic metastatic disease that may be amenable to curative-intent resection. Additionally, colonoscopic surveillance for precancerous adenomas and polyps can reduce the risk of a second primary malignancy developing. As the

majority of recurrences will recur within three to five years, this is when surveillance is most beneficial.

Several systematic reviews or meta-analyses, including a Cochrane review, have demonstrated significantly improved overall survival for patients who have more intensive post-surgical follow up for early-stage CRC, although, notably, not all randomized trials comparing 'intensive' with 'minimal' surveillance have shown a survival advantage for the 'intensive' arm [336–339]. Interestingly, the optimal methods or timings of surveillance investigations are not definitively established. A more recent systematic review of 15 studies comparing different surveillance programmes was inconclusive, largely due to the heterogeneity of surveillance programmes among studies, and recommended future randomized trials with larger sample sizes to help establish the best surveillance practices [340]. In fact, 'intensive' surveillance in one study may be akin to 'minimal' surveillance in another; hence, the difficulty when attempting to ascertain which practice is optimal. Several such trials are currently underway at the time of writing including the GILDA, FACS, and COLOFOL randomized studies.

As such, to date, clinical practice guidelines for optimal surveillance vary somewhat between countries. Surveillance generally includes clinical examination, colonoscopic surveillance, imaging (most commonly CT), and testing of serum carcino-embryonic antigen (CEA) [313]. FDG-PET imaging is currently not used as a surveillance tool, but rather when investigating suspected recurrence, for example in the setting of an increased CEA without CT changes. A randomized trial of 130 patients from France comparing PET with conventional surveillance found that recurrences were found after a shorter time in the PET group, and these were more frequently cured by surgery [341]. Another single-arm European surveillance study in 132 patients found that CT/PET had the highest sensitivity and specificity for detection of recurrence [342]. However, from a practical and financial perspective, PET is unlikely to be part of routine surveillance in most centres and is not currently recommended as part of evidence-based guidelines [343].

By nature of the methods of regular surveillance recommended, multidisciplinary involvement already exists in that surgeons and radiologists are involved; not uncommonly, a medical oncologist will also continue to follow the patient, especially if adjuvant chemotherapy has been administered. In some models of care, a family physician, general practitioner, or nurse specialist may assume a dominant role in overseeing patient follow-up [319, 344]; in others, this rests with the patient's primary specialist centre.

A number of guidelines are now available, each based on a literature review and expert opinion. It should be noted that these guidelines are for standard-risk patients; higher-risk patients such as those with a familial cancer syndrome or inflammatory bowel disease should have more frequent colonoscopic surveillance, again available using the various guidelines [345, 346–349].

Beyond the physical: the multidisciplinary approach to psychosocial sequelae and survivorship

The majority of patients diagnosed with early-stage colon cancer will survive the disease. Stage I and II disease have a 90% five-year survival rate and stage III up to 70% [350]. Even in metastatic disease, a small percentage of patients are alive years later due to the aggressive surgical management of oligometastatic disease and improved drug strategies. Overall, close to 65% of patients with CRC are considered 'cured' after five to ten years [351]. As such, there are tens of thousands of colon cancer survivors in the community, and this number is sure to increase given, firstly, advances in CRC screening and, secondly, improved survival outcomes for those diagnosed with the disease. However, the term 'management' should not extend only to the duration of adjuvant chemotherapy or the completion of recommended surveillance tests. Colonoscopies, serum CEA tests, and CT scans are only one (physical) component of the ongoing patient management after a diagnosis of colon cancer. To be diagnosed with any malignancy is understandably challenging for an individual and their family, and both symptom management and psychological support both during and after the diagnosis should be, in ideal circumstances, readily available. A systematic review of ten studies detailing long-term quality of life in CRC survivors (more than five years) concluded that overall quality of life was good, although depression scores were worse than the general population and ongoing bowel symptoms and cancer-related distress remained prominent [352]. A five-year prospective study of quality of life in CRC survivors found that although quality of life measures improved with increasing time from diagnosis, psychological distress measures remained static [353]. Ongoing healthcare provision for CRC survivors should continue to be addressed [354]. Aside from standard surveillance strategies, a more holistic approach to CRC survivorship should ideally address the role of diet, exercise, and maintaining a healthy body weight, as, in particular for exercise and body mass index, evidence indicates maintaining a healthy weight range and exercising regularly may reduce the risk of cancer recurrence or even second primary cancers [355, 356].

Conclusion

The management of early-stage colon cancer continues to evolve as science and medicine grow a deeper appreciation of not only the molecular, cellular, and genetic aspects of this disease, but also its effect on the individual, the family, the medical system, and society as a whole. Colorectal cancer will continue to be one of the most common malignancies in the developed world and increasingly in the developing world, and due to significant advances in screening, diagnosis, and management over the last several decades, there are increasing numbers of people surviving or living with the disease, rather than dying from it. These promising advances necessitate a multidisciplinary approach to CRC across the spectrum from prevention, through diagnosis and treatment, to palliative care. We need to encompass appreciation of the genetic makeup of a single cell from an individual's tumour, but also understand the impact of CRC from a global public health perspective, and everything in between these two extremes. Multidisciplinary management is the way forward in the optimal management of CRC.

Introduction to pancreatic cancer

Pancreatic cancer comprises several different exocrine and endocrine malignant diseases. The most common form is pancreatic adenocarcinoma, the tenth most common solid cancer in most of the Western countries [1], which is discussed in this chapter. The lifetime risk of developing such a disease is 1.5% with a mean age of diagnosis in the seventh decade [2]. Unfortunately, no specific symptoms of this disease exist. Typically patients present with unspecific abdominal discomfort, weight loss, and early satiety. More specific symptoms are painless jaundice and signs of endocrine or exocrine pancreatic insufficiency. Management of pancreatic cancer is complex and should best be performed by a multidisciplinary team. The individual components of such an approach are described in this chapter.

Epidemiology and risk factors

Pancreatic cancer is estimated to result in about 269,000 deaths per year worldwide (153,500 in developed countries) [3]. Incidence rates only slightly exceed the mortality rates of the disease (48,960 estimated new cases versus 40,560 deaths in the USA in 2015) which reflects the poor prognosis of pancreatic cancer, resulting in an overall five-year survival rate of 4-6% [4]. In the USA, pancreatic cancer represents the fourth leading cause of cancer-related death for women and men, affecting the latter slightly more often [4]. Since the 1970s, in the US population there have been no significant trend changes in the death rate of pancreatic cancer [4]. Pancreatic cancer typically affects patients in their later adult life, most frequently occurring in their seventh and eight decades [5]. Unlike other pancreatic neoplasms, it is exceptionally rare before the age of 40 years [5, 6]. Globally increased lifespan, especially in Asian countries, are likely to result in higher absolute numbers of pancreatic cancer [7].

Pancreatic cancer usually arises sporadically. Nevertheless, a hereditary etiology of pancreatic cancer has been estimated for about 10% of patients [8]. Autosomal dominant hereditary syndromes associated with pancreatic cancer include, among others, hereditary pancreatitis (PRSS1, SPINK1 genes; cumulative risk of 25–70%), familial atypical multiple mole melanoma syndrome (CDKN2A; risk 13–17%), hereditary breast and ovarian cancer syndrome (BRCA2, PALB2, BRCA1; risk 1.2–6.9%), Peutz–Jeghers syndrome (STK11/LKB1; risk 5–36%), and hereditary non-polyposis colorectal cancer syndrome (MLH1, MLH2, MSH6 etc; risk 3.7%) [8]. Furthermore, a familial pancreatic cancer syndrome has been described, whose underlying genetic alterations are yet to be defined [9].

Beyond hereditary syndromes and family history, smoking has been identified as a dominant risk factor for pancreatic cancer. Cigarette smoking has been reported to double the risk and account for 20% to 25% of pancreatic cancers [7, 10]. Although the smoking–carcinoma linkage seems to be less pronounced than in lung cancer, pancreatic cancers from smokers were shown to harbour more mutations than those from non-smokers [10]. Further risk factors for pancreatic cancer include chronic pancreatitis for more than five years, long-term diabetes mellitus type 2, obesity, and high caloric intake, and a non-0-bloodgroup [7].

Molecular biology

Knowledge of the molecular changes and pathways involved in tumorigenesis is essential for exploration of new methods of detection, diagnosis, and treatment of cancer in pancreatic ductal adenocarcinoma, which has one of the poorest survival rates of all carcinomas.

While there are fundamental similarities in the series of molecular events required for the development of cancer, some cancer types have specific profiles [11]. This section will discuss the series of events that led to the development of pancreatic ductal adenocarcinoma, the pathways that are involved in proliferation and the complex interaction between the tumour cells and the surrounding stroma (desmoplastic reaction) that characterizes this killer disease (see Figure 40.1).

Profile of genetic disruption

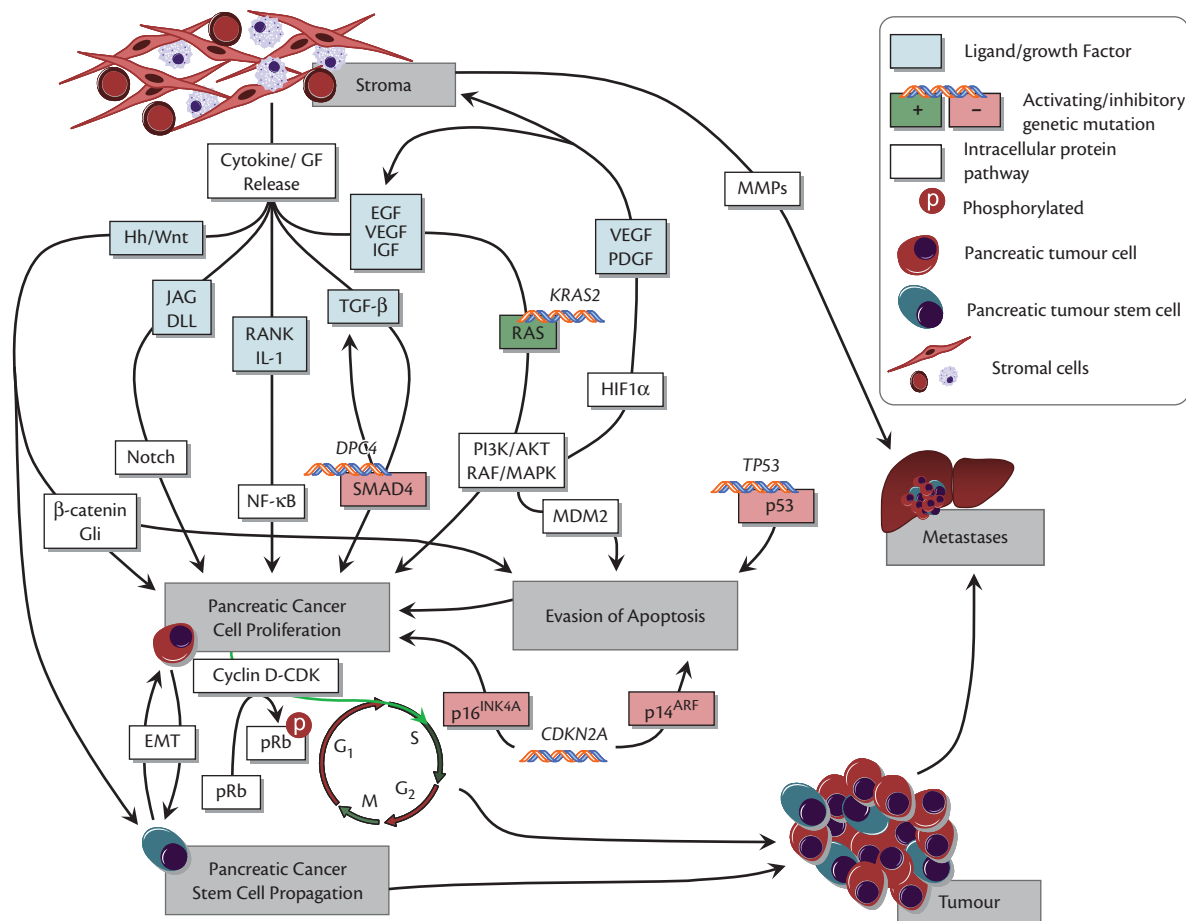
Whole genomic analysis of pancreatic cancer tissue has revealed the genetic alteration of 12 core pathways in the majority of cases,


Fig. 40.1 A summary of the key pathways involved in the development of pancreatic adenocarcinoma and their interaction with surrounding stroma. Signature lesions, such as KRAS2, TP53, CDKN2A, and DPC4 mutations result in uncontrolled cellular proliferation and upregulation of cytokines. The cytokines stimulate stroma and lead to the activation of other paracrine signalling pathways (Hh, Notch, Wnt, and NF-κB) that further propagate cellular proliferation, epithelial-to-mesenchymal transition (EMT) and tumour cells capable of metastatic dissemination.

although the specific genes involved vary widely [6]. Order can be brought to this complex disease process by focusing on the following key signature pathways that are almost universally disrupted [12], rather than the many individual mutations that alter their normal signal transduction:

◆ Regulation of G1/S phase transition (KRAS and p16^{INK4A}).

◆ Apoptosis and DNA damage control (p53 and p14^{ARF}).

◆ TGF-β signalling (SMAD proteins).

◆ Cellular organization pathways (Hedgehog, Notch, Wnt and NF-κB).

Next-generation sequencing of metastatic disease has revealed the genomic instability present during pancreatic cancer development persists following dissemination, resulting in metastatic colonies that are genetically distinct from the original tumour [13]. Detailed analysis of primary and metastatic tumours from the same patient has demonstrated that the majority of mutations are present in all metastases, suggesting they are early events that occurred before the tumour spread [14]. Mutations found only in metastases may indicate the events required tumour cells to become capable of dissemination and seeding a distant site [12, 13].

Precursor lesions

There is evidence that pancreatic intraepithelial neoplasia (PanIN), intraductal papillary mucinous neoplasms (IPMNs) and mucinous cystic neoplasm (MCNs) can lead to the development of pancreatic ductal adenocarcinoma. PanINs are the most common lesions believed to precede development of pancreatic adenocarcinoma [10]. They are classified under histological examination by the extent and type of hyperplasia present as: PanIN-1(A/B), PanIN-2, and finally PanIN-3, which represents carcinoma in situ [15]. Quantification of the genetic mutations present in these lesions has indicated a series of events that lead to the development of pancreatic cancer. Activating *KRAS* mutations are found in all forms of PanIN lesion and even some benign pancreatic cells, suggesting that this defect alone is not sufficient for tumorigenesis. Further mutations and progressive shortening of telomeres occur with increasing PanIN grade: inactivation of *CDKN2A* is observed from PanIN-2 onwards and alterations in the *TP53* gene in PanIN-3 lesions. Finally, mutations of the *DPC4* gene resulting in inactivation of the SMAD4 protein are associated with invasive carcinoma and correlate with poor prognosis.

Similarly to PanINs, KRAS activation is an early event in IPMN and MCN and is associated with dysplasia; inactivation of CDKN2A

is also important early in IPMN. Likewise, *TP53* and *DPC4* are seen later in IPMN and in invasive carcinoma from MCN [16].

Telomere shortening

Telomeres are regions of repetitive nucleotide sequences, present at the ends of chromosomes. They act as a mitotic counter by shortening naturally with each cell division due to an inability of duplication enzymes to reach the end of the chromosome. It is thought that this progressive shortening plays an anticancer role by eventually inducing cellular senescence [17].

Telomeric shortening is one of the earliest events seen in the development of pancreatic ductal adenocarcinoma and is demonstrated in 90% of PanIN lesions. Shortening of telomeres may predispose these cells to genetic instability and therefore the mutations necessary for tumorigenesis [15]. To avoid entering senescence and to promote the capacity for continuous division, a cancer cell must develop the ability to maintain telomeric length, either through expression of telomerase reverse transcriptase (hTERT) or through alternative lengthening of telomeres (ALT) [18]. The former is seen in 85–90% of pancreatic tumours [19].

KRAS

Growth signalling pathways ultimately exert their effect on the tumour suppressor, retinoblastoma protein (pRb) that controls the release of E2F transcription factors and thereby the transition from G1 into S phase and cellular proliferation. The RAS family of proteins are early upstream proteins that exist in an inactive form bound to guanosine diphosphate (GDP) and an activated guanosine triphosphate (GTP)-bound complex that initiates two cellular proliferation pathways: RAF/MEK/ERK and PI3K/AKT/mTOR [6].

In pancreatic cancer, mutation of the *KRAS2* gene is found in >90% of cases. This gene is located on chromosome 12p and encodes for Kirsten rat sarcoma protein (KRAS). The mutations are most commonly point mutations of codons 12, 13, or 61 and inhibit the hydrolyzing effect of GTPase, resulting in a persistently activated KRAS protein and cellular proliferation [8]. Initiation of the RAF/MEK/ERK pathway results in G1 to S-phase transition by phosphorylation of pRb. Activation of the PI3K/AKT/mTOR pathway inhibits GSK-3, which stabilizes Cyclin D assembly with CDK 4/6 and allows cellular proliferation. Evasion of apoptosis is the result of p53 inhibition via activation of the murine double minute protein (Mdm2).

TP53

The TP53 gene located on chromosome 17 codes for the tumour suppressor protein p53, which acts as a molecular check for DNA damage and, if detected, forces the cell into senescence or apoptosis. Under normal conditions, p53 levels are kept low by Mdm2, which acts in two ways: the first is to transport p53 from the nucleus into the cytosol and the second is the ubiquitination of p53, thus marking it for proteasome degradation [20]. Mdm2 is inhibited under conditions of cellular stress, such as DNA damage or oncogenic activation, and p53 levels increase, resulting in cell cycle arrest and initiation of apoptosis or cellular senescence. *TP53* is found to be mutated in 50–75% of tumours resulting in cells that are susceptible to further genomic instability as DNA damage-control checks are bypassed and apoptosis evaded [8].

CDKN2A

The CDKN2A gene is located on chromosome 9p and codes for two protein products: p16^{INK4A} and p14^{ARF}. Normally, p16^{INK4A} inhibits CDK4/6, preventing formation of a complex with Cyclin D complex and subsequent phosphorylation of pRb, thus impeding cell cycle progression. In pancreatic cancer, *CDKN2A* is subject to a hypermethylation event in >95% of cases and results in an inactive form of p16^{INK4A} that allows pRb phosphorylation and consequently cellular proliferation [8].

The protein, p14^{ARF}, is an alternate reading frame product of CDKN2A that is transcribed in response to overexpression of oncogenes (e.g., *RAS* or *MYC*) and blocks the degradation of p53 by Mdm2. Dysfunctional p14ARF protein therefore promotes evasion of apoptosis by reducing p53 levels in the nucleus [21].

DPC4

Transforming growth factor-β (TGF-β) binds to type II tyrosine kinase receptors that recruit and phosphorylate type I receptors thereby initiating the Smad signalling pathway. Smad2/3 form a complex with Smad4 and translocate to the nucleus where transcription of genes coding for the CDK inhibitors p15, p21, and p27 occurs, thus preventing progression into S phase [22].

SMAD4 stands for deleted in the pancreatic cancer 4 (*DPC4*) gene located on chromosome 18q and is inactivated in 55% of pancreatic cancers by either homozygous deletion or intragenic mutation [8, 23]. This leads to loss of TGF-β signal transduction, and loss of one of the pathways controlling Cyclin D-CDK4/6 complex formation and cellular proliferation.

Stroma and growth factors

Stroma is the 'scaffold' that surrounds tumour cells and is comprised of cells of three distinct groups: mesenchymal cells, including fibroblasts, myofibroblasts and pancreatic stellate cells that secrete components of extracellular matrix (ECM) such as collagen; immune cells, such as cancer-associated macrophages, lymphocytes, mast cells, and neutrophils that respond to inflammatory cytokines such is IL1/6; and finally, endothelial cells that form the vasculature and lymphatics and respond to growth factors expressed by tumour cells. Stromal cells interact with tumour cells through growth factors and developmental signalling pathways that form a complex paracrine loop that stimulates tumour proliferation and invasion [3].

Growth factors are often over-expressed in cancers as they play an important role in cellular proliferation and evasion of apoptosis. Increased sensitivity to growth factors can be as a result of up-regulation by tumour cells of the factors themselves or their receptors. More recently, it been demonstrated that the surrounding stroma plays an important role through complex paracrine interaction with the tumour mediated in part by growth factors [24].

Epidermal growth factor receptor (EGFR or HER1) is a member of the ErbB family of tyrosine kinase receptors of which EGFR, ErbB2, and ErbB3 are over-expressed in pancreatic cancer [25]. Up-regulation of *EGFR* is seen in 70% of pancreatic cancer cases with two principal binding ligands that are similarly over-expressed: epidermal growth factor (EGF) and transforming growth factor-α (TGF-α) [20]. On binding of EGF or TGF-α to the extracellular domain, phosphorylation of the receptor occurs providing a binding site for an SOS/GRB2/SHC protein complex that triggers exchange of GDP for GTP on RAS proteins and subsequent activation of RAF/MAPK and PI3K/AKT pathways [26].

Vascular endothelial growth factor (VEGF) is an angiogenesis-inducing agent that is expressed in response to hypoxic stimuli or oncogenic signalling [9]. As the tissue environment of

pancreatic cancer is typically hypovascular, up-regulation of VEGF is found in 90% of pancreatic cancers [7]. In addition, VEGF binds to VEGF receptors (VEGFR1–3) on the surface of the tumour cell, promoting cell growth and survival through induction of RAF/MEK and PI3K/AKT pathways [26]. Hypoxia-inducible factor 1α (HIF-1α) expression is induced by both the PI3K/AKT and RAF/MEK pathways, which in turn stimulates further VEGF expression [27].

Insulin-like growth factor receptor 1 (IGF1R) is a further tyrosine kinase receptor that acts via insulin receptor substrate (IRS) proteins to recruit PI3K to the cellular membrane, resulting in the phosphorylation of PIP2 and initiation of the PI3K/AKT pathway [4]. IGF1R is overexpressed in up to 60% of pancreatic cancers [28]. These receptors are activated by the insulin-like growth factor protein (IGF), which is likewise elevated in pancreatic cancer [29].

Platelet-derived growth factor (PDGF) has been implicated in many pathways that signal for tumour growth, angiogenesis, invasion, and metastasis. Although this is not completely understood, upstream regulators of PDGF secretion include urokinase plasminogen activator (uPA), interleukin-1β (IL1β), and reactive oxygen species (ROS) such as hydrogen peroxide [30]. Up-regulation of PDGF acts to drive tumour cell proliferation via pathways including RAS (PI3K/AKT and RAF/ERK), NFκB and Notch. More importantly, associations have been made with matric metalloproteinases (MMPs), enzymes that are capable of degrading basement membranes and ECM, a process thought to be crucial in the development of metastatic spread [31].

EMT, stem cells, and signalling pathways

Epithelial-to-mesenchymal transition (EMT) describes the process whereby tumour cells lose their epithelial characteristics and acquire invasive stem cell-like features that expand their ability for local invasion and metastases. These changes have even been described in PanIN-2 and -3 lesions in mice, challenging the classical model that metastases occur late in development of cancer. Genetic mutation that enables cells to invade and seed distant sites was previously considered a late event [32, 33].

Pancreatic stem cells (PSCs) account for 0.2–0.8% of pancreatic tumour cell population and exhibit up to a 100-fold increase in tumorigenic potential [34]. Additionally, they possess properties such as self-renewal, ability to produce differentiated progeny, and up-regulation of the embryonic signalling molecule sonic hedgehog, which that are usually associated with typical stem cells [35]. They could, however, offer new treatment opportunities as depleting the PSCs in a tumour can almost entirely deplete the metastatic potential of a tumour in a mouse xenograft model [36].

Notch

Notch is an important cell-to-cell developmental signalling pathway that is inappropriately activated in pancreatic cancer and leads to tumour initiation and progression [37]. In the normal adult pancreas, Notch signalling is largely inactive, although reactivation has been observed following pancreatic injury, such as in pancreatitis, and is thought to be involved in cellular regeneration [38]. Notch signalling occurs through binding of five known ligands (delta-like—DLL1/3/4 or jagged—JAG1/2) to Notch receptors (NOTCH1-4) and results in a series of proteolytic steps that release the Notch receptor intracellular domain (NICD). Following translocation to the nucleus, the NICD initiates a transcriptional

cascade that includes the oncogenes *CCND1* (Cyclin D), *MYC*, and *BCL-2* [39].

Inappropriate activation of the Notch pathway in pancreatic cancer is thought to occur via growth factor signalling, such as TGF-α, and therefore stromal cells are likely to play in important role [40]. It has been shown that Notch signalling is involved in both acinar-to-ductal metaplasia, thought to occur early in development of pancreatic adenocarcinoma, and epithelial-to-mesenchymal transition, leading to cells with the ability invade surrounding tissue and metastasize [40, 41].

Hedgehog

Hedgehog (Hh) is an embryonic signalling pathway that is employed in the gastrointestinal tract for normal organ development. Three subgroups of Hh ligands (sonic, Indian, and desert) combine with two transmembrane receptors, patched (PTCH) and smoothened (SMO), to direct cellular development via the glioma-associated oncogene homologue (GLI) family of proteins [35]. In the majority of adult tissues the pathway is inactivated by the absence of ligand, allowing inhibition of SMO through the binding of PTCH, although it remains important in the proliferation of adult stem cells, such as the haematopoetic system [42].

Although inactivating mutations of the PTCH receptor occur, it is ligand over-expression that is thought to be the major contributor to the abnormal Hh signalling that is implicated in initiation and growth of the pancreatic tumours [35]. Abnormal Hh ligand expression is seen in approximately 75% of pancreatic cancers and is thought to be an early event as it has been detected in PanIN lesions [43]. The contribution of stromal cells that secrete growth factors in response to increased Hh ligand, initiating RAS-mediated tumour cell proliferation also appears important [44]. Finally, aberrant Hh signalling is thought to be essential for the proliferation of pancreatic cancer stem cells, as blockade of the Hh pathway eliminates these cells and prolongs survival in mice [45].

Wnt-β-catenin

Wnt-β-catenin signalling is another developmental pathway involved in the proliferation and differentiation of several organs. Wnt ligands bind to Frizzled receptors and trigger the release of intracellular Dishevelled (Dvl) protein that blocks the degradation of β-catenin by a complex comprised of adenomatous polyposis coli (APC), Axin, and GSK-3β proteins [35]. B-catenin accumulates in the nucleus as a result and activates target genes through the transcription factors of the TCF/LEF family, thus driving proliferation.

The role of Wnt-β-catenin remains contentious in pancreatic cancer as, although accumulation of β-catenin has been demonstrated, genetic lesions affecting the proteins involved in β-catenin signalling are rare [35]. Although the exact mechanism of β-catenin accumulation is currently unknown, increasing levels of β-catenin correlate with PanIN grade, and inhibition of β-catenin moderates proliferation and prompts apoptosis in pancreatic cancer cells [46, 47].

NF-κB

The nuclear factor of κ-light-chain-enhancer of activated B cells (NF-κB) protein complex controls transcription factors that are rapidly activated in by harmful cellular stimuli and play an important role in the cellular response to inflammation. The principal components are the receptor activator of nuclear factor κB (RANK), a type of tumour necrosis factor receptor (TNFR), and the interleukin 1

receptor (IL1R). Upon binding of their respective ligands (RANKL/IL1), receptor activation is mediated via TNF receptor associated factor (TRAF) proteins that activate IκB kinase (IKK) enzymes and release NFκB from inhibitor of κB proteins (IκB). Nuclear gene transcription then occurs, resulting in cellular proliferation, and protects the cell from apoptosis.

In 95% of pancreatic cancer, this pathway is activated in either of two ways. The first is in an autocrine loop instigated by KRAS, causing direct activation of IKK via the PI3K/AKT pathway and production of the transcription factor activator protein 1 (AP-1), which is responsible for transcription of several cytokines, including IL1 [8, 48]. The second is paracrine activation of RANK and IL1R by cytokines, such as TNF-α, which is synthesized by stromal cells, such as macrophages and emphasizes the importance of the desmoplasia that characterizes pancreatic cancer [49].

Pathology

Gross findings

The term 'pancreatic cancer' comprises a number of various malignant epithelial pancreatic neoplasms. Most commonly, however, it refers to pancreatic ductal adenocarcinoma, which will be the focus of this chapter. Pancreatic cancer most frequently arises in the pancreatic head (60–70% of cases), where it is typically located in the superior part between the bile duct and the main pancreatic duct. Of tumours 5–15% arise in the body, 10–15% in the tail, and 5–15% affect the entire gland [50]. In rare instances, pancreatic cancer has been reported to arise from ectopic pancreas [51]. On the cut surface, pancreatic cancer characteristically imposes as firm, solid, white-yellow mass with ill-defined borders. The lobulated architecture of the pancreas is lost within most tumours. Necrosis is not typical but may occur, as well as areas of small cystic transformation, the latter frequently displaying obstructed, dilated non-neoplastic pancreatic ducts. In resected specimens, tumours show a median size of approximately 3 cm (1.5–5 cm), and the vast majority display infiltration of the peripancreatic fatty tissue [51, 52]. When located in the pancreatic head, tumours frequently infiltrate the duodenal wall and the intrapancreatic bile duct. Furthermore, infiltration of the portal vein and the stomach are common, the latter especially when tumours arise from the pancreatic body or tail. Small tumours that are restricted to the pancreas are rare and typically represent incidental findings in specimens of chronic pancreatitis, or areas of invasive cancer within larger cystic pancreatic neoplasms such as intraductal papillary mucinous neoplasms or mucinous cystic neoplasms [52].

Microscopic findings

See Figure 40.2. The majority of pancreatic cancers are well to moderately differentiated and consist of glandular and duct-like epithelial formations that are embedded in a usually abundant desmoplastic stroma [51]. As summarized in Table 40.1, grading is based on histological and cytological criteria, such as the mucin production and nuclear features, and the mitotic activity. Well-differentiated carcinomas display glandular and duct-like formations of neoplastic epithelia that are typically well formed and of angular or irregular shape. They consist of cuboidal to columnar mucinous cells with little polymorphism. The cytoplasm is eosinophilic but may also be pale or with a clear cell appearance. Mitoses are rare [51]. Moderately differentiated carcinomas resemble well-differentiated tumours; however, the growth pattern and the cytology are more variable. Thus, moderately differentiated carcinomas consist of medium-sized duct-like structures and small tubular glands of variable size and shape, including incompletely formed glands and cribriform patterns. The tumour cells show a moderate polymorphism; nucleoli may be prominent. The mitotic rate is increased. The cytoplasm is usually eosinophilic, but a clear cell aspect may occur [51]. In poorly differentiated pancreatic cancer, the tumours display densely packed, small irregular glands, solid sheets and nests, and isolated tumour cells [51]. There is a marked nuclear pleomorphism and high mitotic activity [51]. In contrast to well and moderately differentiated ductal adenocarcinomas, poorly differentiated tumours frequently show only little or no desmoplastic stroma, which may cause difficulties in the gross detection of the masses. In case of intratumoural heterogeneity, the highest tumour grade must be reported, even if only present in a minor fraction of the neoplasm [51].

Distinction of pancreatic cancer from non-neoplastic ducts may be difficult in the setting of chronic pancreatitis. As a rule, neoplastic glands display an irregular, haphazard architecture while a lobular architecture is maintained in chronic pancreatitis. On the cellular level, even well-differentiated adenocarcinomas display some loss of polarity, the nuclei of neoplastic cells are greater than in non-neoplastic ducts, and there is some variation in size. Close proximity of ductal structures to muscular vessels suggests the diagnosis of pancreatic cancer [50].

Immunhistochemical and molecular markers

Pancreatic cancer shows immunoreactivity for keratins 7, 8, 18, 19, and less frequently keratin 20 [52, 53]. CEA, B72.3, CA125, CA19-9, MUC1, MUC3, MUC4, and MUC5AC usually stain positive, in contrast to MUC2 [51]. Pancreatic cancer may contain scattered synaptophysin and chromogranin A-positive neuroendocrine cells [51]. Their immunohistochemical profile discriminates pancreatic ductal adenocarcinoma from other exocrine and neuroendocrine pancreatic neoplasms. However, distinction from non-neoplastic ducts or bile duct cancer is not possible based on immunohistochemistry alone.

Several other molecular markers, such as Smad4 or p53 may be assessed immunohistochemically, as discussed in detail in the chapter on 'Molecular Biology' .

Tumour spread

Pancreatic cancer is a highly aggressive neoplasm that typically shows extensive local spread at the time of the clinical diagnosis. Depending on the tumour location within the pancreas, this may include, among others, infiltration of the peripancreatic fatty tissue, the duodenal wall, mesenteric vessels, the stomach, the spleen, the mesentery and peritoneum, as well as the large bowel. Besides direct infiltrative growth of the tumour cells, the infiltration of nerves may significantly contribute to the local spread, showing intense tumour-nerve interactions [55]. Further common findings are infiltration of blood vessels and lymphatics, and about 75% of resected pancreatic cancers reveal lymph node metastases [52]. Distant metastases most frequently affect the liver, as well as the peritoneum, lung, bones, and adrenals [51, 56].

The staging of pancreatic cancer considers size and extent of the tumours for the local stage [57, 58]. A full explanation of the TNM staging for pancreatic cancer can be accessed at the website of the American Cancer Society [59]
Fig. 40.2 Microscopic findings of: (A) well-differentiated pancreatic ductal adenocarcinoma; (B) moderately differentiated pancreatic ductal adenocarcinoma with perineural invasion; (C) poorly differentiated pancreatic ductal adenocarcinoma; (D) adenosquamous carcinoma showing ductal and solid, squamous differentiation; (E) anaplastic carcinoma with osteoclast-like giant cells (right bottom); (F) noncystic mucinous adenocarcinoma; (G) acinar cell carcinoma; (H) neuroendocrine tumor; (I) solid-pseudopapillary neoplasm with regressive changes; (J) pancreatic intraepithelial neoplasia grade 1; (K) intraductal-papillary mucinous neoplasm with heterogeneous grade of dysplasia; (L) mucinous cystic neoplasm with ovarian-type stoma and low-grade dysplasia.

Table 40.1 Grading of pancreatic ductal adenocarcinoma

Grade	Glandular differentiation	Mucin production	Mitoses (per 10 HPF)	Nuclear features
G1	Well-differentiated	intensive	5	Little pleomorphism, polar arrangement
G2	Moderately differentiated duct-like and tubular structures	irregular	6–10	Moderate polymorphism
G3	Poorly differentiated glands, abortive mucoepidermoid and pleomorphic structures	abortive	<10	Marked polymorphism, increased size

Abbreviation: HPF, high power fileld.

Remarkably, the T4 stage is defined by infiltration of the celiac axis or the superior mesenteric artery, which usually implements inoperability of the patients. The regional lymph node status should be determined on examination of at least ten lymph nodes [57].

Prognosis and predictive factors

Inoperable tumours, which make up about 90% of cases, result in median survival times of three to five months [51]. In resected pancreatic cancer the median survival is ten to 20 months, with five-year-survival of 15–25% [51]. Prognostic factors, identified in larger series of resected pancreatic cancer, include the TNM system, resection status, grade, age, preoperative insulin-dependant diabetes mellitus, CA19-9 levels, and a stratification of risk factors leads to an improved survival prognostication [52, 60]. Concerning R status, a revised R0-classification, defined by tumour-free distance of 1 mm to the margins, has been shown significantly to improve the prognostic value [52]. Therefore, resected specimens should be examined systematically, considering the transection margins of the pancreas, bile duct, duodenum/stomach, resected large vessels, and the peripancreatic margins, inked for topographic orientation [61, 62].

Precursor lesions

PanIN are morphologically well-characterized precursor lesions of pancreatic cancer [63]. It has been suggested that PanIN originate from the centroacinar compartment [64, 65]. Paralleling an increase of dysplasia grade (PanIN 1A/B, 2, 3) they accumulate mutations, epigenetic changes, and microRNA phenoytpes that are typical for pancreatic cancer [63, 66]. The evolution from PanIN lesions to invasive pancreatic cancer could also be reproduced in genetically engineered mice [63]. The frequency of PanIN lesions increases with age and in chronic pancreatitis [63]. As especially low-grade PanIN lesions are by far more frequently detected than pancreatic cancer and may already be seen in children, a 1% probability of a single PanIN lesion progressing to invasive cancer has been estimated [67]. More recently, flat atypical lesions have been reported as precursor lesions in animal models and some human pancreatic cancer kindreds with a strong family history [68]. Furthermore, lobulocentric atrophy with associated PanIN was reported to accumulate in pancreatic cancer patients with familial predisposition [51].

Cystic neoplasms, intraductal papillary mucinous neoplasm and mucinous cystic neoplasms, may progress to pancreatic cancer (Table 40.2).

Variants of pancreatic ductal adenocarcinoma

Pancreatic ductal adenocarcinoma may contain substantial areas of mixed squamous, neuroendocrine and/or acinar differentiation. Non-cystic mucinous carcinomas are characterized by extensive mucin production. Rarely, tumours contain signet ring cells [50]. Anaplastic carcinomas which may lose their epithelial and gain mesenchymal characteristics were shown to evolve from PanIN and conventional ductal adenocarcinoma [69]. Although they are highly aggressive neoplasms, long-term survivors were observed in cases containing osteoclast-like giant cells [70]. Medullary and hepatoid carcinomas are exceedingly rare.

Pancreatic cancer other than pancreatic ductal adenocarcinoma

Besides pancreatic ductal adenocarcinoma and its variants, various neuroendocrine and exocrine malignancies arise from the pancreas (Table 40.3). Acinar cell carcinomas typically show acinar, solid, or trabecular growth patterns, express acinar markers (e.g., trypsin) and lack a marked desmoplastic stroma [50, 41]. They metastasize early to lymph nodes and/or liver. The overall five-year survival rate is poor (6%), but it has been suggested that patients with limited metastatic disease may benefit from surgery [71]. In addition to an epithelial component resembling acinar cell carcinoma, pancreatoblastomas contain squamoid bodies and eventually neuroendocrine or primitive-appearing small cell areas [51]. The overall survival is 50%, with a highly unfavourable outcome in non-resectable patients [51]. Solid pseudopapillary neoplasms display solid-appearing cell-rich areas containing thick-walled capillaries. Degenerative changes result in cystic changes with pseudopapillary aspect. These low-grade malignant neoplasms predominantly affect young females and have a good prognosis even in cases with liver metastasis [50, 51]. A centroacinar origin of these tumours has been suggested. Neuroendocrine tumours/carcinomas express neuroendocrine markers (Chromogranin A, Synaptophysin) and show similar growth patterns to acinar cell carcinomas [50]. Proliferation activity (mitotic count, Ki67) is essential for tumour classification [51]. In serous cystic neoplasms, malignancy, as defined by metastases, is exceedingly rare [51].

Role of frozen section

Frozen section is primarily useful to examine the pancreatic transection margin. While there is general agreement that this should be free of invasive cancer, the significance of PanIN in the transection

Table 40.2 Intraductal papillary mucinous neoplasms and mucinous cystic neoplasms

Macroscopy	Histology/immunohistochemistry	Comment
Intraductal papillary mucinous neoplasm		
Cystic tumours involving main duct and/or branch ducts, filled with mucin	Mucinous epithelium with low-, intermediate- or high-grade dysplasia or invasive cancer (ductal or colloid phenotype) Gastric (MUC5AC), intestinal (MUC2, MUC5AC), pancreatobiliary (MUC1, MUC5AC, MUC6), and oncocytic (MUC1, MUC6) types	Marked heterogeneity within tumours may require complete sampling
Mucinous cystic neoplasm		
Uni-or multilocular cystic tumours without duct association (>95% tail)	Mucinous epithelium with low, intermediate, or high-grade dysplasia or invasive cancer (ductal or anaplastic phenotype). Ovarian-type stroma. Cytokeratins 7, 8, 18, 19, MUC5AC	Strong preponderance for women

margin is debated, and it has been suggested that even the presence of PanIN 3 in the transection margin does not influence the survival of pancreatic cancer patients [72]. Secondly, preoperatively unclear masses and cystic lesions can be diagnosed by frozen sections, helping to plan the extent of operations.

Surgical management of pancreatic adenocarcinoma

In resectable pancreatic adenocarcinoma, surgery remains the cornerstone of therapy; advances in applied surgical technique have led to a decrease of perioperative mortality from more than 30% decades ago to less than 5% in high-volume centres today [73–75]. Unfortunately, about 80% of patients present with an advanced often metastasized disease with surgery not being the primary treatment option [75, 76].

Treatment algorithm

Once a pancreatic malignancy is suspected, patients should be thoroughly examined following standardized algorithms and categorized into one of the three treatment groups described below (see also 'Definitions of resectability') [74, 77, 78]. As a volume–outcome relationship has been confirmed in studies, patients should be offered referral to high-volume centres for further management [79, 80]. The main question that needs to be answered is whether the primary tumour is resectable. It is well known that experienced surgeons will judge cancers as resectable, even with advanced disease and vessel infiltration, which would otherwise be denied the possibility of surgery [81–83].

Pancreatic cancers can be categorized into localized and systemically metastasized disease. The group of patients presenting with systemic disease is treated with systemic chemotherapy, palliative surgery, endoscopic intervention, and best supportive care [77].

Patients in the localized pancreatic cancer group should be divided into resectable, borderline-resectable, and unresectable cases. Treatment will follow a standardized algorithm; patients with resectable tumours will undergo exploration laparotomy and resection of the tumour with the goal of R0 status with curative intent. In case of a borderline-resectable cancer, neoadjuvant therapy should be contemplated. However, some surgeons still opt for a primary surgical approach, as preoperative assessment of resectability is still not optimal and the term 'borderline-resectable' is defined differently among surgeons, despite efforts to standardize these definitions (see 'Definitions of resectability'). Patients primarily categorized as locally unresectable should undergo neoadjuvant (radio)chemotherapy for local downsizing followed by laparotomy with the goal of curative R0 resection [77, 78].

If the intraoperative judgement is that an R0 resection is not possible and/or systemic disease exists (distant metastases, peritoneal seeding), palliation surgery may be performed in the same session, for example by a double bypass (gastro-enterostomy and bilodigestive anastomosis).

Preoperative workup

The standardized preoperative workup always involves an interdisciplinary team approach of a team familiar with routine treatment of this disease. Members of this expert team include surgical oncologists and/or pancreatic surgeons, radiologists, medical oncologists, radiation oncologists, and endoscopy experts [77, 78, 84].

A standardized workup consists of abdominal ultrasound and CT scan according to special pancreas protocols. Pancreas protocol MRI might evolve as an alternative for selected patients. Endoscopic ultrasound (EUS) is optional. The role of PET/CT remains uncertain outside of clinical trials. Histological confirmation of pancreatic adenocarcinoma is contraindicated in patients with resectable and borderline resectable disease if primary surgical resection is planned, due to prolonged waiting time for surgery and risk of tumour cell dissemination and the missing of a therapeutic consequence [77]. However, histological confirmation of pancreatic adenocarcinoma, preferably via EUS-guided fine needle aspiration (FNA), is mandatory before induction of neoadjuvant or palliative treatment options.

Definitions of resectability

The group of patients with locally confined disease can be further divided into resectable, borderline-resectable, and non-resectable cases (see also 'Multidisciplinary management of complex cases'). According to current consensus on definitions, these are defined as follows [77, 85].

Resectable

- Tumours recognized as being locally resectable will present without any signs of distant metastases (including para-aortic lymph node metastases).

- Resectable tumours have no signs of superior mesenteric vein (SMV) or portal vein infiltration, no tumour thrombus, and no venous encasement.

- Resectable tumours have no signs of arterial involvement (clear planes around the superior mesenteric artery (SMA), the celiac trunk and the hepatic artery.

Borderline resectable

- Borderline resectable tumours present without any signs of distant metastases (including para-aortic lymph node metastases).

- Borderline resectable tumours may present with portal vein/ SMV involvement, including impingement, narrowing of the lumen, encasement, occlusion, tumour thrombus, infiltration. Venous involvement has to be with sufficient clear venous vessel allowing for safe venous resection and reconstruction.

- Borderline resectable tumours may present with gastroduodenal artery encasement up to the hepatic artery (including short segment encasement of the hepatic artery), but without any involvement of the celiac trunk.

- Borderline resectable tumours may have tumour abutment of the SMA not exceeding involvement of 180 degree of the vessel wall.

Unresectable

- Any pancreatic adenocarcinoma presenting in the stage of systemic disease (distant metastases).

- Aortic invasion or encasement.

- Involvement of more than 180 degree of the circumference of the SMA.

- Any celiac trunk involvement.

- Unreconstructible SMV and/or portal vein infiltration

Operative technique

Surgery should be performed in specialized high-volume pancreatic cancer centres [79, 80]. The goal of every potentially curative pancreatic resection should be a R0 resection with complete removal of the tumour and a standardized lymphatic dissection with a safe reconstruction technique.

Standard resection techniques are the pylorus-preserving Kausch–Whipple resection (pylorus preserving pancreaticoduodenectomy; PPPD), the pancreatic left (tail) resection and the total pancreatectomy, depending on the location and extent of the tumour.

History of pancreatic surgery

The first documented pancreatic resection has been attributed to Friedrich Trendelenburg, who performed a distal pancreatectomy and splenectomy in a patient with a sarcoma originating from the tail of the pancreas in 1882, more than a century ago [86]. The first modern pancreaticoduodenectomy has been credited to Walther Carl Eduard Kausch, who described a two-staged pancreaticoduodenectomy, which he performed in Berlin, Germany in 1909 [87]. A one-stage pancreaticoduodenectomy had been performed in 1912 by Georg Hirschel of Heidelberg, Germany [88]. In 1935 a landmark article was published by Allen Oldfather Whipple describing his surgical experience in three cases of pancreatic ampullary carcinoma, linking his name to the procedure of pancreaticoduodenectomy [89]. Recent advances have been extended vascular resections, neoadjuvant therapies for primarily unresectable disease, the introduction of laparoscopic techniques as well as stapling devices into the field of pancreatic cancer surgery [83, 90–93].

Standard and pylorus-preserving Kausch–Whipple operation

Nowadays, the pylorus-preserving pancreaticoduodenectomy (PPPD or pp-Whipple surgery) is the option of choice for most adenocarcinomas located in the pancreatic head (see Figure 40.3). The pylorus-preserving modification of the classical Kausch–Whipple operation was described by Traverso and Longmire in 1978 [94, 95]. Current studies have shown the superiority of this modification with respect to operation time and intraoperative blood loss, while maintaining equal morbidity and short- and long-term mortality rates [96]. The classical Kausch–Whipple procedure should still be performed in tumours close to/or infiltrating the proximal duodenum and/or the stomach.

Both the classical Kausch–Whipple surgery and the pylorus-preserving modification start with a meticulous exploration of the abdomen to rule out peritoneal carcinomatosis and/or distant metastases. Any suspicious areas will be biopsied and analysed by a pathologist via frozen sections to exclude systemic disease. The next step is the mobilization of the right colonic flexure, the duodenum, and pancreatic head by a Kocher manoeuvre. After dissection of the gastrocolic ligament or the greater omentum from the transverse colon, access to the lesser sac is obtained. Next the SMV is identified and tumour size, tumour relation to the portal vein, and retroperitoneal infiltration are investigated at this point. Careful preparation of the hepatoduodenal ligament will provide details about potential arterial involvement and any potential accessory hepatic arteries.

The operation continues with the resection phase, which consists of a cholecystectomy, standard lymphadenectomy, and transection of the hepatic duct, gastroduodenal artery, and the duodenum (preserving a short postpyloric segment).

The standard lymphadenectomy includes the lymph nodes within the hepatoduodenal ligament, around the common hepatic artery, portal vein, SMV, right-sided from the celiac trunk and the SMA root. Extended lymphadenectomy has not provided better outcome results with regard to survival, while producing a higher morbidity rate, and should therefore not be performed [97–99].

The pancreas will then be cut above the portal vein via sharp dissection, and pancreas and bile duct resection margins will be sent to immediate histopathological analysis via frozen section to confirm clear resection margins. After complete mobilization of the pancreatic head and uncinate process from the SMA, the horizontal part of the duodenum is cut with a linear stapler and the resection phase ends (Figure 40.3A). The medial resection margin (i.e. the SMA margin) is well known to be the most critical for a margin-positive resection (R1) [100]. It is currently under examination whether alternative surgical strategies (e.g., artery first approach) may lower the high positive margin rate [101].

The most important part of the reconstruction phase is the pancreatic anastomosis. This can be either performed via a pancreaticojejunostomy or pancreaticogastrostomy. Both techniques can be regarded as equal, as long as a tension-free anastomosis in well-perfused tissue without obstruction is performed [102]. The biliodigestive anastomosis is performed as an end-to-end anastomosis approximately 15 cm arborally from the pancreatic anastomosis. The duodenum is anastomosed antecolically with the jejunum 50 cm distally from the hepaticojejunostomy (Figure 40.3B). Antecolic reconstruction has been shown to reduce the incidence of delayed gastric emptying [103]. Drainage placement has not been shown to improve surgical outcome; however, many surgeons still use drains for two to three days post-operatively to measure enzyme activity [104].

The classical Whipple procedure is similar to the modified version with the difference that the distal 1/3 of the stomach is resected and gastrointestinal continuity is reestablished via an antecolic gastrojejunostomy.

Left resection (pancreatic tail resection)

Resection of the pancreatic tail will be performed in tumours of the left side and pancreatic corpus. The lower resection rate in this type of surgery results from the usually more advanced disease in left-sided pancreatic cancer, as symptoms usually only appear in a very late (unresectable) stage of disease. In most cases a splenectomy with resection of the splenic vessels will be performed simultaneously to achieve R0 status.

After transection of the gastrosplenic ligament and mobilization of the left colon the pancreas is undermined above the SMV. After transection of the splenic artery and vein the pancreatic tail can then be removed together with the spleen; care should be taken to obtain a negative retroperitoneal resection margin.

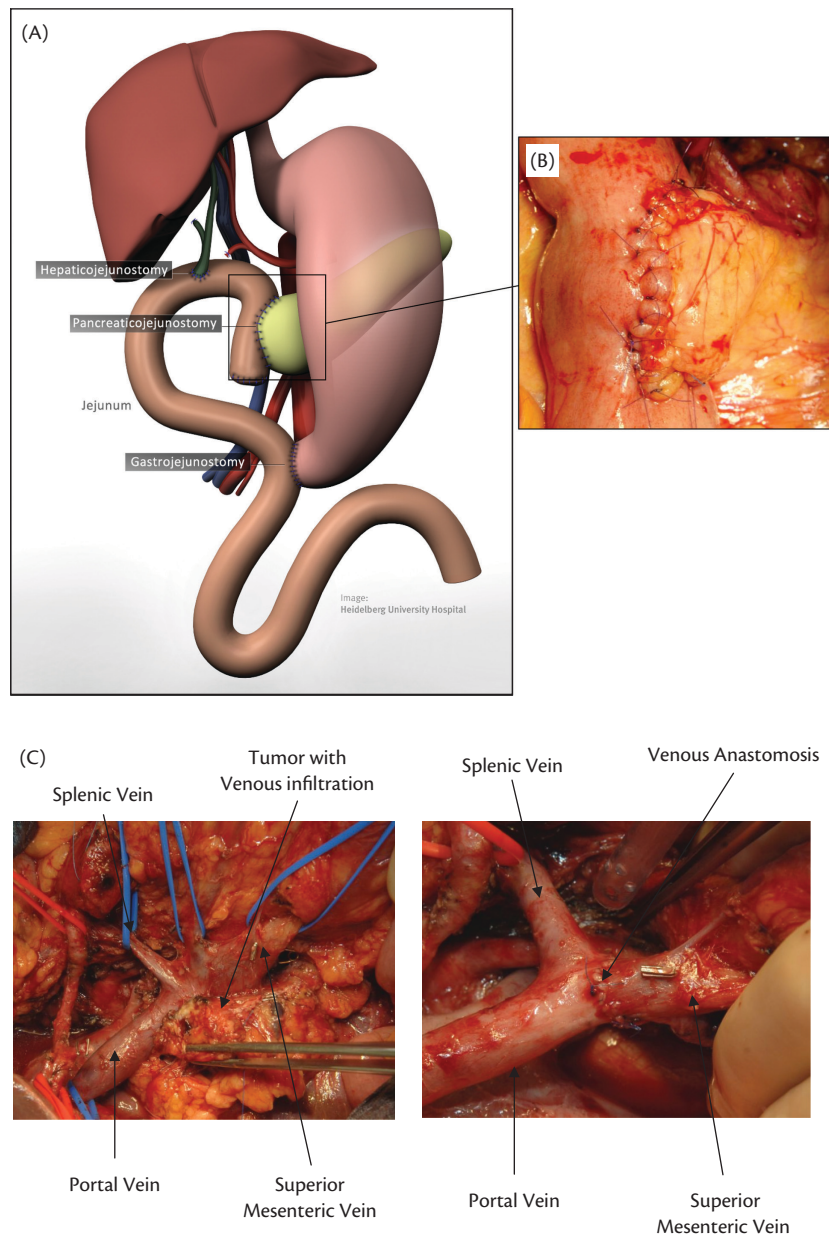
The critical part of this operation is the closure of the remaining pancreas with an incidence of pancreatic fistulas in the literature ranging from 0–70%. A recent trial has compared closure with a stapling device compare to hand suture and found no significant difference with regard to the fistula rate [92].


Fig. 40.3 (A) Status after pancreatic head resection with standardized lymph adenectomy; (B) standard reconstruction after a pylorus preserving pancreaticoduodenectomy (inlay: pancreaticojejunostomy); (C) portal vein resection for advanced pancreatic cancer.
Image 40.3(A) reproduced courtesy of Heidelberg University Hospital.

Total pancreatectomy

If a clear resection margin cannot be achieved with a Whipple procedure or for multifocal tumours in the pancreas, a total pancreatectomy might be indicated if R0 resection status can then be achieved. Due to the possibly higher long-term sequelae after total pancreatectomy, indications should be reviewed carefully and PPPD should be preferred whenever possible.

Laparoscopic pancreatic surgery

In recent years laparoscopic pancreatic surgery has evolved in some high-volume centres. Indications should be reviewed critically and laparoscopic surgery for pancreatic malignancies should be performed within clinical trials in high-volume centres only. In experienced hands good results, even including extended resections with vascular reconstructions, can be achieved [91, 93, 105].

Vascular resection

Venous infiltration is common for pancreatic cancer and results in vascular resections involving the SMV and/or portal vein in 20–25% of the cases. En bloc venous resections can be performed with equal perioperative mortality and morbidity rates as standard resections. Median survival after venous resection is superior to palliative chemotherapy, and long-term survival is a possibility. Therefore venous resection should be performed if necessary and R0 situations can otherwise not be achieved [83] (Figure 40.3C).

Resection of arterial structures is technically feasible; however, its potential benefits are controversially discussed. There is consensus that arterial involvement of the hepatic arteries and/or SMA will be a sign of aggressive and/or advanced cancer with a dismal prognosis. However, there are individual cases where R0 resections can be achieved via hepatic artery resection or SMA resection and reconstruction. A recent meta-analysis has shown that arterial resections are associated with an increased risk of perioperative mortality and poor one- and three-year survival rates. However, the results were still more favourable compared to no resection in advanced cases [106]. There have been documentations of small series for advanced disease within the corpus/cauda with extended pancreatic left resections plus splenectomy, gastrectomy, and celiac trunk resections (Appleby operation) [107].

Management of post-operative complications

Comparison of post-operative morbidity remains difficult among centres and between different surgical techniques, as consensus regarding the definition of typical post-operative complications has only been made recently by the International Study Group of Pancreatic Surgery (ISGPS). Typical morbidities after pancreatic surgery include pancreatic fistulas, early and late post-operative bleeding, and delayed gastric emptying.

Safety of pancreatic cancer surgery has steadily improved over the recent years, shown by a reduction of mortality rates from 30% in the 1970s to less than 5% in high-volume centres today with average hospital admission times of eight to ten days. However, perioperative morbidity remains high at 30–40% [108, 109].

Pancreatic fistula

Pancreatic leakage due to post-operative pancreatic fistula (POPF) represents the major cause for procedure-related perioperative morbidity and mortality in pancreatic surgery [110]. A standard definition of POPF has only recently been agreed upon by the International Study Group on Pancreatic Fistula Definition (ISGPF) [111, 112].

Various techniques have been described in the literature aiming for a lower fistula rate including fibrin glue techniques, drainage, various types of stent, the use of octreotide, and different surgical anastomosis techniques. However, none of these techniques have provided evidence for a lower incidence of POPF [113–117]. Known risk factors for POPF are the texture of the pancreas (with a higher incidence of POPF for soft pancreas), smaller pancreatic ducts, which make anastomosis technically more challenging, and obstructions located distally from the anastomosis [90].

Post-operative haemorrhage

Post-operative haemorrhage after pancreatic surgery has been reported at a rate of 2–15% and is one of the major causes of perioperative mortality [118]. A definition of postpancreatectomy haemorrhage (PPH) has been created by the ISGPS [119]. Bleeding can be divided into early bleeding (<24 hours post-operatively), usually from an anastomotic site or insufficient haemostasis or late bleeding (>24 hours), which is usually due to erosion of vessels by leakage from the pancreatic anastomosis and/or resulting pseudoaneurysms. Late haemorrhage is usually severe and should be thoroughly examined; initial radiological intervention should be performed whenever possibly and necessary. Surgical revision is necessary if radiological intervention cannot be performed or fails [120, 121]. Mortality rates of up to 40% have been described for late post-operative bleeding [122].

Delayed gastric emptying

Due to inconsistent definitions the incidence of delayed gastric emptying ranges from 14–70% in the literature. A standard definition has been provided by the ISGPS and validated [123, 124]. Delayed gastric empting is a common morbidity after pancreatic surgery and describes the inability to return to normal diet after surgery. The patency of the pancreatic anastomosis (gastrojejunostomy or duodenojejunostomy) should be investigated endoscopically and a retropancreatic abscess should be excluded by abdominal cross-section imaging after prolonged times of delayed gastric emptying.

Long-term outcome

Pancreatic cancer, even when resected completely, is known for its dismal prognosis. The overall five-year survival rate for all patients is about 6% [125]; after resection the five-year survival rate approaches 20%. Several risk factors of a worse prognosis have been defined, such as age, preoperative CA 19-9 levels, T status, R status or grading (Table 40.3). In the subgroup of patients without any adverse prognostic factor a five-year survival of 55% was observed in a recent study, whereas in subgroups of patients with more risk factors less favourable outcome was observed [126].

Palliative surgery

In primarily locally unresectable cases or cases with systemic disease, histological confirmation of adenocarcinoma is mandatory prior to induction of palliative therapy or neoadjuvant therapy regimes. The goal of palliation therapy will be to ameliorate the suffering of the patient while ensuring the best possible quality of life.

Most patients undergoing palliative chemo- or chemoradiotherapy after diagnosis of non-curable pancreatic cancer will need some kind of interventional therapy due to disease progression. Typical indications are jaundice caused by biliary obstruction and/or duodenal stenosis due to local tumour infiltration/encasement. Generally, the surgical approach compared to the endoscopic/interventional approach is associated with a higher short-term morbidity but might provide better long-term results, due to stent obstructions, cholangitis, and duodenal stenosis [127–129].

When a hepaticojejunostomy is performed, or if during a surgery with curative intent systemic disease and/or local unresectability is diagnosed, surgical prophylactic double bypass might be indicated—even in the absence of duodenal stenosis. The prophylactic gastrojejunostomy and hepaticojejunostomy can usually be carried out with low morbidity and mortality [127–129].

A primary R2 resection of pancreatic tumours (tumour debulking) is of no survival benefit for the patients, while having a higher risk of post-operative complications, and thus should be avoided.

Surgical management of premalignant lesions

The classic premalignant lesions of ductal adenocarcinoma of the pancreas are PanINs. In addition, premalignant lesions of the pancreas are present in a high percentage of cystic tumours of the pancreas (e.g., IPMNs and MCNs). The knowledge regarding the risk of malignant transformation as well as the diagnosis and treatment of such lesions has developed rapidly over the last decade. The present section summarizes the evidence available on this topic.

With the use of modern multidetector computed tomography (MDCT) and MRI, an increasing number of cystic pancreatic

lesions are detected incidentally. Recent studies have shown that in approximately 2% of the general population unsuspected pancreatic cysts are found [130, 131]. Although these lesions are often benign and harmless, about 10% of cystic pancreatic tumours are IPMNs and MCNs. Both lesions are known to have the potential to progress to invasive pancreatic cancer. It is estimated that there is a time lag of at least five years between the first presence of a cystic pancreatic neoplasm and the occurrence of associated invasive carcinoma [132]. It has been reported that pancreatic cancers in general tend to metastasize fairly late in their genetic evolution [133]. Thus, there remains a time window for detection and therapeutic intervention for premalignant lesions at a potentially curable stage.

Although cystic pancreatic lesions are generally detectable with modern abdominal imaging, it remains challenging to predict accurately which cyst can be safely followed conservatively, and which lesion is likely to progress to invasive cancer and therefore should be surgically resected before neoplastic changes occur. A five-year survival of >90% has been reported for patients with non-invasive IPMNs compared to a survival of only 40–50% if the IPMN is associated with invasive carcinoma. Overall, it is estimated that one-third of IPMNs are associated with invasive cancer at the time of surgical resection [134].

The risk of harbouring malignancy of cystic pancreatic neoplasms depends on their morphology and anatomical location. Today, it is well established that IPMNs arising in the main pancreatic duct (main-duct type) display a markedly higher risk of harbouring malignancy (60–70%) compared to IPMNs of the branch-duct type (25–35%) [135]. The prevalence of invasive cancer reported in MCN varied widely between 6% and 36%. In contrast to IPMNs, MCNs are generally solitary and do not recur after complete surgical resection. In 2006, a consortium of the International Association of Pancreatology met in Sendai, Japan and established evidence-based treatment guidelines for IPMNs and MCNs [136]. According to these 'Sendai criteria', surgical resection is recommended for all IPMNs located in the main pancreatic duct (main-duct IPMN and mixed-type IPMN). In patients with suspected branch-duct type IPMN, only those with a cyst diameter of more than 3 cm, with symptoms, with mural nodules or positive cytology should undergo resection. MCNs, unless there are contraindications for surgery, for example due to relevant comorbidity, should always be considered for surgical resection. The reason for this approach is that most MCN patients are relatively young at the time of diagnosis. Considering life expectancy and the ongoing risk for progression to invasive cancer, surgical resection is recommended in most cases. In experienced centres, surgical resection for MCNs can be performed with minimal morbidity and mortality. Since the majority of MCNs are located in the body or tail of the pancreas, resection can often be accomplished by laparoscopic means.

From preoperative imaging and even during intraoperative exploration, it is not always possible to ascertain with reliability the invasiveness of cystic pancreatic lesions. Thus, whenever any doubt exists, a formal oncological resection with lymph node dissection is warranted. Only small lesions without any preoperative signs of malignancy can be treated with limited pancreatic resection, which includes segmental pancreatic resection, middle-segment pancreatectomy, or local enucleation. However, this approach is only recommended when the intraoperative histopathological assessment is negative for malignancy and as long as negative resection margins can be obtained. Whenever intraoperative margins are positive for malignancy (high-grade dysplasia or invasive carcinoma), patients should undergo further resection, and even total pancreatectomy, if necessary. The treatment of patients with resection margins positive for benign IPMN remains debatable. Most pancreatic surgeons refrain from further resection in case IPMN with only low-grade dysplasia is found in the resection margin after pancreatectomy.

Beside from mucinous cystic neoplasms (IPMNs or MCNs), infiltrating carcinomas of the pancreas can arise from histologically defined precursor lesions in the small ducts and ductules of the pancreas [137]. These lesions are PanINs and display precursors for the common ductal adenocarcinoma of the pancreas. In contrast to cystic mucinous neoplasms of the pancreas, PanINs can only be detected by histopathologic examination. Thus, these lesions are found either incidentally in specimens resected for benign pancreatic diseases (e.g., chronic pancreatitis) or in intraoperative frozen sections of resection margins after pancreatectomies. According to the grade of dysplasia, PanINs are divided into three categories. In case PanIN 2 or 3 lesions are found incidentally on histological examination, resection should be tailored to the individual situation.

With regard to the poor prognosis of pancreatic cancer and the lack of an effective chemotherapy, early detection of premalignant lesions is crucial. Even with the use of modern abdominal imaging and fine needle aspiration, it remains difficult reliably to predict malignancy in cystic pancreatic lesions. In future, molecular biomarkers will eventually allow screening for pancreatic cystic lesions in order to enable appropriate treatment stratification.

Radiotherapy in pancreatic cancer

Pancreatic cancer is localized in a region of the body that has been particularly difficult for radiation oncologists to treat. This is due to the organs at risk surrounding the pancreas, namely stomach, duodenum, jejunum, liver, kidneys and spinal cord. However, radiotherapy has recently undergone a dramatic technical revolution in terms of high precision and protection of organs at risk which now allows the safe application of effective doses. Some of the keywords of this progress are intensity-modulated radiotherapy (IMRT) and image-guided radiotherapy (IGRT). Chemoradiotherapy which is standard for most of the situations in which radiotherapy is used in pancreatic cancer has also been refined alongside the technical improvements of radiotherapy. At the time of the publication of this book most of the clinical trials that are available were still using the technical standards prior to the above-described revolution in radiation oncology, which makes it difficult adequately to estimate the value of radiotherapy for the current situation. This is why one of the key messages of this section is that every patient with pancreatic cancer should ideally be treated within a clinical trial. In parallel to technical developments, molecular targeted approaches have also started to contribute to the progress of radiotherapy [138, 139].

Before focusing on the respective stages of pancreatic cancer, it is important briefly to address the overarching understanding of the disease with specific relevance to radiotherapy: again and again it has been shown that surgery is the only potentially curative therapeutic option underscoring the relevance of locoregional treatment. On the other hand, metastatic disease is very frequent in pancreatic cancer which only can be dealt with by systemic treatment. A post-mortem study of pancreatic cancers of all stages from patients who have succumbed to the disease

has shown that uncontrolled local growth is the cause of death in 30% of patients with pancreatic cancer and DPC4 immunolabelling status was highly correlated with widespread metastases versus locally destructive tumours [140]. Therefore, finding the right balance between locoregional and systemic treatment is of the highest importance when the radiotherapy is integrated into the treatment of pancreatic cancer (Figure 40.4).

Locally advanced (unresectable) disease and palliation

Locally advanced pancreatic cancer (LAPC) is encountered in about one-third of the patients at initial presentation. LAPC is defined as unresectable disease without any detectable metastases. In the past, LAPC has often not been separated from metastatic disease especially in trials testing chemotherapy and also not from borderline resectable pancreatic cancer (BRPC). BRPC will be discussed below but it is important to remember that practically all trials reported so far have not distinguished between LAPC and BRPC.

Whenever radiotherapy is prescribed for LAPC it should be performed with chemotherapy based on a number of reports. A small prospective randomized trial comparing chemoradiotherapy versus best supportive care detected a median overall survival (mOS) of 13.2 versus 6.4 months. Additionally, quality of life was significantly better and distant metastases were significantly fewer in the chemoradiotherapy group [141]. Following a previous study [142], chemoradiotherapy was compared with radiotherapy only in a three-armed trial of the Gastrointestinal Tumour Study Group (GITSG) comparing split-course radiotherapy (60 Gy) with two arms of chemoradiation (40 Gy, 60 Gy) [143]. Median overall survival time was 8.3 and 11.3 months with chemoradiotherapy compared to 5.5 months with radiotherapy only (P < 0.01). An important detail of this trial was the requirement for laparotomy proof of LAPC and the continuation of 5-FU chemotherapy until further progression. This may explain the conflicting results of another randomized trial accruing between 1983 and 1989 [144]. This ECOG trial compared radiotherapy only to a total dose of 59.4 Gy with additional chemotherapy (5-FU: 1 g/ m2/day by continuous infusion, days 2 to 5 and 28 to 31; mitomycin-C: 10 mg/

m2 day 2) with no additive chemotherapy where median OS was 7.1 versus 8.4 months (P = n.s.). The comparison of the effects of chemoradiotherapy with chemotherapy only in LAPC is currently being intensively investigated. Based on two trials in the 1980s chemoradiotherapy was commonly accepted to be superior to chemotherapy only because these two trials demonstrated improved local control and overall survival [145, 146]. However, a recent randomized phase III trial reported inferiority of chemoradiotherapy versus gemcitabine only [146]. After chemotherapy, mOS was 13 versus 8.6 months after chemoradiotherapy. This result can be explained at least partly by the specific details of the chemoradiotherapy used: of particular importance is an excessively large radiotherapy planning treatment volume (PTV) to an unusual high total and single-dose (60 Gy in 30 fractions). This was combined with an unusual chemotherapy regimen (cisplatin and 5-FU) and resulted not only in a high rate of grade 3/4 toxicities but also of incomplete treatment in the chemoradiation arm (58% versus 27% received less than 75% of chemoradiotherapy versus chemotherapy; six versus ten cycles of maintenance chemotherapy after chemoradiotherapy). This contrasts with the results of the ECOG 4201 phase III trial which employed a much smaller PTV to a lower dose in combination with gemcitabine versus gemcitabine chemotherapy only [148]. Chemoradiotherapy followed by chemotherapy resulted in a higher rate of stable disease compared to chemotherapy only (68% versus 35%) as a result of a reduced rate of progressive disease. This resulted in prolonged overall survival at 12, 18, and 24 months (mOS 11 versus 9.2 months, P = 0.032) at the cost of an elevated rate of mainly haematological grade 4 toxicity but also fatigue and nausea/vomiting. The concomitant dose of gemcitabine at 600 mg/m2/week for six weeks is high compared to a number of other trials using gemcitabine-based chemoradiotherapy, explaining the toxicity. Classically, fluoropyrimidine-based chemoradiotherapy is regarded to be standard in pancreatic cancer [141, 149]. After the publication of a meta-analysis comparing 5-FU with gemcitabine-based chemoradiotherapy [150], gemcitabine can also be recommended for concurrent chemoradiotherapy provided that the specific rules (gemcitabine dose and PTV) for this combination, as described in more detail in the section 'Irradiation techniques', are respected. The meta-analysis comprised 229 patients. Gemcitabine-based compared to 5-FU-based chemoradiation resulted in superior 12-month-overall survival with a relative risk of 1.54 (95% CI: 1.05–2.26). However, the meta-analysis also noted the higher toxicity of gemcitabine-based chemoradiotherapy. The studies included into the meta-analysis were conducted from the late 1990s through to 2005 and no IMRT, high-conformality or systematic gastric mucosa protection were utilized to limit toxicity (see 'Irradiation techniques').

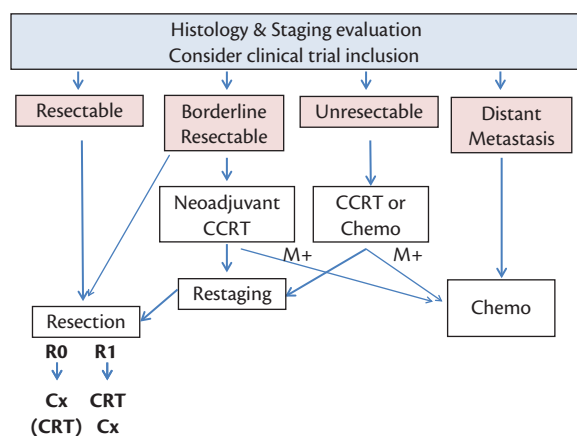
Induction chemotherapy before chemoradiotherapy started to be investigated during the last decade [138, 151–153]. Whilst the results of the first randomized controlled trials are still awaited [153], the collective evidence of early-phase and retrospective studies suggests that induction chemotherapy is suitable to select patients without early distant metastatic progression for chemoradiotherapy. In these trials duration of induction chemotherapy ranged from one to six months. The comparison between two analyses from the GERCOR group points to a minimum of three months of induction chemotherapy required for adequate selection because of the high rate of distant metastases after the completion of the chemoradiation element when only two months of gemcitabine-oxaliplatin


Fig. 40.4 Treatment algorithm for the multidisciplinary treatment of pancreatic cancer; tissue diagnosis should be obtained in primary non-surgical approaches of pancreatic cancer.
Abbreviations: CCRT, induction chemotherapy followed by chemoradiotherapy; Cx, chemotherapy; M+, distant metastasis; R0, R0-resection, i.e. clear margins; R1, R1-resection, i.e. microscopically positive margins.

induction chemotherapy were given [151, 152]. After three months of induction chemotherapy with various gemcitabine-based combinations, almost 30% of 181 patients had developed distant metastases. In the remaining patients mOS was 15 months after chemoradiotherapy (72 patients) versus 11.7 months after continued chemotherapy (56 patients; P = 0.0009). A retrospective report compared 247 patients with primary chemoradiotherapy with 76 patients who had 2.5 months' induction chemotherapy followed by chemoradiotherapy resulting in 11.9 versus 8.5 months mOS (P <0.001). Two months of induction chemotherapy in 69 patients with combined gemcitabine-oxaliplatin-cetuximab followed by capecitabine-cetuximab-based chemoradiotherapy produced a remarkable mOS of 19.2 months and was very well tolerated. Recently, the results of a randomized trial comparing gemcitabine- versus capecitabine-based chemoradiotherapy in patients with locally advanced pancreatic cancer being stable or responding to 12 weeks of induction chemotherapy (gemcitabine and capecitabine) were reported [155]. Even though the primary endpoint (nine-month progression free survival) was not different between the two groups (62.9% versus 51.4%), patients in the capecitabine group had a longer median overall survival (15.2 versus 13.4 months, P = 0.012) and experienced less treatment-associated toxicity.

An important and often missed opportunity after chemoradiotherapy in LAPC is secondary tumour resection. This was analysed in a systematic review and meta-analysis in 2010 [156]. For the patients with initially non-resectable tumours the trial reported a resectability rate of 33%, resulting in a median overall survival rate of 20.5 months, thus giving a similar prognosis compared to patients with initially resectable tumours. Whereas the survival rates of this meta-analysis are relatively robust, the rate of secondary resectability is probably an overestimation because resectability criteria were not clearly defined in more than half of the studies included in the analysis. Resectability criteria are based on the amount of vascular involvement, which is discussed in the section 'Borderline resectable pancreatic cancer' [157–159]. We recommend reevaluating patients six to eight weeks after completion of chemoradiotherapy for potential resection, but tumour response may also appear several months after completion of chemoradiation. CT restaging may underestimate tumour response, as it fails to discriminate adequately residual tumour from fibrosis. It has been suggested that the addition of PET/CT restaging might provide additional information [139, 160, 161]. However, future prospective studies will have to confirm these observations.

Adjuvant treatment

The concept of adjuvant chemoradiotherapy aims to reduce locoregional relapse, which has been identified as an important site of failure of 50–80% in several reports analysing the patterns of failure after surgical resection [162–165]. Most adjuvant studies additionally used systemic chemotherapy to reduce distant relapse. Since positive resection margins are found in 20–75% of the patients [166], chemoradiotherapy also specifically aims to control R1 disease after surgery. However, to date, the use of adjuvant chemoradiotherapy is a matter of great controversy and reflects the fact that all published phase III trials testing chemoradiotherapy have either been subject to serious criticism [167–170] or inadequate to testing the role of adjuvant chemoradiotherapy [171]. Much hope that this issue may be resolved surrounds the RTOG 08-48 trial,

currently recruiting, which randomizes between chemotherapy and chemoradiotherapy for patients without progressive disease after five cycles of adjuvant chemotherapy. Up to now the most convincing level I data are from adjuvant chemotherapy where the CONKO-001 trial validated gemcitabine after surgery compared to best supportive care [172], whereas the ESPAC-3 trial could not find a significant difference between gemcitabine and the Mayo Clinic 5-FU regimen [173]. In summary, the above-mentioned criticisms of the randomized trials were (1) poor recruitment of only 49 patients in eight years into the well-designed, randomized GITSG trial [168] comparing surgery only versus chemoradiotherapy (mOS 21 versus 10.9 months, P = 0.005) followed by chemotherapy which could not be invalidated by registering an additional 30 patients in a non-randomized way despite the confirmation of improved survival [170]. (2) Similarly, a trial conducted by the EORTC was underpowered and additionally confounded by including patients with periampullary cancer (mOS for pancreatic cancer 17.1 versus 12.6 months, P = 0.099) [167]. In this trial, 20% of the patients in the experimental arm never received chemoradiotherapy and no additional chemotherapy after chemoradiotherapy was given. (3) Finally, the ESPAC-1 trial was performed using a complex 2 x 2 factorial design, allowing 'background' therapy in addition to protocol therapy [169]. There were no quality assurance guidelines for radiotherapy. This might explain the poor overall survival rates in this trial of 13.9 months after adjuvant chemoradiotherapy compared with 16.9 months after surgery alone. (4) The RTOG 97-04 trial had chemoradiotherapy in both arms and compared only gemcitabine versus 5-FU in the sandwich chemotherapy, and is therefore inadequate to demonstrate the effect of chemoradiotherapy in adjuvant treatment. Two meta-analyses addressing adjuvant chemoradiotherapy mainly include data from the above-discussed trials and therefore cannot provide a solution to the above-described concerns [174, 175]. However, the meta-analysis from Stocken et al. pointed to an additional aspect of adjuvant therapy: after R1-resections adjuvant chemoradiotherapy showed a reduction of the hazard ratio by 28% whereas chemotherapy showed no significant effect on survival [174]. A retrospective analysis of 30 patients after R1-resections showed a mOS of 22.8 months after adjuvant chemoradiotherapy and consolidation chemotherapy, and appears to confirm this effect on a lower level of evidence [176]. In the absence of appropriate data from appropriately conducted phase III trials the conflicting results of large numbers of non-randomized studies should be highlighted in a recently published collaborative analysis of the Johns Hopkins Hospital and the Mayo Clinic in 1092 patients [177]. Adjuvant treatment was 5-FU-based chemoradiotherapy in 583 patients from the two centres and mOS was 21.1 versus 15.5 months (P <0.001) after adjuvant treatment or surgery only. In order to account for biases associated with non-random allocation of patients to adjuvant therapy or surgery alone, propensity score and matched-pair analyses were performed and the latter resulted in mOS of 21.9 versus 14.3 months (P < 0.001). In summary, adjuvant chemotherapy is currently standard after R0-resections and adjuvant chemoradiotherapy is reserved for clinical trials at this time at least until completion of the RTOG 08-48 trial. Chemoradiotherapy is an option in the R1-situation but requires further investigation. There are also studies of gemcitabine + nab-paclitaxel to gemcitabine alone, as well as the triple regimen FOLFIRINOX compared to gemcitabine alone.

Neoadjuvant treatment

The theoretical advantages of neoadjuvant treatment include possibly increased efficacy due to a more effective chemotherapy delivery with intact blood supply compared to reduced blood flow and increased hypoxia in the post-operative situation. Analogous to the observations made in rectal cancer it is hypothesized to achieve a higher rate of R0 –resections [178, 179], of nodal negative tumour stage (ypN0) [180], and of locoregional control, all of which have prognostic importance. Radiotherapy target volumes are difficult to define after surgery and therefore larger. This has important consequences for the acute toxicity of the treatment and limits the total dose because the gastrointestinal reconstruction receives the full dose of radiotherapy. In addition, post-operative treatment is impeded by delayed recovery after Whipple's resections in 25% of the patients [181, 182]. Moreover, neoadjuvant chemoradiotherapy is being tested in clinical trials with the hope of reducing the rate of patients who are found to be unresectable intraoperatively due to undetected metastatic disease or underestimated tumour contact to peripancreatic vessels [183]. Patients with rapid development of metastatic disease during neoadjuvant treatment can be spared a major surgical procedure. Potential disadvantages of neoadjuvant treatment are that in the absence of laparoscopic staging, patients with metastatic disease will unnecessarily receive radiotherapy. This is a realistic concern as up to 30% of the patients without evidence of metastatic disease at imaging were shown to have distant metastases during staging laparoscopy [184–186]. Concerns that neoadjuvant chemoradiotherapy increases the rate of post-operative complications have not been substantiated [185, 187]. It is also important to stress that a group of patients included in neoadjuvant trials cannot be directly compared with a group of patients treated in adjuvant trials because the intention to resect always relies on imaging which had a negative predictive value of 0.74 only with modern MDCT [186]. Where it is not possible to obtain a tissue diagnosis patients are not eligible for neoadjuvant treatment and this is typically the case in smaller tumours.

Neoadjuvant therapy for resectable disease

Patients with resectable tumours at diagnosis should not be treated with neoadjuvant chemoradiotherapy outside of clinical trials because only one randomized controlled trial has been reported so far as an abstract [185]. This multicentre trial tested primary surgery versus neoadjuvant chemoradiotherapy followed by surgery. The trial aimed to recruit 254 patients but was stopped for pure accrual after 73 patients. Of the 68 patients eligible for analysis 33 had primary tumour resection and 30 the experimental treatment. Four patients refused the allocated chemoradiotherapy and another four had tumour progression thereafter. At explorative laparotomy four versus two tumours were locally not resectable and distant metastases prevented resection in five versus eight patients respectively (primary versus neoadjuvant). Tumour resection was performed in 24 versus 20 patients by intention-to-treat analysis and the R0-resection rate was 67% versus 90% with a pN0 status of 38% versus 70%. Post-operative complications were comparable in both groups with one post-operative fatality in the arm of primary resection due to perioperative myocardial infarction. Intention-to-treat mOS was 14.4 months versus 17.4 months and analysis per protocol showed a mOS of 18 versus 25 months. An important lesson from this trial is that from randomization through to surgery,

four versus eight patients were found to have distant metastases in the arm with primary resection versus pretreatment followed by surgery. This is expected with a mainly locoregional therapy where chemotherapeutic agents are administered at reduced doses. The literature for the group of patients with resectable disease is practically devoid of trials testing induction chemotherapy followed by chemoradiotherapy and resection, whereas this sequence has been described to be very active in more advanced disease and this should be a focus of future investigations [138, 151]. A recently published systematic review and meta-analysis identified 35 trials with resectable tumours and 57 trials with tumours non-resectable before treatment, and almost all studies (104/111) contained radiotherapy [156]. The grade 3/4 toxicity for the group with resectable tumours was 26.3%. Response rates after neoadjuvant treatment were comparable between resectable and non-resectable tumours: in all patients, 3.9% had complete response, 29.1% partial response, 43.9% stable disease, and 20.8% progressive disease. In the group of patients deemed resectable prior to treatment 88.1% were explored. There was an estimated rate of 73.6% for resections and 82.1% of these were R0-resections. The estimated median survival was 23.3 months with resection and 8.4 months without resection in this cohort. This is very similar compared to the results after adjuvant chemotherapy (21.7 and 22.1 months after R0 and R1 resection) [188].

Similar rates of distant metastases were reported in a large single-arm neoadjuvant phase II trial including 86 patients: 9.3% had distant disease at restaging and another 10.5% intraoperatively. In total, 74% of the patients underwent resection and achieved a mOS of 36 months [178]. Very recently, Duke University reported a large retrospective comparison of immediately operated patients (92 patients) with patients having preoperative chemoradiotherapy for resectable disease (144 patients) [188]. Resection was not performed because of distant metastases in 19% of the neoadjuvant group and in 17% of the surgery-only group. In patients with tumour resection mOS was 27 months versus 17 months in the other groups (P = 0.04).

Neoadjuvant therapy for unresectable and borderline resectable disease

Classically, neoadjuvant treatment was discriminated for resectable versus non-resectable tumours. Recently, a new category of BRPC has been introduced, which better defines the cohort of patients who might benefit from neoadjuvant therapy [158, 159, 190]. One of the problems of the currently available literature is that there are large undefined discrepancies between the definitions of resectability, and therefore it is highly recommended to use definition of BRPC consistently. On the expert consensus statement published by Callery see 'Definitions of resectability' [190]. Most of the patients reported to have had successful resection after neoadjuvant therapy for non-resectable disease are believed to be part of the group with BRPC but resection rates from such trials are influenced by patients with clearly non-resectable tumours in the literature. The system review and meta-analysis published by Gillen reported on 57 neoadjuvant studies for unresectable disease [156]. In this group 47% of the patients were explored, with an estimated rate of 33.2% resections (79.2% of these were R0 resections). The estimated mOS was 20.5 months with resection and 10.2 months without resection. Therefore, the prognosis of patients with BRPC after resection is equally good compared to those with primary resectable tumours.

Consequently, trials testing adjuvant therapy specifically in BRPC have been activated.

Of particular interest in this context is a prospective comparative study where patients with non-resectable tumours (68 patients; T3, N0-1, M0; third AJCC classification) were treated with split-course chemoradiotherapy (5-FU, streptozocin, and cisplatin) with the plan of subsequent resection compared with patients undergoing immediate resection in less advanced tumour stages (91 patients). In the neoadjuvant group, 20 patients (29.4%) were resectable and had a mOS of 32.3 months compared to 14 months for all patients with initial tumour resection (P = 0.006) and 16 months for the 69% with adjuvant chemo(radiotherapy) therapy. A different retrospective comparison of the same nature reported a mOS of 21 months after immediate resection (58 patients) versus 54 months after neoadjuvant treatment (21 patients) [191].

In summary, neoadjuvant chemoradiotherapy remains experimental. However, especially in the situation of BRPC, resectability should be reevaluated after chemoradiotherapy/chemotherapy as this is the population where the current evidence points to a particularly high impact on survival. For resectable disease, future trials should include induction chemotherapy prior to chemoradiotherapy because of the higher rates of distant metastases described in the literature.

Irradiation techniques

The previous sections have made clear that the technique of radiotherapy is of the highest importance for adequate effectiveness and tolerance, and this has recently been highlighted in a radiation therapy quality analysis of the RTOG 97-04 trial in 416 evaluable patients with adjuvant chemoradiotherapy [192]. The survival of the 52% of the patients treated according to protocol was significantly longer compared to those treated below the standard (20.9 versus 17.5 months mOS, P = 0.019), demonstrating that insufficient quality of radiotherapy can lead to false negative outcomes in the radiotherapy arm of clinical trials. Consequently, consensus panel guidelines for the delineation of the clinical target volume (CTV) in post-operative treatment, including an atlas, have been introduced [193]. Similar guidelines have been developed for the definition of treatment volumes in LAPC and for neoadjuvant therapy derived from the distribution of lymph node metastases in surgical series [194]. In the latter setting, especially, groups using full-dose gemcitabine exclude elective nodal irradiation altogether.

Chemoradiotherapy is standard for definitive, adjuvant, and neoadjuvant therapy, except for rare cases of palliative treatment. Radiotherapy should be conventionally fractionated (1.8–2.0 Gy) and standard total doses range between 50 Gy and 55 Gy. Higher doses up to 60 Gy were reported to be safe with IMRT or highly conformal treatment. Commonly accepted standard concomitant chemotherapy is either continuous infusional 5-FU or capecitabine, and gemcitabine chemoradiotherapy is an emerging alternative standard [150]. Gemcitabine appears to be more effective than fluoropyrimidines but can also be more toxic if the PTV is not carefully restricted [150, 195]. Contouring should be performed on contrast-enhanced CT scans for adequate visualization of the GTV, vessels, and small bowel. 4D treatment planning is useful to limit the expansion margins of the GTV but the recommendation is to use IGRT in parallel to avoid geographical misses [195]. Whenever possible, the classic four-field approach should no longer be used. 3D-conformal or preferably IMRT planning is recommended, as

this was recently shown to have a better toxicity profile [197, 198]. Dose constraints for organs at risk (OAR) are particularly important for the liver, kidneys, and spinal cord, as well as the stomach, duodenum, and small bowel. Gastrointestinal toxicity (acute toxicity and bleeding) is of high importance and critically depends on dosimetric values to these organs [199]. Active supportive therapy is an integral component of radiotherapy and consists of proton-pump inhibitor therapy, anti-emetic therapy, analgesia, and dietary support.

Medical management of pancreatic cancer

Given the high rates of mortality associated with resected pancreatic cancer, significant efforts have been made to improve these outcomes with the addition of chemotherapy and/or chemoradiation to patients who have undergone potentially curative surgical resection. The initial GITSG evaluated the efficacy of the addition of chemoradiation (40 Gy with weekly bolus of 5-FU for two years) versus surgery alone [200]. Median overall and two-year survival were both significantly increased in the chemoradiation group (20 months versus 11 months and 42% versus 15%, respectively). Despite the small number of patients enrolled (43), chemoradiation became a standard of care for resected pancreatic cancer, particularly in the US (Table 40.4). A second, larger EORTC study comparing the addition of infused 5-FU (5-FU dose of 25 mg/kg per

24 hours) concurrently with 40 Gy radiation was negative [201]. However, as a trend was seen towards a benefit for chemoradiation it has been argued that this trial was underpowered. Finally, the RTOG 9704 study randomized 451 patients with resected pancreas cancer to either pre- and post-chemoradiation infused 5-FU or gemcitabine. Survival was not significantly different between the arms (16.7 months for gemcitabine and 18.8 months for 5-FU, P = 0.34) [202]. Although used to support the principle of chemoradiation, survival in this study is comparable and possibly inferior to that seen in subsequent trials utilizing chemotherapy alone. It is also noteworthy that the majority of patients in each arm received the other chemotherapy as salvage treatment on recurrence, thus potentially confounding these results.

The only study comparing all four potential adjuvant treatment approaches for resected pancreatic cancer is the randomized ESPAC1 (European Study Group for Pancreatic Cancer) study, which was initially conceived as a 2 x 2 factorial analysis of the benefits of chemotherapy ('Mayo-Clinic'-style bolus 5-FU/leucovorin; split course 5-FU-based chemoradiation; both chemotherapy and chemoradiation; or post-operative observation [203]). Analysis of the 289 patients restricted to the original factorial design demonstrated a survival benefit for chemotherapy but not for the addition of radiation. Five-year survival was 29% for patients receiving chemotherapy only, and 13.2% for patients receiving chemoradiation followed by chemotherapy. However, this was superior to those treated with chemoradiation alone (7.3%), which was comparable to the observation arm (10.7%) [204]. However, changes to the study design during the course of recruitment, and concerns regarding radiation quality control and treatment compliance have led to questions regarding the validity of this trial's results [205, 206]. Following this the CONKO-001 study compared the gemcitabine chemotherapy to surgery alone in resected patients (R0 or R1 surgical resection and a preoperative CA 19-9 level <2.5 times the upper limit of normal). The primary endpoint of an improvement in disease-free survival was achieved; this was increased from 6.9 months in the surgery-alone arm to 13.4 months for gemcitabine-treated patients (P <0.001) [207]. A survival update on this study presented in abstract form demonstrated a statistically significant overall survival benefit for the interventional arm (22.8 months versus 20.2 months, P = 0.005, five-year survival 21% versus 9%), confirming the utility of adjuvant chemotherapy in this setting [208]. Building on the perceived success of adjuvant chemotherapy in the ESPAC1 study, the ESPAC3 trial was a large (1088-patient) two-arm randomized trial comparing the benefits of six months of bolus fluorouracil and leucovorin with six months of gemcitabine [209]. Although no significant difference was seen in the two arms with respect to overall survival (23 months for fluorouracil and 23.6 months for gemcitabine, HR 0.94: 95% CI0.81–1.08), toxicity profiles favoured the gemcitabine-containing arm with lower levels of diarrhoea and stomatitis, although this did not appear significantly to impact on quality of life. Thus, both gemcitabine and 5-FU may be considered reasonable options for the adjuvant treatment of resected pancreatic cancer, although, based on tolerability, gemcitabine is more commonly selected. Additions to the gemcitabine backbone design include the current ESPAC4 trial will assess the benefit of a capecitabine/gemcitabine combination versus gemcitabine alone, and the CONK0-005 trial, which examines the addition of erlotinib to standard gemcitabine therapy.

Finally, given the number of patients in whom complete surgical resection is not possible, a neoadjuvant chemotherapy and/or chemoradiation approach is attractive. Potential benefits of this treatment strategy include assessment of chemosensitivity in vivo, reduction in tumour volume presurgery with increased respectability for 'borderline tumours', and selection of those with less aggressive disease biology who do not progress on neoadjuvant therapy to undergo a surgical procedure associated with significant morbidity. However, despite promising single-institution studies and uncontrolled trials, randomized data in this setting is lacking and it remains an experimental treatment approach [210].

Gemcitabine

For patients with advanced pancreatic cancer, meta-analysis demonstrates that chemotherapy is associated with superior survival when compared to best supportive care alone (HR 0.64 months 95%, CI 0.42–0.98) [211]. Gemcitabine (2',2'-difluorodeoxycytidine; Gemzar®, Eli-Lilly), a nucleoside analogue with structures in common with cytarabine, has until recently been the backbone of most cytotoxic chemotherapy regimens for this disease. Early studies in patients with untreated advanced pancreas cancer (800 mg/m2 IV q weekly three of four weeks) demonstrated modest response rates of 6.3–11% [212, 213]. However, given the difficulty associated with radiological assessment of response for patients with pancreatic cancer and the frequent presence of disease-related symptoms in these patients, a separate endpoint of 'clinical benefit rate' has frequently been used to assess the efficacy of chemotherapy regimens in this disease. This endpoint, a composite of changes in pain score, Karnofsky performance status (KPS), and weight was first used in conjunction with traditional measures of radiological response in a study by Rothenberg et al. of gemcitabine (1000 mg/m2 weekly x 7 followed by one week of rest, then weekly x 3 every four weeks thereafter) in 5-fluoropyramidine refractory advanced pancreas cancer patients [214]. Clinical benefit was defined as ≥50% reduction in pain intensity, ≥50% reduction in daily analgesic consumption, or ≥20 point improvement in KPS that was sustained for ≥4 consecutive weeks. Although radiological response rate in this second-line setting was comparable to other studies at 10.3%, 27% of patients derived a clinical benefit, the median duration of which was 14 weeks. Following this, the clinical benefit rate of gemcitabine in the first-line setting was demonstrated in a randomized study comparing both this and traditional measures of response and survival for patients with treatment-naive pancreatic cancer [215]. Gemcitabine was superior to 5-fluorouracil in terms of radiological response (5.3% versus 0%), progression-free survival, and overall survival (nine weeks versus one week and 5.65 months versus 4.41 months, respectively, P = 0.0025). One-year survival was nine times more likely for patients in the gemcitabine-containing cohort (18% versus 2%). Finally, the clinical benefit rate was 23.8% for gemcitabine-treated patients compared to 4.8% for those treated with 5-FU (P = 0.0022). It is of note, however, that assessors of clinical response rate in this study were not blinded to the treatment assignment leading to a potential source of bias. The results of this study led to licensing of gemcitabine for the first-line treatment of advanced pancreatic cancer.

Fixed-dose-rate infusion gemcitabine

In theory, administration of gemcitabine over a longer period may have pharmacokinetic advantages. Deoxycytidine kinase which

metabolizes gemcitabine to the active gemcitabine triphosphate becomes saturated at infusion rates of >10 mg/m2/min [216, 217]. That a longer 'fixed-dose rate' infusion could impact on efficacy was suggested by a randomized phase II study of 92 patients with advanced pancreatic cancer, where those treated with gemcitabine (1500 mg/m2 over 150 minutes) compared to those treated with gemcitabine (2200 mg/m2 over 30 minutes, 'dose intense regimen') demonstrated not only elevated levels of gemcitabine triphosphate in peripheral white cells, but also superior survival to those treated with a conventional schedule (eight months versus five months, respectively) [218]. This benefit was not replicated in a larger phase III randomized study of 832 patients in which patients received standard-dose gemcitabine (1000 mg/m2 weekly x 7 followed by one week of rest, then weekly x 3 every four weeks thereafter), fixed-dose rate gemcitabine (1500 mg/m2 over 150 minutes weekly for three weeks of four), or a fixed-dose rate gemcitabine-oxaliplatin combination [219]. Median overall survival were 4.9 months and 6.5 months in the standard and fixed-dose arms, respectively, which did not meet the prespecified criteria for superiority. Thus, administration of gemcitabine outside of standard methodology is not recommended at this time.

Gemcitabine combination chemotherapy regimens

In an effort to improve the modest response rates associated with gemcitabine and to improve survival, multiple gemcitabine-based combination chemotherapy regimens have been investigated. These include the addition of cisplatin [220–223], oxaliplatin [219, 224], taxanes [225–229], fluoroyrimidines [230, 231], and irinotecan [228, 229, 232]. Although most gemcitabine-containing doublets were associated with increased response rate, none of these combinations have been demonstrated to result in a statistically significant improvement in overall survival. A possible exception to this is the combination of gemcitabine and the oral fluoropyrimidine capecitabine; the largest phase III randomized trial conducted by Cunningham et al. examining this regimen demonstrated not only an increase in response rate and progression free survival for the doublet, but when the three studies examining this combination were combined in meta-analysis, the increased number of patients involved moved the difference in overall survival into statistical significance (HR 0.84, 95%, CI 0.75–0.98, P = 0.02) [233]. However, the margin of benefit achieved remains debatable, as the improvement in overall survival seen for patients treated with the gemcitabine–capecitabine combination in these studies ranged from only less than one month to 1.3 months maximally [230, 231, 233].

Two further meta-analyses have examined the utility of adding a second agent to gemcitabine. Heinemann et al. compared gemcitabine + X in a combination of 15 controlled trials and a total of 4465 patients [234]. They found a significant survival benefit for doublet chemotherapy with a pooled hazard ratio (HR) of 0.91 (95% CI 0.85– 0.97, P = 0.004). This benefit was seen for both platinum- and fluoropyrimidine-containing combinations, but not in the group of trials containing gemcitabine with other agents. However, the clinical relevance of this result is again brought into question by a further meta-analysis by Vacarro et al. which compared the results of seven trials containing gemcitabine in combination with only cisplatin, oxaliplatin, and capecitabine [235s]. The conclusions of the authors were that although the addition of a second agent was associated with a statistically significant survival benefit for all classes of drug examined, the absolute benefit was clinically insignificant, with power calculations outruling a >5% benefit in survival at one year.

5-FU-containing regimens

Prior to the adoption of gemcitabine as the chemotherapy of choice for advanced disease, fluoropyrimidine regimens were in common use. However, in both phase II and randomized controlled trials, both bolus and infusion leucovorin modulated 5-FU-containing regimens are associated with low response rates and survival inferior to that seen with gemcitabine [215, 236–238]. Single-agent capecitabine (1250 mg/m2 BD orally for 14 of 21 days) was associated with a clinical benefit rate of 24% in a phase II study of 42 patients with advanced pancreatic cancer, despite a low radiological response rate of 7%. Capecitabine in combination with oxaliplatin (CapeOx) was examined in a German AIO study in comparison with both GemCap and GemOx regimens [239]. No statistically significant differences between the arms were seen with respect to overall response rate (ORR), progression-free survival (PFS), or OR, implying that the Cape-Ox combination could be considered in gemcitabine-intolerant patients. Irinotecan in combination with 5-FU (modified FOLFIRI) has been investigated in a small phase II study, and was associated with an encouraging ORR response rate of 37.5% and a survival of >12 months [240]. However, these findings have not been confirmed in a controlled setting, and contrast with the failure of irinotecan to improve survival for patients with advanced pancreatic cancer when added to gemcitabine chemotherapy [232, 241].

FOLFIRINOX—a new standard for metastatic pancreatic cancer

A significant advance in the treatment of metastatic pancreatic cancer was demonstrated on the presentation of the recently reported FOLFIRINOX study by Conroy et al. [218]. An initial phase II non-randomized trial of 46 patients treated with oxaliplatin 85 mg/m2 and irinotecan 180 mg/m2 plus leucovorin 400 mg/m2 followed by bolus FU 400 mg/m2 on day 1, then FU 2400 mg/m2 as a 46-hour continuous infusion yielded a response rate of 26%, a time to progression of 8.2 months, a median overall survival of 10.2 months and an impressive one-year survival (for all patients) of 43% [242]. In sharp contrast to the repeated failure of gemcitabine-containing combination regimens FOLFIRINOX demonstrated clear superiority with respect to ORR, PFS, and OS when compared to single-agent gemcitabine (1000 mg/m2 weekly for seven of eight weeks and then weekly for three of four weeks) [243]. Objective response rates were 31.6% in the FOLFIRINOX arm versus 9.4% in the gemcitabine arm (P <0.001), PFS was improved from 3.3 months to 6.4 months, and overall survival from 6.8 months to 11.1 months, respectively (HR 0.57; 95% CI 0.45 to 0.73; P <0.001). This enhanced efficacy did occur at the cost of increased toxicity; ≥grade 3 neutropenia and febrile neutropenia were both increased in the FOLFIRINOX arm (45.7% versus 21%, P <0.001 and 5.4% versus 1.2%, P = 0.03, respectively). However, the rate of toxic death was low, with two occurrences overall, one in each arm. This may be attributed to the high use of granulocyte colony stimulating factor in the FOLFIRINOX arm (42.5%), although this was not a prerequisite at the time of treatment initiation. Importantly, quality of life measurements were not detrimentally affected by the triplet combination regimen, and time to

definitive decline in global health status was significantly longer in the FOLFIRINOX arm (31% at six months versus 66% for gemcitabine, HR 0.47; 95% CI 0.30 to 0.70; P <0.001). As this mirrors the benefits seen in PFS this may also reflect that the toxicity associated with an effective treatment in advanced pancreas cancer may be balanced by control of cancer-related symptoms with effective treatment.

FOLFIRINOX selection criteria

It is pertinent to note that the eligibility criteria for this study were particularly stringent. No elevations of bilirubin beyond 1.5x the upper limit of normal were permitted, which led to both low rates of patients with pancreatic head tumours compared to other studies, and to low rates of biliary stents (14%). Furthermore, patients with an ECOG performance status of ≥2 were excluded, as were those over the age of 75 years. This may in part explain the relatively low rates of febrile neutropenia and cholangitis, which have been more common in other studies of combination regimens. As such, the generalizability to the general populace of advanced pancreas cancer patients has been questioned. Although there is no doubt that this combination is superior to gemcitabine (and gemcitabine-containing regimens investigated to date), the potential difficulties associated with the addition of other targeted agents to a polychemotherapy backbone leaves the desirability of this as a basis for future developments in question.

Second-line therapy for pancreatic cancer

Multiple non-randomized studies utilizing fluoropyrimidines, taxanes, platinums, and camptothecins demonstrate overall survivals of between 3.9 months to 7.6 months for single-agent chemotherapy in the second line setting [225]. Until recently, there was a lack of randomized data in this treatment setting; however, a recently reported randomized phase III trial comparing the use of oxaliplatin/5-FU and folinic acid to best supportive care for patients with gemcitabine refractory pancreatic cancer demonstrated a statistically significant benefit with respect to overall survival for the treatment arm of 2.3 months versus 4.8 months (0.45 (95% CI: 0.24–0.83), P = 0.008), despite early closure of the study due to poor recruitment [244]. For good performance-status patients with gemcitabine refractory pancreatic cancer, this regimen could now be considered a standard of care. For patients not suitable for doublet chemotherapy, monotherapy with fluoropyrimidines remains a treatment option. Following treatment with FOLFIRINOX, Conroy et al. reported that 82.5% of patients were treated in the second-line setting with gemcitabine, with a smaller proportion (12.5%) treated with gemcitabine combinations [218]. Interestingly, survival following institution of second-line therapy was comparable at 4.4 months for patients treated initially with either gemcitabine or FOLFIRINOX, implying that first-line therapy did not have appear to have an impact on the efficacy of treatment in the second-line setting.

A novel encapsulation of irinotecan in a long-circulating nanoliposome (MM-398, Merrimack) has been shown to extend OS as well as PFS, when it was added on to 5FU and leucovorin as a second-line therapy [245]. These results come from a 417-patient phase III trial known as NAPOLI-1.The combination of MM-398 with 5-FU and leucovorin improved overall survival to 6.1 months compared with 4.2 months with the control group of 5-FU and leucovorin (P = 0.012; HR 0.67). The addition of MM-398 also improved PFS to 3.1 months compared with 1.5 months in the control group (P = .0001; HR 0.56). This drug has not yet been commercially approved.

Targeted therapy for pancreatic cancer

Several treatment approaches using a gemcitabine backbone plus a novel targeted agent have been pursued; however, to date none have surpassed the OS seen with the FOLFIRINOX regimen. The most promising of these approaches was seen using the oral tyrosine kinase inhibitor erlotinib. In a randomized phase III trial of 569 patients with locally advanced or metastatic pancreatic cancer treated with gemcitabine (1000 mg/m2/week) plus or minus erlotinib (100 mg/day) a statistically significant benefit was seen with respect to overall survival (HR 0.81, P = 0.038) [246]. However, it is arguable whether the absolute benefit seen in survival (an increase from 5.9m in the control arm to 6.2 m in the experimental arm) is of clinical relevance. Of note, ≥ grade 2 rash developing with erlotinib therapy appeared to predict for improved survival with combination therapy (5.3 months versus 10.3 months). Alternate mechanisms of targeting the EGFR pathway in pancreatic cancer using the monoclonal antibody cetuximab have not been successful; one large randomized trial (n = 702) comparing gemcitabine alone to a gemcitabine–cetuximab combination did not demonstrate any benefit with respect to response rate, PFS, or OS, and EGFR expression had no impact on these outcomes [247]. Another phase II study of the addition of cetuximab to gemcitabine and cisplatin produced similar results [248].

Targeting the tumour vasculature using antiangiogenic agents has not proved fruitful to date in pancreatic cancer. This may be due to the relative hypovascularity of this disease. In one large (n = 707) placebo-controlled randomized trial examining the efficacy of the addition of bevacizumab to a gemcitabine–erlotinib doublet, a statistically significant one-month benefit in PFS was seen (3.6 months versus 4.6 months); however, no statistically significant improvement was seen in OS [249]. The orally available multitargeted antiangiogenic axitinib demonstrated no better success in a 632-patient phase III randomized trial in combination with gemcitabine, with identical PFS and OR in both control and experimental arms of the study [250]. A combined approach using gemcitabine, capecitabine, erlotinib, and bevacizumab yielded encouraging results in an initial phase I dose-finding study with an impressive median overall survival of over 12 months [251]. These findings were replicated in a larger phase II study presented in abstract form; however, at this time no controlled data exist to support the use of this regimen outside the experimental setting [252].

Nab-paclitaxel—a novel chemotherapy agent for pancreatic cancer

A more promising approach using a novel chemotherapeutic agent for pancreatic cancer was recently initially demonstrated in a phase I/II study by von Hoff et al. using nab-paclitaxel, an albumin-bound form of the taxane drug [253]. This drug formulation attaches in vivo to SPARC (secreted protein acidic and rich in cysteine) which is over-expressed in pancreatic tissues, in particular in peritumoral fibroblasts which produce the hypovascular desmoplastic stroma in pancreatic cancer, which in turn may be responsible for the decreased rates of intratumoral drug delivery characteristic of this disease [227, 254]. In combination with gemcitabine (1000 mg/m2/

week three out of four weeks), nabpaclitaxel 125 mg/m2/week on the same schedule was associated with a response rate of 48%, a PFS of 7.9 months, and an OS of 12.2 months [253]. A confirmatory phase III study in 861 patients randomised to gemcitabine alone or a gemcitabine-nabpaclitaxel doublet demonstrated a significant improvement in response rate and an overall survival benefit for the combination; median overall survival was 8.5 months in the nab-paclitaxel–gemcitabine group and 6.7 months in the gemcitabine group (HR 0.72; 95% CI, 0.62 to 0.83; P<0.001) [255].

Assessment of response in metastatic disease

Assessment of the primary tumour in pancreatic cancer may be difficult due to tumour hypovascularity and a frequent desmoplastic response in the surrounding tissue. As a result, endpoints other than objective response have been considered useful in many pancreatic cancer trials. These include both CA19-9 levels and 'clinical benefit rate'. Clinical benefit rate may be defined as those who have an improvement in symptoms such as pain, weight loss, and analgesic use whilst demonstrating minimal or no objective radiological response. Data on CA19-9 as a surrogate for tumour response are conflicting; in two series of patients with metastatic pancreatic cancer, decreases in CA19-9 of 20–25% were associated with significantly increased overall survival [256, 257]. In the first of these series, an elevation of CA19-9 above the median was also a poor prognostic marker [255]. However, these findings were not replicated in a larger case series of 175 patients treated with gemcitabine ± capecitabine [257]. The final series may have been influenced, however, by the necessity of demonstrating a 50% reduction in CA19-9 levels over a relatively short period of time (eight weeks), whilst the half-life of the tumour marker is 15 to 33 days [239]. It is also notable that people who do not express Lewis a or b blood antigens are classified as CA19-9 non-secretors; surveillance using this marker in these cases is not useful [243]. For these reasons the use of CA19-9 as a solitary marker of response in pancreatic cancer is not currently recommended [259]. Guidelines suggest that CA19-9 levels should be measured at treatment initiation and then every one to three months during treatment. If progressive disease is suggested by an increase in CA19-9, this should be confirmed radiologically.

Symptomatic care and management of comorbidities

Patients with pancreatic cancer are frequently affected by issues of pain, nutrition, and medical comorbidity such as diabetes and thromboembolism in addition to the devastating psychological effects of a poor-prognosis cancer diagnosis. For this reason, symptomatic and supportive care are an essential component of therapy.

Pain is a frequent occurrence in patients with advanced disease, and may often require opiate-based therapy. The use of celiac nerve blockade with local injection of alcohol to ablate the afferent nerve fibres of the celiac plexus has become more common. This may be achieved intraoperatively, percutaneously, or at endoscopy. This procedure may be more effective for the relief of pain than oral opiates, without the systemic toxicity associated with this form of medication [246]. Palliative radiation therapy may also be considered; however, this has a longer time to onset of action than either oral analgesia or celiac blockade.

Obstructive jaundice may often be the presenting complaint for patients with pancreatic cancer, and ensuring adequate biliary drainage is often a prerequisite to commencing effective therapy.

Placement of expandable metal stents is often sufficient to ensure this, with surgery reserved for those in whom stent placement is not possible [260]. The endoscopic and percutaneous approaches may have equal efficacy, although morbidity is increased with percutaneous placement, which additionally is less convenient for the patient due to the external position of the drain [261–263]. Although stent placement is associated with lower morbidity than surgery, complications such as reocclusion with recurrent jaundice or infection with cholangitis may occur. Plastic stents are more easily placed and removed than metal stents, but are also more prone to recurrent occlusion [260, 264]. Covered metal stents are equivalent to uncovered stents in terms of efficacy; however, may also be more easily removed and are therefore the preferred option [225]. Endoscopically placed expandable stents are also useful in the presence of duodenal obstruction, which occurs in up to 20% of patients with advanced pancreatic cancer. In this setting, stents are associated with shorter hospital stays than surgical bypass procedures and successful outcomes in up to 81% of cases [265].

Patients with pancreatic cancer have an increased (20–30%) risk of thromboembolic complications which are associated with a poor prognosis [221]. However, although the use of prophylactic anticoagulation is associated with a decreased risk of symptomatic thromboembolism, this did not in a randomized clinical trial lead to an improvement in OS, and is not recommended in routine practice [233].

Pancreatic cancer is often associated with significant cachexia and weight loss with subsequent need for intensive nutritional support. This may be complicated in many patients by a concurrent diagnosis of diabetes. Exocrine pancreatic insufficiency is treated with pancreatic enzyme replacement therapy which is associated with a decrease in protein or fat malabsorption and an increase in weight gain [266, 267].

As a result of the complexity of management of these multiple issues in those with pancreatic cancer, early involvement of palliative care services for both medical and psychological support is mandated for these patients.

Medical management of pancreatic cancer summary

Although for most patients, a diagnosis of pancreatic cancer remains associated with a poor prognosis, for selected populations significant improvements in overall survival have been demonstrated with novel chemotherapy combinations such as FOLFIRINOX. Targeted therapy has not yet yielded the benefits seen in other tumour types; however, targeting the tumour stroma may be a promising treatment option for patients with advanced pancreatic cancer. Other future directions of interest include inhibition of Hedgehog and insulin growth factor receptor pathways and anti-mucin-based therapies. Finally, supportive therapies such as pain control and nutritional interventions will also continue to remain paramount for this disease.

Multidisciplinary management of complex cases

Introduction to multidisciplinary management of complex cases

Metastatic disease will be present at the time of diagnosis in approximately 60% of patients with pancreatic adenocarcinoma. In

the remaining patients, 25% will present with borderline resectable or locally unresectable tumours, and 15% will have radiographically resectable lesions. The following section will focus on the multidisciplinary approach to patients who present with borderline or locally unresectable tumours. Effective treatment for this patient population requires interaction between experienced diagnostic and interventional radiologists, pancreatic surgeons, gastroenterologists, radiation oncologists, and medical oncologists. This multidisciplinary approach is necessary to optimize patient selection for both operative and multimodal treatment approaches [268, 269]. A combination of definitive chemotherapy, radiation, and/or resection for patients who present with borderline or locally unresectable pancreatic cancer has been suggested as a cause of the reported improvement in overall survival in recent years as compared to historical series.

The multidisciplinary team

The experience and expertise of the members of a multidisciplinary team is one of the most important factors in delivering high-quality care for patients with locally unresectable or borderline resectable pancreatic cancer. A high-volume pancreatic surgeon should first determine if the tumour is locally resectable. This is essential as the subsequent treatment recommendations will vary depending on the determination of local resectability. Unresectable disease typically manifests as circumferential encasement of foregut arterial structures (superior mesenteric artery and hepatic artery) and/or thrombosis of the portal vein and/or superior mesenteric vein for a length of several centimetres that cannot be reconstructed [270]. A hepatobiliary radiologist is extremely important in establishing the designation of 'resectable' with the surgeon. Both the quality of the imaging and the quality of the interpretation is vital, as one without the other may result in misinterpretation of either distant or local sites of disease. A previous study from MSKCC found that the addition of triphasic imaging and interpretation by a hepatobiliary radiologist increased the yield for identification of distant metastatic disease by an additional 10% [271].

Within the group of patients deemed radiographically resectable, the primary management issues include the management of preoperative jaundice and the role of neoadjuvant systemic therapy or chemoradiation. Due to a lack of randomized controlled data, there is substantial variability from surgeon to surgeon and from centre to centre regarding neoadjuvant therapy [272, 273]. Neoadjuvant treatment offers several theoretical advantages over an initial resection and adjuvant treatment paradigm, including the early delivery of systemic therapy for all patients, and thus early intervention on micrometastatic disease, a higher negative margin resection rate (when radiation is included), and enhanced patient selection for surgery, collectively leading to potentially improved survival [274, 275]. This approach, however, has not been subjected to randomized trial design and thus many favour an initial operative approach, with cited concern being the theoretic risk of disease progression during therapy because of unfavourable tumour biology and/or ineffective treatment. The management of preoperative jaundice has been evaluated in prospective and randomized trials, including a recent multi-institutional study evaluating preoperative internal biliary drainage [276]. In general, these trials have demonstrated an increased infectious risk to preoperative biliary drainage in patients with moderate elevation in the bilirubin, and because of this our preference is to avoid biliary stenting when possible. In

patients who require prolonged preoperative evaluation, or when resection cannot be done in a timely manner, internal biliary drainage should be considered.

The current treatment recommendation for patients with locally unresectable pancreatic adenocarcinoma is for initial systemic therapy or chemoradiation. Conversion of a locally unresectable patient to resectable status is an uncommon event. However, this appears to be occurring more commonly with systemic regimens such as FOLFIRINOX. In general, locally unresectable patients are treated similarly to patients with metastatic disease, with an initial focus on systemic therapy and radiation reserved for patients who have stable or responsive disease. When response to resectability is observed, resection is generally recommended, as long-term survival has been reported following resection in patients with initially unresectable disease [269]. A similar approach is generally recommended in patients who present with borderline resectable lesions. The National Comprehensive Cancer Network (NCCN) guidelines currently recommend either initial exploration or initial systemic therapy; however, an initial systemic approach appears to be gaining favour.

The MSKCC approach to borderline resectable and locally unresectable tumours

We recommend all patients who present to our institution with a pancreatic mass and suspicion for pancreatic adenocarcinoma to have assessment with high-quality pancreatic protocol CT imaging (non-contrasted then arterial, parenchymal, and portal venous phase contrasted). Patients that have borderline resectable or locally unresectable tumours are presented at a multidisciplinary conference to determine the most appropriate treatment course. At our institution, a dedicated team of hepatobiliary specialists are present at this conference and this includes radiologists, surgeons, medical oncologists, gastroenterologists, and radiation oncologists. Typically, multiple members of each specialty are present to provide opinions. One member of the team leads the conference and the physician who performed the initial evaluation presents the patient. In general, borderline resectable patients with venous involvement undergo surgical exploration with reconstruction of venous structures as needed. Borderline patients with evidence of possible arterial involvement are generally treated initially with systemic therapy, and in selected cases chemoradiation is given. After completion of treatment, repeat CT imaging is performed and the patient is once again assessed for resectability. For patients that demonstrate stable disease, chemoradiation is typically implemented in an attempt to obtain local response. Interval imaging is performed and patients are considered for exploration if and when they are judged to be resectable. For patients who eventually undergo resection, gemcitabine-based adjuvant chemotherapy is generally recommended. Post-operative radiation treatment is typically reserved for those patients with R1 or R2 resections.

Case presentation

In order to demonstrate the complex care of these patients, the following case is presented. A 62-year-old male presented to his local hospital with symptoms of gastric outlet obstruction. CT imaging suggested a mass in the head of the pancreas and the patient underwent upper endoscopy. Visualization was poor and the procedure was aborted. The patient was subsequently transferred to our medical centre for further evaluation. A pancreatic protocol CT scan

Prior to Chemotherapy and Chemoradiation

(A)

After Treatment

(B)
Fig. 40.5 CT scan before and after neoadjuvant chemotherapy followed by gemcitabine-based chemoradiation. Red arrow indicates tumour, yellow arrow indicates SMV, black arrow indicates SMA.

demonstrated a hypoattenuated pancreatic head mass measuring 4.6 x 2.9 cm with compression of the duodenum and encasement of the SMV and ill-defined infiltration around the SMA (Figure 40.5). The patient underwent EGD and was found to have a duodenal obstruction. A duodenal stent was successfully deployed and during the same procedure the patient had an EUS fine needle aspiration biopsy performed of the mass. The EUS also confirmed mesenteric vascular involvement. The gastric outlet symptoms resolved and the patient was discharged home. Fine needle aspiration cytology demonstrated adenocarcinoma. The patient was deemed locally unresectable by the admitting surgeon and subsequently the patient was started on gemcitabine and cisplatin for four cycles. Imaging following this treatment revealed very little change in the mass. Gemcitabine-based chemoradiation was then initiated. A CT scan eight months after initial diagnosis demonstrated a reduction in the size of the mass (from 4.6 x 2.9 cm to 4.2 x 2.0 cm) with regression from the SMV but persistent abutment of the SMA (Figure 40.5). Given the mild but definable radiographic response, the lack of encasement of the SMA, and the lack of systemic disease, the patient was taken to the operating room for attempted pancreaticoduodenectomy. The tumour was dissected free of the mesenteric vessels without difficulty and no vein resection was required. The final pathology was T3N0, with negative surgical margins. The patient suffered a wound infection requiring gauze packing but had no other complications.

This case highlights the importance of a multidisciplinary approach to patients with pancreatic adenocarcinoma. A successful outcome in this patient (i.e. R0 resection) required a team approach across multiple specialties. Unfortunately, the patient developed peritoneal recurrence 1.5 years following resection. However, he was maintained on systemic therapy for another 1.5 years until his death from disease almost four years after initial diagnosis.

Conclusion

In order to obtain optimal patient outcomes in patients with pancreatic adenocarcinoma, an experienced team of physicians is paramount. Borderline resectable and locally unresectable patients represent a unique subset of pancreatic cancer patients that are best served with multidisciplinary care to address their specific challenges. Because of a lack of randomized clinical trials to help guide management decisions, the multidisciplinary team should employ strategies that are most likely to yield successes in their practice setting.

CHAPTER 41

Hepatobiliary cancers

Graeme J. Poston, Nicholas Stern, Jonathan Evans, Priya Healey, Daniel Palmer, and Mohandas K. Mallath

Introduction to hepatobiliary cancers

The liver, and with it the gall bladder and bile ducts, are some of the most frequent sites of primary and metastatic cancers. Unfortunately, the cancers frequently remain asymptomatic until at an advanced stage and most are therefore detected late, beyond any hope of potentially curative intervention. However, significant advances have been made in detection (particularly radiology), interventional radiological and endoscopic management, surgery, and most significantly in systemic therapies, which means that the prognosis is now brighter than that endured barely a decade ago. This chapter will explore recent advances in radiology and endoscopy before covering the contemporary management of the common primary cancers that affect the liver, gall bladder, and bile ducts.

Epidemiology of hepatocellular carcinoma

The majority of hepatocellular carcinomas (HCCs) occur in patients with underlying parenchymal liver disease, particularly cirrhosis (see Figure 41.1). While chronic liver disease has many aetiologies, cirrhosis per se should be considered the major risk factor for the development of HCC. There are, however, some particular risk factors that have been shown to carry a significantly increased risk for the development of HCC. These include infection with hepatitis B [1, 2] and C [3, 4] viruses, as well as alcoholic liver disease [5, 6]. One of the largest increases in cause of liver disease in the West is non-alcoholic steatohepatitis (NASH)-related cirrhosis. As the liver end-organ disease related to the metabolic

Fig. 41.1 Post-mortem liver specimen showing large HCC arising against background cirrhosis.

syndrome, NASH-related cirrhosis is associated with diabetes mellitus, dyslipidaemia, hypertension, and the other end-organ diseases of coronary artery disease and cerebrovascular disease. Most cases previously described as cryptogenic cirrhosis are likely to be NASH-related cirrhosis, and this appears to have led to a significant risk for the development of HCC [7]. Common causes of chronic liver disease are shown in Box 41.1.

Epidemiology of biliary cancer

Gall bladder cancer

The incidence rates of gall bladder cancer (GBC) vary widely around the world [8]. Highest rates of GBC are reported from Chile, Bolivia, and Peru. High incidence is also reported from Northern and Eastern India, Pakistan, and Bangladesh, as well as several East Asian countries like Korea and Japan [8, 9]. The incidence of GBC is generally on the lower side in North America and western and northern Europe. However, GBC is more common among Native Americans and Mexican Americans [9]. Some of the lowest incidence rates for GBC are found in African countries as well as among African Americans [8, 10]. Within each ethnic group, the incidence of GBC is several-fold higher in women and steadily increases with age [8–10]. On the whole, the incidence rates for GBC is declining in most parts of the world and much of this is attributed to widespread application of laparoscopic cholecystectomy [11], see also Table 41.1.

Chronic inflammation of the gall bladder mucosa triggered by cholelithiasis is the most common mechanism for the development of GBC [12]. In a small subset of patients having anomalous pancreatic biliary duct (APBD) junction, the carcinogenesis is triggered by the reflux of pancreatic juice into the biliary tree resulting

Box 41.1 Aetiology of chronic liver disease
Hepatitis B virus
Hepatitis C virus
Alcohol-related liver disease
Non-alcoholic steatohepatitis (NASH)
Hereditary (HFE Gene related) haemochromatosis
Primary biliary cirrhosis
Auto-immune hepatitis
Alpha-one antitrypsin deficiency
Drugs

Table 41.1 Incidence rates of GBC among women worldwide

Incidence rates in women*	Countries
Very low 0.1–1.0	Nigeria, Mongolia, Philippines, Iceland, Uganda, Sri Lanka, United Kingdom, Kenya, Iraq, Egypt
Low 1.1–2.0	Malaysia, Greece, South Africa, Iran, Russian Federation, Norway, Canada, Cuba, USA, Sweden Indonesia, Denmark, The Netherlands, Australia, New Zealand, China, Israel, Spain, Finland, United Arab Emirates, Austria, Switzerland
High 2.1–4.0	Democratic Republic of Korea, Thailand, Germany, Brazil, India, Pakistan, Saudi Arabia, Ireland, Singapore, Argentina, Italy, Qatar, Poland, Colombia, Uruguay
Very high 4.1–13.4	Japan, Czech Republic, Mexico, Republic of Korea, Bangladesh, Peru, Nepal, Bolivia, Chile

* The rates are per 100,000 and adjusted for age.

Source: data from Ferlay J. et al., GLOBOCAN 2008 v2.0, *Cancer Incidence and Mortality Worldwide: IARC CancerBase No. 10*, International Agency for Research on Cancer, Lyon, France, Copyright © 2010, available from <http://globocan.iarc.fr>.

in biliary epithelial damage and chronic inflammation [12]. The molecular alterations found in GBC tissues in patients with an APBD junction are different from those in the setting of gallstone disease. Most GBCs are strongly associated with genetic and environmental factors facilitating the development of gallstones. There is a strong association between gallstones and GBC in numerous studies [12–14]. Gallstones are found in 70 to 90% of patients with GBC. However, the overall incidence of GBC in patients with cholelithiasis is only 0.2 to 3%. Less than 1% of gall bladders removed for symptomatic stone disease show evidence of incidental GBC. The risk of GBC is higher with larger gallstones and of long-standing duration. The risk of GBC in porcelain gall bladder is lower than what was initially reported [15].

There are several other risk factors for GBC including gall bladder polyps, chronic infections, congenital anomalies, exposure to toxins, obesity, diabetes, etc. The proportions of GBC attributable to these risk factors vary widely in different geographic regions. Gall bladder polyps are mucosal protuberances detected incidentally on ultrasonography or after cholecystectomy. The gall bladder polyps mostly occur in the absence of cholelithiasis, and chronic inflammation is usually absent [12]. The benign polyps are sub-classified as non-neoplastic (e.g., cholesterol and inflammatory polyps, adenomyomas) or neoplastic (e.g., adenomas, leiomyomas) depending on the histopathologic features. The malignant potential of an adenoma is variable, and the frequency of progression from adenoma to carcinoma is unclear.

Several reports have associated biliary cysts and APBD junction and GBC. Biliary cysts are congenital or acquired dilatation of the biliary tree, often associated with other anatomic abnormalities of the biliary tract [16]. The APBD and biliary cysts are more common in East Asians. There is a strong association between GBC and chronic infection of the gall bladder and biliary tract by *Salmonella* and *Helicobacter* in endemic regions. Socio-economic factors that facilitate chronic infections of the gall bladder and biliary tract by pathogenic bacteria like *Salmonella* and *Helicobacter* are also

important. The chronic carrier state occurs most often in individuals with cholelithiasis, and gallstones appear to be the primary cause of the ongoing infection and inflammation. While typhoid carrier state is an established strong risk factor for GBC, the causal role of *Helicobacter* infection needs more studies [17]. Cigarette smoking, obesity, and diabetes have been associated with GBC in several large studies [18–20]. A small proportion of GBCs are associated with drugs like methyldopa, isoniazid, and oral contraceptives; exposure to industrial toxins among occupations handling oil, paper, chemicals, shoe, textiles, and cellulose acetate fibres; and manufacturing industries and miners exposed to radon.

Cholangiocarcinoma

The term cholangiocarcinoma is used to include intrahepatic, perihilar, and extrahepatic bile duct cancers. These tumours accounts for about 3% of all digestive cancers. The proportions of intrahepatic cholangiocarcinoma (IHCC) are variable and make up about 15% of all primary liver cancers and the prevalences of extrahepatocellular carcinoma (EHCC) vary in different parts of the world and constitute about one-third of all cancers grouped as gall bladder cancers. The recent time trends for cholangiocarcinoma are noteworthy [21, 22]. The incidence of IHCC has been rising in most parts of Europe, North America, Asia, Japan, and Australia like the HCC trends. The incidence rates of EHCC have been declining like GBC trends. This is partly attributed to changes in the International Classification of Disease classification, and better diagnostic methods [23]. However, part of this trend is related to increase in risk factors such as chronic liver disease. The decreasing incidence of EHCC is largely unexplained, and is attributed to reducing risk factors such as uncontrolled inflammatory bowel disease, smoking, and biliary infestations and infections. In contrast to GBC, the incidence of cholangiocarcinoma is several-fold higher in men [8]. The incidence of cholangiocarcinoma steadily increases with age, but those associated with primary sclerosing cholangitis (PSC) and choledochal cysts occur few decades earlier [24].

The risk factors for cholangiocarcinoma vary widely in different geographical regions [22]. Chronic inflammation is the trigger for the development of cholangiocarcinoma like GBC [25]. IHCC is strongly associated with chronic liver diseases and EHCC is associated with inflammatory conditions of the biliary tract [22–27]. In Western countries, PSC and choledochal cysts are the major risk factors for cholangiocarcinoma [24]. In Asian regions, chronic intrahepatic stone disease, recurrent pyogenic cholangitis, and parasitic infestations are the common causes of EHCC [28].

Chronic inflammation of the biliary tree due to PSC causes fibrosis and stricturing of the intrahepatic and/or extrahepatic bile ducts. Symptomatic or asymptomatic ulcerative colitis is very frequently found in PSC and about 30% of patients with EHCC have ulcerative colitis. The lifetime risk of cholangiocarcinoma in patients with ulcerative colitis has been is estimated to be 10 to 15% but autopsy studies reveal higher risk. Tobacco and alcohol abuse and genetic predispositions also contribute to the risk of cholangiocarcinoma in patients with PSC. Patients with choledochal cysts of various subtypes are at increased risk of developing cholangiocarcinoma at a younger age. The postulated mechanism involves chronic inflammation triggered by biliary stasis, reflux of pancreatic juice, or deconjugation of carcinogens.

Parasitic infection with liver flukes of the genera *Clonorchis* and *Opisthorchis* are associated with IHCC [28]. The highest

parasite-related cholangiocarcinomas are reported from Thailand. The fluke larvae present in fish enters the human body by eating undercooked fish and reach maturity in the biliary tract. Adult flukes lay eggs in the biliary tract and initiate a chronic inflammation. Secondary bacterial infection, smoking, and alcohol are found to be cofactors. Increased risk (lower than for GBC) between gallstone disease and cholangiocarcinoma has been reported [14]. Chronic intrahepatic stone disease, also called recurrent pyogenic cholangitis or hepatolithiasis, is associated with cholangiocarcinoma. This disease is endemic in many parts of East Asia and is rare in Western countries. The exact cause of hepatolithiasis is unknown, and is probably related to congenital ductal abnormalities or chronic infection by bacterial or parasitic infestations. The intrahepatic stones are composed of calcium bilirubinate (brown pigment stones), suggesting that bacterial deconjugation of stagnant bile is responsible.

The finding of IHCC in explanted cirrhotic livers indicates that chronic hepatic inflammation is an important mechanism for the development of IHCC. A cohort study from Denmark reported a ten-fold higher risk for IHCC in patients with chronic liver disease compared to the general population. Several studies have reported an increased risk for IHCC (lower than for HCC) in patients with hepatitis C virus (HCV)-related chronic liver disease. An increased risk of IHHC in patients with chronic hepatitis B virus infection has been reported. Chronic liver disease from non-viral etiology is also associated with IHCC. Populations of HIV infected individuals are at increased risk of IHCC, and some of this association is due to coexisting chronic liver disease.

Exposure to Thorotrast (a radiologic contrast now banned) has been associated with the development of cholangiocarcinoma. Other associations include exposure to occupational toxins among those working in the automotive, rubber, chemical, and wood-finishing industries. Hereditary non-polyposis colorectal cancer, biliary papillomatosis, and hemochromatosis are some genetic disorders with increased risk of cholangiocarcinoma. Cigarette smoking, obesity, and diabetes have also been associated with GBC in several large studies.

Microbiology and pathology of hepatobiliary cancer

The majority of hepatobiliary (HB) cancers are caused by chronic inflammation of the liver parenchyma or the epithelium of the bile ducts. Over 80% of the global burden of hepatocellular cancer (HCC) is attributed to chronic hepatitis caused by hepatitis B virus (HBV) or hepatitis C virus (HCV) [29, 30]. A small proportion of HCCs are caused by mixed HBV and HCV infections or co-infection of HBV carriers with hepatitis delta virus (HDV) [30, 31]. Chronic HBV and HCV infections also cause IHCC [32]. Most of the IHCCs in high-incidence regions are caused by chronic infestation of intrahepatic bile ducts with liver flukes [33]. A strong association between gall bladder cancer and carrier state of *Salmonella typhi* and *S. paratyphi* has been reported in many studies. This may be a secondary phenomenon as the majority of these patients harbour gallstones. There are increasing reports associating various Helicobacter species (*H. bilis, H. hepaticus*, and *H. pylori*) with gall bladder cancer. More studies are needed to confirm if this association is causal. The wide variations in the incidence rates of HB cancers are explainable by regional variations in the prevalence of chronic infection with HBV, HCV, other parasites, and other environmental toxins.

Hepatitis B

There is a strong causal association between chronic HBV infection and HCC and the geographical incidence of HCC closely follows the regional HBV carrier rates classified as high, intermediate, and low-prevalence regions. Most of the HBV infection has been acquired vertically by perinatal transmission in high-prevalence regions, while horizontal transmission is more often the mechanism in low-incidence regions. Decades of HBV vaccination has reduced the incidence of HBV-related HCC [34]. Although patients with chronic HBV can develop HCC in the absence of cirrhosis, over 70 to 90% of patients with HBV-associated HCC have cirrhosis. Several HBV-related factors modify the risk of developing HCC. This includes the viral load of HBV, the presence of hepatitis B e antigen (HBeAg), the presence of hepatitis B surface antigen (HBsAg), the genotype of HBV, the presence or absence of cirrhosis, and the use of antiviral therapies [35–40]. The risk of HCC is proportional to the viral load of HBV DNA and the risk is lower in those who have low levels. The HBV DNA load is an independent risk factor for HCC after adjusting for other known risk factors including male sex, older age, smoking, alcohol consumption, HBeAg status, serum alanine transaminase (ALT) level, and the presence of cirrhosis. The HBV DNA load tends to fluctuate and a single measurement can be misleading. Presence of high HBV DNA loads and active inflammation (elevated ALT) are indicators of high risk of developing HCC and such patients are advised to undergo regular surveillance for HCC. Active viral replication suggested by HBeAg positivity is also an independent predictive marker for the progression to HCC after adjustment for other risk factors. Patients with inactive carrier state (HBsAg positive but HBeAg negative) and those having serologically resolved infections (HBsAg negative, HBsAg positive) are also at an increased risk of developing HCC compared to the general population. Suppression of the viral replication with antiviral therapies helps in reducing the incidence of HBV-related HCC. Systematic review of multiple studies indicates that the relative risk for developing HCC is reduced substantially with effective anti-HBV therapies. The development of antibiotic resistance increases the risk for HCC. Dual infection with HCV and co-infection with HDV are associated with a higher risk of developing HCC. Several other risk factors such as older age, family history of HCC, habitual alcohol consumption, cigarette smoking, exposure to aflatoxin, the presence of core and precore mutations, and higher hepatic iron reserves increase the risk of developing HCC in patients with chronic HBV infection.

Hepatitis C

There is a strong causal association between chronic HCV infection and HCC [41]. Chronic HCV is an increasing cause of HCC in developed countries and is responsible for the rising incidence rates of HCC in North America, Europe, and Japan. The cumulative lifetime risk for developing HCC with chronic HCV infection is higher in men. Like HBV-related HCC, patients with higher HCV viral loads have increased risk of developing HCC. It is generally agreed that HCC arises as a result of chronic inflammation caused by the hepatitis C virus and HCV-induced HCC correlates well with the degree of inflammation and necrosis. Advanced stages of hepatic fibrosis or cirrhosis are found in nearly 90% of patients

with HCV-associated HCC. HBV-related HCC, on the other hand, does not correlate very well with hepatic inflammation, as oncogene activation by replicating HBV is an important mechanism for the development of HCC. The HCV genotype can modify the risk of developing HCC, and antiviral therapy that reduces the viral load and achieves sustained virologic response (i.e., viral clearance) reduces the risk of developing HCC in these patients [42]. Other cofactors that increase the risk of HCC in patients with chronic HCV include heavy alcohol use, diabetes mellitus, increased hepatic iron, and non-alcoholic fatty liver disease [43]. Reductions of HCV infections are now achievable with interferon, ribavirin, and protease and polymerase inhibitors; although achievable with some toxicity and cost, these treatments could reduce the development of HCC in some populations.

Liver flukes

Several liver flukes (trematodes) infest humans as opportunistic hosts and are an important cause of cholangiocarcinoma [44–45]. They include: *Clonorchis sinensis, Opisthorchis* species, *Metorchis conjunctus*, and *Fasciola hepatica. Clonorchis sinensis* (Chinese liver fluke) is endemic in many regions of the Far East in Japan, China, Korea, Taiwan, Vietnam, and parts of eastern Russia [33, 44–47]. Clonorchis is a fish parasite and infests fish-eating mammals like dogs and cats, which serve as the common reservoirs. It is estimated that there are over 600 million people at risk and more than 35 million people have been infected worldwide. Opisthorchiasis is generally caused by accidental infestation of humans by *O. felineus* or *O. viverrini*, a fish parasite which infests fish-eating mammals that also serve as the common reservoirs. *O. felineus* is seen in South-east Asia and in central and eastern Europe (Siberia and other parts of the former Soviet Union). It has been estimated that over 16 million people have been infested and the prevalence rates are very high up to 40 to 95% in some regions. *O. viverrini* is an endemic liver fluke in Thailand, Cambodia, Laos, and Vietnam. It is estimated that over 23 million people are infected worldwide, with prevalence rates of 24 to 90% in some regions of Thailand and 40 to 80% in Laos. *Metorchis conjunctus* is a liver fluke endemic to North America and Russia. It is in the same Opisthorchiidae family as *C. sinensis, O. viverrini*, and *O. felineus* and share same life cycle. This fluke is common among native Canadians. It is unknown whether prolonged infection and biliary complications can occur with *M. conjunctus*.

The adult flukes take about a month to mature and may range in size from a few millimetres to several centimetres depending on the species. The adult liver flukes can remain in the bile ducts for two or more decades. Repeat infections are frequent as protective immunity is ineffective, and cumulative worm burden can be high in endemic regions. Symptomatic infection is delayed for many years and commonly manifests in older adults. Travellers and immigrants from endemic areas harbouring the flukes may take it to non-endemic areas as demonstrated in surveys of South-east Asian immigrants. Frozen, dried, and pickled fish may contain surviving larvae and infect individuals who have never travelled to endemic areas. Biliary stones may be formed over dead parasites or ova. Obstructive jaundice, pancreatitis, recurrent cholangitis, and pyogenic liver abscesses, cholangiohepatitis, are some of the common clinical manifestations. Chronic irritation of the epithelial cells eventually leads to hyperplasia, dysplasia, and fibrosis. This may result in pigment stone formation, biliary strictures, dilation of intrahepatic bile ducts, with fibrosis of hepatic cells and IHCC as delayed complications. There are community-based programs running in Thailand and other East Asian regions to control liver fluke infestation by various interventions to reduce the incidence of cholangiocarcinoma [45].

Pathology

The World Health Organization (WHO) classification is used for pathological subtyping of HB cancers [48]. Histopathology subtypes of liver cancers include hepatocellular carcinoma (HCC), intrahepatic cholangiocarcinoma (IHCC), combined hepatocellular and cholangiocarcinoma (CHCC), bile duct cyst adenocarcinoma, hepatoblastoma, and undifferentiated carcinoma. The subtypes of extrahepatic bile ducts and gall bladder cancer include: adenocarcinoma, papillary adenocarcinoma, adenocarcinoma, intestinal type adenocarcinoma, gastric foveolar type, mucinous adenocarcinoma, clear cell adenocarcinoma, signet-ring cell carcinoma, adenosquamous carcinoma, squamous cell carcinoma, small cell (oat cell) carcinoma, large cell neuroendocrine carcinoma, undifferentiated carcinoma, and biliary cystadenoma. There is no pathognomonic immunohistochemical stain to confirm the cell type of origin of HB cancers. Immunohistochemical staining for cytokeratin-7 (CK-7) and hepatocyte paraffin 1 monoclonal antibody (Hep Par 1) is used to support the pathological diagnosis of cholangiocarcinoma and HCC.

When patients are on a screening program, most of the HCCs are diagnosed non-invasively using defined radiological criteria. An image-guided biopsy (core biopsy is preferred) is needed in patients with atypical features, when the diagnosis is uncertain and before using chemotherapy or targeted therapy in non-resectable cancers. The HCCs are often multicentric in nature. The microscopic appearance vary from well-differentiated (malignant hepatocytes appearing nearly identical to normal hepatocytes) to poorly-differentiated lesions (large multinucleate anaplastic tumour giant cells). Central necrosis is common in larger cancers. The surrounding liver has features of the primary cause of the chronic liver disease and dysplasia in a cirrhotic liver is the only finding. The cholangiocarcinomas are classified by their location in the biliary tree: IHCC, hilar cholangiocarcinoma, and EHCC. Simultaneous involvement of multiple sites is infrequent. Adenocarcinomas comprise nearly 90% of all cholangiocarcinomas with varying desmoplastic reaction. The gross appearance may be papillary, sclerosing, nodular, and combined type. The cholangiocarcinoma tends to grow slowly, invade locally, produce mucin, invade perineural sheaths, and distant metastases are uncommon. Preoperative diagnosis by biopsy or cytology is difficult due to the desmoplastic fibrosis. Cholangiocarcinoma caused by chronic biliary disease (e.g., hepatolithiasis) may harbour precancerous lesions like dysplasia and carcinoma in situ. Adenocarcinomas comprise nearly 90% of all primary gall bladder cancers. The gross appearance may be papillary, infiltrative, nodular, and combined type. GBC with papillary subtypes have the best prognosis. Gall bladder cancers invade the wall and beyond to the liver and other adjoining organs easily because of the lack of a well-defined muscularis layer.

Imaging of hepatobiliary cancers

Ultrasound is conventionally the first-line modality in imaging the liver and biliary tract for detection of focal liver lesions (FLL)

and assessment of biliary tract dilatation. Good quality ultrasound can characterize a definite benign lesion (e.g., cyst), from a definite malignant lesion (e.g., metastasis). However, due to considerable overlap in appearance of benign and malignant lesions, accurate characterization is often not possible using unenhanced ultrasound alone.

Obese patients and those with altered anatomy can be particularly difficult to evaluate with ultrasound. Fatty liver attenuates ultrasound resulting in poor liver penetration, reducing confidence in accurate evaluation of the entire liver; it should not be used when there is a high clinical suspicion of malignancy. Although ultrasound is frequently used to assess biliary dilatation, it is less useful in determining the aetiology. Dilatation of the ducts can suggest the presence of malignancy in a high-risk patient, but due to frequent overlying gastric and duodenal gas, the ducts are rarely seen throughout their entire course.

The advent of ultrasound contrast bubbles (CEUS) has significantly increased the sensitivity and specificity of FLL [49]. CEUS assesses real-time lesion vascularity with a temporal resolution superior to that of other imaging modalities [50]. CEUS enhancement pattern of FLL is similar to that of contrast enhanced computed tomography (CT) and magnetic resonance (MR). Portal venous invasion and tumour thrombus being well depicted [51], CEUS is particularly useful in patients with renal failure, where CT and MR contrast agents are contraindicated due to the risk of increasing renal failure and nephrogenic systemic fibrosis.

CT is widely used to assess HB cancers. The spatial resolution and ability to perform multiphase and multiplanar images result in a high sensitivity and specificity in detecting, characterizing, and staging cancers. It is also the first-line imaging modality used for patients with liver metastases from an unknown primary.

Triphasic scans are conventionally used to assess HB tumours (Figure 41.2). The phase depends on the type of tumour being assessed. An unenhanced, arterial, and portal venous phase scan is used to assess cirrhotic livers. Hyperdense nodules corresponding to iron-rich regenerative nodules appear denser than the surrounding liver, giving false positive readings of arterial enhancement. An unenhanced scan of the liver is performed to assess nodule density before contrast is administered. This phase provides a more accurate assessment of arterial enhancement and washout when assessing small HCCs. Due to the angiogenesis of HCC in cirrhotic livers [52], it can be difficult to differentiate a regenerative nodule from well-differentiated HCC. In these patients, short-term follow-up is often necessary to assess for change in the enhancement characteristics of nodules. Due to the heavy radiation burden of CT, MR or CEUS is considered more appropriate for these patients.

Cholangiocarcinomas are hypovascular, and due to the desmoplastic reaction typically seen within these lesions, and there is progressive enhancement of the lesion with time. Therefore, an arterial, portal, and delayed five-minute scan is performed to assess the full extent of the tumour. Vascular contact and invasion is accurately depicted on CT.
Fig. 41.2 HCC. Arterial phase CT (A) showing lobulated tumour enhancement and fat within the tumour. Arteriography at the time of TACE showing tumour arterialization in the early phase (B) followed by contrast staining a few seconds later. (C) Arterial CT (D) after three TACE procedures over six months showing reduced size and disappearance of arterial enhancement.

Whole body CT is performed to assess for distant metastases. Multiplanar reformats aid the surgeon in assessing the vascular supply to the liver and variants in the vascular and biliary structures. CT is conventionally used in the follow-up of patients post-treatment due to the uniformity and reproducibility of the images for the purposes of RECIST criteria.

MR of the liver can be superior to CT in characterizing liver lesions and detecting small liver metastases [53, 54]. The advent of liver specific contrast agents have significantly improved lesion characterization and detection [55, 56] particularly in differentiating small HCC from regenerative nodules [57]. These contrast agents are taken up by normally functioning hepatocytes. A lesion not containing hepatocytes will not take up contrast, and will appear dark against an enhancing liver. These contrast agents are now being used more frequently due to the ability to detect more lesions on the liver specific phase together with the conventional sequences, than on conventional contrast enhanced CT alone. This is particularly important for colorectal liver metastases prior to consideration of liver resection [58].

Although the biliary tract is seen well on CT, MR is superior in assessment of the biliary tree. Contrast MR and magnetic resonance cholangio-pancreatography (MRCP) is the imaging modality of choice in the assessment of the liver and biliary tree particularly in hilar (mostly infiltrating) and intraductal cholangiocarcinoma for the purposes of resectability [59]. The 3D maximum intensity projection (MIP) image of the biliary tree depicts the extent of duct dilatation, stricturing, and invasion of the intra- and extrahepatic ducts necessary for tumour staging. Contrast enhanced MR depicts the extent of the lesion and vascular contact, and the presence of satellite lesions. Liver-specific MR contrast agents are excreted in bile, providing further assessment of the biliary tract with an enhanced MRCP image. Diffusion weighted imaging of the liver has been shown to be useful in the characterization of FLL. This sequence has found to be particularly useful for the detection of small liver metastases [60] and has proved useful in the identification of an HCC amongst regenerative nodules in the cirrhotic liver [61]. Its role in the assessment of tumour responsiveness to chemotherapy and follow-up is being evaluated [62].

Positron emission tomography (PET) utilizes the increase in glycolysis in cells to depict metabolically active lesions. This is not only seen in tumour cells, but also in normal and inflamed tissue. Therefore PET can be sensitive, but not always specific. The uptake of tracer is variable in HCC, with low sensitivity compared to CT. Regenerative nodules can show increased tracer uptake compared to HCC. Disease staging using PET is only useful if the primary tumour is metabolically avid [63]. Peripheral cholangiocarcinomas are hypermetabolic but hilar and intraductal cholangiocarcinomas demonstrate low uptake of tracer. PET CT may be used in staging and characterizing peripheral tumours but its use is otherwise limited. PET MR is an emerging technique for assessment of colorectal liver metastases and has been shown to be superior to PET CT in their detection [64]. There is limited literature to date about the usefulness of PET MR in primary liver and ductal carcinomas.

Interventional biliary endoscopy

With improved cross-sectional and diagnostic imaging modalities, interventional biliary endoscopy is now rarely required for diagnosis. MRI now provides high quality cholangiography and cross-sectional imaging (65–67). Endoscopic ultrasound (EUS) [68, 69] provides views from the gut lumen which are particularly useful for diagnostic imaging of the extrahepatic biliary tree and pancreas. The improved quality of CT [70–72] provides accurate diagnosis and staging of HB malignancies, thereby avoiding the risks of endoscopic retrograde cholangio-pancreatography (ERCP).

Endoscopic ultrasound

EUS evaluates the extrahepatic biliary tree, including indeterminate lymphadenopathy at the porta hepatis and para-aortic regions. EUS provides detailed views of the bile ducts, ampulla, pancreas, and liver hilum. EUS does not carry the associated risks of ERCP. Radial EUS provides a 360° image, whereas linear EUS provides a view in the plane of the scope and allows for the sampling of tissue via biopsy or fine needle aspiration (FNA) [73, 74]. EUS is also the most sensitive tool for diagnosing small bile duct calculi.

Endoscopic retrograde cholangio-pancreatography

ERCP provides access to the biliary tree and is complimentary to percutaneous transhepatic cholangiography (PTC) in both the investigation and management of biliary tract tumours. Initially a diagnostic tool, ERCP is now largely a therapeutic modality in view of the associated complication rate. At ERCP, a side viewing duodenoscope is passed to the second part of the duodenum, sitting opposite the Ampulla of Vater to enable cannulation. The duct of choice (normally the common bile duct), is then accessed, normally using a wire guided cannulation technique. A 0.035″ diameter wire is passed into the duct of choice and a cholangiogram obtained with fluoroscopic screening to provide diagnostic imaging. Tissue acquisition can be performed at the time for suspected malignant disease using brush cytology sampling, which carries a relatively low diagnostic yield [75, 76], or by the passage of small biopsy forceps into the duct to enable formal biopsy, with increasing diagnostic yield.

In biliary malignancy, therapeutic ERCP is often used to investigate obstructive jaundice [77]. The type of intervention depends on the site and stage of tumour, and the planned treatment course. ERCP and biliary drainage must only be performed following high quality cross-sectional diagnostic imaging and discussions regarding operability for patients with proximal cholangiocarcinoma. As the surgical options for hilar cholangiocarcinomas involve major liver resections, communication between the liver surgeon and endoscopist is essential to allow accurate planning of any preoperative ERCP with appropriate drainage of the planned future liver remnant (FLR). There is increasing use of self-expanding metallic stents (SEMS) to decompress obstructed bile ducts prior to such planned liver surgery [78]. Given the complex and multidisciplinary nature of these decisions, drainage procedures for proximal biliary malignancies should only be performed in specialist hepatobiliary units.

The majority of patients undergoing endoscopic stenting for proximal biliary malignancies will not be operable, and in these cases adequate biliary drainage is paramount for good palliation of jaundice, but the decision about whether to drain proximal biliary obstruction endoscopically or percutaneously may be unclear. However, in potentially operable cases, the goal is to enable adequate internal biliary drainage of the appropriate segment(s) of the FLR. It is not uncommon that combined endoscopic and percutaneous interventions will be necessary. The choice about whether these interventions should be primarily endoscopic or

percutaneous depends on available local expertise: however, both modalities should be available to maximize the chances of successful biliary drainage for all cases.

When performing ERCP on patients with hilar tumours it is essential to ensure drainage of all opacified segments, as failure to do so increases biliary sepsis and mortality [79, 80]. Adequate biliary drainage can be achieved to palliate jaundice by draining just 30% of the liver, which involves unilateral drainage of the FLR [81, 82]. With more aggressive biliary drainage and reduction of sepsis complicating biliary obstruction, patients will be palliated for longer; therefore, draining just 30% of the liver is unlikely to be adequate long-term, especially given the risks of sepsis associated with systemic chemotherapy. Therefore, drainage of at least 50% of the liver volume should be done, which will often involve bilateral stents. One should avoid drainage of atrophic liver segments, which increases the risks of sepsis, while not providing drainage to the FLR.

Direct endoscopic cholangioscopy

Cholangioscopy enables direct visualization of the bile ducts, either operatively or endoscopically. Originally, mother and baby ERCP cholangioscopy only visualized the biliary mucosa of the common duct, and required two endoscopists to operate. This has changed with the development of the new SpyGlass™ (Boston Scientific) cholangioscope. SpyGlass™ cholangioscopy enables a single operator to visualise the biliary mucosa to at least second and third order ducts, with the benefit of a working channel to allow directly visualised biopsies and therapy applied. Directly targeted biopsies improve the diagnostic yield to >80% in patients with indeterminate biliary strictures [83, 84]. While the use of diagnostic ERCPs has decreased significantly, the benefit of direct ERCP cholangioscopy is clear. In our practice, such cholangioscopy is only performed following a specialized multidisciplinary review of all non-invasive and cross-sectional imaging.

Multidisciplinary management of HCC

Diagnosis and staging: surveillance for HCC in high-risk groups

There is little strong evidence for the surveillance of patients with cirrhosis, or other high-risk groups for HCC. Only one randomized controlled trial has been performed in a Chinese population with predominantly chronic Hepatitis B infection [85]. While this study did show detection of earlier stage disease and better outcomes in the surveillance group, this was only adhered to in about 60% of patients. The authors concluded that the benefit may be greater if surveillance protocols were more rigidly followed. Other uncontrolled (mostly retrospective) studies have shown detection of earlier stage disease and better survival in surveillance groups [86–88]. There are no randomized controlled trials examining HCC surveillance in Western populations.

Despite the lack of grade one evidence, most authorities on liver disease advocate the surveillance of identified high-risk groups (cirrhosis, non-cirrhotic chronic Hepatitis B and C infection) [89–92]. Given the wide use and recommendation of surveillance strategies in managing these patients, it is unlikely that a randomized controlled trial of surveillance for HCC will take place in a Western country. Currently, surveillance is recommended in the form of six-monthly liver ultrasound scans and serum alpha-feto

Table 41.2 Child-Pugh score

	1	2	3

protein (AFP) measurement. It is hoped that this regimen will diagnose more tumours in their earlier stages where active treatments are available for either potential cure or disease control. The goal of surveillance is cost-effective monitoring of high-risk groups to diagnose disease at an early and treatable stage. Given current methods, AFP is not raised in a large proportion of HCCs, particularly in those small enough for potentially cure, so while cheap, AFP may not be particularly effective as a sole surveillance marker [93, 94]. Ultrasound, whilst more expensive to perform, has a better sensitivity and specificity for the identification of liver lesions that can then be characterized further using more detailed imaging methods [95]. While surveillance of at risk groups is useful, a significant proportion of patients present with HCC without a known prior history of chronic liver disease and, increasingly, HCC is seen as the presenting problem in patients with NASH cirrhosis.

Assessment of severity of cirrhosis

Assessment of the liver function is necessary to determine the appropriate treatment of patients with HCC with cirrhosis. For patients to be treated with either loco-regional therapies or occasionally surgical resection requires preserved hepatic synthetic function. The severity of liver disease and degree of liver failure can be measured using various clinical and laboratory parameters. The standard bedside assessment, and that used as a part of the Barcelona Clinic for Liver Cancer (BCLC) staging algorithm [96] involves the use of the Child-Pugh score [97]. The Child-Pugh score is detailed in Table 41.2, where a Child-Pugh score ≤6 relates to well-compensated cirrhosis or good liver function with a good prognosis (Child-Pugh A). A Child-Pugh score ≥10 equates to decompensated liver disease or liver failure with a bad prognosis (Child-Pugh C); while Child-Pugh score 7–9 (Child-Pugh B) relates to a prognosis between A and C. When assessing patients for liver transplantation for parenchymal liver failure, transplant centres tend to stratify severity using the model of end-stage liver disease (MELD) [98], or in the UK a variant on this which includes the prognostic value of a serum sodium level, the United Kingdom end-stage liver disease score (UKELD) [99] (Table 41.3).

Decision making in hepatocellular carcinoma

While the decision making algorithm for most cancer patients depends on both staging of the disease and patient fitness (performance status), the severity and stage of liver disease is a third aspect that needs to be taken into consideration in patients with cirrhosis and HCC. The diagnosis of HCC is frequently made

Table 41.3 MELD and UKELD Scores

MELD Score	MELD = 9.57 × log$_e$(creatinine, mg/dl) + 3.78 × log$_e$(total bilirubin, mg/dl) + 11.2 × log$_e$(INR) + 6.43
UKELD Score	5 × [1.5 × log$_e$(INR) + 0.3 × log$_e$(creatinine, μmol/l) + 0.6 × log$_e$(bilirubin, μmol/l) − 13 × log$_e$(serum sodium, mmol/l) + 70]

against a background history of chronic liver disease, an elevated or rising serum AFP and radiology of the liver (see above). Biopsy should only be a last resort, and then only performed at the tertiary liver centre because of the real risk of tumour seeding (see Figure 41.3). For the majority of treatment modalities, synthetic liver function has to be preserved (Child-Pugh A or B). Treatments for HCC are decided largely according to the BCLC criteria (Figure 41.4) [96]. The BCLC staging system encompasses tumour characteristics as well as performance status and liver function. BCLC as a tool to stage and direct treatment has been adopted as the preferential system for both the European (EASL-EORTC) and American (AASLD) guidelines for the treatment of HCC [89, 90, 92].

In those with good performance status and well-compensated liver disease, the options for treatment are based on tumour factors, particularly the number of and size of the HCCs. The other significant tumour factor relates to the presence of extrahepatic disease and vascular involvement which contraindicate resection, transplantation, or loco-regional therapies. Potentially curative options include surgery: resection, transplantation or ablation of the HCC. Many patients are not amenable for curative treatment and benefit from palliative approaches with loco-regional or systemic therapies.

Surgery

Resection

Resection should be considered in all non-cirrhotic patients with HCC. In those fit to undergo liver resection, the site of the tumour
Fig. 41.3 Operative photograph of macroscopically visible liver capsule deposit of HCC at site of previous diagnostic biopsy.

and relationship to vessels will determine operability. In those patients with cirrhosis, the decision to resect is more complex, with an increased risk of parenchymal liver failure (jaundice, ascites, coagulopathy) following resection. This risk of liver failure is greatest in those with portal hypertension complicating their cirrhosis. A small minority of patients, with well compensated (Child-Pugh A) cirrhosis and no portal hypertension may be amenable to undergo liver resection for HCC. With HCC resection, particularly in cirrhosis, as with ablative therapies, the underlying liver disease is not altered and the risk of recurrent disease continues, so ongoing surveillance is necessary [100]. One of the technical challenges in such surgery is the propensity of the tumour to grow down blood vessels and bile ducts (Figure 41.5).

Liver transplantation

Liver transplantation treats both HCC and the underlying liver disease. It should always be considered and is often the treatment of choice. While there is always a risk of recurrent disease in immunosuppressed post-transplant patients, the development of stringent criteria to select patients for transplantation reduces that risk. The widely used Milan criteria have been shown to give good outcomes, with five-year survival in excess of 70% post-transplant [101]. Milan criteria constitute a cirrhotic liver with a single lesion ≤5 cm or three lesions all ≤3 cm with no involvement of the portal vein and no extrahepatic disease [101]. While outcomes from liver transplantation for HCC within Milan criteria are good (and in keeping with those transplanted for non-tumour parenchymal liver failure), it has been felt to be restrictive, since patients with larger volumes of disease are still likely to benefit from transplantation. Extended criteria have been developed that appear to have similar outcomes when considering long-term survival.

The University of California at San Francisco (UCSF) produced and validated an extended criterion, comprising a single lesion ≤6.5 cm in diameter or three nodules, the largest ≤4.5 cm and total diameter ≤8 cm [102, 103]. While this study did not compare those within Milan criteria to those outside of it, the overall survival was comparable [102, 103]. A further, 'up to 7' criteria, based on a large volume review of factors present in those with positive outcomes from transplantation outside of Milan criteria has also been shown to have good post-transplant outcomes with comparable five-year survival rates [104]. The 'up to 7' criteria consist of the sum of size (in cm) and number of tumours for any given patient. This would allow one 6 cm tumour, two 5 cm tumours, three 4 cm tumours, etc. [104].

The major limitation for transplantation, and a significant factor in not extending the transplantation criteria for patients with HCC, is the shortage of available donor organs. It is accepted in both a recent review relating to this subject [105] and a recent published international consensus [106] that liver transplantation should be reserved for HCC patients who have a predicted five-year survival comparable to non-HCC patients, and that the Milan criteria be used as a benchmark for selection of HCC patients for liver transplantation, and as the basis for comparison with other suggested criteria. A caution to increasing the criteria beyond Milan has also been raised regarding the availability of organs for non-malignant indications. Markov modelling has shown that extending the criteria for transplantation for HCC would lead to an increase in deaths amongst those on the transplant waiting list for other indications [107].

Loco-regional treatments for hepatocellular carcinomas

Interventional techniques for hepatobiliary malignancy

Interventional radiology plays an ever increasing role in managing HB cancers. Minimally invasive treatment of HB malignancy is delivered either percutaneously using tissue ablative techniques or trans-arterially. Endoscopic therapies are covered elsewhere in this chapter. The liver has distinct attributes that allow targeted treatment, and there is considerable interest in the synergistic effect of systemic chemotherapy and targeted liver treatments for liver dominant disease. Even with significant extrahepatic disease burden, it is disease progression in the liver that determines survival.

HCC often arises against background chronic liver disease where liver resection carries high morbidity and recurrent tumours are common in the residual liver. Targeted treatment such as ablation or trans-arterial chemoembolization (TACE) preserve liver function to a great extent, and can frequently be repeated. HCC surveillance programs are detecting tumours much earlier, allowing more effective ablative techniques. Tumours up to 3 cm in maximal diameter are ablated with very low rates of residual disease leading to tumour recurrence [108]. A combination of ablation and TACE, or TACE alone, is used when the tumour exceeds 3.5 cm.

Thermal ablative technologies such as radiofrequency ablation, laser, microwave, and cryoablation have all become established in routine practice. High intensity focused ultrasound (HIFU) is still under development, but offers the opportunity to thermally ablate tumour without puncturing the skin [109]. Irreversible electroporation (IRE) is a non-thermal technique which may allow
Fig. 41.5 (A) CT scan showing HCC tumour thrombus occluding the portal vein, so causing cavernous transformation and portal venous collaterals. This patient is inoperable. (B) Operative photograph of HCC tumour thrombus retrieved from the common hepatic duct.

treatment of tumours deemed inaccessible for thermal ablative techniques [110].

Image guidance

All targeted treatments require high quality image guidance for maximum treatment efficacy and safety, CT and ultrasound being the most commonly used modalities. CEUS improves tumour visualization and assesses devascularization at the time of treatment [111]. Modern interventional suite fluoroscopy can create CT-like images while intra-arterial contrast is being injected. The exact artery supplying the tumour can be identified and TACE administered accordingly [112].

Catheter delivered treatment

The portal vein provides in excess of 80% of the blood supply to the normal liver, while the hepatic artery is the main supply to both primary and secondary liver tumours. This situation can be exploited when targeting tumours with trans-arterial drug-delivery systems. The venous outflow via the hepatic veins into the inferior vena cava can be occluded. The liver vascular dynamics are therefore relatively easy to manipulate [113].

Technique

Arterial access is usually via the common femoral artery, after which the coeliac and superior mesenteric arteries are imaged using a 4-5F catheter. A microcatheter (2-3F) is advanced within the 4F catheter to allow selection of the appropriate intrahepatic artery. If a solitary tumour is being treated then the catheter should be within the appropriate segmental artery, whereas if there is diffuse lobar disease the catheter is placed in the lobar artery. Total liver treatment with TACE is inadvisable due to the side effects, and most operators would treat individual lobes on separate occasions [114]. Conventional TACE for HCC involves injecting a slurry of particulate matter combining lipiodol (an oil-based contrast agent with a partial embolic effect) with chemotherapy, thereby slowing the passage of the chemotherapeutic agent through the tumour. It is highly visible on fluoroscopy and persists in the malignant microvasculature, due to the lack of Kupffer cells. This also aids targeting treatment at subsequent sessions [115] (see Figure 41.6).

Drug-eluting beads

Drug-eluting beads (DEB) overcome the problems of conventional TACE, where a significant amount of the cytotoxic component passes straight through the tumour capillary bed. The cytotoxic agent is bound to 30 um beads which do not to completely embolize the vessel supplying the tumour, but transport the cytotoxic agent to the tumour. The drug is then released into the surrounding tumour at a steady rate to ensure prolonged exposure and minimal systemic side effects [116, 117]. The bead size is selected to allow deep penetration into the tumour, without the risk of shunting into the systemic circulation. Doxorubicin is the drug of choice when used with DEB TACE for HCC while irinotecan is preferred when using DEB TACE to treat colorectal liver metastases [116, 117].

Selective internal radiation treatment

For many years, external beam radiation has not been used for liver tumours due to the unacceptably high risk of radiation hepatitis and damage to the adjacent soft tissue. However, many primary and secondary tumours are very susceptible to radiation and with improved technology in micro-catheter construction and carrier particles it is now possible to deliver radiation treatment internally.

Either a resin or glass bead is used to carry yttrium 90, a β-emitter, to the tumour capillary bed where it becomes trapped. β photons can penetrate up to 11 mm in soft tissue and so treatment remains localized to the liver. The half-life of yttrium 90 is 64 hours which, combined with the short range of penetration, means that the patient poses little or no radiation risk to others in close proximity. Up to 50% of liver replacement by tumour is considered safe so long as the background liver function is satisfactory, and the portal vein patent [118, 119].

Treatment is usually performed in two stages. An initial arteriogram demonstrates the anatomy, especially vessels that may supply extrahepatic structures. It is very important to identify all such vessels as a single mal-deployed particle will cause tissue necrosis. It is common practice to embolize the gastroduodenal artery (GDA) and the right gastric artery, both of which usually arise close to the origin of the right and left hepatic arteries. Reflux of particles into these vessels is likely to lead to gastroduodenal ulceration or pancreatitis. During the initial angiogram, and after embolization, a bolus of technetium bound to macro-aggregated albumin (MAA) is injected at the same site as the proposed SIRT injection. MAA is roughly the same diameter as SIRT particles and is a good surrogate to predict SIRT distribution. The patient undergoes radionuclide imaging immediately after injection of the technetium-MAA to look for sites of extrahepatic migration, and evidence of significant arterio-venous shunting into the pulmonary capillary bed. If there is significant shunting (>10%) then dose reduction should be considered. The patient returns to the interventional suite within two to three weeks for SIRT treatment. Unlike TACE, the embolic effect of SIRT is low which allows single session whole liver treatment with an acceptable side effect profile.

Chemosaturation

The liver can be excluded from the systemic circulation by placing a double occlusion balloon catheter in the inferior vena cava (IVC); one balloon in the supra-hepatic IVC and the other in the supra-renal IVC. High dose chemotherapy is then delivered to the whole liver via the hepatic artery. As for SIRT, any branches of the coeliac axis that may allow the chemotherapy to enter extrahepatic sites must first be occluded with embolization coils. The liver is remains saturated with chemotherapy for 30 minutes, before being removed from the isolated segment of IVC through a lumen in the balloon catheter. More than 90% of the chemotherapy is removed from the blood using a filtration and pump system, before being returned to the patient via an internal jugular vein sheath. The technique has shown promise in a phase II trial for ocular melanoma and sarcoma liver metastases [120].

Ablative techniques

Thermal ablation causes irreversible cell death by either heating or freezing tissue. Radiofrequency ablation (RFA), laser therapy, and microwave ablation are needle based systems that cause cell death by heating tumour cells to a temperature that produces coagulative necrosis or lesser degrees of irreversible cell death. Prolonged heating of cells at 50–55°C or short exposure to temperatures above 60°C produces irreversible cell death. RFA uses an alternating current to vibrate molecules creating frictional heat [121]. The ablation volume is gradually increased to avoid tissue desiccation which would be detrimental to current flow. A 4 cm diameter ablation can take 20 minutes to achieve with RFA, whereas microwave ablation takes approximately 2–4 minutes to achieve the same tissue
Fig. 41.6 Small HCC segment 7/8. (A) Arterial phase CT showing marked enhancement and (B) venous phase showing rapid washout of contrast. (C) Treated with CT guided RFA and follow-up scan at four weeks and (D) showing low attenuation ablation site.

destruction. As with other types of thermal ablation, the ablation zone size and shape is variable. Proximity of adjacent vessels has a significant adverse effect due to the cooling effect of the flowing blood, preventing adjacent tumour from reaching 60°C (heat sink effect) [122].

Irreversible electroporation

Irreversible electroporation (IRE) is a non-thermal tissue destruction technique which uses short blasts of electric current, passing between two or more parallel needles, to create irreparable holes in the cell membrane. This leads to uncontrollable ion transfer and apoptosis. Unlike thermal ablation, cell death does not depend on temperature-related coagulative necrosis and so the heat sink effect does not apply. There is also very little or no scarring following treatment. IRE destroys only cells, sparing collagen-based structures such as blood vessels, bowel wall, and bile ducts. These inherent qualities mean that it could be used at sites where thermal ablation is too dangerous, or where the heat sink effect is significant. IRE should avoid bile duct and arterial injury, allowing safe treatment of central liver tumours [123]. This is still a very novel technique requiring further evaluation.

Medical management of hepatocellular carcinomas

Surgical therapy, including transplantation, or local ablation may offer the prospect of cure for patients with hepatocellular carcinoma but are applicable to only a minority of patients. For other patients with preserved liver function and a patent portal venous system, chemoembolization may afford a modest survival benefit. However, as tumour size increases, the frequency of vascular invasion (micro and macroscopic) and the incidence of intrahepatic and extrahepatic spread increases thereby limiting the impact of local control. This forms the basis for guidelines, based on tumour size and number, above which local treatments are inappropriate. For patients beyond these criteria systemic therapy may be appropriate. Traditionally, this has taken the form of cytotoxic chemotherapy or endocrine manipulation although more recently molecular targeted therapies have been employed with some success.

Cytotoxic chemotherapy for advanced hepatocellular carcinoma

A large number of mostly uncontrolled studies have been performed using the major classes of chemotherapeutic drugs alone or in combination. Response rates for single-agent chemotherapy are low and durable remission is rare. The anthracycline, doxorubicin, has been the most studied agent. The overall response rate for more than 700 patients treated in a number of studies was 18%. The small, non-randomized design and patient heterogeneity in these trials make it difficult to assess any effect of doxorubicin on overall survival. One small randomized trial has compared doxorubicin with best supportive care. This reported a statistically significant survival advantage in favour of doxorubicin. However, with median survival of 10.6 weeks versus 7.5, the absolute difference in survival was modest with very short survival in both arms, suggesting

inclusion of patients with very advanced disease and/or poor liver function [124].

In five trials involving 118 patients treated with mitoxantrone, an anthracenedione, the response rate was 16%, with less toxicity; this became the first systemic agent to be licensed for use in HCC [125] although it has never been widely adopted as a standard of care.

A randomized trial has compared the oral fluoropyrimidine, UFT, with supportive care. UFT comprises tegafur, an orally active 5-FU prodrug metabolized by the liver to 5-FU, and uracil, a biochemical modulator of 5-FU via inhibition of dihydropyrimidine dehydrogenase (DPD, the rate limiting enzyme of 5-FU metabolism). HCC is reported to have high levels of DPD, which may explain resistance to 5-FU and, therefore, DPD inhibition may enhance 5-FU activity. Although objective responses to UFT were uncommon, there was a significant prolongation of survival (median 51 vs 27 weeks; p <0.01). This was a small study with only 28 patients per arm and larger studies are required, but it does suggest that radiological response may not correlate with survival [126]. In two recent large-scale trials drugs that had shown promising activity in early phase trials, Ti67, a novel tubulin-binding drug [127] and nolatrexed, a thymidylate synthase inhibitor [128], were tested against doxorubicin as the control arm. In the former, there was no survival improvement; in the latter, the patients in the doxorubicin arm survived significantly longer (6.9 compared to 4.7 months, hazard ratio 0.753) suggesting a possible impact of doxorubicin on survival and highlighting the uncertainty in predicting phase III trial outcome based on apparently promising phase II data.

Combination chemotherapy for advanced hepatocellular carcinoma

On the basis of its modest activity as a single agent, doxorubicin has been investigated in combination with a variety of other drugs. A phase II study of cisplatin, interferon alpha-2b, doxorubicin and 5-fluorouracil (PIAF) was encouraging; although the response rate was modest (26%), 9 of 13 partial responders had their disease rendered resectable and, in some of these, there was a complete pathological response [129]. Despite this encouraging activity, a prospective randomized study comparing PIAF to doxorubicin failed to demonstrate any improvement in survival with the combination [130].

Recently, a randomized phase III trial compared FOLFOX with doxorubicin in 371 Chinese patients with predominantly HBV-associated HCC. Although there was a trend to prolonged survival with FOLFOX (6.4 vs 4.9 months; HR 0.797), this difference was not statistically significant (p = 0.085) [131]. Despite some encouraging data, there remains no convincing evidence of survival benefit for systemic chemotherapy for HCC and chemotherapy in this setting may be poorly tolerated due to coexisting chronic liver disease resulting in unpredictable drug metabolism. Thus, many non-cytotoxic systemic therapies have been investigated.

Endocrine therapy for advanced hepatocellular carcinoma

Up to one-third of HCC express oestrogen receptors (ER) and animal models of liver carcinogenesis, as well as epidemiological studies, suggest a role for sex steroids in its pathogenesis. Initial studies suggested promising activity for tamoxifen. For example, a small trial randomizing 38 patients to tamoxifen or supportive care reported one-year survival of 22% and 5% respectively [132]. However, several larger studies have reported no benefit or, in the case of high-dose tamoxifen, a detrimental effect over placebo. For example, the Italian CLIP study including almost 500 patients randomized to tamoxifen or placebo reported median survival of 15 and 16 months, respectively (p = 0.54) [133]. In the setting of breast cancer, it is clear that ER-negative tumours derive no benefit from endocrine therapy. However, these HCC studies did not select patients on the basis of ER status. A randomized trial of tamoxifen compared with placebo has attempted to address this question. Of 119 patients, the ER status was determined in 66 but there was no difference in survival between patients with ER-positive or ER-negative tumours [134].

Targeting angiogenesis

HCC is a highly vascular tumour and, indeed, this forms the therapeutic basis of TACE. More recently, the molecular mechanisms mediating tumour angiogenesis have been elucidated and these have provided potential pharmacological targets. In particular, the fundamental role of angiogenic growth factor receptor signalling, most notably the importance of vascular endothelial growth factor (VEGF) signalling has been recognized. This process can be perturbed in a number of ways. Bevacizumab is a humanized monoclonal antibody against VEGF ligand and phase II trials have indicated activity against HCC, although there are concerns regarding the risk of GI bleeding and recent studies has mandated prophylactic treatment of varices prior to treatment [135]. VEGF receptor signalling can also be inhibited by small molecules targeting receptor tyrosine kinase activity.

Sorafenib for advanced hepatocellular carcinoma

Sorafenib is a small molecule inhibitor of tumour-cell proliferation and angiogenesis and induces apoptosis in a range of tumour models including HCC. It acts by inhibiting the serine–threonine kinases *Raf*-1 and B-*Raf* and the receptor tyrosine kinase activity of vascular endothelial growth factor receptors (VEGFRs) 1, 2, and 3 and platelet-derived growth factor receptor β (PDGFR-β). Results of a phase II study involving 137 patients with advanced hepatocellular carcinoma and Child-Pugh class A or B status indicated that sorafenib had encouraging activity [136]. On this basis, it was tested in a large phase III, double-blind, placebo-controlled trial. Median survival was 10.7 months in the sorafenib group and 7.9 months in the placebo group (hazard ratio 0.69; p <0.001) [137]. Diarrhoea, weight loss, hand-foot skin reaction, and hypophosphatemia were more frequent in the sorafenib group. A smaller confirmatory randomized phase III study, with the same eligibility criteria, was conducted in patients from the Asia-Pacific region (with predominantly HBV-driven cancers). Sorafenib again significantly prolonged survival (median 6.5 months vs 4.2 months, hazard ratio 0.68, p = 0.014) compared to placebo [138]. In the Asia-Pacific trial, more patients had extrahepatic disease, a greater number of hepatic lesions, and a poorer performance status which may, in part, explain the lower absolute overall survival and time to progression figures in this trial, although the aetiology of the predisposing liver disease may also be significant.

Sorafenib is thus the first systemic therapy to unequivocally demonstrate a survival advantage in selected patients with advanced HCC, good performance status and well compensated liver disease,

with the relative magnitude of benefit being similar to that achieved by targeted therapies in other cancer types, and has been approved by the United States Food and Drug Administration and by the European Medicines Agency for the treatment of advanced HCC.

Notably, there was no statistically significant difference in the median time to symptomatic progression between the two arms in either study. This may be explained by the validity of the assessment tool used, the counterbalance between improving tumour-related symptoms and treatment-related side effects and the additional complexity of cirrhosis-related symptoms, which may not improve despite effective anti-cancer therapy.

Use of sorafenib in patients with compromised liver function

These phase III trials were deliberately restricted to patients with well-preserved liver function in order to capture the potential survival benefit of sorafenib without confounding from deaths related to advanced liver disease and there remain limited data on the safety and efficacy of sorafenib in patients with Child-Pugh class B or C cirrhosis. In the phase II trial, 38 of the 137 patients enrolled had Child-Pugh B cirrhosis and the pharmacokinetic and toxicity profiles were similar to those with Child-Pugh A cirrhosis. However, patients with Child-Pugh class B status had a worse median overall survival (14 weeks vs 41 weeks) and an increased rate of encephalopathy and worsening ascites. For patients with Child-Pugh B cirrhosis, the available data suggest that sorafenib should be used with caution, and further prospective evaluation in this group is required.

Other targeted agents for advanced hepatocellular carcinomas

A growing number of molecules are now in clinical trials in patients with HCC and several large trials have been completed. The first of these investigated sunitinib, a potent inhibitor of VEGF and PDGF receptors as well as c-kit and flt-3, in a 1200 patient study [139]. However, again despite encouraging phase II data, sunitinib was significantly inferior to sorafenib (median survival 7.9 vs 10.2 months, HR 1.3; p = 0.001). There was greater toxicity and, consequently reduced dose intensity, in the sunitinib arm which may have contributed to its inferior efficacy. However, this study may also indicate the importance of *raf* inhibition in mediating the efficacy of sorafenib. Similarly disappointing results were reported from a large phase III trial of the potent VEGFR inhibitor, linifanib, which was terminated early due to toxicity, again reflecting the challenges of investigating systemic therapies in patients with HCC and underlying cirrhosis [140].

Since fibroblast growth factor (FGF) is an important alternative pathway of angiogenesis, it may contribute to resistance to VEGF-targeted drugs and thus brivanib, a VEGF and FGF receptor tyrosine kinase inhibitor, may have the potential to delay the emergence of such resistance. However, a recent large phase III trial of this drug also failed to improve outcomes compared with sorafenib [141].

A number of randomized trials have also been undertaken in the second-line setting and, whilst first-line trials have shown that agents with broadly similar mechanisms of action to sorafenib do not result in clinically significant increments in survival, there may be scope for sequential therapy when resistance emerges to first line treatment. This is exemplified by a small study using bevacizumab following sorafenib failure reported a median survival of 9.5 months despite patients largely having poor performance status and often a Child-Pugh score of 7 [142]. Similar data has been observed using axitinib as a second-line agent in the setting of renal cancer. However, a phase III trial of brivanib following sorafenib failure has failed to demonstrate improved survival compared with best supportive care [143].

A better understanding of the mechanisms of resistance to VEGF-targeted therapies may help improve therapeutic strategies. For example, there is evidence that hepatocyte growth factor (HGF) signalling through its receptor, c-met, may play a role in mediating such resistance and, indeed, may contribute to the emergence of a more aggressive phenotype during anti-VEGF therapy. This suggests a potential role for c-met inhibition as a second line strategy, or in combination with anti-angiogenic therapy. The c-met inhibitor ARQ197 has been investigated in a randomized phase II trial for patients with HCC and significantly prolonged time to progression, the primary endpoint of the study, compared with best supportive care (HR 0.64). An exploratory analysis of survival according to c-met expression assessed by immunohistochemistry on tumour biopsies suggested that c-met was an adverse prognostic factor and that patients with high c-met may derive greatest benefit from ARQ197, although this requires further prospective evaluation [144].

Processes other than angiogenesis also contribute to the pathogenesis of HCC. Specific inhibitors of epidermal growth factor receptors (EGFRs) are growth inhibitory in HCC models in vitro and in vivo and early phase trials of anti-EGFR monoclonal antibody (cetuximab) and of small molecule EGFR tyrosine kinase inhibitor (erlotinib) suggest clinical activity [145, 146]. Downstream pathways of growth factor receptor signalling include the Map Kinase (*ras/raf/mek/erk*) and PI3Kinase/akt/mTOR cascades. Indeed, sorafenib works, in part, through *raf* inhibition. The PI3K pathway is commonly upregulated in HCC leading to activation of mTOR, a key regulator of cell growth and proliferation. Inhibition of mTOR has shown promise in preclinical models and clinical trials using mTOR inhibitors are underway with promising data emerging [147].

There are a number of other pathways that are commonly perturbed in HCC, including wnt/β-catenin and hedgehog signalling cascades but, as yet, these have not lent themselves to pharmacological manipulation.

Combination therapy

Combination of signal transduction inhibitors acting at different points in the same pathway offers the potential to maximise pathway inhibition to produce additive clinical benefit and to reduce potential development of resistance. Thus, EGFR activation results in secretion of angiogenic cytokines, including VEGF, such that EGFR inhibition may also mediate anti-angiogenic effects. Indeed, preclinical models suggest that EGFR signalling is a prerequisite for angiogenesis in HCC via upregulation of VEGF. This process appears to be mediated through phosphorylation of AKT rather than ERK/MAPK and thus may be specifically susceptible to EGFR or mTOR inhibitors [148]. A phase II trial has investigated the combination of bevacizumab with erlotinib, with an objective response rate of 25% (including one complete response), median progression free survival of nine months and median survival 15.6 months [149]. This combination is being further investigated

in a phase III trial against sorafenib. Combination of mTOR inhibitors with VEGFR antagonists has synergistic effects in preclinical models and a phase II trial of everolimus with bevacizumab has demonstrated safety of this combination [150]. However, in a phase I trial exploring the combination of everolimus with sorafenib, it was not possible to safely escalate the dose of everolimus to target therapeutic levels [151]. There is also cross-talk between IGF and VEGF receptor signalling suggesting that combining drugs to target both may be beneficial. However, one such study combining an anti-IGF-1 receptor antibody with sorafenib was closed early due to problems with toxicity of the combination [152]. These latter studies emphasize that tolerability, even with so-called targeted agents, can be an issue in the setting of HCC and may limit the use of some regimens despite a strong scientific rationale for their combination.

Targeted therapies in combination with conventional chemotherapy

HCC is generally regarded as resistant to conventional chemotherapeutic drugs. However, pathways that are inhibited by novel targeted therapies, including *raf/mek/erk* may contribute to this resistance and so combination of these agents with chemotherapy may overcome chemoresistance. There is preclinical evidence of synergy between doxorubicin and *raf* inhibition. In a vascular endothelial model, resistance to doxorubicin is, at least in part, mediated via FGF-mediated *raf*-dependent survival signals, and can be overcome by inhibition of *raf*, providing rationale for combining doxorubicin with sorafenib or inhibitors of FGFR such as brivanib [153]. Furthermore, there is clinical evidence of benefit from the combination of anti-angiogenic agents with conventional chemotherapy in other tumour types. A randomized phase II study has investigated the combination of sorafenib and doxorubicin compared to doxorubicin alone [154]. The overall survival in the combination arm was more than double the control arm (13.7 months compared to 6.5 months, HR 0.45) To determine whether this benefit is attributable to synergy between the two agents or to sorafenib alone requires a further randomized trial of the combination using sorafenib as the control arm.

Improving efficacy of systemic therapies through application in earlier stage disease

Although effective local control can be achieved by loco-regional therapies, as tumour size increases, so does the frequency of vascular invasion and with it the risk of metastases thereby limiting the impact of local control. Systemic therapy might be applied in two settings to ameliorate this problem. Firstly, in the neoadjuvant setting it might downstage a non-resectable tumour to resectability and this has occasionally been reported with doxorubicin and doxorubicin based combinations [129]. However, this is less likely to be achieved with drugs such as sorafenib where significant tumour shrinkage is rarely seen. Secondly, use in the adjuvant setting may eradicate micrometastases. The Sorafenib as Adjuvant Treatment in the Prevention of Recurrence of Hepatocellular Carcinoma (STORM) trial is a randomised, double-blind, placebo-controlled phase III study to evaluate the safety and efficacy of sorafenib versus placebo in patients with HCC after potentially curative treatment with surgical resection or local ablation, taken continuously for up to four years. This study has recruited 1100 patients, with

final survival results awaited. The toxicity profile will be of particular interest, as these patients would otherwise be expected to be well and asymptomatic. Unlike other cancers, as well as the risk of disease recurrence through micrometastases (which may conceivably be eradicated by an active systemic therapy) there is also a risk of de novo tumour formation in the remaining diseased liver. It is for this reason that a four-year duration of therapy was selected in this trial, although to date there is no evidence that sorafenib may prevent the progression of premalignant lesions to invasive cancer and, undoubtedly, such prolonged therapy will have significant health economic implications.

The addition of a systemic agent such as sorafenib to chemoembolization may also be beneficial since TACE induces profound tumour hypoxia, activating hypoxia-inducible signalling pathways and angiogenic factors such as VEGF, b-FGF, and IGF-2, which may mediate the revascularization that is characteristic of TACE failure, or stimulate the growth and vascularization of micrometastases. A randomized phase III trial of sorafenib vs placebo after TACE, in Japanese and Korean patients with unresectable HCC, has recently been completed with 458 patients enrolled [155]. No significant prolongation of TTP was observed for patients treated with sorafenib. Notably, over half of patients commenced sorafenib more than nine weeks after chemoembolization, and three-quarters of the sorafenib-treated patients required dose reductions. Since pro-angiogenic mediators are upregulated immediately following TACE, the timing of sorafenib in relation to the TACE procedure may be critically important and may explain the failure of this study. Inhibiting the action of VEGF by administering sorafenib simultaneously with TACE may result in better efficacy and this is being tested in ongoing clinical trials. The sorafenib or placebo in combination with TACE for intermediate stage hepatocellular carcinoma (SPACE) trial is a multinational, randomized, double-blind, placebo-controlled phase II study being conducted that has completed its accrual of 300 patients and has met its primary endpoint of prolonging TTP with the addition of sorafenib given simultaneously with TACE [156]. However, it was not sufficiently powered to determine an overall survival benefit and there remains a need for further phase III trials.

Whether sorafenib, or other systemic therapy, could have a significant impact on recurrence as an adjuvant to liver transplant seems unlikely since with currently employed criteria recurrence is already very rare and any impact would likely be marginal. This may be different if transplant criteria were broadened but at present this is primarily limited by availability of donor organs.

Hepatitis B virus reactivation and chemotherapy

Hepatitis B virus (HBV) carriers are at risk of virus reactivation when receiving cytotoxic chemotherapy. A prospective study of 102 HBsAg-positive patients with HCC receiving doxorubicin-based chemotherapy showed that 32 patients developed hepatitis attributable to HBV reactivation of whom 30% died as a consequence [157]. Reactivation can be reduced by antiviral therapy such as lamivudine. A non-randomized comparison of HBV-positive patients receiving chemotherapy reported reactivation rates of 4% compared to 24% in patients receiving lamivudine or not, respectively. Since lamivudine prophylaxis was not routinely used prior to this, it is quite possible that HBV reactivation contributed to apparent toxicity in earlier chemotherapy studies, especially those conducted in HBV-endemic regions.

Cases of HBV reactivation have also been observed in patients treated with mTOR inhibitors, such that HBV carriers receiving this class of drug may also benefit from prophylaxis [158].

Multidisciplinary management of biliary tract cancer

Surgical management of gall bladder cancer

Population data in the US from 1988 to 2003 suggested more than 95% of surgically resectable gall bladder cancer has been treated with only simple cholecystectomy [159]. Although recent advances in surgical technique and perioperative management have allowed an increased role for radical surgery in appropriately selected cases, the outcomes of majority of patients with advanced gall bladder cancer remains poor.

Patients with gall bladder cancer usually present in one of three ways:

(1) advanced unresectable cancer;

(2) detection of suspicious lesion preoperatively and resectable after staging work-up;

(3) incidental finding of cancer during or after cholecystectomy for benign disease. Advanced is defined as tumour penetrating through gall bladder wall (T3 or greater), metastasizing to regional lymph node (N1) or distant organ (M1). In the AJCC staging system, this is staged as II or higher on 6th edition [160] and as III, IVa, or IVb on the 5th edition system [161].

Clinical presentation and work-up

Most patients with gall bladder cancer present when the disease is at an advanced stage, and majority of patients are diagnosed when the disease is beyond the borders of resection [162–166]. The most common symptoms at presentation are abdominal pain or biliary colic [162, 165, 166]. Patients with advanced disease may also present with jaundice from tumour invasion of the biliary tree or with systemic signs such as malaise and weight loss. Jaundice is well recognized as predictor of worse outcomes. In the series from Memorial Sloan-Kettering from 1995 through to 2005, one-third of patients presented with jaundice and only 7% had resectable disease [163].

The diagnosis is often suspected on an ultrasound done to evaluate right upper quadrant abdominal pain. Echogenic or discontinuous gall bladder mucosa, submucosal echolucency, or a mass should lead one to suspect gall bladder cancer. The presence of gallstones trapped within the tumour during its growth is a useful sign of possible gall bladder cancer [167, 168]. Although the detection of early lesions is challenging, ultrasound has a sensitivity of 85% and accuracy of 80% to diagnose advanced gall bladder cancer [167, 169]. Doppler ultrasound is helpful not only to identify the presence of hepatic arterial or portal venous invasion, but also to improve specificity of US by differentiating malignant tumour from benign lesions by measuring blood flow into the suspected lesions [170].

ERCP or PTC is useful to identify the spread of gall bladder cancer into biliary tree. A mid-bile duct stricture is a classic sign of gall bladder cancer involving bile duct. For patients with jaundice, cholangiography is useful for localizing the obstruction and also facilitating stent placement and establishing a diagnosis of cancer via brush cytology [171].

If gall bladder cancer is suspected, abdominal cross-sectional imaging (CT or MRI) is mandatory to evaluate for nodal or metastatic disease as well as to further define the local extent of disease (see Figure 41.7). Lymph nodes involved by cancer are usually >1 cm diameter and ring-shaped heterogeneous enhancement with IV contrast. Ohtani et al. reported the positive predictive value of conventional CT scan for detecting involvement in various lymph node stations as 75–100% despite of lower sensitivity as 17–78% [172]. These same authors reported the sensitivity of CT scan to detect of tumour invasion into liver, bile duct, or other adjacent organs such as pancreas and transverse colon as 50–65% and the positive predictive value as 77–100% [173]. The use of spiral CT provides a better diagnostic accuracy in both nodal spread as well as in-depth invasion than conventional CT scan [174, 175]. In a report by Yoshimitsu et al., the sensitivity of detecting tumour invasion into liver or other adjacent organ was 80–100%. MRI is less frequently used for staging of gall bladder cancer, but sometimes the use of MRCP or magnetic resonance angiography (MRA) provides more information than ultrasound or CT. Schwartz et al. demonstrated in retrospective analysis of 34 patients with gall bladder cancer that combination of conventional MRI and MRCP achieved a sensitivity of 100% for liver invasion and 92% for lymph node involvement [176].

PET using fluorine-18-labelled fluoro-deoxyglucose (FDG) is an emerging imaging modality that may prove to be of clinical value in the preoperative work-up of patients with gall bladder cancer. Multiple studies have shown that PET scans reliably detect primary and metastatic gall bladder cancer [177, 178] as well as residual tumour after cholecystectomy [179]. Corvera and his colleagues demonstrated that PET added information and altered management in 23% of selected patients with gall bladder who were preoperatively staged using US/CT/MRI [180]. Since PET is not routinely available, and the data for real contribution to preoperative staging is relatively limited, the role of PET in the multimodality work-up of patients with suspected gall bladder cancer is still being defined and its use should be individualized.

Principles of surgery

Although many studies have suggested improved survival in patients with early gall bladder cancer with radical surgery including en bloc resection of gall bladder fossa and regional lymphadenectomy, its role for those with advanced gall bladder cancer remains controversial. First, patients with more advanced disease often require more extensive resections than early stage tumours, and operative morbidity and mortality rates are higher [181]. Secondly, the long-term outcomes after resection, in general, tend to be poorer; long-term survival after radical surgery has been reported only for patients with limited local and lymph node spread. Therefore, the indication of radical surgery should be limited to well-selected patients based on thorough preoperative and intraoperative staging, and the extent of surgery should be determined based on the area of tumour involvement.

Surgical resection is warranted only for those who with loco-regional disease without distant spread. Because of the limited sensitivity of current imaging modalities to detect metastatic lesions of gall bladder cancer, staging laparoscopy prior to proceeding to laparotomy is very useful to assess the abdomen for evidence of discontinuous liver disease or peritoneal metastasis and to avoid unnecessary laparotomy. Weber et al. reported that 48% of patients with potentially resectable gall bladder cancer on preoperative
Fig. 41.7 CT scan appearance of T3 gall bladder cancer with invasion into the gall bladder fossa.

imaging work-up were spared laparotomy by discovering unresectable disease by laparoscopy [182]. Laparoscopic cholecystectomy should be avoided when a preoperative cancer is suspected because of the risk of violation of the plane between tumour and liver and the risk of port site seeding.

The goal of resection should always be complete extirpation with microscopic negative margins. Tumours beyond T2 are not cured by simple cholecystectomy and as with most of early gall bladder cancer, hepatic resection is always required. The extent of liver resection required depends upon whether involvement of major hepatic vessels, varies from segmental resection of segment IVb and V, at minimum to formal right hemihepatectomy or even right trisectionectomy. Invasion of the right portal pedicle structures is not considered a contraindication to potentially curative resection, but invasion of the common portal vascular structures is considered a contraindication to surgery by many surgeons (see Figure 41.8). The right portal pedicle is at particular risk for advanced tumour located at the neck of gall bladder, and when such involvement is suspected, right hepatectomy is required. Bile duct resection and reconstruction is also required if tumour involved in bile duct. However, bile duct resection is associated with increased perioperative morbidity [183] and it should be performed only if it is necessary to clear tumour; bile duct resection does not necessarily increase the lymph node yield.

Because of its propensity to spread to regional lymph nodes at early stage, resection of the liver involved and regional lymph node should be included for definitive treatment. In fact, frequency of

metastasis to regional lymph nodes (hilar, celiac, peripancreatic, periduodenal) is fairly high for advanced tumours: pT3/4 60–81% vs pT1/2 0–62% [184–187]. The most common lymph nodes involved are pericholedochal (42%) and retropancreatic (37%). Other nodal stations including celiac, SMA, para-aortic are involved in 20–25% of patients [188]. However, optimal extent of lymphadenectomy is ill-defined. It is the authors' practice to include extirpation of lymph nodes within the hepatoduodenal ligament but not retropancreatic or celiac nodes as patients with involvement in these nodal basin are unlikely to benefit from resection. Nodal metastasis beyond the hepatoduodenal ligament on exploration is associated extremely poor outcomes [181] and we generally do not proceed with operation if gross metastasis is discovered on exploration.

In the other hand, direct involvement of colon, pancreas, or duodenum is not an absolute contraindication of surgery. Several authors have reported that en bloc resection of adjacent organs [183, 189–191], such as duodenum or pancreas, can be associated with prolonged survival. In a recent study, resection of adjacent organ was performed in 21 patients for presumable malignant involvement; the resected adjacent organ was histologically involved only in half of the cases and only 16 of 21 cases were node negative, emphasizing that the finding of adherent organs does not necessarily imply advanced disease. Most importantly, adjacent organ resection was not associated with changes in long-term survival of patients [183].
Fig. 41.8 (A) Hepatic arterial angiogram in patient with gall bladder cancer showing involvement of right hepatic artery. This patient is resectable. (B) Hepatic arterial angiogram in patient with gall bladder cancer showing involvement of common hepatic artery. This patient would rarely be considered resectable with curative intent. (C) Indirect portal vein angiogram in patient with gall bladder cancer showing involvement of common portal vein. This patient would rarely be considered resectable with curative intent.

Outcomes

Although advances in surgical technique and improvement in perioperative care allows us to perform radical resection for patients with gall bladder cancer safely, the outcomes for those with advanced cancer remain disappointing. The five-year survival rates for patients having radical surgery ranged from 0% to 51%; most of them fall in 20–30% (Table 41.4). Nodal status and histological margin have been reported as predictive factors of survival after radical resection for this group of patients throughout the literature. For example, Behari and his colleague reported that positive node was associated with incomplete resection and none of the patients with N1 disease survived beyond five years [187]. Endo and his colleague reported in their analysis of 55 patients who underwent complete resection, a 77% five-year survival for patients without nodal involvement, 33% for those with single lymph node involvement and 0% for those with two or more lymph nodes involvement [192]. These findings suggest that radical resection should not be performed for patients with gross lymph nodes involvement or extensive tumour infiltration to adjacent structure on perioperative

Table 41.4 Outcomes of radical surgery for advanced gall bladder cancer

Authors	Year	Number	Stage	5-year survival rate	Note
Fong et al. [156]	2000	58	III/IVa*	28/25%	
Kondo et al. [207]	2002	38	III/IVa**	33/17%	
Behari et al. [181]	2003	24	III/IVa*	28/0%	
Shih et al. [191]	2007	39	II***	34%

evaluation, both of which make complete resection with histological negative margin unlikely.

Medical management of gall bladder cancer

Because of its propensity to spread to regional lymph nodes at early stage and high rate of loco-regional recurrence, adjuvant chemotherapy, and/or chemoradiation therapy seems a rational therapeutic option for gall bladder cancer. Traditionally, 5-FU based chemotherapeutic regimen has been used with or without combination of chemoradiation. However, there are few data to support its efficacy. The rarity of gall bladder cancer and further limitation of patients who can undergo complete resection make the randomized trial difficult to conduct. To date, there is only one randomized trial examining the efficacy of adjuvant chemotherapy for gall bladder cancer. This study reported significant improvement in five-year overall survival rate (26% vs 14.4%) with postoperative mitomycin C and 5-FU following surgery compared with surgery alone as well as improvement in five-year disease free survival rate (20.3% vs 11.6%) [193]. However, definitive conclusion from this trial is limited by the small numbers of patients and the inclusion of patients undergoing incomplete (i.e., R1) resections. Indeed, subgroup analysis of patients who underwent a complete resection showed no survival benefit with adjuvant treatment. Most other data for the use of adjuvant or neo-adjuvant therapy in patients with gall bladder cancer is derived from phase II trials, in which treated patients were compared with historical controls [194, 195]. Kreral and his colleagues reported a 64% five-year survival rate of patients who received 5-FU and external beam radiation following surgical resection compared to 33% of those their historical control [195]. In contrast, Houry and his colleagues reported no survival benefit from adjuvant chemoradiation therapy on patients who underwent curative resection [196]. Unfortunately, no study has provided conclusive evidence for benefit of adjuvant chemo or chemoradiation treatment for gall bladder cancer.

Most patients with gall bladder cancer present with advanced, incurable disease and many are not candidates for surgical resection. The median survival of patients with advanced gall bladder cancer who are deemed inoperable ranges between 2 and 4 months [163, 166, 197] and palliation of symptoms should be the primary goal. Symptoms and conditions associated with incurable gall bladder cancer include jaundice, cholangitis, pain, and gastrointestinal obstruction. For obstructive jaundice or gastrointestinal

obstruction, palliative intervention may be required. The common procedure for biliary obstruction due to gall bladder cancer is a segment III bypass [198]. In their series of 41 consecutive segment III bypass for patients with advanced gall bladder cancer, Kapoor and his colleagues reported 87% success rate with 12% mortality and 51% morbidity rate [199]. Because of poor survival, biliary stent is a preferred option for most of the patients. It can be placed either via percutaneous transhepatic route or endoscopic approach with minimal morbidity. Intestinal bypass should be performed only in patients who have symptomatic obstruction.

Systemic chemotherapy and radiation therapy have, in general, little impact on unresectable gall bladder cancer. Multiple regimens have been tested including combinations of 5-FU, leucovorin, mitomycin C, doxorubicin, and methotrexate. However, the effects have been mostly disappointing with poor response rates of 10–20% [200]. Recent phase II trials using combination of gemcitabine and oxaliplatin showed an improved response rate ranging 40–50% [211, 212, 215], and large-scale randomized trial is warranted.

Surgical management of cholangiocarcinoma

Cholangiocarcinoma usually arises in the major bile ducts near the porta hepatis and so usually presents as painless obstructive jaundice of insidious onset. Despite recent major advances in surgical and anaesthetic techniques, due to vascular involvement or distant spread the majority remain unresectable at time of presentation. The imaging characteristics of cholangiocarcinoma are discussed earlier, as are the interventional strategies (endoscopic and radiologic) to palliate obstructive jaundice. However, the usual presentation is one of painless obstructive jaundice, and the diagnostic imaging demonstrating a hilar stricture, with associated hepatic parenchymal atrophy of the lobe from which the tumour originally emanated (Figure 41.9). If surgery is not possible, then palliative biliary stenting should employ long-lasting coated metal stents, rather than temporary plastic stents, which have a propensity to silt up, lasting on average only three months (Figure 41.10).

Principles of surgery

Surgery is the only therapeutic modality which offers any chance of cure. Historically, median survival of patients with unresected cholangiocarcinoma remained less than one year. However, good multidisciplinary management, including aggressive and repeated biliary/percutaneous stenting can now achieve median survivals that approach or even surpass two years. No consensus has been achieved with regard to the criteria for surgery because of the small number of patients in each reported series. While, in general, the operative principles are very similar to those required to deal with Stage 3 gall bladder cancer, some authors consider that positive peri-portal lymph nodes detected at frozen section during exploratory laparotomy are a contraindication to resection [201], while others disagree and report long-term survival following resection in such patients [202, 203]. Furthermore, there is no consensus with regard to the optimal surgical procedure, although it is clear that a positive surgical resection margin is associated with a poorer prognosis [201, 204, 205] as is tumour invasion along Glisson's capsule or along neurovascular bundles (see Figure 41.11) [206, 207]. If resection is technically possible then five-year survival rates of over 30% can be achieved [208].

An alternative, but controversial, strategy currently being explored at a number of centres is orthotopic liver transplantation after neoadjuvant chemoradiotherapy. However, the numbers of patients studied remains small, none are randomized, and the treatment only offered to patients with early stage disease, so reported outcomes could be susceptible to selection bias [209].

Medical management of cholangiocarcinoma

Adjuvant strategies

There have been no reported randomized controlled trials to demonstrate any benefit from postoperative adjuvant therapy following apparently curative resection for cholangiocarcinoma, although the CRUK BILCAP study of surgery versus surgery plus adjuvant gemcitabine continues to recruit in the UK.

Systemic therapies

Evidence supporting a role for chemotherapy in advanced biliary cancer (ABC) was until recently limited to small, single arm, phase II trials [210–212]. This was partly due to the relatively low incidence of biliary cancer combined with the challenges of ensuring adequate biliary drainage and managing biliary sepsis. In addition, trials were often hampered by the inability to obtain a histological diagnosis and the lack of radiologically measurable disease. Most of these trials utilised traditional single arm phase II endpoints, and did not allow comparisons between treatment regimens. However,
Fig. 41.9 Klatskin cholangiocarcinoma. (A) MRCP demonstrates a tight stricture at the bifurcation of the intrahepatic ducts with a normal calibre common duct. (B) Arterial phase and (C) portal venous phase scans demonstrate a hypovascular lesion in the left lobe of the liver infiltrating the intrahepatic ducts with dilatation of the right and left ducts.
Fig. 41.10 (A) Good long-term biliary drainage achieved with a coated metal wall stent in hilar cholangiocarcinoma presenting with obstructive jaundice. (B) Rapid silting with biliary debris in temporary plastic biliary stent.
Fig. 41.11 Histological slide of resection margin following surgical resection of hilar cholangiocarcinoma showing neurovascular invasion, predictive of a poorer outcome.

more recently, a small number of randomised phase II and III trials have been successfully performed, due in the main to multi-centre collaborations and technical advances in securing biliary drainage and obtaining tissue diagnosis [213, 214].

The results of the UK ABC-02 trial in 2010 [215] provided a standard of care in the systemic management of locally advanced and metastatic biliary cancer for the first time. This phase III trial demonstrated a significant survival advantage for the combination of gemcitabine and cisplatin over gemcitabine alone. A total of 410 patients were recruited to the trial, making it the largest trial to date in advanced biliary cancer. Progression-free survival and overall survival were both significantly improved in the gemcitabine/cisplatin arm. The median OS was 11.7 months in the combination arm and 8.1 months following single-agent gemcitabine (hazard ratio, 0.64; 95% confidence interval, 0.52 to 0.80; p < 0.001). Importantly, the combination of gemcitabine and cisplatin was not associated with significantly increased toxicity. While the combination increased neutropaenia, this did not translate into an increased infection rate. The good tolerability of this regimen now provides a suitable chemotherapy backbone upon which to investigate the addition of novel therapeutics. However, a better understanding of the molecular pathogenesis of biliary cancers is required in order to select appropriate targeted therapies for clinical trials.

Introduction to peritoneal mesothelioma

Mesothelioma is a neoplasm originating from the mesothelial cells lining the human body cavities (Figure 42.1). Mesothelioma may involve the pleura, less frequently the peritoneum, and rarely, the pericardium and tunica vaginalis testes. In the past, peritoneal mesothelioma was a rapidly fatal peritoneal surface malignancy with a median survival of less than one year [1, 2]. It represents about one-fifth to one-third of all forms of mesothelioma; there are approximately 400 new cases in the United States each year [3].

The most common age range at presentation is between 40–60 years [4]. Asbestos exposure appears to be causative in some cases of peritoneal mesothelioma, but a search for other carcinogens continues [5–7]. The initial clinical presentation of patients is usually non-specific with symptoms of abdominal pain and increasing abdominal girth being the most common [8]. The predominance of abdominal symptoms as a clinical feature of malignant peritoneal mesothelioma (MPM) is a reflection of the natural history of the disease, as MPM typically remains confined to the abdominal cavity; morbidity and mortality is a consequence of intra-abdominal disease progression and is characterized by small bowel obstruction and cachexia [9]. Computed tomography (CT) is the most commonly used imaging modality in the diagnostic workup, but tissue biopsy with immunohistochemical staining is obligatory for definitive diagnosis. The use of cytoreductive surgery (CRS) and hyperthermic perioperative chemotherapy (HIPEC) has become the accepted initial management for suitable patients with MPM. MPM treatment centres have shown that CRS and HIPEC is associated with a durable improvement in survival from a historical median survival of six months [10] for patients with untreated disease to 34–92 months for selected patients [11–16]. This chapter describes the most recent experience with MPM and analyzes symptoms, clinicopathologic features, survival after aggressive local-regional treatment, and examines future prospects for improved management.

Epidemiology

In the Washington Cancer Institute data of 51 MPM patients, the mean age was 53 years, with a range of 16 to 78 years. A majority of patients were Caucasian; there was one African American and one Asian American. Sixteen patients had no history of exposure to asbestos, 20 had a positive history, and no data are available on 15 patients. Nineteen patients had a family history of cancer in a parent or sibling and five had more than one first-degree relative with a malignancy; no data are available on nine patients [17]. MPM is strongly linked with prior asbestos exposure with latency period of decades before its formal diagnosis. This disease is mostly observed in countries with a higher socio-economic status due to the historical use of asbestos in the construction industry and the availability of current medical technology that allows its diagnosis [18]. In 2009, there were 2558 patients diagnosed with mesothelioma and this incidence has demonstrated an increasing trend since the 1970s with an exponential increase noted since year 2000 from 0.5 to 3 persons per 100 000 [19]. Peritoneal mesothelioma accounts for one-third of all mesotheliomas [20].

The exact pathogenesis of MPM is unknown; however, several hypotheses have been proposed. It is thought that inhaled asbestos may form expectorate that may subsequently be swallowed. Upon entry into the gastrointestinal tract, it penetrates the luminal surfaces of the intestinal mucosa to enter the lymphatic and splanchnic circulation [21]. This triggers a foreign body reaction resulting in a series of inflammatory responses. Together, the chronicity of this
Fig. 42.1 Malignant peritoneal mesothelioma with whitish tumour nodules present on parietal and visceral peritoneal surfaces of the abdomen and pelvis.

inflammatory reaction leads to disruption and alterations of the genetic make-up of mesothelial cells [22]. Evidence from clinical studies to support this association have shown that patients with malignant mesothelioma have higher levels of interleukin (IL)-10, a cytokine that drives further production of transforming growth factor (TGF)-ß. Both IL-10 and TGF-ß are postulated to play a role asbestos-related carcinogenesis [23].

Molecular biology and pathology of peritoneal mesothelioma

Molecular features as prognostic biomarkers

Thus far, the presence and prognostic relevance of a handful of biomarkers, mainly related to cell cycle control, receptor tyrosine kinase (RTK)-mediated signalling and telomere maintenance, have been investigated. These molecular features have been studied as 'prognostic biomarkers'.

Cell cycle-related markers

A reduced expression or loss of p16 protein, a cyclin-dependent kinase (CDK) inhibitor which prevents progression through the G1-S restriction point of the cell cycle by blocking the activity of CDK4/6, has been frequently observed in MPM [24, 25], although the prognostic significance of such an alteration is still controversial. In fact, while Borczuk et al. [24] found that p16 loss was associated with increased risk of death at multivariate analysis, such a finding was not confirmed by Nonaka et al. [25]. Homozygous deletion of the 9p21 locus harbouring the p16 coding gene CDKN2A, which represents one of the most common genetic alterations in pleural mesothelioma, has been also recorded in small but significant percentages of MPMs (25–35%) [26, 27]. In addition, patients with CDKN2A deletions were found to have worse overall and disease-specific survival [27]. Studies aimed to evaluate the prognostic relevance of another cell kinetic parameter, mitotic count (MC), showed that high MC was an indicator of an unfavourable prognosis on univariate [28] and multivariate [29] analyses.

Cell signalling pathway-related markers

Epidermal growth factor receptor (EGFR) was consistently shown to be over-expressed in more than 90% of MPMs examined in different studies [30–32], but its prognostic value is still unclear [25]. Foster et al. [31] detected point mutations in the catalytic tyrosine kinase (TK) domain of EGFR in 31% of examined samples. Nine different mutations were identified: the known L858R activating mutation described in non-small cell lung cancer and eight novel EGFR TK domain point mutations. Although no statistically significant difference in survival was reached, all patients with EGFR mutations were alive with a mean survival of 24 months, whereas 5 out of 18 of the wild-type group died of disease with a mean survival of seven months. However, two subsequent studies failed to detect mutations in the EGFR TK domain of MPM surgical specimens [32, 33]. Specifically, we found the expression/phosphorylation of EGFR as well as of platelet-derived growth factor receptor β (PDGFR-β) in most of the samples analyzed, and platelet-derived growth factor receptor α (PDGFR-α) activation in half of them. Expression of the cognate ligands transforming growth factor α (TGF-α), PDGF β, and PDGF α in the absence of RTK mutation and amplification suggested the presence of an autocrine/paracrine loop. In addition, RTK downstream signalling analysis

demonstrated the activation/expression of AKR mouse thymoma kinase (AKT) and mammalian target of rapamycin (mTOR) in almost all the MPMs [32]. More recently, Varghese et al. [34] reported that the activation of phosphoinositide-3-kinase (PI3K) and mTOR signalling pathways were associated with shortened survival in MPM patients.

Telomere maintenance-associated markers

In a study aimed to investigate the prevalence of the two currently known telomere maintenance mechanisms, telomerase activity (TA) and alternative lengthening of telomeres (ALT), and to assess their prognostic relevance in MPM, we found that 86.4% of the samples expressed at least one mechanism. Specifically, ALT or TA alone was found in 18.2% or 63.6% of lesions, respectively, whereas 4.6% of the cases expressed both mechanisms. In addition, at a median follow-up of 38 months, TA expression correlated at multivariate analysis with both reduced disease-free and cancer-related survival, whereas ALT failed to significantly affect clinical outcome [35].

Based on currently available information, a consensus on which biological factors are specific biomarkers for MPM has not yet been achieved owing to large inconsistencies in the data collected. Discrepancies could depend on diverse experimental variables, including selection of the case series and the experimental assays used. Studies encompassing larger and more homogeneous MPM case series are warranted to properly validate new biomarkers in view of their possible translation into medical practice.

Pathology

The correct pathological diagnosis of MPM is necessary in that a variety of other abdominal and pelvic malignancies will present with peritoneal seeding. Approximately 10% of patients with primary colon cancer will have peritoneal carcinomatosis. Up to 30% of patients with gastric cancer and pancreatic cancer have peritoneal seeding at the time of exploration for resection of the primary malignancy. A majority of patients with papillary serous ovarian cancer have peritoneal seeding. Unless the pathologist carries a high index of suspicion, diffuse peritoneal involvement by cancer can be falsely identified as carcinomatosis; in reality, the proper immunostains would show MPM (Table 42.1).

Also, the simultaneous occurrence of one of these common cancers coincidentally with a primary peritoneal mesothelioma can occur [17]. Interestingly, one patient in our series who was diagnosed with peritoneal carcinomatosis of colorectal origin presented two years later with peritoneal mesothelioma. In a review of the pathology the peritoneal implants were MPM and not colorectal peritoneal metastases [36].

Tumours arising from the mesothelial cells lining the abdominal cavity cover a wide spectrum of biological aggressiveness [37]. Adenomatoid tumour and solitary fibrous tumour are truly benign lesions that very unlikely recur after simple excision. Multicystic peritoneal mesothelioma (MCPM) and well-differentiated papillary peritoneal mesothelioma (WDPPM) are exceedingly rare lesions with uncertain malignant potential and enigmatic natural history. At the other extreme, MPM is a rapidly lethal malignancy, with an overall survival of approximately one year using standard treatments.

Classification of peritoneal mesothelioma according to clinical presentation, biological behaviour, and histopathological features

Table 42.1 Immunostains of adenocarcinoma and malignant peritoneal mesothelioma. The data summarize the percentage of positive staining to be expected

	Gastrointestinal adenocarcinoma	Mesothelioma
VIMENTIN	0–6	40
CEA	90–100	0–10
EMA	83	80–100
PAN-Cytokeratin	100	100
B72.3	81	0–5
BER-EP4	90–100	0–11
CD15 (LEU-MI)	58–100	0–10
PLAP	50	0
Calretinin	6–9	42–100
S-100	31	0–11
CA125	90	14–94
P53	43–53	45

is shown in Table 42.2. Adenomatoid tumour is a solitary asymptomatic lesion which most often involves the peritoneum of the genital region in women of reproductive age. Solitary fibrous tumour affects primarily men in their sixth decade. Recent immunohistochemical and ultrastructural studies have suggested that this lesion

arises from sub-mesothelial mesenchymal tissue [38]. The subsequent sections of this chapter centres on borderline and malignant peritoneal mesotheliomas, which attract more interest on the part of the medical community and pose substantial problems in clinical practice.

Malignant peritoneal mesothelioma

MPM is characterized by multiple variably sized grey-white nodules throughout the abdominal cavity. As the disease progresses, the nodules become confluent to form plaques, masses, bowel encasement, or uniformly cover peritoneal surfaces. Abundant effusion is often present.

Similar to the more frequent pleural counterpart, MPM histological features may be classified into three types as described by Battifora and McCaughey: epithelial, sarcomatoid, and biphasic (mixed) [39]. However, the incidence of biphasic tumours is lower than in pleural disease, and pure sarcomatoid MPM is rare. Epithelial MPM is composed of polygonal, oval, or cuboidal cells exhibiting cytonuclear features and architectural formations ranging from well-differentiated to anaplastic/pleomorphic. Sarcomatoid tumours and the sarcomatoid component of biphasic MPM consist of spindle cells arranged in fascicle or storiform pattern [40, 41].

Epithelial MPM can be further categorized by the patterns observed for the malignant epithelial component. The tubulo-papillary pattern is one of the most common patterns. It consists of a mixture of small tubules and papillary structures with fibrovascular cores lined by bland flat, cuboidal, or polygonal cells. The solid pattern consists of nests, cords, or sheets of round, oval, or polygonal cells with abundant eosinophilic cytoplasm and

Table 42.2 Classification of malignant peritoneal mesothelioma by clinical behaviour, biological behaviour, and histopathologic features

Clinical presentation	Biological behaviour	Histological subtype	Histological pattern	Prevalence (%)
Localized	Benign	Adenomatoid tumour		Uncommon
		Solitary fibrous tumour		Uncommon
Diffuse	Borderline	Multicystic		Uncommon
		Papillary well-differentiated		Uncommon
	Malignant	Epithelial	Tubulo-papillary	75–80%
			Solid	
			Small cells	
			Adenomatoid	
			Acinar	
			Clear-cells	
			Signet-ring cells	
			Deciduoid	
			Rhabdoid	
		Biphasic (mixed)	Mixed epithelioid and desmoplastic	10–15%
		Sarcomatoid	Desmoplastic	4–6%
			Linpho-istiocytoid	
			Anaplastic	
			Giant-cell	

round, vesicular nuclei with prominent nucleoli. The adenomatoid (micro-glandular), acinar, clear-cell, decidoid, signet-ring cell, small-cell, and rhabdoid patterns are less common [38–41].

Sarcomatoid MPM may demonstrate anaplastic, giant-cell, and desmoplastic features, or osteosarcomatous/chondrosarcomatous areas. On occasion, atypical histiocytoid-appearing cells within an intense lymphoplasmacytic infiltrate can be seen (lymphohistiocytic pattern).

Lymph node metastases within and outside the abdominal cavity can occur even as the initial manifestation of MPM. Node involvement has been reported in 7–14% of patients undergoing extensive cytoreductive surgery. By contrast, metastatic disease outside the abdominal cavity is uncommon, except for direct invasion of pleural spaces through the hemidiaphragms [42].

Multicystic and well-differentiated papillary peritoneal mesothelioma

Both these rare disease entities generally affect women of reproductive age with no history of asbestos exposure and show indolent clinical behaviors. MCPM is often associated with previous abdominal surgery, inflammation, or endometriosis. However, early recurrences requiring multiple surgical interventions, transformation into truly malignant disease, lymph node involvement, and even death have been described. This, along with the reported clear evidence of diffuse disease distribution throughout the peritoneum and invasion into peritoneal surfaces, suggest that MCPM and WDPPM should be considered as borderline or low-malignant potential conditions, rather than benign tumours [43, 44].

At macroscopic examination, MCPM forms multiple variably sized thin-walled cysts involving primarily the pelvis, but often spreading throughout the abdominal cavity. Microscopically, cysts are separated by fibrous/adipose septa, and lined by single layers of flattened to cuboidal cells with no or little atypia. WDPPM is characterized by multiple small nodules and, at microscopic level, by well-developed papillary structures with fibrovascular core. The papillae are covered by bland cuboidal cells. Mitoses and atypia are rarely present. Because the natural history of WDPPM is distinct from MPM, the differential diagnosis with similar histology but more aggressive clinical behaviour of tubulo-papillary epithelial MPM is important [41].

According to the consensus opinion of expert pathologists from the International Mesothelioma Interest Group (Chicago, October 2006), the diagnosis of MPM must always be based on an adequate biopsy in the context of appropriate clinical, radiologic, and surgical findings [38]. A history of asbestos exposure should not be taken into consideration when diagnosing MPM. There is still limited role of cytology in the primary diagnosis, despite the increased accuracy of immunohistochemical and ultrastructural techniques.

MPM can exhibit highly variable morphological features and grows in a wide range of histological patterns. Accordingly, the disease can be confused with a variety of neoplastic and non-neoplastic conditions. The objectives of an accurate pathological workup are:

- Separating benign from malignant mesothelial proliferations.
- Differentiating MPM from other metastatic or primary peritoneal malignancies.
- Defining the histological subvariant and other relevant prognostic determinants.

The first step for the diagnosis of mesothelioma is haematoxylin-eosin stain. Immunohistochemical studies are adjuncts to diagnosis. Demonstration of stromal invasion into visceral or parietal peritoneum (or beyond) is the key feature in the differential diagnosis with reactive mesothelial proliferations, and can be highlighted with pancytokeratin or calretinin immunostaining. However, invasion must be carefully differentiated from entrapment, and the distinction between the rare desmoplastic MPM and reactive fibrosis may be difficult [45, 46].

Peritoneal (versus pleural) location, sex of the patient, and basic histological type affect the differential diagnosis. Any carcinoma of gastrointestinal origin and, in women, ovarian, primary peritoneal, and, more rarely, lobular breast carcinoma, should be considered for epithelial MPM. The differential diagnosis for sarcomatoid MPM includes sarcoma and other spindle cells neoplasms, such as sarcomatoid renal carcinoma and, particularly for biphasic MPM, synovial sarcoma [38]. Since no immunohistochemical marker is entirely specific and sensitive for mesothelioma, the standard is to use panels of positive and negative markers. Mesothelioma is characterized by positive staining for EMA, calretinin, Wilms Tumour-1 antigen, cytokeratin 5/6, HBME-1, podoplanin, and mesothelin. Depending on the tumour being considered in the differential diagnosis, CEA, Leu-M1, Ber-Ep4, claudine, B72.3, Bg8, and MOC-31 can be used as negative marker. Electron microscopy may help in difficult cases [38–41, 47].

To date peritoneal mesothelioma lacks a grading system. However, histomorphologic parameters can be used to help select treatment options and estimate survival. Biphasic/sarcomatoid histology and MCPM/WDPPM have, respectively, poorer and better prognosis than epithelial MPM. However, the low incidence of biphasic/sarcomatoid and borderline mesotheliomas restricts the clinical utility of this variable. For the same reason, rare secondary histological patterns that seem to have lower survival are of limited utility [42].

An exhaustive clinicopathological analysis of 62 patients undergoing comprehensive treatment at the Washington Cancer Institute revealed that nuclear and nucleolar size (rated by a four-tiered score) correlated with survival [48]. Clinical data from the Milan Peritoneal Malignancy Program demonstrated that both pathologically involved lymph nodes and inadequate nodal sampling correlate with poor prognosis. Accordingly, careful examination of lymph nodes that drain the visceral and parietal peritoneum is recommended, including bilateral iliac, right gastroepiploic, and ileocolic nodes [42]. Proliferative activity has been reported to be useful for prognostic stratification. It may be quantified either by means of mitotic count or immunohistochemical staining with Ki-67 antigen, an excellent marker of cellular proliferation. Proliferative activity is generally low in MPM, but higher rates correlates with poor outcome [49–51].

Surgical management of peritoneal mesothelioma

Diagnosis and staging

The initial symptom that led to a diagnosis of MPM was prospectively recorded in 51 patients. In the past, it was assumed that the initial symptom in virtually all patients was an expanding abdomen from malignant ascites. However, as shown in Table 42.3,

Table 42.3 Symptoms and signs of peritoneal mesothelioma in 51 patients treated at Washington Cancer Institute

Symptom	Total	Men	Women
Increased abdominal girth	16 (31%)	12 (35%)	4 (24%)
Pain	17 (33%)	11 (32%)	6 (35%)
Increased abdominal girth and pain	5 (10%)	3 (9%)	2 (12%)
New onset hernia	6 (12%)	5 (15%)	1 (6%)
Incidental finding	4 (8%)	0	4 (24%)
Other	3 (6%)	3 (9%)	0
Total	51	34	17

Fig. 42.2 CT of wet type of malignant peritoneal mesothelioma. Fluid conforms to the shape of the small bowel and its mesentery. A small volume of solid tumour is layered out on the parietal peritoneum.

these patients can present with a variety of symptoms. We categorized the patients into three groups based on presenting symptoms: approximately one-third present with abdominal distention, one-third with abdominal pain, usually localized, and the remaining third present with combined symptoms of distention, pain, and other findings. We have designated these three types as a 'wet type' of peritoneal mesothelioma presenting with symptoms of malignant ascites causing increased abdominal girth, a 'dry-painful type' presenting with a focal mass seen on computed tomography (CT) scan causing pain, and a 'combined type' characterized by both pain and ascites. We correlated histologic findings with patient symptoms at presentation but no significant relationships were apparent [52].

Patients may present with an acute abdomen with peritoneal mesothelioma. Four patients had the sudden onset of severe pain requiring evaluation at an emergency treatment facility; three had acute appendicitis, and one of these three had a perforated appendix. A single patient presented with an incarcerated umbilical hernia. In addition to pain, increased abdominal girth and new-onset hernia, signs and symptoms included weight loss, infertility, shortness of breath, fever, and night sweats.

In patients with advanced disease, the increase in peritoneal tumour burden may result in an increase in abdominal compartment pressure leading to the development of a new onset hernia. The masses that develop on the peritoneum may lead to malignant adhesions and fluid production that develop amongst intestinal loops to result in a partial bowel obstruction and ascites [53]. The diagnostic pathway is often tedious and is arrived upon following exclusion of other more common gastrointestinal malignancies.

Computed tomography diagnosis

Park et al. used the terminology of 'dry' and 'wet' as descriptors of the CT features of peritoneal mesothelioma with the dry appearance consisting of peritoneal-based lesions and the wet appearance consisting of ascites, irregular or nodular thickening of the peritoneum, and an omental mass that may scallop or directly invade adjacent abdominal viscera [54]. The two clinical types of peritoneal mesothelioma, wet or dry-painful type, correspond well to these different appearances by CT examination. In the wet type, there is little or no evidence of solid tumour. Occasionally, small nodules lining the parietal peritoneal surfaces are evident,
especially beneath the right hemidiaphragm (Figure 42.2). The CT/radiologic presentation of the dry-painful type of peritoneal mesothelioma may disclose several mass lesions, but often there is a dominant mass isolated to one part of the abdomen. Likewise, the tumour mass is commonly associated with the greater omentum. Usually, the symptomatic mass lesion seen on CT is mistaken for intra-abdominal abscess or a large primary adenocarcinoma. Only at laparotomy is the definitive diagnosis evident in these patients presenting which solid tumour in the absence of ascites (Figure 42.3).

CT imaging of the abdomen and pelvis detect peritoneal tumours as well-defined masses with features that demonstrate omental thickening and nodularity of the mesentery. This predominant central abdominal and pelvic disease burden observed may be a characteristics pattern of presentation [55].

The CT appearance of multicystic peritoneal mesothelioma (MCPM) can be contrasted to CT of MPM. Despite an immense distortion of the abdominal and pelvic space by fluid-filled cysts and ascites, there is no disruption of intestinal function or segmental bowel obstruction. Compartmentalization of small bowel is seen on CT (Figure 42.4).
Fig. 42.3 CT of dry painful type of malignant peritoneal mesothelioma. Discrete masses are present at multiple sites around the abdomen. These masses are painful to deep palpation.
Fig. 42.4 CT of multicystic peritoneal mesothelioma. Thin walled cysts filled with clear fluid fill the abdominal and pelvic spaces. The small bowel is pushed to the side (compartmentalized). This separation of viscera from tumour is associated with a good prognosis with cytoreductive surgery plus intraperitoneal chemotherapy.

Fig. 42.5 CT of abdomen in a patient who had lateral trochar sites in a laparoscopy to diagnose malignant peritoneal mesothelioma.

Tumour markers for diagnosis

Standard haematological and serological panels including tumour markers (CEA, CA 19-9, CA-125 and mesothelin) are required. CA-125 and mesothelin are observed to be elevated in MPM but are not considered specific for diagnosis as they may be elevated in other malignancies including ovarian cancer and in infective processes such as tuberculosis [56, 57]. These tumour markers are, however, more suited for disease monitoring following treatment rather than for diagnosis. A markedly elevated CA-125 indicates poor prognosis.

Endoscopic procedures

Clinically, the vague nature of the symptoms and signs and the young age of presentation often lead to a delay in diagnosis. Diagnostic procedures include oesophago-gastroduodenoscopy and colonoscopy to exclude a gastrointestinal malignancy following which tumour biopsies may be performed through a diagnostic laparoscopy. Laparoscopy was the most common diagnostic test required for definitively diagnosing mesothelioma (64%). Cytology of fluid removed by paracentesis rarely resulted in a definitive diagnosis. Diagnostic laparoscopy could also provide an opportunity to evaluate the peritoneal disease burden to assess potential for cytoreductive surgery. An important caveat must accompany the recommendation for laparoscopy in the diagnosis of MPM. In our follow-up, port site recurrence is observed at nearly all trochar sites. Our recommendation is to limit the puncture sites to along the linea alba. As seen in the CT scan shown in Figure 42.5, cytoreductive surgery plus intraperitoneal chemotherapy may stabilize the peritoneal surface disease while disease within lateral trochar sites may progress rapidly.

Preoperative workup

The peritoneal disease burden of MPM is assessed systematically using the Sugarbaker's peritoneal cancer index. The peritoneal cancer index (PCI) has a score ranging between 0 and 39. Lesion size is determined as 0 to 3 within 13 abdominopelvic regions (Figure 42.6) [58]. The Peritoneal Surface Oncology Group International (PSOGI) has collaborated to combine their experiences of managing patients with peritoneal mesothelioma. They enrolled patients collectively into a multi-institutional registry database to formulate a clinicopathologic staging system through prognostic parameters identified from patients treated uniformly with CRS and HIPEC at eight international institutions. The staging system adopts the common nomenclature of the tumour-node-metastasis (TNM) system comprising of elements the tumour burden (T) assessed by the PCI subgrouped into four categories: T1 being PCI 1–10, T2 being PCI 11–20, T3 being PCI 21–30, and T4 being PCI 30–39. Abdominal nodal disease commonly affected by peritoneal mesothelioma includes the iliac chain, para-aortic, coeliac axis, mesenteric, and the porto-caval lymph nodes; any involvement of nodes would be classified as N1. The M element refers to the presence or absence of extra-abdominal metastases. Formal stage-wise classification was done in a reverse fashion following analysis of the prognostic impact of the PCI, lymph node, and metastasis status prior to arriving at four clinical stages (Table 42.4). Patients with T1N0M0 were designated as stage I, T2-3N0M0 as stage II and stage III comprised of patients with T4, N1, or M1 disease. From the complete clinicopathologic data of the 294 patients that formed the cohort used to derive this staging system, stratification of stage-based survival was achieved with five-year survival associated with stage I, II, and III disease being 87%, 53%, and 29%, respectively. This proposed TNM staging system is being evaluated in prospective studies and hopefully will be formally endorsed by the American Joint Committee on Cancer in future [59].

Medical management of malignant peritoneal mesothelioma

Systemic therapies

Malignant peritoneal mesothelioma patients with surgically unresectable disease or whose medical co-morbidities preclude surgery are considered for palliative systemic therapy. Due to its relatively low incidence and inherent difficulties of radiologic assessment, few studies of systemic therapy have been conducted. Treatment recommendations are often extrapolated from pleural mesothelioma. A variety of chemotherapeutic drugs have been reported to be effective and used in MPM with the most commonly used agents being cisplatin, gemcitabine, doxorubicin, and pemetrexed.

Peritoneal Cancer Index
Fig. 42.6 Sugarbaker's scoring of the peritoneal disease burden using the Peritoneal Cancer Index (PCI).

Historical data from the Dana-Farber Cancer Institute and Brigham and Women's Hospital's experience of 180 mesothelioma patients of which 37 patients had MPM reported a median survival of 15 months following a variety of palliative chemotherapy treatments [60]. A randomized trial was performed by the Cancer and Leukemia Group B (CALGB) comparing cisplatin and mitomycin versus cisplatin and doxorubicin in 79 patients with pleural mesothelioma or MPM. This trial reported an overall response rate of 26% and 14%, median time to treatment failure of 3.6 months and 4.8 months, and median overall survival of 7.7 months and 8.8 months in the cisplatin-mitomycin and cisplatin-doxorubicin groups respectively [61]. This study had only 4 of 79 patients with MPM.

Pemetrexed-based therapies

Pemetrexed, a multi-targeted antifolate that inhibits thymidylate synthase (TS), dihydrofolate reductase (DHFR), and glycinamide ribonucleotide formyltransferase (GARFT) was approved for use in pleural mesothelioma based on results of a phase III trial which demonstrated improved response rates and overall survival with cisplatin and pemetrexed over cisplatin alone in chemotherapy-naive patients who were not eligible for curative surgery [62]. Activity of pemetrexed in peritoneal mesothelioma was observed in two Expanded Access Programs (EAP) which allowed access to pemetrexed for eligible patients prior to its regulatory approval in pleural mesothelioma [63, 64]. Notwithstanding the many biases of such analyses, for example lack of randomization, absence of uniform response criteria and high censoring rate, data from EAPs suggest a role for pemetrexed-based combination chemotherapy in MPM.

In the international EAP, 109 patients with chemo-naive or previously treated surgically unresectable MPM received pemetrexed (500 mg/m^2) alone or with cisplatin (75 mg/m^2) or carboplatin [area under curve (AUC) 5] every 21 days until disease progression [63]. The response rate and one-year survival rate in the overall population were 18.7% and 47.4%, respectively. Combination chemotherapy was well tolerated. Although response rates were higher with combination treatment (20.0–24.1%) compared with pemetrexed alone (12.5%), patients in the latter group were older and had more prior treatments.

In the United States EAP, 73 patients with chemo-naive or previously treated surgically unresectable MPM received pemetrexed (500 mg/m^2) alone or with cisplatin (75 mg/m^2) every 21 days for six cycles or until disease progression [64]. Response rates were 26%, 19.2%, and 29.8% in the overall population, pemetrexed alone and pemetrexed/cisplatin groups, respectively. Response rates were similar in chemo-naïve and previously treated patients (25% and 23.3%, respectively). Median survival was 13.1 months for patients who received pemetrexed with cisplatin and 8.7 months for pemetrexed alone.

In chemo-naive patients, combination of pemetrexed (500 mg/m^2 on day 8) with gemcitabine (1250 mg/m^2 on days one and eight) administered every 21 days for six cycles or until progressive

Table 42.4 Proposed TNM staging for malignant peritoneal mesothelioma with corresponding survival rates

Stage	Tumour	Node	Metastasis	Five-year survival rates (%)
I	T1	N0	M0	87
II	T2-3	N0	M0	53
III	T4	N0-1	M0-1	29
	T1-4	N1	M0-1	
	T1-4	N0-1	M1	

T1 (PCI 1–10), T2 (PCI 11–20), T3 (PCI 21–30), T4 (PCI 30–39).

N0—nil lymph node, N1—positive lymph node involvement.

M0—nil metastasis, M1—metastatic disease.

Reproduced from Yan TD et al., A novel tumour-node-metastasis (TNM) staging system of diffuse malignant peritoneal mesothelioma using outcome analysis of a multi-institutional database, *Cancer*, Volume 117, Issue 9, pp. 1855–1863, Copyright © 2011 John Wiley and Sons Ltd.

disease was evaluated in a phase II study [65]. Of the 20 patients with MPM who enrolled, the combination yielded response rates of 15%, median time to disease progression of 10.4 months, median overall survival of 26.8 months and one-year survival rate of 67.5%, but resulted in significant toxicities including one treatment-related death. Grade 3 to 4 neutropenia and febrile neutropenia were observed in 60% and 10% of patients respectively. Myelosuppression is the most significant toxicity associated with the administration of pemetrexed, gemcitabine, or platinum. For pemetrexed, prophylactic supplementation with vitamin B12 and folic acid can abrogate haematologic toxicity without adversely affecting survival [62].

Other systemic therapies

In a retrospective single-institution report of 17 patients, combination of cisplatin and irinotecan yielded a response rate of 24% [66]. Other chemotherapy agents that are used alone or in combination for MPM based on data suggesting efficacy in pleural mesothelioma include vinorelbine [67], doxorubicin, mitomycin, and trimetrexate [68]. There are isolated reports of the role of whole-abdominal radiation; however, this treatment has not been adequately studied naturally owing to the potentially high morbidity. Nonetheless a study on surgery and intraperitoneal chemotherapy with whole abdominal radiation was reported to achieve improved disease-free survival [69].

Limited data are available to guide the sequencing of chemotherapy in relation to surgery, i.e., adjuvant versus neoadjuvant. Since CRS and HIPEC achieve complete cytoreduction in less than 50% of the patients [70] and recurrence is common even among patients who undergo a complete cytoreduction [71], adjuvant systemic chemotherapy is being explored in combination with intraperitoneal chemotherapy [72].

In summary, based on extrapolation from the pleural mesothelioma data and from analyses of EAP data, systemic therapy with pemetrexed and cisplatin should be considered in patients with surgically unresectable MPM [62–64]. Carboplatin may be a reasonable alternative to cisplatin in the elderly and patients with poor performance status considering its better safety profile [63]. In patients who cannot tolerate platinum, combination of pemetrexed and gemcitabine may be considered, although it is associated with significant toxicities [65].

Cytoreductive surgery and intraperitoneal chemotherapy

As MPM is confined within the peritoneal surfaces of the abdominal cavity before metastasizing to lymph nodes and extra-abdominal regions later in the disease history, a proof of concept to treat this disease with intraperitoneal chemotherapy to allow direct targeting of disease by Markman and Kelsen was conducted. They treated 19 patients with intraperitoneal cisplatin and mitomycin [73]. In this study, the treatment was well tolerated with control of ascites achieved in 47% of patients. Amongst the 19 patients, the median survival was nine months; however, four patients with minimal volume peritoneal disease were reported to survive more than three years. This suggested that if peritoneal tumour cytoreduction could be achieved and intraperitoneal chemotherapy may serve as an adjunct to achieve peritoneal disease control and prolong the disease-free survival.

Cytoreductive surgery for peritoneal tumours was introduced by Sugarbaker who described six peritonectomy procedures that allowed removal of all peritoneal lining of the abdominopelvic cavity [74]. Some groups advocate complete peritonectomy be performed even for peritoneal surfaces that are uninvolved by tumour [75]. In a case-control study by Baratti et al. comparing complete peritonectomy versus selective peritonectomy, five-year survival was 63.9% and 40%, respectively, without any difference in morbidity and reoperation rates [76]. The importance of nodal sampling and its impact on outcome has been shown to be important. In a multivariate analysis controlled for other prognostic variables, negative lymph nodes were an independent predictor of improved survival [77]. In their study, negative nodes as compared to positive or non-assessed nodes were associated with increased survival and hence the need for careful nodal sampling when performing cytoreduction. Although node positivity ultimately bears a poorer outcome and survival is unlikely to be modified through extended lymphadenectomy, an approach to standardized lymph node sampling would assist in disease staging [59].

HIPEC has been commonly used as an intraoperative adjunct to cytoreduction. It may be administered using either an open or closed abdomen technique. For MPM, the drugs commonly used include cisplatin alone or cisplatin with doxorubicin with the abdominal cavity being perfused with the chemotherapy solution at a temperature of 40 to 43°C. From the PSOGI registry of 405 patients treated uniformly with CRS and HIPEC, an overall median survival of 53 months, three- and five-year survival rates of 60% and 47%, respectively, were achieved. Epithelioid tumour subtype, absence of lymph node metastasis, optimal cytoreduction, and HIPEC were independently associated with improved outcome [70]. MCPM was also studied as a subgroup analysis from the PSOGI registry. There were 26 patients (6.4%) with MCPM with a large preponderance of females (20 women and 6 men). Following cytoreduction and a median follow up of 54 (range 5 to 129) months, all patients treated are alive and free of disease. Clearly, this represents a distinct subtype with a favourable disease biology where long-term survival may be achieved through complete eradication of the cystic peritoneal lesions [78]. Another interesting finding that emerged from this registry study that was the impact of gender difference [79]. From clinical observation, females tended to have lower PCI and hence lower stage of disease. Post- cytoreduction survival rate was 68% compared to 39% at five years in females compared to males. When the survival was stratified according to the staging criteria and gender, females continued to show superior survival over males for each TNM stage. The five-year survival for females was 97% (Stage I), 70% (Stage II), and 40% (Stage III); and for males was 70%, 40%, and 30%, respectively.

The apparent survival benefits of CRS and HIPEC are obvious over palliative chemotherapy. However, this treatment is highly specialized and has evolved from years of experience and learning to perform the extensive peritonectomy procedures required for CRS and the delivery of HIPEC [80]. Today this treatment is considered to have an acceptable morbidity for the survival benefits it derives. The risk of mortality ranges from 1 to 5% and major morbidity ranges from 12% to 52% which is comparable with other major gastrointestinal oncologic surgery [81].

Adjuvant bidirectional chemotherapy with intraperitoneal pemetrexed combined with intravenous cisplatin

CRS with HIPEC has been used in a number of centres worldwide showing median survivals of 36–92 months and has become the preferred therapy for eligible patients [70]. Yet, a significant proportion of patients with mesothelioma treated with this modality are not able to achieve complete CRS and therefore need further treatment with chemotherapy. Even in patients who have a complete CRS and HIPEC, recurrent disease is common and it usually occurs in the abdomen [71]. Pemetrexed is a multitargeted antifolate agent that was shown in Phase III studies to significantly improve response rates in patients with advanced pleural mesothelioma and MPM. At the Washington Cancer Institute the adjuvant treatment with intraperitoneal pemetrexed combined with intravenous cisplatin in patients with MPM who underwent CRS and HIPEC has become standard of practice.

Peritoneal port placement and maintenance

Peritoneal ports are placed at the time of CRS and HIPEC in all patients. Immediately prior to abdominal closure, the port is placed using the following technique: a 5 cm transverse incision is made lateral to the umbilicus on the left side overlying the lateral border of the rectus sheath. The tissues are dissected to the abdominal fascia and a small opening made in the fascia to accommodate the catheter that is placed in the abdomen with the tip directed at the pelvis. Blunt dissection is used to create a subcutaneous channel and pocket 10 cm cephalad to the skin incision where the port is positioned. A right angle non-coring needle (Gripper Plus, Smith Medical ASD Inc, St Paul, MN) is then used to access the port, secured in position with sutures and left in place for 10 days during post-operative recovery to prevent port twisting [82].

Adjuvant bidirectional chemotherapy

The treatment consists of pemetrexed 500 mg/m^2 given intraperitoneally and cisplatin 50 mg/m^2 given intravenously simultaneously on day one of every 21-day cycle for six cycles. Pemetrexed is mixed in one litre of peritoneal dialysis solution and administered through an implantable peritoneal port (Port-a-Cath, Smith Medical ASD Inc, St Paul, MN) placed at the time of cytoreductive surgery.

All patients receive folic acid 1000 μg orally daily and vitamin B12 1000 μg intramuscularly every nine weeks beginning two weeks before starting therapy and continued through the end of the last cycle of therapy. The patients also receive dexamethasone orally on the day before, the day of and the day after pemetrexed.

Using this regimen, nine of ten patients were able to complete all six cycles of therapy without treatment delays or dosing modifications. One patient developed a catheter infection after cycle three and required catheter removal. He was switched to intravenous pemetrexed and cisplatin for one cycle, then had a new peritoneal catheter placed and subsequently completed cycles five and six according to protocol. The most common toxicities were fatigue, nausea, and abdominal pain but were generally mild. The only grade three toxicity was the above mentioned catheter infection. There were no deaths related to treatment and no hospitalizations due to treatment side effects [72].

Pharmacokinetics of intraperitoneal pemetrexed

In four patients the pharmacokinetics of intraperitoneal pemetrexed was studied on the first cycle of adjuvant treatment (Figure 42.7). The area under the curve (AUC) of peritoneal fluid concentration times time was 84 150 μgmL^{-1}. The AUC of plasma pemetrexed concentrations times time was 1250 μgmL^{-1}. The increased exposure of peritoneal surfaces to chemotherapy as compared to plasma (AUC ratio) was 70. The peak plasma concentration was 6.5±3 μg/ml at 180 minutes. In summary, this study showed that an adjuvant
Fig. 42.7 Concentration times time graph of pemetrexed in peritoneal fluid and plasma from four different pharmacologic studies. The AUC ratio of peritoneal fluid to plasma was 70. Peak plasma concentration was 0.05 (+0.02) μg/mL at 30 minutes.
Fig. 42.8 Altered/activated molecular pathways, as detected in malignant peritoneal mesothelioma clinical and experimental models, relevant for the identification of novel prognostic biomarkers and therapeutic targets.

protocol of combined intravenous and intraperitoneal chemotherapy can be successfully implemented for patients with MPM following CRS and HIPEC with low morbidity. Our practice of placing the intraperitoneal port at the end cytoreductive surgery was successful and only one significant catheter problem was observed. We recommend this regimen to be tested as a multi-institutional adjuvant protocol for patients with this rare cancer [83].

Novel therapeutic targets

A few published studies have focused on the identification of deregulated pathways in MPM that can be specifically targeted to obtain a direct therapeutic effect or to increase the tumour sensitivity to conventional anticancer agents (Figure 42.8).

Inhibitors of apoptosis proteins

We initially demonstrated that the dysregulation of apoptotic pathways may play a role in the relative chemoresistance of MPM and

that surviving and other members of the inhibitors of apoptosis protein family (i.e., IAP-1, IAP-2, and X-IAP), which are overexpressed in most MPMs, could represent new therapeutic targets. Indeed, we found that RNAi-mediated survivin knockdown in MPM cells enhanced both spontaneous and drug-induced apoptosis [84], thus supporting the notion that survivin antagonists (such as YM-155, which is currently being tested in clinical trials) may provide new approaches to the treatment of MPMs.

Cell signalling pathways

The existence of a ligand-dependent activation and co-activation of EGFR and PDGFRB, as well as of a connection between them and the downstream pathway of mTOR we observed in clinical MPM specimens, strongly suggested the opportunity of combined treatment with RTK and mTOR inhibitors in the disease. Consistent with this hypothesis, cytotoxicity studies carried out on a human MPM cell line showed a supra-additive antiproliferative effect after

sequential treatment with sorafenib and RAD001 [32]. In this context, Varghese et al. [34] recently demonstrated the potential of the combined targeting of PI3K and mTOR signalling pathways for the treatment of MPM. Specifically, using the dual-class PI3K and mTOR inhibitor BEZ235, they observed a significant inhibition of cell proliferation and downstream cell signalling in two human MPM cell lines.

The ubiquitin-proteasome pathway

Searching for differentially expressed functional gene categories in MPM histologic subtypes through a microarray analysis, Borczuk et al. [85] identified the ubiquitin-proteasome pathway as up-regulated in biphasic tumours, suggesting its potential relevance as a therapeutic target in this category of poor prognosis tumours. Indeed, cytotoxicity experiments carried out in 211H cells derived from a human (pleural) biphasic mesothelioma demonstrated a synergistic antitumour effect of sequential treatment regimens containing the proteasome inhibitor bortezomib and oxaliplatin, as a consequence of an increased apoptotic response.

Although experimental evidence of deregulated expression/function suggests a possible role for selective gene pathways in the development of the disease, no definite conclusions can be drawn on their relevance as therapeutic targets. In this context, a major issue to be addressed is related to the development of in vivo MPM experimental models able to properly recapitulate the features of clinical tumours in order to clarify the antitumour potential of novel therapeutic approaches rationally designed on a biological basis in view of possible translation of experimental research advances into the clinical setting.

CHAPTER 43

Cancer of the breast

Martine Piccart, Toral Gathani, Dimitrios Zardavas, Hatem A. Azim, Jr., Christos Sotiriou, Giuseppe Viale, Emiel J.T. Rutgers, Mechthild Krause, Monica Arnedos, Suzette Delaloge, Fabrice Andre, and Felipe Ades Moraes

Epidemiology of breast cancer

Breast cancer is the most frequent cancer among women with an estimated 1.7 million new cancer cases diagnosed in 2012. Incidence rates vary almost fivefold between more and less developed regions of the world. The disease is now the most common cancer both in developed and developing regions with around 690 000 new cases estimated in each region. Incidence rates for the disease are increasing in less developed regions of the world, and are largely thought to be due to changing lifestyles and reproductive patterns of women in these parts of the world [1].

Reproductive risk factors

There is a large body of evidence from both experimental and epidemiological studies which points to a major influence of ovarian hormones, oestrogen in particular, on breast cancer risk.

An increased risk of breast cancer is associated with early menarche and late menopause. The effects of menarche and menopause are not equivalent, in that the excess risk associated with lengthening a woman's reproductive years by one year at menarche is greater that than the excess associated with one year's lengthening at menopause [2].

Childbearing and breastfeeding are of considerable importance when considering subsequent breast cancer risk. Childbearing reduces the risk of breast cancer; the higher the number of full-term pregnancies, the greater the protection. The risk of breast cancer reduces by 7% with each full-term pregnancy and overall, women who have had children have a 30% lower risk than nulliparous women. Women who breastfeed reduce their risk of developing breast cancer compared with women who do not breastfeed. The longer a woman breastfeeds, the greater the protection: risk is reduced by 4% for every 12 months of breastfeeding [3]. Abortion, either spontaneous or induced, has not been shown to have any effect on subsequent breast cancer risk [4].

The use exogenous hormones such as the oral contraceptive pill in reproductive life and by hormone replacement therapy in non-reproductive life is widespread and both have an influence on breast cancer risk, but the effects are largely reversible. Current users of the combined oral contraceptive pill are at a 25% increased risk of breast cancer but this excess risk falls after cessation of use, such that after ten or more years after use stops no significant increase in risk is seen [5]. Current users of hormone therapy are also at an increased risk of developing breast cancer and the risk is greater for users of oestrogen-progesterone combined hormone therapy than for users of oestrogen-only hormone therapy. Overall, the evidence suggests that the risk is increased whilst the women are taking hormone therapy and that the effect wears off quickly once use has ceased [6].

Non-reproductive factors

The incidence of breast cancer increases with age, with 80% of all breast cancer occurring in women over the age of 50 in the UK [7].

The anthropometric factors of body mass index and height are determinants of breast cancer risk. The incidence of breast cancer in obese postmenopausal women is twice that of the non-obese and is related to increased levels of circulating oestrogens due to the peripheral aromatization of oestrogen in adipose tissue [8] whereas obese pre-menopausal women have a 20% reduction in cancer risk. Taller women are at an increased risk of breast cancer compared to shorter women [9].

The role of diet in the aetiology of breast cancer remains controversial. Interest in the role of diet in the aetiology of breast cancer is stimulated by the observation of the lower incidence of breast cancer in Asian populations where intake of animal products is lower than that of Western populations [10]. Studies to date exploring the relationship of diet and breast cancer incidence and mortality have not demonstrated any difference between vegetarians compared to non-vegetarians [11]. Alcohol consumption does have an effect on breast cancer risk; the relative risk of breast cancer is increased in women who report drinking alcohol compared to women who report no alcohol intake for an intake of 35–44 g per day alcohol [12].

Up to 5% of breast cancer in Western countries may be a result of a genetic predisposition to the disease. High-risk allele mutations probably account for most of the families with four or more cases of breast cancer and for around 20–25% of the familial breast cancer risk overall, but for only 5% of all breast cancers [13, 14]. Women who have a positive history of breast cancer are at a two-fold increased relative risk of breast cancer. However, most of these women will never develop breast cancer and most who do will do so after the age of 50. Furthermore, eight out of nine women who

develop breast cancer do not have an affected mother, sister, or daughter [15].

Molecular biology of breast cancer

Personalized cancer medicine, envisioned more than 30 years ago [16], has been exemplified by the discovery of the oestrogen receptor (ER) and its consequent therapeutic targeting, as well as by the therapeutic targeting of HER2 oncogene. Recently, large-scale gene expression profiling studies have shed light onto the complex molecular background of breast cancer (BC), holding the potential for more accurate prognostication and personalized treatment decision-making. This chapter highlights the most important advances made recently in the molecular biology of BC, emphasizing their clinical relevance.

Molecular classification of breast cancer

The advent of DNA microarray platforms enabled BC gene expression profiling, representing a major step towards unravelling its molecular complexity [17, 18]. Initially, four intrinsic molecular subtypes were identified: luminal A (ER-positive, histologically low-grade and slowly proliferative tumours); luminal B (high-grade ER-positive tumours); HER2-positive (tumours driven by amplification of HER2 gene and other genes in the same amplicon); and, finally, basal-like (tumours characterized, although not invariably, by negative expression for ER, progesterone receptor [PR] and HER2, also referred to as the triple negative phenotype).

Despite the recognized importance of this molecular classification, there are important impediments to implementing it clinically. One problem is how to discriminate between the luminal A and B subtypes, with these tumours being defined on the basis of proliferation-related genes, which constitute a continuum of expression levels, rather than a binary set of characteristics. An immunohistochemical (IHC) score based on Ki-67 expression levels has been proposed as a potential tool to distinguish the luminal A and B tumours [19]; however, false-positive and false-negative rates reach up to 25%. Another problem concerns HER2-positive tumours. Defined by microarray assays, they show IHC overexpression of the corresponding protein in 70% of the cases; conversely, however, not all cases of HER2 IHC overexpression are classified as HER2-positive by microarray analysis [20].

Basal-like tumours are associated with several additional challenges. Although they have been approximated by the triple negative phenotype in the clinic, the lack of absolute concordance between basal-like and triple negative BC is well known [21]. Within basal-like tumours, additional molecular subtypes have been reported: (i) the claudin-low subtype [22] displaying a gene expression profile of mesenchymal features, immune response genes, and high enrichment for epithelial-to-mesenchymal transition markers; and (ii) the molecular apocrine class [23], characterized by positivity for the androgen receptor and downstream signalling. The heterogeneity of triple negative BC was recently even further elaborated with the identification of six subtypes overall [24].

Additionally, methodological problems have been identified. The gene expression-based BC classifiers use large sets of intrinsic genes, with questionable stability and quality assessment remaining difficult [25]. An alternative approach to large gene sets has been presented [26], namely a subtype classification model called SCMGENE assessing the expression levels of three key genes: oestrogen regulated gene (ESR1), HER2, and AURKA. This simplified classification model was concordant with its more complex multi-gene counterparts, providing comparable prognostication and representing a readily available alternative approach.

Despite incremental refinements in our ability to classify BC, its molecular complexity leaves much to be explored. This has been recently demonstrated by landmark work investigating the genomic and transcriptomic architecture of almost 2000 breast tumours [27], which identified ten novel molecular groups (intclust 1–10), hence splitting the intrinsic subtypes recognized to date.

Oncogenic signalling pathways in breast cancer

The aforementioned gene expression profiling studies and the advent of high-throughput molecular screening tools has led to the identification of multiple oncogenic molecular alterations in BC. One common characteristic emerging from those studies is the genomic heterogeneity of the disease, both between and within individual tumours. In the following sections we present an overview of the major deregulated oncogenic signalling pathways across the distinct molecular BC subtypes.

Luminal breast cancer

Evidence of activated insulin growth factor (IGF) signalling has been found in up to 90% of BC cases [28], with several lines of evidence supporting its implication in luminal subtypes. IGF activates its target receptor IGF-1R, leading to a cascade of signal transduction via the Ras and phosphatidylinositol 3-kinase (PI3K) pathways. Direct cross-talk between ER and IGF-1R has been demonstrated and found to mediate tamoxifen resistance [28]. Furthermore, an IGF-1R signature was manifest mainly in ER-negative BC and a small subset (around 25%) of ER-positive tumours, suggesting that IGF activation may confer hormone resistance [29].

Fibroblast growth factor (FGF) receptors and their corresponding ligands represent another important molecular network in luminal BC [30]. FGFR1 represents one of the most commonly amplified genes in BC (approximately 10%) particularly in the luminal B subtype (16% to 27%) [31]. FGFR1-amplified BC cells are resistant to endocrine therapy, a feature that is reversible upon FGFR1 knock-down [31].

The PI3K signalling pathway represents a molecular 'highway', transducing oncogenic signals from a plethora of upstream receptors. Increased PI3K activity [32] is conferred by multiple molecular aberrations affecting its key molecular components such as PIK3CA, Akt and/or phosphatase and tensin homolog (PTEN). PIK3CA mutations are common in luminal-A and luminal-B BC, and increased expression of PI3K pathway genes was recently found in luminal-B cases [33], with evidence supporting that hormonal resistance is mediated by PI3K signalling activation. However, the prognostic impact of PI3K pathway activation remains to be defined. In the largest molecular study of PI3K in BC conducted to date [34], genomic and proteomic analyses from a cohort of patients with early luminal BC-associated PIK3CA mutations and a corresponding gene expression signature with better clinical outcome.

HER2-positive breast cancer

The HER2-positive BC subtype is driven by the amplification of the HER2 oncogene. HER2 acts through the formation of homo- or hetero-dimers with other members of the HER family. The HER2/HER3 heterodimer is the most potent activator of the PI3K/Akt

signalling pathway, thus making HER3 an attractive therapeutic target [35].

Further molecular aberrations involved in activating signalling pathways such as FGF, IGF, and PI3K/Akt have also been described. These are likely clinically important because they have been shown to mediate resistance to HER2-targeted therapies [36]. Importantly, an unbiased, genome-wide RNA interference screen showed that PIK3CA mutations and PTEN loss were important mediators of resistance to trastuzumab treatment [37]. Furthermore, truncation of the HER2 receptor itself [38] was also suggested to confer resistance to trastuzumab with these findings requiring further clinical validation.

Approximately half of HER2-positive BC cases are also ER-positive, and there is solid data proving bidirectional cross-talk between HER2 and ER-positive signalling pathways [39]. Specifically, activation of the HER2 signalling pathway appears to mediate a decrease in the sensitivity to hormonal manipulations [40]. It has been shown that ER status does not determine the overall genetic profile of HER2-positive BC [41], indicating that HER2 remains the main driver of oncogenesis in ER/HER2 over-expressing tumours.

Basal-like breast cancer

The DNA repair BRCA pathway is responsible for homologous recombination, and it has been found to be commonly deregulated in basal-like BC. Its deregulation may be mediated either through germ-line inactivating mutations or alternatively through BRCA1 gene promoter methylation, BRCA1 transcriptional inactivation, and/or overexpression of BRCA1 negative regulators like ID4 (inhibitor of DNA binding 4). This deregulation offers the potential to exploit therapeutically the concept of synthetic lethality (i.e., the situation whereby two different gene defects lead to cell death, whereas each of them separately does not) through the use of PARP inhibition. PARP-1 is a nuclear enzyme essential for the base-excision repair pathway, an alternative DNA repair pathway. BRCA1-deregulation sensitises breast cancer cells to PARP-inhibition, which causes cell-cycle arrest and apoptotic death [42].

High expression of epidermal growth factor receptor (EGFR) [43]—the first member of the HER family of cytoplasmic receptors, mediating multiple oncogenic effects—has been reported in a subpopulation of basal-like BC. Importantly, PTEN loss is observed with high frequency across this molecular subtype [44], conferring PI3K pathway activation, which can mediate resistance to anti-EGFR treatment.

Several other features are also salient in basal-like BC. The expression of KIT, a cytoplasmic cytokine receptor, has been found in higher frequency across these tumours than in other molecular subtypes [45], and was recently found to be highly expressed in breast tumours from individuals with BRCA1 germline mutations [46]. Basal-like BC also shows a higher incidence of nuclear accumulation of p53 or TP53 gene mutations [47]. Besides these molecular defects, a higher frequency of copy number alterations has been reported in basal-like BC than in the other subtypes [48], indicating genomic instability.

Next generation sequencing in breast cancer

Next generation sequencing (NGS) has numerous advantages over older technologies and has already led to important new insights about BC, ranging from the nature and diversity of gene mutations to early diagnosis and monitoring of disease progression. It allows millions of individual templates to be sequenced in parallel [49]. Moreover, NGS can determine the prevalence of any given DNA sequence within a cell population, thus enhancing scientists' ability to determine the mutational heterogeneity of individual tumours. NGS is also informative with respect to structural alterations in DNA molecules, i.e. point mutations, deletions, insertions, copy numbers, translocations, and gene fusion events.

Studies in BC employing NGS have already led to important conceptual advances. Initial results suggest that a larger than previously anticipated repertoire of cancer gene mutations [50] need to be functionally elucidated. In particular, 'drivers', i.e., mutational events driving oncogenic progression, need to be distinguished from 'passengers', i.e. mutations lacking functional importance. Moreover, the mutational burden has been found to be lower in early-stage lobular BC [51], where a significant mutational evolution parallels disease progression. Importantly, it has been shown that extended somatic mutational heterogeneity was present before the emergence of any selective pressure induced by exposure to anticancer agents. A large-scale, paired-end sequencing strategy recently identified three different patterns of somatic rearrangements in BC genomes and their potential contribution to malignant progression [52].

Other NGS studies have revealed that mutations in BC are non-recurring, with individual tumours exhibiting unique mutational blueprints. For example, a recently reported study of 50 luminal BC cases [53] showed that from among more than 1700 different mutations identified, only three genes were mutated at frequencies approaching or exceeding a threshold of 10%. This inter-tumour heterogeneity was further exemplified in another study exploring the metastatic progression of a basal-like BC [54]; it revealed that, despite the significant overlap of mutational events between the primary tumour and a corresponding brain metastasis, significant changes in the allelic frequencies of those mutations had occurred during the metastatic dissemination.

NGS techniques can contribute with regard to monitoring disease progression and early diagnosis. In one study, circulating nucleic acids were identified in the serum of BC patients [55], with a diagnostic specificity level of 95% and a sensitivity of 90% when compared with healthy and non-malignant controls. This discovery in turn led to the development of a serum-based routine laboratory test for BC screening and monitoring. Similar efforts have been undertaken by other researchers. Using massively parallel sequencing techniques, they identified translocations in BC patients serving as personalized biomarkers [56].

Prognostic gene expression signatures in breast cancer

Gene expression profiling has contributed to the development of genomic tests improving prognostication beyond what is provided by classical clinicopathological parameters, with two different tests having been adopted. The first assessed the epithelial cellular compartment of BC, being mainly proliferation-driven. This approach led to the development of several gene signatures [17], some of which are currently clinically available (MammaPrint®, Oncotype Dx®, MapQuantDx®, Theros®, and EndoPredict®). The second approach took into account not only the epithelial cancer cells, but also the stroma and immune-related compartments.

The proliferation-driven 'first-generation' signatures have led to the identification of a low-risk group of patients, but only within the ER-positive BC population [17]. These signatures assign nearly all patients with HER2 amplification or the triple negative phenotype to high-risk categories [57, 58]. This is not surprising, because most of the assessable genes in the signatures are cell-cycle and proliferation-related, and the ER-negative subtypes are highly proliferative [59]. Despite this limitation, these signatures have been shown to add significant prognostic information to clinical variables like tumour size and nodal size [59]. Because they capture similar biological phenomena, they have similar prognostic ability, and using more than one signature does not improve the ability to predict prognosis [59, 60]. It should be noted that these signatures accurately predict mainly recurrences occurring during the first five years following diagnosis [60]. To date, there is no clear consensus about the clinical utility of the prognostic signatures, with two large phase III randomized trials addressing this issue: the Microarray in Node Negative and 0 to 3 Positive Lymph Node Disease May Avoid Chemotherapy Trial (MINDACT) in Europe (testing MammaPrint®) [61], and the Trial Assigning Individualized Options for Treatment (TAILORx) study in the United States (testing Oncotype DX®) (Figure 43.1) [62].

Several 'second generation signatures' were then developed as the result of efforts to overcome the conceptual drawbacks of their first generation counterparts, with the latter disregarding that ER and HER2 expression status define fundamentally different molecular profiles of BC and that its biological behaviour is influenced by tumour-associated stroma and immune activation status. These concepts were corroborated by a meta-analysis [57] showing that stroma and immune-related gene modules are key determinants of clinical outcome in patients with HER2-positive BC, while immune-gene modules define clinical outcome in basal-like tumours.

Well-conducted studies of separately micro-dissected breast stroma and cancer cells have identified extensive changes in the gene expression profile of BC stroma during tumour progression [63]. Stromal collagen deposition was found to facilitate malignant progression in BC cells, through a β1-integrin-dependent mechanism [64] and through collaboration with COX-2 [65]. Moreover, the presence of tumour-associated-macrophages is associated with aggressive biological behaviour [66], since the macrophages induce increased angiogenic activity through the production of angiogenic factors (e.g., VEGF and IL-8) and matrix metalloproteinases (MMPs). Tumour angiogenesis [67] is an important feature, providing tumours with the nutrients necessary to facilitate metastatic dissemination. In BC, a tumour microenvironment of metastasis was recently identified [68], referring to perivascular macrophages guiding BC cells and facilitating their local invasion in newly formed blood vessels, thus promoting haematogenous metastatic dissemination.

Recently, tumour immune microenvironment was shown to regulate the response to chemotherapy through the recruitment of macrophages [69]. These findings offer hope for new therapeutic avenues, with blockade of macrophage recruitment combined with chemotherapy, significantly decreasing primary tumour formation and reducing metastatic dissemination [69].

Further data supporting the role of the immune system in mediating the response to chemotherapy were recently presented in a study of almost 1000 BC patients treated with neoadjuvant chemotherapy [70]. Gene expression modules describing important biologic processes correlated with response to neoadjuvant chemotherapy, and, independently of other clinical variables, the immune module was found to be predictive for pCR, especially in the HER2-positive subtype.

Finally, cancer-associated fibroblasts are also important mediators of BC malignant progression [71]. This is mainly due to their ability to secrete stroma-derived-factor 1 (SDF-1/CXCL12), a chemokine serving a dual function and facilitating: (1) the recruitment of endothelial precursor cells, thus promoting angiogenesis; and (2) tumour cell invasion in the stroma.

A comparison of tumour stroma and matched normal stroma from BC samples generated a 26-gene signature, called the stroma-derived prognostic predictor (SDPP) [72], being highly prognostic independently of ER, HER2, and clinical prognostic factors. In addition, it provided accurate prognostication in the HER2-positive subtype, out-performing MammaPrint®. In ER-negative BC, an immune-response-related 7-gene module [73] was found to accurately predict prognosis as well. Similar results were obtained by another group using a 14-gene signature [74]. The pivotal role of stromal and tumour cell interaction was further elucidated through the generation of a 12-gene CD10+ stromal signature [75], being prognostic in patients with the HER2-positive subtype and predictive of nonresponse to chemotherapy for those patients.

Additional levels of complexity with respect to the BC genetic heterogeneity have arisen through the identification of microRNAs (miRNAs) [76], which are conserved, noncoding short RNA molecules regulating gene expression. Microarray-based studies using deep sequencing recently led to a 9-miRNA-signature [77], able to identify women with poor prognosis BC.

Apart from the abundance of genomic changes, epigenetic differences (i.e., DNA methylation and histone modifications) have also been observed across different molecular subtypes of BC [78]. Specific DNA methylation patterns were found to identify luminal BC patients with different risks of relapse independently of other clinical variables [79], proving that the profiling of perturbed epigenetic phenomena holds promise for improved prognostication.

Role of gene expression signatures in predicting response to primary systemic therapy

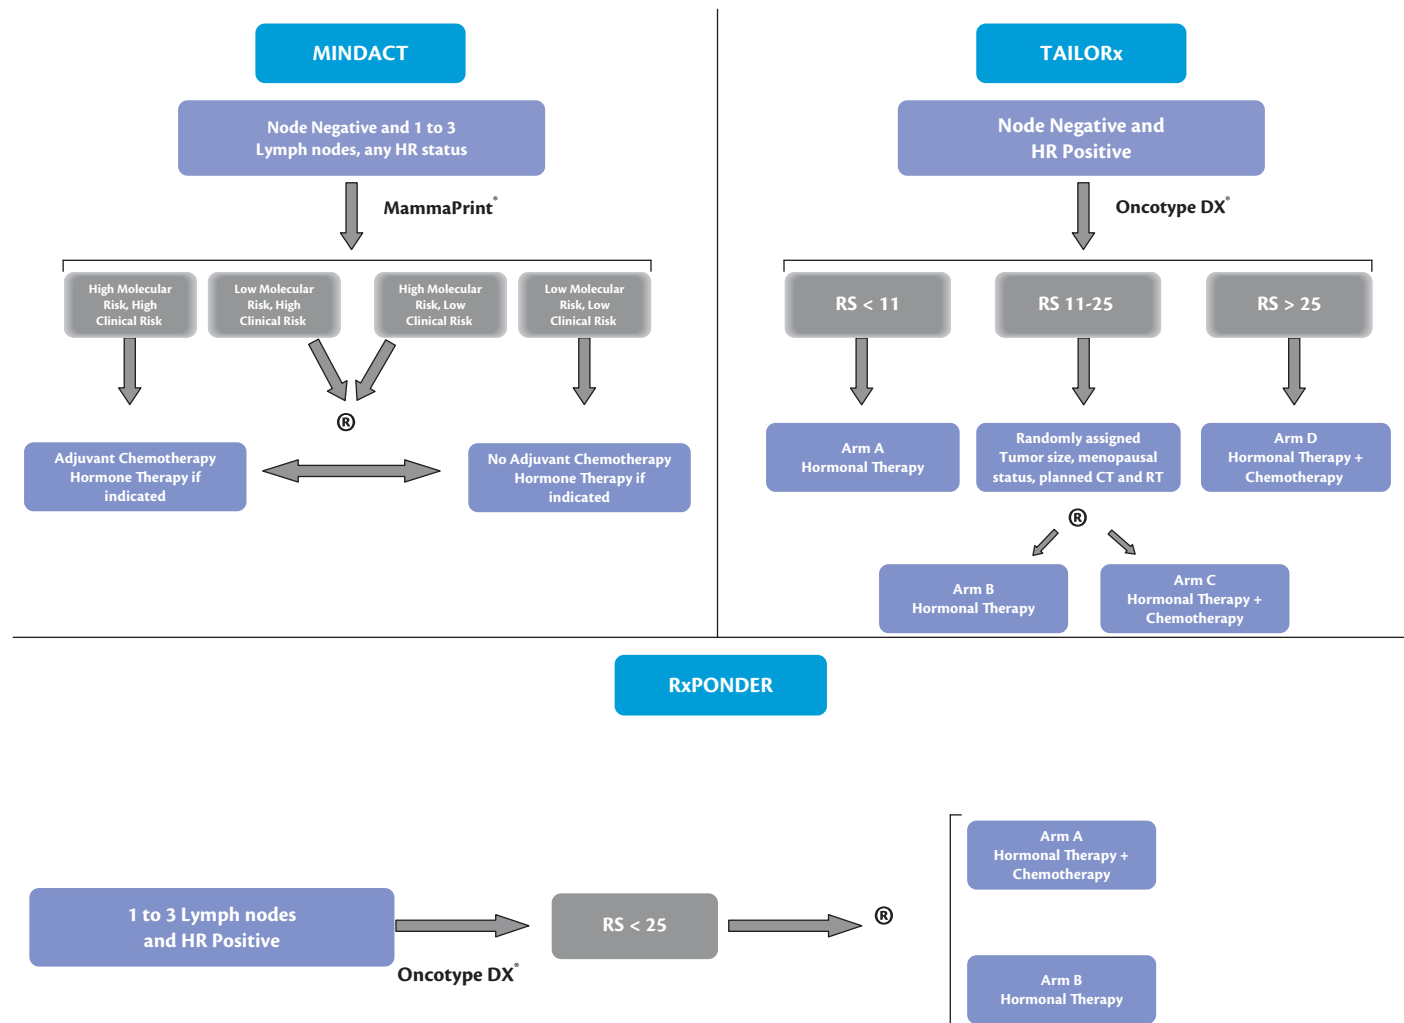
More limited information is available about whether proliferation-related gene expression signatures can predict benefit from chemotherapy. Since conventional cytotoxic agents target highly-proliferating cancer cells, it should come as no surprise that 'first generation signatures' predict chemo-sensitivity [80], particularly in ER-positive BC. Importantly, those gene signatures 'capturing' the generic chemosensitivity of highly-proliferating tumour cells challenge the currently applied clinicopathologic criteria to predict benefit from adjuvant chemotherapy. The 21-gene recurrence score assay (Oncotype DX®) was recently proven to predict benefit from anthracycline-based chemotherapy, irrespectively of the tumour stage [81]. Patients with infiltrated lymph nodes and a low recurrence score did not seem to benefit, whereas patients with a higher recurrence score showed a major benefit, independently of the number of positive nodes. The randomized, prospective RxPONDER trial ('Rx for Positive Node, Endocrine Responsive Breast Cancer') will reveal whether chemotherapy benefits patients


Fig. 43.1 Phase III studies establishing the clinical utility of prognostic signatures.

with node positive BC who have low to intermediate recurrence scores with Oncotype DX® (Figure 43.1).

Efforts to develop multigene classifiers that can predict sensitivity to specific therapeutic agents have also been presented, for example the 'anthracycline-based score (A-score)' predictive for response to anthracyclines [82]. The A-score—a combination of a topoisomerase IIα signature, a stroma signature and an immune-response signature—was found to have high negative predictive value for sensitivity to anthracyclines independently of HER2 expression status. Another approach for prediction of anthracycline resistance employed integrated genomics [83]. A small number of over-expressed and amplified genes from chromosome 8q22 were associated with early disease recurrence, despite anthracycline-based adjuvant chemotherapy. Overexpression of two of those genes, namely the antiapoptotic gene YWHAZ and the lysosomal gene LAPTM4B, was associated with poor tumour response to anthracyclines in the neoadjuvant setting, and thus appears to be a potential predictor of anthracycline resistance.

The prediction of response to endocrine treatment has also been pursued through gene expression profiling experiments, leading to the development of the sensitivity to endocrine therapy (SET) index comprising a set of 165 distinct genes co-regulated with the ESR1 gene [84]. The SET index was found to be predictive of response to any type of endocrine treatment, and it improved the predictive stratification when combined with existing clinicopathological standards. It was recently integrated into a predictive testing algorithm [85] together with newly developed predictive signatures for excellent pathologic response and for extensive residual disease in HER2-negative BC cases after sequentially administered taxane- and anthracycline-neoadjuvant chemotherapy. This combined predictive test was shown to add significantly to a multivariate clinicopathologic model assessing age, tumour size, nodal status, grade, ER status, and the type of taxane administered.

Lastly, attempts to predict sensitivity to specific therapeutic regimens through genetic testing of BC cells in vitro, with the implementation of functional testing (i.e., RNA interference) in some cases, have been presented [86]. However, the results from these experiments have failed to be reproduced robustly in humans, possibly because of the intrinsic limitations of using cultured cell lines as a model for human pharmacology.

Future directions

Accumulating molecular biology data has been critical, because it has helped us move away from the 'one-size-fits-all' paradigm in the clinical management of our BC patients. Identifying 'driver' mutational mechanisms through functional genomics and elucidating the molecular mechanisms that govern heterotypic signalling networks between BC cells and their surrounding microenvironment hold the promise for more efficient therapies. However, before the implementation of this new knowledge into clinical practice, it will be necessary to interpret all the information generated through deep genome, transcriptome- and epigenome-sequencing analyses of breast tumours, which poses a significant challenge. To address this challenge, it will be essential to make significant advances in bioinformatics, systems biology, statistics, and the systems architecture of information technology. Moreover, issues of intra-tumour heterogeneity still need to be addressed, as was recently emphasized by findings in support of the view that distinct aberrations

may vary between different biopsy samples of the very same tumour [87]. Ultimately, it will be necessary to conduct prospective clinical evaluations of new versus current classical approaches before we can change clinical practice.

In situ pathology of breast cancer

Until novel and more sophisticated approaches, for example serum proteomics or gene expression profiling of circulating tumour cells, will be readily available, the primary tumour of patients with breast cancer will remain the main source of information to assess the risk of disease recurrence and to inform the choice of the most appropriate systemic treatment. Accordingly, it is the main responsibility of pathologists to ensure that all the relevant information is derived from the primary tumour with the highest accuracy and reproducibility. Compliance with guidelines and recommendations issued by regulatory agencies and scientific bodies, as well as implementation and continuous participation in internal and external quality assurance program may assist the pathologists in coping with this unprecedented and very demanding task.

A comprehensive approach that includes the accurate evaluation of the morphological features of the tumour, with special reference to the histological type and grade, and the assessment of the main prognostic and predictive parameters should offer the patients and treating physicians a robust background upon which final therapeutic decisions can be safely taken. The robustness of this background, however, depends on the expertise and knowledge of pathologists, and on the accuracy and reproducibility of the assays for the assessment of relevant markers.

Classification of breast carcinoma

Breast cancer is unanimously considered a highly heterogeneous disease in several ways. Indeed, different tumour types exhibit variable histopathological and biological features, different clinical outcome, and different response to systemic interventions. Due to such a high degree of heterogeneity, breast cancer cannot be viewed as a single clinicopathological entity, but it must be necessarily dissected into a number of more homogeneous entities. Hence, there is a need for a classification that should be scientifically sound, clinically useful, easily applicable, and widely reproducible. Unfortunately, however, despite all the efforts in the past and in more recent years, the 'perfect' classification of breast cancer still has not been written.

The histopathological classification of breast carcinoma is based on the diversity of the morphological features of the tumours. In its current version, as endorsed by the WHO in 2003 [88], it includes some 20 major tumour types and 18 minor subtypes. This classification is adopted worldwide, it is reasonably reproducible, but has a major limitation. Indeed, some 70–80% of all breast cancers will eventually belong to either one of the two major histopathological classes, namely invasive ductal carcinoma not otherwise specified (IDC NOS) or invasive lobular carcinoma (ILC). This implies that the classification is unable to actually reflect the much wider heterogeneity of breast cancer with respect to the biological features, the clinical outcome, and the response to systemic therapy. It is also debatable whether the two major classes of breast cancer, ductal and lobular, do actually reflect clinical differences, and whether ILC per se constitutes a prognostically different group as compared to IDC [89, 90].

Interestingly, it is the correct identification of some minor tumour subtypes, the so-called 'special' tumour types, or of 'variants' of the main tumour types that may actually provide clinically useful information, because these tumours have distinct prognostic profiles. This is the case, for example, of the tubular and cribriform carcinomas, pursuing an almost indolent clinical course with an extremely good overall survival [91], and of the adenoid-cystic carcinomas, carrying a very favorable prognosis in the vast majority of the cases [92]. Conversely, other subtypes of breast cancer, like the metaplastic carcinomas, may have a significantly worse clinical outcome when compared with IDC NOS [93].

Another aspect of the WHO classification that has generated increasing debate is the appropriateness of using the term 'in situ carcinoma' for the non-invasive tumours of the duct and lobules (ductal carcinoma in situ or DCIS and lobular carcinoma in situ or LCIS). This terminology has been criticized for the dramatic psychological impact of the word 'carcinoma'. Indeed, in the understanding of patients 'carcinoma' often implies an incurable and life-threatening disease. It has been therefore suggested to replace the DCIS and LCIS terminology with the less frightening designation of 'ductal intraepithelial neoplasia (DIN)' and 'lobular intraepithelial neoplasia (LIN)' [94, 95].

The histopathological classification remains an essential component of the pathological report of breast cancer, despite its limited usefulness in assessing the prognosis of the disease, and in informing the choice of the systemic therapy.

Due to the limited prognostic and predictive power of the histopathological classification, at the beginning of this century new approaches have been taken to unveil the molecular basis for the heterogeneity of breast cancer. By using a hierarchical clustering analysis of gene expression profiling, Perou and colleagues were able to identify molecularly defined classes of breast cancer (luminal, HER2-enriched, basal-like and normal-like) with distinctive biological and clinical features [99–98]. This molecular classification has been shown to have prognostic value and also to be predictive of the response to chemotherapy [99].

The original molecular classification has been derived from investigations on fresh frozen tissue and it is not applicable to formalin-fixed and paraffin-embedded (FFPE) material. This jeopardized the wider application of the molecular classification in clinical practice. More recently, however, a gene expression assay using 50 genes (PAM50) has been developed for use on FFPE tissue. The assay, based on quantitative real time reverse transcription-PCR (qRT-PCR), accurately identifies the major molecular subtypes of breast cancer and generates risk-of-relapse scores [100]. Its prognostic value has been confirmed in several retrospective investigations using tumour samples of patients with long-term follow-up data and of patients enrolled in randomized clinical trials [101, 102].

Another attempt to bring the molecular classification of breast cancer into clinical practice has been to look for surrogate markers that would allow identifying the molecular subtypes using a more familiar immunohistochemical approach. Accordingly, the combined evaluation of oestrogen receptors (ER), progesterone receptors (PgR), HER2, and Ki67 immunoreactivity would approximate the molecular classification of luminal A, luminal B, HER2-enriched, and basal-like breast cancers [103]. It should be noted, however, that the immunohistochemically- and molecularly-defined classes do not overlap completely. As an example, some basal-like breast cancers (according to the molecular classification) will not show the expected triple-negative (ER-, PgR-, and HER2-negative) immunophenotype, and vice versa not all the immunohistochemically triple-negative breast cancer will be classified as basal-like by gene expression profiling [104].

Despite the lack of a complete overlap between the molecular classes and their immunohistochemical surrogates, the panellists of the 2011 St Gallen Consensus have endorsed the use of the immunohistochemical assays to identify breast cancer subtypes and to inform the choice of systemic treatments [105]. Interestingly, however, the panellists also stressed the fact that some 'special' types of breast cancer defined according to the more traditional histopathological classification, while belonging to one of the more recently defined classes, most likely could benefit from a different treatment approach.

The assessment of prognostic and predictive parameters

In the last decades, a major effort has been done to better inform the choice of systemic treatment for breast cancer patients. Risk assessment has been traditionally regarded as the main driver for the selection of the most appropriate therapy. Several histopathological parameters have been shown to correlate with the likelihood of tumour recurrence following local therapy of early breast cancer, including tumour size and grade, occurrence of peritumoral vascular invasion, extent of the intraductal component, and status of the regional lymph nodes. Some of these parameters may also be combined in prognostic scores such as the Nottingham Prognostic Index, constructed on tumour size, number of involved lymph nodes and tumour grade.

To reliably define the risk of tumour recurrence, all the above parameters should be assessed accurately, according to standardized protocols and recommendations, and eventually included into the final pathology report. The macroscopic size of the tumour should be confirmed histologically, to allow the measurement of the invasive component and the classification of the tumour according to the pT categories of the TNM classification [106]. Grading of breast cancer may be poorly reproducible and lose its prognostic significance if it is not performed strictly following the recommended thresholds for scoring the three parameters of the modified Bloom-Richardson-Elston grading system (also called the Nottingham system), namely tubule formation, nuclear atypia, and mitotic index [107, 108].

More recently, however, the concept of using risk assessment to inform systemic treatment has been challenged by the alternative option of relying on the expected responsiveness of the tumours to different therapeutic approaches, and then to fine-tune the treatment according to the patient's risk of relapse. This has been best exemplified at the 2009 St Gallen Consensus, with the panellists agreeing that the systemic therapy of early breast cancer is mainly informed by expression of hormone receptors and HER2 status [109].

It became, therefore, of primary importance for the optimal systemic therapy of patients with early breast cancer to ensure the most accurate assessment of these parameters in a reproducible and timely manner. The panellists of the 2009 St Gallen Consensus took the seminal decision of defining ER-positive and PgR-positive tumours as showing 1% or more immunoreactive cells [108]. This definition has been subsequently endorsed by the expert panel

issuing the ASCO/CAP guideline recommendations for immuno-histochemical testing of ER and PgR in breast cancer [110]. In case of ER- or PgR-positive tumours, the actual percentage of neoplastic cells showing definite nuclear immunoreactivity must be reported, because the higher the number of positive cells, the larger is the expected benefit of endocrine therapies. Indeed, a higher expression (e.g.: >50% immunoreactive tumour cells) of ER correlates with a favorable outcome for patients treated with endocrine therapy, which cannot be significantly improved by the addition of chemotherapy, whereas patients with endocrine non-responsive tumours or lower expression of ER achieve the greatest benefit from systemic chemotherapy (with or without endocrine treatment) in both the neoadjuvant and the adjuvant settings [111–113].

In addition to the actual percentage of the positive cells, it is recommended to report on the average intensity of the staining, whereas the use of a combined scoring system (like the H score or the Allred score) [114, 115] is considered optional.

Guidelines and recommendations describing how to optimally perform the immunohistochemical and in situ hybridization assays for assessing HER2 status and evaluate and score the results have also been issued and recently updated [116, 117]. These assays have been clinically validated in several studies demonstrating the high predictive value of a HER2 positive status for the efficacy of HER2-targeted treatments. According to regulatory agencies worldwide and the trastuzumab package insert, only patients whose tumours over-express HER2 in more than 10% invasive tumour cells, or show HER2 gene amplification (four or more copies of the gene/cell, or a ratio ≥2 between the gene copy number and the chromosome 17 centromeres) are candidates for trastuzumab treatment.

Tumour proliferation is one of the most important prognostic parameters in breast cancer. In clinical practice, the evaluation of the tumour proliferative fraction is most commonly performed by the immunohistochemical staining of the Ki67 antigen [118]. The use of Ki67 immunolabelling as a prognostic and predictive marker has been extensively investigated in both the neoadjuvant and adjuvant settings [119–121]. The panellists of the 2009 St Gallen Consensus have included the assessment of Ki67 among the useful parameters to inform the choice of adding chemotherapy to endocrine therapies for patients with ER-positive and HER2-negative disease. Recognizing the relatively poor standardization and reproducibility of Ki67 evaluation, an ad hoc committee (the International Ki67 in Breast Cancer Working Group) has issued recommendations for optimal testing [122].

Predicting the response of patients with breast cancer to the different therapeutic options remains one of the most challenging tasks for translational and clinical researchers. Traditional markers play a major role in the selection of candidate patients to systemic interventions, but they are of limited value in predicting the actual response of the patients to different treatments, especially when these markers are evaluated individually. Future investigations will have to exploit the predictive value of the traditional markers when used in combination, so to offer a more comprehensive assessment of the biological features of the tumour cells [123]. More sophisticated molecular assays, based on gene expression profiling, are already available to complement the information provided by established markers [124]. The combined evaluation of clinical features, of established pathological markers and of gene expression profiles will eventually lead to more personalized treatment of patients with breast cancer.

In situ surgical management of breast cancer

Surgery for breast cancer has changed gradually over the past 30 years. For many decades, radical mastectomy was the only treatment for all types of cancer. Loco-regional surgery has evolved to a far less mutilating approach, while improving local control rates. These include breast-conserving therapy (BCT) with whole breast irradiation (WBI), mastectomy with immediate reconstruction, skin-sparing mastectomy with or without nipple preservation, and neoadjuvant chemotherapy followed by breast conservation. Treatment selection is nowadays based on the combination of extent of disease, the different surgical possibilities and patient preference [125]. More recently, axillary clearance as a staging procedure has largely been replaced by the sentinel node (SN) procedure, leaving axillary lymph node clearance only for those patients with a positive SN. The limited role of surgery is further evolving by the omission of axillary dissection in some node-positive women and preservation of the nipple areolar complex (NAC).

To obtain a high surgical standard proper training in breast surgery is mandatory, followed by protocolized surgical procedures in general practice and a sufficient caseload per surgeon. The most important determinant for high standard surgical cancer care is, however, a skilled surgeon who is very much interested in and dedicated to breast cancer, working in the setting of a structured breast clinic within a multidisciplinary breast team [126–128].

An optimal surgical technique provides for:

- The least possible mutilation with the best possible cosmetic result.

- The least possible complication rate.

- Conditions for the best locoregional control.

- Optimal information on the nature and extent of the disease locally and regionally.

The surgeon is the key to the information on local extent of the tumour (particularly in breast conservation) and regional-axillary-dissemination, which information influences adjuvant treatment, including radiotherapy and/or systemic therapy [129]. Lymphatic mapping followed by SN biopsy according to established procedures represents an important instrument to this aim.

Diagnosis and staging of breast cancer

In 2010, almost 50 000 new cases of invasive and almost 6000 new cases of non-invasive breast cancer were diagnosed in the United Kingdom. Approximately one-third of these were screen-detected cancers and two-thirds were diagnosed as a result of a symptomatic presentation. Of the screen-detected cancers, 80% were invasive cancer and 20% were non-invasive cancer [130].

Breast cancer is diagnosed through triple assessment, incorporating physical examination, radiological evaluation, and tissue diagnosis. Each element is scored (1–5) according to the degree of suspicion for the presence of cancer. Where there is concordance between the three elements, the diagnostic accuracy of triple assessment is around 99% [131].

Breast cancer staging is based on the TNM classification for solid tumours, taking into account the tumour size or extent (T), number of loco-regional nodes involved (N), and the absence or presence of distant metastasis (M). Staging is largely either clinical or

pathological. The clinical staging (cTNM) is based on information gathered through clinical and radiological assessment prior to any treatment. The pathological staging (pTNM) is given after pathological assessment of a surgical specimen. Other prefixes include 'y' (yTNM) to indicate that the stage was assessed after neoadjuvant treatment (usually chemotherapy). Using the TNM classification, patients can be assigned to a stage which can give an idea of overall prognosis. Early breast cancer is considered to be stage 1 and 2, stage 3 represents locally advanced breast cancer, and stage 4 is metastatic breast cancer. A full explanation of the TNM staging for breast cancer is available on the website of the American Cancer Society: <http://www.cancer.org/cancer/breastcancer/detailedguide/breast-cancer-staging>.

Preventative surgery

Since 1994, human genes BRCA1 and BRCA2 have been discovered with, when mutated, an estimated lifetime risk of up to 85% of developing breast cancer [132, 133]. To reduce their increased risk from dying of breast cancer carriers of BRCA1 and BRCA2 mutations may consider (bilateral) salpingo-oophorectomy and/or prophylactic mastectomy as an alternative to intensive surveillance. A limitation of the surgical procedure is the possibility of incomplete removal of all glandular tissue, leaving a small risk of developing breast cancer. Thus, clinicians may be inclined to continue to follow the women with routine imaging after preventive surgery. However, in clinical practice, the risk of developing breast cancer after risk-reducing surgery appears extremely low at less than 1% at ten years [134–137]. This very low risk does not warrant surveillance for breast cancer after preventive surgery [137]. Further, given the very low risk of invasive cancer at the time of preventive surgery, a SN procedure during preventive bilateral mastectomy is not indicated [137].

Not only do asymptomatic carriers benefit from the risk-reducing procedure, also carriers who have developed breast cancer may benefit from secondary prophylactic measures. A number of studies found a substantial risk reduction from contralateral prophylactic mastectomy, even suggesting survival benefit [138–140].

If a breast cancer gene carrier chooses preventive mastectomy, such a procedure should be performed within the framework of psychosocial support, the availability of a plastic-reconstructive surgeon for immediate reconstruction, and a surgical oncologist to explain all pros and cons of such a procedure. Preferably, such women are treated in specialized centres.

In situ carcinoma

With increasing screening activities, in situ carcinoma of the breast is more frequently diagnosed. About 15% of all screen-detected malignancies appear to be in situ carcinoma [141].

Lobular carcinoma in situ is usually an incidental finding in a breast biopsy and can be considered as a marker lesion for the development of breast cancer. In these patients a wait-and-see policy with intensive surveillance is advocated [142].

Ductal carcinoma in situ is essentially a uni-segmental disease, originated within a specific part of the gallactoforic tree. DCIS consists of a wide range of different lesions defined by the nuclear grade of the tumour cells, the amount of necrosis, the architectural display, etc. Well-, intermediate-, and poorly-differentiated subtypes can be classified histologically. Diagnosis is preferably established by image- guided (ultrasound or stereotactic) biopsies. Diagnosis by core biopsies may underestimate, however, the risk of invasive breast cancer; in 15–20% of patients invasive cancer at excisional biopsy or mastectomy is seen [141].

DCIS is essentially treated by complete excision. In case of non-palpable lesions excision is performed after localizing the tumour with some form of localization technique, such as guide wire, ROLL technique, and Iodine-125 seed. The ROLL technique (radioguided occult lesion localization) is done with an image-directed (ultrasound- or stereotactic-guided) injection of a radioactive tracer (for instance Tc99 labelled albumin colloid). The excision is directed using the gammaprobe.

As the breast is not divided in anatomically recognizable segments, and DCIS is essentially a microscopic disease, the surgeon is not able to define the complete local excision clinically. Depending on the extent of the micro-calcifications, a treatment plan should be drawn with a wide local excision or an ablative procedure, preferably offered with an immediate breast reconstruction. A complete local excision with good cosmetic outcome can be facilitated with oncoplastic procedures [143]. Free margins of 1–2 mm are sufficient; wider margins hardly improve local control rates [144]. Axillary dissection is not indicated. In patients with extensive lesions diagnosed as DCIS by core biopsies (and thus limited sampling, insufficient to exclude invasive cancer), and for whom ablative surgery is the preferred treatment option, a SN procedure is reasonable. Further, since the risk of invasion is larger in patients with a palpable lesion, in DCIS grade III and in patients younger than 55 years of age, a SN procedure can also be performed [145].

Preoperative workup

Breast-conserving therapy now is widely accepted as a result of the convincing data generated by randomized studies [146]. The recent long-term outcomes from the EORTC trial 10801 show that also for larger tumours the results are equivalent to those of mastectomy [147]. Since breast-conserving therapy always involves wide local excision with a minimal macroscopic circumferential margin of 0.5–1 cm, in many instances the size of the lump will affect cosmesis. Therefore, one important consideration is the size of the tumour in relation to the size of the breast. The size of the tumour has to be judged on clinical grounds and the appearance on mammography and/or ultrasound. If there is doubt on the extent of the tumour and consequently the feasibility of breast conservation, MRI can be a helpful tool [148]. Further, to improve complete excision and cosmetic outcome, oncoplastic techniques should be applied.

If histology does not reveal risk factors for local recurrence (grossly incomplete excised invasive cancer, incomplete excised ductal carcinoma in situ (DCIS), extensive vascular invasion of the tumour, young age of the patient <35 yrs) breast conservation can safely be performed with good local control rates [129, 146]. Margins should be clear of invasive and of in situ cancer [149]. A specific 'safe' margin width cannot be given [150]. If the breast cancer involved area is too extensive to allow for a good cosmetic outcome and local control, a mastectomy is indicated, again preferably with the possibility of immediate reconstruction.

In selected cases, nipple-sparing procedures will result in good cosmetic results and local control rates [151]. It should be noted that a significant minority of the well-informed patients who are good candidates for breast conservation choose mastectomy [152, 153].

The management of the axilla

The knowledge whether regional and axillary lymph nodes contain metastatic disease is important for two reasons:

1. It provides prognostic information: should the patient receive adjuvant systemic treatments? It should be kept in mind that nowadays important prognostic information can also be gathered from the primary tumour: grade, lymphatic invasion, size, and gene expression arrays. It can be foreseen that in the near future lymph node status will become far less important as a prognosticator.

2. To guide elective treatment in case of metastasis in the lymph nodes: axillary lymph node dissection or radiotherapy to the axilla or to the other regional lymph node basins.

Involvement of regional lymph nodes can be detected by ultrasound of the axilla and guided FNA cytology or core biopsy of suspicious nodes, axillary lymph node dissection, the sentinel node procedure or PET/CT scanning [154]. US of the axilla is a cheap, simple and helpful tool to detect larger metastasis, and thus may spare an unnecessary SN procedure in 10–20% of patients with clinically negative nodes [155].

From the ever-growing published experience on the SN procedure in breast cancer, it is clear that this procedure is standard of care for those patients with clinically or ultrasound unsuspicious axillary lymph nodes. In experienced hands, the SN procedure offers the same staging opportunities as a full axillary clearance [156]. Two large European multicentre studies [157, 158] show a high SN identification rate. Both trials had an intensive audit and quality control program, which has led to these satisfactory figures. The same is seen in the NSABP B-32 trial, where also, even more importantly, no differences in axillary relapse and survival rates are observed [159].

Unless ultrasound of the axilla is negative, SN procedure is reliable in almost every clinical situation:

- Larger cancers (up to 5 cm); cancers at any location in the breast.
- Multifocal cancers.
- Before or after neoadjuvant chemotherapy; both have advantages and limitations.
- In pregnancy.
- In male breast cancer.
- In DCIS diagnosed on core biopsy where there is some risk of missed invasive cancer.
- After previous surgical procedures in the breast.
- In cases of breast relapse after breast conservation.

If the quality criteria are met, the clinical false-positive rate, i.e., the number patients with axillary lymph node metastases after a negative SN procedure, is low: approximately 0.3% after an average of three to five years of follow-up [156, 159]. Taking into account a SN false negative rate of 5–10% and an axillary recurrence rate of 0.3%, fewer than 6% of patients with microscopic residual disease will have clinical manifestation. This low rate of clinical manifestation is confirmed by five small series of patients with positive SNs who declined axillary dissection. If not treated, the two- to three-year risk of an axillary 'relapse' in these series is 0–1.4% [160–164]. These

findings were confirmed in a prospective trial examining outcome of patients with SN metastases, the American College of Surgeons Oncology Group Z0011 trial. Patients with tumour-positive SN detected by standard H and E were randomized to undergo ALND after SLND (445 patients) versus SLND alone (446 patients) without specific axillary treatment. Loco-regional recurrence was evaluated. Patients in the two groups were similar with respect to age, Bloom-Richardson score, oestrogen receptor status, use of adjuvant systemic therapy, tumour type, grading, and tumour size. Patients randomized to SLND+ALND had a median of 17 axillary nodes removed compared with a median of only two SN removed with SLND alone (P <0.001). ALND also removed more positive lymph nodes (P < 0.001). At a median follow-up time of 6.3 years, there were no statistically significant differences in local recurrence (P = 0.11) or regional recurrence (P = 0.45) between the two groups. Regional lymph node relapse after SLND only was observed in four patients (0.9% and after SLND+ALND in two (0.5%). The conclusion of Giuliano et al. was that, despite the potential for residual axillary disease after SLND, SLND without ALND can offer excellent regional control and may be reasonable management for selected patients with early stage breast cancer treated with breast conserving therapy and adjuvant systemic therapy [165].

Two limitations of this clinical trial include: (1) the fact that it did not complete its planned accrual, and (2) the uncertainty of generalizing its results to all breast cancer subtypes or to patients who underwent a mastectomy (all patients in the 2011 trial received radiotherapy to the breast and lower axilla).

Take home messages for the surgical management of the axilla

- SN procedure is standard of care in all patients with invasive breast cancer and clinically and ultrasound unsuspicious axillary lymph nodes.
- No axillary treatment is indicated in patients with a negative SN, including those with small metastases <0.2 mm.
- Axillary clearance is indicated in patients with proven macrometastases in the axilla (by US and FNAC).
- In patients with limited cancer involvement of the removed SN and who will receive adjuvant systemic treatment and whole breast irradiation, axillary clearance can be omitted.
- Patients with higher risk of further axillary lymph node metastases after SN biopsy, ALND is still standard of care, and radiotherapy to the axilla can be considered as alternative.

Neoadjuvant chemotherapy and surgery

The use of primary systemic therapy, or neoadjuvant chemotherapy, has gained an important role in the treatment of breast cancer. Firstly, the rate of breast-conserving surgery can be increased due to primary systemic therapy, because of reduction of tumour load. In a recent meta-analysis, Mieog et al. describe an increase in breast-conserving surgery of 18% [166]. The efficacy of primary systemic therapy to this end can further be improved by tailoring the regimen to tumour characteristics and by switching regimen based on interim evaluation. Applying these strategies, adequate

breast conservation can be achieved in about 40% of patients who were otherwise candidates for mastectomy [167]. It is imperative to mark the cancer in the breast before the start of chemotherapy to facilitate optimal local excision in case of a very good partial or complete remission.

In case of primary systemic therapy, the type of surgery of the breast, breast-conserving or mastectomy, is dependent on clinical tumour response and imaging, where MRI of the breast appears the most helpful tool [168–170]. In general, the same rules as in primary breast conserving apply: to obtain clear margins after local excision and adequate radiotherapy. For staging purposes, extra-axillary lymph node metastases and distant metastases, new generation 18F-FDG PET/CT scanning appears to outperform conventional imaging techniques, and will have impact on patient management [171].

Radiotherapy in breast cancer

Indications and prediction of outcome

Applied to the majority of patients, radiotherapy is today one of the mainstays of breast cancer treatment. As a part of combined treatment schedules, its aim is to improve local tumour control and hereby to increase survival. Breast-conserving surgery of invasive breast cancer followed by radiotherapy yields similar local control and survival rates compared to mastectomy [172]. Loco-regional tumour control rates range today between 70 and 95% after 10 years [173, 174]. The risk of loco-regional recurrence highly depends on patient age with young patients being at highest risk. Histopathologic risk factors include extensive ductal carcinoma in situ, vascular invasion, tumour size, or multicentricity and nodal involvement [175]. Attempts to classify patients into risk groups for local recurrence according to tumour gene expression profiles have been unsuccessful so far since they did not yield independent additive predictive value for treatment decisions [176]. There is currently no patient group in whom adjuvant radiotherapy can be safely omitted after BCS, while after mastectomy radiotherapy is only applied in high-risk patients (see below).

Radiotherapy after breast conserving surgery of invasive breast cancer

Whole breast radiotherapy

Radiotherapy of the whole breast improves local tumour control after breast-conserving surgery of invasive breast cancer. Independent on tumour stage, the advantage seems to be a reduction of local recurrences by ~50% and a reduction of the risk of death by about a sixth. One breast cancer death within 15 years of follow-up can be avoided by four recurrences avoided within 10 years of follow-up [174]. The absolute benefit of radiotherapy is higher in patients who express a high baseline risk of recurrence. A meta-analysis of individual data from >10 000 women in 17 randomized trials yielded absolute risk reductions for local recurrence in patients without nodal involvement between <10 and >20% dependent on age, grade, oestrogen-receptor status, tamoxifen use, and extent of surgery. Corresponding reductions in the risk of breast cancer death varied between 0.1% and 8% [174].

The standard radiotherapy treatment schedule for whole breast irradiation consists of a total dose of 45 to 50 Gy to the whole breast with a dose per fraction of 1.8 to 2.0 Gy (conventional fractionation). The long-term experience described above is mainly based on conventionally fractionated schedules. Applying this schedule for whole breast radiotherapy is a safe and effective treatment. Recent clinical trials have established alternative fractionation schedules, namely hypofractionated radiotherapy for breast cancer treatment. Here, total doses of 40 to 42 Gy are applied with doses per fraction of 2.67 to 3.2 Gy. In randomized trials, hypofractionated radiotherapy has been shown to be equally effective as compared to conventional fractionation [177–179]. Hypofractionated irradiation schedules are based on the evidence of a relatively high fractionation sensitivity of breast cancer, i.e., a high recovery between irradiation fractions. Thus, applying fewer fractions with higher dose per fraction allows reduction of the total dose without affecting the tumour control probability. It has to be mentioned that this fractionation sensitivity of the surrounding normal tissues like lung, heart or soft tissue lies in the same range (α/β-value 3–4 Gy), so that the therapeutic window, i.e., the ratio between tumour control probability and risk of severe late toxicity, is not expected to be improved. Although there is sufficient evidence for an equal efficacy and toxicity of hypofractionated schedules for patients in lower risk groups, i.e., aged ≥50 years, disease stage pT1-2 pN0, patients who did not receive chemotherapy, and who were treated with a high radiation dose homogeneity [180], follow-up of the trials is still not long enough to safely conclude on very late toxicity, in particular cardiotoxicity. Caution is necessary when applying hypofractionated schedules to patient groups that were not adequately represented in the trials and that may have a different tumour biology like very young patients, patients with locally advanced tumours or patients with indications for regional radiotherapy [180]. Regarding regional radiotherapy, the possibly very high fractionation sensitivity of the neural tissue (plexus brachialis) has to be kept in mind [181, 182].

Boost to the tumour bed

Boosting the tumour bed by an additional dose of 16 Gy further improves local tumour control by another 40–50% in all age groups, without further improving survival. The absolute benefit is highest in young patients below the age of 40 (14% local recurrences instead of 24% within 10 years) [173]. Other studies with shorter follow-up have shown a similar efficacy when using 10 Gy as boost dose [183]. Between 10 and 26 Gy boost dose, no further increase in local tumour control could be documented in patients with microscopic residual tumour [184]. Boost application has become standard for patients with invasive breast cancer after breast conserving radiotherapy. However, as boost irradiation also increases fibrosis, definition of subgroups of patients with a very low absolute benefit from the boost application can be a helpful tool for clinical decisions [185].

Partial breast irradiation

Recent research strategies aim at lowering the risk of chronic side effects by reducing the irradiated volume. Several clinical trials were performed to compare standard whole breast irradiation with partial breast irradiation using external beam or brachytherapy approaches. So far, equal efficacy of both approaches is not proven for any patient group by results of large-scale randomized clinical trials. However, patients with very low risk of local recurrence may be the best candidates for partial breast irradiation [186, 180]. In contrast to the first publication [187], a recent update of a randomized trial has shown significantly more recurrences after intraoperative radiotherapy (IORT) by kV x-rays versus whole breast

Table 43.1 Published and ongoing clinical trials on partial breast irradiation

Protocol	Conventional arm	Experimental arm	Result	Remark
TARGIT	Adjuvant whole breast radiotherapy	IORT (kV X-rays)	LR 0.95% (whole breast) vs 1.2% (IORT) at 4 years, average follow up 2 years (ns)	14% of patients in the IORT arm received additional whole breast radiotherapy
ELIOT	Adjuvant whole breast radiotherapy	IORT (electrons)		Closed, data not finally published
IMPORT-LOW (UK)	Adjuvant hypofractionated whole breast radiotherapy	Adjuvant dose-modified whole breast radiotherapy or partial breast irradiation		Closed, awaiting results
RAPID/Ontario Clinical Oncology Group	Adjuvant hypo- or normofractionated whole breast radiotherapy vs	Adjuvant hypofractionated partial breast irradiation		Closed, awaiting results
NSABP-B-39, RTOG-0413, SWOG-NSABP-B-39, NCT00103181	Adjuvant whole breast radiotherapy	Adjuvant partial breast irradiation		Ongoing
CDR0000629768 ICR-IMPORT-LOW, ICR-CTSU/2006/10001, ISRCTN12852634, EU-20896, IMPORT LOW, NCT00814567	Adjuvant hypofractionated whole breast radiotherapy	Reduced whole breast or partial breast irradiation		Ongoing
ISRCTN 34086741, MREC No. 99/0307, UKCRN ID 7265, NCT00983684	Adjuvant whole breast radiotherapy	IORT (kV X-rays)		Ongoing
RTS02-SHARE AFSSAPS, NCT01247233	Adjuvant normo- or hypofractionated whole breast radiotherapy	Adjuvant Accelerated partial breast irradiation		Ongoing
GEC-ESTRO	Adjuvant whole breast radiotherapy	Adjuvant partial breast irradiation using interstitial brachytherapy		Ongoing

IORT, intraoperative radiotherapy; ns, not significant.

radiotherapy in low-risk patients, although the current difference of 2% is still below the predefined criteria for non-interiority [188]. Beside the still short follow-up (mean < 5 years), interpretation of the data is limited mainly by the fact that some patients in the IORT arm got additional whole breast radiotherapy. The data of this trial are still in line with the improvement of local tumour control by 50% after adjuvant radiotherapy compared to no adjuvant radiotherapy [189, 190]. Although the dose distribution of electrons is much more favourable a as compared to low-energy photons, another randomized phase III trial on intraoperative partial breast irradiation using electrons compared to whole breast irradiation showed higher recurrence rates in the IORT arm (ELIOT, data presented, not published so far). Further randomized trials are ongoing (see Table 43.1).

Radiotherapy treatment planning and technique

For whole breast radiotherapy, the clinical target volume (CTV) consists of the whole gland of the breast. The boost CTV includes the surgical cavity, which should intraoperatively be marked with surgical clips (Figure 43.2A). Ideally, up to six clips (e.g., titanium) are placed at all margins of the surgical cavity and positions of the clips are described in the surgical report. Correct placement has to be checked by the radiation oncologist by comparing the planning-CT with information from pretreatment imaging and the

surgical report. Determining the boost volume without clips by the visible tissue changes after surgery and the pretreatment imaging information is especially error prone after oncoplastic surgery, in patients with a dense breast, or after a long time interval between surgery and radiotherapy.

Standard radiation treatment is a 3D-conformal, CT-planned radiotherapy (Figure 43.2B). Photon treatment technique consists of tangential fields including a modification for different body diameters (wedges or field-in-field). To prevent under- and over-dosage, often more than two fields are applied today (Figure 43.2B–E). For boost or partial breast radiotherapy, electron or multifield photon techniques are used or radiotherapy is applied by brachytherapy techniques. The latter is expected to be advantageous especially in patients with large breasts and deep seated tumours closed to organs at risk like heart or lung. Novel radiotherapy techniques that may in the future reduce late toxicity to the normal tissue include deep-inspiration breath hold radiotherapy for left-sided breast cancer, aiming to separate the heart from the target volume, thereby reducing the heart dose [191].

Radiotherapy after mastectomy

After mastectomy, radiotherapy of the chest wall is given to patients with a high risk of local or regional recurrence. Indications are a large primary tumour size, incomplete resection, or very close
Fig. 43.2 Radiotherapy treatment planning and technique. (A) Contoured whole breast CTV/PTV (pink, orange), boost CTV/PTV (pink/yellow), and normal tissues (lungs, heart, left anterior descending artery, contralateral breast). A surgical clip is visible inside the boost CTV as well as a skin mark for the scar. In this case, no clear surgery-related tissue changes are visible, so that for the safety of the definition of the boost CTV the surgical clips are of high importance. (B) Tangential field arrangement for whole breast radiotherapy, here with nine fields coming four angles (field-in-field). (C) Single electron beam for boost irradiation. (D) Homogeneous dose distribution for whole breast irradiation. (E) Cumulative dose distribution for whole breast and boost irradiation.

surgical margins, or patients with four or more involved lymph nodes. However, also for patients at medium risk, i.e., with up to three positive lymph nodes, radiotherapy has been shown to improve loco-regional tumour control and should therefore be strongly considered [192, 193]. Subgroup analysis of the randomized DBCG 82 b&c trials revealed an even higher advantage for the group with up to three positive lymph nodes on survival as compared to the high-risk group with more than three lymph nodes, while both groups expressed a clearly lower loco-regional recurrence rate after post-mastectomy radiotherapy [194]. A likely reason is the lower risk of distant metastases in this group.

Radiotherapy to the chest wall is performed using conventional treatment schedules with a total dose of ~50 Gy and doses per fraction of 1.8 to 2 Gy. Hypofractionated schedules are not established for this indication, as this group of patients was underrepresented in the trials.

Radiotherapy treatment planning and technique

CTV is the soft tissue in the former area of the breast gland. The skin needs to be included if it was involved (e.g., inflammatory breast cancer or exulceration). Treatment technique is similar to the one applied to patients after breast-conserving radiotherapy. Electron beams can be used if feasible.

Regional radiotherapy

There are currently no randomized data with sufficient follow-up on the use of regional radiotherapy vs local radiotherapy alone. For patients with negative sentinel lymph node, the risk of regional recurrence is low and regional radiotherapy is therefore not recommended [192, 195, 196]. Regional radiotherapy of the supra/infraclavicular region is recommended for patients with four or more involved axillary lymph nodes and should be strongly considered for patients with up to three involved lymph nodes [192]. Axillary radiotherapy is recommended if there was no adequate axillary surgery or if there is residual tumour in the axilla. Individual decisions for axillary radiotherapy may be made in cases of massive axillary involvement [197]. Internal mammary nodes are to be irradiated if they are clinically involved. For all other patients there is currently not enough evidence for a strong recommendation. Inclusion of clinically non-involved internal mammary nodes is controversial and not done on a routine basis, because late toxicity (especially heart in left-sided cancer) may be higher due to the depth of the irradiated volume and the clinical advantage is not proven so far. Randomized trials on this question have been performed or are underway, with final publications awaited within the next few years (CAN-NCIC-MA20 [NCT00005957], NCIC-CTG MA.20, EORTC

22922/10925). Early data from one randomized clinical trial support the use of regional radiotherapy at least for patients with risk factors [198].

Radiotherapy treatment planning and technique

CTV includes the lymph node areas that were not treated with axillary dissection by the surgeon previously, i.e., level III of the axilla, supra- and infraclavicular lymph node areas and, if indicated, internal mammary lymph nodes.

Male breast cancer

Because of the rarity of this disease, no randomized trials are available for radiotherapy of male breast cancer. As a mastectomy is usually the surgical treatment of choice, the indications for adjuvant radiotherapy as well as the techniques should be applied similarly to the post-mastectomy situation for females. Small datasets support the improvement of loco-regional tumour control when radiotherapy is applied in high-risk patients with positive lymph nodes, insufficient resection margins or locally advanced tumours [199, 200]. The use of alternative fractionation schedules cannot be recommended, as the biology of such tumours may be different and male patients were not included in the respective clinical trials.

Radiotherapy after neoadjuvant chemotherapy

As is done for patients receiving adjuvant chemotherapy, the tumour staging before chemotherapy, i.e., the initial clinical staging, needs to be considered for radiotherapy treatment decisions. The uncertainty of this staging can be reduced by performing the sentinel lymphadenectomy in patients without enlarged lymph nodes before the start of chemotherapy.

Ductal carcinoma in situ

The aim of radiotherapy in patients with ductal carcinoma in situ (DCIS) is to prevent local invasive or non-invasive recurrences. The relative rate of in-breast events (ipsilateral recurrence of DCIS or invasive breast cancer) is reduced on average by ~50% with radiotherapy [201, 202]. The absolute reduction is ~15% (28% without radiotherapy versus 13% with radiotherapy) [201]. This improvement is evident in all patient groups. By the nature of the disease, the reduction of ipsilateral in-breast events does not translate into a reduced rate of breast cancer death within 10 years of follow-up [201]. Radiotherapy is indicated in all patients after breast-conserving surgery. Exceptions include elderly patients and low-grade tumours with wide surgical margins, after discussion with the patient [203]. After mastectomy with sufficient surgical margins, there is no proof of an advantage from post-operative radiotherapy. Treatment fractionation, planning, and technique are similar to those applied for invasive breast cancer with the difference that there is no indication for boost irradiation.

Time interval between surgery and radiotherapy and sequencing of radiotherapy and systemic treatment modalities

Scheduling of radiotherapy and chemotherapy

If there is an indication for adjuvant chemotherapy and for radiotherapy, chemotherapy is mostly applied before radiotherapy. A simultaneous approach may slightly increase anti-tumour efficacy but also increases toxicity [204]. Comparing sequential schedules, there seems to be no major difference between the efficacy of adjuvant chemotherapy followed by radiotherapy or radiotherapy followed by chemotherapy [205]. However, prolonging the time interval between surgery and the start of radiotherapy can increase the risk of local recurrence, a factor that is especially important for higher-risk patients [206, 207]. The prolongation of the time interval before radiotherapy by the administration of adjuvant chemotherapy is in most cases justified, as for the respective patient group the risk of distant metastases is relatively high, calling for an early start of systemic treatment. If in individual patients the risk of local recurrence appears to be more important, radiotherapy can be performed before the start of chemotherapy.

Radiotherapy and anti-HER2 therapy

Simultaneous radiotherapy and trastuzumab does not seem to increase cardiac toxicity of trastuzumab in clinical trials and is therefore adopted in clinical practice for patients with HER2 amplified tumours [208]. However, whether very late radiation-induced cardiac toxicity is increased can only be clarified after long-term follow-up.

Radiotherapy and anti-hormonal treatment

Anti-hormonal treatment is started either during or after the end of radiotherapy. Both tamoxifen and aromatase inhibitors do not compromise tumour response to radiotherapy in vivo, but there is some evidence that tamoxifen can increase radiation-induced lung disease (RILD) [209, 210]. However, as the overall rates of symptomatic RILD are very low after breast cancer radiotherapy, this fact should not be seen as a contraindication for simultaneous application of both treatments. Instead, the therapeutic advantage has to be weighed against the potential risk of toxicity. Postponing the start of tamoxifen treatment should especially be discussed for patients with other risk factors for RILD, like a high radiation dose to the lung.

Radiotherapy of in-breast recurrences

Without pre-irradiation, the indications for radiotherapy are similar to the primary situation. After whole breast pre-irradiation, mastectomy is standard of care. Breast-conserving surgery followed by re-irradiation is not supported by prospective trials. However, there is experience from small series of patients where re-irradiation was performed as an individualized treatment in selected low-risk patients [211, 212, 213, 214, 215]. Such re-irradiation should be performed in experienced centres. It has to be considered that late toxicity, especially fibrosis and changes in breast appearance, is increased after re-irradiation. Radiotherapy should be preferentially performed as brachytherapy with the aim of reducing the non-involved irradiated volume. Also, external beam radiotherapy is possible, namely for tumours that are not suitable for brachytherapy.

Radiotherapy in the context of metastatic breast cancer

Palliative radiotherapy for multiple metastases

Palliative radiotherapy of distant metastases aims to reduce or prevent symptoms that affect quality of life without inducing a high risk of treatment-related toxicity. Typical indications are painful metastases, e.g., those affecting the skeleton, beginning or imminent paralysis through metastases of the spine, or brain metastases that are usually not sufficiently treated by systemic drugs. In

all cases, short radiation treatment schedules between one and ten fractions are routinely used.

High-dose radiotherapy to single or oligo-metastases

In selected cases of distant metastases, high-dose radiotherapy may be indicated with the aim to inactivate the tumour manifestations. This applies to solitary or oligometastases appearing in patients in good overall condition who are expected to have a decent survival. Small metastases, e.g., in the brain, can be treated successfully by single-dose stereotactic radiotherapy (radiosurgery) with or without combined whole brain irradiation, a procedure that leads to similar local control rates as compared to surgery [216]. At other sites, e.g., solitary bone metastases, fractionated radiation treatment with doses of 50 Gy or higher as well as hypofractionated or single-dose stereotactic radiotherapy are used to induce a longer-term freedom of progression.

Acute toxicity of radiotherapy

Severe acute toxicity is a rare event in breast cancer radiotherapy, except in the context of a few known genetic diseases. Factors determining a relatively higher risk of toxicity are chemotherapy applied before or during radiotherapy, large breast size for skin reactions, or pre-existing cardiac diseases for cardiac side effects. The most frequent acute side effect is dermatitis within the irradiated area. Radiation pneumonitis is relatively frequent when radiographic changes are evaluated; however, only few patients (~1%) develop symptoms and therefore require treatment. Other rare events are esophagitis if supra/infraclavicular lymph nodes are irradiated or arrhythmia in patients with a previous medical history.

Late toxicity of radiotherapy

Fibrosis of the irradiated tissue is a common late toxicity after radiotherapy. After breast-conserving treatment, 15–30% of the patients develop fibrosis that impacts the cosmetic outcome. The likelihood increases with dose, boost application, infections, haematoma, and seroma after surgery. With modern techniques, teleangiectasia has become a rare event. Oedema of the breast often occurs transiently during irradiation. Chronically, oedema of the breast or arm can be caused by the sum of treatment, i.e., surgery and radiotherapy. The likelihood increases with the extent of treatment and is highest after axillary dissection followed by regional radiotherapy. Chronic fibrosis of the lung can develop from a pneumonitis; however, symptomatic chronic pneumopathy is a rare event. Cardiac side effects like myocardial fibrosis, sclerosis of the coronary vessels or cardiomyopathy are of importance especially for patients with a good prognosis and a long life expectancy. A measurable increase of the risk of cardiac-related death in the treated population occurs beyond 10–15 years [217]. Using modern techniques, the dose to the heart can today be considerably reduced in comparison to the one applied in patients for whom long-term follow-up data are available [217], however, more time is needed before one can prove reduction of late toxicity. Other rare late effects are osteoradionecrosis of the ribs or lesions of the plexus brachialis. Secondary cancers, e.g., of the contralateral breast, lung, oesophagus, or soft tissue, increase decades after radiotherapy, thus mainly affecting patients at younger age during radiotherapy. However, this risk is smaller than the survival benefit from radiotherapy [218].

Medical management of breast cancers

Four families of medical treatments have been shown to provide benefit in patients with breast cancer: (i) chemotherapy, (ii) endocrine therapy, (iii) targeted therapy, and (iv) bone-modifying agents. The primary aim of medical treatments for patients with non-metastatic breast cancers is to avoid metastatic relapse and eventually to cure patients. In the metastatic setting, the primary aim is to prolong survival while preserving quality of life. The major question for patients with breast cancer relates to the optimal definition of who should receive which treatment, and at which moment during the natural history of the disease.

Chemotherapy for breast cancer patients

Adjuvant and neoadjuvant chemotherapy

Adjuvant chemotherapy is defined as the post-operative administration of chemotherapy, while neoadjuvant chemotherapy is administered before the surgical procedure. A meta-analysis that included more than 100 000 women indicated that the administration of post-operative chemotherapy improves survival of patients with early breast cancer [219]. It is estimated that the administration of chemotherapy reduces the relative risk of mortality by about one-third. Although these numbers appear impressive, they must be interpreted in the context of absolute risks of death. As illustration, in the same meta-analysis, the average absolute gain in mortality was 5% for patients treated with a second-generation chemotherapy schedule as compared to no chemotherapy, suggesting that there is no or minimal benefit from chemotherapy for a significant number of patients.

The oncologist faces three sets of decisions in relation to chemotherapy: (i) Should my patient receive chemotherapy? (ii) Which regimen? (iii) Should the chemotherapy be given preoperatively?

Indications for adjuvant chemotherapy

To obtain benefit from adjuvant chemotherapy, a patient must present with both a significant risk of relapse and also to be sensitive to chemotherapy. The tumour staging (tumour size and lymph node involvement) and the standard pathological parameters (oestrogen receptor expression, tumour grade) remain important decision criteria. These parameters are integrated in the web-based tool Adjuvant! Online [220]. These criteria, that roughly evaluate tumour burden and aggressiveness, could represent the starting point to evaluate the risk of breast cancer death. Several tools have become recently available that improve the performance of Adjuvant! in evaluating which patient harbours a low risk of relapse and could therefore avoid adjuvant chemotherapy.

First, the use of molecular classification defined by immunohistochemistry (IHC) could allow the identification of a group of patients with very good prognosis. This classification includes expression oestrogen receptor (ER), status of human epidermal growth factor receptor-2 (HER2) and Ki67 determination [221]. Since HER2 overexpression has been shown to be associated with poor outcome in breast cancer patients [222] and could also define a subset of patients who are highly sensitive to chemotherapy [223, 224], it is therefore considered that HER2-overexpressing breast cancer patients with a tumour size above 5 mm should receive chemotherapy (<http://www.nccn.org/professionals/physician_gls/f_guidelines.asp#breast>, last accessed 23 April 2012). Patients with a triple negative breast cancer (absence of expression

of ER and PgR and lack of overexpression of HER2 [225]) are also eligible for adjuvant chemotherapy [225, 226].

The controversies about who should receive adjuvant chemotherapy are mainly focused on patients with ER+/HER2-negative breast cancers. It has been proposed to divide this group of patients in two different categories (luminal A and luminal B) according to tumour grade and level of Ki67 expression. The luminal A breast cancers are characterised by low tumour grade and/or low Ki67 expression (<14% staining) and confer a better prognosis [227, 228, 229]. Immunohistochemistry could be used to identify patients with good prognosis if the other parameters do not indicate a large tumour burden. The problem here, however, resides in the poor standardization and evaluation of Ki67 staining (reviewed in [228]).

Genomic tests could also improve the prediction of outcome usually determined by clinical and pathological staging. Several genomic signatures have been developed to address this question (reviewed in [230]). The vast majority of these signatures only apply to patients with ER+/HER2-negative breast cancers. The recurrence score (Oncotype DX®) is a 21-gene signature assessed by RT-PCR on paraffin-embedded samples [231]. This signature has been consistently reported to identify a population of patients who presents a low risk of metastatic relapse [230]. Interestingly, this recurrence score has also been reported as predictor of the relative efficacy of chemotherapy in two retrospective studies [232, 233]. Two prospective studies are currently ongoing to evaluate the medical usefulness of the recurrence score (<http://www.clinicaltrials.gov>, NCT 00310180 and NCT01446185). The 70 genes signature from Amsterdam (Mammaprint©, Agendia) is the second most investigated gene signature for outcome prediction [230]. This signature has been validated in retrospective studies, and is currently being prospectively validated in the large randomized MINDACT trial [234]. Other gene signatures are being investigated, including the genomic grade (Mapquant®) and the breast cancer index [230].

Overall, considering the amount of consistent data obtained with samples from randomized trials, several national or international guidelines propose to include the recurrence score as a tool for decision about the indication of adjuvant chemotherapy (<http://www.nccn.org/professionals/physician_gls/f_guidelines.asp#breast>, last accessed 23 April 2012) [221].

The definite proof of the clinical utility of the various genomic signatures will hopefully emerge from the results of the already completed studies—mainly TailorX and MINDACT. These trials will generate greater confidence that a subgroup of women with ER positive, low proliferative tumours can be spared adjuvant chemotherapy. Additional molecular, non-genomic tests include UPA (Urokinase-type plasminogen activator)/PA1 assay [235]. This biomarker has been validated in a large meta-analysis and is now considered level I evidence for clinical use in several recommendations [236].

The other situation where chemotherapy could be spared is in the group of patients who present a significant risk of relapse, but whose tumours are resistant to treatment. Several attempts have been made in order to identify those patients whose tumours are insensitive to adjuvant chemotherapy. As mentioned before, the recurrence score has been suggested to be associated with resistance to chemotherapy in two small retrospective studies [232, 233]. Currently, though, the amount of evidence is not yet strong enough to use these results in patients with a high risk of relapse. Ki67 has also been reported to be associated with resistance to treatment with docetaxel [237]. Nevertheless, other groups have found this biomarker as not predictive of benefit from CMF [238] and FAC [239] treatments. Overall, it is considered that, although its prognostic value is well documented, there is not enough data to consider Ki67 as a predictive biomarker for the resistance to adjuvant chemotherapy [229].

Which regimen should be used?

Chemotherapy schedules using anthracyclines, cyclophosphamide, and taxanes have been reported to improve outcome as compared to anthracycline-alone based chemotherapy [219]. Several different regimens are considered as optimal third generation chemotherapy. These include the sequential use of anthracyclines and cyclophosphamide, followed by three weekly docetaxel or weekly paclitaxel for a total of six to eight cycles [240]. Taxanes have been shown to be effective both in node-positive and node-negative [241] breast cancer.

Several other regimens have been evaluated. The administration of four cycles of docetaxel and cyclophosphamide was less effective than sequential use of anthracyclines and taxanes [242], but could be acceptable in selected cases where the absolute expected benefit from chemotherapy is low.

The concomitant use of anthracyclines, docetaxel, and cyclophosphamide seems to be more toxic than their sequential use. Finally, anthracycline-free regimens have shown good results in patients with HER2-overexpressing breast cancer [243].

When to use chemotherapy in the preoperative setting?

The use of neoadjuvant chemotherapy is usually recommended when a conservative surgery is not feasible and the tumour presents some features of chemosensitivity (ER-negativity, high grade, HER2 overexpression). The tumour shrinkage induced by chemotherapy allows breast conservation in a significant number of patients [244]. Several studies have compared the preoperative versus postoperative administration of chemotherapy and concluded that the timing of chemotherapy does not matter in terms of breast cancer mortality [245]. The residual disease after neoadjuvant chemotherapy is a robust prognostic indicator [246].

Chemotherapy in the metastatic setting

In the metastatic setting, the decision to administer chemotherapy, together with the choice of the drugs, is driven by the tumour biology (ER, HER2, grade), the resistance to the chemotherapy regimens administered in the adjuvant setting and the presence of symptoms that might require rapid tumour response. Overall, the recent guidelines recommend the use of chemotherapy as first-line treatment in patients with triple-negative breast cancer (TNBC) or in HER2-overexpressing breast cancer. In patients with ER-positive breast cancer, it is usual to administer endocrine therapy and to switch to chemotherapy at the acquisition of endocrine resistance. This rule does not apply for patients with aggressive ER-positive disease, for which cytotoxic regimens are used front line.

Both taxanes and anthracyclines have been shown to be effective in the metastatic setting [247, 248]. Nevertheless, their use is limited by the fact that most patients in Europe and the US have received these agents as adjuvant treatment. The use of these drugs is therefore limited to patients who present with stage IV disease

at diagnosis or in case of long interval between adjuvant chemotherapy and metastatic relapse (at least two years).

A large number of cytotoxic agents have been shown to be active in patients with metastatic breast cancer previously treated with anthracyclines and taxanes [249]. Overall, current recommendations favour a sequential use of these drugs, with the exception of patients presenting with a very aggressive disease where a rapid response is required [250]. In these latter patients, a combination strategy could be indicated.

Capecitabine is approved in most of the countries and is a treatment of choice in patients who are resistant to anthracyclines and taxanes. Ixabepilone (Ixempra®, Bristol-Myers Squibb Company, Princeton, NJ) and nab-paclitaxel (Abraxane®, Abraxis Bioscience, Celgene Corporation, NJ) have been shown to improve progression-free survival in patients who are resistant to anthracyclines and taxanes [251, 252].

Until recently [253], there has not been any level I evidence that adding a new line of chemotherapy after two previous regimens was associated with survival improvement. Eribulin is the first agent shown to improve survival in patients previously treated with at least two different chemotherapy treatments in the metastatic setting [253].

Finally, other drugs are commonly used in this indication, including gemcitabine and vinorelbine [249].

A specific case is represented by cisplatin. Although there is no evidence that cisplatin improves outcome in patients with metastatic breast cancers, some data from small studies suggest that this drug could be effective in patients who present lack of BRCA1 function [254]. Ongoing randomized trials are evaluating this hypothesis.

Endocrine therapy

Adjuvant endocrine therapy

Endocrine therapy is the treatment of choice in patients with ER-positive tumours. A meta-analysis has shown that tamoxifen treatment when administered in the adjuvant setting could reduce the absolute risk of breast cancer death by around 10% [255]. This effect is observed specifically in patients with ER-expressing tumours. Based on the strong magnitude of the effect, it is recommended that endocrine therapy be given to all patients with invasive breast cancer that expresses ER.

The oncologist faces several additional questions in daily clinical practice. First: which endocrine therapy should be proposed? Second, what is the optimal duration for endocrine therapy?

As previously mentioned, tamoxifen is the cornerstone treatment in premenopausal women. In postmenopausal women, aromatase inhibitors have been shown to improve disease-free survival (DFS) as compared to tamoxifen in a meta-analysis. In the same meta-analysis, aromatase inhibitors marginally improved overall survival (absolute difference: 0.7%) [256, 257]. The BIG1.98 has explored whether letrozole should be administered frontline or after tamoxifen, and to what extent this drug can be safely switched to tamoxifen after two to three years. Results have shown that starting with aromatase inhibitors improves DFS as compared to starting with tamoxifen then switching to letrozole [257]. This effect was more pronounced in patients with node-positive disease. Interestingly, no difference was observed between five years of letrozole and two to three years of letrozole followed by tamoxifen. Overall, recent recommendations propose initial treatment in postmenopausal women with an aromatase inhibitor. If the treatment is not well tolerated, it is reasonable to propose a switch to tamoxifen after a two to three year exposure, especially if the risk of relapse is low.

The optimal duration of endocrine therapy is still in debate. This is due to the occurrence of late relapses in the population of patients with ER-positive breast cancer. Randomized trials have compared five to two years tamoxifen and could not provide evidence for an improved outcome [258]. One trial compared five years of tamoxifen followed by two to four years of letrozole to five years of tamoxifen alone and reported an improved outcome for the switch to letrozole, especially in node-positive disease [259]. For patients with low/intermediate risk recurrence, it seems reasonable today to propose a total of five years of endocrine therapy. For patients with high-risk breast cancer, the optimal duration is a matter of controversies, but there is an increased trend for using seven to ten years of endocrine therapy in this latter population.

Endocrine therapy for metastatic breast cancer patients

It is usually recommended to treat metastatic ER-positive breast cancer patients first with endocrine therapy. However, in some patients presenting with significant visceral involvement and/or highly aggressive disease, the treatment should start with chemotherapy.

Two different situations are being faced in the clinical practice. On one hand there are patients who are endocrine-naïve (stage IV) or relapse a long time after the end of adjuvant endocrine therapy. On the other hand, another group of patients will present a metastatic relapse while being treated with endocrine therapy in the adjuvant setting. For postmenopausal women, endocrine-naive (or long-term relapse) patients, there is a large body of evidence suggesting that aromatase inhibitors (AI) improve outcome as compared to tamoxifen in the metastatic setting [260]. After failure of a first line of endocrine therapy, it is usual, to start a second-line endocrine therapy especially in those patients who experienced prolonged (>12 months) disease control under first-line hormonal treatment. Several options are available in postmenopausal, metastatic breast cancer resistant to non-steroidal AI. The first one is the use of the steroidal AI, exemestane [261]. However, a more recent large trial [262] suggests that this approach is suboptimal. The second option is the use of fulvestrant. Initially, low-dose fulvestrant did not show benefit over exemestane in patients who present with non-steroidal aromatase inhibitor failure [263]. Nevertheless, recent data suggest that high-dose fulvestrant (500 mg/month) is more effective than the lower dose used in previous studies (250mg/month) [264, 265].

Overall, for patients who present with an endocrine sensitive disease defined by ER-positivity combined with a low aggressiveness, a sequential use of endocrine therapies is recommended before concluding about endocrine resistance and switching to chemotherapy.

Targeted agents

Four families of targeted agents have shown efficacy in patients with breast cancer. They include HER2-inhibitors, mTOR (mammalian target of rapamicin) inhibitors, angiogenesis inhibitors and Poly (adenosine diphosphate-ribose) polymerases (PARP) inhibitors.

HER2-inhibitors

HER2 is a transmembrane tyrosine kinase receptor encoded by the *ERBB2* gene that mediates oncogenesis. Around 10–15% of breast cancer present with an amplification of *ERBB2* that leads to HER2

receptor overexpression. Trastuzumab (Herceptin®, Genentech Inc, South San Francisco, CA) is a monoclonal antibody that targets HER2. Trastuzumab, in combination with chemotherapy, has been shown to improve survival in two randomized trials that included patients with metastatic, HER2-overexpressing breast cancer [266, 267]. Given these two pivotal trials, trastuzumab is considered as the cornerstone treatment of patients with HER2-positive breast cancer. Since HER2-overexpressing breast cancers present aggressive features, it is usually recommended to use trastuzumab in combination with chemotherapy (except anthracyclines). Nevertheless, several studies have shown that HER2 inhibitors can improve outcome when combined with endocrine therapy in the small subset of patients presenting HER2-overexpressing breast cancer without aggressive features [268, 269].

Six randomized trials have evaluated the efficacy of trastuzumab in the adjuvant setting [270]. All but one have concluded that the addition of trastuzumab to standard treatment is associated with improved outcome. Trastuzumab is therefore recommended in all HER2-over-expressing breast cancer patients presenting with a tumour size above 5 mm. Several questions remain open regarding the optimal use of adjuvant trastuzumab: (i) should trastuzumab be used concomitantly or sequentially with chemotherapy, and (ii) what is the optimal duration of trastuzumab?

The randomized trial NCCTG N9831 compared trastuzumab administered concomitantly with taxanes versus a sequential administration of trastuzumab [271]. This trial has reported that the concomitant administration of trastuzumab and taxanes was superior to sequential use. Based on this study, and some other indirect arguments [270], oncologists favour the administration of trastuzumab concomitantly with chemotherapy but formal statistical significance has not been tested.

Although most of the trials reported to date have evaluated a one year administration, there is controversy about whether shorter duration could be as effective as long duration. This originated from a small Finnish trial showing that shorter treatment could improve outcome. Several clinical trials are currently addressing the hypothesis that trastuzumab could safely be administered for a shorter period of time [272]. Only one trial—the HERA trial—has evaluated a longer administration of trastuzumab [273] (e.g., two years). Until the results of these comparisons become available, the actual recommendation is to administer adjuvant trastuzumab for one year.

More recently, combinations of HER2 inhibitors have been developed:

- Lapatinib is a tyrosine kinase inhibitor targeting HER2 and EGFR. This drug has been shown to improve progression-free survival when used in combination with capecitabine [274], in trastuzumab-resistant patients. Interestingly, the combination between lapatinib and trastuzumab has been shown to improve efficacy endpoints both in the neoadjuvant [275] and in the metastatic setting [276]. This combination is being evaluated in the large ALTTO trial in the adjuvant setting (<http://www.clinicaltrials.gov>, NCT00490139).

- Pertuzumab (Omnitarg®, 2C4, Genentech, San Francisco, CA) is a monoclonal antibody that inhibits heterodimerization between HER2 and HER3. The concomitant administration of pertuzumab and trastuzumab has been shown to improve outcome in the context of a phase III randomized trial in the metastatic

setting [277]. These results confirmed previous findings from a phase II randomized trial performed in the neoadjuvant setting [278].

- Finally, other new compounds are being developed in order to improve efficacy over trastuzumab. As illustration, several phase II trials have suggested that TDM1 (trastuzumab-emtansine, Genentech, San Francisco, CA) an immunoconjugate between trastuzumab and emtansine (cytotoxic anti-microtubule agent) could reverse resistance to trastuzumab [279].

Other targeted agents

The development of new targeted agents is the focus of most of the current efforts in the breast cancer field. mTOR inhibitors have been developed with the aim of reversing the resistance to conventional treatment (endocrine therapy and trastuzumab). mTOR is a serine threonine kinase that mediates protein translation, metabolism and that induces phosphorylation of oestrogen receptor [280]. Several mTOR inhibitors are being developed in the field of breast cancer. Everolimus, a rapalog, has been shown to markedly improve progression-free survival in patients with ER-positive metastatic breast cancer who are resistant to NSAI [262]. This finding is consistent with two previous phase II randomized trials [278, 281] and opens new avenues in the field of targeted agents for ER-positive breast cancer.

Several others targeted agents have been assessed in breast cancer including bevacizumab and PARP inhibitors. Bevacizumab has been associated with improved outcomes in randomized trials [282]. Nevertheless, the magnitude of this efficacy was modest in most trials and no impact on overall survival was observed even in a pooled analysis of the randomized clinical trials. New research on biomarkers could allow the identification of the small subset of patients who derive clear benefit from this drug [283].

PARP1 is a protein involved in DNA repair. Preclinical studies have shown that PARP inhibition could lead to tumour cell death when BRCA1 or 2 is deficient [284]. In a phase II trial [285], the PARP1 inhibitor olaparib has shown major clinical efficacy in patients with BRCA1/2 mutations. Nevertheless, whether this drug improves outcome as compared to the standard of care still needs to be determined.

Bone-modifying agents

Zoledronic acid is a bisphosphonate that has initially been suggested to reduce the incidence of skeletal-related events (SRE) in patients with metastatic breast cancer with bone lesions [286]. The drug has then been developed in patients with early breast cancer. In this setting, zoledronic acid decreases the incidence of osteoporosis both during treatment with aromatase inhibitors [287] and after chemotherapy [288] (premenopausal women). Interestingly, in one trial, zoledronic acid has also been shown to improve DFS [289]. These latter data still need confirmation since results are not consistent across trials [290, 291].

More recently, antibodies directed against RANK ligands (denosumab) have been developed. One study suggests that denosumab could delay the onset of SRE as compared to zoledronic acid in patients with metastatic breast cancer [292]. This drug is now being evaluated in the adjuvant setting (D-CARE trial).

Overall, ASCO recommends the use of bone-modifying agents in patients with metastatic breast cancer with bone lesions [293]. Nevertheless, these guidelines do not make a recommendation

between zoledronic acid and denosumab. Finally, more data, including biomarkers, are needed to have a clearer picture of the efficacy of bone-modifying agents in early breast cancer.

Summary of medical management of chemotherapy

The implementation of adjuvant chemotherapy and endocrine therapy has led to a dramatic improvement of breast cancer survival in the last three decades. In recent years, the most striking advance has been the development of trastuzumab along with efforts directed at high quality HER2 testing in order to select the right patients for this targeted therapy. The next decade will certainly be dedicated to the development of new targeted agents and their companion diagnostic tests with the aim of improving survival, and decreasing side effects of current conventional treatments.

Multidisciplinary management of complex cases

Clinical case study 1

In a small hospital, a 63-year-old postmenopausal patient was treated for an infiltrating ductal cancer of the left breast.

Tumour characteristics were as follows:

- Size: 1.7 cm
- Pathology: poorly differentiated (grade 3)
- ER: 0% cells positive
- PR: 0% cells positive
- HER2: IHC 1+ out of 3+
- Axillary nodes: 1/15 positive

She was initially treated with a lumpectomy, axillary lymphadenectomy, FEC-100 × 6 cycles, and radiation therapy.

Two and a half years later, she began complaining of fatigue. Her ECOG performance status was 1. A CT of the abdomen showed three nodules (less than 2 cm in size) in the liver. All other workup exams were normal.

The patient sought a second opinion.

> **What would you propose as the next step?**
> 1. A systemic treatment?
> 2. A liver biopsy?
> 3. Other?

Discussion—clinical case study 1

For over 30 years, researchers have investigated the extent to which expression of tumour receptors in the primary tumour are consistent with those in metastases, due to possible implications in clinical practice [294].

A meta-analysis of 62 studies comparing HER2 expression in matched primary and distant metastatic tumours estimated a discordance of 23% (95% CI 16–28%) between negative HER2 in the primary tumours to positive HER2 in the metastases. The discordance from positive HER2 in the primary tumours to negative HER2 in the metastases was 4% (95% CI 0–6%). This study reveals that if no biopsy of the metastatic site is done, nearly a quarter of patients may be denied the benefit of a HER2-targeted therapy [295].

Optimal testing for HER2 and HR remains challenging across different laboratories, as shown in a large clinical trial with central pathology review. Discordances are seen in up 12.1% of the cases for ER and 14.5% for HER2 [296]. There is, therefore, a rational for retesting the receptor expression in the present case. Biopsies of metastatic sites can provide valuable information for making treatment decisions; therefore, it is recommended to biopsy such sites if feasible and safe.

Follow-up—clinical case study 1

The patient underwent a liver biopsy. Her pathology revealed adenocarcinoma with the receptor expression as follows:

ER7/8, PgR-negative

HER2+++, FISH+

> **What treatment regimen would you have recommended to this patient?**
> 1. Trastuzumab + taxane or vinorelbine
> 2. Lapatinib + taxane
> 3. Docetaxel + trastuzumab + bevacizumab
> 4. Trastuzumab + pertuzumab + docetaxel
> 5. Letrozole + lapatinib
> 6. A clinical trial (with an investigational anti-HER2 therapy)
> 7. Other options

Treatment—clinical case study 1

An increasing body of evidence from clinical trials conducted in the neoadjuvant and metastatic settings suggests that dual HER2 blockade offers a significant advantage over single blockade for patients whose tumours overexpress the HER2 receptor.

In the neoadjuvant setting, a recent study of trastuzumab combined with lapatinib showed such benefit. The NeoALTTO trial randomized 455 patients to receive, prior to surgery, either trastuzumab, lapatinib, or the combination of both drugs, with weekly paclitaxel in all three study arms. The rate of pathological complete response (pCR) was 51.3% for the combination, 29.5% for trastuzumab alone, and 24.7% for lapatinib alone [297]. The NeoSphere trial randomized 417 patients to four treatment arms to receive preoperative trastuzumab and docetaxel, pertuzumab and docetaxel, the combination of trastuzumab and pertuzumab without cytotoxic chemotherapy, or the combination with docetaxel. Patients receiving the combination of pertuzumab and trastuzumab with docetaxel showed significant improvement in the pCR rate (45.8%) when compared to those who received trastuzumab plus docetaxel (29%), pertuzumab plus docetaxel (24%), or pertuzumab plus trastuzumab (17%) [298].

In the metastatic setting, Blackwell et al. tested the combination of lapatinib and trastuzumab in patients whose cancer progressed after a trastuzumab-containing treatment. The 296 patients included in the study had previously received a median of three trastuzumab-containing regimens. They were randomized to receive either lapatinib alone or trastuzumab combined with lapatinib. Patients receiving the combination had a superior median progression-free survival (12 weeks vs 8.1 weeks) and showed a trend towards better overall survival (51.6 weeks vs 39 weeks, HR = 0.75; CI 0.53 to 1.07; p = .106); however, their treatment was associated with a moderate increase of toxicity [299].

In another study for advanced breast cancer, CLEOPATRA, a dual HER2 blockade with pertuzumab and trastuzumab plus docetaxel was tested against trastuzumab, docetaxel and placebo, in the first-line metastatic setting. A clinically and statistically significant

improvement of six months was observed in patients receiving the dual blockade (18.5 months vs 12.4 months). The cardiac safety profile was similar for both regimens, an increase of grade 3 neutropenia and diarrhea was observed in the dual HER2 blockade arm. There was a trend towards improved overall survival for patients receiving the dual blockade, but this analysis is still immature and requires more events [300]. In the light of these data, we consider that the combination of pertuzumab and trastuzumab with docetaxel is likely to become the reference first-line treatment for patients with HER2-positive metastatic breast cancer.

Another acceptable approach is to propose a clinical trial testing novel anti-HER2 drugs or their combinations. Trastuzumab-emtansine (TDM1) is an antibody drug conjugate that consists of a potent cytotoxic drug inhibiting microtubule polymerization coupled with trastuzumab [301]. In preclinical models exploring resistance to trastuzumab and lapatinib, TDM1 was shown to have antitumour activity [302, 303]. Trials testing the effectiveness of this target cytotoxic alone and in combination with pertuzumab are already in phase 3 (NCT00829166, NCT01419197, NCT01120184).

Treatment follow-up—clinical case study 1

With pertuzumab and trastuzumab given as 'maintenance' therapy, the patient enjoyed a long period of disease control (14 months). Upon complaint of a slight persistent headache, however, a brain MRI was performed and revealed two small brain lesions (3 and 4 mm).

What would you have recommended to the patient at this point in time?

1. Whole brain radiotherapy
2. Stereotaxic radiosurgery (Gamma Knife®)
3. Capecitabine + lapatinib

Whole brain radiotherapy (WBRT) is an effective treatment modality for controlling symptoms and improving survival in breast cancer patients with brain metastasis [304, 305]. However, it is associated with late neurological toxicity, leading to decreased neurocognitive function and quality of life [306].

An alternative to WBRT for patients with small lesions in the brain is stereotaxic radiosurgery (SRS), the so-called Gamma Knife®. It delivers a limited number of high-dose beams to a specific region of the brain, sparing normal cerebral tissue from radiation and, thereby, reducing neurologic toxicity [307]. There are no prospective data available comparing the efficacy of WBRT to SRS; however, retrospective studies suggest an improvement in outcome in favour of SRS alone [308, 309]. In retrospective and uncontrolled studies, SRS seems to be as effective as brain surgery with respect to metastasis control rate and survival [310, 311]. The addition of WBRT after definitive SRS was tested in a prospective study including multiple tumour types. Although it reduced the number of local relapses, the addition of WBRT failed to improve performance status and overall survival [312]. If a radiotherapeutic approach is chosen, SRS without WBRT is generally recommended.

For patients with HER2-positive breast cancer, an alternative is to start the treatment of brain metastases by administering lapatinib combined with capecitabine, postponing the radiotherapy approach. A single-arm phase II study evaluated this combination as upfront treatment before WBRT. 90% of the women included in the study had been previously treated with trastuzumab and more than 90% had PS 0 or 1 with minimal symptoms. In the preliminary analysis, progression-free survival was 5.5 months, and the time elapsed prior to WBRT was 8.3 months [305]. This treatment option makes it possible to delay brain irradiation and its adverse effects in a selected group of patients.

For HER2-positive disease treated with SRS where the systemic disease is under control with use of chemotherapy and a monoclonal antibody such as trastuzumab, it is recommended to continue with this same treatment. Monoclonal antibodies and most of the cytotoxic agents cannot pass through the intact blood-brain barrier. In the absence of systemic progression, it is likely that the treatment is still active against the disease elsewhere in the body.

Final remarks

Clinical cases illustrate some of the challenges of breast cancer management in daily practice. Each patient's case is unique, and the main objective of the attending multidisciplinary team is to offer the best possible treatment based on the best scientific data available and to always examine all suitable treatment modalities for each specific situation, whether clinical, surgical, or radiotherapeutic. However, there are situations for which strong evidence-based data is not available (and perhaps never will be). In these situations, good clinical judgment is crucial.

Epidemiology of gynaecological cancers

Gynaecological cancers affect the female reproductive system including the vulva, vagina, cervix uteri, corpus uteri, ovary, placenta, and other unspecified organs.

Cervical cancer

Worldwide, cervical cancer is the third most common cancer in women, accounting for an estimated 529,800 new cases of cancer and 275,100 deaths annually. In contrast with endometrial cancer, developing countries have much higher rates of cervical cancer than developed countries. It is a model of viral carcinogenesis: high-risk human papilloma virus (HPV) infection is the major cause of almost all cervical cancers. Other cofactors associated with increased risk of cervical cancer include smoking, sexual behaviour, oral contraceptive use, HIV/AIDS, and lower socio-economic status. The incidence and mortality rates of cervical cancer have been reduced considerably with screening programs, which in combination with HPV vaccination may offer a promising way to lower the global burden of this disease.

Endometrial cancer

Worldwide, there are more than 287,100 newly diagnosed cases of endometrial cancer and around 73,900 deaths annually. It is the most common cancer among women in the developed world, with an incidence double those of the less developed countries. Most of the established risk factors for endometrial cancer are associated with excessive unopposed estrogen stimulation on the endometrium, including hormone replacement therapy, tamoxifen use, nulliparity, obesity, and diabetes. Physical activity, use of combined oral contraceptives, pregnancy and childbirth reduce the risk. There is no evidence-supported screening test for endometrial cancer, as most cases (85%) are diagnosed at low stage because of early symptoms like postmenopausal bleeding and survival rates are high.

Ovarian cancer

Approximately 225,500 ovarian cancers are diagnosed annually worldwide. It is the leading cause of gynaecological cancer death (140,200 worldwide annually), which accounts for more deaths than all the other gynaecological cancers combined. Although the aetiology of ovarian cancer is not yet clear, the strongest known risk factors are increasing age and certain gene mutations such as BRCA1 and BRCA2. Pregnancy and use of oral contraceptives are established protective factors. Large-scale randomized controlled trials have been conducted to screen preclinical ovarian cancers with transvaginal ultrasound and CA125. Preliminary results show that population-based screening or screening in a high-risk population are not recommended because no effective detection of early stage ovarian cancer is present and therefore no mortality benefits could be demonstrated compared with usual care.

Vaginal and vulvar cancers

Each year in the UK, approximately 280 and 1200 women are diagnosed with vaginal and vulvar cancers, respectively. The associated mortality rates are 90 and 410, respectively. HPV infection is the primary risk factor for vaginal and vulvar cancers; others include non-HPV sexually transmitted infections, smoking, exposure to diethylstilbestrol (DES) in utero (only for vaginal cancer), and iatrogenic immunosuppression.

Molecular biology and pathology of gynaecological cancers

Gynaecologic cancer may basically occur at four major sites: the uterus (cervix and corpus uteri, the latter including endometrium and myometrium) and its adnexae (ovary and fallopian tube), the vagina, and the vulva. These cancers are histologically biologically different according to their site and tissue of origin and, in particular, based on their aetiology and molecular pathogenesis. The incidence of these neoplasms is strongly influenced by key pathogenetic factors, although the aetiology has not been unravelled for all of these tumours. In the industrialized countries with an aging population, the most frequent gynaecologic cancers are endometrial and ovarian carcinoma, whereas cervical carcinoma has become rare compared to most developing countries due to early

detection of precursors by screening programs. Histologically, most cancer types are carcinomas, whereas sarcomas and haematological neoplasms are rare. Anatomic and molecular pathology does not only provide insight into the tumorigenesis of the various types of gynaecological cancers but is also strongly involved in the diagnostic procedure, which precedes and accompanies the therapeutic process.

Molecular biology of cervical cancer

Cervical carcinoma is a global burden, although it has become infrequent in most industrialized countries. In South-east Asia, Africa, and most parts of Latin America the incidence is six- to tenfold that of Europe, the US, Canada, and Australia. The incidence of cervical carcinoma is strongly associated with early detection of its precursors by screening programs and by the availability of efficient screening for the population, respectively. This is even reflected by a strikingly different incidence within the EU.

The development of cervical carcinoma and its precursors is strongly related to HPV since HPV DNA is found in almost all cervical carcinomas except for some rare histological subtypes. High-grade squamous intraepithelial lesion (SIL)/cervical intraepithelial neoplasia (CIN) and squamous cell carcinoma, as well as adenocarcinoma in situ (AIS) and adenocarcinoma are associated with high-risk HPV types, in particular HPV 16, 18 and 31, 33, 45, and some others. These HPV types harbour oncogenic potential by affecting crucial mechanisms of the host cell. In particular, two viral proteins, E6 and E7, bind to the regulatory proteins p53 and Rb, respectively, and further activate cyclins A and E and inhibit the cyclin dependent kinase inhibitors WAF-1 and p27. Constitutive over-expression of E6 and E7 due to chronic viral infection of the host cell finally results in a block of unrestricted cell proliferation as well as of the apoptotic pathway. These changes impair the infected cells to respond adequately to damage by oncogenic factors by apoptosis or DNA repair after cell cycle arrest. Loss of function of p53 and Rb by inactivation, therefore, leads to an accumulation of genetic alterations and increasing genomic instability. In particular, loss of 3q where the FHIT gene is located is considered a frequent genetic alteration in cervical squamous cell carcinoma. Mutations of p53 and K-Ras are rare in cervical carcinoma. It is assumed that the basal cells of the cervical mucosa are infected by HPV after microabrasions. Proliferation of these transformed basal cells leads to an architectural change of the squamous epithelium that subsequently, in the setting of high-grade SIL, is completely composed of atypical basal cells and lacks terminal differentiation. In contrast to low-grade SIL, HPV DNA is integrated in the genome of the host cells of high-grade SIL/CIN and invasive squamous carcinoma as well as AIS and invasive adenocarcinoma. In this pathogenetic concept, HPV is considered the key factor that is able to infect and even transform cells but needs cofactors in particular for the development of invasive carcinoma. Immunosuppression, in particular by co-infection, cigarette smoking, use of oral contraceptives, and dietary factors are considered relevant cofactors for the development of cervical carcinoma. Nevertheless, only one-third of HPV-positive women show cytological abnormalities and viral clearance is supposed to occur in more than 90% of infections. Currently, persistence of infections by high-risk HPV for more than two years is currently considered the greatest risk for the development of cervical carcinoma.

Pathology of cervical cancer

Grossly, cervical cancer presents as enlargement of the cervix by tumour tissue, often with ulceration. It needs to be emphasized that small carcinomas, in particular microinvasive carcinomas, may present without grossly visible tumour. Histologically, the most frequent tumour type is squamous cell carcinoma, which may show keratinization. Adenocarcinoma with several variants is another major histological type. Rare histological type include neuroendocrine tumours (including small cell carcinoma), glassy cell carcinoma, adenosquamous carcinoma, adenoid cystic, and adenoid basal cell carcinoma. The latter type does not seem to be related to HPV. Based on data from the US and other countries, the percentage of adenocarcinoma has increased in relation to squamous cell carcinoma during the last three decades although the total number of cervical cancer cases has decreased. This may be due to the fact that early detection of adenocarcinoma and AIS by cytological screening may be more difficult compared to high-grade SIL. About 75% of endocervical adenocarcinoma reveal a similar histological pattern and are therefore named 'usual type'. The mucin content of endocervical adenocarcinoma cells may be sparse and may lead to the misconception of endometrioid carcinoma, which infrequently occurs in the cervix as a primary site. Other histological types, such as serous and clear cell carcinoma, are rare. Since tumour volume is an important parameter for the clinical course, early carcinoma stages have been designated as microinvasive carcinoma (MIC). By definition, MIC is limited to a horizontal tumour spread of 7mm and a depth of invasion of 3mm (pT1a1/FIGO stage IA1) and 5 mm (pT1a2/FIGO stage IA2), respectively. Microinvasive squamous cell carcinoma is associated with a very low frequency of lymph node metastases (less than 3% at stage IA1 and less than 8% at stage IA2), which also implicates a different therapeutic strategy. The role of lymphovascular space involvement (LVSI) as a predictor of lymph node metastases in MIC is, so far, unclear and has been controversial. However, most studies have shown that LVSI is an adverse prognostic factor and may be able to predict recurrence after cone biopsy and residual carcinoma within the hysterectomy specimen. Microinvasive adenocarcinoma is less well studied with respect to behaviour than squamous MIC and may be difficult to assess, in particular if it is associated with extensive AIS. The presence of AIS at the surgical margins is more problematic with respect to residual tumour compared to high-grade SIL/CIN3. Extension of cervical carcinoma involves the vagina (pT2a and 3a/FIGO stages IIA and IIIA), the parametria (pT2b and 3b/FIGO stages IIB and IIIB), the urinary bladder, and the rectum (pT4/FIGO stage IVA). Involvement of the uterine corpus does not affect stage and metastases to the adnexae are rare (less than 1%), but somewhat higher in the case of adenocarcinomas. Infiltration of the cervix by malignant lymphoma is unusual but needs to be recognized in cervical biopsy. Immunohistochemistry may be important for the distinction of lymphoma from other undifferentiated neoplasms and in some cases for the distinction between primary endometrial and cervical carcinoma.

Molecular biology of endometrial cancer

Endometrial carcinoma is the most frequent malignancy of the uterine corpus. In contrast to cervical carcinoma it is more frequent in the industrialized countries (except for Japan) compared to developing countries. This is most likely related to several factors

such as higher age of the population, use of hormone replacement therapy, higher body mass index and others. One of the most important risk factors for endometrial carcinoma is unopposed oestrogen stimulation of the endometrium, which may not only be caused by exogenous oestrogen (e.g., for hormone replacement therapy) but also by endogenous factors such as non-ovulatory cycles, polycystic ovary syndrome, high BMI with conversion of DHEA to oestrogens by aromatase in the adipose tissue and oestrogens producing neoplasms such as granulosa cell tumour. However, about 15–20% of endometrial carcinomas do not seem to be oestrogen-related. Therefore, endometrial carcinoma is roughly divided into two biologically distinctive types, which can also be separated on the molecular genetic level. Type 1 carcinomas, at 80% the great majority, are related to oestrogen, which present at low stage and show a favourable clinical course. Histologically, they mostly represent low-grade (FIGO grade 1 and 2) endometrioid adenocarcinomas and its variants. They develop through atypical endometrial hyperplasia following an adenoma-carcinoma pathway. In contrast, the non-oestrogen-related type 2 carcinomas are frequently diagnosed at high stages, often with extensive extrauterine disease and/or distant metastases, and are typically associated with poor clinical outcome. The histological prototype, which is best studied, is serous carcinoma but also clear cell carcinomas, undifferentiated carcinomas, high-grade/FIGO grade 3 endometrioid carcinomas, carcinosarcomas, or mixed malignant Müllerian tumours (MMMT) are encountered among type 2 cancers. For serous carcinoma, a flat precursor lesion has been characterized and named serous endometrial intraepithelial carcinoma (SEIC); for the other histological types no precursors have been defined. It is likely that some type 2 carcinomas develop through low-grade type 1 carcinomas by tumour progression. Type 1 and type 2 endometrial carcinomas are also distinctive on the molecular level. Type 1 carcinomas show an adenoma-carcinoma sequence with a stepwise accumulation of molecular alterations comparable to colorectal carcinoma. Mutations in PTEN, K-Ras, ß-catenin, and PIK3CA as well as inactivation of Pax-2 occur in atypical hyperplasia and/or in low-grade endometrioid carcinoma and, therefore, are considered early events. In contrast, p53 mutations are typically found in high-grade endometrioid carcinoma, which suggests a late event

during tumour progression. Some of the abnormally expressed genes in type 1 carcinomas such as PIK3CA are related to endometrial homeostasis and regulated during menstrual cycle, in particular, by a link to ER expression. A subset of about 25–40% of type 1 carcinomas reveal a mutator phenotype which is characterized by a high degree of microsatellite instability (MSI). In sporadic endometrioid carcinoma, MSI is most frequently caused by inactivation of the mismatch repair protein MLH1 by methylation. Less than 5% of endometrial carcinoma is considered hereditary, most of which is associated with hereditary non-polyposis colorectal cancer (HNPCC, Lynch syndrome) and typically associated with germline mutation of one of the mismatch repair proteins MSH2, MLH1, or MSH6. Type 2 endometrial carcinomas are characterized by a high degree of genomic instability. The most frequent molecular alteration is p53 mutation, which affects more than 80% of serous carcinomas and leads to accumulation of inactive p53 in the nucleus. Over-expression of p53 can be demonstrated by immunohistochemistry and may show two different immunoreactive patterns: either intensely diffuse or less frequently flat negative. Recent studies using next generation sequencing have confirmed the high frequency of p53 mutations in endometrial serous carcinomas and found novel mutations in the genes FBXW7, PIK3CA, and PPP2R1A occurring in about 18–23% of endometrial serous carcinoma. Altered FBXW7 leads to overexpression of cyclin E1 in a subset of SEIC and serous carcinoma. Recently, the TCGA Research Network tried to characterize four different groups of endometrial carcinoma based on the amount of copy number alterations and was able to stratify them for overall survival. A subgroup with excellent prognosis characterized by mutations in the novel gene POLE was found. The molecular alterations in other type 2 carcinomas are less well defined. p53 mutations are found in about 30–40% and PTEN mutations in about 10–20% of clear cell carcinomas (see Figure 44.1).

Pathology of endometrial cancer

The various histological types of endometrial carcinoma are typically adenocarcinomas with distinctive features. Endometrioid carcinoma usually consists of well-preserved glands with straight luminal borders that more or less resemble proliferating
Fig. 44.1 The two major types of endometrial carcinoma, endometrioid (A) and serous (B) adenocarcinoma. Endometrioid adenocarcinoma, if well differentiated forms well preserved glands and shows mild to moderate nuclear atypia, whereas serous adenocarcinoma is characterized by highly atypical nuclei, detachment of tumour cells, and tumour cell necrosis. HE, 100 ×.

endometrium and, if poorly differentiated, reveals a predominantly solid pattern. FIGO grading of endometrioid carcinoma is based on its amount of solid, non-squamous growth. Grade 1 carcinomas contain 5% or less; grade 2, 6–50%; and grade 3 carcinomas more than 50% of a solid, non-squamous growth pattern. Variants of endometrioid carcinoma may show various histological patterns of differentiation such as squamous, secretory, mucinous, and ciliated type. Rarely, pure mucinous carcinoma may occur in the endometrium, which is biologically encountered among type 1 cancers. One hallmark of serous carcinoma is the combination of a well-differentiated architecture and a high degree of nuclear atypia. It is furthermore important to emphasize that not all serous carcinomas show a papillary pattern but may reveal glandular or even solid growth. In contrast to endometrioid carcinoma, the cells of serous carcinoma form buds and are frequently detached. Serous carcinoma may be confused with the villoglandular variant of endometrioid carcinoma which is typically composed of delicate papillae covered by pseudostratified endometrioid type epithelium with low to moderate degree of nuclear atypia. Clear cell carcinoma is composed of hobnail shaped or polygonal cells with clear or less frequently eosinophilic cytoplasm arranged in a tubule-cystic, solid, or papillary pattern. The secretory variant of endometrioid carcinoma should not be confused with clear cell carcinoma because of its better prognosis. Mixed malignant Müllerian tumours (MMMT, carcinosarcoma) are considered carcinomas with a sarcoma-like component. Recently, a group of carcinomas composed of a well-differentiated and an undifferentiated component was named dedifferentiated carcinoma. For optimal therapeutic management histological typing and grading needs to be performed on curettage specimen. Immunohistochemistry including a panel of p53, ER, Ki67, PTEN, and p16 may be helpful for typing. It needs be emphasized that diffuse p16 immunoreactivity is not only typical for the majority of serous carcinomas but also for mucinous carcinomas. For the extent of surgery in low-grade endometrioid carcinomas the intraoperative assessment of myometrial invasion by frozen section may be important. Usually, preoperative ultrasound gives an impression if T1 or T2 tumours are present. If it is not clear in the first procedure, laparoscopic total hysterectomy and bilateral oophorectomy is performed. If, in the final histology report, pT1b is documented a second surgery with pelvic and para-aortic lymphadenectomy is necessary. The determination of early myometrial invasion may be difficult, in particular if the endo-myometrial junction is extensively involved but does not affect pathological stage in the 2009 FIGO/UICC staging system. Tumours with infiltration of adenomyosis without invasion of the surrounding myometrium should be staged as tumours confined to the endometrium. LVSI is of prognostic value and needs to be recognized. Positive peritoneal cytology is an adverse prognostic factor although it is not included in FIGO staging. Several parameters and models have been tested for the prediction of prognosis. So far, histological type and grade, depth of myometrial invasion, and vascular space involvement are the strongest predictors of prognosis. Among molecular factors, a combination of p53 and p16 positivity has been demonstrated to detect tumours with poor prognosis.

Molecular biology of ovarian carcinoma

During the recent years new concepts for ovarian tumorigenesis have been introduced. Currently, two major pathways are distinguished for ovarian carcinoma comparable to that of endometrial

carcinomas. Type 1 carcinomas, including low-grade serous, mucinous, endometrioid, and transitional cell carcinomas (malignant Brenner tumours) develop through the stage of a borderline tumour which can be considered an adenoma-carcinoma sequence. They are mostly slow-growing neoplasms that are frequently diagnosed at low stage and are associated with good prognosis. In contrast, type 2 carcinomas, to which high-grade serous and high-grade endometrioid carcinomas are encountered, seem to develop without an adenoma or borderline tumour stage. They are typically diagnosed at high stage and usually show rapid growth and poor outcome. MMMT (carcinosarcomas) and undifferentiated carcinomas are further included within the type 2 ovarian carcinoma category. There is strong evidence that the fallopian tube is strongly involved in the development of at least a subset of high-grade serous carcinomas, which seem to arise from a highly atypical precursor in the fimbria, named serous tubal intraepithelial carcinoma (STIC). The progression of STIC into high-grade serous carcinoma may lead to ovarian carcinomas with prominent surface involvement and early spread to the peritoneum. Furthermore, it has been demonstrated that serous inclusions are derived from the fallopian tube epithelium rather than from the ovarian surface. The development of ovarian inclusion cysts seems to be related to ovulation, which may explain the hypothesized association between the frequency of ovulation and the incidence of ovarian carcinoma. This may further explain the decreased ovarian carcinoma incidence with oral contraceptive use. Ovarian inclusion cysts are the origin of cystadenomas and borderline tumours and, therefore, most likely the origin for the type 1 carcinoma pathway, particular for low-grade serous carcinomas. Mucinous neoplasms are supposed to develop through mucinous metaplasia in inclusion cysts but may less frequently arise from mucinous cysts in teratomas. Endometrioid and clear cell carcinomas are frequently associated with ovarian endometriosis which may be caused by retrograde menstruation. Brenner tumours seem to develop from Walthardt nests. The molecular alterations in type 1 and type 2 ovarian carcinomas are significantly different and can be compared to the dualistic model of endometrial carcinoma. Low-grade serous carcinomas frequently harbour mutations of K-ras and B-raf and partially show a mutator phenotype with a high frequency of MSI, whereas low-grade mucinous carcinomas frequently harbour K-ras mutations. P53 mutations seem to occur late, when low-grade serous and mucinous carcinoma progress into high-grade carcinomas. In contrast, high-grade serous carcinomas show frequent p53 mutations which are also present in STIC and, therefore, are considered an early event. Low-grade endometrioid carcinomas are characterized by mutations of ß-catenin, PTEN, and ARID1A, whereas clear cell carcinomas show frequent PIK3CA mutations. The degree of chromosomal instability is low in type 1 carcinomas and high in type 2 carcinomas. Ongoing research is particularly focused on type 2 carcinomas with its poor prognosis. Recently, a model for the prognostic stratification of high-grade serous carcinoma based on the expression profile of 879 genes has been proposed by the TCGA Network. A Japanese/US group showed that expression of the gene FNB1 is associated with early recurrence of high-grade serous carcinoma.

Pathology of ovarian carcinoma

See Figure 44.2. Histologically, almost all ovarian carcinomas are adenocarcinomas with a spectrum of differentiation similar to

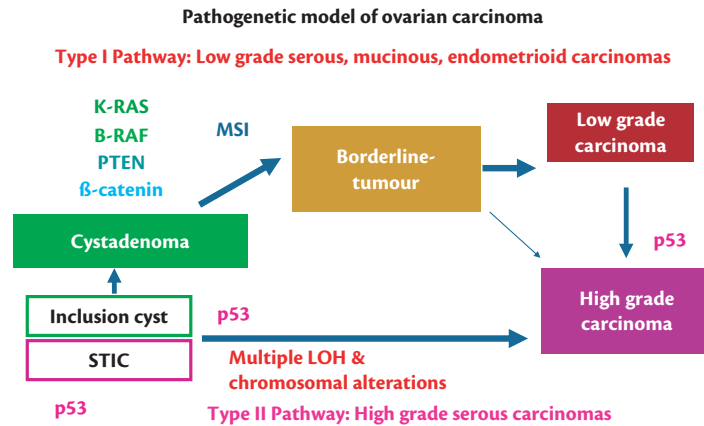
Pathogenetic model of ovarian carcinoma


Fig. 44.2 Pathogenesis of ovarian carcinoma: currently, two major pathways are considered for the development of ovarian carcinoma. Type 1 carcinomas typically develop from an adenoma through a borderline tumour to a low-grade carcinoma following an adenoma-carcinoma sequence whereas type 2 carcinomas seem to occur de novo from an inclusion cyst or a high-grade intraepithelial lesion deriving from the fallopian tube (STIC).

the uterine corpus. The most frequent histological type is serous carcinoma which most closely resembles the fallopian tube epithelium. Serous carcinomas are characterized by a frequent, but not exclusive, papillary architecture and by budding and detachment of the tumour cells. A glandular or solid growth pattern may also be found. Traditionally, serous carcinoma have been graded by a 3-tiered system, which was recently changed into a 2-tiered system (low- vs high-grade) based on nuclear atypia and the number of mitosis. Mucinous carcinomas are mostly low grade, typically show a glandular or papillary architecture and consist of mucin-producing cells. Endometrioid and clear cell carcinomas closely resemble their counterparts within the endometrium and are typically associated with endometriosis. Malignant Brenner tumours usually reveal the histological features of transitional cell carcinomas of the urinary tract. Grading of mucinous and endometrioid carcinomas follows the rules for endometrial endometrioid carcinoma. For clear cell carcinomas, nuclear grading is used. Since some ovarian carcinomas may be heterogenous and may be associated with borderline tumours, careful gross inspection and adequate sampling is necessary. In difficult cases, immunohistochemistry may be helpful for differential diagnosis using a panel of several antibodies, in particular for p53, ER, WT1, ß-catenin, p16, vimentin, PTEN, and HNF1. In particular, WT1 positivity is typical for extrauterine serous carcinomas and not found in the other histological types. However, most serous carcinomas originating from the endometrium are also WT1 negative. High-grade serous carcinomas are further diffusely positive for p16, positive for ER, CA125 and PTEN and lack vimentin and nuclear ß-catenin staining. Mucinous carcinomas are negative for ER, PR, and CA125and can be focally positive for p16. Endometrioid carcinomas are positive for ER and frequently show nuclear ß-catenin staining and lack of PTEN and WT1, clear cell carcinomas are ER, WT1, and HNF1 negative. Mucinous neoplasms in the ovary may be in fact metastases from the gastrointestinal tract and mimic mucinous borderline tumours or carcinomas. Basically, metastases are more frequently bilateral and usually smaller, often less than 10 cm in diameter. They often show a nodular growth pattern, involvement of the ovarian surface, and pseudomyxoma peritonei and ovarii, which means mucin on the ovarian surface and within the peritoneal cavity and within the ovarian stroma, respectively. For differential diagnosis of primary ovarian and metastatic mucinous neoplasms, a panel

of CK7, CK20, and cdx2 may be useful only for a subset of cases. Metastatic neoplasms from the pancreatobiliary system may show the same immunoprofile as ovarian mucinous neoplasms and ovarian mucinous neoplasms derived from teratomas and may show the same immunoprofile as metastatic neoplasms from the colon. Thus, clinical and radiological information is very important for the pathologist. Metastatic colorectal carcinomas may also mimic endometrioid neoplasms. In this setting, immunohistochemistry is more reliable for differential diagnosis and may include oestrogen receptors in addition to CK7, CK20, and cdx2.

Since preoperative histological diagnosis of ovarian carcinoma is not possible except for cases with extensive peritoneal disease, intraoperative frozen section plays an important role for the therapeutical strategy. The sensitivity of frozen section is excellent for the typical, mostly high-grade serous carcinoma (more than 90%) but less good for borderline tumours (60–70%), and poor for metastases (less than 50%). In particular, the recognition of metastatic colorectal carcinoma is important since it changes the surgical procedure significantly. The most important prognostic factors are stage, residual tumour after surgery, histological type and grade. Currently, prognostic molecular markers are under development.

Molecular biology of vaginal carcinoma

Most women with vaginal carcinoma have associated carcinomas and/or intraepithelial neoplasias of cervix or vulva. A potential field effect has been discussed. It has been observed that radiation therapy of cervical carcinoma predisposes to subsequent HPV-related lesions in the vagina. Although the data are limited, the same molecular pathogenesis can be assumed as for HPV-related neoplasms of cervix and vulva.

Pathology of vaginal carcinoma

In contrast to carcinomas of the cervix and the vulva, vaginal carcinoma is rare. Histologically, it is typically a squamous cell carcinoma. It is very frequently associated with or preceded by vaginal intraepithelial neoplasia (VAIN). For the definition of primary vaginal carcinoma the tumour must be located in the vagina without involvement of cervix or vulva, which excludes bulky tumours of the upper vagina with infiltration of the cervix. Due to the thin wall of the vagina the tumours spread early to other pelvic tissues and structures. Microinvasive carcinoma is not separately defined but

carcinomas with less than 3 mm of invasion show a low frequency of lymph node metastases. As with vulvar cancers, verrucous carcinoma is associated with excellent prognosis. A recently described type of vaginal cancer, with controversial prognosis and similarity to transitional cell carcinomas, is papillary squamotransitional carcinoma. Clear cell adenocarcinoma has been associated with exposure to diethylstilbestrol (DES) but may also occur unrelated to DES in the postmenopausal setting. It shows a tubule-cystic or solid pattern and spreads locally via lymphatics and even to the peritoneum. However, its general prognosis is favourable, particularly after DES exposure.

Molecular biology of vulvar carcinoma

Two molecular pathways are distinguished for vulvar carcinoma, one HPV-related, the other non-HPV-related. The HPV-related type is associated high-risk HPV, develops through warty or basaloid vulvar intraepithelial neoplasia (VIN) and occurs in women of middle age (mean age 50 years). These patients may further show other HPV-related lesions, e.g., in the vagina or cervix. Heavy cigarette smoking and chronic immunosuppression are further risk factors. The non-HPV-related type occurs in the postmenopausal age group (mean age 77 years) and is frequently associated with lichen sclerosus or rarely other chronic skin diseases such as granulomatoses. Differentiated VIN is considered a potential precursor of the latter type of vulvar carcinoma. P53 over-expression and mutation, respectively, may occur both in differentiated VIN and non-HPV-related invasive squamous cell carcinoma as well as overexpression of TGF-ß. If stratified by age, the older age group is rarely associated with HPV, while the younger age group is mostly HPV-related.

Pathology of vulvar carcinoma

The major histological type is squamous cell carcinoma of which several subtypes are distinguished. For therapy, tumour stage is important, which includes the tumour size as determined by the maximum diameter and the depth of invasion. An invasion of 1mm or less is considered most favourable for outcome. In addition, tumour thickness and the presence or absence of vascular space involvement needs to be included in the pathology report. Between 1 and 2 mm of invasion, the frequency of lymph node metastases rises from 0 to 12%. Verrucous carcinoma is a rare variant with pushing borders, rare lymph node metastases, and excellent prognosis if complete excision is possible. Adenocarcinoma of the vulva is very unusual. Sentinel lymph node biopsy has become a standard procedure for vulvar carcinoma.

Surgical management of gynaecological cancers

Surgical management of gynaecological tumours remains a cornerstone of the treatment of these tumours. Therefore, surgical intervention has diagnostic, staging, and therapeutic value. Surgical management at each location encompasses treatment of the initial tumour and lymph nodes, which remain the first site of spread.

Cervical cancer

Cervix cancer is the second cause of female cancer worldwide. Although surgery is particularly indicated at early stages of the disease, it can be selectively indicated after shrinkage of the tumour burden with chemotherapy or chemoradiation or in case of a local recurrence. Its unique HPV aetiology has prompted the development of efficient vaccines that, combined with an organized screening policy, should eradicate this disease over time.

Diagnosis and staging

Although ultrasound can be used, MRI is now recognized as the best imaging method for the assessment of local disease parameters such as the tumour size, paracervical extent, and to a lesser degree node involvement [1]. Hybrid 18-FDG PET CT is better indicated for assessing the extent of advanced disease or recurrence and/or to plan chemoradiation therapy [2]. However, the detection limits of functional imaging explain why diagnostic surgery may still play a role at any stage of the disease [3].

Principles of surgery

Surgical management of cervical carcinomas can be differentiated in three directions: diagnostic surgery to adapt the future treatment, radical surgery to cure patients, and preventive surgery to avoid morbidity and complications related to other treatments (especially radiation therapy).

Diagnostic and therapeutic surgery
Conization

Conization aims to remove the squamo-glandular junction in the cervix, better known as the transformation zone where cancer begins. This resection can be diagnostic or therapeutic provided all intraepithelial neoplasia has been excised with free margins. The use of a large electrical loop to excise the transformation zone has now systematically replaced the cold knife or CO2 laser conization, both of which gave rise to a higher rate of post-operative morbidity [4] or difficulties during specimen examination. However, cervix stenosis or obstetrical morbidities do not seem to be significantly different whatever the conization method [5]. But the rate of cervical insufficiency is less in the case of loop excision in comparison to cold knife excision.

Lymphadenectomies

Due to its prognostic and management impact, nodal involvement is an important event in the evolution of cervical cancer. As underlined above, the accuracy of either morphologic (MRI, CT) or functional (PET/CT) imaging techniques is not reliable enough for planning adequate treatment although improvements are in the pipeline. Surgery, including lymphadenectomies, is the gold standard method for achieving a reliable result. Anatomical principles for a comprehensive dissection have been studied [6], which have led to a clarified definition of the different levels of node resection [7].

Pelvic lymphadenectomy

The goal is to remove all nodes around the iliac pedicles down to the level of the obturator and ilio-lumbar nerves, from the obturator foramen caudally, up to the aorto-caval bifurcation cranially [8]. If dissection via laparotomy was the first and reference approach, laparoscopic dissection was subsequently introduced in the early 90s. No significant technical modifications have occurred since the first publication on the technique. Results compare favourably with the open trans- and extraperitoneal approaches in terms of the number of nodes, morbidity, and quality of life. Indeed, since the pioneer series, perioperative morbidity of laparoscopic lymphadenectomy is very low, especially after fulfilling learning curve requirements. Although infrequent, leg oedema remains the most debilitating distant complications [9].

Para-aortic lymphadenectomy

Due to a stepwise spread of nodal disease from the pelvis to the subclavicular area, the detection of para-aortic nodal disease can alter patient management. Indeed, para-aortic nodal disease is effectively treated with extended-field chemoradiation, but with significant haematological and digestive toxicity [10]. This drawback justifies reserving this treatment for patients with proven para-aortic nodal involvement. PET scanning has been suggested for the detection of para-aortic nodal disease; unfortunately, the results are disappointing in case of microscopic involvement [3].

Surgical staging is a good way to assess both the presence of intraperitoneal disease as well as nodal disease, especially at the para-aortic level, but is confounded by significant morbidity. However, among experienced teams, the laparoscopic para-aortic node dissection results in less morbidity, especially when radiation therapy is considered. As for laparotomy, Dargent's extraperitoneal laparoscopic approach seems to be superior to its transperitoneal counterpart for this indication [11].

In early-stage disease with positive pelvic nodes, the rate of para-aortic involvement attains 15%. Although this rate approaches 20%, the therapeutic value of this exploration in locally advanced cervical carcinomas is more questionable. Although a randomized study published in 2003 did not demonstrate any advantage of pretherapeutic surgical staging [12], more recent results seem to show a survival advantage of resecting microscopic nodal disease that is undetectable by PET scan [13]. Only a randomized trial, incorporating PET imaging, could address this important issue regarding the possible advantage of pretherapeutic surgical para-aortic staging in locally advanced disease (tumour size >4 cm).

Sentinel node

In order to limit the morbidity of extensive lymph node dissections and to improve the detection of nodal disease, the sentinel node concept, already validated for breast cancers, was recently implemented in cervical cancer. A recent prospective study compared the results of sentinel node resection, systematically followed by the comprehensive dissection of each hemi-pelvis. In addition to 15% of uncommon sentinel node sites, this study showed that nodal detection and examination had an overall sensitivity rate of 92% and a negative predictive value of 98.2%. If sentinel node detection is bilateral, the negative predictive value approaches 100% [14]. These results prompted a randomized study comparing sentinel node detection alone versus a full pelvic dissection; the study is currently accruing patients.

Radical surgery

Radical hysterectomy and trachelectomy

According to the pattern of spread of cervical cancer, a radical hysterectomy aims to remove the uterus and the tubes, with or without the ovaries (according to the patient's age), the upper part of the vagina, and a variable proportion of the paracervical tissues. A new classification of radical hysterectomies, based on internationally recognized anatomical landmarks, is attempting to clarify the different procedures and their indications [7, 15].

For young patients who wish to preserve their fertility, and fulfilling all criteria, a radical operation limited to the cervix and preserving the corpus is feasible and is called a radical trachelectomy or Dargent's operation, a radical vaginal trachelectomy [16].

Regarding lymphadenectomies, different approaches are available when performing a radical hysterectomy (or trachelectomy): abdominal (Wertheim-Meigs-Okabayashi operation), vaginal (Shauta-Amreich or Schauta-Stöckel operation),

laparoscopic with (coelio-Schauta) or without (coelio-Wertheim) vaginal assistance, or robotic surgery have been extensively described by the authors and recently reviewed [17, 18].

Eventually, in the absence of a randomized comparative study, the choice of the type and approach for a radical operation will be based on patient and tumour characteristics as well as on hospital facilities and the surgeon's own experience!

Nowadays, the mortality of these operations is regularly less than 2%, and perioperative morbidity is directly related to the extent of the radicality of the procedure: haemorrhage, fistulas, and ureteral stenosis, ranging from 5–15%. By contrast, the rate of functional sequelae remains significant: almost 20% of patients suffer from urinary voiding disorders, sexual disturbances, or severe constipation. Most of these adverse effects can be limited by a more precise pelvic dissection, especially preserving, whenever possible, the autonomous pelvic nerves [19, 20]. An innovative new therapeutic surgical concept is the total mesometrial resection (TMMR) with resection of the embryologically-defined uterovaginal (Müllerian) compartment and therapeutic lymphadenectomy for higher local control and avoidance of adjuvant radiotherapy even in case of risk factors. In this case, the vascular and the ligamentous mesometrium will be resected and the uterus and tubes and part of the vagina, but sparing the nerves [21].

Exenteration

In selected locally advanced cervix tumours or recurrences, an exenterative procedure may be required. It consists of the removal of at least two pelvic organs: anterior (bladder and uterus); posterior (uterus and rectum); total (both compartments). Another classification has been suggested according to the height of the resection from the levator ani [22]. Reconstruction of the pelvic floor, by means of musculo-cutaneous, omental flaps, or human cellular dermal matrix [23], with or without a colpoplasty, is important to fill the empty pelvis and prevent bowel occlusion or fistulas. In the case of a latero-pelvic recurrence, a laterally-extended endopelvic resection can be successfully performed with acceptable morbidity and promising survival results [24]. Although the mortality engendered by the procedure has been reduced to less than 5% through improvements in intra- and perioperative care, morbidity remains high, especially if patients have previously received high-dose radiation therapy [25].

Surgery to reduce treatment-related morbidity

This concept aims to reduce the effects of post-operative radiation therapy.

Ovary or adnexal transposition

This procedure, initiated by Lerue Charlus, consists in disconnecting one or both adnexae from the uterus and mobilizing them along with their pedicle outside the future pelvic radiation field. They are transposed and secured high in the paracolic gutters, directly or through the prior extraperitonization of their vascular pedicle. The procedure can be performed by laparoscopy. Preservation of hormonal function can be obtained in more than 50% of cases [26]. Indications for this procedure are limited to patients devoid of risk or at a low risk of ovarian spread (stage IB1, squamous tumour without extracervical spread).

Pelvic exclusion prior to radiation therapy

The goal is to prevent radio-induced bowel damage by installing a mesh (resorbable or omental mesh) around the pelvic sling or placing a temporary breast implant [27].

Endometrial cancer

Due to early symptoms, the diagnosis of endometrial cancer (EC) is often made at an early stage and the prognosis is generally good. Major advances in recent years have been achieved in the knowledge of pathology. A new molecular classification defined two different molecular pathways of carcinogenesis [28]. Type I endometrioid tumours are oestrogen-related lesions. They occur more frequently in overweight patients, grow indolently, and, overall, carry a better prognosis. This group comprises hereditary tumours, especially those related to the hereditary non-polyposis colon cancer (HNPCC, Lynch) syndrome. This discovery, concerning 5% of endometrial cancer patients, should trigger genetic counselling and specific surveillance for colorectal cancer. By contrast, type II tumours consist of more aggressive subtypes such as papillary serous, clear cell, and carcinosarcomas. They are hormone-independent and are found in generally older and non-overweight postmenopausal women. Evolving more rapidly, they carry a worse prognosis than type I tumours.

In addition, the FIGO classification of endometrial cancer, based on thorough pathological staging, was updated in 2009 [29]. Surgery is the first treatment of endometrial cancer in most cases. Its extent is based on both pre- and intraoperative explorations. According to the FIGO stage, radiation therapy may or may not be used as adjuvant treatment. Medical treatments are currently reserved for patients with advanced disease, but are currently being investigated in early stage high-risk tumours.

Principles of the workup for endometrial cancer

Gynaecological bleeding in a postmenopausal woman, whatever the degree, is a uterine cancer until proven otherwise. After a complete general and gynaecological clinical examination, imaging is indicated. Pathological proof is necessary which can be obtained by biopsy or after a hysteroscopy-dilatation-curettage, especially if a biopsy is not possible or informative.

The imaging workup is useful to precisely define the disease extent. Due to its simplicity and reproducibility, ultrasound is usually the first examination performed if there is any suspicion of endometrial cancer. However, its accuracy is examiner-dependent. If MRI is currently the best morphological imaging method for precisely defining the intrauterine extent of disease, it is less accurate for the diagnosis of minimal node disease. Although results have improved through the use of nanoparticles of iron oxide, this procedure is not routinely performed and has not replaced surgery. Due to their propensity for distant spread, PET scan imaging may be useful for staging type 2 tumours in locally advanced or recurrent disease [30].

Principles of surgical treatment: diagnosis, staging, treatment

The results of peritoneal cytology, due to its controversial prognostic value, are no longer part of the new FIGO staging system. Total hysterectomy is the standard of care for clinical stage I endometrial cancer since occult cervical disease may exist in spite of a normal MRI or negative endocervical curettage. The question as to whether an intra- or extra-fascial hysterectomy is the most adequate has not been properly answered so far. If a systematic radical hysterectomy is not appropriate in stage I patients (less than 1% of positive parametrial involvement), it seems a logical indication in clinical stage II tumours but it must be balanced with the patient's general status [31]. Similarly, the role of the upper colpectomy is discussed and balanced with the simplicity and efficacy of post-operative vaginal high-dose rate brachytherapy. Bilateral adnexectomy is mandatory due to the rate (1–2%) of occult ovarian metastasis. In addition, patients are at an age of onset of ovarian cancer and bilateral adnexectomy may prevent this pathology.

A lymphadenectomy is the main controversial issue. Nodal involvement does indeed justify radiation therapy and adjuvant chemotherapy. Two recent randomized trials confirmed that systematic pelvic lymphadenectomy does not afford a survival advantage in early-stage well-differentiated endometrioid tumours, but increases morbidity [32, 33]. Adding a para-aortic node dissection was assessed in a recent controlled study. Only patients at intermediate or high risk of recurrence (IB grade 3 or type 2 tumours) benefited from a survival advantage of the combined procedure over a pelvic dissection alone [34]. If a para-aortic dissection is indicated, it should be performed bilaterally and up to the renal vessels [35]. In these extensive nodal dissections, the general condition and tolerance of the patients should always be balanced, to avoid exposing them to excessive morbidity. The sentinel node technique has been suggested to address the question of assessing the nodal status in early endometrioid carcinomas [36]. However, so far the reliability of the procedure has not been sufficiently confirmed to include it in routine practice [37]. Other staging procedures such as peritoneal biopsies or an omentectomy can be associated, especially for type 2 tumours [38].

The surgical approach is to be discussed according the patients' status and wishes, as well as the characteristics of her tumour (type, local extent) and uterus (size, vaginal accessibility).

A laparotomy is the standard approach for any endometrial cancer, whatever the stage of the disease or the uterine volume. However, morbidity may be high, especially in the aged with frequent co-morbidities (obesity, numerous other medical disorders).

The vaginal approach was successfully used very early in the history of gynaecological oncology. But, as removing the adnexae proved difficult and it was impossible to perform adequate staging via the same route, the indication was restricted to medically-compromised patients with a small uterus and a good vaginal access. The results were not so poor in this context, which still deserves to be applied to selected patients with an early type 1 tumour that does not require extensive staging [39, 40].

Since the late 80s, other minimally invasive approaches have been developed. Childers first described the laparoscopic management of endometrial cancer in 1992 [41]. Since that date, experience has grown rapidly all over the world, and several randomised studies in Europe confirmed the advantages of this approach over laparotomy in terms of perioperative outcomes, quality of life, and survival rates in patients with early stage endometrial cancer [42]. Even the largest American randomized study (LAP2), on the same topic including type 2 tumours, confirmed the perioperative advantages of laparoscopy, in spite of a 23% conversion rate due to a high percentage of obese patients and mandatory systematic thorough staging [43]. The late results of this trial, recently published, seem to confirm the absence of a detrimental effect of laparoscopic surgery on survival rates, with a low 0.24% incidence of port site recurrences [44].

Recently introduced, robot-assisted laparoscopy offers the possibility for 'abdominalist' surgeons to provide minimally invasive surgery to a larger proportion of patients. Although the additional costs of robotic surgery may be an issue [45], this assistance seems particularly interesting in the case of morbid obesity [46]. Robotic

assistance has been shown to enable the surgeon to perform adequate staging with a lower rate of conversion in this group of patients [47]. However, a longer follow-up is needed as well as the results of controlled studies to confirm the long-term effects of this approach. Pooled results of different series comparing laparotomy to either laparoscopy or robotics seem to confirm the advantage of both laparoscopy and robotics over laparotomy.

Fertility-preserving surgery

Although very rare, with an incidence of less than 5% before 40 years of age, endometrial cancer may occur in young patients who wish to preserve their fertility. If all criteria are fulfilled (well-differentiated endometrioid tumour, confined to the mucosa, with no evidence of nodal, ovarian, or peritoneal involvement at pretherapeutic surgical staging), conservative treatment may be offered. It should be based on thorough curettage followed by at least six months of progestin therapy [48]. However, the recurrence rate is high [49], and possibly lethal but successful pregnancies have been reported, naturally or after assisted procreation [50].

Vaginal cancer

Preoperative workup for vaginal cancer

Vaginal tumour extension requires a very careful gynaecological examination (potentially under general anaesthesia). FIGO staging (that has a clear influence on further treatment) is based on clinical data [52]. The primary vaginal cancer (PVC) is preferentially located within the upper third of the posterior part and the lower third of the anterior part of the vagina, and 40 to 50% of the tumours are multifocal.

Standard imaging, such as that used in uterine cancers, is based on MRI that identifies tumour dimensions, potential extension beyond the vagina (bladder, rectum), and documents enlarged pelvic and para-aortic nodes and metastases [53]. FDG-PET was found to be relevant for detecting primary disease in all cases and nodal disease twice as often as CT and physical examination [54].

Principles and indications for surgery for vaginal cancer

Two types of treatments have been reported in primary carcinoma of the vagina: surgery or radiation therapy but given the rarity of primary carcinoma of the vagina, no randomized trial has been performed, particularly to assess the respective role of surgery and radiation therapy [55–59].

Unlike in the case of other gynaecological malignancies, surgery has not yet been really well codified in PVC. Surgical treatment concerns the primary tumour and lymph node staging.

Surgical treatment of the primary tumour can be limited (simple and limited vaginal excision), total simple colpectomy or more radical, such as radical colpectomy or pelvic exenteration. Basically, in stage 0 (in situ disease), surgery, a simple excision, is the treatment of choice. In stage I disease, two treatments are proposed in the literature: surgery (partial or total radical colpectomy) vs radiation therapy. In stage II to IVA disease, most teams consider that radiation therapy is the treatment of choice. Concomitant chemoradiation therapy in these situations has probably a key place but very limited experience has been reported [60].

The comparison between surgery and radiation therapy (for stage I disease) remains difficult in the light of the literature analysis. Several studies have reported poorer survival in patients treated with radiation therapy compared to patients treated by surgery [51, 58, 61]. Nevertheless, this comparison is heavily biased because other factors such as age and the general status could play a role in the choice between surgery and radiation therapy and furthermore could also have an impact on survival in disfavour of radiation therapy [51]. As in cervical cancer, if surgery is performed it should be 'sufficiently' radical to reduce the risk of involved margins (which then require adjuvant radiation therapy with a higher risk of morbidity) to a minimum (ideally to 0). Consequently, even in stage I disease (or in patients with stage 0 (in situ) disease but affecting a large length of the vagina), such surgery could impose a total resection of the vagina with a clear impact on quality of life (particularly sexual activity) since 15% of patients with invasive carcinoma are <49 years [51]. Even if reconstructive surgery of the vagina is done, no publication has focused on the sexual quality of life after surgery in PVC. The use of radiation therapy does not exert the same anatomical (and functional) impact because the organ is not surgically resected. This point also explains why, even if surgery remains the treatment of choice of stage 0 (in situ) disease, brachytherapy could play a role in young patients with recurrent disease and a previous history of colpectomy or in lesions affecting a large length of the vagina and requiring a total colpectomy. A recent series reported excellent local control with this treatment in these particular indications [62]. Basically, the place of the surgery has decreased during the past four decades, particularly in Stage >I disease.

Concerning lymph node staging, lymphatic extension of vaginal tumours is complex and correlates with the double embryologic origin of the vagina: the upper two-thirds drain towards the iliac nodes while the lower third drains towards the hypogastric and inguinal nodes [60]. Drainage of the posterior septum is located in the haemorroidal and sacral nodes. Consequently, these nodes should be treated (surgically or included in the radiation therapy field) at the same time as the PVC. Nevertheless, the complexity of the lymphatic drainage also explains why nodal staging surgery is not really codified in this tumour. Most reports concerning the surgical treatment of PVC have a low proportion of patients who underwent comprehensive nodal surgery (pelvic, para-aortic, or inguino-femoral). In the series by Stock et al. concerning 100 patients with PVC (53 of whom were treated surgically), 40 underwent a lymph node dissection [63]. Patients with positive inguinal nodes had involvement of the lower third of the vagina [63]. In the series by Davis et al. among 48 patients undergoing pelvic and para-aortic node assessment for stage I/II PVC, only one patient with stage I disease (6%) had nodal involvement but eight (26%) had nodal spread in stage II disease (in the pelvic area in seven and para-aortic nodes in one) [64].

Two papers recently reported the authors' experience of the feasibility of the sentinel node procedure in primary (or recurrent) VC [65]. In the experience reported by Frumovitz et al. (using a combined technique with blue dye and radiocolloid), three out of nine patients treated initially with radiation therapy had their radiation field altered based on the results of lymphoscintigraphy findings [65].

Vulvar cancer

Surgery is the cornerstone of the management of vulvar tumours and is associated with a high cure rate. According to the disease extent or definitive pathological results, radiation therapy can be used as adjuvant therapy or, combined with cisplatin chemotherapy, as neoadjuvant treatment in locally advanced tumours [66].

Principles of surgery

Vulvar surgery

A radical vulvectomy is the gold standard of treatment of invasive carcinomas defined as a tumour invading the stroma beyond 1 mm of depth. Its aim is to remove the tumour along with a sufficient amount of healthy skin. The adequate free margin should be at least 8 mm after formalin treatment, which corresponds to at least 1 cm on the patient [67]. New data concerning the resection margins show that 3 mm in each direction seem to be sufficient [68]. The underlying fatty tissue is resected down to the urogenital diaphragm covered by the superficial perineal aponeurosis. Indicated for invasive tumours, cosmesis issues should not interfere with the mandatory oncological radicality. A skinning vulvectomy, indicated for non-invasive neoplasia, removes the tumour and 5 mm of free skin laterally and within the underlying tissue. Except when unavoidable, a total radical vulvectomy along with a bilateral inguinal lymphadenectomy is no longer performed through the classic Basset-Taussig butterfly incision. Separate incisions for the vulvectomy and the inguinal lymphadenectomies are now the rule [69]. The incision is drawn taking into account the need for 1 cm free margins.

Partial vulvectomy

It consists of the resection of only a part of the vulva including the tumour and the required free margins. It is indicated whenever the tumour is isolated, small, and at least 10 mm away from the midline. In the case of a median but small tumour, a partial anterior or posterior resection is also feasible.

Principles of inguinal dissections

The inguino-femoral lymphadenectomy removes all nodes between the superficial aponeurosis and the saphenous vein within the limits of the Scarpa triangle. In addition to all nodes located medially to the femoral vein, a deep inguinal lymphadenectomy removes tissue from the pectineus muscle up to the inguinal ligament. The Cloquet node is the upper lymphatic structure in this area.

Principles of reconstructions

Whatever the technique (primary closure or flap reconstruction), the surgeon must ensure that the urethra is kept in its normal position, to avoid any uncomfortable deviation of the urinary stream. If necessary, up to 1cm of the urethra can be resected without incontinence. The use of a graft/flap is discussed whenever the primary closure seems under tension, with a high risk of secondary wound breakdown and for sufficient cosmetic and functional reconstruction.

Principles of perioperative care

Post-operative care of vulvar cancer patients is of paramount importance, combining careful nursing of clean and dry sutures, good nutrition, and efficient postoperative analgesia. Indeed, the morbidity engendered by this surgery remains high. In the series of 101 patients reported by Gaarenstrom, complications were observed in 76% of cases, especially wound breakdown and/or infection (56%), lymphocysts (40%), and lymphoedema (28%) [73]. If vacuum-assisted therapy has improved the management of wound breakdowns, its efficacy has been shown to prevent secondary breakdowns in case of large defects [70].

Indications for treatments of vulvar carcinoma

For a unifocal stage 1 tumour (T1a N0 M0) in a healthy vulva, a partial resection (lateral hemivulvectomy or subtotal anterior or posterior vulvectomy) with a minimal 1 cm free margin around the tumour, is acceptable. However, in the case of skin abnormalities, a total radical vulvectomy will avoid contralateral recurrences. An inguinal node dissection via a separate incision will be unilateral in the case of a lateral tumour and bilateral for a lesion which is less than 10 mm from the midline. The extent of the lymphadenectomy can be based on the frozen section analysis of the resected superficial nodes, with a false negative rate of 5–7% [71]. Sentinel node detection after intradermal double labelling (by 99m Technetium and patent blue), along with the ultrastaging examination (serial sections of sentinel node[s] and conventional haematoxylin-eosin staining plus pancytokeratin immunohistochemistry), seems an efficient way to reduce the morbidity of lymph node dissection, without jeopardizing oncological outcomes, as demonstrated in a recent international comparative study [72].

In the case of a stage IB-II tumour (T1b-2 N0M0), a total radical vulvectomy, with or without a urethra/anal skin resection, is required along with a bilateral inguinal node dissection.

In advanced stage III tumours (T1-2, N1-2M0) and some stage IVA (T1-2, N3M0 or T3 any N, M0), a total radical vulvectomy, with or without a urethra/anal skin resection and a bilateral complete node dissection, is required.

For stage IVA tumours, definitive chemoradiation therapy or an exenterative procedure are discussed after a thorough clinical evaluation under general anaesthesia. Patients with stage IVB disease (any T or N but M1) are managed according to their general status, either with cisplatin-based chemotherapy or the best supportive care.

Ovarian cancer

Preoperative workup

Ovarian cancer is renowned for its capacity to disseminate intra-peritoneally and via lymphatic spread. Thus, surgical staging (or surgical resection) of peritoneal sites and lymph nodes remain the two strategic steps in the surgical treatment of this tumour. The reference imaging technique used to evaluate the spread of this tumour before the surgical procedure is the thoraco-abdomino-pelvic CT scan.

Principles and indications for surgery

Surgery is a crucial part of the management and treatment of ovarian tumours. It allows the clinician to make the diagnosis, to determine disease spread (surgery remains the most accurate procedure for evaluating the level of spread of the tumour in the abdomen), and is the cornerstone treatment for removing the tumour. The surgical procedures required depend on the disease stage. Besides stage, the postoperative residual tumour is the most important risk factor [94].

Early stage (patients with disease macroscopically confined to the ovary)

The surgical procedures required are well-defined and codified. In patients older than 40 years, radical treatment based on a hysterectomy and bilateral salpingo-oophorectomy is the standard of care. The rationale behind the use of a hysterectomy is twofold: (1) the presence of synchronous endometrial carcinoma associated with the ovarian tumour (15% to 20% of the endometrioid subtype) and (2) the uterine serosa could harbour microscopic peritoneal

spread undetectable to the naked eye. Those two reasons explain why the uterus should be removed in patients who do not desire to preserve their fertility. In young patients (<40 years) desiring the potential for pregnancy, a unilateral salpingo-oophorectomy with preservation of the uterus could be proposed and seems to be safe in selected patients with early-stage disease and excellent prognostic factors (conventional histological subtypes such as low-grade serous, mucinous, or endometrioid lesions; macroscopic and radiological unilateral tumour; and absence of macroscopic and microscopic histological or cytological peritoneal spread after a definitive analysis of the specimen removed during staging surgery [grade 1 or 2 disease]) [73]. In such cases, uterine curettage is then required to verify the absence of synchronous endometrial cancer [73].

Whatever the procedure used on the uterus and ovaries (conservative or radical), staging surgery is required to identify the precise stage of the disease, in order to guide postoperative management and indications for adjuvant chemotherapy. In fact, patients with stage IA or IB and grade 1 disease could be treated exclusively with surgery. In patients with advanced stages, or grade 3 disease (or a clear cell tumour), adjuvant chemotherapy should be used after the surgical procedure.

Staging surgery is then crucial to accurately identify the disease stage. This staging surgery is, according to the potential spread of the tumour, peritoneal and/or nodal staging [74]. Peritoneal staging is based on peritoneal cytology, omentectomy, multiple peritoneal biopsies and an appendectomy (the latter only in mucinous tumours or in the case of involvement [75]). If lesions look suspicious on the peritoneum, they should be removed. Patients are restaged based on microscopic involvement of at least one of these specimens in nearly a third of the cases without any macroscopic suspicious lesion on the peritoneum or omentum [74].

The interest of the lymph node staging is debated more extensively. Indeed, this procedure is extremely useful because nearly 15% of patients will exhibit nodal involvement. Furthermore, 12% of patients with no cytological or histological peritoneal spread were upstaged solely based on nodal involvement [76]. Some of them then receive adjuvant chemotherapy exclusively based on the detection of this nodal involvement and would not have received such therapy with peritoneal staging alone [77].

The distribution of nodal involvement is very ubiquitous between the pelvic and para-aortic area. Fifty percent of patients with nodal involvement will have metastases in these areas, 25% exclusively in pelvic nodes and 25% exclusively in para-aortic nodes [77]. The rate of contralateral nodal involvement in patients with a stage I unilateral ovarian tumour is nearly 16% (series are summarized in Table 44.1). Consequently, if a lymphadenectomy is carried out in epithelial ovarian cancer, it should include the removal of pelvic and para-aortic nodes, up to the level of the left renal vein (the most frequent site of nodal metastasis is the nodal group between the inferior mesenteric artery and the left renal vein) and bilaterally even in patients with a macroscopic unilateral tumour. The rate of nodal involvement is correlated with the tumour grade (higher risk with grade 3 lesions) and the histological subtype of the tumour.

The point most discussed currently is the real therapeutic impact (in terms of improving survival) of this nodal surgery in addition to peritoneal staging in advanced stages with macroscopic complete resection. Some authors who consider that this surgery should not be used argue that the only randomized trial on this topic failed to demonstrate an improvement of survival using complete

Table 44.1 Laterality of nodal spread in stage I epithelial ovarian cancer

Series years	Ipsilateral or bilateral	Contralateral
Onda 1996 (n = 9) [78]	8	1
Baiocchi 1998 (n = 11) [79]	8	3
Sakuragi 2000 (n = 9) [80]	9	0
Suzuki 2000 (n = 4) [81]	2	2
Cass 2001 (n = 10) [82]	7	3
Morice 2003 (n = 9) [83]	8	1
Nagishi 2004 (n = 8) [84]	8	0
Nomura 2010 (n = 9 but stage I/II) [85]	7	2
Powless 2011 (n = 10) [86]	9	1
Total (n = 79)	66	13 (16%)

lymphadenectomy [87]. Nevertheless, the conclusions of this trial continue to fuel debate, the authors themselves stating that the trial was probably underpowered due to the number of patients (nearly 135 patients in each arm) to attain statistical significance (there was a trend towards a difference in overall and event-free survival which was not statistically significant). Nevertheless, many teams and national guidelines consider that this procedure should be included in the standard of care of early-stage epithelial ovarian cancer. Those different staging procedures (peritoneal and nodal) should be performed laparotomically (in the hands of surgeons trained to perform this type of surgery) [88]. Rare data exist that laparoscopic approach could be somewhat less accurate for staging.

Advanced stage ovarian cancer (patients with extra-ovarian macroscopic disease)

In patients with abdominal peritoneal disease (stage >II), the strongest prognostic factors compared to the others is the size of the residual disease (measured as the largest size of the bulkiest residuum at the end of debulking surgery, if residual disease is left in place) [89]. This debulking surgery requires experienced gynaecologic oncologists and teams (to optimize peri- and post-operative care in order to reduce morbidity) for advanced surgery. As the rate of achieving optimal cytoreductive surgery is correlated with the surgeon's skills in this kind of surgery, ovarian cancer is the best example among solid tumours of the fact that the surgeon alone may be a prognostic factor in this disease.

Technical procedures required in advanced stage ovarian cancer (ASOC) are the most complex because, in addition to the previous procedures detailed in early-stage disease that are also required (hysterectomy, omentectomy, bilateral salpingo-oophorectomies), as peritoneal spread of the tumour is very frequent, large peritonectomies, diaphragmatic surgery, bowel resection, and a splenectomy are frequently needed to remove the complete tumour. Thus, this surgery is a pan-abdominal surgical intervention requiring gynaecologic oncologists who are skilled in all kinds of abdominal procedures that are mandatory in this context. For multivisceral surgeries an interdisciplinary team is recommended [90]. The most frequent site of the bowel resection required is the recto-sigmoid colon. En bloc resection with the removal of the uterus, ovaries and fallopian tubes, Douglas' pouch, and the peritoneum of the pelvic cavity

exhibiting macroscopic disease could then be easily removed using an extraperitoneal approach such as that described by Hudson et al. [91]. Nevertheless, other types of bowel resection could then be needed: transverse, ileo-caecal, or a small bowel resection [90].

This type of surgical procedure, so-called 'debulking' surgery, has been 'historically' qualified as 'optimal' if the remaining residual disease is small (the size of this cut-off has evolved during the last three decades: 2, 1, and 'now' 0 cm) and 'suboptimal' when larger residual disease is left in place [89, 90, 92, 94]. In fact 'optimal' surgery involves 'complete' cytoreductive surgery with absence of macroscopic residual disease. There is a clear difference in terms of the survival between patients with complete cytoreductive surgery and patients with minimal residual disease (considered as having undergone optimal surgery) [93, 94]. Only patients submitted to complete macroscopic resection of peritoneal spread would then be considered as having undergone 'optimal' cytoreductive surgery [95, 96]. This should be the first goal and the standard management of debulking surgery in epithelial ovarian cancer. When macroscopic residual disease is left in place the surgical procedure would then be considered suboptimal, whatever the size of the residue. Thus, in patients with stage IIIC disease, this kind of debulking surgery could require six to eight hours. This operative time also explains why the management of these tumours requires not only experienced surgeons but also multidisciplinary teams: gynaecologic oncologists, abdominal surgeons, anaesthesiologists, nurses, and intensive care clinicians to undertake the most adequate peri- and post-operative management in order to reduce morbidities.

Nevertheless, this cytoreductive surgery has been exposed to a good deal of criticism because of the significant morbidity engendered, particularly in patients with residual disease at the end of the surgery [97]. Post-operative morbidities are dominated by septic complications, post-operative bleeding, and post-operative anastomotic leakage requiring a transient enterostomy. Such complications could then delay the initiation of the first course of post-operative chemotherapy, which also appears to be a prognostic factor in ovarian cancer. Neoadjuvant chemotherapy should be an exception with a maximum of three chemotherapy cycles before interval surgery, for example, in the case of acute myocardial infarction or acute lung embolism. A prospective randomized phase III trial has not demonstrated that by reducing the size of peritoneal spread, this neoadjuvant chemotherapy decreases the radicality of surgical procedure required to remove the entire tumour and therefore reduces morbidity [98]. But in addition, only the 19% that had a macroscopic complete resection within primary surgery had a significant improved survival of seven months in comparison to the 40% that got complete resection after neoadjuvant chemotherapy [98]; therefore, primary surgery is the gold standard. However, the use of such neoadjuvant chemotherapy should not be an excuse for 'poor surgery'. If it is possible to totally remove peritoneal spread initially during surgery, it should be done [95, 96]. If disease spread is too massive and residual disease of more than 1 cm would be present after primary surgery, then neoadjuvant chemotherapy could be considered followed by interval debulking surgery. In the case of FIGO IV, patients also have a benefit after macroscopic complete resection [99]. Neoadjuvant strategies could be used in patients with a medical or a nutritional status that is too poor to enable them to undergo such initial debulking surgery.

The last question concerning the surgical procedures in ASOC concerns the addition of pelvic and para-aortic node resection.

There are strong arguments in favour of its use because of, firstly, the high rate of nodal spread in stage III or IV disease (nearly half to two-thirds of the patients) and, secondly, the dogma regarding the need to achieve a complete macroscopic resection that is now considered the standard of surgical care in ASOC. Nevertheless, as we observed in early-stage disease, a phase III trial failed to demonstrate an improvement of overall survival using a complete lymphadenectomy (but event-free survival was enhanced) [100]. Nevertheless, a large recent analysis reporting on patients included in three different trials testing different chemotherapy regimens focused on the impact of nodal surgery on survival. This series demonstrated that this surgery is of interest to improve the survival of patients undergoing a complete removal of peritoneal disease [101]. If this intraperitoneal debulking surgery fails to remove all the disease, then retroperitoneal nodal surgery is pointless [101]. Two randomized trials are ongoing in France and Germany to test the therapeutic interest of the lymphadenectomy in ASOC. Fortunately, the German LION trial has completely recruited and we hopefully expect the final results of this prospective randomized trial in 2018.

Role of radiotherapy

Since the early days of radiotherapy more than a century ago, radiotherapy and especially brachytherapy (Radium) were successfully performed in various gynaecologic cancers. Nowadays, radiotherapy is well established as an essential part in modern multimodality treatment and is being used for primary, neoadjuvant, adjuvant, and palliative purposes.

Cervix cancer

Primary, neoadjuvant, and adjuvant radiochemotherapy have been described as treatment options for cervix cancer. Patient selection for the different treatment approaches is mainly based on the tumour stage (FIGO) and lymph node status. However, since prospective randomized controlled trials addressing the question of patient selection for different therapy options (surgery vs radiotherapy vs combined treatments) are limited, the decision which treatment modality is applied is still a matter of debate and varies between countries and institutions. But two major findings should be respected in this discussion: primary surgery in patients with (extensive) parametrial involvement leads to a high number of incomplete resections (and thus to local tumour progression), and the combination of surgery and radiotherapy leads to an increased morbidity in comparison to each treatment modality alone ([102–104]. Therefore, there has been a consensus that radiochemotherapy is the treatment of choice in locally advanced stages (≥FIGO stage IIB distal, >4cm and/or positive lymph nodes) [105], whereas in earlier stages both treatment strategies can be performed as single modalities with similar outcome. Pre-invasive stages and the FIGO stage IA are usually restricted to surgery. In consequence, precise staging including assessment of local tumour extension (gynaecologic examination, ultrasound, MRI), regional lymph node involvement (CT, MRI, PET CT, laparoscopic lymph node staging) and distant metastasis (CT, PET CT) is crucial.

Primary radiochemotherapy

Primary radiochemotherapy consists of external beam radiotherapy with concomitant delivery of chemotherapy and brachytherapy.

External beam radiotherapy aims for initial tumour shrinkage as well as for treatment of suspected regional microscopic or macroscopic lymph node involvement. The clinical target volume in external beam radiotherapy includes the primary tumour, the complete uterus, parametria, upper vagina (depending on the extent of vaginal infiltration), internal, external, and common iliac lymph node stations as well as the obturator and presacral lymph nodes [106]. Target definition and treatment planning is generally based on computed tomography. Currently, different treatment techniques in external beam radiotherapy are applied. Most commonly 3D conformal techniques with four fields ('four field box') are used, which allow for a homogeneous dose distribution within the pelvis. More advanced external beam radiotherapy techniques such as intensity modulated radiotherapy (IMRT), tomotherapy or particle therapy are being investigated and show more heterogeneous dose profiles leading to reduced (high-dose) irradiation of the surrounding organs at risk (urinary bladder, rectum, colon, small bowel, femoral heads). The standard prescription dose for the target volume varies between 45–50 Gy at a dose per fraction of 1.8–2 Gy. An additional local boost of approximately 10 Gy to bulky lymph nodes appears reasonable; however, definite evidence for benefit is lacking. Irradiation of the para-aortic region in case of lymph node involvement showed contradictive results but may be beneficial in selected cases at the sake of increased morbidity. Based on five randomized trials, concomitant chemotherapy (5–6 cycles cisplatin 40mg/m2 +/− 5 fluorouracil) has been integrated into primary radiotherapy since 1999 as standard of care. Radiochemotherapy significantly improved local tumour control and survival compared to radiotherapy alone. An absolute improvement of ~6% overall survival has been demonstrated in a meta-analysis with 10 year follow-up [107, 108]. Apart from the systemic effect, concomitant chemotherapy is mainly considered as a radiosensitizer. Tumour regression during external beam radiotherapy and concomitant chemotherapy may be up to ~75%. Tumour size, tumour volume, tumour stage, lymph node involvement, tumour hypoxia, and histology are discussed as prognostic parameters for response to radiotherapy. The residual tumour volume after external beam radiotherapy is then treated by brachytherapy. Brachytherapy is performed in an operation theatre, where an applicator system (tandem-ring, tandem-ovoid, etc.) is placed directly at the cervix and in the uterine cavity. The specific dosimetric characteristics of brachytherapy (high-dose at the source with sharp circular dose fall off in the periphery) allow for high-dose delivery at the residual tumour while sparing the surrounding organs at risk. The former application of radium sources has widely been replaced by the use of afterloading systems with high-dose rate or pulsed-dose rate schedules. Dose prescription is generally performed to predefined dose points ('2D brachytherapy') in relation to the applicator such as 'point A' or 'point B' and varies according to centres and traditions between 2–6 fractions of 4–8.5 Gy for high dose rate (HDR) and 1–2 fractions of 20–35 Gy for pulsed dose rate (PDR) schedules.

Primary radiotherapy leads to a complete remission rate of approximately 98%. The five-year local tumour control ranges between 81–97% for stage IB and IIA, 74–82% for stage IIB, 44–66% for stage III and 18–25% for stage IVA and the five-year overall survival ranges between 80–90% for stage IB and IIA, 65–75% for stage IIB, 30–50% for stage III, and 10–15% for stage IVA. Acute side effects imply mainly urogenital and gastrointestinal symptoms such as increased urinary frequency and diarrhoea. Late side effects

range from vaginal dryness (frequently) to incontinence and fistula (rare). Recently, major improvements have been described in the field of image-guided adaptive brachytherapy ('3D brachytherapy'). In image-guided adaptive brachytherapy dwell point optimisation is performed based on the integration of modern imaging techniques (CT, PET/CT, mainly MRI) into the treatment planning process leading to individually adapted treatment plans with an increased dose to the primary tumour while simultaneously sparing the surrounding organs at risk. The treated volume may be increased and additionally shaped by the insertion of interstitial needles, if indicated. A prospective multicentre study demonstrated that with image-guided adaptive brachytherapy a reduction of severe side effects by 50% is achievable with a simultaneous improvement of local tumour control in comparison to the standard 2D approach [109]. Retrospective single-centre trials showed a local tumour control rate of >95% for all locally advanced stages and severe side effects for the gastrointestinal and urogenital tract <5% [110, 111]. Prospective trials are ongoing; in the future, efforts to reduce distant metastasis and further improve quality of life will be necessary [112].

Neoadjuvant and adjuvant radiochemotherapy

Neoadjuvant brachytherapy for FIGO stage IB1 tumours and neoadjuvant external beam radiotherapy with concomitant chemotherapy followed by brachytherapy for higher stages (and/or regional lymph node involvement) has been performed by many centres. However, it has been shown that the addition of surgery seems to increase the morbidity rate without any evidence of benefit in local tumour control, progression-free survival or overall survival in comparison to radiochemotherapy alone. In consequence, surgery should be limited in this cohort to patients with persistent local disease six to eight weeks after radiochemotherapy.

Adjuvant radiotherapy after surgery is indicated in case of R1 or R2 resections, lymph node involvement, microscopic parametrial infiltration, lymphangiosis, infiltration of vessels, G3, and tumour size >4cm with deep stromal invasion for improving local and regional tumour control [113]. The radiotherapy technique is similar to the primary treatment but with brachytherapy only in selected cases (e.g., close or positive resection margin in the vaginal vault, macroscopic residual tumour) [114]. The standard prescription dose is 50 Gy with 1.8–2 Gy in a single dose. Concomitant delivery of chemotherapy (cisplatin, 5-fluorouracil) is recommended. Adjuvant radiochemotherapy significantly improves progression-free survival and overall survival in early-stage cervix cancer with high-risk factors in comparison to radiotherapy alone, whereas adjuvant radiotherapy alone only demonstrated a decrease in local recurrences without a long-term survival benefit in comparison to no adjuvant radiotherapy [115].

Endometrial cancer

Treatment of endometrial cancer is a multimodality therapy tailored according to clearly defined risk factors, with surgery as the cornerstone. Radiotherapy is mainly indicated as adjuvant treatment. Several randomized controlled trials [116–119] defined the role of radiotherapy and redefined treatment concepts recently. Primary radiotherapy is limited to inoperable patients or patients treated in palliative intention.

Adjuvant radiotherapy

After primary surgery alone, up to 30% loco-regional recurrences have been reported. Therefore, adjuvant radiotherapy has been

integrated into the treatment concept of endometrial cancer for improving local tumour control. Currently, adjuvant radiotherapy is performed dependent of the presence of major prognostic factors, which are FIGO stage, age, histology, grade, depth of myometrial invasion, and lymphovascular space invasion. Based on these prognostic factors patients are divided into three risk groups: low-, intermediate-, and high-risk group. Low risk is defined as FIGO stage IA (with <50% myometrial invasion), G1 or 2 with endometrioid histology. Patients are classified as intermediate risk in case of FIGO stage IB (>50% myometrial invasion) and G1 or 2, or FIGO stage 1A and G3. All patients with FIGO stage II, III and FIGO stage IB with grade 3 or with non-endometrioid histology are considered high risk (Figure 44.3).

Low-risk patients have an excellent outcome after surgery with 95% five-year relapse-free survival and adjuvant radiotherapy is not recommended. Patients in the intermediate risk group should receive adjuvant radiotherapy as vaginal vault brachytherapy. The rationale for this treatment concept is mainly based on the findings that in these patients: (1) loco-regional recurrences after surgery alone occur after five years in up to 15%, (2) loco-regional recurrences are located in 75% in the vagina, (3) adjuvant external beam radiotherapy significantly improved locoregional tumour control but did not show any survival benefit in these patients, and (4) with vaginal vault brachytherapy similar local (vaginal) tumour control rates with significantly less morbidity and better quality of life is achievable in comparison to external beam radiotherapy [120–123]. External beam radiotherapy, however, may be used as an alternative. Vaginal vault brachytherapy is usually performed with vaginal cylinders as applicator systems, which are directly placed in the vagina. The target volume for vaginal vault brachytherapy should encompass the vaginal scar and the vaginal lymphatic drainage in 5 mm depth in the upper one-third to two-thirds of the vagina (approximately 3–5 cm). 30–50 Gy in four to five days for PDR schedules or 15–25 Gy in 3–4 fractions with 5–7 Gy HDR single dose prescribed at 5 mm depth from the applicator surface is recommended. Vaginal vault brachytherapy is well tolerated with generally only few (low grade) vaginal, urogenital, and intestinal side effects. Vaginal recurrences after vaginal vault brachytherapy occur in 1.6% after five years. Lymph node recurrences appear more frequently than with external beam radiotherapy, since vaginal vault brachytherapy does not allow for treatment of regional lymph nodes (2.1% vs 5.1% [120]). Adjuvant radiotherapy in high-risk patients is usually performed by a combination of external beam radiotherapy and brachytherapy. Treatment planning for external beam radiotherapy is performed on CT with 3D conformal or intensity modulated radiotherapy techniques. The target volume
Fig. 44.3 CT images of a patient with intermediate-risk endometrial cancer (A) and high-risk endometrial cancer (B) in coronal (A and B) and sagittal (C and D, respectively) view. Note the difference in the treated volume of vaginal vault brachytherapy (C) and external beam radiotherapy by IMRT (D).

should include the complete uterus, parametria, upper vagina and the presacral, obturatrial, common, internal and external iliacal lymph node areas [114]. Dose prescription ranges from 45–50 Gy with 1.8–2 Gy in a single fraction. Brachytherapy follows the same principle as for intermediate-risk patients, but with a reduced dose scheme. In general, 11–15 Gy in 2–3 fractions (HDR) or 25 Gy over two days (PDR) are recommended. Side effects of combined external beam radiotherapy and brachytherapy are similar to primary radiotherapy in cervix cancer. Evidence for adjuvant radiotherapy in high-risk patients is limited, but in selected patients a survival benefit was shown in retrospective series. However, the high rate of distant metastases stresses the need for systemic treatment. Combined radiotherapy and chemotherapy is currently being investigated in prospective trials. First studies in this field demonstrated an increase in progression-free survival if chemotherapy is added (e.g., NSGO 9501/EORTC 55991: 79% vs 72% [124]).

Primary radiotherapy in endometrial cancer

Primary radiotherapy is indicated in inoperable patients or in patients treated in palliative intention. Literature for primary radiotherapy in endometrial cancer is limited. In patients with low-risk factors, brachytherapy can be performed as single modality, whereas in patients with higher-risk factors (G3, large tumour with deep myometrial infiltration) a combination of external beam radiotherapy and brachytherapy should be applied. Standard applicators for brachytherapy are the Heyman packing system or the Norman-Simon applicators. When using these applicator systems, small capsules, which are connected to the afterloader, are placed in the uterine cavity in an operation theatre. In stage I the target volume is the macroscopic tumour and the complete uterine corpus and in stage II the cervix is additionally included. Treatment planning should be preferably based on CT or MRI. The dose is prescribed to the uterine serosa. Typical fraction schedules are 6× 7 Gy (HDR) for brachytherapy as a single modality or 3× 7 Gy in case of a combined approach after 50 Gy external beam radiotherapy. External beam radiotherapy is performed in the same way as for adjuvant treatment. Treatment results are inferior to primarily surgically treated patients. In (clinical) stage IA, IB, and II, 86%, 68%, and 60%, respectively, can be locally controlled. Five-year overall survival ranges from 68–86% in stage I, ~60% in stage II, and 33–41% in stage III [125, 126].

Vaginal cancer

Primary vaginal cancer is a rare tumour site with subsequently only very limited data available. The direct proximity of vaginal cancer to surrounding organs as well as the submucosal tumour spread within the vagina impedes surgical procedures. Radical resections can often be reached only by complete colpectomy and/or pelvic exenteration. In contrast, primary radiotherapy offers the possibility of organ preservation. Therefore, primary radiotherapy in curative intent is the treatment method of choice in the majority of cases. Due to the similarity of cervix cancer and vaginal cancer (histology, pattern of tumour spread, topography, biology) experiences and treatment concepts from cervix cancer were mainly transferred and adapted for vaginal cancer.

Primary radiotherapy

Primary radiotherapy of locally advanced vaginal cancer consists usually of external beam radiotherapy and intravaginal brachytherapy. In limited disease (FIGO Stage 0/I, superficial lesions with ≤5 mm invasion depth) brachytherapy can be performed as single modality. Brachytherapy is performed with a vaginal cylinder or with individually adapted applicators ('mould technique'). Usual dose prescription for brachytherapy only is 40–45 Gy in weekly fractions of 5–8 Gy (HDR) or 50–70 Gy for PDR brachytherapy prescribed in 5 mm depth. The dose may be increased in case of poor response. In advanced disease (≥FIGO II or involvement of regional lymph nodes) external beam radiotherapy allows for downsizing of the initial tumour volume and treatment of the pelvine lymph node areas. Target volume definition and the performance of external beam radiotherapy are similar to cervix cancer radiotherapy with 45–50 Gy in 1.8–2 Gy in a single fraction. In case of tumour involvement of the lower third of the vagina, the inguinal lymph node area should be included in the clinical target volume. Concomitant delivery of chemotherapy (cisplatin 40mg/m^2, 5–6 weekly doses) appears reasonable. After or in the end of external beam radiotherapy (+/– chemotherapy) the residual tumour volume should be treated by intravaginal brachytherapy. If the invasion depth of the residual tumour is ≥5 mm, a combined intravaginal and interstitial brachytherapy should be applied for better dose distribution. Interstitial needles are usually inserted via a perineal template in lithotomy position. It is recommended to apply 3–6 fractions of 5–8 Gy HDR brachytherapy or ~30–40 Gy PDR brachytherapy prescribed in 5mm from the applicator surface or as tumour encompassing reference isodose (in case of >5mm invasion). Due to the proximity to surrounding organs at risk, the larger therapeutic window of PDR schedules may be advantageous in comparison to HDR schedules. Excellent results have been achieved for small tumours (stage 0 + I) with 5-year disease-specific survival ranging from 83–100%. Locally advanced tumours (stage II–IVA), however, still represent a major therapeutic challenge. Local failures are the main site of recurrence. In locally advanced tumours, the 5-year local tumour control rate ranges from 68–84% for stage II, from 40–80% for stage III, and from 0–69% for stage IVA. Five-year overall survival ranges from 77–100%, 45–61%, 14–30%, and 0–18% for stages I, II, III, and IVA, respectively [127–133]. Acute side effects are mainly local inflammation, proctitis, and cystitis. Frequent late side effects are vaginal mucosal atrophy, vaginal shortening, narrowing, and vaginal fibrosis. Severe late side effects such as ulceration, necrosis, vesicovaginal or rectovaginal fistula are less frequent (~10% after five years), but mainly encountered in case of tumour involvement in the respective areas. Recently, in accordance with cervix cancer, image-guided adaptive brachytherapy was described as feasible for treatment of vaginal cancer. First retrospective studies demonstrated a local tumour control rate of >90% for all stages [134].

Adjuvant radiotherapy

Adjuvant radiotherapy in vaginal cancer may be indicated—depending on the localization of the primary tumour—in accordance to the procedures in cervical or vulvar cancer.

Vulvar cancer

Vulvar cancer is a rare disease with only very limited data available. In limited disease (T0, T1, T2) surgery is the therapy of choice, whereas in more advanced tumours individual treatment regimes are necessary with surgery, radiotherapy, and chemotherapy complementing one another. Outcome is highly dependent

on the presence of lymph node metastasis. Inguinal lymph nodes are the first site of metastatic disease. If positive inguinal lymph nodes are detected, pelvic lymph node metastasis can be found in 20–30% [66].

Adjuvant radiotherapy

Adjuvant radiotherapy in vulvar cancer is mainly applied for treatment of regional lymph node areas and is adapted to the type of surgery and histopathologic findings. Adjuvant radiotherapy of the vulva is only indicated in case of positive or close resection margins (<3mm) [68] and if the primary tumour was infiltrating surrounding organs (T3, T4). Adjuvant radiotherapy of the inguinal lymph nodes is indicated (1) after lymph node debulking in c(p)N+ patients, or (2) after bilateral lymph node dissection if two or more lymph nodes were involved or if an extracapsular spread was detected [135], or (3) in cN+ patients if lymph node dissection could not be performed. Elective radiotherapy in cN0 patients without lymph node dissection and adjuvant radiotherapy in patients with one (intranodal) lymph node metastasis after lymph node dissection has to be discussed on an individual basis. Adjuvant radiotherapy of the inguinal lymph nodes may be only unilateral if the primary tumour as well as the suspected microscopic disease was/is strictly unilateral and was >10mm away from the midline. Adjuvant radiotherapy of the pelvic lymph nodes is only indicated in patients with positive inguinal lymph nodes. The role of adjuvant combined radiochemotherapy is currently unclear. Adjuvant radiotherapy is performed by external beam radiotherapy with the use of photon beams or a combination of photon and electron beams after CT-based treatment planning. The prescribed dose is usually 50 Gy with 1.8 Gy per fraction. A local boost up to a dose of at least 60 Gy is recommended in case of macroscopic residual tumour, positive resection margins, or (residual) macroscopic lymph node metastasis. Five-year survival is substantially influenced by the lymph node status and ranges from 25–41% and 70–93% in patients with and without inguinal lymph node metastasis, respectively. Adjuvant radiotherapy significantly reduces inguinal lymph node recurrences (24% vs 5%), significantly improves survival in patients with positive lymph nodes (68% vs 54%) and significantly reduces local recurrences in patients with close or positive resection margins (58% vs 16%) [136–138]. Side effects of adjuvant radiotherapy affect, apart from urogenital and gastrointestinal symptoms, mainly the vulvar and inguinal skin leading to local inflammation and desquamation and requiring local supportive measures. Late side effects of the skin include atrophy, telangiectasia, fibrosis, and pigmentary changes. The combination of lymph node dissection and radiotherapy has an increased risk for chronic lymphoedema.

Primary/neoadjuvant radiotherapy

Primary radiochemotherapy is indicated for locally advanced tumours, if surrounding organs are infiltrated and/or exenteration is necessary for achieving radical resection. In consequence, radiochemotherapy may be used for improving resectability or as single treatment. At first external beam radiotherapy is performed following the same principle as for adjuvant treatment. Primary radiotherapy is usually combined with concomitant chemotherapy. In accordance to the treatment of cervix or anal cancer, cisplatin, 5-FU, or mitomycin C is delivered. Depending on the localization of the primary tumour and the response to external

beam radiotherapy and concomitant chemotherapy, interstitial (+/− intravaginal) brachytherapy should be considered for local dose escalation if surgery is not planned. The application technique has to be individually adapted using, e.g., flexible tubes for superficially located tumours or similar techniques as in vaginal cancer for deeper infiltrating tumours. PDR-schedules are recommended with 0.4–0.6 Gy per pulse up to a total (boost) dose of 14–24 Gy.

After (neoadjuvant) radiochemotherapy, operability can be achieved in 63–92% of the cases. A recent study demonstrated a complete clinical and pathological remission rate of ~50% and ~33%, respectively [139–142]. A Cochrane analysis between radiochemotherapy (primary or neoadjuvant) and primary surgery did not show a significant difference in overall survival or treatment-related side effects [143]. Primary radiochemotherapy with brachytherapy for limited stages achieves comparable results to surgery with 75–100% local tumour control. Side effects are similar to adjuvant radiotherapy and primary radiotherapy of vaginal cancer.

Ovarian cancer

Surgery and adjuvant chemotherapy are the cornerstones in primary treatment of ovarian cancer. Radiotherapy is currently not part of the primary treatment concept in the majority of cases. Historically, whole abdominal irradiation with 25–30 Gy in 1–1.5 Gy per fraction was performed due to the predominantly peritoneal tumour spread but was omitted because of advances in chemotherapy. However, radiotherapy is mainly applied in palliative intent for metastatic disease such as bone or brain metastasis and especially for inoperable isolated pelvic recurrences.

Medical management

Cervical cancer

This entity shows high sensitivity for radiotherapy. Combined radiochemotherapy with weekly 40 mg cisplatin in addition to radiotherapy led to an improved survival and apart from systemic effect chemotherapy is mainly considered as a radiosensitizer in this setting [107].

Neoadjuvant chemotherapy is an option in bulky disease with the aim of shrinkage of advanced disease. Neoadjuvant chemotherapy with dose dense weekly paclitaxel and carboplatin followed by standard combined radiochemotherapy is a feasible approach and is associated with a high response rate (67%) in locally advanced cervical cancer [144]. Another small study with neoadjuvant platinum-taxane based chemotherapy showed a response rate of 78.3% and the surgery completion rate was 78.3% [145].

In case of metastatic disease the combination chemotherapy with cisplatin and topotecan was the standard treatment since the randomized phase III GOG-179 trial cisplatin plus topotecan compared to cisplatin monotherapy showed a significantly prolonged progression-free survival (PFS) (4.6 vs 2.9 months, p = 0.014) and overall survival (OS) (9.4 vs 6.5 months, p = 0.017) [146]. These results led to the approval of the Food and Drug Administration (FDA) in 2006. The GOG-169 compared cisplatin/paclitaxel with cisplatin alone and showed only a significantly increased PFS, but no significant OS prolongation [147]. The ambitious phase III GOG-204 trial compared four different platinum-based doublets containing topotecan, paclitaxel, vinorelbine, and

gemcitabine in advanced cervical cancer. No doublet was superior to cisplatin (50mg/m^2)/paclitaxel (135mg/m^2 over 24 h) in terms of OS. However, the trend in response rates, PFS, and OS favoured cisplatin/paclitaxel [148].

Kitagawa et al. recommended carboplatin/paclitaxel as the new standard treatment for stage IVB or recurrent cervical cancer. OS data showed no inferiority in comparison to cisplatin/paclitaxel, but milder toxicity profiles and quality of life [149].

For further chemotherapy lines, monotherapies with anthracyclines or taxane are recommended. Data of a phase III trial show an improved OS with bevacizumab in recurrent and metastatic disease [150].

Endometrial cancer

Endometrial cancer shows the highest incidence in gynaecologic malignancies. Early stages are most common due to early symptoms. Low-risk early stage endometrial cancer needs surgical treatment only and no adjuvant chemotherapy.

Chemotherapy has evolved into an important modality in high-risk early stage and advanced stage disease and in recurrent endometrial cancer. Multi-institutional trials are in progress to better define optimal adjuvant treatment for subsets of patients [151]. Type II endometrial cancers are very aggressive and behave like ovarian cancer and therefore should get adjuvant platinum/taxane-based chemotherapy.

The most active agents for chemotherapy-naïve patients in endometrial cancer are platinum agents, taxanes, and anthracyclines, all producing response rates of 20–30%. For patients able to tolerate aggressive therapy, multiagent chemotherapy produces higher response rates than single-agent therapy. A phase III study (GOG 209) is currently assessing carboplatin and paclitaxel versus cisplatin. Within a GOG trial in stage III or IV disease eight cycles of doxorubicin and cisplatin were compared to whole abdominal radiotherapy. A significant 5-year survival increase of 13% for patients was present for patients who got chemotherapy relative to the radiotherapy arm [152].

Meta-analysis of nine prospective, randomized trials with 2197 patients showed that adjuvant chemotherapy in high-risk endometrial carcinoma can decrease lethality by 25% [153]. The most favourable benefit/risk profile seems to have carboplatin/paclitaxel, but platinum/anthracycline and platinum/anthracycline/taxane combinations are effective also [154].

Hormonal therapy is standard treatment in metastatic hormonal receptor positive endometrial cancers, but not in the adjuvant setting. Hormonal therapy, primarily with progestins, is less toxic than chemotherapy and 20% response rates are seen in properly selected patients [155]. Tamoxifen shows modest response rates with 10% in phase II trials [156]. Limited phase II data are available for aromatase inhibitors with response rates from 9 to 11% [151].

For women with early stage, low-grade endometrial cancer that involves only endometrium and who declare a wish for fertility-preserving treatment, progestin, usually medroxyprogesterone acetate (100 to 800 mg/d for 4–14 months) is an option, but not a standard treatment with response rates of 57–76%. Control hysteroscopy and curettage is necessary and recommendation of hysterectomy and oophorectomy after childbearing [157].

For endometrial cancer, targeted agents including mammalian target of rapamycin (mTOR) inhibitors, have been discussed.

Promising results of a phase II study of temsirolimus in patients with advanced endometrial cancer are documented. Although no correlation of molecular markers of the PI3K/AKT/mTOR pathway with the clinical outcomes were demonstrated, single-agent activity, especially in chemotherapy-naive patients, with 14% partial response and 69% stable disease was shown [158]. Promising data were documented in a phase II trial with an LHRH agonist treatment in LHRH positive tumours [159].

Vulvar cancer

Vulvar cancer is a rare disease, usually diagnosed in a stage still amenable to potentially curative treatments, including surgery and/or radiotherapy with or without chemotherapy. Prognosis of metastatic or recurrent disease not amenable to salvage surgery or radiotherapy is very poor. Evidence about the efficacy of chemotherapy in this setting is limited and its role still remains unclear. Combined radiochemotherapy with cisplatin can be used in the adjuvant setting as well as in the neoadjuvant setting in locally advanced tumours [66]. At present, patients with advanced vulvar carcinomas and patients with metastatic disease are usually treated with schedules adopted for chemoradiation or extrapolated from cervical cancer [160]. Criteria for the indication and performance of chemo/radiotherapy of the vulva, groins, and pelvis are still not fully established and vary between different countries and institutions due to the low level of evidence. Often an individualized therapeutic approach aside from guidelines is necessary to treat these patients adequately [66]. Most common applicated chemotherapy combination regimens in case of distant metastases are cisplatin/5-FU or a platinum/taxane-based chemotherapy.

Vaginal cancer

Vaginal cancer shows very low incidence and therefore phase III trials are missing. Current guidelines have been drawn on retrospective studies. The role of radiotherapy and concomitant chemotherapy with 5-FU and mitomycin C has shown good results in terms of local control [161]. In case of stage IV disease, the use of concomitant chemo-radiotherapy with agents such as 5-FU, mitomycin C, and cisplatin have shown promising results when combined with radiotherapy with complete response rates as high as 85%, but long-term results of such therapies have been variable [162, 60]. For distant metastases chemotherapy schedules similar to cervical cancer are applicable.

Ovarian cancer

For the past decade standard chemotherapy in advanced ovarian cancer was six cycles of carboplatin (AUC 5-6) and paclitaxel 175 mg/m2 q3w [163]. Adding a third cytotoxic drug failed to improve PFS or OS.

The addition of the monoclonal antibody bevacizumab, that inhibits the vascular endothelial growth factor (VEGF), showed a significantly prolonged PFS in first-line therapy [164, 165]. Burger et al. indicated that the use of bevacizumab up to ten months after carboplatin/paclitaxel prolonged the PFS by about four months and Perren et al. showed within the ICON-7 trial a prolongation of about two months with a maximum benefit at 12 months at the completion of planned bevacizumab treatment. PFS and OS were greater among patients at high risk for disease progression [164]. A phase III trial investigating the duration of bevacizumab treatment is

ongoing (15 vs 30 months). In platinum-sensitive relapse the addition of bevacizumab to gemcitabine and carboplatin (GC) followed by bevacizumab until progression showed a significantly improved PFS of four months compared to GC plus placebo [166]. In platinum-resistant relapse situation a nearly doubling of PFS was present with addition of bevacizumab to non-platinum chemotherapy vs no bevacizumab (6.7 vs 3.4 months; HR 0.48) [167]. These data provide robust evidence for the important role of bevacizumab in ovarian cancer treatment.

Although intraperitoneal chemotherapy extended OS by 12 to 17 months [168], it is an option only for women in advanced ovarian cancer with a small amount residual disease after primary surgery and it is not widely used because of the very high toxicity. Therefore, it is recommended within clinical trials only.

Promising significant increased PFS and OS were presented from the Japanese Gynecologic Oncologic Group concerning dose-dense weekly paclitaxel in combination with carboplatin q3w [169]. Data from European clinical trials of dose-dense regimen with paclitaxel weekly could not confirm a survival benefit in comparison to standard treatment [170].

Neoadjuvant platinum/taxane-based chemotherapy in ovarian cancer is recommended only within clinical trials. Subgroup analysis of the neoadjuvant phase III trial of Vergote et al. documented that patients with primary surgery and macroscopic complete resection showed a significantly improved survival in comparison to all subgroups with neoadjuvant treatment [98]. Despite higher complete resection rates after neoadjuvant treatment, no improved survival was present and the documented extent of surgical management within this trial was very questionable [98]. If neoadjuvant chemotherapy was initiated because of contraindication for immediate radical surgery, interval debulking surgery should be performed after a maximum of two to three cycles because of the development of resistance mechanisms in case of later surgery [171].

About 50% of serous epithelial ovarian cancer might have disruption of the homologous recombination pathway—independently on BRCA-1 or BRCA-2 mutations—and be susceptible to PARP (poly adenosine diphosphate ribose polymerase) inhibitors like olaparib [172]. Maintenance therapy with olaparib significantly improved PFS in platinum-sensitive ovarian cancer relapse, but until now no OS benefit has been shown. A very mild toxicity profile was documented for maintenance therapy with olaparib [172].

The management of the very rare, but very aggressive small-cell carcinomas of the gynaecologic tract (cervix, ovary, uterus, vulva, and vagina) requires systemic chemotherapy with cisplatin and etoposide, both in the setting of early and advanced stage disease [173].

Multidisciplinary management of complex cases

Cervix cancer: Squamous cell carcinoma, FIGO IIIB, T3b, cN1 (CT/MRI), M0. Case report 1

A 45-year-old patient presented at the Department of Gynaecology with dyspareunia, vaginal bleeding, and persisting vaginal discharge for approximately three months. Gynaecologic examination revealed a 6cm × 5cm × 5cm (width, height, thickness) tumour located at the cervix uteri with infiltration of the right vaginal fornix, infiltration of the left proximal parametrium, and infiltration of the right parametrium up to the pelvic wall (see Figure 44.4).

General and surgical management

A biopsy was performed and histology showed invasive squamous cell carcinoma, grade 2. For further staging, FDG-PET CT and pelvic MRI were performed. PET CT showed a uterine cervical mass with an increased SUV uptake (SUV max 21), multiple enlarged pelvic lymph nodes but without any FDG uptake and no distant metastasis. T2-weighted MRI depicted a hyperintensive mass in the cervix uteri with infiltration of both parametria up to the pelvic wall and suspected infiltration of the posterior urinary bladder wall. Cystoscopy showed an intact urinary bladder mucosa and thus did not confirm bladder wall invasion. Stage was consequently FIGO IIIB (TNM: T3b, cN1 (CT/MRI), M0). The patient was presented at the gynaecological multidisciplinary tumour board. Due to advanced tumour stage with pelvic wall involvement and the presence of multiple enlarged lymph nodes without FDG uptake it was decided to perform laparoscopic lymph node staging for the assessment of regional and para-aortic lymph node status and resection of enlarged suspicious nodes followed by primary radiochemotherapy. After laparoscopic lymph node staging, 0 of 23 removed lymph nodes (12 pelvic, 11 para-aortic) showed malignant cells indicating a pN0 status.

Radiotherapy management

The patient was referred to the Department of Radiotherapy for initiation of primary radiochemotherapy consisting of external beam radiotherapy, concomitant chemotherapy, and image-guided adaptive brachytherapy. A CT, performed in supine position with maximum bladder filling, was used for target definition and treatment planning of external beam radiotherapy. The clinical tumour-related target volume included the whole uterus, the upper third of the vagina, the whole parametria and the (regional) lymph node areas up to the aortic bifurcation, internal/external/common iliac areas, para-rectal, and pre-sacral areas. An additional margin of 1 cm in all directions was applied to the clinical target volume (CTV) for defining the planning target volume (PTV) in order to adjust for setup errors and organ movement during EBRT. Contouring of organs at risk included rectum, sigmoid, bowel, urinary bladder. In total, 45 Gy in daily fractions of 1.8 Gy were delivered on working days to the PTV by 3D conformal EBRT using the 'four field-box-technique' within a time period of five weeks. Beginning with the first day of EBRT, cisplatin ($40mg/m^2$) was administered in weekly intervals. The fifth cycle of chemotherapy had to be delivered in reduced dosage due to impaired renal function. During EBRT and chemotherapy the patient developed a moderate increase in urinary and stool frequency (CTCV3.0 G1). In the last week of radiochemotherapy pelvic MRI and gynaecologic examination were re-performed for assessment of tumour regression and for brachytherapy pre-planning and revealed residual disease in the uterine cervix reaching up to the distal third of the right parametrium and the left parametrium and the vagina as tumour-free. Maximum asymmetrical tumour dimensions to the right were 5 cm × 3.5 cm × 4.3 cm. In week six, the first brachytherapy application was performed in an operation theatre under spinal anaesthesia. A tandem ring applicator was placed into the uterine cavity and ten interstitial needles were inserted through the ring (Vienna I/II) into the cervix and the right parametrium
Fig. 44.4 T2-weighted MR images (A, C, E: transversal; B, D, F: sagittal) of a patient with locally advanced cervical cancer staged as FIGO IIIB cN1 treated with primary radiochemotherapy and image-guided adaptive brachytherapy. A, B: At the time of diagnosis: 6.8 × 5.2 × 4.1 cm hyperintensive mass at the uterine cervix with infiltration of both parametria. C, D: At the time of brachytherapy after 45 Gy of external beam radiotherapy and five cycles of chemotherapy: 5.5 × 4.2 × 3.0 cm residual tumour indicating poor response; a tandem ring applicator, and ten interstitial needles were inserted for image-guided adaptive brachytherapy. E, F: Complete remission six months after treatment.

under ultrasound guidance. T2 weighted pelvic MRI was performed with applicator and interstitial needles in place for treatment planning. Adaptive tumour-related CTVs were defined on MRI (high-risk CTV, intermediate-risk CTV) according to the Groupe Européen de Curiethérapie and the European SocieTy for Radiotherapy & Oncology (GEC-ESTRO) recommendations based on the residual tumour mass and the tumour regression pattern during EBRT and chemotherapy. The surrounding organs at risk (rectum, urinary bladder, sigmoid colon, and bowel) were delineated. An individual treatment plan was created allowing for high-dose delivery to the CTVs while simultaneously sparing the organs at risk (OARs). With this treatment plan two fractions of HDR brachytherapy were delivered with a 16 hour break in

between and afterwards the tandem ring applicator and the interstitial needles were removed. In week seven, the brachytherapy application, imaging, and treatment planning were repeated and two further fractions of HDR brachytherapy were applied. In total (EBRT + brachytherapy), an iso-effective dose (2 Gy fractions) of 92Gy (EQD2) was delivered to 90% the high-risk CTV (D90) and 85 Gy, 69 Gy, and 72 Gy (EQD2) to 2 cm³ of the bladder, rectum, and sigmoid, respectively.

Follow-up

The patient achieved complete remission as assessed three months after completion of radiochemotherapy. Local treatment of the vagina with anti-inflammatory solution and vaginal dilation were

recommended and performed. Gynaecologic examination, MRI, and CT were regularly used for follow-up investigations. After 42 months, the patient is in continuous complete remission (MRI) and altogether well. Gynaecologic examination shows no evidence of disease and some vaginal shortening and narrowing in the upper third (G2). The patient reports vaginal dryness (G1) and occasional diarrhoea (G1). Rectosigmoidoscopy shows telangiectasia in the proximal anterior rectal wall but without any sign for bleeding.

Discussion

According to international and institutional guidelines based on clinical level 1 evidence this patient was treated with primary radiochemotherapy. Before initiation of radiochemotherapy laparoscopic lymph node staging was performed. The role of surgical lymph node staging is controversial. However, precise assessment of lymph node status is crucial for the definition of the lymph node target volume (pelvic vs pelvic + para-aortic). Furthermore, in lymph node positive patients, removal of bulky lymph nodes is assumed to be associated with a survival benefit.

Cisplatin-based chemotherapy was added to radiotherapy due to the significant overall survival benefit shown in randomized controlled trials. EBRT was performed as 3D conformal radiotherapy using a 'four-field-box technique' as the large bladder removed most of the bowel out of the treated pelvic region. Recent studies indicate that with the use of intensity-modulated radiotherapy (IMRT) acute gastrointestinal toxicity can be reduced by a reduction of high-dose delivery to significant parts of the bowel volume.

Image-guided adaptive brachytherapy (IGABT) using repetitive MRI is a novel treatment approach, which takes into account individual tumour spread, tumour remission, and changing pelvic topography. First studies on IGABT—including a prospective non-randomized multicentre study—indicate an improved therapeutic ratio compared to standard X-ray ('point A') based brachytherapy. The use of interstitial needles allows for significant dose escalation and increase of target dose coverage, if required by the individual tumour situation (e.g., asymmetrical tumour spread with residual parametrial disease as in this particular case) as shown by dosimetric comparisons. Due to these improvements and the resulting high local tumour control rate (~90–95% after three years) distant metastasis are becoming the predominant type of treatment failure. Patients with FIGO IIIB tumour stage, with and without lymph node metastasis, have a probability of approximately 40–60% to develop distant metastasis within five years of follow-up. Studies investigating the impact of additional adjuvant and/or intensified chemotherapy are currently ongoing.

Endometrium cancer: endometrioid adenocarcinoma G2, pT1b, pN0, pL0; FIGO stage IB. Case report 2

A seventy-one-year-old woman was referred by her gynaecologist because of recurrent vaginal bleeding since three months. The gynaecologist described a distinct endometrial hyperplasia diagnosed by vaginal ultrasound. She has three children and feels otherwise healthy. She has overweight with a body mass index of 37. She suffers from hypertension and type II diabetes mellitus. There are no other comorbidities. She has a sister who had breast cancer at the age of 62 years. There are no other malignant diseases in her close family.

The gynaecologic examination shows slight bleeding from the cervical canal. Vaginal ultrasound reveals a normal sized uterus and the endometrium is hyperplastic with a maximum thickness of 11 mm. Adnexal regions appear normal. The patient was scheduled for hysteroscopy and dilatation and curettage. Hysteroscopy showed a suspicious mass in the uterine cavity (fundus) with a diameter of approximately 2.5 cm. The cervical canal was visualized without suspicious findings and curettage was performed. Endometrial sampling revealed moderately differentiated (G2) endometrioid adenocarcinoma of the uterus. The pretherapeutic workup included a CT scan of the thorax and abdomen, a contrast-enhanced MRI of the pelvis and a referral to our pre-anaesthetic outpatient service regarding the planned surgery. CT of thorax and abdomen showed no signs of tumour spread beyond the uterus. Pelvic and peri-aortic lymph nodes appeared to be normal, MRI showed a myometrial tumour invasion of more than 50%.

Surgical management

Total laparoscopic hysterectomy with bilateral salpingo-oophorectomy with pelvic lymphadenectomy was performed. Frozen section analysis revealed a moderately-differentiated endometrioid adenocarcinoma and a myometrial tumour invasion of the outer half of the myometrium. Pelvic lymph nodes were negative. Because of the deep myometrial tumour invasion, the moderate tumour differentiation, and tumour size, peri-aortic lymph node dissection was performed. The histologic results were confirmed in the paraffin sections and all resected lymph nodes (n = 42) were found negative. Surgical-pathological (TNM) staging revealed a moderately differentiated (G2) endometrioid adenocarcinoma pT1b, pN0, pL0; stage IB according to the 2009 staging system of FIGO.

Adjuvant therapy

Based on clinical-pathological findings adjuvant radiotherapy was recommended. The patient received vaginal brachytherapy at a dose of 4 × 5/7 Gy at 5/0 mm corresponding to a total isoeffective dose of 30–40 Gy (EQD2).

Post-treatment surveillance

The patient was followed in our outpatient clinic with physical examination, vaginal vault cytology, abdominal ultrasound, and monitoring for symptoms. Three years after treatment she is free of disease.

Discussion

Treatment recommendations for endometrial cancer depend upon disease stage and additional factors that influence the risk of disease recurrence. Surgery performed as total hysterectomy with bilateral salpingo-oophorectomy, with or without lymphadenectomy, is usually curative for women who are at a low risk of disease recurrence. In patients with highly and moderately-differentiated endometrioid tumours that are confined to the endometrium or the inner half of the myometrium and a tumour size <2cm the risk of lymph node metastasis is less than 1% and lymphadenectomy is therefore not recommended. In patients with highly- and moderately-differentiated endometrioid tumours and deep myometrial infiltration (FIGO IB) or poorly-differentiated endometrioid tumours with an infiltration of the inner half of the myometrium and a tumour size <2cm the risk of lymph node metastasis is 9.3%. We recommend in these cases pelvic lymphadenectomy and frozen section. If pelvic lymph nodes are positive peri-aortic lymphadenectomy should be done.

In all other cases (FIGO IB G1 or G2 and tumour size >2cm, FIGO IB G3, serous-papillary, clear cell) pelvic and peri-aortic lymphadenectomy is recommended.

Patients who are at intermediate or high risk for disease recurrence are candidates for adjuvant therapy.

Based on clinical-pathological findings such as age (71 years), deep myometrial invasion, moderate tumour differentiation (G2), and large tumour size (>2.5cm) our patient was considered to be at intermediate risk of loco-regional recurrence. Therefore adjuvant brachytherapy was performed. Randomized controlled trials showed that vaginal brachytherapy is an adequate therapy for patients at intermediate risk of recurrence. Vaginal brachytherapy is associated with a more favourable toxicity profile (such as a lower rate of diarrhoea and other bowel symptoms) when compared with external beam radiation, resulting in equivalent loco-regional control rates. In addition, external beam radiation therapy seems to reduce long-term survival of patients less than 60 years of age at the time of treatment because of an increased risk of rectal and bladder malignancies. Patients with endometrial cancer at intermediate risk show five-year survival rates of more than 80% and a reduced risk of loco regional recurrences when vaginal brachytherapy is applied. External beam radiation should only be used in cases with lymph node metastasis or in advanced stage disease. The addition of chemotherapy in these cases should be considered.

Ovarian cancer: serous papillary adenocarcinoma G3, FIGO stage IIIC, T3b, N+, M0. Case report 3

A fifty-eight-year-old patient was referred with increasing abdominal pain and abdominal diameter. She had three children, no cases of malignant disease in her family and had been healthy. She had no obvious bowel dysfunction. She recognized that something did change in her abdomen about six months ago. Because of increasing complaints she saw her general practitioner who sent her to have an abdominal CT scan. The CT scan revealed a bilateral adnexal mass, ascites, and an enlarged omentum. CA 125 was elevated to 1.250 U/ml. Our pretherapeutic workup included a clinical gynaecologic examination, vaginal ultrasound, CT scan of the thorax, and a referral to our pre-anaesthetic outpatient service regarding the planned cyto-reductive surgery. We confirmed the already described lesions highly suspicious for ovarian cancer. The CT thorax showed no signs of tumour spread.

Surgical management

Subsequently the patient underwent explorative laparotomy. We found two litres of ascites, large bilateral adnexal masses, involving the complete pelvic peritoneum, uterus, and recto-sigmoid. Peritoneal carcinosis was present in both para-colic gutters, the right diaphragm, and in parts on the mesenterium of the small bowel. There was a solid tumour infiltration of the ileo-coecal region and an omental cake up to the transverse colon. Because of the good medical condition of the patient the tumour was assumed to be completely resectable. Frozen section revealed a high-grade serous papillary adenocarcinoma of the ovary.

We performed an en bloc resection with a complete pelvic peritoneumectomy and a recto-sigmoidal anastomosis, extensive peritoneumectomy in the described areas of tumour involvement, infra- and supra-colic omentectomy, and an ileo-coecal resection. Because there was no macroscopic intra-abdominal tumour left a systematic pelvic and peri-aortic lymphadenectomy was added. An intraperitoneal port system was placed during primary surgery.

The patient recovered well and the post-operative course was uneventful. The definitive histology described a high-grade serous papillary adenocarcinoma of the ovary in all described tumour locations. Four of 26 peri-aortic lymph nodes were positive, 38 pelvic lymph nodes were negative (FIGO stage IIIC).

Chemotherapy

The patient was given intraperitoneal (ip) chemotherapy with carbo-platinum AUC 6 ip and 175 mg/m^2 paclitaxel iv on day one and 60 mg/m^2 paclitaxel ip on day eight of a three week cycle. The patient underwent six cycles of chemotherapy. Chemotherapy was well tolerated. Pain episodes during intraperitoneal therapy were successfully managed by reducing the intraperitoneal infusion amount to 1500 ml and the prophylactic use of paracetamol. The patient developed peripheral neurotoxicity grade 2 in the last two cycles. No dose reduction or interval extension was required.

Follow-up

The patient was followed in our outpatient clinic. Three years after the termination of first-line chemotherapy CA 125 began to rise. The patient felt well and had no symptoms (performance status ECOG 0). The CA 125 continuously increased from normal levels (<10 U/ml) to 289 U/ml. At that point a PET/CT was performed showing a solitary lesion of approximately 6 cm in diameter adjacent to the descending colon. No other suspect lesions could be detected.

Management of recurrent disease

The patient underwent re-laparotomy and a complete tumour resection with segmental resection of the descending colon. No other malignant lesions could be detected after thorough abdominal inspection. After an uneventful post-operative course the patient received platinum-based re-induction chemotherapy with carboplatin AUC 4 iv on day one and gemcitabine 1000mg/m^2 iv on days one and eight of a three week cycle. Beginning with cycle two we added 15mg/kg of bevacizumab iv every three weeks. The patient is well and still on treatment with bevacizumab and there is no evidence of disease.

Discussion

Complete surgical tumour resection is still one of the most important prognostic factors in the therapy of advanced stage ovarian cancer. In centres capable of performing such complex surgical procedures 60 to 70% of patients with advanced stage disease can be debulked to no residual tumour rest. Neoadjuvant chemotherapy should not replace surgical skills. Complete cytoreduction may provide the patient with a median survival of 50 to 100 months, whereas interval cytoreduction after neoadjuvant chemotherapy is consistently associated with a median survival of only 30 to 36 months even if complete resection is attained in this setting.

In addition to optimal (R0) cytoreduction the application of platinum and taxane based chemotherapy is considered as gold standard in the therapy of advanced epithelial ovarian cancer. The use of intraperitoneal chemotherapy is discussed controversially. However, there are three randomized controlled trials showing an advantage of ip chemotherapy in progression free and overall survival.

Bevacizumab has been shown to be effective in the adjuvant treatment, as well as in the treatment of platinum sensitive and resistant disease. Proof of principle was demonstrated in four randomized controlled trials showing a significant improvement in progression-free survival.

In the management of platinum sensitive recurrent disease secondary cytoreduction is recommended if feasible. On the other hand, there are no RCTs supporting this approach. An international AGO trial (DESKTOP III) compares secondary cytoreduction followed by chemotherapy with chemotherapy alone in platinum-sensitive, recurrent epithelial ovarian cancer. This trial will probably define the role of secondary cytoreduction in this setting.

Penile cancer

Introduction to penile care

Penile cancer is a rare malignancy and the diagnosis is often delayed due to patient embarrassment. Over the last 15 years, penile-preserving surgical techniques have been developed to preserve penile length without compromising local disease control. Despite improvements in the management of local disease, patients presenting with widespread metastatic disease continue to have a poor prognosis due to chemoresistance.

Incidence

Penile cancer is a rare malignancy, which in the UK accounts for <1% of all male malignancies. Cancer registries over a 30-year period from 1979 to 2009 in England have shown a 21% increase in the incidence of penile cancer from 1.10 to 1.33 per 100 000 [1]. This figure is similar to other Western European and North American countries, although in parts of Africa, Asia, and South America penile cancer has been reported to account for up to 20% of all male malignancies [2].

Pathology of penile cancer

The majority of tumours arise on the glans penis (80%) or the foreskin (15%). The vast majority are squamous cell carcinomas (SCC) and account for 95% of the tumours, with the remaining 5% comprising melanomas, sarcomas, and basal cell carcinomas. The SCC subtypes are listed in Table 45.1.

Pre-malignant penile lesions are often difficult to differentiate from benign genital dermatoses and often a biopsy is required in order to differentiate the two as there is a risk of progression to invasive disease if pre-malignant lesions are not diagnosed early. The current tumour-node-metastasis (TNM) staging for penile cancer was revised in 2009 and the grading, traditionally by Broder's system of well, moderate, and poorly-differentiated lesions [3], has recently been altered to adopt grades 1–4 with grade 4 being undifferentiated disease. The current TNM staging for penile cancer can be accessed at the website of the American Cancer Society: <http://www.cancer.org/cancer/penilecancer/detailedguide/penile-cancer-staging>.

Diagnosis of penile cancer

Penile SCC can appear as a nodular, ulcerative, or an erythematous lesion, with advanced cases being clinically obvious (Figure 45.1).

However, there is often a pathological phimosis covering the lesion which itself can only be palpated as a hard mass under the non-retractile foreskin. The diagnosis is confirmed by a penile biopsy and, where possible, additional imaging of the penis using MRI helps to define the extent of invasion of the tumour into the distal corpus cavernosum. Patients should also have their inguinal node status evaluated both clinically and using radiological imaging, most commonly CT. When there are palpable inguinal nodes, the risk of these harbouring metastatic disease is high and either an ultrasound guided fine needle aspiration cytology can be performed or an excisional biopsy of a palpable lymph node can be performed. Confirmation of metastatic disease within the inguinal lymph nodes will mean that the patient requires a radical inguinal lymphadenectomy. In situations where there are clinically impalpable inguinal nodes at presentation, the risk of micrometastatic disease in the inguinal nodes is approximately 20%; therefore, a risk-adapted approach is used to manage these patients in order to avoid overtreatment [4].

Management of the primary penile tumour

Up until the last two decades, the traditional treatment option for penile cancer has involved either a partial or total penectomy in order to ensure a 2 cm tumour-free margin. Although radical surgery undoubtedly provides excellent loco-regional control there is an impact on the urinary and sexual function together with the psychological impact of emasculinization [5]. Radical radiotherapy was previously used as an alternative option but the patient is often left with a disfigured penis, meatal stenosis, and even radionecrosis. Furthermore, local recurrence rates of up to 40% have been reported following radiotherapy and are deemed unacceptable.

Current practice utilizes penile-preserving techniques for distal penile tumours located on the glans penis which allows oncological control coupled with a reduction in the anatomical and functional morbidity. This approach stems from the realization that the requirement of a 2 cm margin is historical and cancer control can still be achieved with smaller margins. [6, 7]. In a further study, the resection margins in patients undergoing penile preserving surgery were reviewed together with the local recurrence rates. In this study, 48% had a surgical clearance of ≤10mm, whilst 90% had a clearance of ≤20mm. Local recurrence rates were reported at only 4%, with a mean follow-up time of 26 months. Furthermore, long-term survival does not appear to be compromised by local recurrence, as most cases are surgically salvageable [8].

Table 45.1 Pathologic subtypes of penile carcinoma

Squamous cell carcinoma	Squamous cell carcinoma, normal type
	Warty (condylomatous) carcinoma
	Verrucous carcinoma
	Papillary, not otherwise specified (NOS) carcinoma
	Basaloid carcinoma
	Sarcomatoid carcinoma
	Adenosquamous carcinoma
	Pseudoglandular (acantholytic, adenoid) carcinoma
	Carcinoma cuniculatum
	Mixed carcinoma
Other malignant epithelial tumours	Clear cell carcinoma
	Extramammary Paget's disease
	Malignant melanoma
Non-epithelial malignant tumours	Soft-tissue sarcomas (Kaposi's sarcoma, leiomyosarcoma, others)
	Malignant lymphoma

The treatment options available depend on the site and extent of disease and are reviewed below in the following section.

Carcinoma in situ and superficial verrucous carcinoma (Tis and Ta)

Topical therapy

Although carcinoma in situ (CIS) is not an invasive malignancy, it accounts for approximately 10% of penile lesions at diagnosis [9]. CIS may arise on the shaft of the penis, eponymously called Bowen's disease, or as one or multiple red, moist patches on the mucosal surfaces of the glans penis or inner prepuce, where it is known as erythroplasia of Queyrat (EQ). CIS can easily be misdiagnosed as a benign skin condition such as candidal balanitis, Zoon's balanitis, or lichen planus. It can also coexist with lichen sclerosus. If left untreated, the observed risk of progression to invasive SCC is 5–33% [10]. Provided that there is no evidence of invasive disease, first-line treatment for CIS uses topical 5% 5-fluorouracil (5-FU) cream. Whilst several regimes exist, the most popular is application

Fig. 45.1 A squamous cell carcinoma of the distal penis.

of 5-FU on alternate days for a four- to six-week period. Small studies (<10 patients) have shown excellent response rates approaching 100% at five years [11]. Patients not responding or relapsing can be offered further topical therapy using 5% imiquimod given in a similar regime. The success of this immune modulating cream has only been described in case reports [12].

Laser therapy

Laser therapy has been used in the treatment for both CIS and low-grade/stage invasive disease. Carbon dioxide (CO_2) and Neodymium:YAG (Nd:YAG) are the most commonly used lasers. A study of 19 patients, where eight were managed with CO_2 laser alone and 11 with both CO_2 and Nd:YAG, two recurrences (11%) were reported [13]. Shirahana and colleagues have demonstrated the importance of case selection for laser treatment [14]. Further studies have also used radiological assessment of the depth of tumour invasion; despite this long-term follow-up, a 48% risk of local recurrence has still been reported [15]. Overall, as with any topical therapy, local recurrences are higher than with conventional surgery and close follow-up is mandatory after treatment. The complications following laser therapy are reported in 1–7% of patients and include bleeding, moderate pain, and preputial lymphoedema [16–18].

Surgery for CIS—total glans resurfacing (TGR)

The use of topical therapy for carcinoma in situ requires well-motivated patients who will be compliant with the treatment regimen and close follow-up. Despite this there are still non-responders to topical treatment. The technique of total glans resurfacing (TGR) offers a surgical alternative for refractory disease or patients with recurrent CIS. Although TGR was initially described for the treatment of lichen sclerosus affecting the glans penis [19], it has recently also been used to manage CIS and stage Ta penile cancer [20]. The technique removes the glans epithelium and subepithelial tissues followed by coverage of the denuded corpus spongiosum using a split thickness skin graft harvested from the thigh. Published series have reported no evidence of disease recurrence at a median follow-up of 30 months (range 7–45) with all patients who were previously sexually active remaining sexually active within 3–5 months of surgery [20]. However, there has also been a report of a 28% positive surgical margin rate requiring further surgery [21].

T1 lesions confined to the prepuce

Circumcision/wide local excision

Circumcision is a common operation in the surgical management of penile cancer and is indicated for primary curative therapy when the tumour is confined to the prepuce [22]. If the lesion is more extensive, then a cuff can be taken from the penile shaft skin or the coronal sulcus as necessary [23, 24]. Recurrence rates of up to 30% have been reported following circumcision [25, 26], the majority of these occurring in the first two years following surgery [27]. Close post-operative surveillance is therefore essential, although if salvage surgery is required the long-term disease-specific survival remains unchanged [23, 28].

T1 lesions involving the glans penis

For these lesions, wide local excision (WLE) and primary closure may be possible if the lesion is discrete and not too close to

the external meatus but recurrence rates of up to 50% have been reported, with most occurring in the first two post-operative years [29]. Recurrent disease can be managed successfully with further surgery in most cases without compromising overall survival [28, 30]. Again, close surveillance is essential for early detection of recurrence.

T2 lesions confined to the glans penis

T2 lesions confined to the glans penis are amenable to glansectomy [31]. The extent of tumour invasion can be assessed with preoperative gadolinium enhanced MRI imaging, with an artificial erection [32]. This is useful in assessing the location of the tumour and whether there is any invasion into the distal corpus cavernosum (Figure 45.2).

Total glansectomy

Total glansectomy (TG) involves the excision of the glans penis from the distal corporal heads. A split thickness skin graft is then used to cover the corporal heads and create a neo-glans (Figure 45.3) [27, 33]. A published series of 72 patients (65 new tumours and seven recurrences post-radiotherapy; 49% T1, 51% T2) undergoing glansectomy and reconstruction, 3 late recurrences (6%) with a mean follow-up of 27 months (range 4–68) have been reported [34].

Partial glansectomy for more proximal tumours has also been reported. The key advantage over total glansectomy is a reduction in spraying during micturition due to the preserved urethra [35, 36].

T2 tumours invading the corpora cavernosa

Distal corporectomy (partial penectomy) and split thickness skin grafting

This more extensive technique is required if there is evidence of corporal involvement either clinically or on MRI or if intraoperative frozen sections of the margins are positive (Figure 45.4). Penile

lengthening manoeuvres can be performed at the same time or at a later date to allow patients to engage in penetrative intercourse and to void standing up [37–39].

Salvage surgery post-radiotherapy

Approximately 40% of patients undergoing radical radiotherapy eventually require salvage surgery for local recurrence [40]. The chronic skin changes associated with radiotherapy make clinical detection of disease recurrence difficult. In a series of 17 patients undergoing post radiotherapy, at a mean follow-up of three years (range 1–6) found that 16 of 17 men were recurrence-free [39].

Management of inguinal lymph nodes

Lymph node metastasis remains the single most important prognostic factor for patients with penile cancer [41]. Over half of patients with SCC have clinically impalpable inguinal nodes at presentation, but up to 20% of these will harbour occult micrometastases (<2 mm) [42]. The currently available imaging modalities remain inaccurate for detecting micrometastases [43].

Although prophylactic bilateral inguinal lymph node dissection (ILND) is associated with high cure rates, the operation still has a morbidity rate of 30–50% and a mortality rate of up to 3% [44]. Moreover, up to 80% of patients will be found to have inguinal nodes without metastatic disease. A recent two-centre review of 342 patients with clinically impalpable inguinal nodes who underwent a sentinel lymph node biopsy (SLNB) concluded that 77% of men in the European Association of Urology (EAU) high-risk group for metastases would have had an unnecessary ILND [45].

Attempts have been made to identify subgroups of patients more likely to benefit from an ILND using predictive nomograms. Stage, grade of differentiation, depth of infiltration, and lymphovascular invasion of the primary tumour are known to be predictive factors for nodal metastasis, but relying solely on these factors still leads to unnecessary surgery [45–48].

Development and use of dynamic sentinel lymph node biopsy in penile cancer

The concept of SLNB involves the identification and subsequent removal of specific lymph nodes where tumour cells will travel to first from the primary tumour. This was first proposed for penile cancer in 1977, where the sentinel lymph node (SLN) was identified wholly on anatomical landmarks [49]. This proved difficult to reproduce and the technique subsequently fell out of favour due to a high false-negative rate [50].

Throughout the 1990s, further developments have improved the detection of the SLN both before and during surgery. This focused on the use of radiolabelled nanocolloids and patent blue dye to aid detection. Excellent results achieved in patients with malignant melanoma and breast cancer have now seen the procedure introduced as routine practice in these conditions [51–53]. This led to renewed interest, particularly in penile cancer and other urological malignancies [54].

The Netherlands Cancer Institute (NKI) has pioneered the use of dynamic lymphoscintigraphy and SLNB in the treatment of penile cancer since 1994 [55]. In this centre over a ten-year period, SLNs were identified in 98% of 123 patients with ≥T2 tumours and clinically impalpable inguinal nodes, and 23% of excised nodes contained metastatic disease. The false-negative rate (FNR) amongst this cohort was initially unsatisfactory (18%) but the addition of preoperative ultrasonography, and more specific immunohistochemical staining and serial sectioning of excised specimens has reduced the FNR to ≈5% [56]. The technique is reproducible, with similar results reported in other centres worldwide [57, 58]. More importantly, improved survival has now been reported for patients undergoing immediate LND for occult lymph node metastases detected by SLN biopsy [59]. The disease-specific three-year survival of patients in this group was 84%, compared to 35% for patients with impalpable nodes following clinical surveillance.

A recent systematic review and meta-analysis of the accuracy of SLNB based on 19 studies found favourable pooled sensitivity (88% with 95% CI 83–92) and detection rates (90.1% with 95% CI 83.6–94.1) [60].

With the emergence of long-term data confirming SLNB safety and benefit in both reducing morbidity from unnecessary LND and improved five-year cancer specific survival, it is clear that SLNB has been a major advance for patients with penile cancer and the incorporation into standard management [58, 61, 62]. Modifications continue with the technique and recently co-localization with a hybrid fluorescent-radioactive tracer, indocyanine Green-99mTc-Nanocolloid has been used [63].

Survival following penile cancer

The majority of research regarding survival from penile cancer comprises of single centre studies with relatively low patient

Fig. 45.4 MRI demonstrating an extensive tumour invading the corpus cavernosum (T2 sagittal). Thin arrow: surface of glans; thick arrow: tumour; arrowhead: tunica of corpus cavernosum.
Image reproduced courtesy of Dr Alex Kirkham.

numbers. However, Verhoeven and co-workers have examined the population-based survival of patients with penile cancer in Europe and the USA using data from registries contributing to the European Network for Indicators on Cancer (EUNICE) Survival Working Group and its American equivalent, the Surveillance, Epidemiology and End Results (SEER) program [64]. This incorporated data from 3297 European and 1820 American penile cancer patients, diagnosed with penile cancer from 1985–2007. In Europe, the overall five-year survival has increased marginally, but not to statistical significance, from 65% to 70% between 1990 and 2007. Within this group, a notable exception was Northern Europe, where an improvement from 63% to 77% was seen within the same time frame. Interestingly, the outlook was worse in the USA, with a statistically significant decrease in five-year survival from 72% to 63% from 1990 to 2007. Furthermore, there was no significant improvement in age-specific survival estimates during the period measured [64]. Further European data from the Surveillance of Rare Cancers in Europe (RARECARE) group, revealed a similar overall five-year survival rate of 69% in patients with penile cancer diagnosed from 1995 until 2002 [65]. Verhoeven's study showed a significant increased risk of mortality with increasing age in patients with penile cancer [64], which is broadly supported by Sant and co-workers who found that five-year survival after the age of 75 years was as low as 35% [66]. The reason behind this is unclear, as although there were insufficient data recorded in the EUNICE registries, there is no evidence for more advanced disease stage in penile cancer patients presenting later in life [64]. This is supported by Graafland and colleagues who carried out a study of 2000 patients diagnosed with penile cancer in the Netherlands between 1989 and 2006, and found that stage distribution did not vary significantly between age groups [67].

The reasons for the overall lack of improvement in survival is a matter for debate, and some authors postulate that it is simply because the impact of newer approaches such as SLNB have not had time to become apparent in the data. This may explain the emergence of more promising data from Northern Europe, as this region was the first to adopt the technique [64]. Other authors argue that the poor outcome data should prompt centralization of the treatment of penile cancer, only taking place in specialized units with a higher patient volume [65, 66].

Human papilloma virus

Several types of human papilloma virus (HPV) have been identified in pre-malignant penile lesions and around 50% of penile cancers express HPV types 16 or 18 [68, 69] with higher grade tumours being more likely to be HPV positive [70]. There are two vaccines available that protect against HPV: a bivalent vaccine that provides protection against HPV 16 and 18, and a quadrivalent vaccine that targets HPV 6, 11, 16, and 18. The latter is approved for preventing HPV-related disease in males [68] and both have been shown to be effective and safe [69]. In the UK, immunization with the bivalent vaccine has been in effect since 2008 for girls aged 12–13 years, with the aim of preventing cervical cancer, but no such scheme is in place for boys.

Marty and co-workers used a computer-based model to examine the incremental benefit of vaccinating boys and girls using the quadrivalent vaccine vs girls-only vaccination, looking for several diseases caused by HPV including penile cancer [68]. They found that vaccination of both girls and boys could reduce the incidence

of penile cancer by 68% based on a figure of 70% coverage, but is unlikely to be cost-effective [69].

If one considers the overall benefits of vaccinating men with regards to preventing other diseases associated with HPV and the increased herd immunity, then an economic case can be made [71]. Indeed, the Advisory Committee on Immunizations Practices from the Centers for Disease Control and Prevention has recently changed its guidelines in favour of immunizing boys and men aged between 13 and 26 in the USA [72].

Chemotherapy

Penile cancers have a limited chemosensitivity. Systemic chemotherapy has been used mainly in the palliative setting, for metastatic and advanced loco-regional disease which is not amenable to surgery. It also has a role in down-staging locally advanced tumours prior to surgery.

Single chemotherapeutic agents in the 1970s were characterized by poor response rates and high levels of toxicity [73]. As a result, combination regimes have been used throughout the 1990s and, from these, cisplatin is a key chemotherapeutic agent in the treatment of SCC of the penis [74]. Taxane-based regimens then became more popular in the 2000s with three agent combinations dominating [75]. These included Dexeus' group's regimen consisting of cisplatin, methotrexate, and bleomycin [76]. Their initial study reported promising results with only moderate side effects, but with wider adoption of this protocol, poorer results and more severe side effects were seen [76]. More recent combination regimens comprising differing combinations of cisplatin, 5-FU, and paclitaxel have shown promise in the neoadjuvant treatment of penile cancer [77, 78].

Adjuvant and neoadjuvant treatment

The EAU guidelines recommend adjuvant chemotherapy for N2-3 disease. This is based on a study of 25 patients that revealed an 84% long-term disease-free survival rate [62].

In patients with palpable inguinal lymph nodes, neoadjuvant chemotherapy appears promising. In 2007, Lietje and colleagues showed that 12 out of 19 patients receiving five different neoadjuvant chemotherapy regimens showed a response, with eight achieving long-term disease-free survival after subsequent surgery [79].

Two further studies published in 2007 and 2010 reported up to a 50% response using paclitaxel, cisplatin and ifosfamide [77, 78]. The EAU guidelines therefore recommend neoadjuvant chemotherapy followed by lymph node dissection in patients with fixed or relapsed lymph node metastases [62].

Molecular biology of penile cancer and potential targeted therapy

Epidermal growth factor receptor

The cell-surface receptor epidermal growth factor receptor (EGFR) is involved in a key pathway that controls intracellular signalling [80]. Several types of ligands bind to this receptor to activate intracellular pathways that regulate processes such as cell proliferation, differentiation and apoptosis [81, 82]. This has been shown to be associated with uncontrolled cell division and proliferation of tumours by angiogenesis as well as protecting tumour cell from undergoing apoptosis.

Lavens and colleagues showed overexpression of EGFR in 17 patients diagnosed with penile SCC [81], and Di Lorenzo and

co-workers found similar results in 30 patients, but were unable to identify specific mutations known to cause other tumours associated with EGFR over-expression [83]. A more recent study has demonstrated that the presence of cytosolic phosphorylated EGFR (p-EGFR) predicted recurrence and survival [84]. They therefore put the case forward for the use of p-EGFR status in informing the need for adjuvant therapy in patients with N0 and N1 disease.

Other mutations

Gou examined the expression of EGFR and RAS-association domain family 1A (RASSF1A) as well as mutation status of K-RAS and BRAF in 150 patients with penile SCC [85]. Once again, EGFR overexpression was found in all cases but only 3.42% expressed RASSF1A, one patient displayed the KRAS mutation and none expressed the BRAF mutation. This conflicts somewhat with a series of 28 cases from Spain where KRAS mutations were found in 22% of tumours [86]. Andersson also reported mutations in PIK3CA, HRAS and KRAS [87]. Stankiewicz and colleagues found HER-3 and -4 protein overexpression in penile SCC. Further analysis of their data revealed that HPV positive tumours were more associated with HER-2 expression and less associated with p-EGFR overexpression [88]. Additional work by this group showed HPV positivity was also associated with p16 and p21 expression and RB suppression in a series of 148 patients [89].

With regard to P53 mutations, some studies report an association with lymph node metastasis and poor survival, but others do not [90, 91]. Interestingly Golijanin and co-workers found that cyclooxygenase-2 (COX-2) and prostaglandin-E synthase 1 are highly expressed in dysplasia, penile intraepithelial neoplasia, and carcinoma [92]. This suggests a mechanism for inflammation in the pathogenesis of penile SCC as well raising the possibility of a therapeutic role for COX-2 inhibitors.

Targeted therapy

Given the key role that EGFR appears to play, several studies have examined the use of the monoclonal antibodies panitumumab and cetuximab in penile cancer. Carthorn and colleagues administered monoclonal antibodies together with differing combinations of platinum-based regimens to 13 patients with advanced penile SCC [93]. Median time to progression was 3.4 months and overall survival was 9.8 months, although four patients survived longer which compared favourably to results from chemotherapy [94].

Tyrosine kinase inhibitors may have an important role in targeting angiogenesis in penile SCC. Zhu and colleagues studied the effects of sorafenib and sunitinib on angiogenesis in six patients with penile SCC refractory to chemotherapy treatment [95]. One patient responded partially and four had stable disease; however, one patient died of sepsis and another suffered a ruptured femoral vein.

Conclusions

The last two decades has seen major advances for men diagnosed with penile cancer. Penile preserving techniques provide a surgical option with preservation of sexual and voiding function. The advent of SLNB has proved to be a safe and reproducible option for men with impalpable inguinal nodes. Furthermore, centralization of penile cancer patients to centres of excellence in both the UK and several European countries has allowed for greater experience to be gained by a few and improved research collaboration to take place.

Future challenges to improve survival and reduce morbidity from penile cancer will involve public and medical practitioner education and awareness of the disease. The introduction of a HPV vaccination in boys and girls may also have a beneficial effect on the disease incidence in the future.

Germ cell tumours

Most testicular cancers that arise are germ cell tumours; more rarely, other tumours may be found including lymphomas in more elderly patients (>60 years) and various sarcomas in the adolescent age group. The management of these will not be covered here. Germ cell tumours of the testis are the commonest malignant tumours of young adult males mostly occurring between the ages of 20–40. For therapeutic purposes they are split in to two groups—seminomas (SGCT) and non-seminomas (NSGCT). NSGCT comprise a large number of histological subtypes, such as embryonal carcinoma and choriocarcinoma. Overall, SGCT are slower growing and less likely to metastasize; they are also more susceptible to chemotherapy and radiotherapy. The management of metastatic germ cell tumours is often multidisciplinary and successful outcome may require more than one modality of therapy. Histological analysis is frequently complex particularly when looking at post-chemotherapy specimens and correct interpretation often requires an expert urological pathologist. Germ cell tumours overall have an excellent prognosis. Avoidance of overtreatment with the consequence of long-term side effects is important for the majority of patients currently predicted to have good prognosis.

Presentation

The most common presentation is that of a lump in the testis. This may be painful or painless; it may have grown rapidly (over a few days) or may have been present for many months. Any lump should be presumed to be malignant until proven otherwise. Sometimes patients will present with symptoms due to metastatic disease, with a tumour that may be detected in the testis but sometimes it will not be palpable. Examples of symptoms include the development of back pain due to para-aortic lymph node enlargement, cough, shortness of breath, or haemoptysis due to pulmonary metastases. Patients may rarely present with seizures, gynaecomastia, or infertility.

Diagnosis

The most usual way a diagnosis is made is from biopsy material, most commonly at orchiectomy. A proportion of these tumours produce tumour markers; they can be used alone to make a diagnosis in an emergency where they are elevated and no other cause exists. This can be very important in patients who are acutely ill as it allows the quick initiation of chemotherapy. Germ cell tumours produce hCG (chorionic gonadotropin), AFP (alphafetoprotein), and the non-specific marker LDH (lactate dehydrogenase). An elevated hCG may be detected rapidly by performing a pregnancy test [96].

Staging

The initial staging investigation will often be a testicular ultrasound—this will confirm the presence of a tumour. Both testes should be scanned as bilateral tumours do occur and small testes are more prone to be associated with infertility. The presence of

microcalcification in a small contralateral testis may be an indication for a testicular biopsy [97].

It is often useful to scan the abdomen urgently at this point as it may reveal a large retroperitoneal mass with evidence of ureteric obstruction. In the absence of this or large volume pulmonary metastases seen on chest radiograph the next step is usually a radical inguinal orchiectomy. If time permits, preoperative sperm storage should be offered. Formal staging using CT should then be carried out of the chest, abdomen, and pelvis. Tumour markers should be measured both pre- and post-operatively. Staging using the TNM classification should be carried out and patients are placed into one of three prognostic groups. The prognostic group depends on the level of the markers and the sites of metastases. The outcome becomes less favourable as markers rise and documentation of adverse metastatic sites, placing patients in a poor prognosis group. The current International Germ Cell Consensus Classification (IGCCCG) categories recognize three prognostic groups [98]. Treatment and outcome is dependent on these groups.

If patients have low levels of tumour markers and no non-pulmonary visceral metastases (e.g., brain, bone, and liver) they belong to the good group with a five-year survival of 92%. These patients are treated with fewer cycles of combination chemotherapy than patients with more aggressive disease.

Patients with higher tumour markers but still no non-pulmonary visceral metastases fall into the intermediate group with a five-year survival of 75–80%. Those patients with either very high tumour markers or the presence of non-pulmonary visceral metastases fall into the poor prognosis group with a five-year survival as low as 47%. This data is now over 15 years old and newer data suggests that the outcome for this group is more favourable being in the region of 60%. SGCT are never classed as poor prognosis, instead only the presence of non-pulmonary visceral metastases can place them outside the good group in to the intermediate group (the level of tumour markers is not important). Patients who have symptoms suggesting central nervous system involvement or have very high tumour markers should have a magnetic resonance brain scan.

Treatment

For information on treatment please see Table 45.2.

Stage 1 seminoma germ cell tumour

This is disease confined to the testis. The outcome of patients with stage 1 disease is excellent with a survival of around 99%.

In all cases it is possible either to observe patients (surveillance) and only offer treatment on relapse or alternatively to offer adjuvant therapy (carboplatin AUC 7 X1 or radiotherapy to the para-aortic strip) which will reduce the relapse rate after orchiectomy, allowing a less intensive schedule of visits for blood tests and scans without an adverse affect on overall survival. Many now consider surveillance the preferable option [99]. The risk of recurrence after orchiectomy alone for patients with seminoma is between 11–30% [100]. Two risk factors have been identified: rete testis invasion and maximum tumour diameter of >40mm. If only one risk factor is present the recurrence rate is 18%. Following adjuvant therapy this falls to 4%. If adjuvant therapy is offered it is normally in the form of one cycle of carboplatin with dosing based on Calvert's formula. The dose depends on glomerular filtration and the optimal way of determining it is to perform an EDTA clearance; a single dose of carboplatin AUC7 will also reduce the risk of a contralateral tumour from 2–0.5% [101]. Radiotherapy is an alternative option although not widely given in Europe. In a randomized trial radiotherapy and single-agent carboplatin had a similar outcome. The long-term side effects of both radiotherapy and chemotherapy are undesirable and unquantified in this setting. There is also a lack of data on the optimal follow-up for surveillance. The majority of relapses occur in the first three years [102].

Stage 1 non-seminoma germ cell tumour

As with SGCT, surveillance is attractive in this disease, although adjuvant chemotherapy may be considered in patients with a high risk of relapse. The main risk factor for relapse is the presence of vascular invasion by the tumour or histology. If present the risk of recurrence is between 40–50%. The presence of embryonal carcinoma also raises the risk of recurrence to 25% otherwise it stands between 15–20% [103]. With adjuvant therapy the risk falls to around 4%. The use of one cycle of cisplatin, etoposide, and bleomycin (BEP) has been found to be effective in this situation [104]. The side effects of this therapy include nausea, vomiting, hearing damage, hair loss, ototoxicity, nephrotoxicity, and pulmonary toxicity. Whether long-term side effects may develop after only one cycle of therapy is currently unknown. One potential advantage of offering adjuvant therapy is the avoidance of potentially disruptive retroperitoneal surgery to remove residual nodes present post therapy for metastatic disease.

Table 45.2 Summary of management of patients with testis cancer after orchidectomy

	Stage I	Metastatic*		
IGCCCG risk	NA	Good	Intermediate	Poor
SGCT	Surveillance is preferable. Other options include carboplatin or RT	BEP (X3) combination chemotherapy	BEP (X4) combination chemotherapy	NA
NSGCT	Surveillance is preferable. Other options include BEP (x1)	BEP (X3) combination chemotherapy	BEP (X4) combination chemotherapy	BEP (X4) combination chemotherapy Consider other regimens

* Patients may require emergency chemotherapy prior to orchidectomy.

BEP, bleomycin, etoposide and cisplatin; SGCT, seminoma germ cell tumor; NSGCT, non-seminoma germ call tumor.

Management of metastatic disease

Metastatic disease is frequently managed with BEP chemotherapy. For patients with good prognosis disease three cycles is sufficient [105]. It is known that suboptimal dosing or drug reductions leads to inferior outcomes. The side effects have been described. The risk of infertility is less than 10% if the patient is already fertile. If the patient is infertile due to pre-existing testicular dysfunction or due to hormone imbalance secondary to the tumour then fertility may still recover following chemotherapy. Long-term side effects, namely hypertension and cardiovascular events, occur with an increased risk over time [106].

The risk of bleomycin-induced pneumonitis is low, but careful attention should be paid to patients developing respiratory symptoms. If bleomycin is contraindicated, e.g., because of poor existing lung function, then four cycles of cisplatin and etoposide may be considered [107]. Alternative treatments such as radiotherapy or single-agent carboplatin are given by some institution to patients SGCT with low-risk disease.

Patients who fall into the IGCCCG intermediate or poor prognostic groups are normally managed with four cycles of BEP. If bleomycin is contraindicated then ifosfamide may be substituted (VIP) [108]. Alternative regimens to standard BEP or VIP have not internationally established themselves in this setting. Particularly, high-dose therapy does not appear to have a role here (perhaps with the rare exception of mediastinal GCT). However, it may be possible to give one cycle of BEP and then depending on tumour marker decline reserve an intensive schedule for those whose response is unfavourable. This approach appears to be beneficial for these patients [109].

The role of surgery in GCTs

Following completion of chemotherapy patients may be left with residual masses on CT. If the markers have normalized this is not an indication for further chemotherapy but it is standard to consider surgical resection of residual masses (>3cm for SGCT and 1 cm for NSGCT [102]). The retroperitoneal lymph nodes are often removed first. The histology can be a guide as to what is likely to be found in other masses. The outcome is usually necrosis, viable cancer or mature teratoma. Mature teratoma has the propensity to de-differentiate many years later and is an indication for removal of other sites of disease. The presence of viable cancer indicates a higher risk of subsequent relapse although many patients who have less than 10% involvement are likely to remain disease free.

Managing relapse after chemotherapy

Patients may fail to enter remission (defined as normalization of tumour markers) or alternatively have rises in markers and/or develop new sites of disease following initial remission with chemotherapy. These patients can then be offered further therapy which may be curative. The chance of cure depends on the duration of the response to first-line therapy, tumour markers and the sites of subsequent relapse. Overall, between 25–60% may be cured with further therapy [110]. There is controversy regarding the use of high-dose therapy or conventional dose therapy in this setting. Standard conventional dose regimens include cisplatin and etoposide with either ifosfamide or paclitaxel [111, 112]. The most widely used high-dose therapy consists of high dose carboplatin and etoposide, although a paclitaxel-containing regimen also has

impressive data (TI-CE) [113, 114]. The mortality from high-dose chemotherapy ranges from 5–15%, with the risks being lower in patients who are fit and for whom the procedure is performed at first relapse.

Conclusion—germ cell tumours

Germ cell tumours form a curable group of metastatic cancers. The optimal use of currently available cytotoxic agents with appropriate surgery has led to an improving cure rate. The greater awareness of long-term side effects is likely to lead to attempts to reduce chemotherapy burden, particularly in patients who have low volume metastatic disease. To date the incorporation of targeted agents has failed to produce encouraging responses in this patient group.

Prostate cancer

Introduction to prostate cancer

Prostate cancer is the third most common neoplasm in men and second as far as cause of cancer death is concerned [115, 116]. In 2012, it was estimated that 92 247 men died in Europe from prostate cancer.

There were 399 964 new cases of prostate cancer in Europe in 2012 diagnosed mainly based on biopsy, which constituted 11.9% of total number of new cancer cases [116]. According to the American Cancer Society, approximately one million prostate biopsies are performed annually in the USA with an estimated 220 800 men diagnosed with prostate cancer in 2015, accounting for 26% of all male cancers.

Since there is a high incidence of prostate cancer in the Western world, screening has been proposed in order to reduce the mortality from prostate cancer death. Several screening studies have been executed in the last years in different parts of the world, but the most reliable data can be extracted from the European Randomized Screening Study for Prostate Cancer (ERSPC) [117, 118]. The most recent update with a median follow-up of 11 years demonstrated a relative reduction in prostate cancer death risk of 21% in the screened arm. However, still some questions have to be answered before a population-based screening programme can be introduced, e.g., influence on all-cause mortality, diagnosis of insignificant disease, impact on quality of life, and costs [119, 120]. Because of these uncertainties, the US preventive task services force advised against active screening and in most of the countries it is not advised to start population-based screening programmes, but asymptomatic patients who are well informed about the risks and benefits can be offered further investigations to detect or exclude the presence of prostate cancer [121].

Diagnosis

Medical history and symptoms

Age is one of the most important risk factors for prostate cancer and this is one of the reasons for the expected rising incidence for prostate cancer in the coming years. A second risk factor is a positive family history for prostate and breast cancer. This could be because of a higher awareness amongst family members, but also because DNA variants are being detected which increase the risk of prostate cancer development. Hopefully, this DNA research can identify high-risk groups of prostate cancer patients that need

treatment [122]. There are no specific symptoms that are specific for the presence of prostate cancer. Only at a late stage, symptoms can be present when there is a large prostate cancer volume, e.g., voiding symptoms (irritative or obstructive), or obstruction of the ureter(s) resulting in hydronephrosis and/or uraemia, or when metastases are present, e.g., bone pain. In the majority of cases an elevated PSA (>3 ng/mL) is nowadays the reason for further investigations.

Digital rectal examination

The first step in the workup for prostate cancer is a digital rectal examination (DRE) although the positive predictive value is very low (33–83% in a screening population with a PSA ≥3 ng/mL) [123]. The reason to perform a DRE in a non-screening situation is the chance that high grade tumours can be missed if PSA is not elevated and it is also part of the TNM staging [124].

Prostate specific antigen and others

Prostate specific antigen (PSA) is a protein that is mainly produced by the prostate and as such *prostate tissue specific*, but not *prostate cancer specific*. Its function is to liquefy the semen, but due to disruption of the glandular structures in the prostate (e.g., prostatitis, biopsy), the serum level can be elevated. Also due to a prostatic enlargement the serum level can be increased. Because of these factors the specificity and sensitivity of an elevated PSA (>3 ng/mL) are rather low and only approximately 30% of patients with a PSA level between 3 and 10 ng/mL will show positive biopsies. Several methods have been explored to increase the sensitivity of PSA, e.g., PSA density (PSA level related to prostate volume), PSA velocity (increase of PSA over time), and looking at PSA isoforms, e.g., free PSA, complex PSA, pro PSA, PSA health index [125]. However, in the majority of cases the level of total PSA still determines the indication for further investigations. A relative new laboratory investigation is the PCA3 urinary test, which is a prostate cancer specific gene, which is over-expressed in 95% of prostate cancer cells, with a median 66-fold up-regulation compared to adjacent noncancerous prostate cells [126]. This urinary test is increasing the chance of finding a positive biopsy in case of an elevated PSA, but the test is now only approved in case of a first negative biopsy [127, 128]. The relation of PCA3 level and tumour aggressiveness has resulted in contradictory results and thus cannot be used to determine which patients with low volume disease need treatment or not [129].

Imaging

In case an elevated PSA or an abnormal DRE is found, the first imaging modality is a transrectal ultrasonography (TRUS) of the prostate. Again, the sensitivity and specificity of TRUS alone to demonstrate or exclude the presence of a malignancy is insufficient and nowadays TRUS is only used to aid guiding the biopsies of the prostate. Improvements in TRUS performance are sought by adding ultrasound contrast agents, looking at elastic properties of the prostate tissue (elastography) and using computer techniques to determine tissue characteristics (e.g., HistoScanning™) [130–132]. Multiparametric (mp)-MRI is one of the promising imaging modalities for prostate cancer detection; however, whether it can be applied for the determination to perform initial prostate biopsies in case of a suspicion of prostate cancer remains to be established. But if biopsies are negative there is a role for mp-MRI once the suspicion for prostate cancer remains [133, 134].

In case of a high suspicion for metastatic disease (PSA ≥20 ng/mL, locally advanced disease, Gleason score ≥8) bone scintigraphy is still the standard to exclude osteoblastic bone lesions. Axial skeletal MRI could replace bone scan in the future whereas the role of FDG-PET scan has not been established yet [135–137]. The precise identification of lymph node metastases is still a problem, because none of the imaging modalities are accurate to demonstrate or exclude positive nodes. The use of lymph node-specific contrast agents in combination with MRI improve the sensitivity, but this agent is not available in clinical practice [138, 139].

Biopsy and pathology

Once there is an indication for excluding or demonstrating the presence of a prostate cancer transrectal ultrasound-guided biopsies are performed. Since most of the tumours are not visible by TRUS, so-called random biopsies are taken, with the inherent risk of sampling error. Most of the tumours are located in the peripheral zone of the prostate and for this reason the biopsies are initially directed to this area of the prostate and in total a ten to twelve biopsies are obtained, but this depends also on the volume of the prostate [140]. In case the biopsies are found to be negative for prostate cancer and there remains a suspicion for the presence of prostate cancer, re-biopsies can be taken, because there is still a chance of between 20 to 35% that in these repeat biopsies prostate cancer can be detected [141]. Alternative strategies nowadays are the PCA3 test or mp-MRI investigations to determine the risk on finding cancer in a repeat biopsy session.

Before taking transrectal prostate biopsies a urinary tract infection should be excluded, the patient should receive prophylactic antibiotics and anticoagulation treatment should be interrupted. The complications of this diagnostic procedure are transient haematuria, haematospermia, rectal bleeding, urinary retention, and sepsis.

The biopsy specimens are sent in individual containers or in two containers (left and right) for histologic evaluation. The pathologist has to report the presence of an adenocarcinoma of the prostate and the Gleason grading [142]. The Gleason grading system is based on histological architectural patterns, e.g., tubular differentiation and pattern of stromal invasion [143]. Two dominant growth patterns determine the Gleason sum score (2 to 10) and the most dominant pattern is mentioned first, e.g., 3 + 4 or 4 + 3. Furthermore, the number of cores involved with prostate cancer and the percentage of tumour per core should be reported, because these have prognostic relevance [144].

Risk groups

Based on the diagnostic workup the risk group for the individual patient can be determined using DRE, PSA, and biopsy results. Several risk group determinations have been proposed; a commonly used one is that of the ESTRO/EAU/EORTC, as shown in Table 45.3 [145].

Based on the risk group classification the different treatment modalities are discussed with the patient.

Treatment

Low-risk localized prostate cancer

Since PSA is nowadays the main driving factor for the detection of prostate cancer, a great number of patients are diagnosed with low-risk, low-volume disease. It was shown in the screening studies

Table 45.3 Risk groups in prostate cancer

Low risk	T1c–T2a, Gleason score <7, iPSA <10 ng/mL
Intermediate risk	T2b–c, or Gleason score 7, or iPSA 10–20 ng/mL (in case of two factors high-risk)
High risk	T3, or Gleason score >7, or iPSA >20 ng/mL (one or more factors)

that these patients probably did not need active treatment in the majority of cases. The risk of dying from prostate cancer in this group of patients seems to be the same as for patients without detected prostate cancer in the same age group [146]. Recently, a randomized study comparing radical prostatectomy and observation did not show a benefit for the surgically treated low-risk patients [147]. These observations have led to the so-called active surveillance option for patients with low-risk prostate cancer, meaning that no immediate active treatment is offered to the patient, but observation and in case of demonstrated progression based on PSA or follow-up biopsies a treatment with curative intent is started [148]. This approach does not seem to have a negative impact on cancer-specific survival.

Intermediate-risk and high-risk localized prostate cancer

In these cases usually an active treatment is indicated unless the patient has such comorbidities that an active treatment for his prostate cancer will not be of benefit. In this case, a watchful waiting protocol can be discussed, meaning that palliative treatment will be started once symptoms occur. The treatment options are radical prostatectomy (open, laparoscopically, or robot-assisted laparoscopically) or radiotherapy (external beam or brachytherapy). Unfortunately, no randomized studies comparing these different treatment options have been performed. This means that patient preference is an important decisive factor based on the anticipated side effects that can occur with these treatments.

The results for radical prostatectomy seem not to differ between the three approaches once a sufficient number of surgical procedures are being done. Especially in the high-risk group an extended lymph node dissection is combined with the radical prostatectomy. The outcome is usually excellent with recurrence-free survival rates in the order of 75% [149]. Side effects of the surgical approach are erectile dysfunction and urinary incontinence. The incidence of these side effects depends on the extent of surgery (nerve-sparing or not), age of the patient, and pre-operative complaints, but erectile dysfunction is reported in the literature in the range of 13 to 78% and urinary incontinence in the range of 2 to 40% [150]. Nowadays, standard external beam radiotherapy uses dosage of 78 to 80 Gy given in a six- to eight-week period; for this, advanced radiation techniques are necessary, e.g., intensity modulated radiotherapy (IMRT) or image-guided radiotherapy. Using these techniques improved outcome has been reported for all risk groups [151, 152]. Side effects of external beam radiotherapy are erectile dysfunction (8–85%), voiding symptoms (2–6%), and bowel problems, e.g. blood, diarrhoea, soiling (15–30%) [153, 154]. In case of a high-risk tumour hormonal therapy is usually advised with radiotherapy.

Brachytherapy may be indicated in low-risk and intermediate-risk patients, but patients should not have voiding problems and the prostate volume should be <60 cc. The 10-year disease-free survival for low- and intermediate-risk prostate cancer ranges from 80–97% and 72–94%, respectively [155, 156]. Side effects of brachytherapy are erectile dysfunction (14–61%), urinary incontinence and retention (2–32%) [153, 154].

Experimental treatments

Several local thermal local treatments for localized prostate cancer have been explored over the past years. Cryosurgery aims to freeze the prostate introducing needles transperineally into the prostate. No randomized studies have been reported with this approach; progression-free survival rates of 36–92% have been reported, with a wide range demonstrating that patients with different disease characteristics have been treated [157]. This treatment should still be considered as an investigational approach.

High intensity focused ultrasound (HIFU) uses a transrectal approach where the ultrasound transducer emits focused ultrasound waves that generate heat and the tissue is destroyed by coagulative necrosis. No well-designed clinical trials have been reported, but progression-free survival has been published in the range of 63–87% [158]. The technique has improved over the years and seems to lead to improved outcome data, but evaluation parameters are different (PSA, biopsies) among the published studies [159, 160]. In case a small tumour is found, in the majority of cases not the whole organ is removed (cf. renal tumour, breast cancer) and this has led to the concept of focal therapy for prostate cancer. The prerequisite is that the dominant tumour can be identified with certainty and there is an effective treatment to focally treat the tumour. At present the use of laser alone or in combination with a sensitizer (TOOKAD), and irreversible electroporation (IRE) is being studied [161–163]. Imaging is improving and with mp-MRI there might be a modality to identify the aggressive lesion within the prostate and by using brachytherapy, cryotherapy, laser, and electroporation effective methods are now available to kill the tumour [164]. However, this concept has yet to be proven in prospective studies [165].

Locally advanced disease

Once there is evidence that the tumour has perforated the prostate capsule (T3a) or invaded the seminal vesicles (T3b) a metastatic workup is essential to exclude metastatic lesions. In case the patient is not a candidate for local treatment, watchful waiting should be discussed in case the PSA level is not too high (<50 ng/mL) and/or a PSA doubling time is longer than 12 months. It has been demonstrated that the risk of dying from prostate cancer was not worse if hormonal treatment was started at the time of symptomatic progression [166, 167].

Most studies have been performed using radiotherapy in this situation and it has been shown that the combination of radiotherapy plus hormonal therapy (at least two years) resulted in an improved overall survival (34–58% after 10 years) [168–170].

No prospective studies have been performed that evaluate radical prostatectomy in T3 disease. In patients with a 'small' T3 tumour, surgery is an option in combination with an extended lymph node dissection, because it was shown that pathological downstaging (pT2) is present in approximately 30% of cases. Surgery is, however, usually one step in the multimodal approach for this category of patients. If extensive capsular penetration is demonstrated on

pathological examination the addition of adjuvant radiotherapy has shown to improve biochemical progression-free survival (74% versus 52.6% if no adjuvant therapy was given) [171]. The question at this moment is if all patients should receive immediate adjuvant radiotherapy if pT3 disease has been demonstrated or that early salvage radiotherapy should be given once a biochemical recurrence (PSA >0.2 ng/mL) has been shown, since this seems to give the same results [172].

Metastatic disease

Bone metastases are the most common metastatic sites and these are usually osteoblastic. In this case no curative options are available and palliative treatment can be offered. Nowadays, only a minority of patients present with symptomatic metastatic disease (bone pain, neurological symptoms). The common treatment is the induction of androgen deprivation, since androgens are the driving force in prostate cancer [173, 174]. Androgens are produced in the testes and the adrenals. Several approaches can lower the androgen serum levels (e.g., orchiectomy, GnRH analogues, LHRH antagonist, anti-androgens, oestrogens), and these approaches can induce palliation in the majority of patients, but there is no hard evidence that they leads to a longer survival.

If hormonal therapy is indicated, GnRH analogues are combined with an anti-androgen treatment in the first four weeks to prevent a flare reaction (initial rise of testosterone), especially in extensive metastatic disease. Since this can lead to serious complications (spinal cord lesion, hydronephrosis), this flare prevention is not necessary with orchiectomy or LHRH antagonists that induce an immediate testosterone decline. Combined androgen deprivation (blocking testosterone produced in the testes and adrenals) has been shown not to be of benefit [174]. Because of the lower testosterone levels several side effects can be expected, which can have a clear impact on the quality of life (erectile dysfunction, hot flashes, increase in weight, depression). It has been demonstrated that continuous lowered testosterone levels also influence the bone mineral density (osteopenia) and induce the metabolic syndrome (insulin intolerance, change in lipid profiles). Because of these side effects the timing of hormonal therapy and the scheme of hormonal therapy should be discussed with the patient. There is also a renewed interest in oestrogen therapy for prostate cancer, because this treatment has beneficial effects compared to the other treatments discussed, e.g., no effect on bone loss and preserves cognitive function. The negative effects of oestrogens (thromboembolic events) are absent if the oestrogens are given parenteral or transdermal [175, 176].

It is clear that symptomatic metastatic patients need immediate hormonal therapy, but in asymptomatic patients delay of start treatment should be discussed since this palliative treatment does induce side effects with a clear impact on the quality of life and some deleterious effects. Another approach is intermittent androgen deprivation treatment, where the start and stop of hormonal therapy is based on PSA levels, although different schedules are being used. Reported randomized studies did not show a clear difference between intermittent and continuous androgen deprivation therapy concerning survival, but improvement in quality of life parameters in the intermittent treatment group [177].

Castrate resistant prostate cancer

Androgen deprivation therapy is not a curative treatment and patients will show biochemical (PSA) or clinical progression after a variable period of time. The first step in case of a PSA rise could be to add an anti-androgen to the testosterone-lowering treatment, which can lead to a PSA decrease, but this combined treatment has not shown to influence survival. Once the patient develops again PSA progression with a demonstrated castration level of serum testosterone (<1.7 nmol/L) a castrate resistant prostate cancer (CRPC) is present. Until 2004, no effective agents were available to treat patients, but two studies showed a median survival benefit for docetaxel 75 mg/m^2 three-weekly combined with prednisone 5 mg bid of two to two and a half months [178, 179]. Recently, several new drugs have been introduced for the treatment of CRPC patients: (1) targeting the endocrine pathways (e.g., abiraterone, enzalutamide), (2) vaccine therapy (e.g., sipuleucel-T), (3) second-line chemotherapeutic approach (cabizataxel), (4) bone targeting approach (Radium ^{223}). These new agents have been evaluated pre- and post-docetaxel therapy.

Cabizataxel has been shown to result in an overall survival benefit post docetaxel of 2.4 months compared to mitoxantrone; this second-line chemotherapy did, however, have a number of grade 3/4 toxicities and experience is required to administer this treatment [180].

Abiraterone and enzalutamide have been tested in the pre- and post-docetaxel setting, where enzalutamide showed an overall survival benefit in both situations (pre-docetaxel: 4.8 months); the data pre-chemotherapy have not been published yet, but a 30% reduction in the risk of death was reported. Abiraterone showed also an overall survival benefit in the post-docetaxel setting (4.6 months compared to placebo), but only a radiological progression-free survival in the pre-docetaxel setting (47% reduction in the risk of progression) [181–183].

Sipuleucel-T has been tested in patients CRPC patients with minimal symptoms and it was for the first time that this immunotherapeutic approach showed a survival benefit (4.1 months compared to placebo) [184].

Bone targeting agents are used for painful metastases (e.g., Strontium^{89}, Samarium-153), but it was very surprising when the use of an alpha emitter (Radium^{223}) also showed a survival benefit as well in patients pretreated with docetaxel or not (3.6 months compared to placebo) [185].

With all these agents now available for patients with CRPC the challenge is to decide which treatment is indicated for which patient at which stage. There is no clear evidence for a single best approach and guidelines are contradictory. There are some indications that patients with aggressive disease would benefit from chemotherapy and those patients who had a long response to hormonal therapy might benefit from abiraterone or enzalutamide, but these suggestions have to be validated in prospective studies, where cross-resistance should also be evaluated.

Urothelial cell carcinoma

The urothelium is the epithelial layer that lines up the whole collecting system from renal papilla in the kidney to fossa navicularis in the urethra. It is composed of three to seven layers of cells and is also called transitional epithelium. Its surface is covered by protective glycoprotein plaques [186, 187].

Urothelial cell carcinoma is more often encountered in bladder (95%) than in the upper urinary tract (5%) [188]. This section will be divided according to the two main urothelial cell carcinoma

topographies: bladder and upper urinary tract, comprising caliceal, pelvic, and ureter locations.

Bladder urothelial cell carcinoma

Epidemiology

With a worldwide incidence of 151/100 000 per year reported in 2012, bladder ranks ninth in terms of cancer location and ninth for mortality (52.4/100 000 per year). Males are more affected than females with a gender ratio of 3.6 [189]. Worldwide, 430 000 cases were diagnosed in 2012.

At initial presentation, 70–80% of cases are non-muscle invasive bladder carcinoma (NMIBC) [190]. At initial treatment, about 30% of patients treated for muscle invasive bladder carcinoma (MIBC) harbor detectable metastases [191, 192].

Some risk factors are clearly identified: tobacco is certainly the most important one, responsible for 50 to 60% of bladder cancers (BC) with a strong correlation between disease incidence and smoking exposure (years and total number of cigarettes) [193]. Occupational exposure concerns professions related to dyeing, fabrics, paints, metal, and petroleum industries. The chemical components incriminated are aromatic amines, polycyclic aromatic hydrocarbons, and chlorinated hydrocarbons. Authorities' regulations in Western countries have led to a decrease in the role of occupational hazards in BC for the past decades and it is currently believed to account for 10% of new cases [194–197]. Schistosomiasis has been related to squamous cell carcinoma of the bladder but there is no high level evidence connecting it to urothelial carcinoma [194].

Staging and grading

Like most solid malignant tumours, bladder cancer is staged according to the TNM classification. It was updated in 2009 (no change from 2002). Tumour stage is highly related to oncologic prognosis [198]. The TNM staging for bladder cancer can be accessed on the website of the American Cancer Society: <http://www.cancer.org/cancer/bladdercancer/detailedguide/bladder-cancer-staging>.

An important clinical boundary separates tumours confined to mucosa or submucosa: non-muscle invasive bladder carcinoma (NMIBC) (Tis, Ta, and T1) from tumours invading muscularis propria and beyond: muscle invasive bladder carcinoma (MIBC) (T2–T4).

For NMIBC, another important prognosis factor for recurrence or progression to MIBC is the grade, based on cytological and architectural criteria. Two grading systems are reported in daily clinical practices: the 1973 and 2004 World Health Organization (WHO) grading classifications. The 1973 classification separates NMIBC in 3 grades: 1 (well differentiated), 2 (moderately differentiated), and 3 (poorly differentiated). The 2004 grading is shown in Box 45.1.

Papillary urothelial neoplasm of low malignant potential (PUNLMP) is a lesion composed by normal urothelial cells in a papillar configuration without malignant cytological features. The risk of progression is negligible, although recurrences can occur. This lesion represents the lower spectrum of the NMIBC.

Most of the literature on urothelial bladder cancer grading is based on the 1973 classification and there is still no prognostic validation for the 2004 WHO classification. Therefore, the current guidelines recommend using both grading systems [199]. The two systems are compared in Table 45.4.

Box 45.1 2004 WHO grading of non-muscle invasive bladder carcinoma

◆ Flat lesions
- Hyperplasia (flat lesion without atypia or papillary aspects)
- Reactive atypia (flat lesion with atypia)
- Atypia of unknown significance
- Urothelial dysplasia
- Urothelial carcinoma in situ
- Papillary lesions
- Urothelial papilloma (completely benign lesion)
- Papillary urothelial neoplasm of low malignant potential (PUNLMP)
- Low-grade papillary urothelial carcinoma
- High-grade papillary urothelial carcinoma

Diagnosis

Symptoms

Macroscopic haematuria constitutes the key symptom for urothelial carcinoma (bladder and upper urinary tract). When reported, cystoscopy and CT urography should be scheduled to confirm or rule it out. NMIBC is usually painless. Some less specific symptoms like refractory lower urinary tract symptoms (LUTS) without urinary infection should encourage investigations to rule out a carcinoma in situ (CIS).

Clinical examination

Clinical examination is nonspecific in urothelial carcinoma. However, a pelvic examination should be performed to detect gross lymph nodes. Clinical staging is unreliable [200] but pelvic fixation on digital rectal examination under anaesthesia presumes an inextirpable tumour in the setting of MIBC.

Cytology

Analyses of voided urine or bladder washout to look for exfoliated malignant cells from urinary tract presents high sensitivity

Table 45.4 Shifting from 1973 to 2004 WHO grading classification

WHO 1973	WHO 2004
	Urothelial papilloma
Grade 1 carcinoma	PUNLMP
	Low-grade carcinoma
Grade 2 carcinoma	Low-grade carcinoma
	High-grade carcinoma
Grade 3 carcinoma	High-grade carcinoma
NMIBC are divided into low- or high-grade in the last classification	
MIBC are always high-grade

Table 45.5 Risk group stratification according to 2011 EAU guidelines

Low-risk tumours	Primary, solitary, Ta, G1* (PUNLMP, LG), <3 cm, no CIS
Intermediate-risk tumours	All tumours not defined in the two adjacent categories (between the category of low and high risk)
High-risk tumours	Any of the following: ◆ T1 tumour ◆ G3** (high grade) tumour ◆ CIS ◆ Multiple, recurrent, and large (>3 cm) Ta G1G2 tumours (all conditions must be present in this point)

*low-grade is a mixture of G1 and G2.

**high-grade is a mixture of some G2 and all G3.

CIS, carcinoma in situ; HG, high-grade, LG, low-grade.

in the setting of high-grade carcinoma but sensitivity drops off for low-grade tumours. Thus, cytology is of interest in the follow-up of high-grade carcinoma or CIS.

Imaging

Trans-abdominal ultrasound (US) imaging can detect intraluminal tumours of the urinary tract. For bladder tumours, it can set transurethral resection of the tumour (TURT) indication, bypassing cystoscopic examination. At upper urinary tract level, US can detect tumours and hydronephrosis associated with obstruction. Although it cannot rule out an upper urinary tract tumour, it remains a useful tool in the setting of urothelial carcinoma diagnosis. Uro-CT, or in developing countries intravenous pyelography (IVP), can detect a defect in the upper urinary tract and should be performed at initial assessment of macroscopic haematuria to detect upper urinary tract tumours. For MIBC, contrast agent CT is also necessary to assess TNM staging. However, neither CT nor magnetic resonance imaging are reliable to differentiate bladder T stage under T3b (macroscopic extravesical extension) [201, 202] or N stage when lymph node enlargement is less than 8 mm [203, 204].

Cystoscopy

Cystoscopy is the best examination to identify bladder tumour. It can be performed at the office, under local anaesthesia, with a flexible cystoscope. It allows a thorough visualization of the whole bladder lining.

Markers

In the last few years, many attempts have been made to develop urinary markers that could potentially screen urothelial carcinoma with a less invasive procedure. Unfortunately, at the moment, none of these tests has reached an acceptable accuracy (sensitivity and sensibility) to be implemented in daily clinical practices [199].

Transurethral resection of tumour

TURT is performed under complete or regional anaesthesia, with an operative cystoscope incorporating a diathermic or bipolar loop (resectoscope). TURT is a diagnostic procedure allowing pathological confirmation of bladder urothelial carcinoma but it is also the

first step for NMIBC treatment. Pathological analyses confirm the diagnostic of urothelial carcinoma, grades the tumour and separates patient among two main prognostic groups that will determine the therapeutic strategy: MIBC or NMIBC. In the setting of NMIBC, recurrence and progression to MIBC can be predicted based on the EORTC scoring system and risk tables [205]. Risk factors for recurrence are the number of tumours, tumour diameter, prior recurrence rate, tumour stage (Ta or T1), presence of concurrent CIS and 1973 WHO tumour grade. Automatic calculators of risk groups predicting recurrence and progression at one and five years can be downloaded online on computers or smartphones for easier daily clinical use. (<http://www.eortc.be/tools/bladdercalculator/>). European guidelines panel recommends stratification of NMIBC patients in to three risk groups allowing adapted therapeutic strategies [199] (see Tables 45.4 and 45.6).

Treatment of non-muscle invasive bladder cancer

A complete TURT is the first step in NMIBC management. Since high incidence recurrence (30–60%) and progression (≈10%) is part of the disease natural history [205], adjuvant therapy is a valuable part of treatment.

Table 45.6 2015 European Guidelines treatment recommendations in TaT1 tumours according to risk stratifications

Risk category	Definition	Treatment recommendation
Low-risk tumours	Primary, solitary, Ta, LG/G1, <3 cm, no CIS	One immediate instillation of chemotherapy
Intermediate-risk tumours	All cases between categories of low and high risk	One immediate instillation of chemotherapy followed by further instillations, either chemotherapy for a maximum of one year or one year full-dose BCG
High-risk tumours	Any of the following: ◆ T1 tumours ◆ HG/G3 tumours ◆ CIS ◆ Multiple and recurrent and large (>3 cm) Ta G1G2 tumours (all these conditions must be presented)	Intravesical full-dose BCG instillations for 1–3 years or cystectomy (in highest-risk tumours)
Subgroup of highest-risk tumours	T1G3 associated with concurrent bladder CIS, multiple and/or large T1G3 and/or recurrent T1G3, T1G3 with CIS in prostatic urethra, unusual histology of urothelial carcinoma, LVI	Radical cystectomy should be considered in those who refuse RC, intravesical full-dose BCG installations for 1–3 years.
	BCG failures	Radical cystectomy is recommended

BCG, Bacillus Calmette-Guerin; CIS, carcinoma in situ; GR, grade of recommendation; HG, high-grade; LG, low-grade; LVI, lymphovascular invasion.

Immediate post-operative instillation of chemotherapy

A single instillation of mitomycin C (or epirubicin or doxorubicin) right after resection can decrease the recurrence rate of 11.7% when compared with resection alone [206]. Adjuvant chemotherapy seems more effective among single primary or small tumours groups. Those instillations are contraindicated if the bladder has been perforated during the TURT procedure [199].

Bacillus Calmette-Guérin intravesical immunotherapy

By sustaining patient's immune response against urothelial carcinoma, Bacillus Calmette-Guérin (BCG) therapy prevents recurrence [207, 208] and progression [209, 210] in NMIBC. It is more efficient in low- to intermediate-risk patients. It has been proven superior to intravesical chemotherapy [211]. The best BCG administration schedule is still under clinical trials scrutiny. It is usually delivered according to the original empirical six-weekly schedule introduced by Morales in 1976 [212]. Although it is a topical treatment, BCG-therapy presents toxicity and any clinician should be aware of its side effects ranging from local (cystitis, haematuria, symptomatic granulomatous prostatitis, epididymo-orchitis) to systemic adverse events (general malaise, fever, arthralgia, BCG sepsis, and allergic reactions).

BCG-therapy failure and recurrences after BCG

The aggressive nature of BCG therapy should not be underestimated. Cancer-specific mortality of this patient subgroup is important [213]. European guidelines recommend radical cystectomy as a standard treatment in case of BCG failure, see Table 45.6.

Treatment of muscle invasive bladder cancer

Radical surgery and urinary diversion

Radical cystectomy is standard of care in the setting of MIBC [192]. The surgical procedure includes the dissection of regional lymph nodes as part of the treatment but also to stage the cancer extension and thus, to select properly the candidates for adjuvant chemotherapy. An extended lymph node dissection is preferable and survival has been shown to increase with the number of lymph nodes dissected [214]. The procedure can be performed through a classical open approach, laparoscopically, or robot-assisted laparoscopy. After bladder removal, urinary diversion options are: abdominal diversion (urethrocutaneostomy, ileal, or colonic conduit and some forms of continent pouches), urethral diversion (orthotopic urinary diversion through intestinal neobladder pouches), or rectosigmoid diversion (uretero-rectostomy). The choice depends on predicted post-operative continence, comorbidities, cognitive functions, and life expectancy. Overall, radical cystectomy is a morbid procedure with estimated perioperative mortality of 3% and early complications (within three months of surgery) in up to 50–60% of cases [215]. Adverse events predictive factors are the surgeon and hospital volumes [216], patient's comorbidity, age, previous treatment, other pelvic disease, and type of urinary diversion [217].

Bladder-sparing multimodal therapy

Bladder-sparing multimodal therapy integrating radiotherapy and cisplatin-based chemotherapy can be offered as an alternative to surgical cystectomy for well-selected patients or when surgical extirpation cannot be performed [192]. In this setting, long-term oncologic outcomes are comparable to radical cystectomy [218].

Neoadjuvant chemotherapy

Neoadjuvant chemotherapy is recommended for T2-T4a, cN0M0 bladder cancer and should be a cisplatin-based combination therapy [192]. Several randomized controlled trials and meta-analyses reported an absolute benefit of 5–8% for neoadjuvant chemotherapy [219–221]. However, to date, there is no accurate marker to predict response to chemotherapy and thus, non-responders might lose chance of survival due to postponed surgery.

Metastatic disease

About 30% of patients initially diagnosed with MIBC present with a metastatic stage and about half of patients who underwent a radical cystectomy will eventually develop it during the follow-up. Cisplatin-based combination chemotherapy is the recommended first-line strategy [192]. Reported patients' median survival is of 14 months when they tolerate this treatment [222, 223].

Upper urinary tract urothelial cell carcinoma

Epidemiology

Primary upper tract urothelial cancer (UTUC) is rare and accounts for less than 5% of all urothelial tumours. Men are more affected than women with a gender ratio of 3:1 [224]. It often presents as multifocal and ≈60% of UTUCs are invasive at diagnostic [225]. Pyelocaliceal location is twice as frequent as ureter location [226]. During the three last decades, stage and grade migration have exhibit a trend towards more aggressive disease. However, cancer-specific mortality remains stable [227].

About 17% of UTUCs have concomitant bladder cancer at presentation [228] and 22–47% of patients with primary UTUC will develop tumours in the bladder during their follow-up [229, 230].

Unlike bladder carcinoma, genetic susceptibility for UTUC has been identified in families harbouring hereditary non-polyposis colorectal carcinoma (HNPCC; Lynch Syndrome) [231]. Clinicians should suspect a familial disease when a patient presents with UTUC at a young age, had previous HNPCC-related cancer or a family history of HNPCC-related cancer. In this setting, the family should undergo genetic counseling with DNA sequencing to search for HNPCC mutations [232].

Just like bladder carcinoma, tobacco and occupational exposure are the most important risk factors for UTUCs [233]. However, the Balkan endemic nephropathy is a UTUC's specific risk factor. It is associated with chronic exposure to aristolochic acid contained in *Aristolochia fangchi* and clematis, plants present abundantly in the Balkans or in Chinese herbs [234, 235].

Staging and grading

The grading system is the same as bladder carcinoma with the 1973 and 2004 WHO classifications. The staging classification is comparable and can be found in *AJCC Cancer Staging Manual*, Seventh Edition (2010) published by Springer-Verlag.

Diagnosis

Symptoms

Symptoms are rare in UTUC and when present they denote a locally advanced or systemic involvement. Haematuria with a normal cystoscopy should trigger suspicions of UTUC.

Imaging

Imaging of the upper urinary tract is usually performed after a negative cystoscopy. CT urography with a late post-injection phase

(10–15 minutes) is currently the gold standard (EAU guidelines recommendation grade A) to explore upper urinary tract in the setting of UTUC suspicion. The sensitivity and specificity are, respectively, 96% and 99%, and accuracy ranges from 59–88% [236]. In case of iodine allergy or renal insufficiency MRI is an acceptable alternative. MRI specificity remains high (97%) at a price of a lower sensitivity (≈70%) [236]. Accuracy decreases notably when the lesions are smaller than 1 cm with described sensitivities of 89% for lesions <5 mm and 40% for lesions <3 mm [236]. Retrograde ureteropyelography during cystoscopy can be an acceptable strategy to rule out an UTUC in the setting of positive cytology with no evidence of bladder tumour during the procedure [236]. A cystoscopy is anyway mandatory during diagnostic process of UTUC in order to exclude a concomitant bladder location [236].

Urinary cytology

Urinary cytology can be highly suggestive of UTUC when positive while no tumour had been found in the bladder (cystoscopy) and CIS had been ruled out in the lower urinary tract (bladder and urethra). However, sensitivity in upper urinary tract is not as good as in the bladder. It can be increased by gathering urine in situ (renal cavities with ureteral catheterization) [237].

Diagnostic ureteroscopy

Diagnostic ureteroscopy with a flexible device allows visualization and biopsies of the tumour all along the upper urinary tract. Biopsies tumour grading yield is around 90% [238]. However, undergrading occurs frequently, imposing a thorough follow-up after conservative strategies [239]. European guidelines recommend performing a ureteroscopy systematically (when available) before UTUC treatment [226].

Molecular markers

Several studies assessed the diagnostic value of markers related to molecular pathways involved in urothelial carcinoma pathogenesis (tumour cell adhesion, angiogenesis, proliferation, epithelial-mesenchymal transition, mitosis, and apoptosis among others) [240–243]. However, due to the low incidence of this disease, internal and external validation of such markers on large cohorts is challenging and none of these markers are currently approved in routine clinical practice [226].

Treatment of organ confined disease
Nephroureterectomy

Nephroureterectomy with excision of the bladder cuff is the gold standard treatment. Laparoscopic or open approach appeared to be equivalent based on a prospective study [244]. According to fundamental onco-surgery principles, the specimen has to be removed en bloc in order to prevent tumour seeding from the urinary tract [225]. The bladder cuff can be dissected through an open inguinal approach or cystoscopically with the resection of the distal ureter's intramural section [226]. Just like in MIBC, time from diagnosis to extirpative surgery is related to disease progression [245] and should ideally not exceed 45 days [226]. Lymph node dissection seems to present benefits in terms of oncologic outcomes although clear topographic patterns are still to be defined for each UTUC location (pyelocaliceal versus ureter) [226]. There is a high level of evidence (1b) that immediate postoperative single dose instillation of mitomycin C after nephroureterectomy prevents bladder recurrence [246] (European guidelines recommendation grade B).

Conservative treatment

Conservative treatment can be offered as an alternative to nephroureterectomy when renal function has to be preserved or in well-selected patients: unifocal tumour, less than 1cm, low-grade and non-invasive aspect on CT-urography. Prior histological confirmation of UTUC through a flexible ureteroscopy with biopsies is recommended and because of the significant risk of grade and stage underestimation, a close and stringent follow-up is mandatory. Any recurrence should shift back the therapeutic strategy to the gold standard nephroureterectomy when possible. The different conservative approaches include resection or laser vaporization under flexible ureteroscopic approach, a percutaneous access (pyelocaliceal location) or a segmental ureteral resection with wide margins (ureteral location) [226].

Treatment of metastatic disease

A metastatic stage imposes a systemic treatment. Nephroureterectomy is no more relevant in this setting except for palliative indications (e.g., macroscopic haematuria). Although randomized control trials is still lacking, platinum-based chemotherapy seems to have similar effect as for bladder carcinoma [247].

Follow-up

Follow-up after initial UTUC management should rule out local recurrences, when conservative treatment applied, with ureteroscopy, bladder recurrence with cystoscopy and contralateral recurrence with CT-urography and cytology. CT scans will inform metastatic progression. Box 45.2 shows the 2013 European guidelines for post-UTUC treatment follow-up [226].

Renal cancer

Pathogenesis

Renal cell carcinoma (RCC) has a number of distinct pathological types. The commonest is clear cell histology which accounts for over 70% of renal malignancies. There are two grades of tumour (high and low). This has replaced the Furhman grading system. Clear cell renal cancer is intrinsically linked to von Hippel-Lindau (VHL) mutations and individuals with germ line mutations to VHL are predisposed to a number of vascular abnormalities as well as renal cancer.

Approximately 25–30% of people have metastatic spread by the time they are diagnosed with renal cell carcinoma [248]. The second commonest subtype is papillary renal cancer which is subdivided into types 1 and 2 which are associated with MET (cMET mutations) and FH (fumarate hydratase) mutations, respectively. Less common (and less malignant histological types) include oncocytoma and chromophore tumours.

At least four hereditary syndromes have been associated with renal cell carcinoma: von Hippel-Lindau (VHL) syndrome, hereditary papillary renal carcinoma (HPRC), familial renal oncocytoma (FRO) associated with Birt-Hogg-Dube syndrome (BHDS), and hereditary renal carcinoma (HRC) [249].

Renal cell carcinoma develops in nearly 40% of patients with VHL syndrome. Deletions of 3p occur commonly in renal cell carcinoma associated with VHL disease. The VHL gene is mutated in a high number of tumours with sporadic (non-hereditary) clear cell renal carcinoma. Mutations of the VHL gene result in the accumulation of hypoxia inducible factors (HIFs) that stimulate

angiogenesis through vascular endothelial growth factor (VEGF) and its receptor (VEGFR) [250].

The risk of kidney cancer increases with age; other risk factors include smoking, obesity, hypertension, and the long-term use of non-steroidal anti-inflammatory drugs. Patients with end stage renal failure and tuberous sclerosis also have a higher chance of developing renal cell cancer [249].

Diagnosis

The application of ultrasound and cross-sectional imaging techniques in clinical practice has led to an increase in the detection of asymptomatic renal tumours and small renal masses. Approximately 50% of all kidney tumours are presently detected as incidental masses on non-invasive imaging and these findings by far supersede the classic triad of flank pain, haematuria, and a palpable mass [251]. Less common symptoms that may lead to the diagnosis of renal cell carcinoma are varicoceles, paraneoplastic syndromes as well as specific clinical signs following metastasis.

It is generally agreed that whole body CT imaging should be performed in patients with adequate renal function to assess local and systemic extent of the disease and aid in planning the therapeutic approach [251]. This includes a CT of the chest as the most accurate diagnostic tool to rule out pulmonary metastases. CT imaging sequences should be performed prior to and after injection of intravenous contrast medium. If required, ultrasound or magnetic resonance imaging can be supplemental, especially for visualization of vena cava involvement. There is an increasing role of pretherapeutic percutaneous renal biopsies. This is in part a consequence of the introduction of alternatives for surgical approaches for small renal masses, such as thermal ablation or active surveillance. In these situations, a proper histological diagnosis is desirable for risk assessment and tailoring follow-up. In metastatic disease a biopsy may help to determine the subtype of RCC which has consequences for the selection of targeted therapy.

The most common subtype of RCC is clear cell carcinoma (75–85%) followed by papillary RCC (10–15%), chromophobe RCC (5%), and the rare collecting duct carcinoma (1%). As these subtypes differ in clinical course and response to therapy knowledge of the subtype may be of importance prior to planning therapy in certain clinical settings [252]. Approximately 30% of small renal masses are benign and a pretreatment biopsy may aid in selecting the best approach in patients with comorbidity or renal function impairment.

Following imaging RCC should be staged according to the 2009 UICC/TNM classification. The TNM staging for RCC can be accessed on the website of the American Cancer Society: <http://www.cancer.org/cancer/kidneycancer/detailedguide/kidney-cancer-adult-staging>.

Surgery

Surgical management of RCC is dependent on local and systemic extent of the disease [251]. Due to an increase in the diagnosis of small incidental renal masses nephron-sparing approaches for localized RCC are gaining ground. The role of active surveillance of small renal tumours is controversial and currently under investigation. It is of concern that even tumours smaller than 4 cm carry a risk of developing metastatic disease and the growth rate does not follow a linear pattern but instead may unpredictably increase in 20–25% of patients in active surveillance protocols. As a consequence, nephron-sparing surgery—or partial nephrectomy—is regarded the standard of care for renal tumours of ≥ 4 cm diameter. The surgical approach can be open, laparoscopic, or robot-assisted and will largely depend on the local surgical expertise and facilities. Although experienced single centres have demonstrated that laparoscopic partial nephrectomy can be performed safely with similar outcome in comparison to an open approach, retrospective multicentre data suggest that the surgical complication rate with laparoscopic partial nephrectomy is higher than with an open approach. Of additional concern is the longer warm ischemia time observed with laparoscopic partial nephrectomy that may have long term consequences for renal function. Robot-assisted laparoscopic partial nephrectomy may improve the laparoscopic approach but present data are premature to define the role of this technique. Guidelines, therefore, recommend the open approach as standard and the laparoscopic approaches as options in experienced hands [251].

A randomized trial for cT1a tumours has confirmed the oncological safety of partial nephrectomy in comparison to nephrectomy, and epidemiological data suggest that preservation of renal function is correlated to an improved overall survival independent of the diagnosis of RCC. The extent of the margin of renal tissue surrounding the tumour at surgery is not associated with local recurrence and there are reports suggesting that enucleation of the tumour and even positive surgical margins are without clinical consequences [253]. Increasing retrospective data suggest that it is not the size of the primary tumour but its location within the kidney which limits nephron-sparing surgery and case series report similar outcome and safety in ≥ cT1b RCC. Despite the recommendation of most guidelines that total nephrectomy should not be performed in patients with cT1a tumours it has to be recognized that the resection of some lesions is technically not feasible.

The surgical risk can be assessed prior to surgery with nephrometry scores. Epidemiological data on tumours of ≥ 4 cm show that partial nephrectomy is increasingly performed albeit still at a lower rate than total nephrectomy [254]. Patients with small renal masses can also be treated by thermal ablation such as radiofrequency or cryo-ablation (RFA and CA). The potential advantages of these minimal invasive approaches have led to initial experience in selected elderly and frail patients but more recent case series report safe oncological long-term outcome in general patient populations. Current data suggest that CA, which is often performed after laparoscopic exposition of the renal mass, yields better local control than the percutaneous RFA approach. Most critics of CA, however, argue that the laparoscopic approach abrogates its potential benefits over a laparoscopic partial nephrectomy. However, due to a lack of randomized studies the role of these techniques is ill-defined. Nephron-sparing surgery is the current standard of care but guidelines recognize ablation as a therapeutic option in selected patients [255].

Localized RCCs which are not suitable for partial nephrectomy due to either locally advanced tumour growth or an unfavourable location are best treated by laparoscopic or open nephrectomy. According to most international and national guidelines a laparoscopic nephrectomy should be favoured due to lower morbidity and faster recovery in comparison to open surgery for patients with cT1 and cT2 tumours in whom nephron sparing surgery is not feasible. Long-term follow-up has shown no difference in oncological outcome in comparison to open radical nephrectomy. Retrospective studies on volume and outcome association suggest that laparoscopic nephrectomy has a lower complication rate to open nephrectomy, which are more likely to be fatal [256–258].

Based on large retrospective data sets it is recommended that routine adrenalectomy is not indicated if presurgical cross-sectional imaging reveals no adrenal abnormalities [251].

The role of lymphadenectomy in RCC has been investigated in one single randomized phase III study (EORTC 30881) which failed to show a survival advantage of performing a complete lymph node dissection (LND) in patients with RCC [259]. Despite these results, the role of LND remains controversial since the definition of the extent of LND varies and the EORTC trial population predominantly included tumour stages with a low risk of occult lymph node metastasis. Only 4% of all patients in the LND arm revealed unsuspected lymph node metastases. Randomized trials with sufficient statistical power to specifically investigate the therapeutic or staging value in high risk patients are lacking. Currently, guidelines recommend for patients with clinically unsuspected lymph nodes on cross sectional imaging to perform standard LND for staging purposes only if indicated. However, suspicious nodes on preoperative imaging should be removed [260, 261].

In patients with renal or caval vein involvement without metastatic disease (cT3a-T3c) nephrectomy and thrombectomy can be curative and improve prognosis. To indicate the level of the tumour thrombus and assist in planning the surgical approach—which may be multidisciplinary—the thrombus can be staged as stage I (adjacent to the ostium of the renal vein), II (extending below the liver), III (involving the intrahepatic IVC but below the diaphragm and IV (extending above the diaphragm). While most surgeons would feel comfortable in performing a nephrectomy with thrombectomy in patients with level I or II as an open approach some centres have reported successful laparoscopic procedures. Due to the relative paucity of level III and IV thrombi and the need for potential cardiopulmonary bypasses it is recommended that these patients are treated in selected centres. Due to the unpredictable effect of targeted therapy on tumour thrombus downsizing primary surgical resection is favoured whenever feasible [262].

For patients with primary metastatic RCC and the tumour in situ, cytoreductive nephrectomy, with or without metastasectomy, is controversial. It is recognized that complete surgical removal of the primary tumour and metastases, if feasible, may cure selected patients. However, in the majority cytoreductive nephrectomy is part of a multimodality treatment including systemic therapy, and may at best lead to an improved overall survival. Alternatively, a complete surgical resection may lead to a delay starting systemic therapy, with its own adverse side effects.

Randomized phase III trials of interferon alpha with or without cytoreductive nephrectomy demonstrated a survival benefit of six months for surgery versus no surgery [263]. Currently, phase III trials investigating the role and sequence of cytoreductive nephrectomy are ongoing. Until these trials report it is generally recommended to perform cytoreductive nephrectomy in patients with oligometastatic disease and a good performance. For patients with metachronous metastasis following nephrectomy with curative intent, retrospective data suggest that complete metastasectomy of single, or oligometastases confers a survival benefit [264]. Due to the lack of randomized trials in this setting it still remains unclear in how far a selection of patients with a protracted course of the disease contributes to the beneficial outcome observed after metastasectomy [265].

Medical treatment of patients with metastatic or advanced disease

All randomized studies to date have focused on patients with clear cell renal cancer. A prognostic scoring system, developed out of the Memorial Sloan Kettering Cancer Center (MSKCC) has been widely used to stratify patients into good-, intermediate-, and poor-risk groups.

First-line treatment

Metastatic RCC is notoriously chemoresistant, and until recently, immunotherapy (in particular interferon-alpha) has represented the treatment of choice. However, this has proven to be largely ineffective and toxic, especially in patients with MSKCC intermediate- and poor-risk disease. There is still a role for high dose il-2 in a small subset of good-risk patients. Long-term remission has been extensively described in this group; however, this population is not well defined [266].

The increase in understanding of the biology of RCC has resulted in the development of targeted therapies including vascular endothelial growth factor multikinase inhibitors (VEGF TKIs) (sunitinib, sorafenib, axitinib, pazopanib), VEGF antibodies (bevacizumab), and mammalian target of rapamycin (mTOR) inhibitors (temsirolimus, everolimus) [266].

Both sunitinib and pazopanib are indicated for the first-line therapy of metastatic RCC as a consequence of a positive phase III trial versus interferon-alpha [267, 268]. Common toxicity includes hand-foot syndrome, hypertension, fatigue, and mucositis. Bevacizumab is also indicated in the first-line treatment of metastatic RCC given in combination with interferon-alpha as a consequence of two positive phase III trials [269]. Positive randomized

data also exists for temsirolimus in patients with MSKCC poor-risk disease.

Two recent studies have compared sunitinib and pazopanib [269, 270]. Together, they showed that pazopanib was no less effective than sunitinib. However, symptomatic toxicity and patients preference favoured pazopanib. Liver toxicity was more common with pazopanib. The overall survival for these patients is in the region of 30 months, compared to 12 months in the pre-TKI era.

Second-line treatment

Sequential therapy is established in clear cell renal cancer. However, subsequent therapies follow a law of diminishing returns and cross resistance occurs. This includes VEFG and mTOR targets [271]. Second-line progression-free survival is between three and six months which is half that of first-line therapy. The median overall survival of patients who are resistant to first-line therapy is between one and two years.

Treatment after cytokine therapy

Sorafenib, pazopanib, and axitinib have positive randomized data in this area [270, 272, 273]. However, axitinib is superior to sorafenib in terms of progression-free survival and is therefore perhaps the optimal agent.

Treatment after VEGF-targeted agents

A phase III randomized double blind placebo controlled trial looked at the use of everolimus (mTOR inhibitor) in patients who developed progressive disease following the use of vascular endothelial growth factor targeted therapy. In this study, patients had progressed on sunitinib, sorafenib or both were randomized to receive either everolimus or placebo. Results showed there was an improved median progression-free survival in the everolimus arm (four months, 95% CI 3.7–5.5) compared to the placebo arm (1.9 months, 95% CI 1.8–1.9). The most commonly reported adverse events were stomatitis, fatigue, and rash [274]. Everolimus is therefore recommended in VEGF-refractory disease.

Recent results of the AXIS phase 3 trial demonstrated improved efficacy (progression-free survival) with second-line axitinib compared with sorafenib in patients who progressed on a variety of first-line targeted therapies, including sunitinib and interferon. Results showed that axitinib resulted in a longer progression-free survival compared to sorafenib: 6.7 months with axitinib compared to 4.7 months with sorafenib (hazard ratio 0.665; 95% CI 0.544–0.812; one-sided p <0.0001). The progression-free survival in the sunitinib-refractory patients was also superior for axitinib (4.6 months compared to 3.8 for sorafenib). However, there here was no overall survival difference. The most common side effects for axitinib were diarrhoea, hypertension, and fatigue [273].

In view of these findings, available clinical evidence, individual patient profile, and toxicity concerns should be carefully evaluated when deciding whether to administer everolimus or axitinib after progression on a first-line VEGF TKI.

Third-line treatment

The RECORD-1 study included patients who have failed multiple lines of VEFG-targeted therapy. Therefore, everolimus can be used third- or even fourth-line in VEGF-refractory disease [274]. There is no robust data for sunitinib, axitinib, or pazopanib in this setting.

Dovitinib has recent been tested in the third-line setting. It was compared to sorafenib in patients who had failed first-line VEFG TKI and second-line mTOR inhibitors. Dovitinib is a multitargeted receptor tyrosine kinase inhibitor that offers broader inhibition of the fibroblast growth factor receptor (FGFR) by binding FGFRS 1, 2, and 3. In addition, it also targets the platelet derived growth factor receptor (PDGFR), and VEGF receptors. The primary end-point was not met by the trial. The PFS was 3.7 and 3.6 months in the dovitinib and sorafenib arms, respectively (HR 0.86; p = 0.063). Median overall survival was also early the same at 11.1 months with dovitinib and 11.0 months in the sorafenib arm (HR 0.96; p = 0.357). The main side effects associated with dovitinib were diarrhoea, nausea, and vomiting [275].

Combination therapy

To date, no combination of targeted agents (including three randomized studies) has shown any benefit in combining any of the drugs mentioned above.

Biomarkers

No biomarkers exist to predict response to targeted therapy. Functional imaging has also proven ineffective. Radiological response to treatment and progression on cross-sectional imaging are widely used to determine staring and switching therapy.

Protein, gene, and DNA biomarkers have not been widely explored in this setting. What data is available is largely unhelpful. It appears that baseline angiogenic biomarkers such as VEGF ligand and receptor expression do not predict outcome [276].

Carbonic anhydrase IX (CAIX) was investigated as a predictive marker in patients with metastatic clear cell renal cell carcinoma (CCRCC) receiving high dose interleukin-2. Despite promising preliminary data, prospective data show no predictive effect [277].

Lung cancer

Rafał Dziadziuszko, Michael Baumann,
Tetsuya Mitsudomi, Keith M. Kerr,
Solange Peters, and Stefan Zimmermann

Epidemiology and aetiology

Lung cancer remains the leading cause of cancer-related mortality globally with almost 1.6 million deaths worldwide each year. Estimates of 2008 lung cancer incidence and mortality in 40 European countries indicate 391 000 new cases (12.2% of all cancer diagnoses) and 342 000 deaths (19.9% of all cancer-related deaths) [1]. Lung cancer incidence is very variable across Europe with highest incidence in Central and Eastern European countries (Hungary and Poland) and lowest in Portugal and Sweden. The proportion of newly-diagnosed lung cancer patients in women is also highly variable—from approximately 10% in some Central and Eastern European countries to almost 50% in Denmark and Sweden, reflecting social differences in tobacco consumption. Lung cancer incidence and mortality figures show a stable decline in males in almost all countries, whereas the incidence and mortality in females is rising in majority of European countries except some high-risk countries showing stable or declining trends (Denmark, Iceland, UK). The incidence of lung cancer in never-smokers (persons who smoked less than 100 cigarettes in their life) is approximately two- to three-fold higher in females as compared to that in males [2]. Detailed data on trends in incidence of lung cancer in never-smokers are lacking, with some suggestions of slight increase over time.

It is estimated that almost 160 000 new lung cancer diagnoses occurred in the United States in 2013, with declining death rates in males for two decades and recently observed declining trends in death rates in females [3]. Global lung cancer burden is expected to rise as a consequence of increase in tobacco consumption, particularly in Asian countries. Lung cancer remains a devastating disease, with approximately 10–15% five-year survival rates in European countries and North America.

Active tobacco smoking is the prevailing risk factor for lung cancer development. It is estimated that cumulative lifetime lung cancer risk in heavy smokers may reach 30% as compared to less than 1% in never-smokers [4]. Globally, active smoking is responsible for approximately 50–90% of lung cancers in females and 80–95% of lung cancer in males with wide geographical variation. Passive tobacco inhalation is responsible for approximately 20–50% of lung cancer diagnoses in non-smokers. Tobacco smoke contains more than 50 identified carcinogens, including N-nitrosoamines, polycyclic aromatic hydrocarbons (PAHs), benzene, vinyl chloride, arsenic, and chromium [5]. Exposure of bronchial epithelium to these carcinogens leads to formation of DNA adducts and, if not repaired by DNA repair systems, permanent mutations. The spectrum of genetic and epigenetic changes in airway epithelium from smokers is very broad, including oncogene mutations, gene copy number changes, loss of tumour suppressors, and abnormal methylation pattern. Most of these abnormalities persist over time, explaining elevated risk of lung cancer in individuals who quit smoking. Lung cancer risk depends strongly on the duration of tobacco smoking and age of onset as well as on smoking intensity. Use of low tar and filtered cigarettes is not associated with lower lung cancer risk and contributes to observed phenomenon of increasing proportion of lung adenocarcinomas. Deeper inhalation, related to the need to deliver adequate nicotine amounts to nicotine-addicted individuals, leads to higher exposure of peripheral bronchi to smoke from these cigarettes. The risk of lung cancer gradually decreases after quitting smoking to the level of two- to three-fold of the risk of never-smokers. Other means of smoking tobacco, such as pipes or cigars, are also linked to elevated lung cancer risk, albeit this association appears less strong than for cigarettes—relative risks are within the range of two to five as compared to never-smokers.

Occupational carcinogens associated with lung cancer include asbestos, arsenic, beryllium, cadmium, chromium, nickel, silica, radon, vinyl chloride, and fumes from diesel fuels. Higher risk of lung cancer is also observed in individuals exposed to chest radiotherapy, such as survivors of breast cancer or lymphoma. Exposure to these agents is responsible for approximately 10% of lung cancers among males and 5% in females [6]. Chronic exposure to asbestos in industry workers (asbestos mining, construction, insulation, and shipbuilding industry) is associated with approximately 3–10 times the relative risk of lung cancer. The risk associated with asbestos is greatly increased with consumption of tobacco cigarettes. Exposure to radon (radioactive gas which is a decay product of radium 226 and uranium 238) is of a significant concern not only for mine workers but also for indoor air pollution at residential areas abundant in natural radium and uranium in the soil and rocks. While there is no discussion about the former as a risk factor, harmful effects of low-level radiation from indoor radon continue to be debated. Other occupational lung cancer carcinogens are related to a wide range of industries such as ceramics, glass, steel, mining, and chemical manufacturing.

Molecular biology

Genetic predisposition to lung cancer is highly complex with involvement of high-penetrance, low-frequency genes and genes

with low penetrance occurring with higher frequencies. Lung cancer belongs to the spectrum of tumours found in patients with high-penetrance syndromes such as Li-Fraumeni (germline P53 mutations/deletions), Bloom (germline BLM mutations/deletions), Werner (germline WRN mutations/deletions), and BRCA (germline mutations/deletions of BRCA1 or BRCA2) syndromes. The precise risks of lung cancer development in careers of mutations or deletions in these genes are, however, difficult to estimate due to lack of large-scale molecular epidemiology studies. The majority of studies addressing low penetrance genetic predisposition focus on polymorphic variants of genes that encode enzymes mediating activation, detoxification, or repair of DNA damage caused by tobacco [7]. Most extensively studied phase I (oxidation, reduction, and hydrolysis) and phase II (conjugation) enzymes involved in the metabolism of tobacco carcinogens include CYP1A1, microsomal epoxide hydrolase-1 (mEH/EPHX1), myeloperoxidase (MPO), NAD(P)H quinone oxidoreductase-1 (NQO1), and glutathione S-transferases. Results of these studies revealed several candidate gene polymorphisms associated with significantly elevated or decreased risk of lung cancer with odds ratios typically in the range of 1.5–3, and suggesting important interactions among risk genotypes. Practical implementation of these associations into molecular tests that could be used to support selection of individuals into lung cancer screening programs remains difficult due to large heterogeneity among designs and results of these studies. Other candidate genetic markers of increased susceptibility to lung cancer include genes involved in inflammatory response and cell cycle control.

Intensive research performed during the last ten years with integrative molecular methods such as genome sequencing, comparative genomic hybridization, and transcriptome analysis led to accumulation of a large amount of data on the spectrum of molecular aberrations in lung cancer [8, 9]. Most of lung cancer genomes present hundreds of mutations, deletions/amplifications, gene rearrangements, and abnormal methylation patterns, a feature typical for cancers arising from exposure to tobacco-related carcinogens. Of those, only a few abnormalities lead to significant activation of cell signalling pathways leading to tumour growth, progression, and dissemination. Growth of lung adenocarcinomas may depend predominantly on a single molecular event, such as activating mutations in epidermal growth factor receptor (EGFR) gene, Kirsten ras sarcoma virus (KRAS) gene, ERBB2 (HER2) gene or rearrangements in ALK, ROS1, or RET oncogenes. These events are frequently non-overlapping and indicate different biological behaviour with distinct proliferation rate and chemo- and radio-sensitivity. For example, EGFR mutations indicate a more indolent course of the disease, substantial benefit from EGFR tyrosine kinase inhibitors, increased response rates to chemotherapy and increased radiosensitivity as compared to wild-type EGFR. Activating EGFR mutations and other above-mentioned molecular features fulfill the 'oncogene addiction' model and form the basis for the development of predictive molecular assays for particular targeted therapies, used either in clinical practice (EGFR and ALK inhibitors, briefly discussed below) or within clinical trials. These abnormalities are mainly confined to genes coding for growth factor receptors, intracellular pathway signaling proteins or transcription factors. The most extensively studied and the most frequent mutation of this type occurs in codons 12, 13, or 61 of the KRAS oncogene, which codes for a GTP-ase involved in signal transduction from tyrosine

kinase receptors. Most of the KRAS mutations are G to T transversions resulting in substitution of glycine by either cysteine or valine. KRAS mutations occur in approximately 10–25% of adenocarcinomas (less commonly in squamous cell carcinomas), are associated with smoking history, and are linked with slightly inferior survival or harbour no prognostic significance according to a number of studies performed in operable series of lung cancer patients [10]. With the exception of promising results of a small phase II study that combines the MEK inhibitor selumetinib with docetaxel as second-line therapy of advanced non-small cell lung carcinoma (NSCLC) with KRAS mutations [11], there is currently no effective targeted therapy for patients with tumours showing this mutation.

EGFR mutations are found in tumours from approximately 10–15% of unselected Western and 30–50% of Asian NSCLC patients, more frequently in never or light smokers. These mutations cluster in exon 18–21 of the gene, leading to conformal changes in the ATP-binding pocket of tyrosine kinase portion of the EGFR protein [12]. Most common mutations are small exon 19 deletions or exon 21 point mutations (L858R and L861X), linked with sensitivity to reversible EGFR tyrosine kinase inhibitors such as gefitinib or erlotinib. Rare exon 18 mutations are also associated with sensitivity, whereas exon 20 point mutations and small insertions are linked with resistance to EGFR inhibitors. Exon 20 T790M mutation is the most common mechanism of acquired resistance, which develops after a median of approximately ten months of gefitinib or erlotinib treatment. Clones of cells harboring T790M may be found by sensitive techniques in 30–50% of tumours prior to therapy with reversible EGFR inhibitors and expand during treatment through clonal selection. Current translational and clinical research efforts are directed towards breaking the mechanisms of acquired resistance with novel EGFR inhibitors or molecules aimed at other targets essential for abnormal cell growth.

ALK is a transmembrane protein of insulin-like growth factor receptor superfamily with tyrosine kinase activity. ALK gene rearrangement is found in approximately 3–5% of NSCLCs, almost exclusively in adenocarcinomas. Most frequently, an intracellular portion of ALK tyrosine kinase is fused with an N-terminal portion of microtubule-associated protein-like 4 (EML4), leading to constitutive activation of ALK. More than ten variants of ALK fusion genes have been identified in lung tumours, with EML4 being the most common and KIF5B, TFG, or KLC1less common fusion partners. ALK rearrangement can be detected in tumours by fluorescence in situ hybridization (FISH) break-apart assay or RT-PCR assay. In addition to these two tests, immunohistochemical staining for ALK protein with antibodies specifically validated for lung cancer appears very promising. The optimal testing methodology to define ALK-positive tumours remains to be established, although it should be noted that results of clinical trials with crizotinib, ALK, and MET inhibitor rely on patients with tumours defined as positive by the FISH assay. A testing strategy which relies on immunohistochemistry with specific anti-ALK antibodies followed by FISH break-apart assay in immunopositive cases is commonly adopted in many institutions. The less commonly rearranged ROS1 gene (approximately 1–2% of lung adenocarcinomas) codes for a protein of the same family as ALK, showing approximately 50% of amino acid sequence homology in the tyrosine kinase domain. At least ten fusion partners have been described for the ROS1 gene in lung cancer. Several publications suggest the clinical utility of immunohistochemistry to

detect ROS1 protein and preselect tumours for FISH testing. Patients with ALK and ROS1 rearrangements are typically younger and tend to have no or limited tobacco smoking history. Both rearrangements are predictive for benefit from specific inhibitors, including crizotinib (approved in patients with ALK-positive NSCLC) and several other agents currently in clinical development.

Recent research on driving molecular aberrations in squamous cell carcinoma identified several candidate genes with mutations or amplifications leading to activation of downstream signalling. From a therapeutic perspective, most promising genetic changes include DDR2 and PIK3CA mutations or FGFR1, SOX2, or PIK3CA amplifications. Several clinical trials with inhibitors of the above targets are ongoing.

Dysregulation of tumour suppressor genes (TSGs) is a common finding in lung cancer. P53 gene mutations are almost universal in small-cell lung carcinoma (SCLC) and occur in approximately half of NSCLCs. P53 protein is involved in several cellular processes, such as DNA repair, cell-cycle and apoptosis control, autophagy, senescence, and ageing. Most P53 mutations are missense and cluster in the DNA-binding domain, resulting in the defective p53 protein not being able to transactivate target genes mediating the above processes. In addition, several P53 mutations are linked with gain-of-function properties typical for dominant oncogenes. Clinically, P53 mutations are associated with worse prognosis of surgically treated NSCLC patients and appear to associate with radio- and chemo-resistance. Several strategies to restore functional P53 pathway have been developed and tested in clinical trials. These strategies include retrovirus or adenovirus-mediated gene therapy with wild-type P53 [13], small molecule inhibitors of P53-MDM2 interaction [14], or mutation-specific P53-directed tumour vaccines [15].

Other important TSGs with a relatively high proportion of aberrations (mutations, allele losses, epigenetic modifications) in lung cancer include LKB1, NF1, PTEN, ATM, RB1, FHIT, and APC [8]. Other yet undefined suppressor genes are being unravelled through high-resolution genomic hybridization methods. The diagnostic and therapeutic significance of these abnormalities at present is unknown. Tumours with deleted TSGs may depend on activation of unsuppressed downstream pathways (e.g., loss of LKB1 results in mTOR activation; loss of NF1 results in RAS/RAF/MEK and/or mTOR activation). Inhibition of these pathways is currently explored in clinical trials.

Pathology

The pathology of lung cancer, like the molecular biology of this diverse group of malignant diseases, has become of even greater importance in the approach to diagnosis and treatment of this most common and fatal of malignancies. Traditional pathology is based upon haematoxylin and eosin (H&E)-stained section morphology, underpinning the WHO classification of lung tumours applied to resected cancer specimens. Most pathological tumour diagnosis is, however, made on small biopsy samples or cytology and increasingly, immunohistochemistry is used to resolve diagnostic problems (see below). Therapeutic choices for patients with lung cancer are based on detailed knowledge of tumour pathology, both in the advanced disease setting but also before, during, and after surgical resection. Choice of chemotherapy may be determined by

tumour cell type (small cell, squamous cell, and adenocarcinomas are treated differently) as may be genetic investigations to determine molecular targeted therapy. It is now no longer acceptable to classify lung cancer according to a simple dichotomy of small cell carcinoma; yes or no? The 'category of convenience' that was NSCLC comprises a number of biologically diverse malignant diseases which are treated in different ways. NSCLC should not be considered a single entity.

In the surgical setting, confirmation of malignancy in small samples is usually required before surgical resection. Intraoperative frozen section diagnosis may be used to inform surgical decision making but full diagnosis and classification of disease is made on the complete resection specimen. The 2015 WHO classification of lung tumours [16] is the standard used and names seven major subtypes of lung carcinoma: squamous cell, adenocarcinoma, large cell, sarcomatoid, adenosquamous, neuroendocrine, and salivary-type carcinomas. The pathology report of the resected tumour should subtype and pathologically stage the tumour according to the TNM system 7th edition [17]. Tumour stage is the major determinant of adjuvant therapy.

Adenocarcinoma

Adenocarcinoma is probably the most common type of lung cancer worldwide, although its dominance is less pronounced in Caucasian cohorts where smoking is the predominant aetiological factor. Most adenocarcinomas arise in the peripheral, parenchymal part of the lung, from precursor lesions of atypical adenomatous hyperplasia (AAH) and adenocarcinoma in situ (AIS—formerly known as pure non-mucinous brochioloalveolar carcinoma or BAC). These lesions arise from the peripheral lung epithelial compartment referred to as the terminal respiratory unit (TRU), characteristically expressing thyroid transcription factor 1 (TTF1).

Grossly these tumours show a wide range in size, and may be multifocal, either due to intrapulmonary spread or multiple synchronous primary lesions. A frequent mixed pattern of solid and 'ground glass' features on CT scans corresponds to peripheral parts of the tumour growing around alveolar walls without their destruction (lepidic growth), leading to the 'ground glass' appearance (Figure 46.1).

Relatively early spread to loco-regional lymph nodes is common and in advanced disease, lymphangitic spread in the lung
Fig. 46.1 Lepidic pattern adenocarcinoma which may represent adenocarcinoma in situ. Tumour cells grow around alveoli without destroying them (H&E × 200).
Fig. 46.2 Acinar pattern adenocarcinoma showing invasion of the fibrous stroma (H&E × 200).

is frequent. Their peripheral location and relative propensity for invasive growth, especially in the more aggressive subtypes, makes pleural invasion common.

Five main histological patterns of adenocarcinoma may be recognised: lepidic (formerly called bronchiolo-alveolar), acinar (Figure 46.2), papillary, micropapillary, and solid with mucin. Most lung adenocarcinomas comprise a mixture of two or more of these patterns. In resected cases, tumours which are predominantly of lepidic pattern have a relatively good prognosis and those which are predominantly micropapillary (Figure 46.3) or solid show significantly shorter post-operative survival with greater risk of relapse. By definition, all adenocarcinomas show glandular cells and architecture, and some cases show large amounts of mucin production and mucigenic tumour cells. Some mucinous adenocarcinomas of the lung show a tendency to spread within the lung, with or without tissue destruction, with less of a tendency to distant metastases. These cases were formerly classified as 'mucinous BAC' and often bear KRAS gene mutations. Adenocarcinomas, especially those arising in non-smokers, often bear a particular oncogene mutation. Many of these mutations appear to be mutually exclusive of each other (EGFR, KRAS, BRAF and HER2 mutations, and ALK gene rearrangements), implying biological significance and suggesting
so-called oncogene addiction. The therapeutic importance of these mutations is discussed above. Some of these mutations are associated with particular adenocarcinoma histological features.

Squamous cell carcinoma

In general, this type of lung cancer is the second most prevalent, after adenocarcinoma, though where smoking-induced cancers predominate it may remain the most common type. The archetypal form of the so-called bronchogenic lung carcinoma most commonly arises from the epithelium of central large bronchi, transformed by tobacco carcinogens. Progenitor lesions are well recognized; basal cell hyperplasia/squamous metaplasia gives rise to squamous dysplasia and squamous carcinoma in situ, wherein invasive disease develops. Most squamous cell carcinomas (SCC) are destructive growths which cause early bronchial obstruction and various degrees of obstructive pneumonia. Squamous cell carcinomas arising from smaller, more peripheral airways may be becoming more prevalent, presenting as peripheral solitary nodules akin to adenocarcinoma.

Histologically, these tumours are defined by the presence of squamous differentiation (keratin or intercellular bridge formation) (Figure 46.4) and most cases are relatively poorly differentiated. Invasive growth is often accompanied by a fibrous stroma and inflammation is variable. Endobronchial growth may have a papillary architecture whilst some peripheral SCCs grow within alveolar air spaces causing relatively little tissue destruction. Some SCCs show areas of tumour with smaller densely packed cells of basaloid morphology—this basaloid variant of SCC (basaloid carcinoma) is a relatively aggressive tumour. Necrosis is common and this may lead to tumour cavitation, although this process is not the preserve of squamous tumours. In general, spread to lymph nodes is a relatively late phenomenon, but these tumours can be extremely aggressive. The frequent association with obstructive pneumonia should demand caution in assuming that lymphadenopathy is malignant, as opposed to reactive, in a case of SCC.

Malignant neuroendocrine tumours

By far, the most important tumour in this category is small cell lung carcinoma (SCLC). In many countries this tumour is, like squamous cell carcinoma, declining in incidence, probably due to

Fig. 46.3 A surgically resected adenocarcinoma showing predominance of this micropapillary pattern has a relatively poor post-operative survival (H&E × 200).
Fig. 46.4 Squamous cell carcinoma in a lung core biopsy. Keratinization and intercellular bridges are evident so a confident diagnosis can be made (H&E × 200).
Fig. 46.5 Small cell lung carcinoma in a core biopsy of a paraspinal metastatic deposit (H&E × 200).

Fig. 46.6 Typical carcinoid tumour showing regular islands of small cells and abundant cytoplasm. (H&E × 200).

a fall in tobacco consumption, but where smoking remains common, SCLC still accounts for 15–20% of all lung cancers. SCLC tends to be a central, bronchogenic tumour which often presents with bulky central disease, contiguous with hilar and mediastinal lymph node metastases and direct spread into the mediastinum. Peripherally located, small tumours are uncommon, but may account for those rare cases which present with localized, surgically resectable disease. The vast majority of SCLC is stage 4 at presentation. Consequently, most contemporary pathological experience of SCLC is in small biopsy or cytopathology diagnosis.

These tumours comprise sheets of highly invasive, relatively small malignant cells whose nuclear features (stippled chromatin, moulding) are key to diagnosis. Necrosis, apoptosis, and mitotic activity are all abundant (Figure 46.5). Diagnosis is usually easy by H&E stains and immunohistochemical evidence of neuroendocrine differentiation is not a prerequisite. Sometimes, SCLC may coexist with other forms of NSCLC in the same lesion where, regardless of the amount of SCLC, a diagnosis of combined SCLC is made, and should be treated as SCLC.

Other forms of malignant neuroendocrine tumour (NET) of the lung are much less common than SCLC. Large cell neuroendocrine carcinoma (LCNEC) is another high-grade, aggressive tumour which may arise centrally or peripherally and has an equally poor prognosis to SCLC, at least in surgically resected series. This is a difficult diagnosis to confirm in small diagnostic samples, so the behaviour of LCNEC in the advanced disease setting is not clear. Many cases may be diagnosed as SCLC in small samples but awareness of this tumour type is increasing. Lesions comprise large tumour cells in prominent 'organoid' or 'neuroendocrine' architecture. Unlike SCLC, tumour cells usually have large, obvious nucleoli and abundant cytoplasm.

Carcinoid tumours are rare malignant neuroendocrine tumours which most often arise in central bronchi, grow slowly and often present with obstructive bronchial symptoms. Most are low-grade, so-called typical carcinoid tumours (Figure 46.6). Regional lymph node metastases are found in around 10% of cases; distant metastases are very rare. Atypical carcinoid tumours are morphologically very similar to typical tumours but for the presence of tumour necrosis and/or a slightly higher mitotic rate (between 2–10 mitoses per 2 mm^2 tumour). These are extremely rare tumours with a biological behaviour and post-surgical prognosis similar to SCC.
Typical carcinoid tumours with spindle cell morphology may arise in the lung periphery.

Large cell carcinomas

With the revision of definitions under the 2015 WHO classification, large cell carcinomas (LCC) account for around 4% of resected lung cancers and are defined by the absence of differentiated histological features (squamous or adenocarcinoma) anywhere in the tumours, and a lack of immunohistochemical features which may be associated with SCC or adenocarcinoma (Figure 46.7). This definition is important since it determines the fact that this tumour type can only be diagnosed in the surgical resection setting, when the whole lesion may be examined to exclude squamous or glandular differentiation somewhere in the lesion. These may be central or peripheral tumours, are generally aggressive, invasive, and molecular evidence supports that at least a proportion represents de-differentiated squamous cell or adenocarcinomas.

Sarcomatoid carcinomas

These tumours are diagnosed with certainty only in the surgically resected specimens, when more than 10% of the lesion shows spindle, pleomorphic, or tumour giant cells (Figure 46.8). The
Fig. 46.7 This resected lung carcinoma shows large undifferentiated cells and abundant mitoses. In the absence of morphological differentiation, a diagnosis of large cell carcinoma is appropriate (H&E × 200).
Fig. 46.8 This resected lung carcinoma showed evidence of squamous cell carcinoma but also, over 10% of the lesion showed these pleomorphic tumour giant cells, mandating a diagnosis of sarcomatoid carcinoma (H&E × 200).

remainder of the tumour may be undifferentiated or show squamous cell or adenocarcinoma. Extremely aggressive and invasive, such histological features may be recognized and at least described in small sample diagnosis.

Adenosquamous and other mixed tumours

Tumours showing at least 10% of each lesion as clear-cut squamous cell and adenocarcinoma are diagnosed as adenosquamous carcinoma. This is the best known of the combined lung cancer subtypes but is actually quite rare, if diagnostic criteria are strictly followed. They are usually peripherally located and may carry a relatively poor prognosis and represent another diagnosis that should only be offered in surgically resected cases. Other combinations may be encountered; adenocarcinoma with LCNEC is worthy of mention.

Salivary type carcinomas

These are extremely uncommon, and are found mostly in the trachea and main bronchi. They are the histological counterparts of adenoid cystic and mucoepidermoid carcinomas better known in the salivary glands and probably arise in the large airway seromucous glands.

Small biopsy and cytology sample diagnosis

Most patients with lung cancer present with advanced disease and never have their tumour resected. The only material available for diagnosis, tumour subtyping, and increasingly, for molecular analysis, is a small biopsy or cytology sample (Figure 46.9). Tumour subtyping may be difficult and inaccurate in this situation since most lung cancers comprise significant areas of undifferentiated tumour, which do not reflect the differentiated features present in other parts, which would determine the final, overall diagnosis if these were sampled, or if the whole lesion could be examined.

SCLC is reliably, consistently, and accurately diagnosed in small samples, but diagnosis of squamous cell and adenocarcinoma by H&E morphology alone can be inaccurate and inconsistent. Large cell, sarcomatoid, and mixed carcinomas, by definition, cannot be diagnosed consistently and accurately on such material. Carcinoid tumours should be recognized but usually cannot be ascribed to typical or atypical categories, whilst salivary type tumours may be recognized in good specimens.

Problems in recognizing a proportion of squamous cell and adenocarcinomas in small diagnostic samples led to the reasonable practice of diagnosing those cases where only undifferentiated carcinoma has been sampled as NSCLC not otherwise specified (NSCLC-NOS). This diagnosis may account for 20–40% of cases, depending on case mix, sample type, and pathologist experience or bias. The majority of NSCLC-NOS specimens are derived from differentiated tumours which have been poorly sampled; mostly adenocarcinomas. The need for more accurate subtyping has driven the use of immunohistochemistry (IHC) to predict the tumour subtype (IHC positive for p63, cytokeratin 5/6 or p40 predicts squamous cell carcinoma, TTF1 predicts adenocarcinoma) (Figure 46.10). This approach can accurately predict subtype in over 80% of cases, reducing the NSCLC-NOS rate to below 10%, a figure which cannot be reduced further, given the prevalence of large cell and sarcomatoid carcinomas in an unselected lung cancer population.

Symptoms

Increasing number of asymptomatic lung cancer patients are diagnosed with modern imaging techniques performed due to other indications. Typical symptoms from centrally located lung cancer include haemoptysis, cough, wheezing, dyspnoea, chest pain, and
Fig. 46.9 (A) This cytology cell block of a pleural fluid shows abundant, large cells of metastatic lung adenocarcinoma. These are in a clear majority of the cells in the fluid and numerous—adequate for molecular testing (H&E × 200). (B) This sample of bronchial washings shows a lot of debris, inflammatory cells but only a tiny cluster of tumour cells (bottom left). These were TTF1 positive but molecular testing would be very problematic on a sample like this (H&E × 200).
Fig. 46.10 (A) Mediastinal lymph node biopsy showing undifferentiated carcinoma lacking features to diagnose squamous cell or adenocarcinoma. This is NSCLC-NOS. Immunohistochemistry (B) shows strong TTF1 positivity so the diagnosis may be refined to 'NSCLC, probably adenocarcinoma' (× 200). (C) Lung core biopsy showing undifferentiated carcinoma lacking features to diagnose squamous cell or adenocarcinoma. This is NSCLC-NOS. Immunohistochemistry (D) shows strong p63 staining so the diagnosis may be refined to 'NSCLC, probably squamous cell carcinoma' (× 200).

frequent lung infections due to atelectasis. Peripheral lesion may be manifested by cough, pain due to invasion of chest wall, and dyspnoea. Tumours located in the superior sulcus are frequently associated with shoulder pain irradiating to forearm, fourth, and fifth fingers. Involvement of the lower brachial plexus is sometimes present with various degrees of neurological deficit. Horner's syndrome (myosis, ptosis, enophthalmos, and anhydrosis) is due to direct involvement of sympathetic chain. Mediastinal invasion may cause superior vena cava syndrome (SVCS) [18], dysphagia due to oesophageal compression or phrenic nerve palsy. Tumours or lymph nodes located at the aorto-pulmonary window typically result in hoarseness of voice due to recurrent laryngeal nerve palsy. Pleural involvement frequently results in accumulation of pleural fluid and dyspnoea. Occasionally, no primary tumour is present in radiological examinations of these patients, mimicking a clinical picture of mesothelioma. Pericardial involvement is a relatively infrequent but important cause of dyspnoea and other symptoms of cardiac tamponade. These two latter presentations are more frequent in patients with tumours harbouring ALK translocations [19].

A proportion of patients presents with symptoms resulting from metastatic spread. Brain metastases may lead to symptoms of increased intracranial pressure, seizures, or focal neurologic deficits. Bone metastases may cause pain and pathological fractures. An adrenal mass may occasionally be misdiagnosed as primary adrenal gland malignancy.

Lung cancer is relatively frequently associated with paraneoplastic syndromes [20]. Most common syndromes include syndrome of inappropriate antidiuretic hormone (ADH) excretion (SIADH), Cushing syndrome, hypercalcaemia due to production of parathyroid hormone-related protein (PTH-rp), carcinoid syndrome, neurological syndromes, hypertrophic pulmonary osteoarthropathy, and venous thromboembolism.

Diagnosis and staging

Diagnostic workup of patients with suspected lung cancer should include chest radiograms and computed tomography scans of the chest and upper abdomen. Pathological diagnosis remains the cornerstone of lung cancer management in all stages. For centrally located lesions, fibreoptic bronchoscopy (FOB) with forceps biopsy and brush cytology is recommended as a first step to establish tissue diagnosis. Careful description of bronchoscopic findings is essential for consideration of future surgery or definitive radiotherapy. Cytological examination of sputum is currently less frequently performed due to relatively low diagnostic accuracy. Peripheral lesions are accessible through fine needle aspiration, core needle biopsy, or video-assisted thoracic surgery (VATS), which should establish the diagnosis in 90–95% of cases in experienced hands. Although cytological diagnosis remains a valid proof of malignancy, histological diagnosis should be obtained whenever possible to ascertain precise histological subtyping. In patients with pleural effusions, inspection of pleural space through videothoracoscopy with biopsies of suspected lesions and cytological examination of pleural fluid should be performed. This procedure is often combined with

pleurodesis to prevent further episodes of symptomatic accumulation of fluid in the pleural cavity.

Use of 18-fluorodeoxyglucose (FDG) positron emission tomography integrated with computed tomography (FDG PET/CT) has changed the paradigm of lung cancer staging. FDG PET/CT is currently indicated in all lung cancer patients with no overt dissemination, who are potential candidates for treatment with curative intent—surgery, radiotherapy, or combined chemoradiation. In a randomized clinical trial of FDG PET/CT versus conventional staging, a significant reduction of futile thoracotomies of about 20% was observed [21]. FDG PET is sensitive, but not very specific, for determination of the malignant nature of the primary lesion. According to two meta-analyses, sensitivity and specificity of FDG PET is around 95% and 80%, respectively [22, 23]. Adenocarcinomas with bronchioalveolar component, carcinoids, and salivary gland carcinomas may show low tracer uptake, whereas squamous cell carcinomas are characterized by relatively high standardized uptake values (SUVs) [24]. Tumours less than 1 cm in diameter may show low FDG uptake due to the effect of respiratory motion and low PET spatial resolution.

FDG PET/CT is particularly useful for nodal staging and outperforms conventional CT in terms of diagnostic accuracy. Recent systematic review and meta-analysis of FDG PET/CT for mediastinal lymph node staging indicated pooled sensitivity of 76% and specificity of 88% (patient-based data) [25], which is higher than those formerly reported for conventional CT. High negative predictive value (NPV) of FDG PET/CT exceeding 90% for mediastinal lymph node involvement in most reports indicate that stage I patients with negative mediastinal scan results do not need to undergo invasive mediastinal staging. Due to the relatively high rate of false-positive FDG PET/CT, results of approximately 10–20%, endoscopic biopsies or mediastinoscopy should be undertaken to confirm N2 or N3 disease with the exception of large, radiologically evident metastatic lymph nodes present on CT scans.

Mediastinoscopy, a short surgical procedure done under general anaesthesia, remains standard to assess paratracheal and subcarinal lymph node stations (stations 2–4 and 7 according to International Association for the Study of Lung Cancer (IASLC) nodal classification) [26]. At present, endobronchial ultrasound-guided fine needle aspiration (EBUS-FNA) and transoesophageal endoscopic ultrasound-guided fine needle aspiration (EUS-FNA) have largely replaced mediastinoscopy for initial staging of the mediastinum in lung cancer patients and are considered appropriate for invasive staging of the mediastinum. These techniques can assess a wider range of lymph node stations than mediastinoscopy (EBUS: stations 2–4, 7, 10–12; EUS: stations 2L, 4L, 5, 7, 8, and 9). In the largest randomized trial [27] that compared endoscopic staging with mediastinoscopy, sensitivity to detect lymph node metastases was 79% and 85%, respectively (P = 0.47). In patients with mediastinal lymph node involvement who are candidates for radical surgery after induction treatment, mediastinoscopy should be reserved for assessment of lymph node status after initial staging with endoscopic techniques.

The currently used 7th edition of NSCLC TNM staging system was developed by the IASLC based on the database comprising 46 series of patients from collaborative groups and single institutions (a complete dataset of approximately 67 000 subjects) from more than 20 countries worldwide [28]. The staging classification was endorsed by the International Union against Cancer (IUCC) and the American Join Committee on Cancer (AJCC). The T category is subdivided into four subsets (T1–T4) according to tumour size, relationship to anatomical structures in the thorax, occurrence of satellite nodules, and presence of atelectasis (Table 46.1). Regional lymph node metastatic involvement may include N1 (bronchiopulmonary), N2 (ipsilateral mediastinal), or N3 (contralateral hilar, contralateral mediastinal, or supraclavicular) lymph node groups (Table 46.1). A revised map of thoracic lymph node stations was proposed and should be routinely used by pneumonologists, radiologists, thoracic surgeons, radiation oncologists, and all other health care professionals involved in the care of lung cancer patients (Figure 46.11) [29]. The M category is subdivided into M0 (no distant metastases), M1a (satellite lesions in contralateral lung or pleural involvement), or M1b (distant metastases).

Lung cancer stage definitions according to particular T, N, and M categories are shown in Table 46.2. Compared to previous staging system, approximately 15% of patients are placed into different stage categories leading to more accurate associations with outcome [28]. Most notable changes include shift of T3N0 category from previous IIIA to IIB stage group, distinction of satellite nodules in the same lobe as T3 category, in different ipsilateral lobe as T4 category, in the contralateral lobe as M1a category, and shift of pleural involvement from T4 category into M1a category, resulting in a shift of previous stage IIIB patients with this feature into current stage IV. The proportion of NSCLC patients surviving five years from diagnosis according to pathological stage is approximately 60–80% for stage I, 30–50% for stage II, 15–25% for stage III, and below 10% for stage IV, depending on published series.

Management of early stage non-small cell lung carcinoma

Surgery

Surgical resection of the lung remains the best treatment for patients with lung cancer whose extension is limited to the primary lesion or to the hilar lymph nodes, provided that the patient has good functional reserve. These patients belong to stage IA, IB, IIA, and IIB. Since the stage IIIA is very heterogeneous, surgery for patients with stage IIIA disease is sometimes controversial. A patient with IIIA disease without mediastinal lymph node involvement (T3N1, T4N0–1) can be considered as a surgical candidate usually in combination with chemo- or radiochemotherapy. It should be noted that chemotherapy adds significant, albeit modest, survival benefit. The T4 category ranges from invasion of mediastinal fat tissue to direct invasion to the aorta, or the heart itself. Combined resection of the superior vena cava or left atrium is usually feasible without the aid of cardiopulmonary bypass and sometimes is performed in combination with other modalities of therapy. Resections that require cardiopulmonary bypass are considered to be highly experimental.

Treatment for tumours with mediastinal lymph node involvement (N2 disease) is even more controversial. N2 disease is again heterogeneous in clinical outcome when treated by primary surgery. According to Andre et al., five-year survival rate for N2 diseases that were not detected preoperatively involving one lymph node level ('incidental' N2) was 34% and those with multiple level involvement was 11%, whereas those that were detected preoperatively with one level involvement was 8% and those with multiple level involvement was 3% [30]. Therefore, single station N2 disease candidates are often considered for surgery, usually combined with chemo/

Table 46.1 Definitions of T, N, and M descriptors of 7th TNM classification of lung cancer

T (primary tumour)	
Tx	Primary tumour cannot be assessed, or tumour proven by the presence of malignant cells in sputum or bronchial washings but not visualized by imaging or bronchoscopy
T0	No evidence of primary tumour
Tis	Carcinoma in situ
T1	Tumour ≤3 cm, surrounded by lung or visceral pleura, not more proximal than the lobar bronchus[a]
T1a	Tumour ≤2 cm in greatest dimension
T1b	Tumour >2 but ≤3 cm in greatest dimension
T2	Tumour >3 cm but ≤7 cm or tumour with any of the following features (T2 tumours with these features are classified T2a if ≤5 cm): - Involves main bronchus, ≥2 cm distal to the carina - Invades visceral pleura - Associated with atelectasis or obstructive pneumonitis that extends to the hilar region but does not involve the entire lung
T2a	Tumour >3 but ≤5 cm in greatest dimension
T2b	Tumour >5 but ≤7 cm in greatest dimension
T3	Tumour >7 cm or one that directly invades any of the following: chest wall (including superior sulcus tumours), diaphragm, phrenic nerve, mediastinal pleura, parietal pericardium; or tumour in the main bronchus <2 cm distal to the carina[a] but without involvement of the carina; or associated atelectasis or obstructive pneumonitis of the entire lung or separate tumour nodule(s) in the same lobe
T4	Tumour of any size that invades any of the following: mediastinum, heart, great vessels, trachea, recurrent laryngeal nerve, oesophagus, vertebral body, carina; separate tumour nodule(s) in a different ipsilateral lobe
N (regional lymph nodes)	
NX	Regional lymph nodes cannot be assessed
N0	No regional node metastasis
N1	Metastasis in ipsilateral peribronchial and/or ipsilateral hilar lymph nodes and intrapulmonary nodes, including involvement by direct extension
N2	Metastasis in ipsilateral mediastinal and/or subcarinal lymph node(s)
N3	Metastasis in contralateral mediastinal, contralateral hilar, ipsilateral or contralateral scalene, or supraclavicular lymph node(s)
M (distant metastasis)	
MX	Distant metastasis cannot be assessed
M0	No distant metastasis
M1a	Separate tumour nodule(s) in a contralateral lobe; tumour with pleural nodules or malignant pleural (or pericardial) effusion[b]
M1b	Distant metastasis

[a] The uncommon superficial spreading tumour of any size with its invasive component limited to the bronchial wall, which may extend proximally to the main bronchus, is also classified as T1.

[b] Most pleural (and pericardial) effusions with lung cancer are due to tumour. In a few patients, however, multiple cytopathologic examinations of pleural (pericardial) fluid are negative for tumour, and the fluid is nonbloody and is not an exudate. Where these elements and clinical judgment dictate that the effusion is not related to the tumour, the effusion should be excluded as a staging element and the patient should be classified as T1, T2, T3, or T4.

Reproduced from Goldstraw P et al., The IASLC Lung Cancer Staging Project: proposals for the revision of the TNM stage groupings in the forthcoming (7th) edition of the TNM classification of malignant tumours, *Journal of Thoracic Oncology*, Volume 2, Number 8, pp. 706–714, Copyright © 2007 International Association for the Study of Lung Cancer, with permission from Lippincott Williams and Wilkins/Wolters Kluwer Health.

radiotherapy in clinical practice. As discussed later, it is clear that post-operative adjuvant chemotherapy adds significant and modest survival benefit to stage III patients. However, for patients with N2 disease that were preoperatively diagnosed, there have been no clinical trials that clearly proved the role of pulmonary resection.

Removal of the affected pulmonary lobe (lobectomy) with mediastinal and hilar lymph node dissection remains a standard procedure. The extent of pulmonary resection is primarily based on the results of randomized trial performed by Lung Cancer Study Group reported in 1995 comparing standard lobectomy with limited
Fig. 46.11 Lymph node map for the 7th edition of lung cancer staging system.

Table 46.2 Stage categories according to T, N, and M descriptors of 7th TNM classification of lung cancer

T/M	Subgroups	N0	N1	N2	N3
T1	T1a	IA	IIA	IIIA	IIIB
	T1b	IA	IIA	IIIA	IIIB
T2	T2a	IB	IIA	IIIA	IIIB
	T2b	IIA	IIB	IIIA	IIIB
T3	T3	IIB	IIIA	IIIA	IIIB
T4	T4	IIIA	IIIA	IIIB	IIIB
M1	M1a	IV	IV	IV	IV
	M1b	IV	IV	IV	IV

Reproduced from Goldstraw P et al., The IASLC Lung Cancer Staging Project: proposals for the revision of the TNM stage groupings in the forthcoming (7th) edition of the TNM classification of malignant tumours, *Journal of Thoracic Oncology*, Volume 2, Number 8, pp. 706–714, Copyright © 2007 International Association for the Study of Lung Cancer, with permission from Lippincott Williams and Wilkins/Wolters Kluwer Health.

resections (segmentectomy or wedge resection) for patients with tumours ≤3cm and no lymph node involvement [31]. This trial showed a trend toward worse outcomes in the patients with limited resection (one sided P = 0.062) [31].

Lymph node dissection is aimed to provide accurate lymph node staging and possibly therapeutic benefit. Although there is no doubt that lymph node dissection provides best staging, the therapeutic role of lymph node dissection is not clear as there have been limited numbers of phase III trials asking this question and their results have been inconsistent.

Recently, the American College of Surgeons has performed a randomized trial of mediastinal lymph node sampling vs lymph node dissection during pulmonary resection in patients with N0 or N1 non-small cell lung carcinoma [32]. In this trial, 2R, 4R, 7, and 10R lymph nodes for right-sided tumours and 5, 6, 7, and 10L for left-sided tumours were sampled, and when all these nodes were negative, patients were randomized either to perform complete lymph node dissection (dissection group) or to no further sampling (sampling group) [32]. There was no survival difference between two arms; the median survival was 8.1 years for the sampling group and 8.5 years for dissection (P = 0.25) [32]. The extensive sampling procedure makes the interpretation of the results difficult. The authors offered the caveats that these results are not generalizable to patients staged radiographically or those with higher stage tumours [32].

When the tumour is large and is located close to pulmonary hilus, it is not possible to remove the tumour by lobectomy. If surgery is indicated in such cases at all, pneumonectomy needs to be performed. Such indication should be carefully assessed and weighted against radical radiochemotherapy by experienced surgeon in a multidisciplinary team, because pneumonectomy (especially right-sided) may potentially cause significant morbidity and mortality. It is not always possible, but in some cases bronchoplastic procedure such as sleeve lobectomy can replace pneumonectomy without deterioration of long-term survival. For patients with poor pulmonary reserve or those with tumours with a supposedly benign nature, segmentectomy or wedge resection may be selected depending on tumour size, location, malignant potential, and patients' physiological condition.

Although limited resection is inferior to standard lobectomy, recent innovation of diagnostic imaging has made it possible to diagnose tumours of smaller size and with less opaque (ground glass-like) shadow. For these types of tumours, limited resection may be sufficient. The Japan Clinical Oncology Group prospectively evaluated preoperative thin-section computed tomography for its ability of prediction of non-invasiveness in clinical T1N0M0 peripheral lung tumours [33]. In a group of 545 patients, they concluded that radiological non-invasive peripheral lung adenocarcinoma could be defined as an adenocarcinoma ≤2.0 cm in diameter with ≤0.25 cm consolidation to the maximum tumour diameter [33]. Several clinical trials validating limited resection strategies for patients with tumours measuring less than 2 cm are underway.

There are several ways to access the lung during surgery. Posterolateral thoracotomy has been the standard for pulmonary resection in which the incision is about 30 cm in length and it starts at point midway between the medial border of the scapula and the thoracic spine, then it curves a little below the tip of the scapula and turns to run parallel with the ribs and extends to the submammary crease, usually dissecting latissimus and anterior serratus muscle. Recently, some surgeons prefer to use muscle-sparing thoracotomy in which division of latissimus or anterior serratus muscle is avoided. This thoracotomy can be used for most pulmonary surgeries including pneumonectomies or bronchoplastic procedures.

With the advent of appropriate imaging technology, VATS is becoming popular. It is expected that less invasion to the chest wall will result in less pain, shorter hospital stay, and less morbidity. However, recent systematic review evaluating two randomized and 19 non-randomized trials that compared VATS lobectomy with open lobectomy (most of them are through posterolateral thoracotomy) suggested that there was no statistically significant difference between two groups in terms of prolonged air leak, arrhythmia, pneumonia, or mortality [34].

In general, pulmonary resection has become a safe procedure with 30-day mortality below 3%. For example, in 11 663 pulmonary resections performed in Japan in 2004, grade >3 post-operative complication occurred in 523 (4.5%) and 30-day mortality was 0.4% [35]. Complications after lung cancer surgery are mostly related to cardiopulmonary sequelae.

Adjuvant post-operative chemotherapy

Results of meta-analysis of adjuvant chemotherapy trials in resected NSCLC published in 1995 provided the first unequivocal evidence favoring such treatment (5% survival improvement) [36]. Since then, several randomized trials have been conducted [37–42]. Most of the trials, summarized in Table 46.3, used cisplatin or carboplatin with new generation cytotoxic agents. In two meta-analyses that included recent adjuvant studies, an approximate 5% absolute survival improvement was indeed observed [43, 44]. The benefit was confined to patients with stage II and stage III disease. In stage IB, only patients with tumours larger than 4 cm appeared to benefit, whereas stage IA patients tended to have worse outcomes with adjuvant treatment. A performance status of 2 was associated with no benefit from adjuvant therapy. Current indications for adjuvant chemotherapy include pathological stage II and III NSCLC patients with complete postsurgical recovery and no contraindications to this therapy due to comorbidities. The use of adjuvant treatment in stage IB patients with larger tumours remains controversial. The benefit is observed irrespectively of gender, age, and histological

Table 46.3 Selected large clinical trials with adjuvant chemotherapy in non-small cell lung cancer

Trial [ref]	Number of patients	Chemotherapy agents (number of cycles)	Pathological stage	Survival probability at 5 years (experimental vs control group)	Survival hazard ratio (95% CI)	P value
IALT [36]	1865	Cisplatin/etoposide (3–4) Cisplatin/vinorelbine (3–4) Cisplatin/vinblastine (3–4) Cisplatin/vindesine (3–4)	I-III	44–5% vs 40–4%	0.86 (0.76–0.98)	<0.03

subtype. Since most of the adjuvant chemotherapy trials used platinum doublets with either vinorelbine or paclitaxel, these agents are commonly used in practice. Survival gain from adjuvant treatment appears to be less pronounced after longer observation in some, but not all, clinical trials, indicating possible impact of long-term toxicities from chemotherapy.

Based on the analyses of tumour tissue material from adjuvant chemotherapy trials, several biomarkers were proposed to associate with improved outcomes. Immunohistochemical expression of excision-repair cross-complementary 1 protein (ERCC1, a protein involved in the nucleotide excision repair pathway of DNA damage) appeared most promising for application in routine practice to select patients for adjuvant treatment. High ERCC1 expression was thought to be associated with lack of benefit from (platinum-based) adjuvant chemotherapy. A large validation study performed in the cohort of participant of the IALT adjuvant chemotherapy trial did not confirm the previous observations. No biomarker is currently recommended for use for selection of NSCLC patients to adjuvant therapy outside of clinical trials.

Current clinical research strategies to improve outcomes of NSCLC patients with post-operative adjuvant treatments include the use of targeted therapies in molecularly-selected subsets of patients, use of anti-angiogenic agents or immunotherapeutics, and selection of patients based on molecularly-defined risk scores. Until the results of clinical trials testing these strategies become available, they are not recommended for management of NSCLC patients outside of clinical trials.

Radical radiotherapy

The efficacy of modern conventional radiotherapy in patients with early-stage NSCLC is modest and most of the patients experience local relapse after treatment [45]. Most of the series exploring radical radiotherapy in early-stage NSCLC reported outcomes of those patients who were inoperable due to comorbidities or did not wish to undergo surgery. These patients remain at high risk of death due to other causes, such as chronic obstructive pulmonary disease (COPD) or cardiovascular disease. In patients with node-negative NSCLC, stereotactic radiotherapy (SBRT) is associated with

excellent long-term loco-regional control approaching surgical results of at least 70% and usually in the range of 80–95% [46]. The procedure is now widely used in developed countries and was demonstrated to impact on survival of early-stage NSCLC cohorts according to Dutch cancer registry data [47]. Main inclusion criteria for SBRT are pathological proof of malignancy (positive PET scan is acceptable only in patients for whom pathological confirmation is not possible) and outside of clinical trials size of less than 5 cm, location not adjacent to mediastinal structures or main bronchi and lymph node-negative disease as assessed by PET (mandatory). Strict radiotherapy quality control measures must be in place, including assessment of respiratory movement of the tumour during treatment planning and image-guided radiotherapy delivery. There is no universal agreement on the best fractionation schedule, but 54 Gy in three fractions, 55 Gy in five fractions or 60 Gy in eight fractions are commonly used in Europe and North America, or 48 Gy in four fractions in Japan. Current clinical studies are evaluating SBRT in larger or centrally located tumours. The use of sequential or concomitant chemotherapy or targeted agents in patients with early NSCLC treated with SBRT is not recommended. Patients with stage II disease who are not candidates for surgery should be managed outside of clinical trials with conventional definitive radiotherapy or radiochemotherapy, depending on comorbidities.

Management of locally advanced non-small cell lung carcinoma

Stage III NSCLC, according to the 7th edition of the AJCC TNM classification, describes a very heterogeneous group of different clinical entities, varying from the T3N1 category of patients to those with ipsilateral (N2) or contralateral (N3) mediastinal lymph node involvement. Management of patients with N2 or N3 lymph node stations involved by the tumour continues to be debated, mainly because of lack of sufficient evidence from randomized clinical trials regarding particular subsets. Several sub-classifications according to the extent of N2/N3 disease were proposed [48, 49] to formally address this need, yet none have been introduced into routine clinical practice. One of the proposals suggests describing N2/N3 nodal

involvement as 'incidental' (i.e., unsuspected after careful nodal evaluation with PET and invasive staging), 'discrete', or 'minimal' when single or multiple normal or moderately enlarged lymph nodes are confirmed at staging and 'infiltrative' or 'bulky' when large nodes with possible mediastinal infiltration are present [49]. Other classifications emphasize single versus multiple nodal station involvement.

Historically, patients with 'resectable' stage IIIA N2 disease were treated with surgery and those with 'unresectable' IIIA and IIIB disease were treated with definitive radiotherapy. Results of both treatment modalities were unsatisfactory with five-year survival rates of approximately 5–15% [50, 51]. Patients with 'unsuspected' mediastinal nodal involvement discovered in post-operative pathological evaluation despite thorough preoperative staging according to current standards represent a relatively minor proportion, probably less than 10% of the operable NSCLC population. These patients should be treated with post-operative chemotherapy, with an expected absolute survival benefit of approximately 5% at five years [44]. The role of post-operative radiotherapy in pN2 patients with complete pathological resection (R0) remains unclear and should be a subject of individual risk/benefit evaluation. According to post-operative radiotherapy (PORT) meta-analysis on the role of adjuvant radiotherapy in surgically treated NSCLC [52, 53] patients with mediastinal nodal involvement had neither clear benefit nor detriment from radiation, whereas a survival detriment was clearly demonstrated for patients with pathological stage I and II. Post-operative radiotherapy resulted in improved local control in approximately half of the trials included in the PORT meta-analysis. Since the results of PORT meta-analysis are based on trials conducted more than two decades ago with outdated radiotherapy techniques, current evidence in support or against post-operative radiotherapy in patients with mediastinal nodal involvement remains weak. An ongoing phase III randomized study, Lung ART, should clarify the role of radiotherapy versus observation in patients with post-operative mediastinal nodal involvement. In the meantime, routine post-operative radiotherapy, typically in the dose of 54 Gy, is recommended in some centres in patients with a high risk of relapse (extracapsular extension or by individual assessment by surgeon), whereas other centres do not advocate this therapy. If chemotherapy and radiotherapy is indicated, chemotherapy should probably be administered sequentially to minimize toxicity [49], although no clear evidence exists regarding this strategy.

In patients who have pathologically proven 'potentially resectable' mediastinal lymph node involvement at presentation ('minimal N2') and in patients with unresectable stage III NSCLC ('infiltrative N2' and N3), the role of chemotherapy remains well established and optimal local treatment remains a matter of discussion. Based on two large randomized phase III trials, the role of surgery in both categories of patients appears minimal. The Integroup 0139 trial conducted in the United States randomly allocated patients with stages T1–3 N2 NSCLC to induction radiochemotherapy (radiation dose of 45 Gy with concurrent cisplatin 50mg/m^2 days 1, 8, 29, and 36 and etoposide 50mg/m^2 days 1–5 and 29–33) followed by surgery within three to five weeks in non-progressing patients or to definitive radiochemotherapy (radiation dose of 61 Gy, chemotherapy as above). Patients in both groups received two cycles of consolidation chemotherapy. The trial demonstrated no difference in overall survival (OS) (median of 23.6 months in group with surgery vs 22.2 months in group without surgery; HR = 0.87; P = 0.24). Progression-free survival was longer in patients randomized to surgery (median of

12.8 months vs 10.5 months; HR = 0.77; P = 0.017). Early mortality not attributable to lung cancer was higher in the surgical group (8% vs 2%, respectively), particularly after pneumonectomy. In an unplanned post hoc analysis of patients treated with lobectomy vs matched cohort receiving definitive chemoradiation, approximately 10% long-term survival advantage was noted. The authors concluded that potential benefit for patients treated with surgery was offset by increased complications and mortality from tri-modality treatment. The 08941 phase III trial by the EORTC Lung Cancer Group included patients with 'unresectable N2' NSCLC, a notable difference from the INT0139 trial discussed above. Patients were treated with three cycles of cisplatin or carboplatin induction chemotherapy doublet, most frequently with gemcitabine or a taxane, and then randomly allocated to surgery vs definitive radiotherapy (60–62.5 Gy to involved primary tumour and mediastinal lymph nodes and 40–46 Gy to uninvolved mediastinum). The response rate to induction treatment was 61%. Compliance with assigned treatment was high (92% and 93%, respectively). There was no survival difference for patients allocated to surgery (median of 16.4 months) as compared to radiotherapy (median of 17.5 months).

Based on the above trials, definitive radiochemotherapy is considered a standard treatment for most patients with stage III NSCLC. Given the subset results of INT 0139 and relative good long-term outcomes of some phase II trials [54], a few institutions continue to recommend surgery in very carefully selected patients with N2 disease after induction treatment (chemotherapy or concurrent chemoradiation). The decisions regarding the optimal choice and sequence of treatment must be taken by multidisciplinary teams of thoracic surgeons, radiation oncologists, medical oncologists, radiologists, pathologists, and pulmonologists. The additional value of radiotherapy added to chemotherapy in this setting is being uncertain and questioned [55]. Pneumonectomy after induction treatment should be avoided given high mortality rates of this procedure. Treatment should be given in high volume centres experienced in multimodality care.

Definitive radiochemotherapy should optimally consist of concurrent radiation and two cycles of cisplatin-based chemotherapy. Current radiotherapy recommendations in stage III NSCLC define target volumes around the tumour and involved nodal regions with appropriate margins, with no elective mediastinal irradiation [56, 57]. Technical advances in radiotherapy, such as PET-based treatment planning, control of respiratory motion by 4D CT, and image-guided radiotherapy delivery, are extremely important for achieving good outcomes. Radiotherapy plans should be qualitatively evaluated for dose distribution in critical organs, such as lung, oesophagus, spinal cord, heart, and brachial plexus to minimize radiation-induced toxicity. International guidelines are available to assist radiation oncologists in making appropriate choices based on dose distribution within organs at risk [58–60]. To select an optimal dose-distribution of a treatment plan, radiation oncologists should consider these guidelines within the context of the institutional experience and predefined quality control procedures. Minimal standards for definitive thoracic radiotherapy include 3D conformal radiotherapy planning and image-guided radiotherapy delivery according to the institutional protocol. Intensity modulated radiation therapy (IMRT) is commonly used in order to reduce radiation dose to the lung and oesophagus.

The value of concurrent vs sequential chemotherapy and radiotherapy in stage III NSCLC was tested in several clinical trials.

Meta-analysis of these trials [61] indicated an absolute benefit for concurrent treatment of 4.5% at five years (HR = 0.84, P = 0.004) at the expense of increased G3–4 acute esophageal toxicity (from 4–18%) with no difference regarding acute pulmonary toxicity. Cisplatin-etoposide (at full systemic doses) or cisplatin-vinorelbine (with decreased dose of vinorelbine) remain the most extensively studied regimens. Preliminary results of concurrent treatment with novel agents, such as pemetrexed or cetuximab, do not appear promising, although full results of several studies are awaited. The strategies of induction chemotherapy followed by concurrent radiochemotherapy [62] or concurrent radiochemotherapy followed by consolidation chemotherapy [63] have not led to improvement of survival in stage III NSCLC and are not recommended in a routine care.

In a preliminary report from RTOG 0617 phase III trial, conventionally-fractionated 60 Gy and 74 Gy radiotherapy doses were directly compared [64]. In this factorial design study, patients received concurrent chemotherapy (weekly doses of carboplatin and paclitaxel) and cetuximab or placebo, followed by consolidation treatment. Patients who received higher radiotherapy dose had significantly worse survival (median of 20.3 vs 28.7 months in the control group, P = 0.0007). No survival benefit was observed with the addition of cetuximab. In the RTOG 0617 trial, many centres included only few patients. Potential reasons for the unexpected results may lie in under-reported toxicity and in too-tight target volume margins in the high dose arm of the study. While full explanation of the results of RTOG 0617 awaits clarification, the dose of 60 Gy remains the standard of care with concurrent chemotherapy in stage III NSCLC in many institutions. A considerable number of institutions continue to use higher total radiotherapy doses of 66Gy, often exceeding 2 Gy per fraction (hypofractionation), sometimes with simultaneous integrated boost technique. In patients who are not eligible for concurrent radiochemotherapy due to age or comorbidities, sequential chemotherapy and radiation remains the best option. Those who are not eligible for chemotherapy should be treated with definitive radiotherapy alone.

Hyperfractionated and accelerated treatments were evaluated in a meta-analysis of several trials in non-metastatic NSCLC, most of which assessed different schedules of radiotherapy given alone or after induction chemotherapy. A small, but significant, advantage for accelerated schedules was observed with a 2.5% improvement in five-year survival (HR = 0.88, P = 0.009). Significantly better loco-regional outcomes were associated with highly accelerated schedules, emphasizing the importance of overall treatment time. The duration of definitive radiotherapy in stage III NSCLC should thus not be protracted (six weeks or even shorter whenever possible). Results of the CHARTWEL trial [65] indicate that the short overall time of radiotherapy delivery is particularly important in case of patients who received neoadjuvant chemotherapy (still significant proportion of patients treated worldwide) and for large tumours. Sequential schedules with highly accelerated radiotherapy are considered as important clinical research strategies to overcome the limitations of concurrent treatment.

Management of metastatic non-small cell lung carcinoma

More than half of NSCLC patients are diagnosed with metastatic disease; in addition, the majority of patients treated with curative intent for early or locally advanced disease will eventually relapse and develop metastatic disease. With the exception of a small proportion of patients presenting with oligometastatic disease, the prognosis of patients with stage IV NSCLC is fatal with a median survival of 9–15 months and a one-year survival of 30–58% [66, 67]. Systemic therapy is offered to patients with an Eastern Cooperative Oncology Group (ECOG) performance status (PS) of 0 to 2, aiming at prolongation of survival and maintaining quality of life. Therapy is individualized based on histological subtype, molecular pathology, age, comorbidities, expected toxicity, and patient preferences. Selected, practice-changing clinical trials addressing the role of chemotherapy in advanced NSCLC are summarized in Table 46.4.

Treatment for patients with metastatic NSCLC has historically consisted of systemic cytotoxic chemotherapy [68]. The identification of distinct subsets of NSCLC driven by specific genetic alterations, predicting for the benefit from targeted therapies, has substantially impacted on therapeutic strategies and improved outcome figures for molecularly-defined subsets of patients. Patients with tumours harbouring an activating mutation of the epidermal growth factor receptor (EGFR) or rearrangement of anaplastic lymphoma kinase (ALK) gene should be managed with an EGFR or ALK tyrosine kinase inhibitor (TKI), respectively. Other molecular aberrations, as for example HER2 and BRAF mutations, ROS1, and RET rearrangements, are amenable to targeted therapy and likely to influence lung cancer therapeutic portfolio in the very near future. For all other molecular subgroups representing the vast majority of NSCLC patients, cytotoxic chemotherapy remains the backbone of first-line treatment.

Management of patients with non-small cell lung carcinoma not characterized by a genetic driver alteration

First-line chemotherapy

Chemotherapy prolongs survival as compared to best supportive care, with a meta-analysis reporting a 27% relative reduction in the risk of death equivalent to a 10% improvement in one year survival [69, 70].

Platinum-based combination chemotherapy is considered the standard of care in first-line treatment for patients with good performance status. Third generation cytotoxic agents with documented single-agent activity in NSCLC include vinorelbine, gemcitabine, paclitaxel, docetaxel, irinotecan, and pemetrexed. The addition of a second drug to a single-agent regimen significantly increases the response rate (RR), one-year survival, and median overall survival at the expense of higher toxicity [71]. Three drug regimens further increase RR over two drug regimens, but fail to prolong survival, and are associated with increased toxicity [72].

Three meta-analyses evaluating the role of platinum-based vs platinum-free doublets reported a benefit in one-year survival in favour of platinum-based doublets, albeit of marginal statistical significance. This benefit was shown to be restricted to cisplatin in one analysis, and was absent when platinum-based doublet regimens were compared to third generation platinum-free doublets in another study. Platinum-based treatment was associated with a higher incidence of severe toxicity [73–75].

Three meta-analyses have shown a higher response rates for cisplatin when compared with carboplatin combinations. In the individual patient data meta-analysis of nine randomized trials with

NR, not reported.

almost 3000 patients [76], survival figures with cisplatin regimens were non-significantly better (median survival of 9.1 vs 8.4 months, respectively, P = 0.10). In the subset analysis, significantly superior efficacy was noted in the subgroup of non-squamous tumours and in patients treated with third generation cytotoxics. Cisplatin-based chemotherapy was associated with more nausea and vomiting as well as peripheral neuropathy and renal impairment, while haematological toxicity was higher with carboplatin [76–78].

No single regimen has clearly demonstrated superiority in unselected patients with advanced NSCLC. The largest trial comparing different platinum-based doublet regimens (cisplatin-paclitaxel, cisplatin-gemcitabine, cisplatin-docetaxel, carboplatin-paclitaxel) failed to demonstrate any difference in response or survival among the four arms [66]. Pemetrexed is preferred to gemcitabine in patients with non-squamous tumours based on a survival benefit demonstrated in a planned subgroup analysis of a randomized phase III first-line trial, whereas it was shown inferior in patients with tumours of squamous histology [79].

Maintenance therapy

Prolongation of the initial chemotherapy doublet from four to six cycles did not improve survival and resulted in substantial additional toxicity in a randomized phase III trial [80]. Prolongation of treatment beyond four to six cycles was associated with a statistically significant improvement in progression-free survival (PFS), and a modest but significant improvement in survival in one meta-analysis. Prolongation of treatment, however, was also associated with a higher rate of adverse events and possible impairments of health-related quality of life [81]. Two further meta-analyses evaluating the effects of prolonged first-line third generation platinum doublet chemotherapy beyond four cycles could not demonstrate any improvement in OS [82, 83], establishing the standard of frontline 4 cycles of platinum-based chemotherapy [83].

In clinical practice, only 50–60% of patients receive second-line treatment, with rapid disease progression being the main reason for not administering subsequent therapies. In an attempt to improve the results of first-line combination therapy administered for a standard number of cycles, several maintenance strategies have been tested, either continuing one agent previously administered as first-line (continuation maintenance) or commencing an agent with a different mechanism of action (switch maintenance). Maintenance therapy is given without treatment-free period after the completion of first-line chemotherapy. Numerous randomized trials have demonstrated that maintenance treatment is associated with an improvement of PFS, as well as OS to a variable extent depending on defined strategy [84].

Docetaxel switch maintenance improves PFS with a trend for OS improvement after four cycles of carboplatin and gemcitabine, with no detrimental effect in quality of life [85]. Erlotinib switch maintenance therapy improved PFS in two randomized trials. OS was prolonged with erlotinib in the largest, adequately powered trial to detect such differences, but this benefit was restricted to patients with stable disease after completion of first-line chemotherapy. This benefit was also seen in the patient subgroup without activating mutation of the EGFR gene [86, 87]. These results could not be reproduced with gefitinib switch maintenance [88]. Continuation maintenance with gemcitabine was tested in three randomized clinical trials, with improvement in time-to-treatment failure (TTF) or PFS in two, without improvement in survival, potentially

because of sample size [87, 89]. Pemetrexed, either as switch maintenance or continuation maintenance, improves both PFS and OS, with no significant impact on quality of life [90, 91]. Its use should be restricted to patients with non-squamous tumours [92].

To date, there is no definite clinical parameter or biomarker helping to identify patients at risk of rapid progression that would potentially benefit more from a maintenance strategy. In addition, there is very limited comparative evidence among the different maintenance options, and maintenance decisions are currently often left to the physician's clinical judgment and subject to discussion with the patient.

Maintenance therapy should not be offered to patients with a performance status of 2 or greater or with persistent chemotherapy-induced toxicity. Furthermore, despite the low rate of grade 3 or 4 toxicities during maintenance treatment, the prolonged exposure of patients to grade 1 or 2 toxicities may be of significant concern.

Elderly patients and patients with poor performance status

Age and comorbidity may limit tolerance to chemotherapy. Single-agent chemotherapy offers a survival benefit compared to best supportive care in elderly NSCLC patients, where gemcitabine was shown similar activity to vinorelbine [93, 94]. The combination of monthly carboplatin with weekly paclitaxel in patients aged 70–89 years with PS 0–2 offers an advantage in PFS and survival over single-agent treatment with either vinorelbine or gemcitabine [95]. In patients with performance status of 2, combination therapy of carboplatin and pemetrexed offers a significant survival advantage over pemetrexed alone [96].

Addition of targeted agents to chemotherapy in first-line treatment

Bevacizumab, a monoclonal antibody against vascular endothelial growth factor (VEGF), improved survival when administered concurrently with paclitaxel and carboplatin and continued until disease progression in patients with non-squamous NSCLC [97]. Another large placebo-controlled randomized trial with two doses of bevacizumab combined with gemcitabine-cisplatin failed to demonstrate survival advantage [98], although PFS prolongation was observed. A meta-analysis of four randomized trials demonstrated a clinically marginal survival improvement with bevacizumab (HR = 0.90, P = 0.03) as compared with chemotherapy alone [99]. Bevacizumab treatment is associated with a higher risk of thrombosis, hypertension, bleeding, proteinuria, and pulmonary haemorrhage [100]. When considering bevacizumab therapy, an individualized risk-benefit assessment should be undertaken in all patients. Bevacizumab is contraindicated in patients with squamous NSCLC or history of haemoptysis, but can be used in patients with previously treated brain metastases and in patients with full anticoagulation [101].

Cetuximab, a monoclonal antibody against EGFR, has been tested in two first-line phase III trials in combination with cisplatin-vinorelbine or cisplatin-taxane [102, 103]. A modest survival prolongation was observed in the first trial only. EGFR protein expression intensity was retrospectively identified as a potential predictive biomarker of cetuximab efficacy. Due to conflicting results, cetuximab is no longer being developed in

the indication of NSCLC. Necitumumab, another monoclonal antibody against EGFR, has been tested in two parallel first-line phase III trials in combinations with platinum-based chemotherapy. The first trial, comparing necitumumab plus pemetrexed and cisplatin with pemetrexed and cisplatin alone in patients with previously untreated non-squamous NSCLC was stopped early based on the absence of any difference in overall survival between treatment groups [104]. The second trial, focusing on squamous NSCLC patients using a gemcitabine and cisplatin chemotherapy backbone demonstrated a modest improvement in survival, with no improvement of the objective response rate or median PFS [105].

Second-line and subsequent lines of treatment

All patients inevitably develop progressive disease after first-line chemotherapy. Second-line treatment with either chemotherapy or EGFR TKI may provide symptom palliation and prolong survival. Combination regimens have failed to show any survival benefit over single-agent regimens in one meta-analysis [106]. Erlotinib was shown to improve survival in unselected second-line or third-line NSCLC patients not eligible for further chemotherapy with tumours of all histologies [107]. Docetaxel significantly improved survival compared with best supportive care [108]. Pemetrexed showed similar RR and survival in a comparison with docetaxel, with less toxicity [109]. Erlotinib was also shown to be of similar efficacy compared with docetaxel or pemetrexed in unselected patients refractory to first-line platinum-based chemotherapy [110]. Gefitinib was proven non-inferior to docetaxel [111]. Also in the second-line setting, afatinib, an irreversible second-generation pan-Her TKI inhibiting EGFR, HER2 and HER4, has demonstrated a modest median OS benefit when compared to erlotinib in patients with squamous cell carcinoma of the lung [112]. Median PFS, disease control rate, and global health status/quality of life were also improved, while toxicity was higher. It should be noted, however, that when NSCLC patients are selected by EGFR gene mutation status, those with tumours characterized by a wild-type EGFR demonstrate a better survival when treated with second-line docetaxel as compared to erlotinib [113–115] as shown by a randomized phase III trial and at least two meta-analyses. Thus, assessment of EGFR mutation status in tumours is mandatory for clinical decisions favouring EGFR TKIs or chemotherapy. In case of EGFR mutation-positive or negative NSCLC, EGFR TKIs are not considered an appropriate second-line treatment for patients considered fit to receive chemotherapy.

The addition of anti-angiogenic agents to docetaxel has been shown to improve its efficacy. Ramucirumab, a human monoclonal antibody against the extracellular domain of vascular endothelial growth factor receptor 2 (VEGFR-2), showed improved response rate, median PFS, and OS compared to docetaxel alone, in patients with both squamous and non-squamous histology [116]. The addition of nintedanib, an oral angiokinase inhibitor to VEGFR1-3, fibroblast growth factor receptors (FGFR) 1-3, and platelet-derived growth factor receptors (PDGFR) alpha and beta, showed a benefit in median PFS compared to docetaxel in patients with NSCLC, and a benefit in median OS compared to docetaxel but only restricted to the patients with adenocarcinoma, an effect also shown to be most prominent in those patients who had progressed within nine months after initiation of first-line therapy in a retrospective subgroup analysis [117].

Additional anticancer agents, including gemcitabine, paclitaxel, vinorelbine, topotecan, and irinotecan, show some activity in chemotherapy-pretreated patients, but have not been adequately evaluated in randomized clinical trials and thus are not routinely recommended. Efficacy of all agents in this setting is generally poor, with response rates below 10% and median survival around six months. Significant improvements in overall quality of life with second-line treatment are infrequent. Quality of life can nevertheless be maintained using single-agent docetaxel or pemetrexed [109, 118].

Recent data have shown that docetaxel second-line chemotherapy as a standard of care after platinum-based doublet chemotherapy has been supplanted by immunotherapeutics. Two phase III trials of nivolumab, a fully human programmed-death (PD)-1 immune checkpoint inhibitor, versus docetaxel conducted in squamous and non-squamous histologies, respectively, have demonstrated a superiority in median OS, median PFS, RR, and toxicity for nivolumab, with a hazard ratio for death of 0.57 in patients with squamous NSCLC, and 0.73 for non-squamous histology, while being considerably less toxic than docetaxel [119, 120]. Other promising checkpoint inhibitors are in late-phase clinical development and predictive factors for the benefit from these therapies, such as immunohistochemical evaluation of PDL-1 ligand in the tumour and stroma, are currently being evaluated. The exact sequence of immune checkpoint inhibitors and chemotherapy will be refined over the next years, evaluating first-line immunotherapy strategies as well as combination with chemotherapy or targeted therapies.

Patients progressing after second-line chemotherapy are sometimes considered for further chemotherapy therapy in clinical practice, depending on performance status and toxicities from previous treatments. However, the evidence favouring efficacy of third-line therapy is lacking, with the exception of erlotinib in patients not eligible for further chemotherapy [107]. Clinical trials should strongly be considered in this setting, particularly with designs based on selection of patients based on molecular predictive assays.

Management of patients with non-small cell lung carcinoma harbouring EGFR mutation or ALK rearrangement

EGFR mutations

Sensitizing mutations in the EGFR sequence coding for tyrosine kinase are observed in approximately 15% of lung adenocarcinomas in Caucasian populations. These aberrations occur more frequently in patients from the Far East, never or light smokers and females. Testing for EGFR mutations is not recommended in patients with a confident diagnosis of squamous cell carcinoma, except in never/former light smokers (<15 packs per year). The presence of an EGFR activating mutation confers a more favourable prognosis and is strongly predictive of sensitivity to EGFR TKI therapy. Several randomized studies confirmed the value of first-line reversible EGFR TKIs (gefitinib and erlotinib) as compared to chemotherapy [121–126]. Selected large trials addressing the role of EGFR tyrosine kinase inhibitors vs chemotherapy in patients with tumours harbouring EGFR mutations are summarized in Table 46.5. All but one of these phase III trials were conducted in Asian populations. Cross-study comparisons suggest that, although the incidence of EGFR mutations is lower in Caucasian populations, the response

Table 46.5 Selected trials comparing first-line EGFR tyrosine kinase inhibitor with chemotherapy in patients with an EGFR activation mutation

Study [ref]	Author	EGFR tyrosine kinase inhibitor	Control arm	Number of patients	Tumour response rate	Median progression-free survival [months] Hazard ratio (95% CI; P-value)	Median survival [months] (95% CI) Hazard ratio (95% CI; P-value)
IPASS [121]	Mok et al.	Gefitinib	Carboplatin / paclitaxel	261	71.2 vs 47.3	9.8 vs 6.4 HR = 0.48 (0.36–0.64, P < 0.001)	21.6 vs 21.9 HR = 1.00 (0.76–1.33, P = 0.99)
WJTOG 3405 [123]	Mitsudomi et al.	Gefitinib	Cisplatin / docetaxel	172	62.1 vs 32.2	9.6 vs 6.6 HR = 0.52 (0.38–0.72, P < 0.0001)	35.5 vs 38.8 HR = 1.18 (0.77–1.83)
NEJ002 [124]	Maemondo et al.	Gefitinib	Carboplatin / paclitaxel	228	73.7 vs 30.7	10.8 vs 5.4 HR = 0.32 (0.24–0.44, P < 0.001)	27.7 vs 26.6 HR = 1.04 (0.63–1.24, P = 0.31)
OPTIMAL [125]	Zhou et al.	Erlotinib	Carboplatin / gemcitabine	154	83.0 vs 36.0	13.7 vs 4.6 HR = 0.16 (0.11–0.26, P < 0.0001)	22.7 vs 28.9 HR = 1.04 (0.69–1.58)
EURTAC [126]	Rosell et al.	Erlotinib	Cisplatin or carboplatin / docetaxel Or Cisplatin or carboplatin / gemcitabine	173	58.1 vs 14.9	9.7 vs 5.2 HR = 0.37 (0.25–0.54, P < 0.0001)	19.3 vs 19.5 HR = 1.04 (0.65–1.68)
LUX-lung 3 [127]	Sequist et al.	Afatinib	Cisplatin / pemetrexed	345	56 vs 23	11.14 vs 6.90 HR = 0.58 P < 0.001	28.2 vs 28.2 HR = 0.88 (0.66–1.17)
LUX-Lung 6 [128]	Wu et al.	Afatinib	Cisplatin / gemcitabine	364	66.9 vs 28.0	11.0 vs 5.6 HR = 0.28 P < 0.0001	23.1 vs 23.5 HR = 0.93 (0.72–1.22)

NR, not reported.

rates and PFS are similar in Asian patients with EGFR mutations. All these studies consistently report superior response rates (58.1 to 84.6% vs 14.9 to 47.3%) and PFS (9.7 to 13.7 months vs 4.6 to 6.7 months) to EGFR TKI therapy as compared to standard chemotherapy, with more favourable toxicity profiles and improved quality of life. None of these studies could demonstrate an improvement of survival (median ranging from 19.3 to 30.1 months), probably because of intensive crossover from chemotherapy to EGFR TKI at disease progression in the control arms. The second generation irreversible EGFR TKI afatinib also showed a significant PFS benefit compared with cisplatin-pemetrexed, at the expense of higher incidence of skin rash, diarrhoea, and mucositis [127, 128]. No adequately powered trial has directly compared gefitinib, erlotinib, and afatinib. In a pooled analysis of two trials comparing afatinib with cisplatin-based doublet chemotherapy, overall survival was significantly longer for patients with del 19-positive tumours in the afatinib group than in the chemotherapy group, while there was no significant difference by treatment group for patients with point mutation EGFR Leu858Arg in exon 21 positive tumours. As with first-generation reversible EGFR TKIs, response rates and median PFS were greatly improved in the afatinib group as compared with the chemotherapy groups, in both del 19-positive tumours and

EGFR Leu858Arg-positive tumours [129]. The same observation about differential biology of del 19-positive tumours and EGFR Leu858Arg-positive tumours [129] when treated with EGFR TKI, in particular in terms of PFS, was confirmed in a subsequent meta-analysis [130].

Concurrent continuous administration of chemotherapy and EGFR TKI does not provide any response or survival advantage [131, 132]. EGFR tyrosine kinase inhibitors were also tested with pharmacodynamic separation, i.e., starting the EGFR inhibitor several days after cytotoxic agents and stopping before the next chemotherapy cycle ('intercalated schedules'). A phase III study testing intercalated erlotinib with gemcitabine-cisplatin resulted in improved PFS and survival in the subset of patients with EGFR-mutated tumours, despite extensive crossover to erlotinib in the control arm [133]. Further studies with intercalated schedules in patients with EGFR mutation-positive NSCLC are needed before this treatment strategy is introduced into routine practice. Continuation of gefitinib beyond progression in combination with cisplatin and pemetrexed in patients with acquired resistance to gefitinib does not improve outcome [134], as shown in a phase III randomized trial. Central nervous system penetration of erlotinib or gefitinib is limited (approximately 1–5% of plasma levels), but

are, however, sufficient to obtain responses similar to extracranial disease [135]. Despite initial activity of EGFR TKIs, all patients eventually develop acquired resistance. The most common mechanism of resistance is the EGFR T790M secondary mutation, which accounts for 50–60% of cases, and prevents gefitinib or erlotinib from binding to the ATP-binding pocket of EGFR protein. Second generation EGFR TKIs are effective in preclinical gefitinib- and erlotinib-resistant EGFR T790M models, but their delivery in EGFR TKI resistant patients have shown modest activity to date in the clinic, with low response rates and side effects limiting the ability to administer doses that effectively inhibit T790M EGFR [136, 137]. Third-generation 'mutant-selective' irreversible EGFR TKIs specifically inhibit T790M and other activating EGFR mutations while sparing wild-type EGFR. Among these, mereletinib and rociletinib are in the late phase of their development [138, 139]. Other mechanisms of resistance include MET amplification, HER2 amplification, BRAF mutation, or histologic transformation to small-cell lung cancer [140].

ALK rearrangements

Translocations involving the ALK (anaplastic lymphoma kinase) tyrosine kinase are present in approximately 2–4% of lung adenocarcinomas in Caucasian populations, more frequently in younger patients and light or never-smokers. Patients with tumours harbouring ALK rearrangement more often present with brain and liver metastases as well as pleural and pericardial effusions. The presence of an ALK rearrangement is strongly predictive of sensitivity to ALK inhibitor therapy. Crizotinib, an oral ALK, MET and ROS1 inhibitor, provides increased response rates and PFS compared to either pemetrexed or docetaxel monotherapy, respectively, in the second-line setting [141] (median of 7.7 vs 4.2 vs 2.6 months). Because of significant crossover of patients from the chemotherapy arm at the time of progression, OS was not significantly different. In the first-line setting, crizotinib significantly improves response rate and PFS (median 10.9 vs 7.0 months) when compared to cisplatin or carboplatin plus pemetrexed, establishing crizotinib as the standard first-line treatment in this subgroup [142]. Crizotinib is generally well tolerated and is associated with gastrointestinal disturbance, visual changes, low testosterone levels, and elevated transaminases. Low penetration of crizotinib into the central nervous system might result in underexposure of brain metastases to the drug, leading to 'pharmacodynamic resistance', a phenomenon of exclusive progression in the brain while response in other tumour sites is maintained [143]. Several resistance mechanisms to crizotinib have been identified, including active ALK-dominant (resistance mutations and ALK copy number gain) and ALK non-dominant pathways (the outgrowth of clones containing a separate activated oncogene) [19]. Second-generation ALK inhibitors are more potent against ALK in vitro than crizotinib and can overcome selected ALK kinase domain mutations associated with resistance to crizotinib. Among these, ceritinib and alectinib are in the late phase of their development. Both drugs demonstrate activity against central nervous system disease [144], owing to their related better CNS penetration [145]. Ceritinib and alectinib have been approved in the setting of crizotinib resistance in some countries [146].

Other agents, including third generation ALK TKIs, are under development [147].

Management of oligometastatic disease

Stage IV NSCLC patients presenting with solitary metastases localized to brain, adrenals, or lung can be considered for treatment with curative intent after adequate staging workup has been conducted. Prognosis of patients with oligometastatic NSCLC is worse for synchronous metastases than for metachronous metastases. In the case of solitary brain metastasis, surgical resection, or stereotactic radiosurgery may be of benefit. The addition of whole brain radiotherapy (WBRT) after surgery or stereotactic radiotherapy was tested in a phase III trial in patients with one to three metastases from different primary sites, most commonly from NSCLC [148]. This study, conducted in 359 patients, demonstrated better local control after WBRT but no impact on survival. Five-year survival in patients in whom complete resection of metastases has been achieved ranges from approximately 10% to 30%. In the case of solitary adrenal metastasis, prolonged survival after resection of both primary tumour and adrenal has been suggested, with a five-year survival of 10–26% [149, 150]. There are no data regarding the role of adjuvant chemotherapy in patients who have undergone curative resection of a brain or adrenal metastasis, however most physicians use systemic treatment in this setting. A solitary pulmonary lesion in a different lobe, particularly in the absence of mediastinal lymph node involvement, should be considered as a synchronous second primary tumour and treated with curative intent. The survival of these patients is highly variable according to reported series, with five-year survival ranging from 0 to 50% according to patient selection criteria.

Management of small cell lung carcinoma and other neuroendocrine tumours

Small cell lung carcinoma

Until recently, SCLC has been classified into two stage categories: limited and extensive disease. This practical classification, introduced by the Veterans Administration Lung Cancer Study Group, was used in most clinical trials conducted in SCLC that provided evidence for present standards of care. According to the current 7th edition of the AJCC TNM classification, limited disease corresponds to T1-T4 N0-N3 M0 whereas extensive disease corresponds to any T/any N, M1a or M1b stage categories.

Early stage small cell lung carcinoma (T1-T4 N0-N3 M0)

Prognosis of patients diagnosed with early stage SCLC is characterized by median survival of approximately 16–24 months and five-year survival probability of approximately 20%. Extensive evidence supports chemoradiotherapy as the standard of care in fit early stage patients who are candidates for this treatment. Historically, the introduction of chemotherapy improved very poor outcomes of these patients, some of whom had been previously treated with surgery. Subsequent addition of chest radiotherapy increased three-year survival probability by 5.4% according to the meta-analysis of several trials [151]. Further trials focused on optimization of chemotherapy, optimization of radiotherapy, and better integration of these treatment modalities.

A combination of four to six cycles of cisplatin-etoposide is recommended for treatment of patients with early stage SCLC [152].

Although similar results are achieved with carboplatin-etoposide [153], small number of patients with limited disease in the meta-analysis precludes definitive conclusions regarding equivalence of both schedules. Anthracycline-based schedules are inferior to platinum-based chemotherapy in patients with early-stage SCLC [154] and are more toxic when combined with radiotherapy, and are therefore not recommended. No progress has been observed with other agents or strategies tested to improve systemic treatment results of early SCLC.

Optimal timing of chemotherapy and radiotherapy has been studied extensively in the past. Data from clinical trials and several meta-analyses [155, 156] have yielded conflicting results, with some studies suggesting the benefit from early (starting with the first or second chemotherapy cycle) vs late radiotherapy, whereas other trials did not confirm this finding. When analysis was limited to trials with radiotherapy combined with platinum-etoposide, the benefit from early concurrent treatment was observed, particularly in trials in which dose intensity of chemotherapy was maintained despite early administration of radiotherapy. Another meta-analysis of four randomized trials with platinum-etoposide chemotherapy indicated that time of start of any treatment to end of radiotherapy (SER) of less than 30 days was associated with significantly better five-year survival probabilities at the expense of higher severe esophagitis rates [157]. Thus, combined chemotherapy with early radiotherapy (starting with the first or second cycle) should be considered in fit patients with early stage SCLC. In practice, there are patients who are not candidates for early chemoradiation due to comorbidities or due to large tumour volume affecting planned dose-volume parameters to the extent precluding definitive treatment. In such patients, late or sequential radiotherapy should be considered. Post-chemotherapy target volumes for primary tumour are sufficient in treatment planning, but all initially affected lymph node stations should be included in the radiotherapy field.

Optimal chest radiotherapy dose and fractionation has also been studied extensively. Most radiotherapy departments recommend either a hyperfractionated accelerated schedule of 45 Gy delivered twice daily or a conventionally fractionated or slightly hypofractionated schedule of 54–66 Gy delivered every day. Dose and schedule of concurrent radiochemotherapy in SCLC is often considered individually taking into account planning target volumes and expected toxicity based on dose distribution in organs at risk, particularly lung and oesophagus. The rationale to use accelerated radiotherapy schedules stems from radiobiological data of increased SCLC radiosensitivity to low radiation doses. In the pivotal clinical trial that addressed the issue of accelerated hyperfractionation [158], long-term survival was significantly increased from 16% (standard arm, 45 Gy in 25 fractions once daily) to 26% (experimental arm, 45 in 30 fractions twice daily) at the expense of higher severe esophagitis rates (11% and 27%, respectively). Despite this evidence, recommended also in current European guidelines for management of SCLC [152], some radiation oncologists still use conventionally fractionated doses of 60 Gy or more arguing that radiation dose in the standard arm of the above-mentioned Intergroup study is inadequately low, twice daily radiotherapy is logistically difficult and associated with clinically problematic oesophageal toxicity. Two large clinical trials are ongoing to address the optimal radiotherapy dose and schedule in SCLC (CONVERT trial conducted in Europe and Canada, comparing 45 Gy in 30 fractions and 70 Gy in 35 fractions and the CALGB 30610/RTOG0538

trial conducted in the United States assessing three different fractionation schedules). Results of these trials should provide further evidence to guide clinical practice.

Prophylactic cranial irradiation (PCI) should be given to all patients who have responded to initial treatment. The main goal of this therapy is to reduce the incidence of brain metastases by approximately 50% and to increase long-term survival by approximately 5%, as evidenced by meta-analysis of individual data from seven randomized trials that included mostly patients with limited disease SCLC [159]. The optimal dose of PCI was analysed in the phase III Intergroup trial led by French investigators, in with patients were randomly allocated to 25 Gy or 36 Gy [160]. The incidence of brain metastases at two years, the primary study endpoint, was not significantly different between study arms (29% and 23%, respectively, P = 0.18). Worse survival was observed in the high PCI dose arm due to a higher number of cancer-related deaths (HR = 1.20, P = 0.05). Minor neurological decline in time was noted across both arms of the trial with no difference between radiation doses [161]. While this study established 25 Gy in 10 fractions as a standard dose for PCI in patients with SCLC, some centres continue to use the dose of 30 Gy in 15 fractions, which was not compared in clinical trials. The advantages of PCI may be offset by increased neurocognitive deficits in elderly patients with pre-existing dementia, mandating careful consideration of its use in this patient category.

The value of surgery is debated in very early SCLC with no nodal involvement. In this rare patient category, no comparative evidence-based data exist to guide management. Results of surgical treatment followed by adjuvant chemotherapy are relatively good with long-term survival in the order of 30–50% [162], prompting many physicians to recommend this strategy in highly-selected patients. If this approach is taken, prophylactic cranial irradiation should be also routinely performed and chest radiotherapy should be considered in patients with incomplete resections [152].

Metastatic small cell lung carcinoma (any T, any N, M1a, or M1b)

The first proof of benefit of cytotoxic agents in SCLC was demonstrated in the early 1970s when studies exploring cyclophosphamide demonstrated significant survival prolongation compared to best supportive care. Subsequently, a number of other agents and combination therapies were tested with anthracyclines, etoposide, and platinum compounds selected as the most active in this disease. Combination of cyclophosphamide, doxorubicin, and vincristine (CAV), cyclophosphamide, doxorubicin, and etoposide (CAE), or cyclophosphamide, doxorubicin, vincristine, and etoposide (CAVE) were shown to have similar efficacy to cisplatin-etoposide in patients with extensive SCLC, whereas cisplatin-etoposide was associated with better outcome and was less toxic when combined with thoracic radiotherapy in patients with limited SCLC. Platinum-etoposide is also associated with less myelosuppression as compared to anthracycline-based chemotherapy. The optimal duration of first-line chemotherapy was established to be four to six cycles. Several other strategies were tested in the last two decades in phase II or phase III clinical trials: alternating treatment with different schedules, maintenance treatment, chemotherapy dose intensification with or without hematopoietic growth factor support, addition of other cytotoxic agent to platinum-etoposide,

use of targeted therapies, or immunotherapy. These strategies failed to improve clinically meaningful patient outcomes. Several clinical trials comparing cisplatin and carboplatin were summarized in a meta-analysis from individual data of 663 patients [153]. Median survival of patients treated with cisplatin-based chemotherapy was 9.6 months as compared to 9.4 months for carboplatin (HR = 1.08, P = 0.37). Use of carboplatin was associated with more haematological toxicities, whereas use of cisplatin was linked to higher likelihood of nausea/vomiting, peripheral neuropathy, and renal impairment. In the last decade, a set of studies was conducted with campthotecin derivatives (topoisomerase I inhibitors: irinotecan and topotecan) and amrubicin, an anthracycline with favorable cardiac toxicity profile and high topoisomerase II inhibition potency. A phase II clinical trial conducted by the Japanese Clinical Oncology Group evaluated cisplatin-irinotecan combination versus cisplatin-etoposide as front-line therapy in patients with metastatic SCLC [163]. The trial was closed after interim analysis of 154 patients showed a significantly superior survival favouring irinotecan (median survival of 12.8 months vs 9.4 months, P = 0.002). Phase III trials with irinotecan [164–167] or topotecan [168] conducted in the United States or Europe have not confirmed the superiority of campthotecins over platinum-etoposide, except for one trial in which relatively poor outcome of patients in a control group treated with carboplatin and oral etoposide was reported [165]. Amrubicin-cisplatin has shown similar efficacy to cisplatin-etoposide in one phase III first-line trial in metastatic SCLC [169]. In summary, four to six cycles of cisplatin-etoposide or carboplatin-etoposide combination are recommended in metastatic SCLC. In patients with SCLC who have contraindications to platinum compounds, anthracycline-based chemotherapy (CAE or CAV) should be considered as a reasonable alternative.

Reported response rates in patients with metastatic SCLC to first-line chemotherapy are in the order of 50–70%, median progression-free survival is approximately five months and OS is approximately 9–12 months. In patients who relapse, options for systemic treatment are limited and depend primarily on duration of response to first-line therapy, patient performance status, age, comorbidities, and toxicities from previous chemotherapy. Patients who respond to first-line chemotherapy and progress within three months of last chemotherapy administration are categorized as 'refractory' whereas those who have a longer relapse-free interval are categorized as 'sensitive'. In patients with refractory disease, oral topotecan, intravenous topotecan, anthracycline-based chemotherapy, or best supportive care should be considered. In this category, treatment outcome is poor with response rates of approximately 5–20%. Patients with sensitive disease should be treated with single-agent topotecan, anthracycline-based chemotherapy, or re-induction with platinum-etoposide, particularly if relapse-free period exceeds six months. Reported response rates in this category are typically between 20–40%. In patients who received anthracycline-based chemotherapy as front-line treatment, subsequent therapy with platinum-etoposide should be considered.

Prophylactic cranial irradiation was investigated in metastatic SCLC patients who have responded to first-line chemotherapy in a phase III clinical trial that aimed to demonstrate the reduction of proportion of patients who experience clinical progression in the brain. The trial met its primary endpoint, showing that PCI reduces the risk of brain metastases from 40.4% in the control arm to 14.6% in experimental arm at one year. This trial also showed that the use of PCI is associated with survival benefit (median of 6.7 vs 5.4 months, respectively; HR = 0.68, P = 0.003). Based on the above study, PCI is recommended in metastatic SCLC patients who had a response to initial chemotherapy. Treatment should start within five weeks after the last chemotherapy cycle. The dose of 25 Gy in 10 fractions is most commonly used.

Carcinoid tumours and large cell neuroendocrine carcinoma

The spectrum of neuroendocrine malignancies includes typical carcinoids (fewer than two mitoses per 2 mm^2 or ten high power fields), atypical carcinoids (more than two mitoses per 2 mm^2), large cell neuroendocrine carcinoma (LCNEC), and SCLC discussed above. Two former entities are low and intermediate grade whereas the two latter entities are high-grade neuroendocrine tumours. These two groups share neuroendocrine differentiation markers but have distinct molecular profiles and very different biological and clinical characteristics. Carcinoid syndrome, associated with serotonin and kallikrein secretion by the tumour, is manifested by flushing, diarrhoea, wheezing, and heart failure. Syndrome occurs in up to 3% of patients and is usually associated with a high tumour burden, and typically with liver metastases. Somatostatin receptors are present in the majority of neuroendocrine tumours and may be visualized by somatostatin scintigraphy (Octreoscan™) and indium-111 or gallium-68 radiolabelled PET tracers, used for the purpose of staging. Staging of carcinoids and LCNEC is performed according to current TNM classification. Due to low incidence, comparative evidence for management of carcinoids and LCNEC does not exist and most data are derived from single-arm trials or comparative trials in which pulmonary neuroendocrine tumours usually represent a minor proportion of patients.

Pulmonary carcinoids belong to the group of foregut neuroendocrine tumours, constitute up to 3% of lung malignancies and typically occur in the main bronchi. Peripheral carcinoids are observed in about 30% of cases. Ten-year survival probabilities for patients with typical and atypical carcinoids are approximately 90% and 50%, respectively. Distant metastases occur most commonly in the lungs, liver, and bones. Centrally located stage I and II carcinoids should be managed with lung parenchyma-sparing surgery and mediastinal lymph node dissection or sampling. Surgical margins may be minimal to avoid extensive resections. Atypical carcinoids are more likely to occur as peripheral lesions, hence a lobectomy is often considered in a patient with stage I or II disease and adequate pulmonary reserve, although limited resections may also be an option. Significant controversy exists regarding the optimal management of carcinoids with mediastinal lymph node involvement which is sometimes observed in the case of atypical tumours. In this setting, most physicians recommend a combined modality approach with aggressive surgery if technically feasible. Adjuvant chemotherapy or radiotherapy is not indicated for typical carcinoids and atypical carcinoids with no nodal involvement. Adjuvant chemotherapy is controversial in patients with atypical carcinoids and involved lymph nodes; prognosis of these patients is considerably worse, but there is no evidence of benefit from adjuvant treatment.

Several cytotoxic agents are used in the management of metastatic carcinoid tumours. These agents include cisplatin, carboplatin, etoposide, streptozocin, doxorubicin, and 5-fluorouracil. The response rates to platinum-etoposide or streptozocin-based

regimens depends on tumour grade and is typically in the range of 10% for typical carcinoids and 20–50% for atypical carcinoids, with no clear evidence favouring any particular regimen. Somatostatin analogues, such as octreotide acetate long-acting repeatable (LAR) formulation, provide benefit to the majority of patients with hormone-related symptoms. Objective tumour responses to somatostatin analogues are infrequent (<10%), hence the direct anti-tumour effect of these agents have been debated. The PROMID trial, conducted in 85 patients with functionally active and inactive well-differentiated metastatic mid-gut neuroendocrine tumours, showed prolongation of time-to-progression in patients treated with long-acting octreotide as compared to placebo (median of 14.3 vs 6 months, HR = 0.34, P = 0.00072) [170]. Results of this study have been extrapolated to bronchiopulmonary carcinoids, although no clear evidence exists regarding survival benefit from the use of these agents. Radionuclide therapy with radiolabelled somatostatin analogues have been developed and tested in patients with positive diagnostic octreotide scintigraphy. In a phase II study, 90 patients with various carcinoid tumours refractory to octreotide therapy, received three doses of ^{90}Y-edotreotide every six weeks. Objective responses were observed in 4% of patients, disease control was noted in 74% of patients, and median progression-free and overall survival was 16.3 and 26.9 months, respectively [171].

Recent clinical studies have demonstrated prolongation of progression-free survival in patients with pancreatic neuroendocrine tumours when treated with octreotide LAR combined with everolimus (mammalian target of rapamycin, mTOR inhibitor) or with sunitinib [172, 173]. The impact of these agents on outcomes of metastatic lung carcinoid patients is unknown.

Diagnosis of LCNEC is difficult, particularly in small specimens. LCNEC is an aggressive malignancy, most often diagnosed in locally advanced or metastatic stage, with clinical behaviour and spectrum of molecular aberrations similar to SCLC. The optimal chemotherapy has not been established in comparative trials. A retrospective analysis of patients with pure pulmonary LCNES suggests that platinum-etoposide is more effective than chemotherapy schedules typically used in NSCLC, such as cisplatin-gemcitabine or cisplatin-paclitaxel [174]. A prospective phase II trial exploring the efficacy of platinum-etoposide in 42 LCNEC advanced patients reported median progression- free and overall survival of 5.2 and 7.7 months, respectively. Due to poor survival after surgery alone in stage I LCNEC, adjuvant chemotherapy is suggested similarly to SCLC.

CHAPTER 47

Neoplasms of the thymus

Rebecca Bütof, Axel Denz, Gustavo Baretton,
Jan Stöhlmacher-Williams, and Michael Baumann

Epidemiology

The thymus is located in the anterior mediastinum and involutes during adulthood. The organ contains two types of cells: epithelial cells and lymphocytes. Thymic epithelial cells are the origin of two major groups of thymic malignancies: thymomas and thymic carcinomas. Thymomas are slow-growing, less invasive tumours whereas thymic carcinomas have higher metastatic capacity and local aggressiveness. Thymic tumours are rare, accounting for only 0.2% to 1.5% of all malignancies [1]. Overall, 90% of thymic neoplasms are thymomas with an overall incidence of approximately 0.13 cases per 100 000 persons per year [2, 3]. Thymomas can occur at any age but the frequency is highest within the 40–70 year age group. So far, the aetiology remains unclear and environmental risk factors are currently unknown. However, an association between Epstein–Barr virus infection and thymic malignancies has been discussed in the literature [4, 5].

Diagnosis and staging

In 30–50% of cases, patients have no symptoms at diagnosis. Therefore, thymomas are often detected during routine chest X-rays [1, 5]. A variety of clinical findings can be observed in symptomatic patients mostly depending on the histological subtype: thymic carcinomas may lead to chest pain, persistent coughing, dyspnoea, and superior vena cava syndrome; thymomas are often associated with paraneoplastic syndromes. Myasthenia gravis occurs in approximately 45% of patients with thymoma whereas 2–6% have red cell aplasia or hypogammaglobulinaemia [1]. Furthermore, patients with thymoma have an increased risk of a second synchronous or metachronous tumour. Therefore, lifelong follow-up is recommended.

For diagnosis, computerized tomography (CT) with intravenous contrast should be the first choice of imaging. MRI or 18-FDG-PET may be useful for specific questions as well as in case of contraindications against iodine contrast, or for detection of metastatic disease [1, 5]. Thymomas are mostly located in the anterior compartment of the mediastinum. Consequently, the potential differential diagnoses include lymphoma, germ cell tumours, metastases, or benign conditions (i.e., intrathoracic goitre, thymic cysts, aortic aneurysms). In order to achieve a definitive diagnosis and for determination of the histological subtype a biopsy is recommended (e.g., CT-guided core needle biopsy or open biopsy). Biopsy of a possible thymoma should avoid a transpleural approach. Further diagnostic procedures include blood tests (e.g., serum immunoglobulins,

LDH, beta HCG, alpha fetoprotein), echocardiography, and tests for detection of autoimmune reactions [1].

Thymomas can be classified based on different histological subtypes according to the World Health Organization (see Table 47.1). This system takes into account the morphology of epithelial cells and the lymphocytic/epithelial ratio. Therefore, resulting subtypes A, AB, B1, B2, and B3 represent specific tumours [1, 3, 5]. One meta-analysis has shown significant differences in survival rates between A/AB/B1 vs B2 vs B3 categories [6, 7]. The thymic carcinoma group (type C thymoma) contains histologically and clinically diverse tumours.

In addition to this WHO classification, the Masaoka-Koga staging system has been developed and is commonly used (see Table 47.2). It is based on clinical and microscopic invasion of the tumour [8, 9]. Several studies have demonstrated a significant correlation between Masaoka-Koga stage and survival [5, 10]. For early-stage thymic malignancies, five-year overall survival rates of 80–95% and for locally advanced stages of 40–70% have been published. Although different TNM classifications have been proposed, they have not prevailed in routine clinical practice.

Treatment options

For treatment of thymomas the following methods are used: surgery, radiotherapy, chemotherapy, and targeted drugs. The optimal type of therapy depends on tumour stage, histological subtype, and general health condition of the patient.

Surgery

A complete surgical excision of the tumour with total thymectomy is the mainstay of therapy for all thymic malignancies. A large proportion of these tumours are resectable with an inverse correlation with the Masaoka-Koga stage at diagnosis (e.g., resectability of 100% in stage I and 29% in stage IV) [5, 11]. The completeness of resection is one of the most important prognostic factors for survival. Median sternotomy is used as the most common surgical approach. An en bloc resection is recommended by the International Thymic Malignancy Interest Group (ITMIG) and includes complete thymectomy with all surrounding mediastinal fatty tissue bordered laterally by the phrenic nerves and cranially by the cervical poles [12]. If the tumour invades adjacent structures like pleura, pericardium, lung, or major vascular structures, the resection has to be extended accordingly. Minimally invasive methods like video-assisted thoracoscopic resections, mini-sternotomy, or robotic surgery may be considered if all oncologic goals

Table 47.1 Histological WHO classification of neoplasms of the thymus

WHO type	Definition
A	Spindle cell, medullary thymoma
AB	Mixed thymoma
B1	Lymphocyte-rich, lymphocytic, or predominantly cortical thymoma
B2	Cortical thymoma
B3	Epithelial, atypical, squamoid thymoma, or well-differentiated thymic carcinoma
C	Heterogeneous thymic carcinoma

Reproduced from Springer, World Health Organization, *Histological Classification of Tumours of the Thymus, Second Edition*, Juan Rosai, Springer-Verlag, Berlin, Heidelberg, Copyright © 1999, with kind permission from Springer Science and Business Media.

can be achieved at the level of standard procedure [13]. For well-encapsulated tumours, local recurrence rate after surgery is less than 3% [14]. Surgical mortality rates of approximately 2.5% have been reported in the literature [1, 11].

Radiotherapy

Thymomas are generally classified as radiosensitive tumours; therefore, radiotherapy plays an important role in multimodal treatment approaches. Patients may receive irradiation in case of unresectable disease, preoperatively in order to improve resectability or post-operatively after incomplete resection. It has been shown that adjuvant radiotherapy increases disease-free survival in patients with R1 or R2 resection whereas in cases with limited stage and R0 resection and for thymomas type A, AB, and B1 no benefit could be detected [15]. In contrast, for R0 resected stage III or IV thymic malignancies adjuvant radio/chemotherapy is recommended [5, 14, 16, 17]. Radiotherapy doses and target volumes are not stated consistently in the literature. In the adjuvant situation doses range between 30–60 Gy with 1.8 to 2.0 Gy

Table 47.2 Masaoka-Koga staging system

Stage	Definition
I	Completely encapsulated tumour
IIa	Microscopic transcapsular invasion
IIb	Macroscopic invasion into thymic or surrounding fatty tissue or grossly adherent to but not breaking through mediastinal pleura or pericardium
IIIa	Macroscopic invasion into surrounding structures (i.e., pericardium, pleura, lung) without invasion of great vessels
IIIb	Macroscopic invasion into surrounding structures with invasion of great vessels
IVa	Distant pleural or pericardial metastases
IVb	Lymphogenous or haematogenous metastases

Reproduced from Masaoka et al., Follow-up study of thymomas with special reference to their clinical stages, *Cancer*, Volume 48, Issue 11, pp. 2485–2492, Copyright © 1981 American Cancer Society, with permission from John Wiley and Sons.

per fraction, depending on resection margins and performance status of the patient [14]. Clinical target volume concepts include mediastinal irradiation with involvement of the mediastinal pleura or alternatively limited radiotherapy of only upper and middle mediastinum. For primary radio/chemotherapy doses between 60–70 Gy are recommended. Most commonly used radiotherapy techniques are 3D conformal radiation therapy and intensity-modulated radiotherapy (IMRT). The role of proton therapy has not been sufficiently explored. In order to reduce side effects the dose to organs at risk, i.e. heart, lung, oesophagus, and spinal cord, should be minimized. Possible acute and late toxicities are pneumonitis, oesophagitis, pericarditis, pulmonary fibrosis, and coronary stenosis.

Chemotherapy

Chemotherapy can be used in various indications in the treatment of thymomas. The role of adjuvant chemotherapy alone is currently unknown [5]. In retrospective studies patients with type A, AB, and B1 thymomas or R0 resected stage II tumours do not benefit from systemic chemotherapy alone [5, 18]. In contrast, for incompletely resected tumours or R0 resected stage III thymic malignancies adjuvant chemoradiotherapy is increasingly administered [18]. For locally advanced disease induction chemotherapy might be an option in order to achieve complete resection. After re-evaluation with CT, simultaneous chemoradiotherapy is recommended for patients with incomplete response or inoperability due to poor performance status. Systemic chemotherapy should be the treatment of choice for patients with extensive metastatic disease. Ifosfamide and cisplatin have been applied as monotherapy. The treatment results for combined therapies of cisplatin, e.g., PAC (cyclophosphamide, doxorubicin, and cisplatin) or ADOC (cyclophosphamide, doxorubicin, vincristine, and cisplatin) regimes are better than monotherapy with reported remission rates of 30–100% [1, 3].

Targeted drugs and novel strategies

There is an emerging body of evidence for presence of specific genetic aberrations in thymic malignancies. During the last years targeted therapies have been investigated in order to improve treatment results. Some of the thymic tumours can be treated with octreotide because of their expression of somatostatin receptors. Also, combined therapies with corticosteroids have been shown to increase response rates.

Different molecular pathways are suitable as targets for novel therapeutic approaches. An over-expression of the receptor tyrosine kinase KIT was found in approximately 80% of thymic carcinomas and 2% of thymomas [5]. These patients might therefore benefit from treatment with tyrosine kinase inhibitors such as imatinib [19]. Although epidermal growth factor receptor (EGFR) over-expression is also a common phenomenon in thymomas and thymic carcinomas, response rates were poor after use of EGFR inhibitors [3, 5]. One possible explanation might be that EGFR mutations are extremely rare in thymic tumours. Further suitable targets might be vascular endothelial growth factor (VEGF) receptors and insulin-like growth factor-1 receptor [19]. Ongoing clinical trials will determine the efficacy of specific inhibitors of these targets. Furthermore some case reports about successful treatment with high-dose chemotherapy and peripheral blood stem cell transplantation have been published [1].

Multidisciplinary therapy according to the stage of disease

All patients with thymic tumours should be managed in a multidisciplinary team in order to determine the optimal management for each individual case.

Stage I

Standard treatment for stage I thymoma is surgery alone. There is no indication for adjuvant therapy after complete resection of a well-encapsulated tumour [1, 3]. In rare cases of positive resection margins (R1 or R2) adjuvant radiotherapy is recommended.

Stage II

For stage II thymic malignancies a complete resection should be treatment of choice. Radiotherapy or combined radiochemotherapy should be administered post-operatively for patients with incomplete resection or as primary treatment for unresectable tumours [14]. In cases with clear undisputed R0 resection and for thymomas type A, AB, and B1 adjuvant therapy seems not to be beneficial [1].

Stage III and IV

If feasible, surgical en bloc resection and adjuvant radio/chemotherapy should be performed in stage III or IVa disease [1, 5]. For unresectable tumours, induction chemotherapy might be an option in order to reduce tumour volume and achieve resectability. After re-evaluation, chemo/radiotherapy can be utilized for patients with progressive disease, incomplete response, or inoperability due to poor performance status. It has to be considered that induction chemotherapy has not been directly compared to neoadjuvant radiotherapy or radiochemotherapy. Therefore, the role of neoadjuvant treatment approaches is not yet clear. In some of these locally advanced stages surgery may not be possible, so that radiochemotherapy is the favourable treatment. Nevertheless the prognosis even for patients with partially resected thymoma is significantly better than for patients without surgery [1, 20]. Systemic chemotherapy should be treatment of choice for patients with stage IVb disease.

Recurrent disease

For advanced stage thymomas, and especially thymic carcinomas, high rates of recurrences up to 51% have been reported in the literature [5]. The average time to relapse of five years requires long follow-up care of all patients with thymic malignancies. The treatment option with highest efficacy for recurrent disease is repeated surgical resection, particularly for local relapses [12]. Post-operative radiotherapy is recommended in case of incomplete resection and only for selected patients after R0 resection of recurrent thymoma. For unresectable tumours neoadjuvant radiotherapy or therapy with corticosteroids or definitive radio/chemotherapy could be performed based on pretreatment.

Summary

Thymic tumours are among malignant diseases with very low incidence. Therefore, clinical research and development of new treatment options pose an ongoing challenge. A complete surgical resection is still the mainstay of therapy. For patients with incomplete resection or in locally advanced stages adjuvant radio/chemotherapy is recommended. Neoadjuvant treatment approaches and novel targeted therapies are under investigation. Life-long follow-up is recommended because of possible late recurrences.

Introduction to pleural mesothelioma

Mesothelioma is an aggressive cancer of the pleura associated with asbestos exposure. The latency between exposure and expression of symptoms is long, typically lasting 20–40 years, as it requires decades for cumulative alterations in the cellular apparatus to incite a malignant transformation. Once the diagnosis is made, commonly in the sixth decade of life, patients generally succumb within months as the tumour grows, spreads, and encases the lung, restricting breathing. Median survival without treatment is seven months [1]. Early efforts to treat mesothelioma with single modality therapies, i.e., chemotherapy, radiation, and surgery alone produced dismal results, leading clinicians to add innovative multi-modality approaches to the treatment paradigm.

The current multimodality approach to malignant pleural mesothelioma (MPM) is defined as a macroscopic complete resection (MCR) [2] followed or preceded by some form of therapy for micrometastatic control. The latter usually consists of adjuvant or neoadjuvant chemotherapy and radiation (trimodal therapy), but novel approaches are also being investigated, such as heated intra-cavitary chemotherapy, photodynamic therapy, and novel radiation techniques. Concurrent developments in diagnostic procedures, histopathologic characterization of mesothelial cells, and staging have improved patient selection, but more research is needed to extend survival by limiting the micrometastatic spread of tumours. This chapter updates current trends in surgery-based multimodality management, with special emphasis on promising new strategies.

Epidemiology

Occupational and environmental exposure to asbestos is a global health problem that has reached epidemic proportion, raising the urgency of finding a cure [3–7]. The history of this cancer can be traced to the mining and manufacture of asbestos in the late 19th and 20th centuries. The association between asbestos and mesothelioma was first recognized in 1960 by Wagner et al. who reported the first series of cases in a mining community in North Western Cape Town Province, South Africa [8]. The association between asbestos and cancer was definitively established by Selikoff in the 1970s [9], prompting the first round of regulatory measures to be implemented in developed countries, beginning in the UK and shortly thereafter the US. As a result of this regulation, the incidence of new cases has stabilized in the US at about 2500 cases per year. However, incidence rates in European nations other than the UK have continued to rise, with peak incidences projected in 2020 and beyond [3]. Moreover, asbestos use continues unabated in many developing regions of the world ensuring that this epidemic will certainly continue for decades beyond current projections.

Molecular biology of pleural mesothelioma

Investigation of the molecular characteristics of malignant pleural mesothelioma continues to be an active area of research, since a standard treatment approach has not been defined. Asbestos is regarded as the primary factor in the pathogenesis of mesothelioma, with more than 80% of patients having a history of asbestos exposure at diagnosis [10]. How asbestos fibres confer key gene alterations and induce cellular transformation of normal mesothelial cells remains poorly understood. The remaining 20% of cases, which report no history of asbestos exposure, may be related to other factors. Several candidates have been investigated, including exposure to simian virus 40 (SV40), radiation, other mineral fibres, and the no-longer used contrast reagent Thorotrast [11]. Characterized by a very long latency, typically 20 to 40 years, many years pass before the malignant diagnosis is made. This suggests that multiple somatic genetic events are required for the tumorigenic conversion of mesothelial cells [12]. Genetic predisposition also has been implicated in a small number of cases [13].

The modified expression of several mitogen-activated protein kinases (MAPK) and receptor tyrosine kinases (RTKs), such as the epidermal growth factor receptor (EGFR), c-Met, and the insulin growth factor receptor has been demonstrated in several studies [14, 15]. Constitutive activation of these kinases results in deregulation of downstream signalling cascades, which disrupt the normal cell cycle, causing—among other effects—the inhibition of apoptosis (cell death). However, for the majority of cases no specific molecular aberration has been associated with deregulation of these cellular pathways. Epigenetic studies also have been conducted in MPM to investigate modifications in gene expression [16]. Although promoter methylation associated with changes in

gene expression is a frequent event in MPM, no satisfactory biomarkers have been identified for diagnosis or prognosis.

Chromosomal aberrations

Karyotypic studies and comparative genomic hybridization (CGH) analyses performed on MPM specimens and cell lines have revealed the complexity of the genetic alterations involved in the pathogenesis of MPM. All chromosomes contribute to these numerical changes, with losses being more common than gains. In addition, all chromosomes except Y participate in these structural alterations. Although there is no specific chromosomal aberration common to all cases of malignant mesothelioma, several prominent sites of chromosome loss have been identified [11].

Next-generation sequencing studies

The past decade has seen a remarkable improvement in the application of automated high-throughput DNA sequencing. The new methods, known as next-generation sequencing (NGS), have revolutionized the genetic analysis of mesothelioma and other disease [17]. Transcriptome analyses of four MPM tumours and two controls resulted in the discovery of previously uncharacterized human cancer mutations [18]. These four MPMs displayed unique non-overlapping mutational profiles. Fifteen non-synonymous point mutations were discovered and three of them (COL5A2, UQCRC1, and MXRA5) were found to be present in 4–6% of a larger cohort of MPM tumours. A later study analysed the whole genome of a human primary MPM tumour and its matched normal using a combination of sequencing-by-synthesis and pyrosequencing methodologies [19]. This investigation confirmed that DNA rearrangements represent the dominant type of mutations in MPM. Many more tumour-specific rearrangements than point mutations were uncovered resulting in the discovery of novel, large-scale, inter- and intra-chromosomal deletions, inversions, and translocations. In particular, one large deletion within the DPP10 gene, mapping on chromosome 2q14.1, produced a truncated fusion transcript unique to the tumour's transcriptome. The analysis of 56 additional MPM samples showed this DPP10 transcript in 31 of 56 (55%) MPMs. Patients with tumours expressing DPP10 mRNA had statistically significant better overall survival than patients whose tumours lacked DPP10 expression. This study supported the potential role of chromosomal rearrangements as oncogenic driver mutations, therapeutic targets, and prognostic biomarkers in MPM.

Tumour suppressor genes

Genes, such as *TP53, RAS*, and *RB*, that are found to be mutated at high frequency in other tumours are rarely mutated in MPM. Only a few genes mapping in critical locations on chromosomes 22q, 9p, and 3p have shown a high mutation rate in this malignancy.

NF2

The tumour suppressor gene (TSG) merlin (*NF2*) is located on chromosome 22q12 and is responsible for the hereditary disease neurofibromatosis type 2 (NF2) characterized by nervous system and skin tumours, as well as ocular abnormalities [20]. NF2 protein interacts with cell-surface proteins, proteins involved in cytoskeletal dynamics, and proteins involved in regulating ion transport. Mutations in the *NF2* gene, mostly related to frequent loss of part or all of chromosome 22, have been found in more than 40% of MPM cell lines [21–23]. A recent investigation has confirmed that the disruption of NF2 signalling occurs in most MPM tumour samples and that it is essential for the development of MPM [24].

CDKN2A

CDKN2A encodes, through alternative reading-frames, two important cell cycle regulatory proteins: p16 and p14ARF. Homozygous deletion of 9p21 locus is found at high frequency in MPM cell lines and tumour specimens [22, 25–28]. p16 is a cyclin-dependent kinase inhibitor protein that functions in the retinoblastoma (Rb) pathway, regulating the cell cycle during the G1/S phase [29]. Cells lacking p16 lose their cell cycle control and undergo a neoplastic transformation. p14ARF binds Mdm2, thus preventing the latter from binding p53 and targeting it for degradation [30]. Deletions at this locus are clinically very relevant in MPM, because they are negative prognostic factors, potential targets for gene therapy, and can be used as markers in body cavity effusions [31].

BAP1

In the last few years, two independent investigations have identified the gene encoding *BRCA1* associated protein-1 (*BAP1*) as a TSG located in 3p21.1 in MPM [13, 32]. *BAP1* encodes a ubiquitin COOH-terminal hydrolase originally identified through its interaction with BRCA1. BAP1 is believed to mediate its effects through chromatin modulation, transcriptional regulation, and possibly via the ubiquitin-proteasome system and the DNA damage response pathway [33]. Somatic *BAP1* mutations have been identified in approximately 22% of sporadic MPM samples, whereas congenital *BAP1* mutations were identified in sporadic and familiar MPMs [13]. Because several individuals carrying BAP1 mutations had been diagnosed with one or more additional tumours, the existence of a *BAP1*-related cancer syndrome characterized by mesothelioma, uveal melanoma, and possibly other cancer types has been suggested. It has been hypothesized that when individuals with *BAP1* mutations are exposed to asbestos, mesothelioma predominates. Alternatively, *BAP1* mutation, alone, may be sufficient to cause mesothelioma [13, 34].

Genetic tests

Microarray profiling technology permits simultaneous measurement of multiple levels of gene expression in a single experiment. It has been successfully applied to cancer research for the discovery of novel biomarkers [35]. Recently, a bioinformatic algorithm, called the 'gene expression ratio technique', was developed to translate comprehensive expression profiling data into simple molecular tests that are based on the expression levels of a relatively small number of genes [36]. This method has been used successfully to predict clinical parameters such as differential diagnosis and prognosis in MPM [37, 38]. This study has shown that a molecular test from tissue obtained using minimally invasive techniques can be performed before major surgical interventions to accurately predict post-surgical outcome. This is an important issue in mesothelioma since median survival in patients undergoing multimodality therapy is one to two years, whereas 20% of those patients can live disease-free for 3 to 15 years. The problem lies in the ability to predict which patients will survive with aggressive surgery-based therapy. The ability to predict post-surgical outcome using a simple genetic test based on microarray profiling technology would vastly improve patient selection for aggressive multimodality therapy.

Pathology of pleural mesothelioma

Pathology plays a critical role in the surgical treatment of MPM, from diagnosis and classification to prognosis and treatment planning. Making the correct diagnosis is challenging because the epithelioid type may be difficult to distinguish from adenocarcinoma or thymoma metastatic to the pleura, and the sarcomatoid type may be difficult to separate from other sarcomas or tumours with sarcomatoid histologies.

Diagnosis and preresection lymph node staging

While the initial diagnosis of MPM may be possible with pleural fluid cytology or fine needle aspiration, a core needle biopsy, thoracoscopic or small-incision open biopsy may be required to obtain adequate tissue for pathologic analysis, since multiple techniques are used in the differential analysis. First, there must be evidence of tumour invasion into parietal pleural fibrous tissue, extrapleural adipose tissue, or the chest wall soft tissues. The presence of proliferating mesothelial cells in an organizing fibrinous exudate that may mimic pleural tissue on intraoperative examination does not constitute invasion. In addition, the surgical biopsy should provide sufficient tumour for accurate classification of the histologic type (e.g., epithelioid, sarcomatoid, and biphasic or mixed). Accuracy in predicting cell type varies with the number of biopsy samples obtained, the heterogeneity of the tumour, and tumour histology [39]. As many as 20–25% of diffuse MPM patients with biopsy classified as epithelial on pathologic analysis have been reported to have mixed type on analysis of specimens obtained at surgical resection [39, 40]. This disparity often reflects the limited tissue present in biopsy specimens, particularly if tissue is obtained via closed core needle biopsy. It also emphasizes the importance of adequate biopsy sampling and the value of surgical resection for accurate classification of histologic type [40]. Lymph node status is critical to staging and prognosis for potential surgical candidates [41]. Mediastinoscopy with pathologic examination of lymph nodes in permanent sections remains the pre-resection gold standard for evaluating lymph node status.

Evaluation of surgical resection specimens

Additional specimens are often evaluated intraoperatively with frozen section examination. Although this examination accurately reports the presence of malignancy in most instances, it cannot be relied on for an accurate distinction from adenocarcinoma and the many other tumours that mimic diffuse MPM.

Extrapleural pneumonectomy

The most complete sampling for pathologic staging is provided by extrapleural pneumonectomy (EPP). In general, an EPP specimen contains the lung, surrounding visceral pleura, parietal pleura of the chest wall, diaphragm, mediastinum, ipsilateral hemidiaphragm, and a portion of the ipsilateral pericardium. The procedure for processing such specimens used by the Department of Pathology of the Brigham and Women's Hospital has been described [42]. The procedure includes weighing the specimen and recording its dimensions (total dimensions of the specimen and dimensions of the lung, diaphragm, pericardium, and bronchial margins), assessing areas of pleural involvement, and describing the range in size of the tumour nodules and the range in thickness of the fused and unfused pleura.

Gross examination of the surgical pathology resection specimen also involves the identification of lesions that may be difficult to distinguish from diffuse MPM on gross examination, such as pleural hyaline plaques, talc granulomata, and incidental adenocarcinomas or other tumours [43, 44]. Pleural hyaline plaques are discrete, white, firm-to-hard patches of thickened pleura (1–5 mm) that range in size from 1–10 cm or larger and are often focally calcified. Most occur in the parietal pleura and have shell-like margins unless fused with tumour. Talc deposits resulting from previous talc pleurodesis generate a granulomatous inflammatory response and fibrosis. These lead to the formation of nodular or plaque-like, tan-to-yellow areas that thicken the pleura (1–3 mm) and are recognized as granulomata.

During gross examination of the tumour, we also sample fresh tissue for other tests, including electron microscopy (EM), cytogenetic analysis, and molecular studies. After formalin fixation, approximately 5 cm^3 of fixed lung parenchyma is taken (with care to avoid tumour, hyaline pleural plaque, and talc granulomata) and submitted for asbestos analysis. Asbestos bodies comprise an asbestos fiber core and an iron protein coat. They are visible by light microscopy in H&E sections and may be quantified after digestion of lung parenchyma and filtration through a Millipore filter. Asbestos fibres are invisible by light microscopy but are detected by both scanning and transmission electron microscopy. Elevated asbestos body 'counts' or asbestos fiber levels in lung tissue indicate increased inhalation of asbestos fibres. They are used widely to establish causation in cases of diffuse MPM [45, 46]. Asbestos body and asbestos fiber levels in lung tissue are not reliable aids in establishing a pathologic diagnosis of diffuse MPM, because other tumours that mimic diffuse MPM may also occur in association with elevated asbestos bodies/levels. Conversely, diffuse MPM may occur in the absence of elevated asbestos bodies/fibre levels.

Pleurectomy/decortication

A pleurectomy/decortication (P/D) specimen usually consists of multiple fragments of pleura with tumour implants without identifiable normal structures. These specimens are approached by describing the components, overall dimensions, and weight of the specimen, and the dimensions and gross features of the various fragments of the pleura and tumour. It is important to search for additional structures, such as skeletal muscle, adipose tissue, and/or pericardium that may be invaded by tumour. Any attached normal lung tissue may be used for asbestos body counts.

Histologic features

MPM is classified by light microscopic examination into the following three types: epithelial (epithelioid), sarcomatous (sarcomatoid), and mixed (biphasic) types, with the desmoplastic variant categorized as a subtype of sarcomatous diffuse MPM [47]. The World Health Organization divides diffuse MPM into the four following types: epithelioid, sarcomatoid, biphasic, and desmoplastic [48]. Extensive sampling of resection specimens is necessary for accurate classification of histologic type [39].

Immunohistochemical staining

Immunohistochemistry (IHC) is now widely used by pathologists to distinguish diffuse MPM from its many histologic mimics [49–55]. The most common problem is separating diffuse MPM from metastatic adenocarcinomas. No single antibody has been identified that

is specific for diffuse MPM or adenocarcinoma; therefore, panels of antibodies are used to make this distinction. A panel of four markers, two positive in diffuse MPM, but negative in adenocarcinoma, and two with the converse pattern of immunoreactivity, has demonstrated utility in making this distinction in most cases. We routinely use a panel of the four following antibodies: two that are positive markers for epithelial diffuse MPM: AE1/AE3 keratins, calretinin, WT-1 (nuclear staining), and D2-40 to distinguish diffuse MPM from other epithelioid malignancies. Two are negative markers: pCEA and TTF1. In contrast to its use in epithelial cell type, IHC is less helpful in the differential diagnosis of sarcomatoid diffuse MPM [56–59]. Antibodies that are positive in sarcomatoid diffuse MPM include keratin proteins, calretinin, WT-1, and D2-40, which identify podoplanin and antipodoplanin, but many pleural-based sarcomas and sarcomatoid carcinomas are also positive for these markers. The utility of panels comprising positive and negative (exclusionary) markers for sarcomatoid MPM remains to be determined [52, 53, 56–59].

Electron microscopy

Although immunohistochemistry has largely replaced electron microscopy (EM) in the diagnosis of MPM, it is advisable to take fresh tumour tissue for EM since, occasionally, the diagnosis is not resolved by light microscopy.

Pathologic staging

Only a fraction of patients with diffuse MPM undergo surgical resection. Surgical series large enough to inform staging have generally been retrospective studies from single institutions. Differing degrees of resection, failing to distinguish histological subtypes, variable application of non-surgical therapies, and treatment-related morbidity and mortality—each of which may influence outcome independent of stage—have hampered attempts to elucidate more subtle influences of staging criteria on patient prognosis. These factors have led to the proposal over the past several decades of a number of independent staging systems that differ in the significance attributed to specific classification criteria [60].

All proposed staging systems have been derived from and are primarily applicable to the subset of patients undergoing surgery, which represents the minority of MPM patients. There has been at best modest correlation between these staging systems and patient outcome. Close apposition of multiple vital structures to pleural surfaces does not permit wide surgical margins in surgery for MPM, and this leads to probable underestimation of involvement of adjacent structures in determining pathologic stage. Furthermore, there is poor correspondence between preoperative clinical stage and final pathological stage. In part, this results from the unique morphology and growth pattern of the primary tumour which limits radiographic assessment. The accuracy of clinical staging for the majority of MPM patients who are not treated surgically cannot be directly evaluated, but is likely to be similarly low unless there is unambiguous evidence of metastatic disease.

Surgical management of pleural mesothelioma

Surgery-based multimodality management offers the best chance for extended survival. Several multimodality strategies are being actively explored, and these are discussed under 'Multidisciplinary management of potentially resectable mesothelioma'.

Surgery in malignant pleural mesothelioma: macroscopic complete resection (MCR)

The goal of surgery in MPM is MCR [2]. This entails the complete removal of all grossly visible tumour. Unlike other solid tumours, complete eradication of the tumour with negative surgical margins (R0 resection) is frequently not possible with MPM because of the irregular anatomy of the pleura and close proximity to vital structures which creates a tendency for local invasion of the diaphragm, pericardium, chest wall, and mediastinum. Consequently, foci of microscopic disease often persist at the surgical margins, and patients are treated with adjuvant or neoadjuvant therapies to prevent local recurrence and/or metastases. Despite these limitations, MCR offers the fastest, least morbid, and often only method of cytoreduction to microscopic levels in surgery for mesothelioma.

Two operations have been developed for surgical resection. These are extrapleural pneumonectomy (EPP) and radical pleurectomy/decortication (P/D) (Figure 48.1). EPP is suitable for tumours that invade the lung parenchyma, while P/D is appropriate when the lung parenchyma is spared. The decision hinges on whether or not a macroscopic complete resection can be achieved. Partial pleurectomy is a different operation that is performed in the palliative setting to treat recurrent pleural effusion or to obtain extensive tissue for biopsy and further testing.

Preoperative assessment

The preoperative evaluation for EPP or radical P/D is identical as the decision to proceed with one or the other operation is occasionally made pending intraoperative findings. All patients undergo pulmonary function tests (including spirometry and diffusion lung capacity) and imaging (described below). All patients undergo transthoracic echocardiogram to assess global ventricular function, valvular disease, and, in particular, when EPP is being considered, to evaluate pulmonary artery pressure because of the potential for pulmonary hypertension and right heart strain induced by pneumonectomy. Duplex studies of the lower extremity veins also are done because mesothelioma patients represent one of the highest risk groups for venous thromboembolism. Treatment of deep vein thrombosis (DVT) with anticoagulation (and, if appropriate, inferior vena cava filter) prior to surgery is thought to reduce the risk of life-threatening pulmonary embolus after pneumonectomy.

Surgical patients should have a Karnofsky performance status of greater than 70 [61], normal liver and renal function tests, and normal room air oxygen saturation [62]. While a forced expiratory volume in 1 second (FEV_1) of greater than 2 L is generally adequate for pneumonectomy, quantitative ventilation/perfusion scanning is performed in all patients. The product of the perfusion to the unaffected lung and the preoperative FEV_1 yields the predicted postoperative (PPO) FEV_1. While this value ideally exceeds 1.2 L, patients with a PPO-FEV_1 greater than 800 cc are acceptable candidates for EPP depending on their body mass. Patients with ppo-FEV_1 of less than 800 cc may be considered for P/D if appropriate.

The presence of extensive pain, consumption of high-dose narcotics preoperatively, and/or a contracted hemithorax are clinical indicators of extensive chest wall invasion and the patient is likely unresectable. While chest radiography may suggest invasion, often the resectability of a tumour is not known until surgery. In fact, in

25% of cases, resectability of tumour cannot be determined preoperatively, and if critical mediastinal structures (e.g., aorta, oesophagus, vertebral bodies) are found to be involved at thoracotomy, the tumour is classified as T4, extensive resection is not recommended, and the operation does not proceed. The differentiation between radiographic evidence for the displacement (versus invasion) of mediastinal structures is a critical distinction, as many patients have been erroneously denied surgery based on displacement of mediastinal structures by resectable tumour. Similarly, imaging has limited value in distinguishing compression of tumour on the diaphragm from transdiaphragmatic abdominal invasion. If imaging suggests transdiaphragmatic extension, intra-abdominal tumour, or ascites, staging laparoscopy should be performed to evaluate the peritoneum prior to potential thoracic resection. Finally, patients with limited chest wall invasion on imaging without evidence of locally advanced invasive disease or metastases may be amenable to a surgical resection, and these patients should be considered for exploratory thoracotomy.

Histologic diagnosis is accomplished by thoracoscopic pleural biopsy via a single port placed in the location of a future thoracotomy (such that this can be excised at the time of future resection). We recommend staging cervical mediastinoscopy to rule out involvement of the mediastinal nodes, although there are limitations of this modality in diagnosing most extrapleural nodal disease. Patients who have mediastinal lymph node involvement are

offered induction chemotherapy and reassessment for surgery after two to four cycles of chemotherapy.

Outcomes for surgery

EPP and P/D result in distinctly different amounts of residual tissue previously associated with tumour. This impacts the biology and patterns of recurrence in MPM. With EPP, these potential sites for recurrence are limited to the resection margins of the diaphragm and pericardium, the lateral anterior and posterior chest walls, and the upper mediastinum and apex. With radical P/D, the surface area also includes all lung surfaces, leaving a much broader field for potential recurrence, although the benefit of sparing the lung from removal may offset this disadvantage. The appropriate operation depends on the characteristics of the individual tumour, whether the patient can tolerate the surgery, and which procedure can deliver MCR.

MPM has a distinct pattern of failure [63]. Unlike other solid tumours, in which haematogenous and lymphangitic metastases are the common sources of recurrence, the majority of patients with mesothelioma recur locally. The abdomen is the most common site and most likely represents regional spread by local invasion. It is rare for the tumour to metastasize via haematogenous spread to the contralateral chest. The patterns of recurrence differ between EPP and P/D. In a multicentre study of 663 consecutive patients who underwent surgery for mesothelioma, Flores and colleagues

found that ipsilateral chest recurrence occurred in 31% of patients who underwent EPP and in 63% of patients who underwent P/D [64]. In an updated retrospective review of patients undergoing multimodality therapy at the Brigham and Women's Hospital from 2001–2010, investigators found that ipsilateral chest recurrence was still the most frequent site of recurrence, accounting for 69% of recurrences experienced after EPP [65] and 95% of those after radical P/D [66].

Surgery also plays a role in the treatment of recurrent MPM. In a recent analysis of 1142 Brigham and Women's patients who underwent EPP or P/D between 1988 and 2011, 47 patients were treated with chest wall resection for recurrent disease [67]. Investigators found that chest wall resection for recurrence was safe and feasible and that time-to-recurrence from original disease was associated with overall survival following treatment of recurrence in both epithelial and non-epithelial disease.

The overall median survival for all patients undergoing surgery-based multimodality therapy for MPM is one to two years [41]. Median overall survival with EPP-based multimodality therapy in recent studies has been 10–35 months [63, 68–73]. Median survival with radical P/D-based multimodality therapy has been 8–22 months [64, 73–78]. In contrast, the median survival range for patients who receive cisplatin chemotherapy alone or in combination with pemetrexed is 9.3–13.3 months, respectively [79], and for palliative therapy, seven months [1, 80]. Predictors of longer overall survival for patients treated with surgery include epithelial histology, female gender, young age, and normal haemoglobin [67, 81]. Notably, preoperative anaemia has proved to be an independent prognosticator of poor time-to-recurrence and long-term mortality, regardless of cell type or procedure performed [82, 83].

While critics of surgery for MPM, in general, and of EPP, in particular, have claimed the risks of these procedures outweigh unclear survival benefit, attempts to randomize patients to surgery vs no surgery have not met with success. The Mesothelioma and Radical Surgery (MARS) trial was conceived to evaluate the role of EPP in treating MPM, but its design did not demonstrate feasibility, and exploratory analyses of data derived were performed with inadequate power to draw meaningful conclusions [84–86]. A recent multidisciplinary consensus opinion of surgeons, medical oncologists, and radiation oncologists formulated at the International Mesothelioma Interest Group Meeting (IMIG) in 2012 emphatically supported the role of either EPP or P/D, depending on tumour characteristics and surgeon experience, in the multimodality treatment of MPM [87].

Role of radiation therapy

Designing treatment plans for radiation therapy (RT) in MPM is challenging because of the large size and irregular architecture of the hemithorax, as well as the problematic presence of several normal structures with low tolerance to radiation within or adjacent to the treatment volume. The difficulty lies in devising a plan that can deliver sufficiently high doses of RT to the complex target while maintaining minimal doses to radiosensitive normal organs.

The role of RT in the curative treatment of MPM remains undefined. Published data do not support a role for RT as a single modality for curative treatment of unresected mesothelioma. Intensity-modulated radiation therapy (IMRT) to the circumferential pleural envelope following P/D has theoretical appeal and early

demonstration of feasibility, but long-term data are lacking [88–90]. Pleural IMRT is worthy of further investigation and is a potentially promising approach. RT after EPP is the best studied and perhaps the best indication for RT, and does appear to improve local control [91–93]. Nevertheless, delivering radiation to a field that includes an entire hemithorax with adequate dosing in the pleural recesses remains very challenging.

Moderate-dose radiation therapy (MDRT) (i.e., 30–40 Gy) has reported only fair results. Accordingly, this technique has been replaced by the electron-photon therapy (EPT) technique pioneered by the Memorial Sloan Kettering Cancer Center (MSKCC). EPT delivers a high dose of RT (54 Gy), and although it achieves less than ideal coverage of the target volume, local control rates with EPT are superior to MDRT and toxicities are low [94].

Intensity-modulated radiation therapy (IMRT) achieves the best dosimetry of all three approaches, but the pulmonary toxicity profile can be severe, and complications, although better understood, are difficult to predict [95–97]. RT appears to be effective for MPM and it is likely that IMRT following P/D and EPP will have an ultimate role in the multi-modality treatment of MPM. The challenge is to identify the optimal combinations of modalities such as heated intraoperative chemotherapy, systemic chemotherapy, photodynamic therapy, and targeted agents in addition to RT and surgery and to do this safely. For this reason, new combinations of multimodality therapies are best tested on prospective protocols with safety oversight. Furthermore, IMRT to the hemithorax should be offered only by experienced teams at high-volume centres until further data are acquired. Finally, RT alone may be used for palliation of symptoms in patients with unresectable cancer provided the disease is confined to a tolerable radiation field.

Systemic chemotherapy

Systemic chemotherapy for malignant mesothelioma remains a central component of treatment for most patients with the disease. There are several specific challenges to the development of new agents in mesothelioma. First and foremost is the low incidence of malignant pleural mesothelioma in all countries (e.g., 3300 cases per year in the US) [98]. Owing in part to this low incidence, much of the published literature in mesothelioma consists of single-institution case series or small, single-arm trials, Another obstacle to determining treatment efficacy in mesothelioma is the assessment of tumour response; the applicability of standard Response Evaluation Criteria in Solid Tumours (RECIST) has been limited in mesothelioma, particularly with respect to serial assessments of the pleural rind.

First-line chemotherapy for unresectable disease

The standard first-line therapy for patients with unresectable mesothelioma is cisplatin plus the antifolate agent pemetrexed. In a phase III trial, the addition of pemetrexed to cisplatin was generally well-tolerated by patients and led to measurable improvements in tumour response (41.3% vs 16.7%, p <0.0001), median time-to-progression (TTP) (5.7 vs 3.9 months, p = 0.002), and median overall survival (OS) (12.1 vs 9.3 months, p = 0.02). When poor performance status and/or presence of medical comorbidities preclude patients from receiving cisplatin-based therapy, treatment with pemetrexed plus carboplatin or pemetrexed monotherapy can be considered. The optimal duration of first-line therapy with

platinum-pemetrexed combination chemotherapy has not been firmly established. In the registrational phase III trial, there was no limit to the number of cycles administered. In that study, the range was 1–12 cycles, with a median of six cycles [79]. In practice, physicians often stop after four to six cycles.

Pemetrexed as maintenance therapy or second-line therapy

For patients who do not receive pemetrexed in the first-line setting, use of this agent as a second-line treatment is warranted [99, 100]. Furthermore, for patients who receive pemetrexed in the first-line setting and who do not progress during or shortly after receiving such treatment, consideration should be given to re-initiation of pemetrexed at the time of subsequent progression.

Additionally, both gemcitabine and vinorelbine have demonstrated activity in this disease and could be considered in patients who have progressed after pemetrexed-based regimens.

Trends in radiology

Preoperative evaluation

Accurate preoperative determination of resectability by imaging allows appropriate treatment planning. The initial presentation of MPM is generally heralded by the presence of pleural effusion and other nonspecific signs of pleural disease on plain chest radiographs, but CT continues to be the mainstay of the radiologic analysis of MPM and the primary modality for diagnosis [101]. The constellation of imaging findings include, but are not limited to, unilateral

pleural effusion, circumferential nodular pleural thickening, pleural masses, and contraction of the involved hemithorax. Invasion of adjacent structures, adenopathy, and presence of osseous, pulmonary, and distant metastases are more commonly observed in advanced disease [41, 102]. Detecting chest wall invasion, transdiaphragmatic spread, peritoneal involvement, and lymph node metastases, particularly N2 disease, carries a poor prognosis [103] and continues to be challenging by CT alone (see Figures 48.2 and 48.3), and can be enhanced with a multi-modality approach with complementary information derived from MRI and FDG PET-CT.

Newer and innovative techniques such as tumour volumetric analysis, DCE-MRI (dynamic contrast enhanced MRI), DWI (diffusion weighted imaging), and newer PET tracers can help optimize management strategies.

Multidisciplinary management of potentially resectable mesothelioma

The concept of MCR by EPP and P/D has been described under 'Surgical management of pleural mesothelioma' [2]. Here we discuss four well-documented multimodality strategies.

Extrapleural pneumonectomy followed by chemoradiotherapy

The largest published series to date involving EPP in a multimodality setting with adjuvant chemotherapy and radiotherapy is that of Sugarbaker and the group from Brigham and Women's Hospital in Boston (US) [104–106]. In 1999, they reported 176 patients with
Fig. 48.2 (A–D) Serial axial and coronal images CT images through the chest showing pleural rind encasing the right hemithorax, most marked along the upper chest. There is a small volume right pleural effusion as well. No evidence of chest wall invasion, or contra-, lateral, or intra-abdominal disease.
Fig. 48.3 Axial, coronal and sagittal post contrast MR images (VIBE) (A, B, D–G) showing enhancing circumferential pleural rind encasing the right hemithorax with the bulk of the tumour in the upper hemithorax; there is a moderate right pleural effusion. No evidence of mediastinal invasion, chest wall invasion, transdiaphragmatic spread, or contralateral disease. (C) The tumour has restricted diffusion on DWI with an apparent diffusion coefficient (ADC) value of 1.10 (±0.16) x 10^{-3} mm^2/s which is suggestive of biphasic mesothelioma. (H) Coronal fused PET-CT image showing a right mesothelioma confined to the right hemithorax, no evidence of distant metastasis. The patient underwent an extrapleural pneumonectomy.

a median survival of 19 months and operative mortality of 3.8%. An update published in 2004 reported 183 patients with intention to treat by a trimodality approach and an operative mortality of 3.4%, similar to mortality rates reported for pneumonectomy alone without additional treatments [41]. The Mayo Clinic reported a retrospective evaluation of EPP with adjuvant chemotherapy. Median survival in this series was 16 months (n = 73) with neoadjuvant and/or adjuvant radiotherapy [75]. To date, the best survival was reported in a retrospective study by Tonoli et al. in 2011. This series demonstrated a median survival of four years (four-year survival of 50% with SD +/- 9) in 56 patients treated with EPP followed by various methods of radiation (mostly IMRT) with chemotherapy (generally cisplatin-pemetrexed) given before or after surgery [107]. These results were more promising even than those reported by Aziz et al. in 2002, in which EPP followed by cisplatin-based systemic chemotherapy was associated with a 35-month median survival [73]. Table 48.1 summarizes the reported literature on EPP with adjuvant chemotherapy. Cao et al. report their recent systematic review of the literature on EPP in the context of multimodality therapy (induction or adjuvant chemotherapy with or without adjuvant radiotherapy) [108]. The authors' summary of perioperative outcomes in the 16 studies included in the summary report

perioperative mortality ranging from 0–12.5% and overall morbidity of 50–83%, with major perioperative complications occurring in 24–54% of patients.

Extrapleural pneumonectomy or radical pleurectomy/decortication with heated intraoperative chemotherapy

In addition to trimodality therapy, Sugarbaker and colleagues have evaluated the concept of heated intraoperative chemotherapy (HIOC) after macroscopic complete surgical resection as a means of local disease control, under the theory that local recurrence limits survival in this disease. The protocol for HIOC has been previously described [109–111]. The rationale for bathing the empty thorax with a heated solution of chemotherapy after the surgical specimen has been removed is based on sound pharmacological principles. Hyperthermia increases the cytotoxicity of the compound and systemic toxicity is spared because the majority of drug is delivered locally enabling larger dose delivery to surgical margins. This technique also has been successfully applied to the peritoneum in malignant peritoneal mesothelioma [112]. After testing several protocols to determine the maximum tolerated dose and feasibility of this treatment, the protocol was refined by the addition of chemical agents for organ protection. The results of this multimodality approach have been published in a series of

papers. Most recently, Sugarbaker et al. reported extended interval to recurrence (27.1 vs 12.8 months) and overall survival (35.3 vs 22.8 months) in a group of low-risk patients (n = 72) with epithelial histopathology and other favourable prognostic factors (tumour volume ≤500 cm (3); male gender with a haemoglobin level of ≥13 g/dL; or female) compared with controls (n = 31). The findings were particularly evident among subgroups that did not receive hemithoracic radiotherapy and/or had pathologic stage N1 or N2 lymph node metastases [111].

Extrapleural pneumonectomy after neoadjuvant chemotherapy

The rationale for administering chemotherapy prior to radical resection in MPM is several fold. The primary objective is to downstage the tumour or eradicate the outer tumour layer for better resectability [106]. This concept was prompted by the positive experience with neoadjuvant therapy in patients with stage IIIA NSCLC (non-small cell lung cancer). Further justification for sequencing chemotherapy before surgery is the patient's ability to tolerate the recommended chemotherapeutic regimen. Patients have difficulty complying with the rigours of post-operative chemotherapy after a major resection and often are unable to tolerate the recommended dose and/or complete the recommended cycle. This has been supported in a study of pemetrexed plus cisplatin in NSCLC where

patients who received neoadjuvant chemotherapy were more likely to complete the recommended dose and cycle [113, 114]. Another value to neoadjuvant therapy was demonstrated in a multicentre phase II trial suggesting that initial response to neoadjuvant chemotherapy may have prognostic significance for extended survival in patients undergoing trimodality therapy [70].

The strategy of using neoadjuvant chemotherapy followed by EPP to treat patients with resectable MPM was pioneered by Weder et al. in a pilot study of 19 patients with MPM who underwent extrapleural pneumonectomy after neoadjuvant cisplatin plus gemcitabine [115]. The study was conducted at the University Hospital of Zurich, Switzerland, and yielded a response rate of 31%. Sixteen patients underwent EPP with no perioperative mortality. Median survival was 23 months and two patients remained disease-free six years after surgery. Table 48.2 summarizes the experience with neoadjuvant chemotherapy and EPP or P/D.

Recent reviews confirm that pemetrexed and cisplatin combination produces the best overall survival and quality of life for patients. Four to six weeks is considered the optimal timing after the last cycle of neoadjuvant chemotherapy has been completed for surgical resection.

The choice of operation (EPP or P/D) remains undefined. A large multicentre retrospective review of 663 cases combining the experience of three large centres in the US experienced in EPP and P/D emphasized similarities in outcome irrespective of procedure, although there is a bias in selection and the local recurrence rate for P/D is higher [64]. Conversely, initial analysis of the International Association for the Study of Lung Cancer (IASLC) reported a survival advantage in patients undergoing EPP [116]. Currently, there are no data in the literature that clearly support one or the other procedure, and the only clear indication is for P/D in patients with cardiac or other comorbidities who are physically unable to tolerate EPP.

Extrapleural pneumonectomy plus chemoradiotherapy

As described above, the role of radiotherapy in MPM remains undefined. However, the risk of disease recurrence in the ipsilateral chest is not unforeseen given that EPP is an R1 resection by definition. In 1997, Baldini et al. reported a 35% rate of recurrence in patients undergoing EPP [63]. This experience prompted the investigation of adjuvant radiotherapy in surgically resected patients. The clinical investigation of adjuvant chemotherapy has been adequately described under 'Systemic chemotherapy'.

Pleurectomy/decortication and adjuvant therapy

A variety of adjuvant treatments have been applied in patients undergoing P/D. These studies include chemotherapy, radiotherapy, intrapleural therapy, hyperthermic intracavitary chemotherapy, and photodynamic therapy (Table 48.3).

Photodynamic therapy is a light-based treatment that requires a non-toxic photosensitizing compound, oxygen, and visible light. The treatment is delivered into the empty hemithoracic cavity. The therapeutic principles are similar to HIOC, to control local spread of tumour by achieving greater penetration of tissues at the surgical margins [117–119]. In addition, photodynamic therapy is thought to stimulate immunologic events that boost healing.

The real success in mesothelioma can be found in series that follow a strict paradigm of surgical cytoreduction followed or preceded by adjuvant treatment. Further advances will come with greater understanding of the biology and genetics of the disease and with the use of additional targeted biologic therapies.

CHAPTER 49

Skin cancer: melanoma

John F. Thompson, Richard A. Scolyer,
and Richard F. Kefford

Introduction to melanoma

Melanoma is a malignant, often aggressive, potentially fatal tumour that develops when genetic and metabolic abnormalities occur in melanocytes. The latter are pigment-producing cells that originate in the neural crest and migrate to the skin and other body sites during embryonic development. Because most melanocytes are found in the skin, the majority of melanomas are cutaneous in origin and this chapter will deal principally with cutaneous melanoma. However, melanoma can also arise from melanocytes at non-cutaneous sites. The clinical features and management of mucosal melanomas will be discussed briefly, but ocular melanomas will be considered separately (see Chapter 57, Tumours of the eye and orbit).

Cutaneous melanoma is a steadily increasing health problem in developed countries with mainly fair-skinned populations, and the rate of increase in its incidence is greater than that of any other solid tumour type. Until recently, the treatment of all forms of melanoma was primarily surgical. However, recent advances in knowledge of molecular biology and the recognition that melanoma develops as a result of the accumulation of multiple genetic abnormalities within melanocytes, together with improved understanding of the role of the immune system in regulating melanoma, have led to much more effective medical therapies than were previously available. Fortunately, the great majority of patients who develop melanoma present at a stage when cure can be achieved by relatively simple surgery. Nevertheless, 10–15% of those who present with a primary cutaneous melanoma will eventually develop distant metastases; at the present time in almost all these patients the disease will ultimately prove fatal. Medical therapy for advanced melanoma is, however, a rapidly evolving field, and there are grounds for considerable optimism that within the next few years new systemic treatments will achieve good long-term control and possibly even elimination of metastatic melanoma at distant sites.

Molecular biology and pathogenesis

Sun exposure is calculated to be involved in the causation of more than 80% of cutaneous melanomas. Ultraviolet (UV) radiation induces pyrimidine dimer mutations in DNA, resulting in a characteristic profile of UV-induced damage on whole exome sequencing of melanomas. UV radiation also promotes the production of growth factors from keratinocytes and other skin cells, and suppresses T cell-mediated cutaneous immune defences. The stimulation of melanin production by UV radiation produces reactive oxygen species of melanin that cause DNA damage and suppress apoptotic mechanisms. Melanoma forms as the result of accumulated abnormalities in genetic pathways within the melanocyte that promote cell proliferation and prevent normal pathways of cell death in response to DNA damage. The genetically unstable melanocyte is thereby predisposed to accumulate successive DNA damage. This results in the rapid selection for genetic mutations that permit and promote angiogenesis and evasion of the immune response and allows rapid selection of variants capable of invasion and metastasis. Melanoma cells display resistance to cellular death mechanisms at multiple levels; this probably explains much of the observed resistance of melanoma cells to cytotoxic attack using chemotherapy, radiotherapy, or immunotherapy.

Benign proliferations of melanocytes (naevi) frequently carry mutations in the BRAF oncogene, but are arrested through protective triggering of senescence. Melanomas may arise in naevus precursors when naevus cells escape senescence, although the mechanisms of this remain controversial. The primary somatic genetic mutations in melanoma are unknown, but tumour progression usually involves activation of the mitogen-activated protein kinase (MAPK) pathway by acquisition of mutations in BRAF (50%), NRAS (20%), EGFR (10%), or other mechanisms. One of the principal downstream targets of the MAPK pathway is the master melanocyte-regulator, micropthalmia transcription factor (MITF), which is also mutated in 10% of melanomas. MITF regulates a suite of genes governing cellular proliferation, survival, and invasion. Genes frequently disregulated in melanoma are shown in Table 49.1.

Controversy continues over the role of stem cells in melanoma but the demonstration that the majority of cells within an established melanoma are capable of stem-like behaviour encourages a concept of plasticity in melanoma ontogeny, rather than the classical hierarchical pattern familiar from haematology.

Genetic predisposition to melanoma

Melanoma risk is substantially increased in those with a family history of melanoma. The presence of one affected first-degree relative doubles risk, and risk further escalates with additional affected close relatives, relatives with multiple primary melanomas, and relatives affected at younger ages.

Around 2% of all melanomas are due to identifiable, heritable mutations in highly-penetrant genes, including CDKN2A and, very rarely, CDK4, and BAP1 (Table 49.2). Some, but not all, of these families also display the phenotype of multiple atypical naevi,

Table 49.1 Genes frequently altered somatically in melanoma

Gene	Full name	Function
MITF	MIcropthalmia Transcription Factor	Master melanocyte transcription factor
BRAF	B-Rapidly Accelerated Fibrosarcoma gene	Growth factor signalling
NRAS	N-RAt Sarcoma protein	Growth factor signalling
EGFR	Epidermal Growth Factor Receptor	Growth factor signalling
TERT	TElomerase Reverse Transcriptase	Regeneration of telomeres evading cell death
CDKN2A	Cyclin Dependent Kinase iNhibitor 2A	Cell cycle control
PTEN	Phosphatase and TENsin homologue	Regulation of growth factor signalling
PREX2	Phosphatidylinositol-3,4,5-trisphosphate-dependent Rac EXchange factor 2	Regulation of growth factor signalling

including polypoid atypical Spitz naevi in those with BAP1 germline mutations. The presence of multiple naevi in an individual, whether atypical or not, is a strong marker for melanoma risk irrespective of family history. The presence of naevi alone cannot be used to predict the presence of CDKN2A germline mutations. Certain families with inherited CDKN2A mutations also have an increased risk of pancreatic cancer. Carriers of inactivating mutations in the gene display a risk of melanoma of between 50% and 90% by the age of 80. Inherited mutations in this gene are found in 30–40% of families with three or more melanoma-affected close relatives.

Cancer genetics consultation should be considered according to the 'rule of threes': (1) patients with three or more melanomas in first-degree or second-degree relatives on the same side of family; (2) families with three or more cases of melanoma or pancreatic cancer on the same side of the family; or (3) in lower incidence countries, like Northern Europe, individuals with three or more primary melanomas.

Certain inherited variants of the melanocortin-1 receptor (MC1R) gene confer increased UV-sensitivity and a two- to four-fold elevation in melanoma risk. Alterations in other genes associated with skin pigmentation also confer small elevations in risk (Table 49.2).

Epidemiology and prevention

Cutaneous melanoma is a malignancy that mainly affects fair-skinned people, particularly those with Celtic ancestry. It occurs most frequently when such individuals are exposed to high levels of solar UV radiation, especially when sun exposure is intense and intermittent, particularly during childhood. Other factors associated with melanoma are the presence of many naevi, particularly atypical (dysplastic) naevi, and higher socio-economic status. Individuals with a past history of melanoma are at higher risk, as are those with a history of non-melanoma skin cancer and those with a family history of melanoma.

Worldwide, the incidence of cutaneous melanoma has been increasing steadily for several decades. It now represents a major health problem for many developed nations, with incidence figures already approaching those of lung cancer, breast cancer, prostate cancer, and bowel cancer in countries such as Australia and New Zealand where the majority of the population is fair-skinned

Table 49.2 Genes associated with inherited melanoma risk

	Chromosome	Protein	Function	Penetrance	Population frequency of mutations/variants	Predictive gene testing
High risk						
CDKN2A	9p21	p16^{INK4A}, p14ARF	Cell-cycle regulation, apoptosis	High	Low	Consider, by rule of threes
CDK4	12q14	Cyclin-dependent kinase 4	Cell-cycle regulation	High	Low	Very rarely in specific families
BAP1	3p21	BRCA1-Associated Protein 1	Chromatin modulation, transcriptional regulation, ubiquitin-proteasome system	High	Low	Very rarely in specific families
Low risk						
MC1R	16q24	Melanocortin 1 receptor	Pigmentation	Low	High	No
ASIP	20q11	Agouti signalling protein	Pigmentation	Low	High	No
TYR	11q14	Tyrosinase	Pigmentation	Low	High	No
TYRP1	9p23	Tyrosinase-related protein 1	Pigmentation	Low	High	No
MITF	14q32	Micropthalmia-associated transcription factor	Regulation of melanocyte differentiation and stemness	Medium	Low	No
Unknown	1q21	N/A	N/A	N/A	N/A	No

Table 49.3 Melanoma incidence rates for Australia, the USA, the Netherlands, and the UK

	Age-standardized incidence (10^5/year)	Lifetime risk (incidence)	Incidence trend over 10 years	Mortality trend	Age-standardized mortality (10^5 year)	National Cancer Frequency (ranking)
Australia (2009/2010)						
Men	61.7	1 in 14	42% increase (1991–2009)	No significant increase or decrease (1991–2009)	8.9	3rd
Women	40	1 in 23	18% increase (1991–2009)	No significant increase or decrease (1991–2009)	3.5	3rd
USA (2009/2010)						
Men (whites only)	31.9	1 in 41	19% increase (2000–2009)	11% increase (2000–2009)	4.6	5th
Women (whites only)	20	1 in 61	20% increase (2000–2009)	No significant increase or decrease (2000–2009)	2.0	6th
The Netherlands (2008)						
Men	14.7	1 in 71*	45% increase (1989–2008)	64% increase (2002–2011)	3.0	12th
Women	18.8	1 in 59*	37% increase (1989–2008)	52% increase (2002–2011)	2.0	12th
UK (2010)						
Men	17.2	1 in 55	63% increase (2000–2010)	82% increase (2000–2010)	3.1	6th
Women	17.3	1 in 56	67% increase (2000–2010)	90% increase (2000–2010)	1.8	6th

*Only 2006 estimates of lifetime risk available.

and exposed to high levels of solar UV radiation. Melanoma incidence rates for Australia, the USA, the Netherlands, and the UK are shown in Table 49.3. The table shows that melanoma incidence continues to increase at an alarming rate around the world. In the Netherlands and the UK, melanoma mortality rates continue to rise, but in Australia and the US mortality rates appear to have stabilized since the turn of the century.

The mutagenic effect of UV light, particularly UVB, on melanocytes has been clearly established, and sun-protection education programs are now conducted in many countries where the incidence of melanoma is high. There are some early indications that attempts to reduce the incidence of melanoma through these programs are proving effective, but because the latent period for melanoma development following UV-induced initiation may be several decades, further time will need to elapse before their value can be fully assessed. The dangers of UV exposure through sunbed use, particularly in teenagers and young adults, have also been recognized and for this form of cutaneous UV exposure the latent period for melanoma development may be short.

Clinical diagnosis and biopsy confirmation of diagnosis

The diagnosis of cutaneous melanoma is normally straightforward. However, even for experienced dermatologists it can sometimes be challenging to differentiate an early invasive melanoma from a benign naevus, and the clinical differentiation between a dysplastic naevus and an in situ melanoma can also be extremely difficult. Furthermore, up to 10% of melanomas do not have the typical dark pigmentation but are non-pigmented, often pink lesions when examined with the naked eye; these are termed amelanotic melanomas, and they may be confused with non-melanocytic skin cancers such as squamous cell carcinomas or basal cell carcinomas.

The classical diagnostic features of a melanoma, whether it presents as a change in a pre-existing pigmented lesion on the skin or as a new pigmented lesion, are asymmetry, border irregularity, and colour variegation. Transformation of a previously flat lesion into one that is elevated and palpable should always also arouse suspicion, and a larger lesion (more than 6 mm in diameter) is more

likely to be a melanoma than a smaller lesion. To aid diagnosis, these features have been fitted into an ABCDE system (Asymmetry, Border irregularity, Colour variegation, Diameter >6mm, and Elevation). Some have suggested that 'E' might also be used for Evolution, i.e., change in appearance. When assessing suspicious skin lesions it must always be borne in mind that up to 50% of cutaneous melanomas do not arise in pre-existing naevi but in apparently normal skin.

Critical to the proper assessment of pigmented skin lesions and the diagnosis of melanomas is careful examination with good lighting, preferably with a magnifying device. A hand-held dermatoscope allows suspicious lesions to be assessed in more detail. Dermoscopy has been shown in several large, carefully conducted studies to improve diagnostic accuracy considerably, particularly for clinicians who are not dermatologists. The technique not only provides the requisite magnification and good lighting but additionally it uses epiluminescence microscopy to assist in differentiating benign from malignant melanocytic lesions. Also useful in melanoma diagnosis is computerized imaging, which if repeated can allow suspicious lesions to be monitored carefully and changes identified. High quality whole-body digital photography is another technology that is useful for monitoring. Careful serial assessment of lesions with photography or computerized imaging has been shown to be of value in patients with many lesions, particularly those with numerous atypical (dysplastic) naevi (the 'dysplastic naevus syndrome'). An evolving technique for melanoma diagnosis is reflectance confocal laser microscopy, which allows in vivo microscopic examination in a horizontal plane. Confocal microscopy is particularly useful for defining the extent of in situ melanomas. A detailed description of diagnostic techniques for melanoma is beyond the scope of this chapter, but well-illustrated guides are available in both printed and electronic forms.

When careful clinical examination with use of relevant technological aids indicates that a lesion might be a melanoma, a surgical biopsy should be performed. Complete excisional biopsy with 2 mm clearance margins is preferred, and gives the reporting histopathologist the best opportunity to provide an accurate diagnosis. Incision biopsies and shave biopsies often make interpretation difficult for the pathologist, and it is important to note that the majority of cases of litigation related to misdiagnosis of melanomas involve the use of partial biopsies.

The importance of clinical history in melanoma diagnosis cannot be over-emphasized, and if a patient reports that a lesion has appeared only recently, has become larger, itches or has begun to bleed intermittently, the clinician's level of suspicion must be high and a biopsy performed unless a very confident diagnosis of a benign lesion can be made.

Histopathological features and reporting of cutaneous melanoma, and histological classification

Pathological diagnosis of melanoma

To determine whether a pigmented lesion is a melanoma or a benign naevus, the pathologist must assess a range of microscopic features and correlate these with clinical information, including the anatomical site of the lesion, the patient's age, and more specific details about the lesion such as a history of change or prior trauma. If the clinical features do not correlate with the pathological interpretation, it is usually prudent to review the pathology in the clinical context and, if a partial biopsy has been performed, consider performing a further biopsy of the lesion (preferably complete excision biopsy).

Histologically ambiguous tumours ('melanocytic tumours of uncertain malignant potential')

Whilst the vast majority of melanocytic tumours can be rapidly and accurately classified as naevi or melanomas by routine pathological assessment, it is now well recognized that there exists a small subset of cases which display some benign features and other features suggestive of melanoma. Such lesions have been described using a variety of terms including 'melanocytic tumour of uncertain malignant potential' (MelTUMP), histologically ambiguous melanocytic tumour, or borderline melanoma. These terms should not be regarded as specific diagnoses but rather as a means of communicating uncertainty regarding their biological potential. For such problematic tumours, it is now well-documented that the interobserver reproducibility for their pathological classification is poor, and even tumours regarded as benign by a majority of acknowledged experts may on occasion prove lethal.

There is increasing recognition of the likely existence of a poorly-defined intermediate grade of melanocytic neoplasms with low-grade malignant potential that show frequent involvement of sentinel lymph nodes but infrequent spread beyond the regional lymph nodes to distant metastatic sites. The assessment of risk and prognostic factors (and as a consequence, management decisions) for such tumours remains problematic. In recent years, there have been concerted efforts to develop adjunctive diagnostic techniques, particularly molecular techniques that may assist in the more accurate classification of such tumours.

Molecular assessment of primary melanocytic tumours

Molecular studies have demonstrated that melanomas are characterized by the presence of numerous chromosomal copy number gains and losses and that in most naevi (apart from Spitz naevi, which may occasionally show chromosomal gains in 11p or 7q) such aberrations are not observed. The classification of difficult melanocytic tumours, in which accurate characterization of the tumour as benign or malignant is difficult based on routine histopathology, may be assisted by assessment for the presence of chromosomal copy number aberrations.

Comparative genomic hybridization

Comparative genomic hybridization (CGH) can be used to detect chromosomal copy number aberrations in formalin-fixed, paraffin-embedded tissue. Although this technique has the advantage of being able to detect any aberrations occurring in the genome, there are a number of technical and practical reasons why it is often not an appropriate adjunct to pathological diagnosis in routine clinical practice.

Fluorescence in situ hybridization

Fluorescence in situ hybridization (FISH) is a technique that can be utilized to directly visualize specific chromosomal copy number changes within individual tumour cells. While it has the limitation of being able to test for only a limited number of changes (compared to CGH, which tests for chromosomal aberrations in the entire

genome), FISH is more easily applied in routine clinical practice and can be successfully performed on small tumour samples.

Classification of melanoma

It has long been recognized that melanoma is not a single disease entity but consists of a number of disease subtypes. The traditional clinicopathological classification scheme for melanoma, based on the pioneering work of Clark, McGovern, and others in the late 1960s and the 1970s, includes four main subtypes: superficial spreading melanoma, nodular melanoma, lentigo maligna melanoma, and acral lentiginous melanoma. Other less common melanoma subtypes such as desmoplastic melanoma and naevoid melanoma have been recognized and characterized more recently.

From a clinical perspective, the major importance of the traditional Clark-McGovern melanoma classification scheme is that it highlights the various clinical and histological appearances of melanoma that must be recognized by clinicians and pathologists in order to avoid misdiagnosis. As detailed below, the prognosis for a patient with apparently localized primary cutaneous melanoma is principally determined by tumour thickness [1], and the melanoma subtype does not have independent prognostic significance.

Molecular classification of melanoma

In the past decade, critical molecular alterations in melanomas have been identified, as previously discussed. A comparison of the traditional clinicopathological melanoma classification with a classification based on the somatic mutation status reveals remarkable similarities. For example, melanomas associated with prominent solar damage (lentigo maligna melanomas) commonly have NRAS and sometimes KIT mutations, while superficial spreading melanomas that arise in the skin of intermittently sun-exposed areas often have BRAF mutations. BRAF mutant melanoma is also associated with younger patient age, lack of cumulative sun-induced damage at the primary site, truncal location, and a high body naevus count. A recent study reported that of patients with a BRAF mutation, 73% were V600E, 19% V600K, and 8% other genotypes. There was an inverse relationship between BRAF mutation prevalence and age. All patients <30 years and only 25% of patients ≥70 years had BRAF-mutant melanoma. Amongst BRAF-mutant melanoma, the frequency of non-V600E genotypes (including V600K) increased with increasing age.

The melanoma pathology report

Pathological features of the primary melanoma are strong predictors of outcome for patients with clinically localized primary cutaneous melanomas [2]. Numerous studies have shown that tumour thickness (measured using the method described by Breslow) is the strongest prognostic factor. Multiple recent studies have demonstrated that the mitotic rate of the dermal component of a melanoma is also a strong prognostic factor, as is ulceration.

It has been demonstrated that a structured or 'synoptic' format can facilitate the reporting of all relevant histological features in the pathology report, allowing formulation of an appropriate management plan and an accurate estimation of prognosis (Table 49.4).

Various pathological features and their significance

Breslow thickness

Breslow thickness is the single most important prognostic factor for patients with clinically localized primary melanoma who have

Table 49.4 Example of a structured (synoptic) pathology report format for a primary cutaneous melanoma

Specimen type	Excision
Site	Left thigh
Diagnosis	Primary cutaneous melanoma
Classification/main pattern	Superficial spreading
Breslow thickness	2.7 mm
Clark level	IV
Ulceration	Present
Diameter of ulcer	5.5 mm
% of dermal invasive tumour width	60%
Dermal mitotic rate	12/mm^2
Predominant cell type	Epithelioid
Intravascular/intralymphatic invasion	Absent
Neurotropism	Present (perineural)
Satellites	Absent
Desmoplastic component	Absent
Features of regression	
Early (TILs)	Grade 1 (Focal and mild)
Intermediate	Absent
Late (fibrosis and loss of rete ridges)	Absent
Associated naevus (type)	Dysplastic compound
Actinic/Solar elastosis	Moderate
Margins	
In situ component—nearest peripheral	3.2 mm clear of inferior margin
Invasive component—nearest peripheral	5.2 mm clear of inferior margin
Invasive component—nearest deep	4.4 mm

not had pathological regional node staging. Breslow thickness is measured from the top of the granular layer of the epidermis (or, if the surface is ulcerated, from the base of the ulcer) to the deepest invasive cell.

Ulceration

Ulceration is an integral component of the American Joint Committee on Cancer (AJCC)/International Union Against Cancer (UICC) staging system and an independent predictor of outcome in patients with clinically localized primary cutaneous melanoma. The extent of ulceration (measured either as diameter or percentage of tumour width) provides more accurate prognostic information than the mere presence of ulceration.

Mitotic rate

Multiple recent studies have demonstrated that mitotic rate (of the invasive component of a melanoma) is an important prognostic factor for clinically localized primary melanomas and its routine reporting is recommended by the AJCC (Figure 49.1). Furthermore, the presence or absence of mitotic figures in non-ulcerated thin (≤1.0 mm) melanomas is utilized in the seventh (2010) edition of
Fig. 49.1 Survival curves by number of mitoses/mm^2.

the AJCC Staging System for Melanoma for separating pT1a and pT1b tumours. For consistency and reproducibility, a standardized method for determining the mitotic rate must be used.

Other factors

Other pathological features of the primary melanoma that influence prognosis include the presence of lymphatic or blood vessel invasion, Clark level of invasion, tumour-infiltrating lymphocytes, tumour regression, and the presence of a desmoplastic melanoma component.

Satellites

Up to 13% of melanoma patients (with or without a positive sentinel lymph node [SLN]) develop recurrence between the primary tumour site and regional lymph nodes. Depending on their proximity to the primary tumour site, such recurrences have been termed local recurrences, satellites, and intransit metastases (although the definitions used by different investigators have not been consistent). Apart from true local recurrences due to incompletely excised primary melanomas (persistent primary melanomas), all of these terms represent a biologically similar phenomenon (i.e., local metastasis) and the definitions used for them are therefore somewhat arbitrary The presence of satellites or intransit metastases has serious adverse prognostic impact and, in the absence of synchronous nodal metastases, such patients are included in the same prognostic group as those with nodal metastases (N2c) in the seventh (2010) edition of the AJCC Staging System [1].

Pathology of sentinel lymph nodes

A SLN can be defined as any lymph node that receives direct lymphatic drainage from the primary tumour site. At the present time, although the optimal methodology for SLN pathological examination is not uniformly agreed, there is general consensus that both haematoxylin-eosin stained sections and sections stained immunohistochemically for various melanoma-associated antigens (such as S-100 protein, HMB-45, and MelanA/MART1) should be examined.

Multiple recent studies have demonstrated that both the location and extent of tumour deposits within SLNs are not only strong predictors of the presence of positive non-SLNs in completion lymph node dissection (CLND) specimens but also provide important prognostic information. For example, if there are only a few metastatic tumour cells in the SLN subcapsular sinus, the probability of finding additional metastatic disease in a CLND specimen is extremely small and the patient's prognosis is very good. In contrast, if there are multiple large metastatic foci and the tumour cells extend deeply into the central part of the SLN, the chance of finding metastases in non-SLNs in a CLND specimen is much higher and the prognosis is much worse.

Molecular pathology mutation testing

Molecular genetic testing of melanocytic tumours has the potential to identify subgroups of tumours with specific genetic signatures that may accurately predict their likely clinical course and/or response to treatment. It is usually performed in the context of patients with advanced stage metastatic disease who are being considered for targeted therapies. Mutation testing can be performed on routinely collected archival formalin-fixed, paraffin-embedded tissue. It can also be performed on fresh tissue, but this is not essential. Specimens containing a high percentage of viable tumour cells are the most suitable (thus SLNs containing micrometastases admixed with numerous lymphocytes are often unsatisfactory). Nevertheless, core biopsies and cell blocks made from fine-needle biopsy cytology specimens can often yield diagnostic results.

An important issue to consider when ordering mutation testing is which is the most appropriate specimen to test. At the current time, only limited data are available regarding the concordance of BRAF and NRAS mutation status between primary and metastatic

melanomas from individual patients. In one recent study, the concordance rates ranged from 75–96% in metastases from different locations. Therefore, it would appear most appropriate to perform mutation testing on the most recent distant metastatic melanoma specimen provided sufficient viable tumour cells with minimal admixed non-tumour cells is available. If this is not available, testing of locoregional/in-transit metastases is preferred to testing of the primary melanoma.

Mutation testing assays currently in widespread use in clinical practice include traditional Sanger sequencing, allele-specific reverse transcriptase-polymerase chain reaction (RT-PCR), mass spectroscopy/multiplex assays, and pyrosequencing. Each of these techniques has some advantages and disadvantages, and as a consequence no single testing methodology is ideal. Sanger sequencing, usually supplemented by pre-screening with high-resolution melting curve analysis to select only abnormal specimens for further analysis, has traditionally been considered the gold standard. While it detects all known and new mutations (i.e., it is comprehensive), it has only moderate technical sensitivity (about 25%). Hence, careful macrodissection by pathologists to enrich for tumour cells is an important pre-analytical step with this technique. Allele-specific RT-PCR tests (e.g., the Roche cobas 4800 BRAF V600 mutation test) offer high sensitivity but will only detect specific targeted mutations. For example, the Roche cobas test was designed to detect $BRAF^{V600E}$ mutations and does not detect other BRAF mutations (including a significant proportion of $BRAF^{V600K}$ mutations). This may have important clinical consequences because $BRAF^{V600K}$ mutations have been reported to occur in 19–30% of BRAF-mutant melanomas and may not be identified using some testing methodologies. Pyrosequencing and mass spectroscopy assays offer high sensitivity and the ability to test for the presence of a range of mutations in a single test.

Immunohistochemistry (IHC) may also be used for molecular testing. Recent studies showed high correlation of IHC expression of the $BRAF^{V600E}$-specific antibody VE1 with the presence of the $BRAF^{V600E}$ mutation and, in fact, appeared to be more accurate than testing with traditional molecular techniques in one study. The ability to detect mutations by immunochemistry has a number of potential advantages over traditional molecular techniques including faster turnaround times, cost savings, and availability in most pathology laboratories. Potentially, this may facilitate the rapid triage of patients into appropriate treatment pathways at a time when a delay in initiating treatment may result in an adverse outcome.

Melanoma staging and prognosis

The earliest melanoma staging system had three stages, based on each patient's primary tumour (T stage), regional lymph node status (N stage), and the presence or absence of distant metastases (M stage). This staging system, however, was primarily clinical and did not involve microstaging, and it was not until the AJCC Staging System was published in 1977 and 1978 that microstaging was integrated into the staging system for cutaneous melanoma. The AJCC Melanoma Staging System has since been reviewed and updated several times, most recently in 2009 [1]. The current AJCC Staging System, also used by the European-based UICC, is based on assessment of the primary tumour (with Breslow thickness, ulceration, and mitotic rate as the major prognostic factors), evaluation of the regional lymph nodes (with size of metastatic deposits and number

of involved nodes having prognostic significance) and evaluation of distant metastatic sites as well as serum lactose dehydrogenase (LDH) levels. Based on the large AJCC melanoma database, prognostic models were able to be developed by the Melanoma Staging Committee of the AJCC and clear differences in survival outcome based on AJCC staging and substaging were demonstrated (see Figure 49.2). Electronic tools that provide prognostic estimates for individual patients are now available and are often helpful both to patients and to their treating clinicians.

Initial investigations

For patients who present with a primary cutaneous melanoma of any thickness and who have no clinical evidence of regional node metastasis, there is no evidence that investigations such as blood tests, X-rays, or scans are of benefit. For patients found to have micrometastatic disease in regional lymph nodes on SLN biopsy (i.e., with Stage IIIA disease), there is likewise currently no evidence that staging with blood tests, X-rays, or scans is of value. For patients first presenting with Stage IV disease, however, it is appropriate to perform full staging with either whole body CT scans or a PET/CT scan and a CT or MRI scan of the brain. Serum LDH should be checked in those with Stage IIB, Stage IIIC, or Stage IV disease, and if systemic therapy is contemplated the presence or absence of a BRAF mutation in the patient's melanoma should be determined.

Surgical management of the primary melanoma

Any lesion thought to be a primary cutaneous melanoma is best removed by complete excision-biopsy in the first instance, with 2 mm clearance margins, as previously discussed. This allows full histological assessment and rational treatment planning. Immediate performance of a wide excision is not recommended, even if a confident diagnosis of melanoma is made, because clinical estimates of Breslow thickness are notoriously unreliable. If an immediate wide excision is performed, not only might an inappropriate wide excision margin be taken but the opportunity to perform accurate lymphatic mapping and a SLN biopsy (SLNB) procedure might be lost if the melanoma proves to be thicker than anticipated or to have adverse features such as a high mitotic rate.

Wide excision margins

Having established a diagnosis of primary cutaneous melanoma, definitive treatment can be planned. Currently recommended excision margins for primary melanomas are shown in Table 49.5. They are based on the results of a number of prospective randomized trials.

Management of the regional lymph nodes

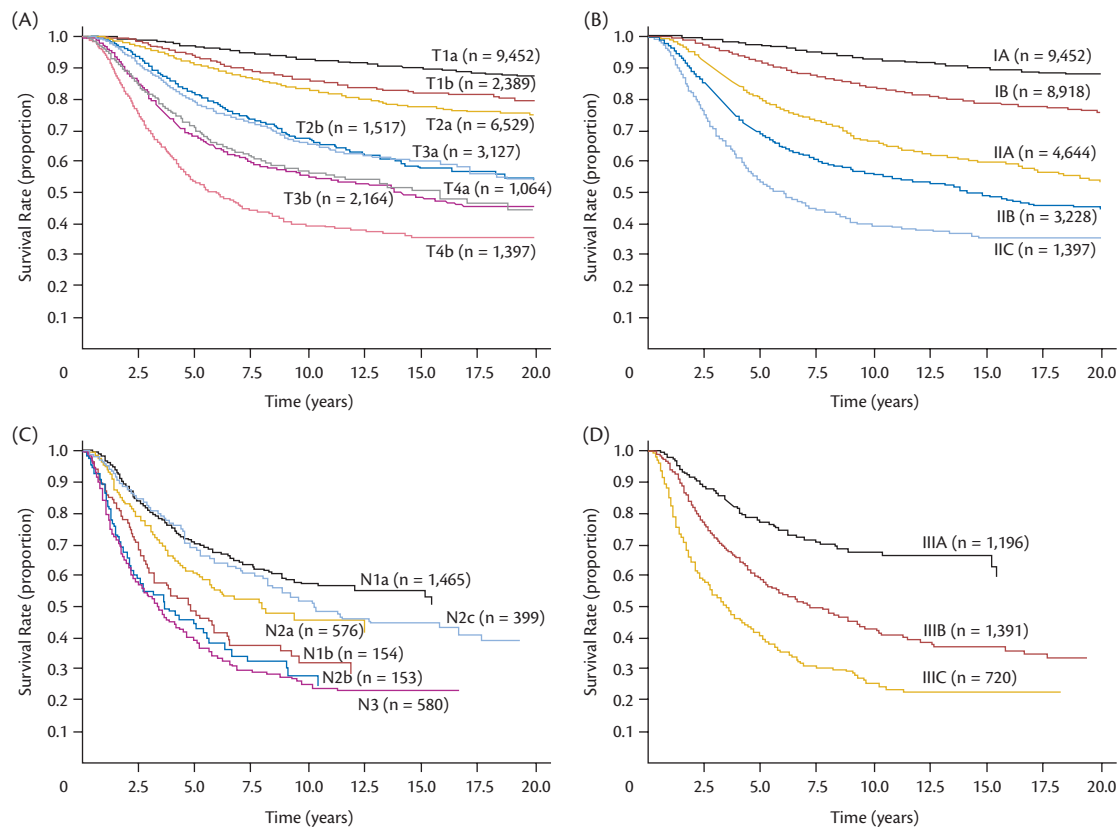
It is well established that the presence or absence of metastatic disease in regional lymph nodes is the most significant prognostic factor in patients with clinically localized cutaneous melanoma. In the late nineteenth century, Snow advocated routine prophylactic CLND for all patients with cutaneous melanoma who had no clinical evidence of metastatic disease in their regional lymph nodes. The rationale was to remove clinically occult metastatic disease in the regional nodes before spread to distant sites occurred.


Fig. 49.2 Survival curves from the American Joint Committee on Cancer Melanoma Staging Database comparing (A) the different T categories and (B) the stage groupings for Stages I and II melanoma. For patients with Stage III disease, survival curves are shown comparing (C) the different N categories and (D) the stage groupings.

However, no prospective randomized trial has shown a convincing overall survival benefit for elective lymph node dissection (ELND), although some studies have suggested a benefit for patients with intermediate thickness melanomas.

Sentinel lymph node biopsy

In the early 1990s, Morton et al. introduced the concept of lymphatic mapping and SLNB as a minimally invasive alternative to ELND [3]. The SLNB concept was simple. Lymphatic drainage from a primary melanoma site is initially to a sentinel lymph node in the regional node field, with subsequent onward passage of lymph to other nodes in that field. If melanoma cells spread via

Table 49.5 Surgical excision margins (as recommended in most national guidelines)

T stage	Breslow thickness of melanoma	Excision margin recommended
pTis	in situ only	5 mm
pT1	<1 mm	1 cm
pT2	1.0–2 mm	1–2 cm

lymphatics to the regional lymph node field, they will lodge initially in the sentinel lymph node. Thus, if this node can be identified and removed, which is possible using preoperative lymphoscintigraphy and intraoperative localization with blue dye and a gamma probe, the presence or absence of metastatic disease in the regional lymph node field can be determined with very great accuracy. After the initial report by Morton et al., several validation studies confirmed that this hypothesis was correct.

The common practice of sentinel lymph node (SLN) biopsy in patients with melanoma does not improve their long-term survival, according to the final results of a landmark international trial published in the *New England Journal of Medicine* [4]. The investigators of the Multicenter Selective Lymphadenectomy (MSLT-I) trial compared SLN biopsy with a watch-and-wait approach (only removing nodes once palpable) in melanoma. The 10-year, disease-specific survival in the overall study population was the primary outcome and was not significantly different between the biopsy and observation arms (81.4% vs 78.3%; p = .18).

Today, SLNB is a standard staging procedure in most melanoma treatment centres around the world; in 2012, an evidence-based guideline produced by the American Society of Clinical Oncology and the Society of Surgical Oncology recommended its use in all patients with intermediate thickness melanomas. SLNB allows these patients to be accurately staged according to the AJCC/UICC staging system. As well, it appears to provide a substantial survival

benefit for those found to be SLN-positive, if an immediate CLND is performed (as outlined above) [5]. In patients with thick (T4) melanomas SLNB is considered unlikely to improve survival outcome, but does reduce very considerably the risk of highly morbid regional node field recurrence and provides useful staging, as it does for intermediate thickness melanomas.

There are also sound reasons to recommend SLNB for patients with melanomas in the 0.75–1.0 mm thickness range, if adverse prognostic features are present (e.g., ulceration, a mitotic rate >1/mm^2 in a subset of T1b tumours), or if the patient is <45 years of age.

Some authors have suggested that preoperative examination of regional nodes with high-resolution ultrasound will identify metastatic disease in regional nodes with an accuracy approaching that of SLNB. However, several large studies have shown very low sensitivity rates for preoperative ultrasound, and there is general agreement that ultrasound cannot replace SLNB for accurate staging of melanoma patients with clinically negative regional nodes.

Technique of sentinel node biopsy

A SLNB procedure involves preoperative lymphoscintigraphy, then injection of blue dye intradermally at the primary melanoma site immediately preoperatively, and SLN localization surgically-based on blue staining of the SLN with a high gamma count.

Major melanoma treatment centres around the world have now accumulated considerable experience with the procedure, and false-negative SLNB results are less common than they were when the technique was first introduced.

Management of positive sentinel lymph nodes

The standard treatment recommendation for patients found to have metastatic disease in a SLN is an immediate CLND, but whether this is always necessary is being tested in a second Multicenter Selective Lymphadenectomy Trial (MSLT-II). In this trial, patients found to be SLN-positive are randomized either to have a CLND or to have the residual nodes in the regional node field monitored carefully using regular high-resolution ultrasound, with CLND only if metastatic disease in a node field becomes apparent (ClinicalTrials.gov Identifier: NCT00297895). A registration trial in Europe (the MINITUB study) is also examining this question in a prospective fashion. However, it will be several years before the results of these studies are available, and until then CLND must remain the standard therapy for patients found to be SLN-positive.

Management of clinically involved regional lymph nodes

Standard management of patients with clinically involved regional lymph nodes involves full regional lymph node dissection. For the axilla this means complete clearance of lymph node levels I, II, and III. For the neck, however, selective node dissections may be performed, depending on the site of the primary tumour. For involved groin lymph nodes, a complete clearance of nodes in the femoral triangle (i.e., below the level of the inguinal ligament) is standard, but whether pelvic nodes need clearance is a matter of ongoing debate. In most centres, an iliac and obturator node clearance is recommended if there are multiple involved nodes below the inguinal ligament, or if these nodes are large. Involvement of Cloquet's node is also regarded by many as an indication to perform an ilio-inguinal node clearance rather than an inguinal node clearance only. The presence of macroscopic disease in regional lymph nodes has serious prognostic implications, because up to 50% of these patients will ultimately die of melanoma [1]. A detailed consideration of surgical techniques for dealing with clinically apparent metastatic melanoma in regional lymph nodes is beyond the scope of this book, but full descriptions are available elsewhere.

Adjuvant systemic therapy and adjuvant radiotherapy for resected Stage III disease

Adjuvant systemic therapy

Because patients with resected AJCC Stage IIIB and IIIC disease are at high risk of dying of melanoma (with <50% 10-year survival) they should be considered for adjuvant systemic therapy. Those at intermediate levels of risk (Stage IIA, IIB, and IIIA) (51–64% 10-year survival) may also be considered for clinical trials of adjuvant therapy. The only drug with demonstrated efficacy as adjuvant therapy for high-risk melanoma is interferon-alpha2b. Phase III clinical trials have compared high-dose interferon (20 MU/m2), intermediate-dose interferon (5–10 MU), intermediate-dose pegylated interferon, and low-dose interferon (1–3 MU) regimens with observation. Multiple trials have shown that adjuvant high-dose interferon improves relapse-free survival by approximately 10% at five years, but initially reported benefits in overall survival have disappeared with longer follow-up periods. Individual patient data meta-analyses of observation-controlled trials of various dosing regimens showed a statistically significant benefit of interferon for event-free survival, and an absolute overall survival benefit of 3% (CI 1–5%) at five years. There was no evidence of any difference according to dose or duration of therapy. Individual Phase III trials of intermediate- and low-dose interferon have not shown a clear advantage for interferon over observation. Long-term pegylated interferon improved four-year relapse-free survival by 7% but had no effect on distant metastasis-free survival or overall survival. High-dose interferon-alpha remains the only FDA-approved systemic adjuvant therapy for melanoma. The toxicity of high-dose interferon-alpha is substantial but reversible and requires experienced medical oncology management, aggressive supportive measures including the use of prophylactic antidepressants, and careful monitoring and dose-reduction strategies, particularly for hepatotoxicity. Because of the toxicity of high-dose interferon and the uncertain benefits of lower dosing regimens, patient participation in clinical trials of new adjuvant therapies is strongly encouraged and observation remains an appropriate comparator in Phase III trials. Experimental approaches undergoing current investigation with prospective randomized placebo-controlled double-blind clinical trials include immunotherapy with anti-MAGE-A3 vaccine, ipilimumab, or PEG-interferon (in patients with ulcerated primary melanomas and microscopic lymph node involvement). Drugs targeting the MAP kinase pathway are also in placebo-controlled adjuvant clinical trials using vemurafenib (GO27826, 'BRIM-8') or the combination of dabrafenib and trametinib (BRF115532, 'Combi-AD').

Adjuvant radiotherapy

Following surgical clearance of macroscopic (clinically detectable) disease in regional lymph nodes, recurrence in the node field is most common when at least one involved node is large (>3 cm),

where multiple nodes are involved, or if there is histological evidence of extranodal spread. To reduce this risk of node field recurrence, adjuvant postoperative radiotherapy to the node field may be given. In the only large prospective trial that has examined the value of this adjuvant radiotherapy following regional node clearance in high-risk melanoma patients, the rate of node field recurrence was 33% in the control group and 18% in the group that received adjuvant radiotherapy, with acceptably low morbidity.

Local and transit recurrences

True local recurrence of a primary melanoma, i.e., within a previous wide excision scar, is rare if adequate margins are achieved. Thus most recurrences adjacent to a previous melanoma wide excision site, like in transit metastases that occur between the primary site and the draining regional lymph node field, are probably due to intralymphatic metastasis. The term 'satellitosis' is frequently used for microscopic or macroscopic recurrences that are within a few centimetres of the primary site. These, too, are likely to be due to the same pathophysiological process, i.e., intralymphatic metastasis.

When local or in transit metastasis occurs, the patient's prognosis becomes much worse. Up to 50% of patients who develop even a single local or in transit metastasis ultimately die of melanoma. The treatment modality employed to deal with local and in transit metastases does not appear to have any effect on ultimate outcome, and the goal of treatment is therefore to deal with the problem of loco-regional disease in the most efficient but least invasive and least morbid way possible. The recent introduction of effective forms of systemic therapy may improve the outcome for patients with in transit metastases not able to be treated by any of the methods outlined below.

Simple excision, ablative techniques, intralesional, and topical therapies

If local or in transit metastases are small and few in number, simple surgical excision is the best treatment option. If the disease is superficial but more extensive, simple ablative techniques such as diathermy-fulguration or CO2 laser ablation are effective. When the disease is unable to be controlled by simple measures such as those just outlined, consideration may need to be given to intralesional therapy (e.g., with BCG, IL-2 or Rose Bengal) and radiotherapy may also be employed if the disease is localized.

Extensive but superficial disease can also be treated with topical agents. One of the most promising of these is topical diphencyprone, which enhances local skin immunity and leads to tumour involution in many patients, even after other forms of treatment, including surgery and radiotherapy, have failed.

Isolated limb perfusion and isolated limb infusion with cytotoxic drugs

When locally recurrent or in transit disease is not suitable for treatment with any of the modalities described above and the disease is confined to a limb, regional chemotherapy with vascular isolation, using the techniques of isolated limb perfusion (ILP) or isolated limb infusion (ILI), is often effective. Both these techniques involve the administration of high-dose chemotherapy to a limb when its blood supply is isolated from the general circulation with a tourniquet. Isolated limb perfusion has been used for more than 50 years, and was developed shortly after the technique of cardiopulmonary bypass was introduced,

using similar equipment and based on similar principles. Large bore cannulas are placed by open operation into the major vein and artery of the affected limb, and the cannulas are connected to an extracorporeal circuit through which circulation is maintained with a pump that incorporates an oxygenator and a heat exchanger, as for cardiopulmonary bypass. The limb is isolated from the vasculature of the body by placing a tourniquet around the root of the limb to occlude all blood vessels, and high-dose cytotoxic agents are perfused through the limb, usually for a period of 60–90 minutes. The drug most commonly used is melphalan, and its efficacy is enhanced by adjusting the temperature in the perfusion circuit so that mild to moderately hyperthermic limb temperatures (39–41°C) are achieved.

Even for patients with extensive in transit disease in a limb, complete response rates of 40–50% are reported after ILP and partial response rates of 30–40%, resulting in good disease control in 80–90% of patients who are treated in this way. Better results for patients with very bulky disease have been reported when TNF has been used with melphalan, but there are significant risks associated with systemic leakage of the TNF, and there has been no clinical trial evidence of superior efficacy of ILP with melphalan and TNF over ILP with melphalan alone.

An alternative but much simpler technique of regional chemotherapy with vascular isolation is isolated limb infusion. This technique was conceived as a method of achieving the benefits of ILP more simply and more safely. In a large experience of the ILI technique in Sydney, where it was developed, complete response rates of 38% and partial response rates of 46% were achieved. An ILI procedure is performed via small calibre catheters that are inserted percutaneously by a radiologist into the axial vessels of the affected limb via the opposite groin. Having applied a pneumatic tourniquet to the root of the limb, cytotoxic drugs in high concentration (normally melphalan and actinomycin D) are infused and circulated in the limb using a hand-held syringe via a three way stopcock in the external circuit (which also contains a blood warmer) for a period of 30 minutes. At the end of this time the limb vasculature is flushed with an electrolyte solution, the venous effluent is discarded, the tourniquet is deflated and the catheters are withdrawn.

Both ILP and ILI inevitably produce an inflammatory reaction in the normal tissues of the treated limb, and occasionally more severe reactions in the limb can occur, with skin and muscle necrosis. The tumour deposits in the limb usually begin to undergo involution within a week of the procedure, but the full effect of the treatment may not be apparent for up to three months.

Limb amputation

When all the above forms of treatment fail to control disease in a limb, amputation is very occasionally required. Even when this is necessary, some patients remain disease-free indefinitely, although the majority go on to develop systemic metastases and eventually die of melanoma.

Follow-up and surveillance for new melanomas and metastatic disease

There are two distinctly separate reasons for periodic review of patients with melanoma. The first is to identify recurrent disease and the second is to diagnose new primary melanomas at an early stage. It is well documented that any patient who has had a primary melanoma

is at greatly increased risk of developing another primary melanoma in the future. The risk of recurrence of the original primary depends on its thickness and other histological features (such as ulceration and mitotic rate). This means that more intensive follow-up schedules are usually recommended for patients with thick melanomas and less intensive schedules for those with thin melanomas. There are, however, no good prospective clinical trial data to indicate the optimal frequency of follow-up visits, and most follow-up schedules are based on very low level evidence. Nevertheless, it is commonly recommended that patients with thin (<1 mm) melanomas be checked at least annually following their definitive melanoma treatment, while patients with intermediate thickness (1–4 mm) and thick (>4 mm) melanomas be checked every three to four months for the first two years, and less frequently thereafter.

In considering follow-up strategies, however, it must be borne in mind that the great majority of melanoma recurrences and new primary melanomas are detected not by doctors at routine visits but by the patient or their partner. In most series where this has been examined, no more than 15–20% of recurrences and new primary melanomas have been detected by doctors at routine visits. A very useful part of melanoma patient care is, therefore, to provide adequate education which will help early recognition of recurrent disease or new primary tumours. Such programs already exist in many major melanoma treatment centres.

The value of routine follow-up blood tests, X-rays, and scans is controversial. Until recently, many clinicians involved in the care of patients with melanoma considered that early diagnosis of systemic metastatic disease in asymptomatic patients was of little benefit because there was no effective therapy. The advent of systemic agents that are effective, at least in the short- to medium-term, means that this nihilistic approach to follow-up investigations may need to be reappraised. With the ready availability of CT and PET/CT scanning in most countries where melanoma incidence is high, it would seem reasonable to offer whole body imaging (either CT or PET/CT scans) at least annually to patients considered to be at high risk of systemic metastasis (e.g., those with treated Stage IIC, IIIA, IIIB, and IIIC disease, as well as those with Stage IV disease following apparently successful surgical treatment).

Surgical treatment of American Joint Committee on Cancer Stage IV disease

For patients with AJCC Stage I, Stage II, and Stage III melanoma, surgery is the standard treatment. For patients with Stage IV disease, however, the role of surgery is less well defined. Resection of metastatic melanoma at distant sites may be considered appropriate if complete removal of all identifiable disease appears to be possible, with potentially curative intent. It may also be considered for patients with resectable disease that is causing troublesome symptoms, or is considered likely to cause troublesome symptoms before the patient dies of the disease. In each patient, the potential benefits of the proposed surgery should outweigh the risks. If surgical excision of metastases can be accomplished with low morbidity, quick and effective palliation (or expectant palliation) is possible.

Surgery with curative intent for patients with Stage IV melanoma

Many studies have demonstrated that complete surgical resection of metastatic disease gives patients the greatest chance of prolonged survival with a good quality of life. Five-year survival rates of 20–30% are reported after complete surgical resection of visceral metastases, compared with five-year survival rates of around 10% in patients treated with the best available systemic therapies. In assessing the results of surgical treatment for distant metastatic disease, it must be borne in mind that the outlook for patients with involvement of distant skin, subcutaneous tissues, or distant lymph nodes is substantially better than the outlook for patients with metastatic disease at visceral sites (see Figure 49.3).

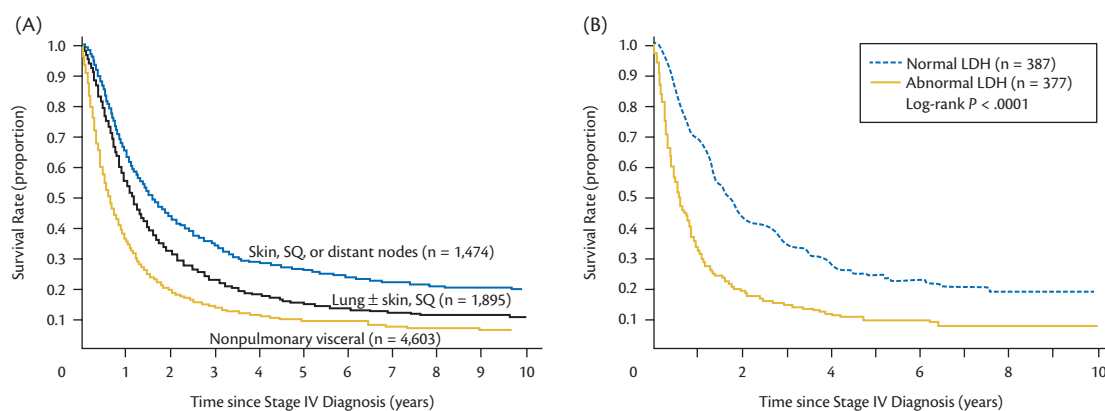
With present day sophisticated imaging techniques, particularly PET/CT and MRI scanning, the identification of patients with metastatic disease that is completely resectable has become easier and more reliable. Even if there is residual metastatic melanoma in the body, not detected by conventional imaging techniques, there is some evidence that the cytoreductive surgery may allow the patient's cellular and/or humoral immunity to more effectively control the growth of residual occult tumour cells. Even when further distant metastases become apparent following previous surgical


Fig. 49.3 Survival curves of 7635 patients with metastatic melanomas at distant sites (Stage IV) grouped by (A) the site of metastatic disease and (B) serum lactose dehydrogenase (LDH) levels. LDH values are not used to stratify patients. Curves in (A) are based only on site of metastasis. The number of patients is shown in parenthesis.

SQ, subcutaneous.

excision of apparently isolated distant melanoma metastases, salvage by repeated surgical excision may be possible. In one study, a 90% five-year survival rate was reported after complete resection for recurrence after initial metastasectomy.

Outcomes after resection of melanoma metastases at specific sites

Skin, subcutaneous tissue, and lymph nodes

These are the most common sites for non-loco-regional metastatic melanoma. When only a few lesions exist in distant skin, subcutaneous tissues, or lymph nodes, excellent results have been reported after surgical excision. Repeated excisions are often necessary, but appear to be worthwhile if there is no evidence of visceral disease. There is no evidence that excision of metastatic disease at these sites with very wide margins is necessary, but it is clearly important that they be removed with a cuff of apparently normal tissue so that histologically clear margins are achieved.

Lung

Melanoma metastases in the lung are diagnosed more frequently than metastases at other visceral sites, perhaps because they are more readily identified with modern imaging techniques than metastases elsewhere. The lung metastases are usually asymptomatic, and they are associated with longer survival (median 10–11 months) than metastases in other viscera. Reports from a number of single institutions and the International Registry of Lung Metastases have demonstrated prolonged survival in appropriately selected patients who have had lung metastases resected. As is the case for patients with melanoma metastases in other viscera, patients with lung metastases are likely to have the best outcome if there is no evidence of metastatic disease at any other site.

Brain

Cerebral metastases account for 20–54% of deaths from melanoma, and post-mortem studies have shown that the great majority of patients who die of melanoma have brain metastases. Without treatment, the median survival for a patient with a symptomatic brain metastasis is only approximately one month without treatment and two months with palliative corticosteroid therapy alone. In the past, the active treatment options for patients with brain metastases were surgical resection or whole brain radiotherapy (WBRT). In more recent times stereotactic radiotherapy has been shown to have similar efficacy to surgery, and is particularly appropriate when multiple lesions require treatment. Several studies have shown that symptoms are relieved and survival times are increased in the great majority of patients whose cerebral melanoma metastases are treated. Symptoms due to cerebral metastases are improved in more than two-thirds of melanoma patients treated with WBRT; however, the median survival after WBRT alone is only 3.5 months. The role of WBRT after surgical resection of cerebral metastases has been controversial.

Gastrointestinal tract

Melanoma metastases in the gastrointestinal tract are also very common in post-mortem studies, but are less frequently symptomatic during life. The most common symptoms are abdominal pain, bleeding (and associated anaemia), and bowel obstruction. In any patient with a history of melanoma who presents with anaemia, the possibility of one or more metastases in the gastrointestinal tract, most commonly small bowel, must be considered. Melanoma metastases in the oesophagus and stomach are best treated by surgical resection if they isolated; as well as achieving good relief of symptoms, long-term survival is sometimes achieved. Patients with small bowel metastases often present with small bowel obstruction due to intussusception. Even when there is disease at other sites, surgery to resect the segment of small bowel containing the intussuscepting metastasis is worthwhile, as it produces immediate relief of symptoms, restores good quality of life, and often extends survival considerably.

Liver and biliary tract

Patients with melanoma metastases in their liver generally have a very short life expectancy (2–4 months). However, patients who have apparently isolated liver metastases that are able to be resected surgically occasionally achieve long-term survival. In recent times, ablative techniques for multiple liver metastases have been introduced, such as cryotherapy and radiofrequency ablation. These have extended the therapeutic options for patients who have multiple hepatic metastases. Regional therapy via the hepatic artery (using agents such as fotemustine and radioactive spheres) is now quite widely used with palliative intent, but has not been shown in clinical trials to improve survival outcome.

Spleen

Isolated melanoma metastases in the spleen are uncommon, and there are usually synchronous metastases at other intra-abdominal sites. For patients in whom the splenic disease is apparently isolated or symptomatic, however, surgery should be considered.

Bone
