OXFORD

Oxford Textbook of

Oncology

Free personal online access for 12 months

Individual purchasers of this book are also entitled to free personal access to the online edition for 12 months on Oxford Medicine Online (<http://oxfordmedicine.com/>). Please refer to the access token card for instructions on token redemption and access.

Online ancillary materials, where available, are noted at the end of the respective chapters in this book. Additionally, Oxford Medicine Online allows you to print, save, cite, email, and share content; download high-resolution figures as PowerPoint® slides; save often-used books, chapters, or searches; annotate; and quickly jump to other chapters or related material on a mobile-optimized platform.

We encourage you to take advantage of these features. If you are interested in ongoing access after the 12-month gift period, please consider an individual subscription or consult with your librarian.

Oxford Textbook of
Oncology

THIRD EDITION

OXFORD
UNIVERSITY PRESS

Preface

The opportunity to compile a third edition of the *Oxford Textbook of Oncology* (after a gap of over ten years) represented a chance to deliver a definitive and comprehensive text detailing the evolution, evidence base, and current best practice in multidisciplinary cancer care. The first half of the textbook opens with introductory chapters covering the basic science that underpins our understanding of how cancer cells grow and function. These are then followed by sections looking specifically at the aetiology of cancer and the general principles governing modern approaches to oncology treatments. The first half of the book ends with a look at the unique challenges presented by treatment of cancer on a larger scale within population groups, and conversely the importance of recognizing and supporting the needs of individual patients both during and after treatment.

Our aim for the second half of the textbook was to provide a series of disease-based chapters written by expert teams from across the globe. Each chapter takes a multidisciplinary approach to the diagnosis and management of cancer, with sections covering the epidemiology, biology and pathology, radiotherapy, medical and surgical management of specific disease types.

When looking at the contents list for the new edition, you may notice that we have not included a chapter on childhood cancers. We felt that any discussion of paediatric oncology that was limited to only one chapter would inevitably be too superficial to cover even the most central aspects of this important discipline. Instead, readers will find that the focus of this volume is on the treatment and management of adult patients. For special paediatric considerations, we refer readers to *Cancer in Children: Clinical Management* (eds Michael C.G. Stevens and Hubert N. Caron, Oxford University Press, 2011). Now in its sixth edition, this book provides an excellent guide to the management of common childhood cancers.

One of the most important innovations in the third edition of the *Oxford Textbook of Oncology* is that it is available both in print, ebook, and online formats. One of the negatives of preparing a major textbook is that it may be out of date by the time of publication. We seek to overcome this with regular online updates when change in knowledge demands. Purchasers of the print book will receive a free 12-month access to the online version of the book. The online version contains all the material from the printed book, as well as extensive reference linking via PubMed. Over the lifetime of the book, additional case studies, figures, and other reference material will be made available as part of a series of regular updates that will be made to the online edition.

We would like to thank Beth Womack, Nicola Wilson, Caroline Smith, and the rest of the OUP team and the many international experts who contributed time, knowledge, and wisdom in writing this book.

This is a time of extraordinary advancement in oncology, with improvements seen in each of the major therapeutic areas, underpinned by basic and translational science leading to an increasingly personalized approach for many cancer patients. Drawing on the combined experience of an extensive list of internationally renowned contributors, we believe that this updated and revitalized third edition provides an essential resource for oncologists in all fields.

Contents

List of abbreviations

2D-CRT	two-dimensional conformal treatment		ALA	aminolaevulinic acid
2GTKI	second generation TKI therapy		ALCL	anaplastic large-cell lymphoma
2-HG	2-hydroxyglutarate		ALFA	Acute Leukemia French Association
3DCRT	3D conformal radiotherapy		ALK	activin-receptor-like kinases; anaplastic lymphoma receptor tyrosine kinase
5-FU	5-fluorouracil			
5-FU/FA	5-fluorouracil and folinic acid (leucovorin)		ALL	acute lymphocytic leukaemia; acute lymphoblastic leukaemia
5-HIAA	5-hydroxy-indole acetic acid			
5-hmC	5-hydroxymethylcytosine		ALT	alternative lengthening of telomeres; atypical lipomatous tumour
5-mC	5-methylcytosine			
5'-TOP	5'-terminal oligopolypyrimidine		allo-HSCT	allogeneic-haematopoietic stem cell transplantation
^{18}F-FDG	^{18}F-fluoro-deoxyglucose			
			allo-SCT	allogeneic-stem cell transplantation
			ALT	alternative lengthening of telomeres
AA	African American; anaplastic astrocytomas		AMC	Advanced Market Commitment
AAH	atypical adenomatous hyperplasia		AML	acute myelogenous leukaemia; acute myeloid leukaemia
aaIPI	age-adjusted IPI			
ABC	advanced biliary cancer; activated B-cell		AMPK	adenosine monophosphate-activated protein kinase
ABVD	Adriamycin® (doxorubicin), bleomycin, vinblastine, and dacarbazine			
			AO	anaplastic oligoastrocytoma
AC	adrenal carcinoma		AOA	anaplastic oligoastrocytoma
ACA	additional cytogenetic abnormalities		AP	accelerated phase
ACC	adenoid cystic carcinoma		APA	aldosterone-producing adenoma
ACF	aberrant crypt foci		Apaf-1	apoptotic protease activating factor 1
ACS	American Cancer Society		APBD	anomalous pancreatic biliary duct
ACTH	adrenocorticotrophic hormone		APC	adenomatous polyposis coli
aCGH	array Comparative Genomic Hybridization		APC	anaphase promoting complex
ADC	antibody drug conjugate; apparent diffusion coefficient		APL	acute promyelocytic leukaemia
			array-CGH	array-based comparative genomic hybridization
ADCC	antibody-dependent cellular cytotoxicity		ARF	alternative reading frame
ADH	antidiuretic hormone		ARHG	AP29 RHOA GTPase-activating protein 29
ADME	absorption, distribution, metabolism, and excretion		ASCO	American Society of Clinical Oncology
ADOC	cyclophosphamide, Adriamycin® (doxorubicin), vincristine, and cisplatin		ASCT	autologous stem cell transplant
			ASOC	advanced stage ovarian cancer
AF	accelerated radiotherapy		ASR	age standardized rates
AFAP	attenuated FAP		Atg	autophagy-related gene
AFP	alpha-feto protein		ATL	adult T-cell leukaemia
AfrOx	Africa Oxford Cancer Foundation		ATM	ataxia telangiectasia mutated
AFX	atypical fibroxanthoma		ATO	arsenic trioxide
AICR	American Institute for Cancer Research		ATP	adenosine triphosphate
AIF	apoptosis inducing factor		ATRA	all-trans retinoic acid
AIS	adenocarcinoma in situ		Auto-SCT	autologous stem cell transplantation
AITL	angioimmunoblastic T-cell lymphoma		AUC	area under the curve
AJCC	American Joint Committee on Cancer		AVC	angiogenic vascular cells
AK	actinic keratosis		AYA	adolescents and young adults

β₂M β₂	microglobulin	CEUS	ultrasound contrast bubbles
β-TRCP	b-transducin repeat-containing protein	CF	conventional fractionation
BAD	BCL-2 antagonist of cell death	CGH	comparative genomic hybridization
BAFF	B-cell activating factor	CGIN	cervical glandular intraepithelial neoplasia
B-ALL	B-cell acute lymphocytic leukaemia	CHCC	combined hepatocellular and cholangiocarcinoma
BAO	basal acid output	CHD	carcinoid heart disease
BC	blast crisis	CHF	congestive heart failure
B-CLL	B-cell lymphocytic leukaemia	CHL	classic Hodgkin lymphoma
BBB	blood-brain barrier	CHOP	cyclophosphamide, doxorubicin, vincristine, and prednisone
BC	breast cancer; bladder cancer		
BCC	basal cell carcinomas; breast cancer cells	CHR	complete haematological response
BCG	Bacillus Calmette-Guérin	CI	confidence interval
Bcl-2	B-cell lymphoma 2	CIN	cervical intraepithelial neoplasia; chromosome instability
BCLC	Barcelona Clinic for Liver Cancer		
BCT	breast-conserving therapy	CIMP	CpG island methylator phenotype
BDWG	Biomarkers Definitions Working Group	CIS	carcinoma in situ
BEAM	BCNU, etoposide, cytarabine, and melphalan	CK	cytokeratin
BEP	cisplatin, etoposide, and bleomycin	CK-7	cytokeratin-7
BER	base excision repair	CKI	CDK inhibitor
BH	Bcl-2 homology	CLC	cardiotrophin-like cytokine
BHDS	Birt-Hogg-Dube syndrome	CLND	completion lymph node dissection
BL	Burkitt's lymphoma	CLL	chronic lymphocytic leukaemia
BM	bone marrow	CML	chronic myeloid leukaemia
BMD	bone mineral density	CMML	chronic myelomonocytic leukaemia
BMP	bone morphogenetic proteins	C-MIN	conjunctival melanocytic intraepithelial neoplasia
BOD	biologically optimal dose		
BP	blastic phase	CMR	complete molecular response
BRCP	breast cancer resistance protein	CMS	Centers for Medicare and Medicaid Services
BRPC	borderline resectable pancreatic cancer	CMV	cytomegalovirus
BRRM	bilateral risk reducing mastectomy	CNA	copy number alterations
BRT	bioradiotherapy	CNS	central nervous system
BSC	best supportive care	CNSL	central nervous system lymphoma
BTK	Bruton's tyrosine kinase	CNTF	ciliar neurotrophic factor
		CoC	Commission on Cancer
CA	cryoablation	COG	Children's Oncology Group
CAE	cyclophosphamide, Adriamycin® (doxorubicin), and etoposide	COO	cell-of-origin
		COPD	chronic obstructive pulmonary disease
CAF	cancer-associated fibroblast	CP	chronic phase
CAG	chronic atrophic gastritis	CR	complete remission
CAK	CDK activating kinase	CRAB	calcium, renal, anaemia, and bone abnormalities
CAIX	carbonic anhydrase IX	CRC	colorectal carcinoma
CALGB	Cancer and Leukemia Group B	CRKL	CRK-like protein
CARES	Cancer Rehabilitation Evaluation System	CRM	circumferential resection margin; continual reassessment method
CAT	computer-adaptive testing		
CAV	cyclophosphamide, doxorubicin, and vincristine	CRPC	castrate-resistant prostate cancer
CAVE	cyclophosphamide, doxorubicin, vincristine, and etoposide	CRRM	contralateral risk-reducing mastectomy
		CRS	cytoreductive surgery
CBE	complete blood count examination	CRT	chemoradiotherapy
CBR	clinical benefit rate	(C)RT	radiotherapy alone or with chemotherapy
CBV	cyclophosphamide, BCNU, etoposide	CS	carcinoid syndrome
cCR	clinical complete remission	CSA	cranio-spinal axis
CCRCC	clear cell renal cell carcinoma	CSC	cancer stem cell
CCRT	concurrent/concomitant chemoradiation therapy	CSF	cerebrospinal fluid
CCS	cancer control strategy	CSR	class switch recombination
CD	coeliac disease	CT	computed tomography
CDC	complement-dependent cytotoxicity	CT1	cardiotrophin
CDK	cyclin-dependent kinase	CTC	circulating tumour cell
CEA	carcino-embryonic antigen	CTL	cytotoxic T-lymphocyte
CED	convection-enhanced delivery	CTV	clinical target volume
CEP	circulating endothelial progenitors	CUP	cancer of unknown primary

CVA	cerebrovascular accidents		EGFR	epidermal growth factor receptor
CVD	cyclophosphamide, vincristine, and dacarbazine		EHCC	extrahepatocellular carcinoma
			eIF4E	eukaryotic translation initiation factor 4E
DAG	diacylglycerol		ELND	elective lymph node dissection
DAPK	death-associated protein kinase		EM	electron microscopy
DC	dendritic cell		EMA	endoscopic mucosal ablation
DCC	deleted in colon cancer		EMR	endoscopic mucosal resection
DCE	dynamic contrast enhanced		EMT	epithelial mesenchymal transformation/ transition
DCE-MRI	dynamic contrast-enhanced magnetic resonance imaging		EMZL	extranodal marginal zone B-cell lymphomas
DCIS	ductal carcinoma in situ		ENB	esthesioneuroblastomas
DD	death domain		ENETS	European Neuroendocrine Tumor Society
DEB	drug-eluting beads		EORTC	European Organization for Research and Treatment of Cancer
DEPTOR	DEP domain-containing mTOR-interacting protein		EORTC QLQ-C30	European Organization for Research and Treatment of Cancer Core QoL Questionnaire
DEXA	dual-energy X-ray absorptiometry			
DFCI	Dana Farber Cancer Institute			
DFS	disease-free survival			
DFSP	dermatofibrosarcoma protuberans		EPC	endothelial progenitor cells
DHAP	dexamethasone/high-dose ara-C/cisplatin		EPO	erythropoietin
DHFR	dihydrofolate reductase		EPP	extrapleural pneumonectomy
DIC	disseminated intravascular coagulation		EPT	electron-photon therapy
DFS	disease-free survival		EPT	endocrine pancreatic tumour
DFSP	dermatofibrosarcoma protuberans		EQ	erythroplasia of Queyrat
DIN	ductal intraepithelial neoplasia		ER	endoplasmatic reticulum
DISC	death-inducing signalling complex		ERAS	enhanced recovery after surgery
DKK	Dickkopfs		ERCP	endoscopic retrograde cholangio-pancreatography
DLBCL	diffuse large B-cell lymphoma		ERR	excess relevant risk; oestrogen related receptors
DLL4	Delta-like ligand 4		ERUS	endorectal ultrasonography
DLT	dose-limiting toxicity		ES	effect size
DM	distant metastases		ESAS	Edmonton Symptom Assessment Scale
DMPM	diffuse malignant peritoneal mesothelioma		ESD	endoscopic submucosal dissection
DOR	duration of response		ESMO	European Society of Medical Oncology
DPD	dihydropyrimidine dehydrogenase		ESS	Edmonton Staging System
DRE	digital rectal examination		ESSO	European Society of Surgical Oncology
DSB	double strand break		ET	essential thombocythaemia
DTC	direct-to-consumer; disseminated tumour cells		ETP	early T-cell precursor
DTI	diffusion tensor tractography		EUNICE	European Network for Indicators on Cancer
Dvl	intracellular Dishevelled		EURECCA	European Registration of Cancer Care
DWI	diffusion-weighted imaging		EUS	endoscopic ultrasound
			EUS-FNA	endoscopic ultrasound-guided fine needle aspiration
EAP	Expanded Access Programs			
EATL	enteropathy-associated T-cell lymphoma		EUSOMA	European Society of Mastology
EB	epidermolysis bullosa			
EBMT	European Group for Blood and Marrow Transplantation		FA	fluorescein angiography
			FACS	fluorescence-activated cell sorting
EBRT	external beam radiotherapy		FACT-G	Functional Assessment of Cancer Therapy
EBUS	endobronchial ultrasound		FADD	Fas-associated DD
EBUS-FNA	endobronchial ultrasound-guided fine needle aspiration		FAMM	facial artery musculo-mucosal; familial atypical multiple mole/melanoma
EBV	Epstein–Barr virus		FAMMM	familial atypical multiple mole/melanoma
EC	endometrial cancer		FAP	familial adenomatous polyposis
ECCO	European CanCer Organisation		FCTC	Framework Convention on Tobacco Control
ECF	epirubicin, cisplatin, and infusional 5-fluorouracil		FDA	Food and Drug Administration
ECM	extracellular matrix		FDG	fluorodeoxyglucose
ECOG	Eastern Cooperative Oncology Group		FDG-PET	18-fludeoxyglucose positron emission tomography
ECT	electrochemotherapy			
EEA	extended endoscopic approaches		FFCD	Fédération Francophone de Cancérologie Digestive
EFS	event-free survival rates			
EGF	epidermal growth factor		FFPE	formalin-fixed and paraffin-embedded
EGRF	epidermal growth factor receptor		FGF	fibroblast growth factor

FGFR	fibroblast growth factor receptor		GTP	guanosine triphosphate
FIT	faecal immunochemical testing		GTV	gross tumour volume
FISH	fluorescence in situ hybridization		GvHD	graft-versus-host disease
FKHR	forkhead transcription factor		GvL	graft-versus-leukaemia
FLIC	Functional Living Index—Cancer		GWAS	genome-wide association studies
FN	fibronectin			
FNA	fine needle aspiration		HAART	highly active antiretroviral therapy
FNAC	fine needle aspiration cytology		HAT	histone acetyl-transferase
FNR	false-negative rate		HB	hepatobiliary
FL	follicular lymphoma		HBeAg	hepatitis B e antigen
FLL	focal liver lesions		HBsAg	hepatitis B surface antigen
FLR	future liver remnant		HBOC	hereditary breast-ovarian cancer
FOB	fibreoptic bronchoscopy		HBV	hepatitis B virus
FOLFOX	5-FU, leucovorin and oxaliplatin		HCC	hepatocellular carcinoma
FOXO	forkhead box O		HCL	hairy cell leukaemia
FRO	familial renal oncocytoma		HCL-v	hairy cell leukaemia-variant
FRS2	FGFR substrate 2s		HCT	haematopoietic cell transplantation
FS	flexible sigmoidoscopy		HCV	hepatitis C virus
FTH	follicular T-helper		HDAC	histone deacetylase
			HDR	high dose rate
GAB1	GRB2-associated binding protein 1		HDT	high-dose therapy
GAP	GTPase activating protein		HDV	hepatitis delta virus
GARFT	glycinamide ribonucleotide formyltransferase		H&E	haematoxylin and eosin
GASTRIC	Global Advanced/Adjuvant Stomach Tumour Research International Collaboration		Hep Par 1	hepatocyte paraffin 1 monoclonal antibody
			HF	hyperfractionated radiotherapy
GBC	gall bladder cancer; germinal centre B-cell		HGF	hepatocyte growth factor
GBM	glioblastoma multiforme		HGFA	HGF activator
GC	gemcitabine and carboplatin		Hh	Hedgehog
GC	germinal centre		HIDAC	high-doses cytarabine
GCP	good clinical practice		HIF	hypoxia inducible factor; hypoxia inhibitory factor
GCSF	granulocyte colony stimulating factor			
GDA	gastroduodenal artery		HIFU	high intensity focused ultrasound
GDF	growth and differentiation factor		HICC	heated intracavity chemotherapy
GDP	gemcitabine, dexamethasone, and cisplatin; guanosine diphosphate		HIPEC	hyperthermic perioperative chemotherapy
			HLA	humoral leukocyte antigen
GEF	guanine nucleotide exchange factor		HNPCC	hereditary non-polyposis colorectal cancer
GHRH	growth hormone-releasing hormone		HNPGL	head and neck parasympathetic paraganglioma
GEJ	gastro-oesophageal junction		HNSCC	head and neck squamous cell carcinoma
GEMM	genetically engineered mouse models		HPC	haemangiopericytoma
GEP	gastroenteropancreatic		HPF	high power fields
GEP	gene expression profiling		HPRC	hereditary papillary renal carcinoma
GF	growth factor		HPV	human papilloma virus
GGR	global genome repair		HR	hazard ratio; homologous recombination
GH	growth hormone		HRC	hereditary renal carcinoma
GINA	Genetic Information Nondiscrimination Act		HRE	hypoxic response elements
GIST	gastrointestinal stromal tumour		HSC	haematopoietic stem cell
GITSG	Gastrointestinal Tumour Study Group		HSP90	heat shock protein 90
GLUT4	glucose transporter type 4		HT	hypertension
GMALL	German Multicenter Study Group for Adult Acute Lymphoblastic Leukemia		HTLV-1	Human T-cell leukaemia virus 1
GMP	good manufacturing procedure; granulocyte/macrophage progenitor		IAP	inhibitor of apoptosis protein
			IARC	International Agency for Research on Cancer
GM-CSF	granulocyte-macrophage colony-stimulating factor		IASLC	International Association for the Study of Lung Cancer
GO	gemtuzumab ozogamicin			
GPS	Glasgow Prognostic Score		IBI	International Breast Cancer Intervention Study
GRA	glucocorticoid-remediable aldosteronism		ICE	ifosfamide, carboplatin, etoposide
GRB2	proteins growth-factor-receptor bound-2		ICER	incremental cost-effectiveness ratio
GSK3	glycogen synthase kinase 3		ICL	interstrand cross-link
GSK3-b	glycogen synthase kinase 3b		ICRP	International Commission on Radiation Protection

ICRU	International Commission on Radiation Units and Measurements	JGCA	Japanese Gastric Cancer Association
ICT	induction chemotherapy	KA	keratoacanthoma
IDC	NOS invasive ductal carcinoma not otherwise specified	KPS	Karnofsky performance status
		KS	Kaposi's sarcoma
IFFIm	International Finance Facility for Immunisation	KSHV	Kaposi's sarcoma-associated herpesvirus
IFL	irinotecan/bolus 5-FU, leucovorin	KSR	kinase suppressor of Ras
IFN	interferon		
IFP	interstitial fluid pressure	LAPC	locally advanced pancreatic cancer
IFRT	involved-field radiotherapy	LAR	long-acting repeatable
IGABT	image-guided adaptive brachytherapy	LCC	large cell carcinoma
IGF	insulin growth factor	LCIS	lobular carcinoma in situ
IGF1	insulin growth factor 1	LCL	lymphoblastoid cell line
IGF2	insulin growth factor 2	LCNEC	large cell neuroendocrine carcinoma
IGFBP	IGF binding proteins	LDDST	low-dose dexamethasone suppression test
IGLC	International Gastric Cancer Linkage Consortium	LDH	lactate dehydrogenase
IGRT	image-guided radiotherapy	LDHA	lactate dehydrogenase A
IHA	idiopathic hyperaldosteronism	LDR	low dose rate
IHC	immunohistochemistry	LEF	lymphoid enhancer factor
IHCC	intrahepatic cholangiocarcinoma	LEF1	lymphoid enhancer-binding factor 1
IIC	infiltrating immune cell	LFS	leukaemia-free survival
IJCN	inflamed juvenile conjunctival naevi	LETZ	loop excision of the transformation zone
IKK	IκB kinase	LIF	leukaemia inhibitory factor
IKKB	IkB kinase b	LIN	lobular intraepithelial neoplasia
IL	interleukin	LMICs	low- and middle-income countries
IL1R	interleukin 1 receptor	LMP-1	latent membrane protein-1
IL6	Interleukin 6	LOH	loss of heterozygosity
ILC	invasive lobular carcinoma	LP	lymphocyte predominant
ILND	inguinal lymph node dissection	LPL	lymphoplasmacytic lymphoma
ILP	isolated limb perfusion	LRR	local and/or regional recurrences
iMR	intraoperative MR	LS	Lynch syndrome
IMRT	intensity-modulated radiation therapy	LSC	leukaemic stem cell
IMWG	International Myeloma Working Group	LUTS	lower urinary tract symptoms
INCTR	International Network for Cancer Treatment	LVSI	lymphovascular space invasion
iNOS	inducible nitric oxide synthase		
INRT	involved-node radiotherapy	MAA	macro-aggregated albumin
Ins(1,4,5)P3	inositol-1,4,5- trisphosphate	mAb	monoclonal antibodies
IOM	Institute of Medicine	MACs	microsatellite and chromosome stable
IORT	intraoperative radiotherapy	MAC-NPC	meta-analysis of chemotherapy in NPC
IOUS	intraoperative ultrasound	MALT	lymphoma mucosa-associated lymphatic tissue lymphoma
IP	intraperitoneal		
IPAA	total proctocolectomy and ileoanal pouch	MAP3K	MAP kinase kinase kinases
IPD	individual patient data	MAPK	mitogen-activated protein kinases
IPI	International Prognostic Index	MAP	MUTYH-associated polyposis
IPMN	intraductal papillary mucinous neoplasms	MBL	monoclonal B-cell lymphocytosis
iPS	induced pluripotent stem cells	mBL	molecular BL
IR	insulin receptor; ionizing radiation	MC	mitotic count
IRA	ileorectal anastomosis	MCC	Merkel cell carcinoma
IRS	insulin receptor substrates	MCD	Multicentric Castleman's Disease
IRT	item response theory	MCL	mantle cell lymphoma
ISGPF	International Study Group on Pancreatic Fistula Definition	MCN	mucinous cystic neoplasm
		MCP-1	monocyte chemotactic protein
ISGPS	International Study Group of Pancreatic Surgery	MCPM	multicystic peritoneal mesothelioma
ITMIG	International Thymic Malignancy Interest Group	MCR	macroscopic complete resection; molecular complete response
ITT	intention to treat		
ITV	internal target volume	MCRC	metastatic colorectal cancer
		MCV	Merkel cell polyomavirus
JAK	Janus kinase	MDCT	multidetector computed tomography
JCOG	Japan Clinical Oncology Group	MDR	multidrug resistant

MDRT	moderate-dose radiation therapy
MDS	myelodysplastic syndromes
MDSC	myeloid derived suppressor cells
MDT	multidisciplinary team
MEC	mucoepidermoid carcinoma
MELD	model of end-stage liver disease
MelTUMP	melanocytic tumour of uncertain malignant potential
MEN	multiple endocrine neoplasia
MET	mesenchymal-to-epithelial transition
MFH	malignant fibrous histiocytoma
MGUS	monoclonal gammopathy of undetermined significance
MIBC	muscle invasive bladder carcinoma
MIC	metastasis-initiating cells; microinvasive carcinoma
MIE	minimally invasive oesophagectomy
MIF	Müllerian inhibitory factor
MIBG	metaiodobenzylguanidine
MiSG	minor salivary glands
MITF	micropthalmia transcription factor
Miz1	Myc interacting zinc-finger protein
MLC	multileaf collimators
MM	multiple myeloma
MMMT	Mixed malignant Müllerian tumours
MMP	matrix metalloproteinase
MMP-9	matrix metalloprotease-9
MMR	mismatch repair
MNGGCT	malignant non-germinoma germ cell tumour
MoAb	monoclonal antibody
MOMP	mitochondrial outer membrane permeabilization
MOPP	mechlorethamine, vincristine, procarbazine, prednisone
mOS	median overall survival
MPA	medroxyprogesterone acetate
MPD	myeloproliferative diseases
MPM	malignant peritoneal mesothelioma
MPN	myeloproliferative neoplasms
MR	minimal response
MRA	magnetic resonance angiography
MRC	Medical Research Council
MRCP	magnetic resonance cholangiopancreatography
MRD	minimal residual disease
MRF	mesorectal fascia
MRI	magnetic resonance imaging
MRP	multidrug resistance-associated protein
MSI	microsatellite instability
MSI-H	high microsatellite instability
MSI-L	low microsatellite instability
MSKCC	Memorial Sloan Kettering Cancer Center
MSS	microsatellite stable/stability
MTC	medullary thyroid carcinoma
MTD	maximum tolerated dose
mTOR	mammalian target of rapamycin
MZL	marginal zone lymphoma
NAC	nipple areolar complex
NAMPT	nicotinamide phosphoribosyltransferase
NASH	non-alcoholic steatohepatitis
NBCC	nodular BCC

NBOCAP	National Bowel Cancer Audit Programme
NCCN	National Comprehensive Cancer Network
NCCS	National Coalition for Cancer Survivorship
NCD	non-communicable disease
NCI	National Cancer Institute
NEC	neuroendocrine carcinoma
NEN	neuroendocrine neoplasia
NER	nucleotide excision repair
NET	neuroendocrine tumour
NETZ	needle excision of the transformation zone
NGS	next-generation sequencing
NHEJ	non-homologous end joining
NHL	Non-Hodgkin lymphoma
NHSCSP	National Health Service Cervical Screening Programme
NICD	Notch intracellular domain
NLPHL	nodular lymphocyte-predominant Hodgkin lymphoma
NLR	neutrophil:lymphocyte ratio
NMIBC	non-muscle invasive bladder carcinoma
NMSC	non-melanoma skin cancer
NNK	N-nitrosamines 4-(methylnitrosamino)-1-(3-pyridyl)-1-butanone
NNN	N'-nitrosonornicenotine
NOS2	nitric oxide synthase-2
NOTES	natural orifice transluminal endoscopic surgery
NPC	nasopharyngeal carcinoma
NPM	nucleophosmin gene
NPV	negative predictive value
NRM	non-relapse mortality
NSABP	National Surgical Breast and Bowel Project
NSAID	non-steroidal anti-inflammatory drug
NSE	neuron-specific enolase
NSGCT	non-seminoma germ cell tumours
NSCLC	non-small-cell carcinoma; non-small-cell lung cancer
NTCP	normal tissue complication probability
OAR	organs at risk
OC	ovarian cancer
OCA	other chromosomal abnormality
ONB	olfactory neuroblastoma
OPC	oropharyngeal cancer
ORR	overall response rate
OS	overall survival
OSCC	oral cavity squamous cell carcinoma; oropharyngeal squamous cell carcinoma
OSM	oncostatin M
OSSN	ocular surface squamous neoplasia
P13K	phosphoinositide 3 kinase
PAC	cyclophosphamide, doxorubicin, and cisplatin
PAH	polycyclic aromatic hydrocarbon; primary adrenal hyperplasia
PAM	primary acquired melanosis
PanIN	pancreatic intraepithelial neoplasia
PAR3	partitioning defective 3
PARP	poly(ADP-ribose)polymerase
PBF	peripheral blood film

PBMNC	peripheral blood mononuclear cell
PBPC	peripheral blood progenitor cells
PBT	proton beam therapy
PCD	programmed cell death
PCI	prophylactic cranial irradiation; peritoneal cancer index
PCL	plasma cell leukaemia
PCM	plasma cell myeloma
pCR	pathological complete remission
P/D	pleurectomy/decortication
PDGF	platelet-derived growth factor
PDGFR-α	platelet-derived growth factor receptor α
PDGFR-β	platelet-derived growth factor receptor β
PDK1	phosphoinositide-dependent kinase 1
PDT	photodynamic therapy
PE	phosphatidylethanolamine
PET	positron emission tomography
PF	cisplatin and fluorouracil
PFE	platinum/5-FU/Erbitux® (cetuximab)
PFS	progression-free survival
PG	paraganglioma
PGP	P170 membrane glycoprotein
PH	pleckstrin homology
PHC	primary health care
PHD	prolyl hydroxylase domain protein
PI3K	phosphoinositide-3-kinase
PI3P	phosphatidylinositol g3-phosphate
PIAS	PIAS protein inhibitor of active STAT
PIKK	PI3K-related protein kinase
PIN	point mutation instability
PKB	protein kinase B
PKD1	protein kinase D1
PLC	phospholipase C
PLGA	polymorphous low-grade adenocarcinoma
PlGF	placental growth factor
Plk	polo-like kinases
PLL	prolymphocytic leukaemia
PMBL	primary mediastinal large B-cell lymphoma
PMF	primary myelofibrosis
PMLBCL	primary mediastinal large B-cell lymphomas
PNET	primitive neuro-ectodermal tumours
PODXL	podocalyxin
POPF	post-operative pancreatic fistula
PPH	postpancreatectomy haemorrhage
PPI	proton-pump inhibitor
PPPD	pylorus-preserving pancreaticoduodenectomy
PPT	pineal parenchymal tumours
PPV	positive predictive value
pre-RC	pre-replicative complex
pRb	retinoblastoma protein
PROCARisE	Project on Cancer of the Rectum
PROMIS	Patient-Reported Outcome Measurement Information System
PRP	platelet-rich plasma
PRRT	peptide receptor-mediated radionuclide therapy
PRV	planning organ-at-risk volume
PSA	prostate-specific antigen
PSC	pancreatic stem cells; primary sclerosing cholangitis
PSOGI	Peritoneal Surface Oncology Group International
PTC	percutaneous transhepatic cholangiography
PTCL	peripheral T-cell lymphomas
PTCL-NOS	peripheral T-cell lymphomas not otherwise specified
PTE	proportion of treatment effect
PTH-rp	parathyroid hormone-related protein
PTLD	post-transplant lymphoproliferative disorders
PTV	planning target volume
PUNLMP	papillary urothelial neoplasm of low malignant potential
PUVA	psoralens and UVA
PV	polycythaemia vera
PVC	primary vaginal cancer
QALY	quality-adjusted life years
RARECARE	Surveillance of Rare Cancers in Europe
RASIP1	RAS-interacting protein 1
Rb	retinoblastoma
RBE	relative biological effectiveness
RCC	renal cell carcinoma
RECIST	Response Evaluation Criteria in Solid Tumours
rESS	revised Edmonton Staging System
RFA	radiofrequency ablation
RFR	relapse-free rate
RFS	relapse-free survival
RHEB	RAS homologue enriched in brain
RIC	reduced-intensity conditioning
RIC-allo-SCT	reduced-intensity conditioned allogeneic-stem cell transplantation
RILD	radiation induced lung disease
RIP	receptor-interacting protein
RIT	radioimmunotherapy
RKIP	RAF kinase inhibitor protein
R/M	recurrent/metastatic
ROLL	radio-guided occult lesion localization
ROS	reactive oxygen species
ROTI	myeloma-related organ and tissue impairment
RPE	retinal pigment epithelium
RPLS	reversible posterior leukoencephalopathy syndrome
RPS	retroperitoneal sarcomas
RR	response rate
RRSO	risk-reducing bilateral salpingo-oophorectomy
RS	recurrence score
RSCL	Rotterdam Symptom Checklist
RT	radiation therapy
RTK	receptor tyrosine kinase
RTOG	Radiation Therapy Oncology Group
RT-PCR	reverse transcriptase-polymerase chain reaction
RQ-PCR	real-time quantitative polymerase chain reaction
S1P	sphingosine-1-phosphate
SAP	serum amyloid P
SBCC	superficial BCC
SBRT	stereotactic body radiotherapy
SCC	squamous cell carcinoma
SCCHN	squamous cell carcinoma of the head and neck
SCLC	small-cell lung carcinoma

sCR	stringent complete response		STIC	serous tubal intraepithelial carcinoma
SDF-1	stromal derived factor-1		SUV	standardized uptake value
SDH	succinate dehydrogenase		SV40-T	simian virus large T antigen
SDPP	stroma-derived prognostic predictor		SVCS	superior vena cava syndrome
SEER	Surveillance, Epidemiology and End results		SWETZ	straight wire excision of the transformation zone
SEIC	serous endometrial intraepithelial carcinoma			
SEMS	self-expanding metallic stents		TA	telomerase activity
SERM	selective estrogen receptor modulators		TACE	transarterial chemoembolization
SET	sensitivity to endocrine therapy		TAM	tumour-associated macrophages
SES	socio-economic status		TBI	total-body irradiation
SFLC	serum free light-chains		TCD	T-cell depletion
SFRP	secreted frizzled-related protein		TCF	docetaxel, cisplatin, infusional 5-fluorouracil; T-cell factor
SGC	salivary gland cancer			
SGCT	seminoma germ cell tumour		TCP	tumor control probability
SH2	Src homology 2		TCR	transcription-coupled repair
SH3	Src homology 3		TEM	transanal endoscopic microsurgery
SHIP	SH2-domain-containing inositol-5-phosphatase		TG	total glansectomy
SHM	somatic hypermutation		TGF	transforming growth factor
SHS	secondhand smoke		TGFβ, TGF-b	transforming growth factor beta
SIB	simultaneous integrated boost		TGR	total glans resurfacing
SIGN	Scottish Intercollegiate Guidelines Network		TIEG1	TGFβ-inducible early-response gene
SIL	squamous intraepithelial lesion; single incision laparoscopy		TIGAR	TP-53-induced glycolysis and apoptosis regulator
sIL-2R	soluble interleukin-2 receptor		TIL	tumour-infiltrating lymphocytes
SIN3	squamous intraepithelial neoplasia 3		TK	tyrosine kinase
SIRT	selective internal radiation treatment		TKI	tyrosine kinase inhibitor
SLAM	signalling lymphocytic activation molecule		TLS	tumour lysis syndrome
SLNB	sentinel lymph node biopsy		TME	total mesorectal excision; tumour microenvironment
SMA	superior mesenteric artery		TNBC	triple-negative breast cancer
SMAC	second mitochondria derived activator		TNFR	tumour necrosis factor receptor
smCC	small-cell cancer		TNFR1	TNF receptor 1
SMM	smouldering myeloma		TNM	tumour node metastasis
SMV	superior mesenteric vein		TORS	transoral robotic surgery
SN	sentinel node		TOS	TOR signalling
SNP	single nuclear polymorphisms		T-PLL	T-cell prolymphocytic leukaemia
SNEC	sinonasal neuroendocrine		TPF	docetaxel, cisplatin, and 5-fluorouracil; Taxotere®, cisplatin, and fluorouracil
SNUC	sinonasal undifferentiated carcinoma			
SOCS	suppressor of cytokine signalling		TPMT	thiopurine methyltransferase
SOS	Son of Sevenless		TPS	treatment planning systems
SPARC	secreted protein acidic and rich in cysteine		TRADD	TNFR1-associated DD
SPB	solitary plasmacytoma of bone		TRAF	TNF receptor associated factor
SPEP	serum electrophoresis		TRAIL	TNF-related apoptosis inducing ligand
SPH	serine proteinase homology		TRAIL-R1	TRAIL receptor 1
SPT	secondary primary tumour		TRAIL-R2	TRAIL receptor2
SRE	skeletal-related event		TRM	treatment-related mortality
SREBP	sterol regulatory element binding proteins		TRU	terminal respiratory unit
SRM	standardized response mean		TRUS	transrectal ultrasonography
SRS	somatostatin-receptor scintigraphy		TS	thymidylate synthase; treatment score
SRS	stereotaxic radiosurgery		TSC2	tuberous sclerosis 2
SSA	single-strand annealing		TSG	tumour suppressor gene
SSA	somatostatin analogue		TSH	thyroid-stimulating hormone
SSB	single-strand break		TTF	time-to-treatment failure
SSCP	single strand conformational polymorphism		TTF1	thyroid transcription factor 1
SSRI	selective serotonin reuptake inhibitors		TTP	time-to-progression
SSS	superior sagittal sinus		TURT	transurethral resection of the tumour
STAT3	transcription 3			
STE	surrogate threshold effect		UFC	urinary free cortisol
STS	soft tissue sarcomas		UFT	uracil/tegafur
STAT5	signal transducer and activator of transcription-5		UGT	UDP-glucuronosyltransferase

UICC	Union for International Cancer Control		WART	whole abdominal radiotherapy
UKELD	United Kingdom end-stage liver disease score		WBC	white blood cell count
uPAR	urokinase plasminogen activator receptor		WBD	whole body dose
UPEP	urine electrophoresis		WBI	whole breast irradiation
UPR	unfolded protein response		WBRT	whole brain radiotherapy
US	ultrasound		WCRF	World Cancer Research Fund
USPIO	ultrasmall superparamagnetic particles of iron oxide		WDLPS	well-differentiated liposarcoma
UTUC	upper tract urothelial cancer		WDPPM	well-differentiated papillary peritoneal mesothelioma
UV	ultraviolet		WGS	Whole Genome Shotgun
			WHEL	Women's Healthy Eating and Living
VAIN	vaginal intraepithelial neoplasia		WIF1	Wnt inhibitory factor 1
VATS	video-assisted thoracic surgery		WINS	Women's Intervention Nutrition Study
VC	vaginal cancer; verrucous carcinoma		WLE	wide local excision
VDA	vascular disrupting agent		WM	Waldenström macroglobulinemia
VEGF	vascular endothelial growth factor			
VEGFR	vascular endothelial growth factor receptor			
VEGF	MKI vascular endothelial growth factor multikinase inhibitors		XP	capecitabine plus cisplatin; xeroderma pigmentosum
VHL	von Hippel-Lindau			
VIN	vulvar intraepithelial neoplasia		ZES	Zollinger–Ellison syndrome
VIP	vasoactive intestinal polypeptide		ZO1	zonula occludens 1

List of contributors

Neil K. Aaronson, The Netherlands Cancer Institute, Division of Psychosocial Research and Epidemiology, Amsterdam, The Netherlands

Ann S. Adams, Massachusetts General Hospital, Department of Surgery, Boston, MA, USA

Felipe Ades Moraes, Hospital Albert Einstein, São Paulo, Brazil

Ahmed Ashour Ahmed, Nuffield Department of Obstetrics and Gynaecology, University of Oxford, Oxford, UK

Richard W. Ahn, Northwestern University, Department of Chemistry, Evanston, IL, USA

H. Richard Alexander, Jr., University of Maryland School of Medicine, Baltimore, MD, USA

SECTION 1

Hallmarks of cancer

CHAPTER 1

The hallmarks of cancer
Perspectives for cancer medicine

Douglas Hanahan and Robert A. Weinberg

Introduction: a conceptual organizing principle

This textbook elaborates the landscape of a disease characterized by extraordinary complexity across the spectrum of organ sites and cell types. The growths that are grouped together under the rubric of cancer exhibit scrambled and mutated cell genomes, diverse histopathologies, highly variable timelines of pathogenesis and progression to symptomatic and metastatic disease, and a plethora of pathological effects. The simple premise in proposing a generic set of cancer hallmarks came from our belief that the bewildering complexity of cancer could be rationalized in terms of an underlying principle.

We envisaged these hallmarks as a set of acquired functional capabilities that act in combination to produce most forms of cancer, despite genetic and pathologic differences that might otherwise suggest a lack of mechanistic commonality. We imagined that each of these capabilities could be acquired by developing cancers through several alternative means, representing different solutions to the common challenges facing all incipient neoplasias. This concept, first presented in 2000 [1] and refined in 2011 [2], has proven to be a useful heuristic tool for distilling the underlying foundations of this disease.

The following sections provide a concise synopsis of this scheme, with a brief perspective on clinical applications in the last section. The reader is referred to the primary publications [1, 2], as well as to another perspective that expands on the roles of stromal cells in enabling the hallmarks of cancer [3]. A textbook on the biology of cancer [4] may provide additional detail on many of the mechanisms of cancer pathogenesis described in outline in this chapter.

The hallmarks of cancer: necessary functional capabilities

In the current conceptualization, there are eight hallmarks—acquired capabilities—that are common to many forms of human cancer (Figure 1.1). Each capability serves a distinct role in supporting the development, progression, and persistence of tumours and their constituent cells, as briefly explained below.

Hallmark 1: sustaining proliferative signalling

The essence of the disease is a deregulated programme that instructs cancer cells to grow and divide, doing so at inappropriate times and places, chronically. Many so-called 'driver mutations' that convert normal cellular genes into oncogenes (by mutational alteration of gene function or amplification in expression) serve to stimulate and sustain progression of cells through their growth-and-division cycles. They act by perturbing multiple nodes in the signal transduction circuits that normally transmit growth signals from the extracellular milieu into the cell nucleus. Many of these mutations alter regulatory circuits involving secreted growth-stimulatory proteins that bind as ligands to activate their cognate cell-surface receptors. Signal transduction into the cell nucleus is accomplished by cascades of protein–protein associations and protein phosphorylations, the most prominent of these signalling channels being growth-promoting signals transmitted through the RAS-RAF-MEK-MAPK pathway. Signal-sustaining mutational alterations of genes in this pathway are commonly observed in a wide variety of human cancers, illustrating its importance in enabling acquisition of this hallmark capability. We note, however, that activation in cancer cells of this central mitogenic pathway does not invariably depend on genetic changes acquired during the course of tumour progression. In certain instances, epigenetic deregulation of autocrine (auto-stimulatory) and paracrine (cell-to-cell) signalling circuits can also provide cancer cells with chronic growth-promoting signals, doing so in the apparent absence of underlying somatic mutations.

Hallmark 2: evading growth suppressors

The essential complement to proliferative signals in normal cells are braking mechanisms that serve either to overrule the initiation of, or to subsequently turn off, cell division stimulated by such signals. These countervailing regulatory mechanisms often involve the tissue microenvironments in which normal cells reside, ensuring that cell proliferation is not an entirely cell-autonomous process. The most prominent brakes are the direct regulators of the cell division cycle, embodied in the retinoblastoma protein (pRb) and several 'cyclin-dependent' kinase inhibitors that block progression of an individual cell through its growth-and-division cycle. The activity of this molecular braking system is regulated in part by extracellular pro- and anti-growth signals transduced by receptors on the cell surface in order to permit transitory proliferation, thereby ensuring normal tissue homeostasis.

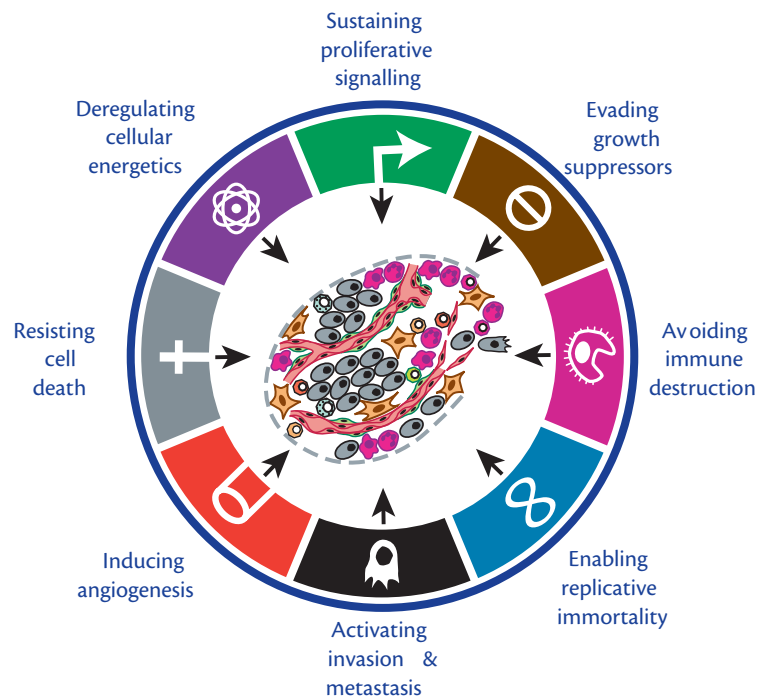
In addition to the brakes that respond to extracellular growth-modulatory signals, an intracellular monitoring system, centred upon the p53 protein, serves to ensure that cells advance only through their growth-and-division cycles when the


Fig. 1.1 The hallmarks of cancer. Eight distinctive functional capabilities—the hallmarks of cancer—are thought to be necessarily acquired during the multistep pathogenesis pathways leading to most forms of human cancer. Certain forms of cancer may be less dependent on one hallmark or another. Thus, adenomatous tumours evidently lack the capability for invasion and metastasis. Leukaemias may not require angiogenesis or invasive capabilities, although progression to lymphoma almost certainly requires both. And, the necessity for metabolic reprogramming or evading tumour immunity may be less pronounced in certain cancers.

physiologic state of the cell is appropriate. Thus, p53 serves to sense unrepaired damage to a cell's genome as well as other unresolved physiologic imbalances, and responds by shutting off the cell division cycle. In cases of severe genomic damage or physiological abnormalities, the p53 pathway can induce programmed cell death (see below), an extreme form of putting on the brakes to cell proliferation.

A number of component genes in both braking mechanisms—of the Rb and p53 pathways—are classified as tumour suppressors (TSGs) by virtue of their frequent loss-of-function via inactivating genetic mutations. Alternatively, the functions of TSGs can be lost by shutting down the expression of these genes through epigenetic mechanisms, notably those involving DNA and histone methylation. For example, while the p53 gene itself is mutated in ~40% of all human cancers, many other tumours carry genetic lesions that compromise p53 signalling in other ways. In sum, elimination or evasion of growth suppressors is clearly necessary to ensure that the chronic cell proliferation of cancer cells is not halted by braking mechanisms that, under normal conditions, would succeed in constraining cell proliferation.

Hallmark 3: resisting cell death

The second, qualitatively distinctive barrier to aberrant cell proliferation involves intrinsic mechanisms that can induce programmed cell death, a more drastic means to counteract inappropriate increases in cell number. The most prominent of these programmes is apoptosis, which helps to maintain tissue homoeostasis by inducing the suicide of aberrant cells, including ones that

are inappropriately proliferating. The apoptotic programme can be triggered by cell-intrinsic as well as non-cell-autonomous signals that detect different forms of cellular abnormality.

The apoptotic cell death programme involves the directed degradation of critical cellular organelles, the shrivelling of the cell, and its engulfment, either by their neighbours or by tissue-monitoring phagocytes, notably macrophages. All this transpires in less than an hour in mammalian tissues, explaining why apoptotic cells are usually relatively rare, even in a population of cells that is actively undergoing apoptosis, such as the cancer cells in tumours being subjected to cytotoxic chemotherapy. The rapid engulfment of apoptotic cell bodies ensures that their death does not release subcellular components that could inadvertently provoke an immune response; the resulting absence of responding immune cells contrasts with the programme of necrosis, which may be activated by various conditions, including oxygen and energy deprivation. Cells that are dying by necrosis rupture, releasing their contents and leaving their carcasses as debris; the relicts of living cells incite an inflammatory response that, as discussed below, can have both tumour-promoting and tumour-antagonizing effects.

A third programme, termed autophagy, serves as a recycling system for cellular organelles that normally helps cells respond to conditions of nutrient deprivation; by degrading cellular organelles, autophagy generates the metabolites and nutrients that cells are unable to acquire from their surroundings. While normally operating as a survival system, extreme nutrient deprivation can lead to hyper-activation of autophagy that results in autophagic cell death

when stressed cancer cells have cannibalized so many of their own organelles that they are inviable.

These three quite distinct mechanisms of programmed cell death must be circumvented or attenuated by cancer cells if they and their descendants are to continue their proliferative expansion in number and their evolution to states of heightened malignancy.

Hallmark 4: enabling replicative immortality

A third intrinsic barrier to chronic proliferation is integral to the linear structure of mammalian chromosomes: the telomeres at the ends of chromosomes record—by progressive reduction of their length during each cell division cycle—the number of successive cell generations through which a cell lineage has passed. The telomeres are composed of thousands of tandem copies of a specific hexanucleotide sequence. When the number of telomere repeats is reduced below a certain threshold, a tripwire is triggered, causing p53-dependent cell cycle arrest or apoptosis, the latter historically being termed 'crisis'. Circumventing these p53-induced anti-proliferative responses (e.g., by mutationally inactivating the p53 gene) does not on its own enable the cancer cell to avoid eventual elimination. Instead, continuing telomere erosion produces unstable chromosomes whose ends are no longer protected by telomeres, which can result in chromosomal translocations and rearrangements. If unchecked, these changes lead to mitotic catastrophe and consequent cell death.

Most cancer cells circumvent the barriers erected by the telomere replication clock by activating a mechanism of telomere maintenance used to preserve the replicative capacity of normal embryonic and tissue stem cells. This mechanism depends on upregulating the expression of the telomere-extending enzyme telomerase. Less frequently, they engage an alternative inter-chromosomal recombination-based mechanism for preserving telomere length. Thus, through one strategy or another, cancer cells acquire the capability to maintain their telomeres at healthy lengths, doing so indefinitely. By avoiding the barrier created by overly eroded telomeres, these cells acquire the unlimited replicative potential—termed cellular immortality—that is required to spawn large tumour masses.

Hallmark 5: inducing angiogenesis

Angiogenesis—the growth of new blood vessels—is critical for most neoplastic growths. Like normal organs, tumours require a steady supply of oxygen, glucose, and other nutrients, as well as a means to evacuate metabolic waste to sustain cell viability and proliferation; the vasculature serves these purposes. The deleterious effect that ischaemia has in normal tissue is well established clinically and experimentally: cells die, via one form of programmed cell death or another, causing tissue and organ degradation and dysfunction. Similarly, the growth of developing nests of cancer cells halts when their ability to acquire blood-borne nutrients becomes inadequate, typically when the nearest capillary is more than 200 microns away.

Cells at the diffusion limit from the nearest capillary activate various stress response systems, of which the most prominent involves the hypoxia-inducible transcription factor (HIF) system, which regulates hundreds of genes, including ones that directly or indirectly induce angiogenesis and other stress-adaptive capabilities. Much like cells in ischaemic tissues, cancer cells beyond the diffusion limit for oxygen and glucose will typically die, doing so

by necrosis, apoptosis, or autophagy. This explains why most vigorously growing tumours are well vascularized with evidence of ongoing active angiogenesis.

Of note, the tumour-associated neovasculature is usually aberrant, both morphologically and functionally. Tumour blood vessels are torturous, dilated, and leaky, with erratic flow patterns and 'dead zones' in which no blood flow is detectable, in marked contrast to the seamless blood flow operating in the normal microvasculature. Moreover, the degree of vascularity varies widely from one tumour type to another, ranging from intensely vascularized renal carcinomas to poorly vascularized pancreatic ductal adenocarcinomas.

Finally, we note that while chronic angiogenesis is a hallmark of the great majority of solid tumours, some may devise an alternative means to acquire access to the vasculature: in certain cases, cancers evidently co-opt normal tissue vasculature by employing the hallmark capability of invasion (see below). Thus, particular types of cancer cells can proliferate and grow along normal tissue capillaries, creating sleeves around the vessels. While vascular co-option is evident in certain cases (e.g., in glioblastoma) and in some tumours treated with potent angiogenesis inhibitors, most tumours rely to a considerable extent on chronic angiogenesis to support their expansive growth.

Hallmark 6: activating invasion and metastasis

The five hallmarks detailed above stand as logical necessities for the chronic proliferative programmes of cancer cells. The sixth is less intuitive: high-grade cancer cells become invasive and migratory. These interrelated programmes enable cancer cells to invade into adjacent tissue, and into both blood and lymphatic vessels (intravasation). Using these vessels as highways for dissemination, cancer cells can reach microvessels in other organs and extravasate across the walls of these vessels into new tissue parenchyma. Having entered the unfamiliar tissue microenvironments, seeded micrometastases generally die or lay dormant. However, on rare occasion, they may adapt to survival in such ectopic tissue locations and develop proliferative programs in these microenvironments, allowing them generate macroscopic metastases—the process termed 'colonization'.

The regulation of the intertwined capabilities for invasion and metastasis is extraordinarily complex, involving both cell-intrinsic programmes and assistance from accessory cells in the tissue microenvironment. Prominent amongst the cancer cell intrinsic regulatory mechanisms is the activation of a developmental programme termed the epithelial-mesenchymal transition (EMT) [2, 4], which is associated with cell migrations and tissue invasions during embryogenesis and organogenesis. A second overlapping regulatory programme engaged by some invasive and metastatic cancer cells is the aforementioned hypoxia response system, which triggers the activation of the hypoxia-inducible transcription factors HIF1a and HIF2a, consequently altering expression of hundreds of genes [5, 6]. Both transcriptional programmes control genes that can facilitate invasive migration as well as survival in the blood and lymphatic systems and in ectopic tissue locations.

Notably, the acquisition of this hallmark capability can occur at various points along the pathways of multistep tumour development that lead incrementally from normal cells of origin to those found in aggressive malignancies. In some cases, this capability for

invasion and metastasis is acquired early, such that cancer cells in an ostensibly benign tumour may be capable of dissemination long before this growth exhibits the overt histopathological phenotypes associated with high-grade malignancy. More often than not, however, the capability arises late, reflecting the accumulated mutational and epigenetic changes that render a tumour overtly malignant and thus its constituent cells capable of disseminating in large numbers to distant sites in the body. Moreover, there are clear indications that in the case of carcinomas, the EMT programme may become transiently active and functionally important for driving dissemination and seeding, thereafter being switched off in macrometastatic colonies [7]. It remains unclear whether the acquired traits of invasion and metastasis are beneficial and hence actively selected during the evolution of primary tumours or, alternatively, represent incidental byproducts of activating global regulatory networks (e.g. EMT, HIF) that facilitate primary tumour formation via functional contributions to the other five hallmarks.

Hallmark 7: deregulating cellular energetics and metabolism

The concept that cancer cells alter their utilization of energy sources—notably glucose—to support their proliferation was introduced almost 90 years ago by Otto Warburg, who observed that certain cultured cancer cells exhibited enhanced uptake of glucose, which was then largely metabolized by glycolysis. This limited breakdown of glucose occurred even in the presence of oxygen levels that normally would favour the oxidative phosphorylation pathway operative in the mitochondria. The result was counterintuitive, since glycolysis is far less efficient than 'OxPhos' at producing ATP, the primary currency of intracellular energy. We now appreciate that the 'aerobic' glycolysis described by Warburg produces, in addition to ATP, many of the building blocks for the cellular macromolecules that are required for cell growth and division. Indeed, the metabolism of cancer cells resembles that of actively dividing normal cells rather than being a novel invention of neoplasia. Moreover, it is important to appreciate that there is not a bimodal switch from mitochondrial Ox-Phos to aerobic cytosolic glycolysis in cancer cells. Instead, cancer cells continue to utilize in different proportions the Krebs/citric acid cycle-associated Ox-Phos and glycolysis pathways, the balance of which may well be required for optimal growth by cancer cells in different tumour microenvironments.

Although glucose is the primary fuel source used by most cancer cells, glutamine is also emerging as another key blood-borne source of energy and a precursor of lipids and amino acids. In most cases, glutamine likely supplements and enhances glucose in supplying energy and biomaterials for growth and proliferation of cancer cells, although in some cases of glucose insufficiency, glutamine may be able to compensate [8].

A third player in metabolic fuelling is lactate. While long considered to be toxic waste that is secreted by cells undergoing aerobic and anaerobic glycolysis, lactate is now appreciated to have diverse tumour-promoting capabilities [9]. In certain cancer cells, particularly those suffering glucose deprivation, extracellular lactose can be imported via specific transporters and used as fuel for generation of ATP and biomaterials. Similarly, some cancer-associated fibroblasts (CAF) can utilize lactate. Hence, metabolic symbioses can be envisaged within some tumours, between glucose-importing/lactose-exporting cells and lactose-importing cells [9].

Finally, we note a still-unresolved question about this hallmark: Is it significantly independent of the six cited earlier in terms of its regulatory mechanisms, or is it controlled by one of these other hallmark traits and in this sense hardly an independently standing hallmark on its own? Thus, certain mutant cancer genes, such as *Kras, cMyc,* and *p53,* have been found able to reprogramme the energy metabolism of cancer cells. Given this ambiguity, we termed the reprogramming of cellular energetics and metabolism as as an 'emerging hallmark' [2]. Irrespective of this qualification, it is clearly a crucial hallmark component of the neoplastic cell phenotype [10].

Hallmark 8: avoiding immune destruction

The eighth hallmark has been apparent on the horizon for decades. As originally proposed, incipient neoplasias must find ways to circumvent active surveillance by the immune system that would otherwise eliminate aberrantly proliferating pre-malignant cells. While clearly demonstrable in highly antigenic tumours in mouse models, and implicated in virus-induced human cancers, the generality of immune surveillance of cancer cells as a barrier to neoplastic progression and subsequent tumour formation is unresolved. One factor militating against this notion is the phenomenon of immune tolerance: because a normally functioning immune system develops a tolerance toward self-antigens, a tumour may pass under the radar and evade recognition and attack, as it expresses only these normal tissue antigens. Exceptions evidently arise, however, if cancer cells come to express embryonic antigens toward which immune self-tolerance was never established, or express fully novel non-self antigens created by gene mutation or by an infectious agent.

In fact, the immune response to the ~20% of virus-induced human tumours is clear: oncogenic viruses express foreign antigens to which the immune system is not tolerant, resulting in humoural and cellular immune responses that can kill virus-infected cells and thus eradicate incipient neoplasias. The fact that virus-transformed cells can nevertheless succeed in evading immune elimination to produce cancer testifies to immune-evasive capabilities evolved by such tumour viruses or developed by these cells during the course of tumour progression.

Although the incidence of non-virus-induced human cancers is not markedly increased in the context of immunodeficiency, suggesting a lack of immune surveillance of incipient neoplasias in the other 80% of human cancers, various lines of evidence suggest that some tumour types must indeed deal with immune recognition and attack during later stages of tumour progression and, in response, acquire immune-evasive strategies. Here, histopathological and epidemiological analyses have shed light on the potential role of immune attack and immune evasion. For example, among patients with surgically resected colorectal carcinomas, those whose tumours contained dense infiltrates of cytotoxic T-lymphocytes (CTLs) had a better prognosis than patients with tumours of similar grade and size that had comparatively few infiltrating CTLs. Such data implicate the actions of the immune system as a significant obstacle to the progressive growth and dissemination of cancer cells, one that is necessarily circumvented in some aggressive tumour types [11]. Indeed, immune phenotyping of tumours, including their associated stroma, is being evaluated as a new metric in the prognosis of certain tumour types that may enable, when combined with traditional criteria, more accurate predictions of prognosis and more effective treatment decisions [12].

For these reasons, we view anti-tumour immune responses as a significant barrier to be circumvented during the lengthy multistage development of many forms of human cancer. However, rules of immune engagement remain ambiguous across the spectrum of human cancers. Thus, it is generally unclear when during organ-specific tumour development the attention of the immune system is attracted (or not), and what the characteristics and efficacy of resultant immune responses are. Nor is it evident how polymorphic genetic constitutions of patients and the tumours that they harbour may affect anti-tumour immunity. Nevertheless, evading immune destruction seems increasingly to be an important mandate for developing tumours and thus an evident (if still emerging) hallmark of cancer.

Taken together, we view these capabilities acquired by most forms of human cancer to constitute a set of eight distinct hallmarks (Figure 1.1). Importantly, one cannot ignore the complex underlying mechanistic realities: different tumours acquire these hallmarks by diverse mechanisms, co-opting distinct homoeostatic and developmental functions in order to achieve them.

Genomic instability and inflammation: facilitators of hallmark capabilities

The lengthy process of tumour development and malignant progression, long appreciated to involve a succession of rate-limiting steps, reflects the need of evolving cancer cells to acquire the eight hallmark capabilities enumerated above. How then are these functional capabilities acquired? Currently, there are two clearly established means by which the hallmarks are acquired: genome instability and the resulting mutation of hallmark-enabling genes, and inflammation by cells of the immune system that help provide such capabilities.

Genome instability and the consequent mutation of hallmark-enabling genes is the primary means of acquiring hallmark capabilities. The cell genome is subject to routine DNA damage inflicted by a variety of chemically reactive by-products of normal metabolism, by environmental insults, and by errors in DNA replication during cell division. The resulting defects, if left unrepaired, can become cell-heritable mutations, explaining the need for an elaborate array of proteins that continuously monitor DNA integrity and, in response to damage, undertake repair. Irreparable genome damage provokes the elimination of cells, a task orchestrated by the p53 tumour suppressor gene, which has therefore been dubbed the 'guardian of the genome'.

The elevated rates and persistence of ongoing proliferation of cells in neoplastic lesions creates cell lineages that have undergone far more successive growth-and-division cycles than is typical of normal tissues, accentuating the potential for mutation-generating replication errors. Moreover, critically shortened telomeres can catalyse chromosomal rearrangements and fusions; if advantageous, hallmark-enabling mutations result, and if telomerase is subsequently activated to stabilize the mutated genome before the telomere crisis become lethal, then mutant clones of cancer cells can selectively expand.

The fundamental association of genome instability and mutation with cancer has been strengthened by numerous demonstrations that many cancer cells carry identifiable defects in the complex machinery designed to monitor and repair genomic damage. Most apparent are the frequently documented mutant alleles of p53 that have been found in perhaps 40% of all cancers; without p53 on duty, damaged DNA can persist unrepaired and mutant cells can survive and pass their damaged genomes on to their progeny. Other specialized DNA repair enzymes are also found in defective form in many tumours, and inherited familial defects in DNA repair can lead to elevated risk of cancer development, again by enabling the acquisition of tumour-promoting mutations.

The critical roles of somatic mutations in cancer pathogenesis are being further substantiated by the development of high-throughput DNA sequencing technologies and the associated ability to systematically analyse large numbers of independently arising cancer cell genomes. Complemented by other methods for genome scanning, such as comparative genomic hybridization to identify copy number variations, and 'chromosome painting' to detect karyotypic abnormalities such as translocations, the derangements of the cancer cell genome are being revealed in unprecedented detail [13–16].

The observations enabled by these various technologies substantiate the fact that almost every form of human cancer involves cancer cells whose genomes have been rearranged and mutated. The density of genetic alterations varies from one tumour type to another over many orders-of-magnitude, from very low numbers detected in certain paediatric cancers to the blizzards of mutations present in the genomes of UV-induced melanomas and tobacco-induced lung cancers. Thus, the aberrations can range from dozens of point mutations to hundreds of thousands per cancer cell genome, and from quasi-diploid chromosomal karyotypes to widespread aneuploidy, translocations, and multiple large-scale amplifications and deletions.

The data generated by these increasingly high-throughput genomic technologies presents a major challenge to determine which of the myriad mutational alterations actually contribute substantively to hallmark capabilities? The numbers that are being catalogued in many cancer cells greatly exceed those that are likely to be important in reshaping cell phenotype. The recurrence of specific mutations or mutated genes in multiple independently arising tumours of the same cancer type or subtype presents one compelling line of evidence concerning the functional importance of the involved gene. Yet other mutations may simply occur as consequences of the rampant stochastic mutations that accumulate in patients' tumours and, being non-recurrent, can be dismissed as 'passenger mutations' having little likelihood of contributing to tumour development; thus, such mutations would not seem to afford selective advantage and clonal expansion during tumour growth and progression. These phenomena have led to the emerging concept that cancer cells contain two classes of mutations: 'drivers' and 'passengers', the former being functionally important in driving tumour progression forward, while the latter are not. Identifying the important drivers becomes increasingly important as the effort to find potential therapeutic targets within cancer cells accelerates. An added dimension of complexity comes from the observations that certain hallmark traits may be conferred by driver mutations in some tumours, while in others comparable phenotypic advantage may be acquired by changes in the epigenome—the spectrum of heritable changes in chromatin that are not reflected by alterations in nucleotide sequence [17]. The field of cancer genetics is poised for an extraordinary decade during which tens of thousands of cancer cell genomes will be comprehensively

analysed for multiple parameters (DNA sequence and copy number, gene transcription, and histone and DNA methylation). The challenge and the opportunity will be to distill the contributions of specific genomic alterations to hallmark-enabling functions from the mammoth datasets that are being generated, and to exploit such knowledge for improved detection, evaluation, and informed treatment of human cancers.

Tumour-promoting immune infiltration (inflammation) is the second important means by which developing cancers can acquire hallmark capabilities. Above we discussed the mandate of developing tumours to avoid immunological destruction by cells of the adaptive immune system, often by blocking or pacifying infiltrating cytotoxic T cells. At the same time, it is clear that most tumours are nevertheless infiltrated by other cells of the immune system (so-called infiltrating immune cells, or IICs [3]) that are often components of the innate arm of this system and function as mediators of inflammation. In principle, such inflammation by IICs might reasonably be thought to represent failed attempts by the immune system to eradicate tumours. However, the evidence now clearly shows a quite different role: IICs help in the acquisition of multiple hallmark capabilities, encompassing six of the eight hallmarks [3]. Many of these functions reflect the roles that IICs play in the processes of wound healing and associated transient inflammation. Thus IICs can variously supply proliferative and survival signals, pro-angiogenic factors, and facilitate local invasion and blood-borne metastasis. In addition, some of these IICs (T-regulatory and myeloid-derived suppressor cells) can actively suppress the cytotoxic T lymphocytes that have been dispatched by the immune system to eradicate cancer cells.

The identities of the recruiting signals that bring IICs into tumours—including an ensemble of chemokine and cytokine signalling factors—are still incompletely understood. In some cases, the nature of the neoplastic lesion may trigger tissue abnormality signals that attract IICs; in particular, innate immune cells and possibly also B and T lymphocytes of the adaptive arm of the immune system. In other cases, oncogenic signalling, by activating transcriptional networks, induces expression of cytokines and chemokines that recruit IICs. In early stage lesions, the recruited IIC can help incipient cancer cells to proliferate, survive, evade anti-growth controls, or activate angiogenesis. At later stages of progression, IICs at the margins of tumours can facilitate invasiveness. Some experiments reveal that IICs can pair with cancer cells as they migrate through the circulation and become established in distant locations [18]. Additionally, certain IICs, such as macrophages, can subject cancer cells to DNA-damaging reactive oxygen species, thereby contributing to the mutational alteration of the cancer cell genome.

Most types of solid tumours are associated with tumour-promoting immune infiltrations that range from histologically subtle to the obvious inflammatory responses recognized by pathologists. In addition, the long-appreciated epidemiologic association between chronic inflammation and carcinogenesis supports the proposition that pre-existing inflammatory conditions create fertile breeding grounds for the inception and progression of certain forms of cancer. Moreover, chronically inflamed tissues share features with wound healing; both involve induction of angiogenesis and stimulation of cell survival, proliferation and migration/invasion, involving the inflammatory IIC and other cell types (e.g., myofibroblasts) that they activate in the affected tissue. These multiple processes stimulated by inflammatory

cells are of course hallmark capabilities, explaining why inflammation represents an important enabler of many types of cancer.

The tumour microenvironment (TME)

Historically, the simplistic description of the stroma posited that endothelial cells, through the process of angiogenesis, provided oxygen and nutrients, while carcinoma-associated fibroblasts (CAFs) provided structural support, and the IICs, discussed above, represented ineffectual anti-tumoural immune responses. We now appreciate the fact that the diverse cells forming the tumour-associated stroma can contribute to acquisition by cancer cells of seven of the eight hallmarks [3]. These three classes of stromal cell—angiogenic vascular cells (AVC), consisting of endothelial cells and pericytes; cancer-associated fibroblasts (CAF); and infiltrating immune (inflammatory) cells (IIC)—remain the most important actors within the TME in terms of their ability to facilitate tumour progression [3]. In fact, there are a number of distinct subtypes of mesenchymal cells within the stroma that have, in the past, been labeled simply as CAFs. The three most prevalent of these originate from alpha-smooth muscle actin-expressing myofibroblasts, mesenchymal stem cells, or connective tissue fibroblasts. These subtypes of CAFs are evidently generated by epigenetic reprogramming of their respective normal cells of origin by paracrine signals produced in the TME, reflecting similar signals that are responsible for orchestrating the complex process of wound healing.

The IIC cells described earlier are now known to be more diverse than previously appreciated. The list of tumour-promoting IICs includes various forms of macrophages, neutrophils, partially differentiated myeloid progenitors, and in some cases specialized B and T lymphocyte subtypes. The endothelial cells and pericytes of the tumour-associated vasculature are, superficially at least, relatively simple by comparison. However, both epitope and gene expression profiling have revealed tissue- and tumour-type-specific features of the endothelial cells, likely with subtle functional implications in terms of their ability to contribute to acquisition of hallmark phenotypes by nearby cancer cells.

This recent and more nuanced view of stromal cells elevates their importance in understanding the disease, by virtue of their hallmark-enabling functional contributions [2, 3]. CAFs, as an example not discussed above, can in different neoplastic contexts secrete proteases and signalling ligands that can, in turn, liberate epithelial cells from the growth-suppressive effects imposed by normal tissue architecture. Alternatively, CAFs may foster tumour-promoting inflammation, facilitate both local invasion and metastatic seeding, and even provide cancer cells with metabolic fuel. CAFs can also induce angiogenesis and, remarkably, act in an immune-suppressive fashion to blunt the attacks of tumoricidal CTLs.

Looking to the future, an important goal will be to continue mapping the multidimensional landscape of stromal cell types and subtypes operating within different tumour types and at different stages of progression, annotating the means of their recruitment and programming, and their respective functional contributions to hallmark capabilities and tumour phenotypes.

Finally, we note an additional dimension of intra-tumoral complexity revealed by findings indicating that most cancers contain distinct subpopulations of cancer cells with a greatly elevated ability to seed new tumours. Such tumour-initiating cells (TICs), often

termed cancer stem cells (CSCs), contrast with the bulk of cells in most tumours, which lack tumour-initiating ability. CSCs typically proliferate relatively slowly and often express the distinctive cell-surface markers of tissue stem cells [7, 19]. The initial concept was that CSC spawned cancer cells much like normal tissue stem cells spawn differentiated progenitors, and indeed there are such cases. For example, the CSCs in squamous cell carcinomas of the skin, which produce partially differentiated cancer cells much as normal skin stem cells produce the squamous epithelium. But in other cases, there appears to a dynamic bidirectional relationship between CSCs and cancer cells, in that cancer cells can be converted into CSCs, and vice versa; in some such cases, the EMT appears to switch on the CSC phenotype in cancer cells, while its converse (the mesenchymal-to-epithelial transition, MET) does the opposite to CSCs [7, 19]. Independent of this interconvertibility, there are indications that more slowly proliferating CSCs are often more resistant to existing anti-cancer drugs, enabling their persistence after initial treatment, laying the foundation for the regrowth of tumours that leads to clinical relapse. As such, therapeutic targeting of CSCs may be crucial to achieving enduring cancer therapies.

Applications to cancer medicine?

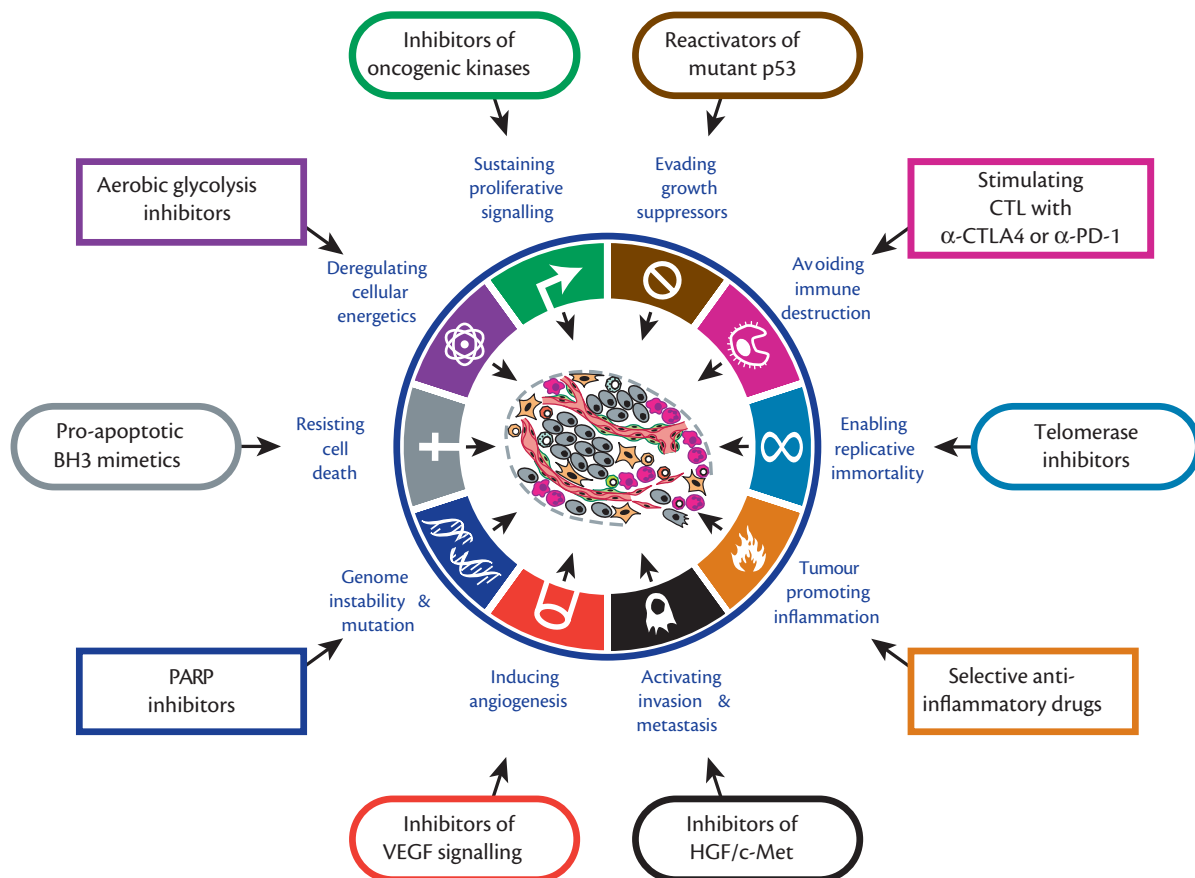
What then are the applications to translational and clinical oncology research of this conceptualization that common principles underlie the diversity of human cancer? The most apparent is in helping elucidate the molecular and cellular mechanisms by which particular forms of human cancer develop and progress to malignancy. A wealth of data is being generated by multiplatform analyses of cancer cells and neoplastic lesions in different tumour types (see, for example, [20]). Moreover, there will be other extrapolations of such analytic technologies, including the comparison of the cells present in multiple stages in tumorigenesis and tumour progression including metastatic growths, as well as comparisons of tumours and metastases during the response and relapse phases. The hope is to distil these complex datasets into insights that enable the development of novel mechanism-targeted therapies. The challenges are indicated by a number of formidable problems, including developing computational strategies that will make it possible to integrate all of this information in order to reveal the key determinants of particular tumorigenic pathways, to identify new therapeutic targets within cancer cells, to identify modes of


Fig. 1.2 Therapeutic targeting of the hallmarks of cancer. Drugs have been developed that disrupt or interfere with all eight of the hallmark capabilities, and with the two enabling facilitators (genome instability and tumour-promoting inflammation). Some of these hallmark-targeting drugs are approved for clinical use, while others are being tested in late-stage clinical trials; moreover, there is a pipeline full of new hallmark-targeting drugs that are in development and preclinical evaluation. Recognizing that eventual adaptive resistance during therapeutic treatment is apparent for virtually all of these hallmark-targeting drugs, a hypothesis has emerged: perhaps, by co-targeting multiple independent hallmarks, it will be possible to limit or even prevent the emergence of simultaneous adaptive resistance to independent hallmark-targeting drugs; clinical and preclinical trials are beginning to assess the possibilities.

adaptive resistance to therapy, and to use all of these data for diagnosis, prognosis, and treatment decisions. It is plausible, albeit still unproven, that conceptualizing these problems in terms of cancer's hallmarks will prove useful in this integration and distillation.

The hallmarks concept may prove useful in a second way. Thus, there are either approved drugs or drugs in late-stage clinical trials that target each of the eight hallmark capabilities and both of the enabling characteristics (Figure 1.2). For most of the ten, there are multiple drugs targeting a small set of mechanistic effectors. Unfortunately to date, such mechanism-based therapies targeting individual hallmarks have not proven to be been transformative for the treatment of late-stage, aggressive forms of human cancer. Typically, after a period of clinical response by tumours, adaptive resistance mechanisms kick in, enabling the surviving cancer cells (and CSCs) to resume progressive growth.

While different solutions can be proffered, one strategy involves applying the concept of the hallmarks as independent (or quasi-independent) and necessary components of a malignant cancer: by concomitantly targeting multiple hallmarks, it may be more difficult for cancer cells to concurrently develop multiple resistance mechanisms, allowing improvements in both initial efficacy and duration of clinical responses. As is always the case with multi-drug treatments, a major complication will arise from the toxicities that often accompany application of such therapeutic protocols. Anticipating such complications, genetically engineered mouse models of cancer and patient-derived xenografts may prove highly useful in reducing the numbers of drug combinations that should be tested in early phase clinical trials [21].

In conclusion, the hallmarks of cancer may provide the student of modern oncology with a foundation and a framework for absorbing the subsequent topical chapters of this textbook, and more generally for investigating and interpreting mechanisms, and applying such knowledge towards the development of more effective treatments for human cancers.

Growth factors and uncontrolled proliferation

Shujuan Liu and Ahmed Ashour Ahmed

Introduction to growth factors and uncontrolled proliferation

In spite of the significant diversity in their protein structures, growth factors have a remarkably similar overall mechanism of relaying signals (Figure 2.1). In general, ligand binding to receptors induces dimer formation (Figure 2.2) and autophosphorylation followed by recruitment of docking proteins and the activation of downstream signalling pathways that eventually modulate transcription. The specificity of growth factor signalling is governed by tissue-specific expression of pathway receptors, modulators, adaptors, and signalling molecules. The orderly regulation of components of growth factor pathways is governed by feedback loops that modulate the intensity and duration of a particular signal. A central feature of the majority of known cancers is the deregulation of one or more components of such feedback loops. Therefore, growth factor signalling pathways have attracted extensive drug discovery and drug development efforts that led to the introduction of many successful targeted therapies in cancer management. In general, these therapies have targeted the inactivation or blockage of ligands, receptors, or downstream signalling pathways (Figure 2.3). Here we outline the mechanisms involved in the regulation of some of the major growth factor signalling pathways, their deregulation in cancer and current approaches for growth factor targeted therapies.

Hepatocyte growth factor

Hepatocyte growth factor (HGF) was originally identified as a growth factor produced by platelets that stimulated DNA production in rat hepatocytes in primary culture that was biochemically distinct from platelet derived growth factor [1]. Subsequently, HGF and its ligand, the MET receptor tyrosine kinase [2] were implicated in various physiological and pathological processes.

HGF belongs to the plasminogen family of proteins and is transcribed and secreted in its inactive form as a single polypeptide, pro-HGF [3]. Subsequent site-specific proteolysis results in the formation of a dimer and this process is required for the biological activity of HGF [4]. This proteolytic step is mediated by a thrombin-like soluble enzyme called HGF activator (HGFA) or by the membrane bound proteolytic enzymes matriptase and hepsin [5, 6]. The activation of HGF is inhibited by proteolytic inhibitors HAI1 and HAI2 [7, 8].

Once HGF is activated, its serine proteinase homology (SPH) domain binds to the semaphorin (Sema) transmembrane domain of its receptor MET at the surface of cells. This binding results in the dimerization of the receptor and subsequent autophosphorylation of multiple tyrosine residues in its kinase domain. This results in subsequent activation and autophosphorylation of the substrate recognition site of the kinase and the adaptor proteins growth factor receptor-bound protein 2 (GRB2) and the GRB2-associated binding protein 1 (GAB1). It is important to note that the dimerization of the receptor is followed by internalization by endocytosis through clathrin-mediated coated pits and vesicles. Internalized receptor retains activity and there is recent evidence to suggest that certain MET mutations result in cytoplasmic localization of the receptor [9]. Once phosphorylated, MET, GBR2, and GAB1 act as docking sites for multiple substrates such as phosphoinositide 3 kinase (PI3K), CRK-like (CRKL) protein, and the protein tyrosine phosphatase SHP2 (also called PTPN11). Cytoplasmic MET becomes either degraded or recycled back to the membrane. Through docking these proteins, the HGF-MET pathway regulates several biological processes such as metabolism (PI3K signalling), proliferation (RAS/MAPK and PI3K signalling), epithelial mesenchymal transformation (EMT) and migration (RAC1/CDC42) [10]. Through modulating these signaling pathways, the HGF-MET pathway regulates important processes such as regeneration after skin [11, 12] or liver damage [13, 14] and EMT of myogenic progenitor cells in development [15].

The physiological regulation of HGF and MET is lost in cancers through multiple mechanisms including transcriptional deregulation, inadequate degradation, receptor crosstalk or synergies in downstream signalling pathways [2, 10, 16]. Induction of germ-line mutations of the HGF pathway in mice results in the generation of a variety of malignancies such as carcinomas, lymphomas, and sarcomas [17]. In addition, conditional activation of MET in the mammary gland results in the formation of basal-like carcinomas [18] and overexpression of MET is observed in a variety of tumours such as lung and renal carcinomas [19]. The activation of this pathway results in persistent activation of the RAS/MAPK pathway and the PI3K/AKT pathway that in turn results in increased proliferation, growth, and resistance to apoptosis. HGF/MET signalling is also a potent inducer of endothelial cell growth and angiogenesis [20–22]. Activation of MET results in increased VEGFA production and inhibition of thrombospondin production and this leads to enhanced angiogenesis [23]. MET also plays an important role in promoting metastasis of cancer cells through its role in regulating the RAS/MAPK [24] and RAC1/CDC42 regulation of the cytoskeleton [25].
Fig. 2.1 General perspective of growth factor signal transduction. The basic mechanism of activation of growth factor signalling pathway starts by: (1) binding followed by (2) ligand-induced receptor dimerization, activation of intrinsic kinase activity and autophosphorylation at specific tyrosine residues or serine/threonine residues (in the case of TGFβ), then (3) the phosphorylated receptors act as docking sites for adaptor proteins or could directly bind to a wide range of molecules that could (4) activate downstream signalling pathways which, ultimately, regulate a variety of cellular processes. Most of these signalling pathways relay signals from the membrane through the cytoplasm to the nucleus, except for IL-6 which via STATs transmit signals directly from the membrane to the nucleus.

Because of its established role in transformation, tumour growth, metastasis, and angiogenesis, the HGF-MET pathway has been established as a target for therapy in many tumour types [19]. So far, there are several strategies targeting the HGF/MET pathway, including inhibitor of HGF/SF activators, anti-HGF humanized antibodies, MET decoy receptors as well as MET extracellular domain monoclonal antibodies. In addition, several selective and non-selective MET kinase inhibitors are under evaluation in clinical trials. In addition, several combinations of targeted therapies are ongoing in Phase II and Phase III studies [10, 19]. Promising results were obtained from a clinical trial of a MET antibody (METMab®) in combination with an EGFR inhibitor (erlotinib) to treat patients
Fig. 2.2 Ligand binding could induce different types of receptor dimer formation depending on both the structural characteristics of the receptors. The most common form of dimerization is the formation of homodimers as is the case with HGF, VEGF, FGF, and PDGF receptors. EGF receptors form heterodimer complexes as not all of them can interact with ligands (e.g., ERBB2) or possess kinase activity (e.g., ERBB3). The TGFβ and IL-6 receptors usually form heteroterametric complexes (sometime hexamerization for IL-6) composed of two different isoforms of the receptor (for TGFβ, they are type I and type II TGFR. For IL-6, they are IL-6Rα and gp130). The IR and IGF1R isoforms are 'half' receptors that comprise a predominately extracellular α-chain and an intracellular β-chain. When actived, two half receptors form a holoreceptor for downstream signalling.

Fig. 2.3 Principles of pharmacological inhibition of growth factor signalling in cancer therapy. In general, the strategies targeting growth factor signalling pathways are divided into two major groups: (1) approaches for blocking the ligand or (2) blocking the receptor. The ligand can be blocked by neutralizing antibodies, dimeric soluble receptor extracellular domains, aptamers (stabilized oligonucleotides which could bind ligand proteins with high specific) or antisense oligonucleotides that target the ligand mRNA. Among the blocking receptor approaches, the receptor kinase inhibitors are the most widely developed pharmacological agents in cancer therapy. In addition, neutralizing antibodies targeting receptors and receptor kinase inhibitors are the most efficient and widely developed pharmacological approaches in cancer therapy.

with non small cell lung carcinoma (NSCLC). The combination treatment increased the progression-free survival (PFS) in cancers with high c-MET expression when compared with the group receiving erlotinib alone. Cancers with low or no c-MET expression showed no response to METMab® and patients had worse overall survival [10].

Insulin growth factor

Insulin is secreted from the β cells of the pancreas and functions as a classic hormone by influencing glucose uptake and carbohydrate metabolism in target cells that are distant from the pancreas. Insulin signals through insulin receptors (IR) that are formed of two αβ glycosylated polypeptides that together form a holoreceptor. The α chain of the receptor is predominantly localized at the surface while the β chain is transmembranous and harbours the kinase domain of the receptor [26]. Binding of insulin to the α chain of the receptor results in its activation and increased glucose uptake and downstream induction of glycolysis. This basic physiological process is crucial for the regulation of circulating glucose levels. IGFs have characteristics of both hormones and tissue growth factors. Similar to insulin, insulin-like growth factor 1 (IGF1) and IGF2 signal through a specific receptor, IGF1R, to regulate glucose metabolism, signal transduction, and a variety of physiological processes. Unlike insulin, IGF1 and IGF2 are widely expressed by many cell types and function in autocrine, endocrine, and paracrine fashions [27]. These ligands and their receptors have been implicated in driving the growth of many tumours [28, 29]. IRs exist in two splice variant isoforms: IRA and IRB, but the IGF1 receptor only has one isoform. IRB recognizes only insulin while IRA, which is most commonly expressed in tumours, recognizes both insulin and IGF2.

IGF1R shares 70% homology with IR (84% homology with its kinase domain [30]) and is a holoreceptor that is formed of αβ chains and together they form part of the transmembrane receptor tyrosine kinase superfamily. IGF1R acts as a receptor for both IGF1 and IGF2. Upon ligand activation, IGF1R undergoes conformational changes that result in binding of ATP to residue Lys1003 and activation of the kinase by autophosphorylation at tyrosine residues 1131, 1135, and 1136 [31] and subsequent binding and activation of docking substrate proteins such as insulin receptor substrates (IRS1-4). IRS tyrosine phosphorylation increases its affinity to the PI3K complex that results in translocation of PI3K to the membrane and its subsequent activation. IGF1R-mediated activation of PI3K as well as RAS/RAF/MAPK represent the key pathways through which IGF regulates cell proliferation and metabolism [27, 32].

There are several lines of regulation of IGF signalling. In general, IGF binding proteins (IGFBPs) have high affinity to insulin growth factors and limit their bioavailability to bind to IGFR1 [33]. IGFBPs expression is induced by p53, as well as many growth inhibitors such as vitamin D, anti-estrogens, retinoids, and transforming growth factor β [28]. Decreased expression of IGFBPs or mutations in TP53 result in increased IGF signalling and increased tumour proliferation [34]. Another line of regulation is through allelic dosing by imprinting and silencing of the maternal-derived allele of IGF2. Loss of imprinting carries a fivefold increased risk of colorectal neoplasia [35]. In addition, IGF2R, which specifically binds IGF2, lacks the kinase activity of IGF1. Therefore, IGF2R binding to IGF2 is thought to be a mechanism of inhibition of the pathway, and loss of function mutations of IGF2R have been found in a variety of tumours [36]. There is strong evidence that IGF signalling is either required for or facilitates the transforming signals of oncogenes. In vivo models demonstrated that loss of IGF2 reduced tumour development following TP53 or PTEN deletions in mice [37, 38].

Because of the strong evidence that the IGF signalling pathway is involved in driving tumour growth [28, 39, 40], it has been intensively investigated as a possible target for therapy. Several strategies

have been evaluated including targeting the ligands or decreasing their bioavailability, developing blocking antibodies targeting the IGF receptors or blocking of downstream signalling via activation of the AMPK pathway. In spite of the continuing enthusiasm in evaluating IGF signalling as a target for therapy, the results from clinical trials have not been encouraging [29].

The IL6/JAK/STAT3 pathway

Initially identified as a T-cell-derived regulating factor in B cell differentiation, Interleukin 6 (IL6) was found to play important roles in a wide range of biological activities such as immune regulation, haematopoiesis, and oncogenesis [41]. IL6 belongs to a group of cytokines that include IL11, leukaemia inhibitory factor (LIF), cardiotrophin (CT1), cardiotrophin-like cytokine (CLC), ciliar neurotrophic factor (CNTF), and oncostatin M (OSM), which all share a common receptor: glycoprotein receptor 130 (gp130) [42]. IL6 binds to its receptor IL6R (composed of ILRα and gp130) leading to its tetramerization/hexamerization, which in turn leads to activation of JAK1/JAK2/TYK2 kinases [42–44]. Activated JAK1/JAK2/TYK2 leads to tyrosine phosphorylation of the cytoplasmic domain of the IL6R leading predominantly to recruitment of signal transducer and activator of transcription 3 (STAT3) via its SH2 domain and its subsequent phosphorylation by JAK1/JAK2/TYK2. Once phosphorylated, STAT3 dissociates from the receptor and forms active dimers in which a phosphorylated SH2 domain of one molecule of STAT3 binds to the phospho-tyrosine 705 of the other molecule. Unlike many other signalling pathways that relay signals from the membrane through the cytoplasm to the nucleus, STATs offer a direct route of signalling from the membrane to the nucleus. STAT3 activation leads to the transcription of pro-survival proteins such as the anti-apoptotic protein BcL-xl, the cell cycle promoter cyclin D1, MCL-1, XIAP, Fas, and the oncogene c-Myc, as well as angiogenic factors [45, 46]. The regulation of the IL6/JAK/STAT3 pathway is mediated by the SOCS (suppressor of cytokine signalling) feedback inhibitors and PIAS (protein inhibitor of active Stat) proteins [41]. In addition to activation of STAT3, IL6 also activates Ras, MAPK, Cox-2, Wnt and PI3K/AKT pathways [47].

Overexpression of IL6 and activation of IL6 pathway are reported in many tumour types such as ovarian cancer, breast cancer, prostate cancer, endometrial cancer, lung cancer, renal cell carcinoma, oral squamous cell carcinoma, and colon cancer [41]. IL6 and STAT3 have also been associated with cancer drug resistance in breast, prostatic, and ovarian cancer. Treatment targeting IL6 or STAT3 could sensitize ovarian cancer to paclitaxel [48–50]. In addition, serum IL6 has been found to correlate with patient survival and could be an independent prognostic factor for cancers [51]. Mutations of IL6 downstream kinases such as the JAK2 V617F have been identified in most myeloproliferative neoplasms [52].

Current therapeutic strategies targeting IL6 mainly focus on monoclonal antibodies against IL6 and IL6R. Several types of chimeric antibodies, such as CNTO 328 (siltuximab) and BE-8, and humanized monoclonal antibodies, such as CNTO 136 and ALD518, are undergoing clinical trials [41, 53]. In addition, strategies have been employed for targeting STAT3 signalling that can be broadly divided into rationalized inhibitor design and screening. Peptides, peptidomimetics, and small molecule derivatives have been developed to interrupt STAT3 dimerization by targeting the SH2 domain or by inhibiting the interaction between STAT3 dimers

and DNA [54]. In addition, high throughput cell-based screening identified quinolines as possible inhibitors of STAT3 phosphorylation [55]. Despite intense research for discovering potent STAT3 inhibitors that could be tested in clinical trials, such agents still do not exist. JAK inhibitors such as ruxolitinib elicited significant responses when tested in phase III clinical trials for patients with myelofibrosis [56].

Epidermal growth factor

Epidermal growth factors (EGF) include 13 polypeptide ligands that share the EGF-like domain, a ~50 amino acid sequence characterized by a consensus six cysteine residue peptide and a β-sheet structure. EGF ligands include EGF, HB-EGF, neuregulins (1 through 6), epiregulin, amphiregulin, epigen, betacellulin, and TGFα. [57–59]

EGF ligands signal through a group of receptor tyrosine kinases called epidermal growth factor receptors (EGFRs, also called the ERBB receptors). The ERBB family of receptor tyrosine kinases includes ERBB1, ERBB2, ERBB3, and ERBB4 and share similar structural features. Broadly, they are formed of an extracellular ligand-binding domain, a transmembrane domain, a juxtamembrane domain, a kinase domain and a c-terminal tail that acts as a docking site for signalling proteins. In general, ligand binding results in homo- or heterodimerization, in which ERBB2-containing heterodimers are formed preferentially, and autophosphorylation on tyrosine residues. The latter provides docking sites for various adaptors or enzymes that initiate many signalling cascades [60]. In spite of broad similarities, ERBB receptors have distinct characteristics. For example, ERBB1, once bound to its ligands, undergoes conformational changes and autophosphorylation followed by binding to multiple docking proteins such as growth factor receptor bound 2 (GRB2) and members of the MAPK family of proteins but not PI3K [61]. Mouse knockouts of ERBB1 are fatal because of brain defects [62]. ERBB2, however, is thought to be a non-autonomous receptor tyrosine kinase that is incapable of binding to ligands but is capable of binding to a wide variety of substrates including the formation of heterodimers with other ERBB receptors and is, therefore, responsible for signal amplification in the EGF pathway [63]. ERBB3, while able to bind to ligands, is also thought to be non-autonomous as it lacks tyrosine kinase activity, albeit similar to the IGFR2 [64]. It does, however, form heterodimers with other ERBB receptors and is capable of binding to PI3K resulting in its relocation to the membrane followed by activation. ERBB4 is an autonomous tyrosine kinase that is capable of binding to ligands such as betacellulin, heparin-binding ligand, HB-EGF and epiregulin. Upon activation it is capable of recruiting GRB2, Shc, STAT5, and PI3K.

ERBB receptors are regulated via positive and negative feedback mechanisms. For example, ERBB receptor activation has been shown to induce TGFα and HB-EGF transcription [65]. Negative feedback loops either pre-exist, or are newly synthesized following stimulation of ERBBs by their respective ligands. The former primarily control receptors dephosphorylation and degradation. The latter, which is transcriptional up-regulated, may affect the ERBBs in multiple processes. For example, EGF stimulation results in the increased expression of the suppressor of cytokine signalling 5 (SOC5) that in turn promotes ERBB degradation through recruitment of E3 ubiquitin ligase [66]. In addition, the transmembrane leucine-rich repeat and immunoglobulin-like domains 1 protein (LRIG1) have been shown to inhibit EGF-mediated transformation of NIH3T3 fibroblast possibly through promoting ERBB receptor degradation [67].

Several mechanisms of deregulation of the EGF pathway have been described in cancer, which include overproduction of ligands, overproduction of receptors, or constitutive activation of receptors. In lung cancer, frequent mutations of ERBB1 at the ATP-binding cleft of the kinase domain have been described [68]. Such mutations are capable of activating downstream signalling pathways and increase the ability of ERBB1 to form heterodimers with other ERBB family members. Further, deletions of exon 2 to 7 of EGFR to form the oncogenic EGFRvIII mutant are commonly observed in glioblastoma [69]. In addition, genomic amplification of ERBB1 has been observed in lung, ovary, pancreas, breast, and head and neck cancers [70–72]. ERBB2 amplification and overexpression is frequently observed in breast cancer [73] and results in poor overall prognosis and resistance to taxane chemotherapy [74]. Overexpression results in EGFR-dependent pathway activation through delayed ligand induced degradation.

EGF targeting has been one of the most successful targeted therapy strategies for cancer treatment. Most efforts have concentrated on ERBB2 and ERBB1 owing to their increased expression in certain tumours, as mentioned before. Therapeutic approaches could be divided into immunological strategies (humanized antibody or naked monoclonal antibody), low molecular weight inhibitors (such as inhibitor of Hsp90), tyrosine kinase inhibitors and drug combinations. For example, trastuzumab, a monoclonal antibody against ERBB2, significantly improves survival in breast cancers that overexpress ERBB2 [75]. Similar results have been obtained with the EGFR monoclonal antibody cetuximab in EGF-expressing colorectal cancers that do not possess RAS mutations [76]. Tyrosine kinase inhibitors gefitinib (Iressa®) and erlotinib (Tarceva®) are also indicated in non-small-cell lung cancer [68]. Lapatinib is an ERBB1 and ERBB2 inhibitor that improves survival in ERBB2 positive metastatic breast cancer [77].

Fibroblast growth factors

Fibroblast growth factors (FGFs) [78] play many important physiological roles in regulating angiogenesis, wound repair, cell survival, and proliferation and differentiation. The FGF family includes 18 ligands and four transmembrane receptor tyrosine kinases (FGFR 1 through 4). FGFs are formed of glycoproteins that are secreted to the extracellular matrix and cell surface and are released from the matrix by the action of heparinases, proteases, or specific FGF-binding proteins that enable them to bind and activate their receptors. The specificity of the FGF–FGFR interaction is established by receptor paralogues, alternative splicing of FGFR, and the tissue-specific expression of ligands and receptors [79].

In general, the released FGFs bind to cell surface heparan sulphate proteoglycans (HPSGs) that stabilize the ligand–receptor interaction. FGF's binding to its receptors results in receptor dimerization, and subsequent formation of a ternary complex that comprises two receptor molecules, two FGFs, and one HSPG chain. The FGF signal leads to a conformational change of receptor structure that induces kinase domain activation and tyrosine phosphorylation of both the kinase domain and the receptor tail. This results in docking of a variety of signalling proteins of which the FGFR substrate 2 (FRS2) appears to be a key adaptor largely specific to FGFR. FGFRs phosphorylate FRS2 on several sites, and active FRS2 allows the recruitment of adaptor proteins, growth factor receptor bound 2 (GRB2) and Son of Sevenless 1 (SOS1) protein to promote guanine nucleotide exchange and activation of the RAS/RAF/MAPK pathway [80] and PI3K [81]. FGFRs are also capable of binding to other receptor tyrosine kinases such as anaplastic lymphoma receptor tyrosine kinase (ALK) [82]. Independently of FRS2 binding, the FGFRs could also bind to the SH2 domain of phospholipase Cγ (PLCγ) via its phosphotyrosin residue at the carboxyl terminus [83] and signals through the PKC/Ref/MAPK pathway. Several other pathways are also activated by FGFRs, such as p38 MAPK, Jun N-terminal kinase pathway, STAT signalling pathway [84], and ribosomal protein S6 kinase 2 (RSK2) [85]. The physiological functions of the FGF family are context dependent subject to cell-type specific expression pattern and cross-talk with other pathways. FGFRs play a key role in differentiation. For example, mutations in FGFR2 result in premature activation in development and premature closure of skull sutures resulting in a syndrome called craniosynostosis.

Important negative feedback mechanisms exist to suppress FGF signalling. For example, activation of the pathway has been shown to activate CBL-mediated monoubiquitylation and degradation of FGFRs [86]. MAPK activation downstream of FGFR results in induction of FRS2 expression which competes for and inhibits the binding of GRB2 to FGFR [82]. Further, FGFR signalling activates the MAPK phosphatase 3 (MKP3) which results in dephosphorylation and inactivation of ERK1 and ERK2 and, therefore, limiting MAPK signalling [87]. In addition, ERK1 and ERK2 signalling results in increased expression of Sprouty which either competes with SOS1 for binding to GRB2 and limits FGF-induced RAS activation, or directly binds to RAF to block the subsequent MAPK signalling [88, 89]. Similarly, the transmembrane form of interleukin 17 receptor D (IL17RD, also known as SEF) can directly bind to FGFRs [90] and inhibit ERK phosphorylation [91].

In cancer, several mechanisms of deregulation of the FGF pathway have been described including genomic FGFR alterations that drive ligand-independent receptor signalling such as gene amplifications, mutations, and translocations and alternation that result in ligand-dependent activation [79]. In a screen of more than 1000 somatic mutations found in the coding exons of 518 protein kinase genes from 210 different human cancers, the non-synonymous mutations of FGF signalling pathways were the most commonly identified mutations [92]. Most notably, mutations in the extracellular domain of FGFR3 that result in constitutive dimer formation have been described in 50% of bladder cancers [93]. Similar mutations have been observed in cervix cancer [94], prostate cancer [95] and multiple myeloma [96]. Mutations of FGFR2 occur in 12% of endometrial cancers [97]. Gene amplifications of FGFR2 are frequently observed in cancers such as being amplified in 10% of gastric cancers [98]. Similarly, amplification of the FGFR1-containing locus occurs in 10% of breast cancers [99]. Translocations that result in constitutive activation have also been observed in multiple myelomas where t(4;14) results in an FGFR3 to immunoglobulin H3 fusion which facilitates ligand-independent binding [100, 101]. In addition to FGFR deregulation, ligand-dependent mechanisms have also been observed in cancers through either autocrine production of ligand in cancer cells or paracrine overproduction of ligand from stromal cells that may be expressed physiologically or in response to cancer cells in a "paracrine loop" [79]. For example, antisense-mediated inhibition of FGFR1 or FGF2 regressed the growth of human melanoma xenografts, indicating that an FGF2–FGFR1 autocrine loop promotes the development of some melanoma [102]. FGF1 overexpression, which

functions in a paracrine manner to promote angiogenesis, has been shown to correlate with poor survival in ovarian cancer [103].

Several mechanisms mediate the oncogenic potential of FGF deregulation. FGF signalling could affect cell proliferation, cell survival, migration, invasion, and angiogenesis in different tumour types. For example, activation of the pathway results in enhanced cancer cell survival and proliferation via activation of the PI3K–Akt pathway [104–106]. In addition, overexpression of FGF2 results in upregulation of the anti-apoptotic proteins BCL2, BCLx, XIAP, and IAP1 through the S6 kinase-mediated pathway, therefore promoting resistance to chemotherapy [107, 108, 109]. FGFR1 activation could result in increased MMP3-dependent invasion [110]. Importantly, endothelial blood vessels express high levels of FGFR1 and FGFR2, and FGF stimulation is known to have a potent angiogenic effect [111, 112].

In spite of the known oncogenic potential of FGF signalling, studies have shown that it has tumour suppressive functions in a context-dependent manner. For example, in a mouse model of developing endochondral and membranous bone, the FGFR3 and FGFR2 can negatively regulate proliferation and positively drive differentiation [113, 114]. Several studies of human tumours and cancer cell lines potentially support a tumour protective effect of FGFR2 signalling. For example, the expression of FGFR2-IIIb in FGFR2-IIIb negative bladder tumour cell lines blocks cell proliferation [115]. Given that in some circumstances FGFR2 signalling is clearly oncogenic, it is recognized that context-dependent differences in signalling can lead to either tumour promotion or senescence in response to active FGF signalling [79].

Several therapies targeting the FGF pathway are currently under investigation. FGFR tyrosine kinase inhibitors such as BIBF1120 [116], TK1258 [117], and TSU-68 [118] are in clinical trials. Such inhibitors have the advantage of targeting multiple pro-angiogenic growth factors (such as VEGF, PDGF, and FGF) but lack of specificity increases the potential side effects and limits the ability to deliver drugs at doses required for FGFR inhibition. Specific antibodies against mutant FGFR3 have been shown to be successful in bladder cancer and t(4;14) myeloma [119]. A third approach for targeting is the development of ligand traps. A fusion protein between the extracellular portion of FGFR1-IIIC and the Fc domain of IgG1 targets multiple FGF receptors by preventing ligand binding and has been shown to have anti-proliferative and anti-angiogenic effects [79]. Finally, recombinant FGF7 to stimulate FGFRs are used in treatment of mucositis induced by myelotoxic therapy requiring haematopoietic stem cell support [120].

Transforming growth factor beta

The transforming growth factor beta (TGFβ) pathway plays important roles in many physiological processes such as adhesion, migration, differentiation, apoptosis, and the determination of cell fate [121, 122]. In embryogenesis it plays an important role in germ line specification and patterning. The transforming growth factor family of ligands includes three TGFβ isoforms, four activin β chains, the protein nodal, ten bone morphogenic proteins (BMPs), and 11 growth and differentiation factors (GDFs) [123].

The basic mechanism of ligand-receptor activation includes dimerization of the pre-ligand protein followed by cleavage to generate an active ligand, followed by receptor binding. TGFβ receptors are formed of an extracellular cysteine-rich domain, a transmembrane domain, and a serine-threonine kinase domain

that distinguish this family of receptors from other transmembrane receptor tyrosine kinases [124]. TGFβ receptors are classified into two families: type I and type II. Type I family includes activin-like receptors (ALK 1 through 7). Type II includes receptors such as TGFRII, ACTRII, ACTRIIB, BMPRII, and AMHRII. Type II receptors are thought to phosphorylate type I receptors upon ligand activation. Phosphorylated type I receptors consequently recruit and phosphorylate the receptor-regulated TGFβ transducers SMAD proteins 1, 2, 3, 5, and 8 (R-SMADs). These SMADs consequently bind to SMAD4 and are translocated to the nucleus where they regulate transcription through regulating chromatin remodelling and histone modification [124]. In addition to the SMAD-dependent functions of the TGFβ pathway, TGFBRII has been shown to modulate disassembly of tight junctions through PAR6 [125].

Negative regulatory pathways exist to regulate the TGFβ pathway. For example, the inhibitory SMADs (I-SMADs), SMAD6 and SMAD7, are thought to inhibit other SMADs and terminate TGFβ-driven signal transduction [126]. TGFβ and BMP signalling and stimulation of R-SMADs results in the increase of transcription of SMAD6 and SMAD7 which compete with R-SMADs for binding to type I receptors and, therefore, limit signal transduction [127]. In addition, E3 ubiquitin ligases play a central role in regulating TGFβ signalling through the degradation of SMADs. Homologous to the E6-accessory protein C-terminus (HECT) E3 ubiquitin ligases, SMAD ubiquitin regulatory factor 1 (SMURF1) and SMURF2 are examples of key ubiquitin ligases involved in this process [128]. SMAD7 mediates the binding of SMURF1/2 to R-SMADs and their consequent degradation [129, 130]. In contrast, the RING-type E3 ubiquitin ligase Arkadia induces ubiquitination and degradation of SMAD7 and, therefore, augments TGFβ signalling [128]. SMAD6 may specifically compete with SMAD4 for binding to BMPR-activated SMAD1 by forming an inactive SMAD1/SMAD6 complex in the cytoplasm [131]. In addition, cross-talk between the TGFβ and the MAPK pathway (which includes ERK1/2, JNK and p38 pathways) is thought to induce positive and negative regulation of TGFβ signalling [132, 133]. For example, JNK, ERK, and p38 phosphorylate SMAD2/3 independent of TGFβ signalling [134–136]. There is also evidence that SMADs act upstream of MAPKs and mediate their activation. For instance, SMAD signalling plays an important role in promoting the invasive phenotype of human head and neck squamous carcinoma cells by p38-mediated upregulating collagenase expression [137]

The dual role of the TGFβ signalling pathway has recently become clearer [138, 139]. In early tumour formation, TGFβ induces a durable anti-proliferative effect by its cytostatic and apoptotic functions [140]. The cytostatic mechanism is thought to involve the upregulation of p21 and p15 and the consequent inhibition of CDK phosphorylation of retinoblastoma protein, halting the cell cycle [141]. In addition, TGFβ downregulates the transcription of c-Myc in a SMAD3-dependent manner. The apoptotic mechanism of TGFβ has important relationship with some pro-apoptotic target genes, which are controlled by SMAD transcriptional complexes such as the TGFβ-inducible early-response gene (TIEG1), the death-associated protein kinase (DAPK), and the SH2-domain-containing inositol-5-phosphatase (SHIP) [140]. Loss of this tumour suppressive function of TGFβ is thought to be a major step towards cancer progression. However, in established tumours, TGFβ signalling is thought to be overexpressed to create a local immunosuppressive environment that fosters tumour

growth and exacerbates the pro-invasive and metastatic behaviour of tumour cells [140]. TGFβ induces the expression of several matrix metalloproteinases (MMPs) that lead to the degradation of the extracellular matrix and facilitate invasion. TGFβ also acts as a potent inducer of angiogenesis through a direct effect on VEGF expression and indirectly through inducing monocytes to release angiogenic cytokines [141]. In vivo models of breast cancer metastasis revealed that TGFβ signalling plays an important role in bone metastasis [142]. In addition, several signalling pathways have been implicated in TGFβ-induced epithelial-mesenchymal transition (EMT), such as SMADs, PI3K/Akt, RHOA, and p38 MAPK [140].

Therapeutic options targeting the TGFβ pathway in tumours have been developed [143, 144]. The most advanced TGFβ signalling antagonists in clinical development are large molecules including monoclonal antibodies and antisense oligonucleotides. For example, DNA oligonucleotides targeting TGFβ2 mRNA has been developed (trabedersen, AP12009, Antisense Pharma) for targeting high-grade gliomas, pancreatic cancer, and malignant melanomas [145]. Similarly, AP11014 is an antisense oligonucleotide against TGFβ1 that has also been developed for targeting non-small-cell lung cancer, colorectal cancer, and prostate cancer [146]. In addition, small-molecular TGFβ type I receptor kinase inhibitors have been the focus of drug discovery efforts, such as the ALK inhibitors SB431542 [147] and SB525334 [148]. Given the dual function of TGFβ signalling and the limitation of these therapeutic molecules, future studies may focus on exploring the potential clinical benefit of large and small molecule combination therapies and on determining the appropriate patient subpopulations for TGFβ therapies [143].

Platelet derived growth factors

Platelet derived growth factors [149, 150] are dimers of disulfide-linked polypeptide chains [151]. They are characterized by growth factor core domains with a conserved set of cysteine residues [152, 153]. The PDGF family consists of PDGFA, PDGFB, PDGFC, and PDGFD. The protein products of the genes form homodimers but PDGF-AB heterodimers have also been described. This family of growth factors is linked structurally and functionally to the VEGF family of proteins. PDGF receptors include PDGFRα and PDGFRβ. The receptors contain five extracellular immunoglobulin loops and a tyrosine kinase intracellular domain. They have structural similarities to FMS, c-Kit, and FLT3 which are the receptors for the CSF1, SCF, and FLT3 ligands, respectively. In vivo evidence confirmed that PDGF-AA and PDGF-CC dimers bind to PDGFRα while PDGF-BB binds to PDGFR-β [152, 154] PDGF expression in cultured cells is induced by several factors including hypoxia, thrombin, cytokines and growth factors including PDGF itself. PDGFA and PDGFC are predominantly expressed in epithelial cells, muscles, and neuronal progenitor cells. PDGFB is expressed in endothelial cells, megakaryocytes, and neurons while PDGFD is expressed in fibroblasts. PDGFR expression is generally low in mesenchymal cells but is increased following inflammation, TGFβ stimulation, estrogen, interleukin 1α, FGF2, and TNFα [151].

Similar to many other receptor tyrosine kinases, ligand binding of PDGF to its receptors induces dimer formation, autophosphorylation of the kinase domain and kinase activation. Phosphorylated sites act as docking sites for downstream signal transduction molecules and activate the RAS/MAPK pathway, the PI3K pathway, and PLC-γ.

GRB2 binds via its SH2 domain to phosphorylated PDGFR and via its SH3 domain to SOS1, which in turn activates RAS which signals to the RAF1 and MAPK pathway [155]. PI3K via its SH2 domain of regulatory subunit binds to PDGFR and actives a wide range of cell processes [156]. PLC-γ activation results in mobilization of intracellular calcium ions and the activation of PKC and downstream effects on cell growth and mobility [154]. In addition, PDGFR activation results in activation of the Src family of kinases promoting Myc transcription and mitogenic responses [157] and the FER/FES tyrosine kinases which induce cytoskeletal remodeling and differentiation.

PDGF signalling is controlled by the balance between the stimulatory signals mentioned above and negative feedback loops. SHP2 tyrosine phosphatase binds to PDGFR through the SH2 domain and dephosphorylates the receptor [158]. In addition, RAS-GAP binds to PDGFR-β and inactivates RAS [159]. Ligand-receptor interaction induces endocytotic receptor internalization and lysosomal degradation [160]. In addition, the adapter protein Alix binds to PDGFRB resulting in its increased ubiquitination and degradation via the CBl RING finger E3 ubiquitin ligase [161]. Phosphatase TC-PTP may also act as a negative regulator of PDGFR-β phosphorylation [162].

Many physiological functions have been attributed to the PDGF family. PDGF signalling plays a role in gastrulation and formation of cranial and cardiac neural crest. PDGFA and PDGFR-α null mice have severe impairment of early mesenchymal derivatives. PDGFR-α knockout mice and PDGFA/PDGFC double knockout mice have defective vertebral arch formation. PDGFs also have a conserved morphogenic function in guiding cell migration through the formation of growth factor gradients in the extracellular space. In addition, PDGF plays a key role in the development of several organs and tissue types such as being required for villous morphogenesis in the bowel tract, alveolar septum development, palate formation, glomerular formation in the kidney, hair follicles, and spermatogenesis. PDGFs are also involved in glial cell development and neuroprotection, and in the development of cardiovascular system, axial skeleton, and teeth [152].

PDGF signalling may be involved in modulating tumour behaviour through both autocrine and paracrine routes. Autocrine PDGF signalling has been implicated in glioblastoma, soft tissue sarcomas, and breast cancer, and contributes to proliferation, survival, invasion, and metastasis. A variety of tumours express high levels of PDGFA, PDGFC, and PDFGR-α. Such increased expression may be secondary to stimulation by other growth factors such as TGF-β in the case of some gliomas. Gene amplification has also been described in glioblastoma and esophageal squamous cell carcinoma. In addition to increased expression, activating mutations and chromosomal rearrangements also lead to autocrine PDGF signalling. For example, gastrointestinal stromal tumours that do not possess mutations in KIT frequently possess gain of function mutations in PDGFR-α. Several myeloid disorders and leukaemia have translocations that involve the PDGF receptors such as the ETV6-PDGFRB fusion that result in constitutive activation of the receptor. In addition, dermatofibrosarcoma protuberans (DFSP), a rare mesenchymal neoplasm of the dermis is characterized by a translocation that repositions the collagen type 1α1 promoter adjacent to the PDGF gene resulting in its overexpression and constitutive activation of PDGFR-β. Imatinib, a tyrosine kinase inhibitor that targets several kinases including PDGFR-β elicits up to 50% responses in this tumour [163]. PDGF signalling was

found to be upregulated during TGFβ-induced EMT in breast cancer and promote metastasis in mouse mammary carcinomas. Paracrine PDGF signalling may play a role in malignant transformation by recruiting different types of stromal cells, such as endothelial cells, pericytes, and fibroblasts, to the tumour mass. Through its effect on these non-neoplastic stromal cells, PDGF signalling may directly and indirectly promote tumour growth, blood perfusion, metastatic dissemination, and drug resistance [164]. For example, in mouse fibrosarcoma, paracrine PDGF/PDGFR-β signalling enhances pericyte recruitment to the tumour vasculature, thereby promoting tumour cell growth, survival, and vessel stabilization [165]. PDGFR-β signalling could regulate interstitial fluid pressure (IFP) in normal tissue, and inhibition of PDGFR could reduce tumour IFP and enhance the uptake into tumours [166, 167]. Therefore, the PDGF signalling may be implicated causally in at least three cancer cell traits: self-sufficient growth, angiogenesis and metastasis, as well as in resistance to cytotoxic therapy [152].

Given the important role of PDGF signalling in tumours, several strategies have been tested for targeting this signalling pathway. Strategies include blocking PDGF and inhibiting PDGFR function. Neutralizing antibodies, recombinant dimeric soluble PDGF extracellular domain and nucleic acids (aptamers) have been employed to target PDGF. PDGFR function could be blocked by antibodies, dominant-negative ligands, and kinase inhibitors. Imatinib (ST1571, Gleevec®) is an oral tyrosine kinase inhibitor that inhibits PDGFR-α and PDGFR-β, as well as BCR-ABL fusion protein, c-Kit, and Flt3. Imatininb has been approved by the Food and Drug Administration for the treatment of patients with Philadelphia chromosome positive chronic myelogenous leukaemia and gastrointestinal stromal tumours. Most of the available PDGFR kinase inhibitors available are not completely specific and act on other tyrosine kinase such as c-Kit and Flt3; thus, it is difficult to determine how much of the response to these agents is actually due to the PDGF blockade [168].

Conclusion

While the general mechanisms of activation of growth-factor-dependent signalling are highly similar across multiple pathways, they serve distinct regulatory roles. The selectivity of growth factor function is largely driven by tissue specific expression of regulatory proteins. Deregulation of regulatory elements result in the development of tissue-specific diseases including tumours. The understanding of these pathways is essential for the development of growth factor targeted therapies. The successful development of many such therapies over the past two decades have already contributed to the control of many cancer types. However, major challenges to theses therapies such as tumour heterogeneity, the inevitable development of drug resistance, and the difficulties in achieving therapeutic selectivity are likely to be the focus of future research directions in this field.

CHAPTER 3

Cell signalling pathways

Stefan Knapp

Introduction to cell signalling pathways

Cellular functions are regulated by highly complex signalling networks containing thousands of interconnected nodes that tightly control cellular growth, migration, metabolism, differentiation, and cell death. However, these regulatory networks are far too complex to serve as predictive model systems for our understanding of cell signalling processes, forcing us to adhere to easier directional pathways that describe the main signalling avenues that transmit environmental cues from the plasma membrane to the nucleus. In most cancer types several key regulators in signalling pathways are perturbed, and each of these perturbations provides the cancer cell with a small survival and growth advantage. The advent of large-scale sequencing revealed that there are on average 80 mutations that alter amino acid residues in signalling proteins in a typical cancer biopsy. These mutations are composed of few commonly mutated genes but the majority of mutations occur with low frequency resulting in a complex picture of the cancer genome landscape. Analysis of these mutations by statistical methods predicts that most of the detected mutations have probably little or no functional consequences. However, it has been estimated that nevertheless around 15 mutations contribute either to the initiation, progression, or maintenance of a tumour. In late-stage metastatic cancer, multiple distinct and spatially separated inactivating mutations of tumour-suppressor genes have been identified within a single tumour leading to a considerable degree of intra-tumour heterogeneity, further complicating molecular mechanisms that lead to deregulation of signalling in cancer and consequently the rational design of new therapeutic strategies that target signal transduction pathways.

However, all cancers need to acquire a set of capabilities that are tightly controlled in normal cells. These hallmark capabilities lead to alterations in signalling that sustain growth factor-independent proliferation, evade growth suppression, suppress apoptotic mechanism and detection of cancer cells by the immune system, overcome the limited replication potential of somatic cells, guarantee sufficient nutrition supply by generating new blood vessel formation and by changing the cellular energy supply. These lead finally to the spread of the tumour in the body by inducing cell migration and metastasis. Here I review the principal regulatory mechanisms that control the main signalling pathways, with a particular focus on pathways that have been successfully targeted in cancer therapy.

Receptor tyrosine kinases and growth factor signalling

Tissue homoeostasis is tightly controlled by extracellular signalling molecules such as growth factors that bind to cell surface receptors located in the plasma membrane. Receptors of extracellular growth factors (GFs) are often receptor tyrosine kinases (RTKs) or receptors that tightly associate with RTKs. GF receptors share a number of characteristic regulatory features that allow efficient transmission of extracellular mitotic signals through the plasma membrane and the activation of downstream signalling pathways that transmit signals to the nucleus where they trigger activation of transcriptional programmes. Dysfunction of growth factor signalling is a hallmark of cancer and involves usually GF independent activation of growth-promoting signalling events. Due to the large diversity of GF receptors the description here is limited to three main receptor systems that play a central role in cancer and that are also current targets of drug development efforts.

Insulin and insulin growth factor signalling

The Insulin and insulin-like growth factor 1 (IGF1) signalling pathway has a pivotal role in regulating cellular proliferation and survival. This pathway evolved very early in evolution to regulate growth, body size, and longevity as a response to nutrient supply. The more specific role in regulation of carbohydrate metabolism evolved much later and is a specialized function of insulin and the insulin receptor (IR). IGF1 is mainly expressed in liver where expression of this growth factor is stimulated by growth hormone (GH). The IGF2 isoform is more widely expressed and is not regulated by GH. Free plasma levels of IGF1 and IGF2 are regulated by IGF binding proteins (IGFBPs). It has been estimated that more than 90% of circulating IGF is bound to IGFBPs which inactivate IGFs by competing with receptor binding. However, IGFBs also stabilize IGFs by prolonging their plasma half-life and may have IGF independent growth-inhibitory and pro-apoptotic functions.

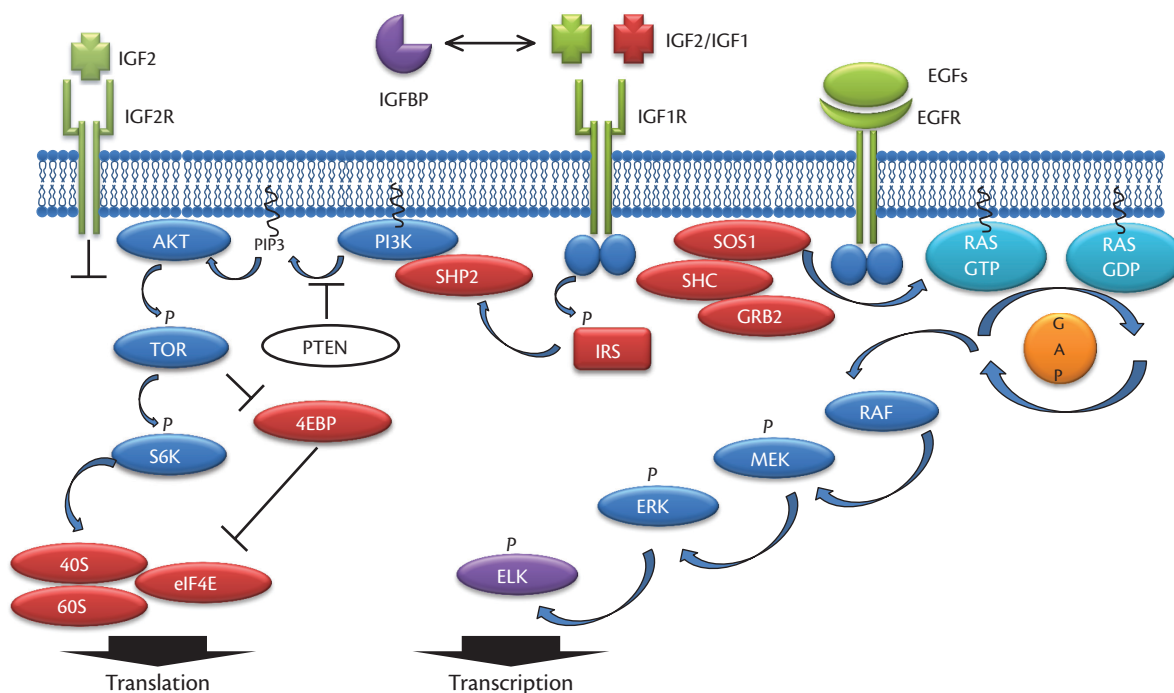
The IRs, IGF1, and IGF2 are tetrameric and are composed of so-called half-receptors consisting of an extracellular binding domain (α-chain) and a transmembrane and cytoplasmic RTK (β-chain). The IR is expressed as two splice isoforms. The isoform 'IRB' recognizes exclusively insulin, but the 'IRA' isoform, which is also overexpressed in tumours, recognizes both insulin and IGF2. Two diverse receptors also exist for IGF (IGF1R and IGF2R). IGF2R has no catalytic domain and functions as a sink for free IGF2 and has therefore tumour-suppressor properties. Depending on their relative abundance IGF1R and IR half-receptors may associate into hybrid receptors. The direct downstream targets of IGF1R and IR are the insulin receptor substrates (IRS proteins) that trigger activation of a number of pathways including phosphatidylinositol 3-kinase, AKT, mammalian target of rapamycin (mTOR), and mitogen-activated protein kinases (MAPKs), which will be


Fig. 3.1 Example of a receptor tyrosine kinase signalling pathway. Kinases are highlighted in blue, receptor tyrosine kinases and their substrates in green, phosphatases in white, GTPases in olive and adaptor and substrate proteins in red.

discussed later in this chapter. A graphical representation of the IGFR signalling pathway is shown in Figure 3.1.

Epidermal growth factor (EGF) signalling

Another group of growth factors comprise epidermal growth factor (EGF)-like proteins and neuregulins which activate members of the EGF receptor (EGFR) family of RTKs and consists of four members (EGFR/ErbB-1, HER2/ErbB2, HER3/ErbB3, and HER4/ErbB4). These RTKs have been originally named ERB because of their homology to the erythroblastoma viral gene product, *v-erbB*. More than 15 diverse ligands have been identified that contain a conserved EGF domain, creating a highly complex signalling network. However, knockout studies of specific EGFR ligands suggested a significant functional redundancy between EGF growth factors. For instance, knockout mice of EGF and the keratinocyte growth factor amphiregulin showed no significant phenotype. In contrast, deletion of the ErbB1 receptor revealed a non-redundant function of this receptor RTK which has a key role in epithelial cell development in many organs. Depending on the mouse strain used, ErbB1$^{-/-}$ mice die at mid-gestation or shortly after birth.

Similar to IR/IGFR receptors, receptor heterodimers, which may also involve receptors that have either a catalytically inactive kinase domain (HER3) or that lack the capacity binding growth factors (ErbB2), add additional layers of regulation to this complex signalling network. EGF receptors consist of a single polypeptide with an extracellular ligand binding domain as well as a cytoplasmic RTK domain which is activated by ligand induced dimerization. Interestingly, the dimerization of the cytoplasmic kinase domain is asymmetric in such a way that one kinase domain serves as an activator of the second catalytic domain through a docking interaction

reminiscent of the activation of cyclin dependent kinases (CDKs) by cyclins. As for other RTKs, kinase activation as well as cross-talk with other receptors and cytoplasmic kinases generates docking sites for adaptor proteins that stimulate signalling. A key adaptor molecule of EGF1R signalling is GRB2 (proteins growth-factor-receptor bound-2) which is responsible for recruitment of RAS and activation of the MAPK pathway. Another direct substrate of EGF1R is STAT5 (signal transducer and activator of transcription-5), which dimerizes upon phosphorylation resulting in nuclear import and increased transcription of a number of growth-promoting target genes. The survival pathway PI3K–AKT is also activated by EGF signalling—not directly but via activation of RAS and signalling through RAS-MAPK and RAS-PI3K pathways.

Inactivation of EGFR signalling occurs primarily through a process called endocytosis which either leads to receptor degradation or to recycling of the receptor to the cell surface. Endosomal trafficking is a key regulatory mechanism controlling receptor turnover. Several internalization mechanisms of membrane receptors have been identified. The best studied one is mediated by clathrin-coated vesicles. Once internalized, the clathrin-coated vesicles containing the receptor fuse with intracellular organelles known as the endosomes. In these early endosomes, which are characterized by low pH and the presence of GTPase proteins, the targeted receptor may be either subjected to a recycling pathway transporting the receptor back to the plasma membrane, or it is ubiquitinylated leading to proteosomal degradation in lysosomes. EGFR degradation is mediated by the ubiquitin ligase Cbl, which is recruited to the receptor by phosphorylation of a single tyrosine residue (Tyr1045). However, it is the stability of the activated ligand–receptor complex in the mildly acidic endosomal environment that determines the level of receptor recycling. For instance, EGFR homodimers are stable and remain bound to Cbl,

resulting in increased receptor degradation, whereas the less stable EGFR–HER2 heterodimers escape lysosomal degradation by dissociating from Cbl, increasing the rate of receptor recycling to the plasma membrane. Interestingly, the oncogenic activity of viral Cbl (v-Cbl) functions by stimulating the receptor recycling pathway.

A number of oncogenic viruses harness EGFR signalling using a variety of different mechanisms that all lead to increased EGF signalling. For example, the hepatitis B virus and Epstein–Barr virus activate EGFR by increasing its expression, whereas the avian erythoblastosis virus expresses a truncated constitutively active viral form of EGFR. The human papilloma virus protein E5 blocks the degradation of EGFR by inhibiting an endosomal ATPase resulting in increased receptor recycling to the plasma membrane. The direct links of EGF pathway dysfunction to cancer development highlight the key role of the EGF pathway in maintaining tissue homoeostasis and offer therapeutic opportunities that have already been successfully explored by the development of HER2/ErbB2 inhibitors and therapeutic antibodies.

Janus Kinases (JAK) and STAT signalling

Janus Kinases (JAK1–3 and TYK2) play an essential role regulating haematopoiesis and proliferation of blood cells. A key discovery in this signalling field was the identification of the point mutation JAK2^{V617F} that leads to activation of the JAK/STAT signalling pathways and development of myeloproliferative diseases (MPD) such as polycythaemia vera (PV), essential thombocythaemia (ET), and primary myelofibrosis (PMF). JAK2^{V617F} is a somatic mutation, which means that it is present only in the haematopoietic cell compartment but not in germline DNA. This mutation has been identified in most MPD patients defining a common genetic mechanism for this disease.

JAKs contain no transmembrane domain and are therefore not receptor tyrosine kinases. They interact with specific cytokine receptors which lacks intrinsic kinase activity. However, much as in RTKs, ligand binding to the cytokine receptor results in JAK activation by autophosphorylation and phosphorylation of the cytokine receptor itself and the recruitment of members of the signal transducer and activator of the transcription (STAT) family. Cytokine receptors have different specificity for one of the JAK kinases, resulting in different signalling outcomes. For instance, genetic ablation of JAK2 blocks erythropoiesis, a result of deficient signalling through the erythropoietin (EPO) receptor that specifically binds JAK2. JAK family members contain seven homology domains (JH1-7) which include the tyrosine kinase domain (JH1), an inactive (pseudo)kinase domain (JH2), and several docking and protein interaction modules (JH3-7). Interestingly, the JAK2^{V617F} point mutation is located in the pseudokinase domain which has an autoinhibitory function. It has been speculated that V617F releases this autoinhibitory block resulting in a constitutively active JAK2 kinase. Indeed, expression of JAK2^{V617F} leads to cytokine hypersensitivity and cytokine-independent growth, a typical feature of haematopoietic colonies grown from PV patients. JAK activity is negatively regulated by binding of SOCS (suppressor of cytokine signalling) ubiquitine ligases which interact with phosphorylations sites on JAK, leading to degradation. JAK also activates the MAPK and PI3K signalling pathway, resulting in increased proliferation and survival of cells harbouring the JAK2^{V617F} mutation.

Signalling downstream of GFRs

A number of protein interaction modules contributed critically to our understanding of the complex molecular events that mediate signalling downstream GFRs. Phosphorylation sites created by activated RTK activity lead to the recruitment of SH2 (Src homology 2) domain containing adapter proteins. The SH2 domain, first identified in the cytoplasmic tyrosine kinase Src, is a small phosphotyrosine specific binding. A second Src homology domain (SH3) is crucial for recruiting further binding partners by interacting with proline rich sequences in target molecules. One of these adaptor molecules is GRB2, which contains one SH2 and two SH3 domains. GRB2 links the activated phosphorylated GFR with the guanine nucleotide exchange factor SOS (Son of Sevenless), named after the Drosophila gene whose inactivation leads to lack of expression of the seventh, central photoreceptor (R7). Interaction with GRB2 stimulates SOS leading to the GDP/GTP exchange and activation of the RAS family of small GTPases. Active GTP-bound RAS activates members of the serine/threonine kinase RAF and consequently the MAPK pathway. Finally the discovery of phospholipid binding pleckstrin homology (PH) domains explained how phospholipid effector molecules can specifically activate protein kinases such as the Ser/Thr kinase AKT also known as protein kinase B (PKB), PKD1 (Protein kinase D1), as well as lipid kinases (PI(3)Ks).

The RAS/RAF/MAPK pathway

The name RAS refers to the discovery of the viral oncogene v-RAS (Rat Sarcoma). Mutations in members of the RAS family of small GTPase (H-Ras, N-Ras, and K-Ras) have been detected in 20–30% of all human tumours, highlighting the central role of these proteins in the regulation of cellular proliferation. Indeed, expression of oncogenic H-RAS is sufficient for driving G0 arrested cells into the cell cycle in the absence of mitotic signals. RAS family members share homology with the G$_\alpha$ subunit of heterotrimeric G proteins (large GTPases). GTPases cycle between a GDP bound-off state and a GTP bound-on state. The exchange of the nucleotide is catalysed by guanine nucleotide exchange factors (GEFs) and GTPase activating proteins (GAPs). RAS by itself has GTPase activity. However, hydrolysis of GTP is very slow in the absence of a GAP, which contributes additional catalytic residues leading ultimately to the inactive GDP-bound state. Inactivation of RAS activity by GAPs is a frequent target of somatic mutations found in oncogenic RAS variants. RAS is reactivated by GEFs such as SOS that facilitate reloading of GTP by a nucleotide exchange mechanism. GTP-bound RAS has high binding affinity for a number of effector molecules including the lipid kinase PI3K. RAS is recruited to the plasma membrane by covalent linkage to lipids (prenylation or palmitoylation). This multistep process involves several enzymes. The C-terminal peptide motif "CaaX box" is first farnesylated at the CaaX cysteine residue, loosely inserting RAS into the membrane of the endoplasmatic reticulum (ER) and other cellular membranes. The C-terminal tripeptide "aaX" is subsequently cleaved by a prenyl-protein specific endoprotease and the new C-terminus is methylated by a methyltransferase completing the insertion cycle.

The GTP-bound form of RAS has high affinity for the serine/threonine kinase c-RAF (RAF1), the proto-oncogene homologue to the viral v-RAF oncogene. There are two additional RAF kinases (A-RAF and B-RAF) encoded in humans and mutations in B-RAF

have been found in several tumours. RAFs are MAP kinase kinase kinases (MAP3Ks) that function as the entry point for the MAPK pathway, a major signalling path that transmits membrane receptor signals to nuclear transcription factors.

RAF kinases harbour an N-terminal regulatory RAS binding domain and a C-terminal kinase domain. Oncogenic v-RAF lacks the regulatory domain and is constitutively active. However, activation of c-RAF is a multistep process. RAS binding exposes an inhibitory phosphorylation site (S259) that locks c-RAF in an inactive state to phosphatases such as PP2A, resulting in pS259 dephosphorylation. Several other kinases target c-RAF, introducing phosphorylation at several sites that modulate c-RAF activity but that are on their own insufficient for activation. Activated c-RAF phosphorylates the dual specificity kinase MEK which in turn phosphorylates and activates ERK. Several regulatory and scaffolding proteins guarantee tight control of this signalling pathway. For instance, the pseudokinase KSR (kinase suppressor of Ras) binds to MEK in quiescent cells but interacts with c-RAF and ERK in stimulated cells, whereas RKIP (RAF kinase inhibitor protein) disrupts the interaction between RAF and MEK. ERK has a large number of substrates, including transcription factors such as ELK1 necessary for activation of the proto-oncogene c-fos and Myc. Transcription factors regulated by MAPKs are of particular importance for the expression of proteins that regulate the cell cycle.

The PI(3)K/AKT pathway

Phosphatidylinositol (PtdIns) is a phospholipid located in membranes that can be phosphorylated at the 3, 4, and 5 positions of the inositol ring to generate seven diverse combinations of phosphoinositides. Phosphorylation of these messenger molecules is regulated by PI3K family members and the antagonizing activity of lipid phosphatases such as PTEN. The lipid kinase PI(3)K is recruited to receptor or IRS phosphotyrosine sites by means of SH2 domains located in its non-catalytic alpha subunit. PI(3)K can also be recruited to the cell membrane by means of Ras. Phospholipase C (PLC) hydrolyses PtdIns to generate two so-called second messengers: diacylglycerol (DAG) and inositol-1,4,5- trisphosphate (Ins(1,4,5)P3). Phosphoinositides stimulate phosphorylation dependent signalling by interaction with PH domains. In the protein kinase AKT (PKB), PtdIns(3,4)P2 binds to the PH domain of AKT, thereby releasing an autoinhibitory conformation resulting in partial kinase activation by the kinase PDK1 (phosphoinositide-dependent kinase 1). Full activation of AKT is accomplished by a second phosphorylation event carried out by mTORC2, the mammalian target of rapamycin complex 2, but other kinases have also been identified as secondary activators of AKT.

AKT was originally identified as an oncogene (v-AKT) of the transforming retrovirus AKT8. Three isoforms (AKT1–3) are expressed in mammals. Knockout of AKT1 in mice results in growth deficiency of the animals but normal glucose homoeostasis. AKT2-deficient mice have only mild growth defects but are diabetic, pointing to a pivotal role of this isozyme in signalling downstream of the insulin receptor. One of the main regulators of AKT is the tumour suppressor PTEN, a phosphatase that dephosphorylates PtdIns(3,4,5)P3 to PtdIns(4,5)P2, which removes AKT from the plasma membrane and significantly decreases the rate of AKT activation, leading to insensitivity to insulin and IGF1 growth signals.

AKT is a key regulator for a number of diverse cellular functions including inhibition of apoptotic pathways, regulation of protein synthesis and glucose metabolism as well as regulation of gene transcription and cell migration. In accordance with these diverse functions more than a hundred AKT substrates have been identified comprising, for instance, forkhead box O (FOXO) transcription factors, glycogen synthase kinase 3 (GSK3) in the insulin signalling pathway as well as the RAB GAP that regulates insulin-stimulated exocytosis of glucose transporter type 4 (GLUT4), the tuberous sclerosis 2 (TSC2) tumour suppressor, the pro-apoptotic protein BCL-2 antagonist of cell death (BAD), and the cell cycle regulators p21 and p27. A graphical representation of AKT activation and some downstream signalling partners is shown in Figure 3.2.

The mTOR pathway controls cellular growth and energy metabolism

Cellular systems have developed complex regulatory networks that allow them to transition between anabolic and catabolic states and which also determine if cells will survive, grow, or break down cellular organelles for the recycling of nutrients as a response to nutrient availability. The serine/threonine PI3K-related protein kinase (PIKK) mTOR (the mammalian target of rapamycin) plays a central role in the regulation of these processes. Dysfunction of mTOR has been linked to many diverse diseases and has stimulated a large number of drug development efforts on this signalling pathway. mTOR signalling is mediated by the two large protein complexes mTORC1 and mTORC2 which share the central mTOR kinase subunit. mTORC1 consists of mTOR, the activating subunits Raptor and mLST8, as well as two negative regulators, PRAS40 and DEPTOR. The scaffolding protein Raptor is regulated by phosphorylation and it facilitates substrate recruitment. The mTORC2 complex is not sensitive to rapamycin and, due to the lack of specific inhibitors, this complex is much less studied. Apart from the mTORC1 components mTOR, DEPTOR, and mLST8, mTORC2 also contains the subunits Rictor, mSIN1, Protor (protein observed with rictor-1), and Hsp70. The mSIN1 subunit is important for recruitment and activation of AKT. mTORC2 is activated by growth factors, stimulates AKT signaling, and regulates GTPases of the Rac and Rho family stimulating cell motility and survival.

mTORC1 is regulated by a large diversity of signalling pathways, as for instance insulin and IGF1, which stimulate the PI3K and Ras pathways. A common feature of effector kinases of these pathways (protein kinase B (AKT/PKB), extracellular-signal-regulated kinase 1/2 (ERK1/2), and ribosomal S6 kinase (RSK1)) is that they all phosphorylate and inactivate the tuberous sclerosis TSC1/TSC2 complex, an inhibitor of mTORC1. TSC1/TSC2 functions as a GAP RHEB (RAS homologue enriched in brain), converting it to its inactive GDP-bound form. Since GTP-bound RHEB strongly stimulates mTORC1 activity by binding to the complex, the GAP activity of TSC1/TSC2 leads to mTORC1 inactivation. To date no GEF for RHEB has been identified that would lead to mTORC1 reactivation. AKT additionally activates mTORC1 by phosphorylation of the mTORC1 inhibitor PRAS40, resulting in its dissociation from the mTORC1 complex.

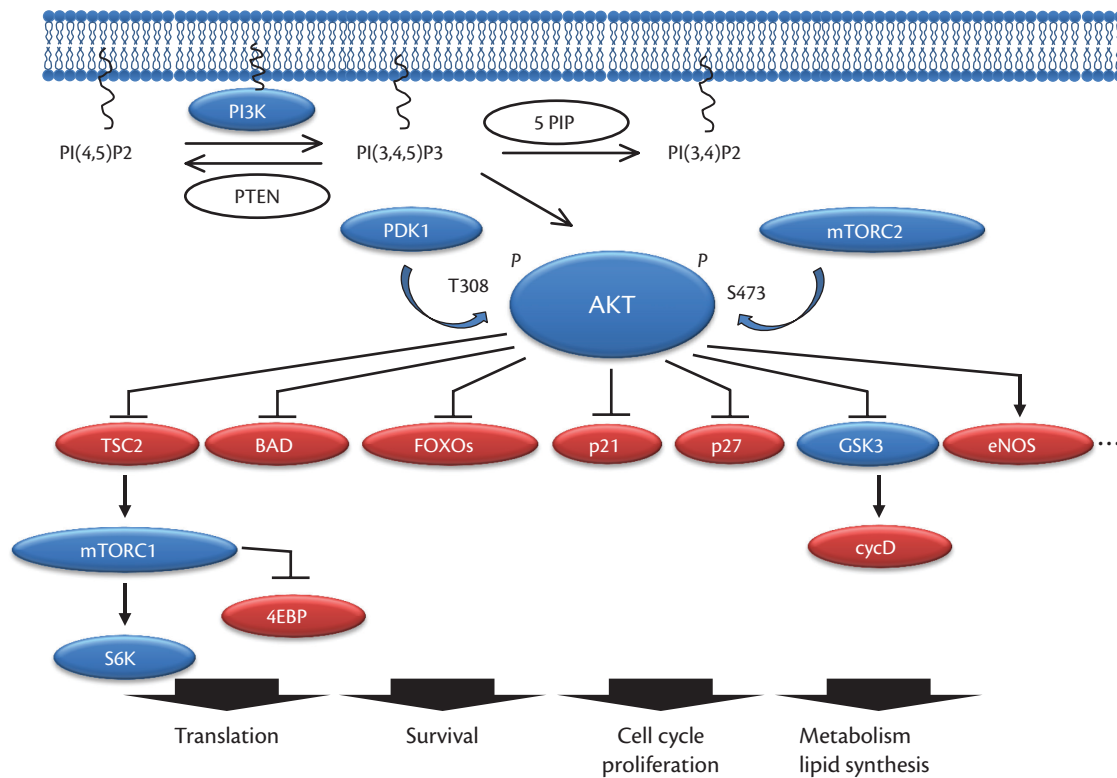
Similarly, mTORC1 can be activated by TSC1/TSC2 phosphorylation by IkB kinase b (IKKb) as a response to inflammatory stimuli such as TNFα or through the Wnt pathway effector glycogen


Fig. 3.2 Activation of AKT and main downstream signalling partners. Colours codes are as in Figure 3.1.

synthase kinase 3b (GSK3-β). Sensing of low nutrient levels or oxidative stress also acts at least in part through regulation of the TSC1/TCC2 complex. For instance, adenosine monophosphate-activated protein kinase (AMPK) phosphorylates TSC2 and increases its GAP activity towards Rheb in response to hypoxia or low energy states, but, similarly to AKT, AMPK also directly regulates mTORC1 by phosphorylation of raptor leading to inhibition of mTORC1.

Regulation of protein synthesis by mTORC1 has been extensively studied. mTORC1 phosphorylates 4EBP1, a binding protein of the translational regulators eukaryotic translation initiation factor 4E (eIF4E). Phosphorylation inhibits the binding of 4EBP1 to the cap-binding protein eIF4E, preventing formation of the eIF4E/eIF4F complex which is required for the initiation of cap-dependent translation. mTORC1 also directly phosphorylates and activates S6 kinase 1 (p70S6K1) stimulating mRNA biogenesis as well as translational initiation and elongation by phosphorylating the 40S ribosomal protein S6. S6 phosphorylation particularly enhances the translation of mRNAs containing a 5'-terminal oligopolypyrimidine (5'-TOP). Interestingly, 4EBP1 and p70S6K1 are specifically recruited to mTORC1 via the TOR signalling (TOS) motif, a conserved five-amino-acid sequence that interacts with the mTORC1 subunit Raptor. mTORC1 activity is also regulated by amino acid levels. Low amino acid levels in the growth medium lead to rapid dephosphorylation of the mTORC1 substrates 4EBP1 and p70S6K1. This effect is quickly reversed when amino acids are resupplied. The pathway regulating this effect is largely unknown but recent reports suggested that MAP4K3 senses amino acid levels and stimulates mTORC1. Several studies identified a negative feedback regulation by p70S6K1 to the upstream insulin/insulin growth factor effector IRS1 which is regulated transcriptionally by mTORC1 as well as

by direct phosphorylation by p70S6K1, preventing IRS1 binding to RTKs leading to down-regulation of PI3K and MAPK signalling.

mTORC1 also regulates another important catabolic process: autophagy, an evolutionary highly conserved process that leads to the degradation of cytoplasmic organelles, toxic protein aggregates, and intracellular pathogens in lysosomes. The autophagic programme allows cells to recycle catabolites by organelle breakdown, which can be used for essential biosynthetic and metabolic processes promoting survival during starvation. During autophagy intracellular vesicles named autophagosomes engulf cellular organelles and fuse them with lysosomes. Nutrient deprivation or specific inhibition of mTORC1 by rapamycin induces this survival programme. Autophagy has been extensively studied in yeast where TOR phosphorylates the protein kinase Atg1 (autophagy-related gene 1) which interacts with Atg13. These studies revealed that TOS motif-dependent phosphorylation of Atg1 by TOR inhibits Atg13/Atg1 complex formation, repressing autophagy. The mammalian Atg1 homologue is a family of four kinases (ULK1-4, UNC-51-like kinase) in which ULK1–3 seem to play a role in autophagy and ULK1–2 have been shown to be directly phosphorylated by mTORC1. The role of autophagy in tumour development and progression is controversial. On the one hand, repressing autophagy may impair tumorigenesis by reducing the ability of cancer cells to survive under energy-poor conditions. On the other hand, studies have shown that mice lacking essential components of the autophagy machinery have an increased rate of spontaneous tumour development, an effect that has been attributed to higher rates of DNA damage induced by reactive oxygen species that accumulate in cells with damaged mitochondria.

Regulation of the cell cycle and mitosis

The decision as to whether cells enter the cell cycle and proliferate is tightly controlled by mitogens that stimulate growth-promoting pathways that have been discussed above. A hallmark of cancer is that cells enter the cell cycle in the absence of mitogenic signals, leading to so-called unscheduled proliferation. The Ras–RAF-MEK–ERK kinase cascade plays a a key role in transmitting mitogenic signals that lead to CDK activation. ERK phosphorylates and stabilizes c-Myc, a transcription factor that induces the expression of cyclin D1 and suppresses expression of CDK inhibitors. Further, the activation of AKT stimulates the cell cycle by two main mechanisms: firstly, AKT inhibits GSK3β, preventing it from phosphorylating and destabilizing cyclin D and c-Myc. Secondly, AKT inhibits FOXO transcription factors, preventing them from entering the nucleus and reaching their target genes, which include the CDK inhibitors (CKIs) p27Kip1 and p21Cip1/WAF1.

Apart from embryonic cells that can proceed through continuous cycles of DNA replication (S phase) and division (M phase), the cell cycle contains four phases in which the S and M phase is interspersed by gap phases (G1 and G2). The G1 and G2 phases allow for the repair of DNA damage and replication errors, but, importantly, also interpret environmental cues that determine whether cells enter a new round of cell division or exit the cell cycle and enter a quiescent state (G0). To ensure proper timing and successful completion of each step, the eukaryotic cell cycle implements a number of checkpoints that includes the restriction point—a point of no return that commits cells to complete a division cycle even if mitogenic signals drop or, failing that, enter an apoptotic programme.

CDKs are the key regulators of the cell cycle. They require the binding of activating cyclin cofactors, which stabilizes the active state of these kinases. However, due to their central role in controlling the cell cycle, CDKs are regulated on several additional levels by activating and inactivating phosphorylation events as well as by interaction with CDK inhibitors (CKIs). Cyclin levels are tightly controlled during the different phases of the cell cycle, regulating CDK activity in a timely manner. In mammals the activity of three interphase CDKs (CDK2, CDK4, and CDK6), a mitotic CDK (CDK1, also known as cell division control protein 2 (CDC2)), and ten cyclins belonging to four diverse families (A-, B-, D-, and E-type cyclins) is orchestrated in a highly dynamic manner during the cell cycle. D-type cyclins are expressed during the initial phase of G1. Cyclin D bind and activate mainly CDK4 and CDK6, resulting in the partial inactivation of the retinoblastoma (RB) tumour suppressor by phosphorylation which imposes the first checkpoint. The partial inactivation of RB leads to the expression of E2F transcription factors and the expression of E-type cyclins which interact with and activate CDK2, resulting in the complete inactivation of RB by CDK2/cyclin E phosphorylation in late G1. From this point onwards the cell cycle progresses independently of mitogenic stimulation (restriction point) into S-phase.

Premature entry into S-phase is prevented by a number of CDK inhibitors comprising p27Kip1 and others, such as p15Ink4b, p16Ink4a, p21Cip1/WAF1, and p57Kip2, that rapidly inactivate CDK catalytic activity by blocking the ATP binding site. A number of mitogenic stimuli release CDK by suppressing p27Kip1 transcription and translation. Once activated, CDK2 rapidly inactivates p27Kip1 by phosphorylation that targets this inhibitor for polyubiquitination mediated by an SCF (Skp1/Cul1/F-box protein)-ubiquitin-ligase complex and degradation by the proteasome system. CDK2 activation is completed by activation by CAK (CDK activating kinase) and by removal of an inhibitory phosphorylation by phosphatase of the CDC25 family.

Transition from G2 to M-phase is controlled by CDK1 which associates with A- and B-type cyclins. Cyclin A and B accumulate during the cell cycle and are rapidly degraded at the onset of anaphase, mediating entry and exit from mitosis. The master regulator CDK1 phosphorylates more than 70 substrates during G2/M to trigger centrosome separation, nuclear envelope breakdown, and chromosome condensation. Once chromosomes are condensed in metaphase, CDK1 activity is rapidly switched off and a number of phosphatases such as the Cdc14 proline-directed phosphatases are activated in order to remove phosphorylation sites generated by CDK1 activity. Elimination of these sites is required for chromosome decondensation, reformation of the nuclear envelope, and cytokinesis. In addition, CDK1 activating cyclins are degraded during anaphase by the anaphase promoting complex (APC).

The faithful replication of DNA is controlled by the p53 tumour suppressor which is short-lived in the absence of DNA damage due to its association with the ubiquitin ligase complex. In response to DNA damage, however, p53 is stabilized and causes cell cycle arrest until the DNA is repaired or apoptosis if the DNA damage cannot be repaired.

DNA damage is sensed by protein complexes containing the protein kinases ATM (ataxia telangiectasia mutated) and ATR (ATM-related). ATM and ATR activate the checkpoint kinases CHK2 and CHK1, which leads to inhibition of CDC25 phosphatases prompting the accumulation of inhibitory phosphorylation of CDKs. Cell cycle arrest is mediated at least in part by activation of the CDK inhibitor p21*waf/cip*, which inhibits cyclin E/CDK2 complexes, whereas apoptosis is induced by p53 activation of the expression of the pro-apoptotic proteins BAX and PUMA. Stability of p53 is increased by ARF which blocks the interaction between p53 and Mdm2. The acronym ARF stands for 'alternative reading frame' since ARF is encoded by the same locus as the CDK inhibitor p16ink4 but it is transcribed from a different promoter using a different reading frame. Interestingly, transcription of ARF is regulated by E2F transcription factors that are controlled by the RB tumour suppressor, suggesting that the loss of this locus in some cancers eliminates two tumour suppressors that control RB as well as p53 function.

The well established model of cell cycle regulation by CDKs has recently been challenged by genetic knockout studies in mice that surprisingly revealed a non-essential function of CDK2, CDK4, and CDK6. Instead, deletion in the mouse germline of each of the three interphase CDKs resulted only in developmental defects in highly specialized cell types. Moreover, deletion of multiple interphase CDKs only led to developmental defects in certain tissue types but had no effect on the cell cycle in general. Only deletion of CDK1 led to cell cycle arrest, preventing embryos from developing beyond the two-cell stage. This surprising observation suggests that CDK1 alone is needed to drive the cell cycle in most tissues and that the mammalian cell cycle is still quite similar to the cell cycle in yeast which expresses only a single CDK1 homologue. However, defects in cell cycle regulators such as overexpression of cyclin D or CDK2, and loss of the tumour suppressors RB and CDK inhibitors (p27Kip1, ARF, p16) are among the most frequent genetic alterations observed in tumours. In addition, c-Myc, is frequently overexpressed in cancer and has a key role in regulating the cell cycle.

All Myc isoforms (c-Myc, L-Myc, and N-Myc) strongly induce the expression of D-type cyclins and in complex with Miz1 (Myc interacting zinc-finger protein), c-Myc inhibits the expression of CDK inhibitors p21Cip1 and p15Ink4b.

Wnt signalling

Canonical Wnt signalling plays an important role in development, tissue homoeostasis, and dysfunction of this pathway has been implicated in the development of a cancer. The Wnt pathway has been discovered by the identification of the Int1 locus (Wnt1) as the factor required for mouse mammary tumour virus-driven tumorigenesis and by mutants in *Drosophila melanogaster* lacking wings (*Wingless* (*Wg*)).

The canonical Wnt pathway is initiated at the plasma membrane by binding for Wnt proteins (there are 19 identified Wnt genes in humans) to Frizzled receptors and their LRP5–LRP6 co-receptors. As for other receptor signalling pathways, there are several inhibitors of this pathways that antagonize Wnt function including secreted Frizzled-related proteins (SFRPs) that sequester Wnt ligands, Dickkopfs (DKKs), and Wnt inhibitory factor 1 (WIF1). The key event of the binding of Wnt ligands to the Frizzled receptor is the stabilization of β-catenin in the cytoplasm followed by translocation of β-catenin into the nucleus where it forms complexes with LEF (lymphoid enhancer factor) and TCF (T-cell factor) transcription factors. Genes activated by the β-catenin complexes with LEF and TGF transcription factors including c-MYC, Cyclin D, VEGF (vascular endothelial growth factor), and FGF4 (vascular endothelial growth factor). The discovery that Wnt signalling increases expression of c-MYC, and indirectly Cyclin D, has linked Wnt signalling with G1-phase progression and cell proliferation. In the absence of Wnt signalling, β-catenin is rapidly degraded by complex formation with APC (adenomatous polyposis coli) and axins as well as by phosphorylation by the serine kinases GSK3β and CK1α. Phosphorylated β–catenin is recruited to the E3 ubiquitin ligase subunit β-TRCP (β-transducin repeat-containing protein) and rapidly degraded by the ubiquitin system. In addition, LEF and TCF transcription factors are inactivated in the nucleus by interaction with proteins of the Groucho family.

Mutations in genes that control β–catenin stability, such as those that encode members of the destruction complex (APC or axins), or β–catenin itself, have been associated with tumorigenesis. Most notable are mutations or truncations in APC that lead to familial adenomatous polyposis (FAP). FAP patients develop large numbers of adenomatous polyps in the colon early in their lives that subsequently develop into malignant carcinomas. Sporadic mutations of the APC gene have also been detected in a large number of colon cancers. A general feature of mutations in the APC, AXIN1/2, and β-catenin locus is the inappropriate accumulation of β-catenin in the absence of Wnt signalling leading to aberrant Wnt pathway activation.

TGF-β signalling

The TGF-β family comprises 33 extracellular signalling molecules that play a key role in embryonic development, stem cell differentiation, immune response, and wound healing. The TGF-β family contains three TGF-β isoforms, the bone morphogenetic proteins (BMPs), growth and differentiation factors (GDFs), and Müllerian inhibitory factor (MIF) as well as activins or inhibins. TGF-β binds to heterodimeric cell surface receptors containing one type I and one type II receptor (TGFβRI and TGFβRII), each containing a cytoplasmic serine/threonine kinase domain. Seven type I receptors, also named activin-receptor-like kinases (ALKs), and five different type II receptors are expressed in humans. Two type III co-receptors (endoglin and betaglycan) have been described that however do not play an active role in signalling but may regulate ligand access to type I and type II receptors. TGF-β binds to the extracellular domains of type I and type II receptors leading to the formation of heterotetrameric active receptor complexes. TGFβRII are constitutively active and phosphorylate a glycine/serine-rich domain in the type I receptor, triggering the recruitment and phosphorylation of downstream effectors of the SMAD family of transcription factors.

The SMAD family is grouped into three classes of effector proteins depending on their function in signalling. The receptor-associated SMADs (R-SMADs) are directly phosphorylated by TGFβRIs leading to R-SMAD activation. R-SMADs are transcriptionally inactive and are retained in the cytoplasm by interaction with retention proteins. The R-SMAD family comprises five members—SMAD1, SMAD2, SMAD3, SMAD5, and SMAD8–which have specificity for different receptor families. After phosphorylation R-SMADs form a complex with the co-SMAD SMAD4. This complex translocates into the nucleus where it interacts with a number of transcription factors and co-activators regulating the expression of a large diversity of target genes. SMAD transcriptional activity is antagonized by inhibitory SMADs (I-SMADs) (SMAD6 and SMAD7) which disrupt the SMAD/Co-SMAD complex, providing a negative feedback loop for this pathway.

TGF-β1 was originally discovered as a factor stimulating growth of cultured rat fibroblasts in soft agar. However, the effect of receptor stimulation by TGF1β binding is highly context dependent. During early embryogenesis and in some adult mesenchymal cells TGF1β signalling promotes growth. In contrast, most adult tissues respond to TGF1β with cytostasis or even by induction of apoptosis. Activation of TGFβ signalling inhibits cell cycle progression in the G1 phase due to transcriptional up-regulation of CDK inhibitors, in particular InK4B and p21, and the inhibitor of protein translation 4EBP, as well as repression of Myc expression. The expression of cell cycle inhibitors such as p21 is transactivated by the SMAD/FOXO complexes. As discussed above, Forkhead transcription factors play a central role in regulating development, metabolism, and longevity under caloric restriction and are linked to the TORC1 pathway by interaction with AKT, which inactivates FOXO. In cancer, the growth-limiting antimitotic signals of the TGFβ pathway are often inhibited by inactivating mutations of the TGFβRs that are common in colon cancer. Other aspects of TGFβ signalling may however promote tumorigenesis.

One of these aspects that may lead to cancer progression is linked to the observation that TGFβ signalling can induce epithelial mesenchymal transition (EMT), a cellular programme that leads to loss of epithelial traits such as loss of cell adhesion by transcriptional repression of E-cadherins, a family of calcium-dependent adhesion proteins that mediate proper cell contacts. Loss of cadherin function results in increased cell mobility, a characteristic feature of mesenchymal cells. Several growth-promoting pathways have been shown to take part in this transformation including Wnt/β-catenin and Ras-MAPK signaling, which leads to activation of two transcription factors: Snail and Slug. Both proteins repress E-cadherin expression leading to destruction of desmosomal function and as a consequence

increased cell spreading. Snail and Slug also regulate expression of p63, a transcription factor of the p53 family required for development of epithelial structures and proper cell polarity. TGFβ has been shown to down-regulate a number of proteins essential for the functions of tight junctions and R-SMAD can directly interact with Snail, resulting in transcriptional complexes that promote expression of EMT associated genes. The precise mechanistic contribution of TGFβ signalling to EMT has still to be clarified, but it is clear that this pathway plays an essential role in the initiation and completion of EMT in development as well as during tumour progression.

CHAPTER 4

Cell cycle control

Simon M. Carr and Nicholas B. La Thangue

Introduction to cell cycle control

All cells arise by the division of existing cells. This process involves duplication of the cell contents, followed by the equal distribution of these contents into two daughter cells. Collectively, this highly regulated series of events is known as the cell cycle. Whilst duplication of cellular contents such as organelles and membranes occurs throughout all stages of the cell cycle, chromosomal DNA is replicated only once at a discrete stage known as S phase. Once DNA replication is complete, distribution of chromosomes and other cellular components occurs during the final stage of the cell cycle, known as M phase, or mitosis. The passage of a cell through the cell cycle is therefore regulated in a temporal fashion, so that entry into subsequent cell cycle stages only occurs once the previous stage has been efficiently completed. The cell has a number of signalling mechanisms at its disposal with which to monitor the integrity of cell cycle progression, and if problems are detected, later cell cycle stages can be delayed whilst these errors are corrected. This chapter aims to give an overview of the major control mechanisms that the cell utilizes to regulate cell cycle progression, and how these checkpoints are circumvented during the onset of cancer.

The cell cycle

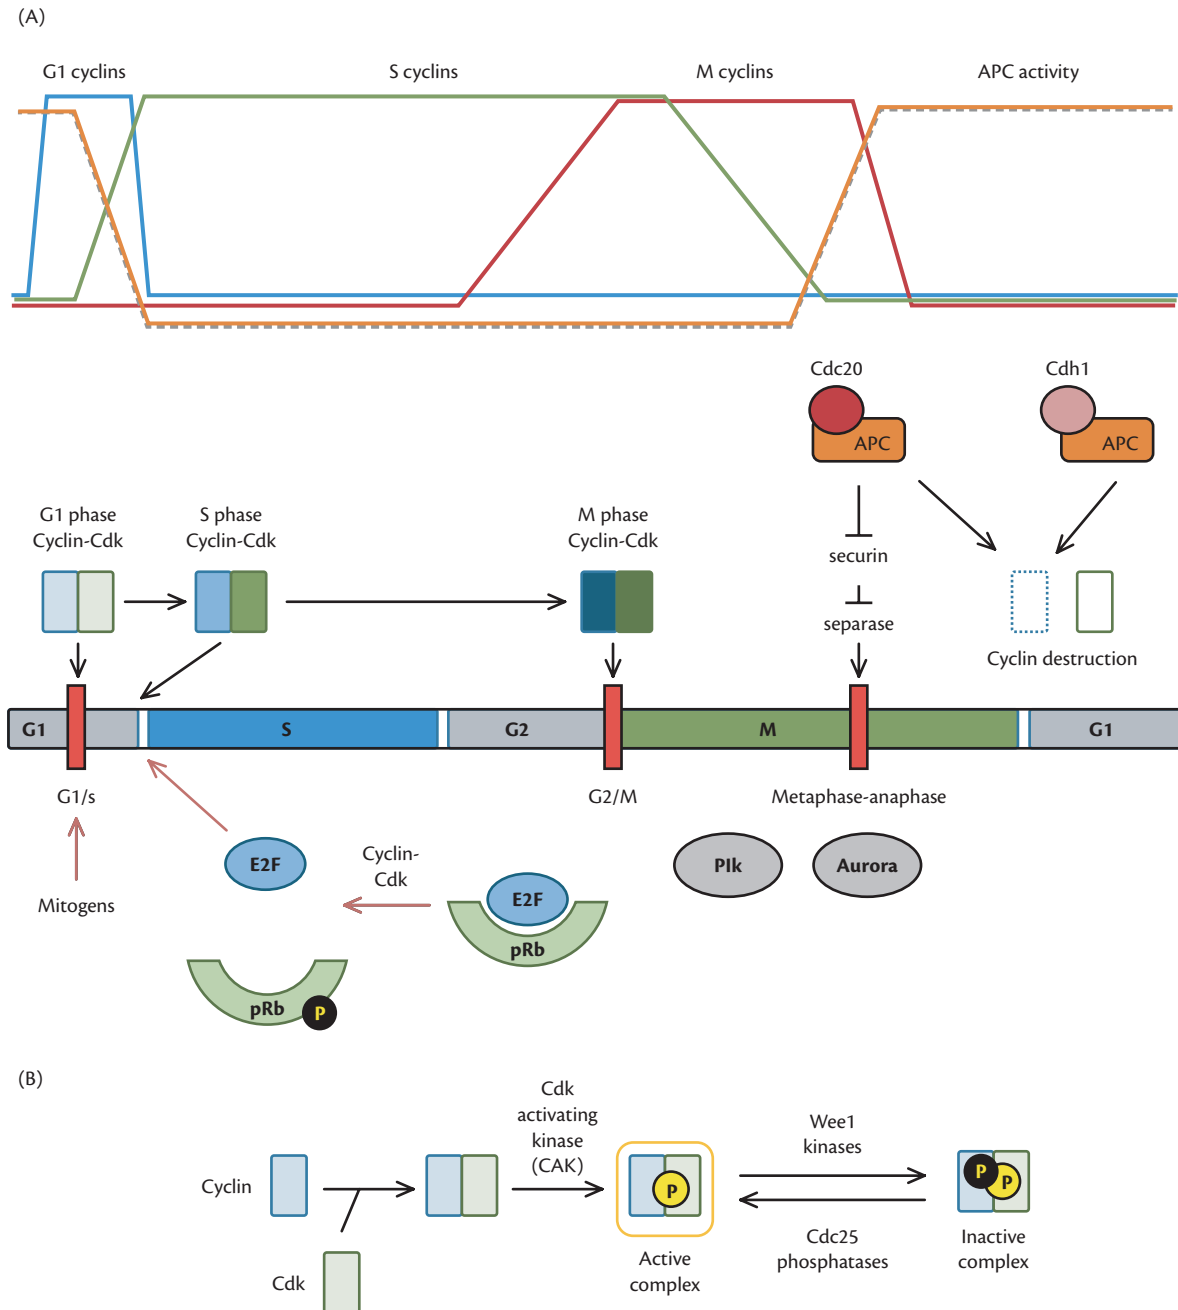
The cell cycle can be divided into a number of discrete phases, based on the cellular activities which occur during each distinct stage [1, 2]. Duplication of chromosomal DNA, for example, is an early cell cycle event which occurs during S phase (Figure 4.1). The timing and coordination of DNA replication is tightly regulated, so that the genetic material within the cell is copied once and only once [1, 2]. Chromosome duplication itself requires the activity of a large number of proteins and enzymes which must be synthesized in the cell prior to the onset of DNA replication [3, 4]. A number of these proteins are involved in maintaining a tight association between the newly synthesized chromosomes, a step which is essential to ensure efficient segregation of the genetic material to daughter cells in a later cell cycle stage known as M phase (Figure 4.1) [1, 2]. At the midpoint of M phase, these linked chromosome pairs, known as sister chromatids, disassociate and migrate to opposite poles of the cell, where they are enveloped into two new daughter nuclei. This process is mediated by the attachment of sister chromatids to an array of microtubules called the mitotic spindle, which pull sister chromatids to opposite poles of the cell [1, 2]. Following chromosomal segregation, the cell pinches in two as a new plasma membrane forms between the daughter nuclei [1, 2].

S and M phases themselves are separated by two additional phases, known as the gap phases G1 and G2 (Figure 4.1). These gap phases provide additional time in which protein synthesis and cell growth can occur, since these processes are coordinated with cell division in most cell types [1, 2]. The gap phases also represent a time in which the cell can monitor extracellular and intracellular signals to ensure conditions are appropriate for it to progress to the next stage of the cell cycle. During G1, for example, cells become committed to cell division unless conditions are unfavourable, in which case they can pause in G1 or enter a prolonged, non-dividing state [5]. During G2, the integrity of DNA replication is assessed to ensure that sister chromatid segregation only occurs once chromosomal duplication is complete [6].

Cell cycle checkpoints

The function of the cellular machinery that carries out DNA replication and cell division is strictly regulated by a complex signalling network known as the cell cycle control system. This central control network is responsible for driving progression of the cell cycle through a number of restriction points known as checkpoints [1, 2]. When conditions are appropriate for cell proliferation, the cell cycle control system will drive the cell through its first checkpoint at the transition between G1 and S phase [5] (Figure 4.1). DNA replication is initiated, and new proteins are synthesized which drive early cell cycle events. The second checkpoint occurs at the entry to mitosis (the 'G2/M checkpoint'; Figure 4.1), where the assembly of the mitotic spindle is tightly controlled [6]. By the midpoint of mitosis (metaphase), sister chromatids are attached to microtubules originating from the cell poles and they are prepared for separation in the next stage of mitosis known as anaphase. This is where the third major checkpoint occurs (the 'metaphase to anaphase transition'; Figure 4.1), which commits the cell to chromatid separation and the completion of mitosis [6]. Progression through all of these checkpoints relies not only on the completion of previous cell cycle events, but also on receiving appropriate signals from the extracellular and intracellular environment.

The cell cycle control system

Whilst numerous proteins are involved in cell cycle control, the central components are a group of enzymes known as cyclin-dependent kinases (CDKs) [7]. These enzymes catalyse the addition of phosphate groups onto a plethora of target substrates involved in processes such as DNA replication, protein synthesis, and cell division. These phosphorylation events can promote or inhibit the activity of the receiving substrate, and can mediate or ablate additional protein–protein interactions. As such, the enzymatic activity of CDKs can be used to fine-tune the function of many cell cycle


(A)

(B)

Fig. 4.1 Overview of cell cycle control. (A) The oscillating expression levels of specific cyclins involved in driving the main transitions between cell cycle phases is simplified in graphical format at the top of this figure. CDK levels generally remain constant throughout the cell cycle, so discrete cyclin–CDK complexes form in parallel with rises and falls in cyclin levels. G1-phase cyclin–CDK complexes commit the cell to cell cycle entry at the G1/S transition by targeting phosphorylation events onto the pocket proteins (i.e. pRb), which induces the release of E2F transcriptional activity and the expression of genes required for S-phase progression. M-phase cyclin–CDK complex activity begins to rise after completion of S phase and drives cells through the G2/M checkpoint by inducing chromosome condensation, nuclear envelope disassembly, and formation of the mitotic spindle. It also results in the activation of APC, which induces the loss of sister chromatid cohesion and triggers chromosome segregation at the metaphase-to-anaphase transition. Completion of mitosis also depends on the activity of the Plk and Aurora mitotic kinases, and on the destruction of S- and M-phase cyclins by APC activity. The main cell cycle checkpoints are indicated by vertical red bars. (B) CDK activity is not simply regulated by the formation of a complex between the CDK and its cyclin partner. Complete activation of CDKs requires a phosphorylation event mediated by CAK. Fully active cyclin–CDK complexes can be inhibited by further phosphorylation events mediated by the Wee1 family of kinases, and reactivated by removal of this phosphate group by Cdc25 family phosphatases. (Activatory phosphorylation events are displayed in yellow whilst inhibitory phosphorylation events are shown in black.)

regulatory proteins, as will be discussed in more detail in later sections of this chapter.

Many different CDK enzymes exist within the cell, and each possesses its own set of substrates, though there can be some overlap in target preference between family members [7]. The activity of each

CDK enzyme must therefore be controlled in a cell-cycle-dependent fashion so that substrates are only phosphorylated in an appropriate temporal way. This control is achieved primarily via the binding of regulatory subunits known as the cyclins [7], whose protein levels oscillate throughout the cell cycle (Figure 4.1A). Different

cyclins are produced at discrete cell cycle stages, resulting in the formation of distinct cyclin–CDK complexes [8, 9]. This leads directly to cyclical changes in the phosphorylation of cell cycle machinery components. For example, at the transition between G1 and S phase, active cyclin–CDK complexes phosphorylate proteins involved in cell cycle entry and DNA replication [5, 10, 11]. During M phase, however, different cyclin–CDK complexes are involved in driving cells through the G2/M checkpoint by phosphorylating substrates involved in microtubule spindle assembly. CDK activity also needs to be switched off as the cell progresses from one cell cycle stage to another, and this is achieved via the degradation of the cyclin subunits themselves. This method of cyclin destruction is particularly prevalent at the end of mitosis, when all CDK activity declines whilst the cell prepares itself for a subsequent round of cell division (Figure 4.1A).

CDK activity is regulated by a variety of mechanisms

Whilst CDK activity requires the binding of a cyclin partner, this alone is not sufficient to fully activate CDKs. The creation and removal of phosphorylation events on the CDK itself are also important determinants of enzyme activity. For example, a phosphorylation event mediated by enzymes known as CDK-activating kinases (CAKs) is required for full CDK activity [7], whilst inhibitory phosphorylation events also occur and are particularly important in preventing the inappropriate activity of CDKs. These inhibitory events are mediated by the Wee1 family of protein kinases (Figure 4.1B).

CDK activity is also kept in check by a number of inhibitor proteins known as the CKIs (CDK inhibitors) that bind to and inactivate cyclin–CDK complexes [12]. These CKIs are expressed in response to cellular stress, and are important in triggering cell cycle arrest when unfavourable conditions, such as DNA damage, exist (discussed in 'The DNA damage response' below). They fall into two families with distinct methods of action, though the function of all is to inhibit those CDKs that drive the initial steps of the cell cycle when commitment to cell division is determined [12].

As discussed previously, destruction of cyclin subunits is another mechanism by which CDK activity can be regulated [13]. These proteins are targeted for destruction by a process known as ubiquitination, which involves the addition of multiple copies of the small protein ubiquitin to the cyclin. This leads to the generation of a ubiquitin chain, which functions to target the cyclin to a large protein complex known as the proteasome, which mediates the subsequent destruction of unwanted proteins in the cell. Ubiquitin is added to cyclins primarily by a multi-subunit enzyme known as the anaphase promoting complex, or APC [13]. Its ability to ubiquitinate substrates is controlled by a number of activator subunits, which vary during different stages of the cell cycle and function to target APC activity towards discrete subsets of cyclin–CDK complexes [13, 14].

The transition from G1 to S phase

E2F transcription factors and their regulation by the pocket proteins

Progression into the cell cycle requires the expression of a host of genes that are involved in cell cycle entry and DNA replication. As discussed above, the expression of a number of cyclin genes is also important to promote CDK activity during this stage. The majority of these genes are regulated by a family of transcription factors known as the E2Fs, of which eight members have been described to date [15–17]. These E2F members can be subdivided into two groups, based on whether they act to promote or inhibit the transcription of their target genes. The E2F 1, 2, and 3 proteins can generally be regarded as the 'activator' E2Fs, whilst E2Fs 4 through 8 are transcriptional repressors that bind to G1/S-phase regulated genes and inhibit gene expression. These two subgroups of E2F therefore work antagonistically towards each other, and the balance of activity between the activator and repressor E2Fs is important for reliable G1/S checkpoint control. Loss of activator E2Fs is often associated with tissue-specific defects in cell proliferation, whilst loss of repressor E2Fs can cause defects in cell cycle exit while cells begin to specialize in function [15–18]. It is also important to note that some E2F target genes function in other stages of the cell cycle too, such as during mitosis or in response to DNA damage, so E2F activity is not just restricted to the transition of cells from G1 to S phase.

The E2F transcription factors themselves are also highly regulated, to ensure that expression of genes required for S phase entry only occurs in proliferating cells. This regulation is primarily mediated by an interaction between E2Fs and the 'pocket' proteins (pRb, p107, and p130) [10, 19–21]. In mammalian cells, the activator E2Fs are bound and inactivated by pRb, whilst p107 and p130 act as co-repressors for E2F4–6 in non-proliferating cells [10, 19–21]. The pocket proteins inhibit E2F-dependent gene expression by binding directly to the domain of E2F involved in mediating its transcriptional activity, and thereby directly block its action. Cells lacking pocket proteins have severe defects in their ability to exit the cell cycle in response to stimuli such as DNA damage, and mutations affecting pRb-pathways are incredibly common in almost all human cancers described [21].

Regulation of E2F activity via post-translational modifications

Before entry into S phase, E2F-dependent gene expression is inhibited by the concerted action of the repressor E2Fs and the p107 and p130 pocket proteins [10, 19–21]. Activator E2Fs are present at very low levels, and their activity is suppressed by interactions with the pRb protein [10, 19–21]. As cells progress into the cell cycle, the pocket proteins dissociate from their E2F partners, causing a switch from a generally repressive environment to one that can promote transcription of genes. The protein levels of the activator E2Fs also increase at this time, favouring their association with promoters and the stimulation of gene expression [15–17]. The genes encoding the activator E2Fs are also E2F-responsive, ensuring a positive feedback loop that enhances further G1/S-phase-regulated gene expression.

The dissociation of pocket proteins from the E2Fs is regulated primarily by phosphorylation events catalysed by cyclin–CDK complexes [10] (Figure 4.1). The initial phosphorylation events are mediated by cyclin–CDK complexes that exist in early G1 [10, 22, 23]. However, this activity alone results in only partial pRb phosphorylation, and complete activation of E2F requires subsequent phosphorylation events mediated in late G1 by additional cyclin–CDK complexes [10, 24, 25]. S-phase cyclin–CDK complexes are also thought to be important for maintaining pRb

phosphorylation levels throughout S phase and into mitosis [10], ensuring that E2F activity remains high as cells transition through the cell cycle. The ability of cyclin–CDK complexes to phosphorylate pRb can also be influenced by additional post-translational modifications [26, 27]. For example, acetylation and methylation of pRb are known to occur during processes such as cellular differentiation [26], or in response to signals mediated by DNA damage [27, 28]. In both scenarios the cell will not wish to begin cell division, so E2F activity must be held in check. This outcome is achieved since acetylation and methylation events act to block the recognition of pRb by cyclin–CDK complexes, effectively preventing its phosphorylation [26, 28].

Regulation of CDK activity in G1 by mitogenic signalling

In multicellular organisms, entry of a cell into a new cell cycle occurs only in response to appropriate extracellular signals mediated by mitogens. Mitogens are usually soluble peptides or small proteins that are secreted by neighbouring cells, and control the rate of division of several cell types in the body. They do this by binding to receptors located on the outer surface of the cell's plasma membrane, which then mediate a signalling cascade within the cell by promoting phosphorylation events. Whilst these signalling events involve a host of additional proteins and are complex in nature, a few key players are known to play an essential role in driving cell proliferation, and are often targeted by mutations in cancer (discussed in detail in Chapter 3). Mitogenic signalling activates a number of transcription factors which drive the expression of cyclin and CDK genes, and other genes involved in regulating cell growth [29, 30]. These signalling events therefore promote the accumulation of active cyclin–CDK complexes, which in turn enhances their ability to target proteins such as pRb and drive cell cycle progression. Signalling pathways involving anti-mitogenic signals are also important in cell cycle control, and these function to arrest the cell and prevent entry into the cell cycle whilst inappropriate environmental conditions exist. Such anti-mitogenic signalling usually leads to an increase in expression levels of the CKIs, which act to repress cyclin-CDK activity.

The degradation of CKIs

The G1/S-transition is driven primarily by the concerted activity of cyclin–CDK complexes, which promote an irreversible commitment to cell cycle entry and S phase [5, 7]. As described above, this depends in part on the ability of cyclin–CDK complexes to initiate E2F-dependent transcription [15–17]. However, the activity of cyclin–CDK complexes is held in check by CKIs during G1 [12], and these CDK inhibitor proteins need to be deactivated before the cell can enter S phase. This inactivation involves the targeted destruction of CKIs mediated by ubiquitin-conjugating enzymes found both in the nucleus and the cytoplasm [31, 32].

The control of DNA synthesis

Once the duplication of DNA begins, it usually proceeds to completion, and does not occur again in the same cell cycle. This ensures that each daughter cell inherits the precise amount of genetic material from the parental cell, a step which is essential to avoid abnormal loss or gain of genetic information which could

cause aberrant function of the cell and lead to diseases such as cancer. This intricate level of DNA replication control is achieved by tightly regulating the initiation process in a temporal fashion that follows the cell cycle stages. In early G1, a complex of initiation proteins called the pre-replicative complex (pre-RC) forms at specific sites on the DNA and primes them for replication [4, 11, 33]. In early S phase, this complex is converted to the pre-initiation complex, which unwinds the DNA and loads the DNA replication machinery [4]. Once DNA replication has been triggered, the pre-RC breaks down, and its reassembly is inhibited until the next G1 [4, 11, 33].

In animal cells, the formation of the pre-RC is regulated by the activity of a number of inhibitor proteins, which are expressed during most stages of the cell cycle and help to prevent the formation of the pre-RC [11, 33]. This inhibition continues to exist until the G1 phase, when these inhibitor proteins are degraded and inactivated [34]. With the inhibitors removed, pre-RC components can be loaded onto the DNA in preparation for DNA replication. Once the machinery required for DNA synthesis has been expressed, the pre-RC is then converted to the pre-initiation complex, and finally, DNA replication itself is triggered by the combined activity of cyclin–CDK complexes and another kinase known as Cdc7 [35]. Once replication has begun, the levels of inhibitor proteins once again climb, resulting in the prevention of further rounds of pre-RC formation [4, 11, 33]. This ensures that re-replication of DNA does not occur during the later cell cycle phases, and that the genetic information in the cell is copied once and only once.

In addition to these inhibitor proteins, cyclin–CDK complexes also play an important role in regulating pre-RC formation, as they can directly phosphorylate pre-RC components and promote their destruction [36]. Since cyclin–CDK complex activity remains high throughout most cell cycle phases, and only begins to decline upon completion of M phase (Figure 4.1A), re-formation of the pre-RC complex is directly inhibited until all CDK activities decline at the end of the cell cycle.

Regulation of early mitotic events

During the approach to mitosis, the cell will confirm that DNA replication has proceeded in an efficient and accurate manner. If this is the case, the cell will then divide into two daughter cells, each containing one copy of the original cell's genetic material. This division process is again highly regulated and involves several steps, including the condensation and organization of chromosomes, breakdown of the membrane surrounding the nucleus, segregation of genetic material to opposite poles of the cell, and the formation of a new cell membrane between the poles to generate the two daughter cells. The following section of this chapter will focus on some of the initial events involved in mitosis, namely how chromosome organization is controlled, and the mechanism by which the genetic material is segregated to the poles of the cell. Once again, the activity of a number of kinases, including cyclin–CDK complexes, represents the main driving force for cell cycle progression, and will be outlined in further detail below.

Control of mitotic cyclin-CDK activity

In multicellular organisms, mitotic entry is regulated primarily by two cyclins and their CDK partners. The first cyclin–CDK complex has already been active during S phase, but will be degraded as

mitosis progresses. It is involved in regulating early mitotic events such as chromosome condensation [6, 37]. The second and perhaps the most important cyclin–CDK complex for driving mitotic events consists of cyclin B and CDK1, and forms as cells progress through G2. This complex has a number of important roles throughout mitosis, and as such its activity is tightly regulated [6, 37].

The activity of CDK1, like most CDKs, is regulated by the binding of its cyclin partner. However, cyclin B-CDK1 complexes initially remain inactive as an enzyme due to an inhibitory phosphorylation event that exists on the CDK1 subunit (see 'CDK activity is regulated by a variety of mechanisms' 4 and Figure 4.1B) [7, 37]. As cells progress into mitosis, this inhibitory mark is removed by members of the Cdc25 phosphatase family, whose protein levels and activity rise markedly at this time. This control mechanism ensures that cyclin B-CDK1 activity is not triggered prematurely, which could result in inefficient segregation of the cell's genetic material.

The cellular localization of cyclin B and its CDK partner are also regulated throughout the cell cycle [6, 37, 38]. As cyclin B levels rise in G2, it is localized exclusively in the cytoplasm, but as mitosis progresses, cyclin B-CDK1 is rapidly relocated to the nucleus, where it is involved in promoting nuclear envelope breakdown [6, 37, 38]. This change in cyclin B-CDK1 localization is governed by the relative rates of the protein's nuclear import and export, and this balance is skewed towards import during early mitosis. Again, this results from phosphorylation events—only this time they occur on the cyclin subunit rather than the CDK itself [39, 40].

Involvement of other mitotic kinases

Several other kinases in addition to CDKs are activated at the onset of mitosis and help coordinate early mitotic events. The most important of these are two families of kinases known as the Polo-like kinases (Plk) and the Aurora kinases (Figure 4.1A). Plk protein levels rise in early mitosis as a result of increased gene expression and remain elevated till the end of mitosis, when the APC complex becomes active and targets Plk for degradation [40, 41]. Plk has a wide range of functions during M phase, being involved in activities such as chromatid separation and the formation of daughter cells [40, 41] (discussed later). Like Plk, Aurora kinase protein levels also rise during mitosis, and they function in regulating many mitotic processes such as chromosome condensation [41, 42].

Chromosome condensation

After DNA replication, chromosomes exists as two tightly associated sister chromatids. These sisters are held together not only by extensive intertwining of their DNA, but also by a protein complex known as cohesin, which links the duplicated DNA molecules together [1, 43]. This helps the cell to organize its replicated genetic material, since without a certain degree of housekeeping the cell would simply contain an unordered mass of DNA. Nevertheless, attempting to separate the sister chromatids in this tangled state would likely lead to extensive DNA breakage. To remedy this situation the sister chromatids are compacted in a process known as chromosome condensation, and this is mediated by a large protein complex called condensin [44]. At the same time, the majority of the cohesin complex holding sister chromatids together is removed, which will permit the separation of sisters at a later stage of mitosis. Condensin activity and cohesin removal are both regulated by the combined activity of several enzymes, including cyclin–CDK complexes, Plk, and Aurora kinases [40, 42–44].

Assembly of the mitotic spindle

At the midpoint of M phase, known as metaphase, the condensed chromosome pairs will be aligned in an ordered fashion across the centre of the cell. Once this step is complete, the sister chromatids can then be separated and pulled to opposite poles of the cell, where they will subsequently be enveloped into two new daughter nuclei. This process requires the creation of an important structure within the cell, known as the mitotic spindle, and the attachment of sister chromatids to this spindle. Without this structure, the correct alignment of chromosomes will not take place, and sister chromatids cannot be segregated to opposite poles of the cell [1, 2]. While the spindle apparatus consists of hundreds of proteins, the fundamental machinery is the spindle microtubules, which are capable of attaching to chromatids and causing their transit through the cell. The mitotic spindle is assembled in early mitosis whilst chromosome condensation occurs, and mitotic spindles are bipolar in nature, each spindle pole being focused at a large multi-protein organelle known as the centrosome [45]. In G1, cells possess a single centrosome, but as they enter the cell cycle this structure becomes duplicated to form two tightly associated centrosomes [46]. Upon entry into mitosis, the centrosomes migrate to opposite poles of the cell and mediate formation of the bipolar mitotic spindle [45, 47] onto which the sister chromatids are eventually attached. Once again, all of these processes are regulated via phosphorylation events, mediated by a number of cyclin–CDK complexes and the Aurora and Polo-like kinases [45–47]. Once sister chromatid separation is complete and the cell has divided, each daughter cell will once again possesses a single centrosome.

Breakdown of the nuclear envelope

In animal cells the nuclear envelope must be removed to allow the mitotic spindle, which exists in the cytoplasm, to gain access to the sister chromatids, which exist in the nucleus. Breakdown of the nuclear envelope requires the disassembly of a number of large protein complexes, which exist both within and attached to the surfaces of the nuclear membranes. This process again likely involves the activity of cyclin B–CDK1, since phosphorylation of the subunits of many structural membrane complexes causes their disassembly from the nuclear envelope [48]. This dismantling process results in a loss of overall nuclear envelope structure, and eventually the nuclear membrane will disperse completely. After mitosis is complete, nuclear membrane proteins are resorted into membranes to reform the nuclear envelope around the segregated chromosomes, a process that is thought to involve the reversal of cyclin B–CDK1 phosphorylation events [48].

Regulation of late mitotic events

After chromosomes have been compacted and attached to the mitotic spindle, they are arranged at the centre of the cell by forces pulling through the microtubules. The cell is now at metaphase, and late mitotic events will lead to the separation and segregation of the sister chromatids. During anaphase, sister chromatid cohesion is destroyed and the sisters separate until finally, in telophase, the mitotic spindle is disassembled and segregated chromosomes are repackaged into daughter nuclei. The metaphase-to-anaphase transition is one of the major cell cycle checkpoints in the cell and is initiated by a process that involves the destruction of several

regulatory proteins by the APC. The dephosphorylation of CDK targets is also an important step in driving the late events of mitosis [49, 50], and together, these two processes help reset the cell cycle control system to its original G1 state.

The activation of APC is essential for anaphase

The APC is a large complex of subunit proteins whose main function in the cell is to trigger the transition from metaphase to anaphase, by tagging specific proteins for degradation via the process of ubiquitination (see 'CDK activity is regulated by a variety of mechanisms'). The activity of APC is regulated by the association of specific activator subunits, which target the APC to specific sets of substrates at different times in the cell cycle. During mitosis, the activator Cdc20 associates with APC, and this complex has numerous targets that function to regulate the completion of M phase. The proteins of most importance to get targeted for degradation by APC are the S- and M-phase cyclins, and a protein known as securin [14]. Securin is a protein which binds to and inhibits a protease known as separase, which in turn is responsible for promoting separation of sister chromatids during mitosis. The destruction of securin by the APC therefore enables chromatid cohesion to be disrupted and permits efficient segregation of sisters at anaphase [43] (Figure 4.1A). In addition to securin, the APC also targets the mitotic cyclins themselves. By promoting cyclin destruction, APC activity effectively inactivates CDK enzymes, which require their cyclin partners to function [14]. The loss of CDK activity subsequently permits the dephosphorylation of CDK targets [50], and this step is an important requirement for many late mitotic events, such as breakdown of the mitotic spindle and nuclear envelope reassembly.

Another APC activator subunit, known as Cdh1, also plays an important role during late M phase, when it functions to target APC activity towards proteins such as the Aurora and Polo-like kinases, which are not targets for Cdc20-containing APC. Destruction of these additional mitotic kinases at the end of M phase helps the cell to reset its cell cycle control machinery to a state that is found in G1 [14].

The spindle checkpoint

Accurate sister chromatid segregation requires that all sister pairs be correctly attached to microtubules originating from both poles of the mitotic spindle before they are separated. This requirement is monitored by the spindle checkpoint system, which only permits anaphase to occur once bi-orientation is attained. In this way, it acts to prevent the mis-segregation of genetic material to daughter cells that would result if the mitotic spindle attempted to separate inappropriately attached sister chromatids. The spindle checkpoint functions by preventing the activation of the APC, and whilst APC activity is held in check, the protein securin can continue to inhibit sister chromatid segregation [51]. However, once microtubules from each pole have successfully attached to the sister chromatids, the 'stop' signal generated by the spindle checkpoint system is silenced, and APC activity will drive the cell into anaphase.

Dephosphorylation of CDK targets is required for completion of anaphase and telophase

Although disruption of sister chromatid cohesion is required for chromosome segregation, normal chromosome movement towards each cell pole during anaphase requires regulated changes to microtubule behaviour (i.e. they need to be instructed to 'pull'). The activity of proteins involved in these processes is controlled in a cell-cycle-dependent fashion by their CDK-dependent phosphorylation in early mitosis and their subsequent dephosphorylation in anaphase once mitotic cyclins have been destroyed [49, 50]. After sister chromatids have been segregated to opposite poles of the cell, they need to be packaged into new daughter nuclei. The mitotic spindle is also disassembled at this time, and compacted chromosomes begin to decondense. Once again, the main driving force of these changes is dephosphorylation of CDK targets resulting from the degradation of cyclins and the inactivation of CDKs, particularly CDK1 [49, 50].

The DNA damage response

Every cell in the body is equipped to respond to the harmful effects of DNA damage, which can occur in a variety of ways in response to factors such as chemical changes or exposure to radiation. This DNA damage can result in gene mutations that impact on essential cellular processes and alter the cell's behaviour in a way that threatens the survival of the organism. The damage received by DNA can take many forms, ranging from small changes in base composition to breaks in both strands of the double helix [1, 52]. Such damage is recognized by sensor proteins that can recruit other enzymes to repair the DNA [52–54]. If the damage is extensive these sensors can also trigger the DNA damage response, which transmits signals to a number of effector proteins involved in transcription of genes involved in DNA repair. Alternatively, these effectors can lead to the activation of cell cycle checkpoints that cause cell cycle arrest [53, 55]. If the damage is subsequently repaired, the cell is permitted to re-enter the cell cycle. In multicellular organisms, however, extensive DNA damage results in a permanent cell cycle arrest or removal of the cell by apoptosis [53, 55].

In all eukaryotes, two protein kinases called ATM and ATR play a central role in the response to DNA damage. These proteins bind chromosomes at the damage site in combination with a number of other sensor proteins that assemble a platform upon which DNA repair complexes can be recruited [56–58]. Association of ATM and ATR with damaged DNA switches on their kinase activity and results in the phosphorylation of downstream targets (Figure 4.2). These initiate a number of signalling pathways that inhibit cell cycle progression and stimulate the expression of genes involved in DNA repair. For example, ATM and ATR activate E2F family members and the tumour-suppressor protein p53, which together trigger the expression of many genes involved in apoptosis or cell cycle arrest [59–61]. Mutations in DNA-damage-responsive components such as ATM, ATR, and p53 generally result in an increase in the accumulation of damaged DNA in cells, which leads to an increased risk of developing diseases such as cancer [54].

The regulation of p53 and E2F-1 activity

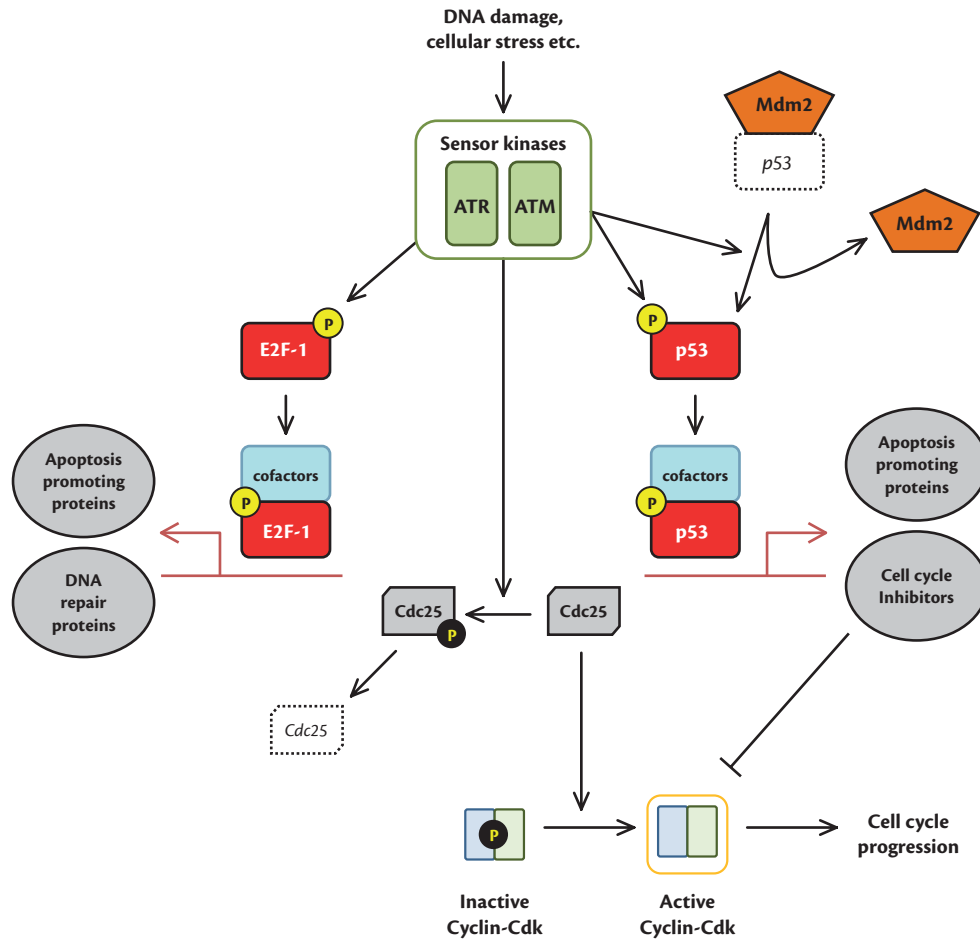
In a multicellular organism, a cell with severely damaged DNA can represent a threat to the survival of the organism as a whole. It is therefore important to prevent badly damaged cells from proliferating by arresting them permanently or removing them via apoptosis. The p53 protein plays an integral role in this response


Fig. 4.2 The DNA damage response. DNA damage received throughout the cell cycle leads to the activation of the sensor kinases ATM and ATR. These kinases have a number of cellular targets including the Cdc25 family of phosphatases. Cyclin–CDK activity is therefore blocked, since inhibitory phosphorylation events on the CDK are not removed, and this prevents cell cycle progression. ATM and ATR are also capable of activating and stabilizing p53, by disrupting the Mdm2-p53 interaction. This promotes p53 activity, which is to drive the expression of genes involved in cell cycle arrest and apoptosis. Damage responsive kinases can also target the E2F-1 transcription factor, promoting its interaction with proteins that enhance E2F transcriptional activity. E2F-1 regulates the expression of several genes involved in cell death and DNA repair. (Activatory phosphorylation [P] events are displayed in yellow, whilst inhibitory phosphorylation events are shown in black.)

to DNA damage, illustrated by the fact that the p53 protein is inactivated in at least half of all cancers described. In the absence of functional p53, the DNA damage response is compromised, resulting in the accumulation of gene mutations that enhance the likelihood that cancer will develop [54, 62]. p53 is activated in response to several forms of DNA damage or cellular stress, and its function is tightly regulated by a number of modifications which result in its increased concentration and transcriptional activity [60, 63].

The major regulator of p53 is a protein known as Mdm2, which can tag p53 with ubiquitin and target the protein for destruction [63, 64]. In the absence of DNA damage, Mdm2 binds to p53 and keeps its concentration and activity low in cells (Figure 4.2). However, when DNA damage occurs, the activity of Mdm2 is reduced, which permits the stabilization of p53 protein levels and helps drive transcription of DNA-damage-responsive genes [63, 64]. p53 acetylation also helps to stabilize p53 protein levels after damage [65–67], and phosphorylation of p53 by kinases such as ATM helps to promote interactions with cofactors that drive transcription of DNA-damage-responsive genes [68, 69].

Like p53, a number of E2F family members are also known to be responsive to events that damage DNA. E2F-1, in particular, seems to be activated in response to stress, and once again, modifications of the protein seem to be important for driving its activity [70–75]. For example, ATM and ATR are both known to target E2F-1 directly (Figure 4.2) [70, 72], and as with p53, these modifications stabilize E2F-1 protein levels and promote interactions with other transcriptional cofactors that drive expression of genes involved in apoptosis and DNA repair [73, 76].

The DNA damage response and cell cycle arrest

Whilst DNA damage can be sustained at any point during the cell cycle, the outcome to this damage is usually the same: the cell either arrests during its current cell cycle stage to halt proliferation whilst the damage is repaired, or if the damage is extensive, the cell will be removed from the organism by apoptosis. These events are triggered by the activation of DNA-damage sensing kinases such as ATM and ATR, which initiate a number of signalling events that enforce cell cycle checkpoints (Figure 4.2).

Cell cycle deregulation during cancer

Mutations cause the subversion of cell cycle checkpoints

Cancer is a broad group of diseases that all share the same underlying property: namely, they are caused by the uncontrolled division of cells. This unregulated division process produces a mass of cells within an organ or tissue, which leads to the formation of a tumour. Under normal conditions, cell division is tightly regulated by the plethora of signalling events that have been described throughout this chapter. In addition, processes that regulate events such as cell survival, cell death, or the conversion of cells into a terminally differentiated state all contribute to determining the ideal number, size, and growth of cells within a tissue or organ [1, 2]. However, during cancer, such controls break down, and cells no longer respond to cues that would normally regulate their behavior [77]. This loss of control results from the acquisition of genetic mutations within tumour cells, which permits them to overcome the checkpoints and barriers that normally act to restrain their proliferation and survival within an organism [77]. Since the checkpoints that govern cell cycle control represent highly complex and often redundant signalling pathways, multiple gene mutations are usually required before a cell develops the ability to proliferate and spread in an uncontrolled fashion (see Table 4.1).

Initially, these mutations will be acquired within genes that enable the cancer cell to divide at an inappropriate rate [77]. For example, pathways that govern the response of cells to mitogenic signalling might be circumvented, allowing cells to divide in the absence of growth factors. Alternatively, some mutations grant cancer cells an ability to ignore signals that would usually promote cellular differentiation, thus allowing them to bypass entry into a non-dividing state [77]. Cancer cells also carry mutations that enable them to survive in conditions that would usually trigger cell death [77, 78], such as in response to DNA damage, meaning that they can escape the normal controls that act to remove potentially damaging cells from the body. Loss of p53 function, for example, is an incredibly common feature found in almost all tumour cells, and this event can impact on cell death since many p53 responsive genes are involved in cell cycle arrest and apoptosis [62, 79].

Mutations, therefore, play a key role in tumour evolution. Whilst a small fraction of these cancer-promoting mutations are inherited and associated with familial disease, most are acquired spontaneously as a result of natural errors during the replication, segregation or repair of DNA [1, 2]. These errors usually occur at a very low frequency, but mutation rates can be accelerated in response to environmental triggers that damage DNA, or in cells that have acquired mutations in genes that regulate the cell cycle control machinery [77, 80, 81] (see Chapter 8 on 'Genetic Instability').

Mutations in oncogenes and tumour suppressors

Throughout this chapter a large number of proteins have been highlighted, and their roles in cell cycle control described. Most of these proteins will fall into two groups: those that positively regulate entry and progression through the cell cycle, and those that function to halt it. The genes that encode these proteins are known as proto-oncogenes and tumour suppressor genes respectively, and both are frequently mutated in many forms of cancer [1, 2].

Proto-oncogenes can be converted to their cancer-promoting oncogenic form by a variety of mechanisms, but all lead to the

Table 4.1 Examples of oncogenes and tumour suppressor genes frequently mutated in cancer

Gene	Associated disease
Oncogenes	
ABL	CML, ALL
AKT	Ovarian, pancreatic cancers
BRAF	Melanoma, colorectal, thyroid, borderline ovarian cancers, NSCLC
CCND1 (Cyclin D1)	CLL, B-ALL, breast cancer
CDK4	Melanoma, familial malignant melanoma
EGFR	Glioma
HRAS	Infrequent sarcomas, rare other types
KRAS	Pancreatic, colorectal, lung, thyroid cancers, AML, others
MYC	Burkitt lymphoma, B-CLL, others
NRAS	Melanoma, MM, AML, thyroid cancer
PDGFR	GIST, AML, CML
Tumour suppressors	
ATM	T-PLL, leukaemia, lymphoma, ataxia telangiectasia
BCL2	NHL, CLL
BLM	Leukaemia, lymphoma, skin squamous cell, Bloom syndrome
BRCA1	Ovarian cancer, breast cancer, inherited ovarian and breast cancer
CDKN2A (p16INK4A)	Melanoma, pancreatic cancer, multiple other
NBS1	Glioma, medulloblastoma, Nijmegen breakage syndrome
PTEN	Glioma, prostatic, endometrial cancers, Cowden syndrome
RB1 (pRb)	Retinoblastoma, sarcoma, breast, small-cell lung cancer
TP53 (p53)	Breast, colorectal, lung, adrenocortical cancer, glioma, sarcoma, many others, Li–Fraumeni syndrome

ALL, acute lymphocytic leukaemia; AML, acute myelogenous leukaemia; B-ALL, B-cell acute lymphocytic leukaemia; B-CLL, B-cell lymphocytic leukaemia; CLL, chronic lymphocytic leukaemia; CML, chronic myeloid leukaemia; GIST, gastrointestinal stromal tumour; MM, multiple myeloma; NHL, non-Hodgkin lymphoma; NSCLC, non-small-cell lung cancer; T-PLL, T-cell prolymphocytic leukaemia.

overproduction or hyperactivity of the protein in question [1, 2]. Errors in DNA replication or DNA repair, for example, can lead to the acquisition of point mutations that lock cell signalling proteins in their active states, or promote the enzymatic activity of kinases. Alternatively, amplification of entire genes can lead to the production of a normal cellular protein at abnormal levels [1, 2]. This amplification could result from chromosomal segregation defects or errors in events that take place during DNA repair [81]. Chromosomal rearrangements such as this can also lead to a situation where the coding sequence of one gene comes under the control of another gene's promoter. A perfect example of this occurs

with Burkitt lymphoma, where a chromosome translocation leads to the overproduction of a transcription factor that functions to drive the uncontrolled proliferation of lymphoid cells [82].

Mutations in tumour suppressor genes usually cause a loss of function; quite often, both alleles of the gene will need to be ablated [1, 2]. Again, this can occur by single point mutations, but often involves large deletions of the tumour suppressor genes themselves, resulting in the loss of large regions of the proteins they encode. For example, the loss of chromosomal regions containing genes encoding for CKIs such as p16 are common mutations found in many cancers [83]. In some cases, mutations in one allele of a tumour suppressor gene can be inherited, meaning an individual is more prone to develop a particular familial cancer disease [84]. Inherited mutations in one allele of the RB gene, for example, make individuals more prone to develop retinoblastoma, since complete loss of gene function now only requires the loss of the remaining normal allele [79, 84].

Conclusion

In every cell there is a complex combination of cell signalling pathways and checkpoint controls, which together constitute the highly conserved network of events that we collectively identify as the cell cycle control machinery. Progression of cells through the cell cycle involves the activity of a plethora of proteins that either permit or restrain advancement to the next stage, and it is this ordered set of events that culminates in the coordination observed between cell growth and division. Many of these cell cycle regulators become mutated in tumours, resulting in a breakdown of cell cycle control which permits cells to proliferate in an uncontrolled fashion—arguably the most fundamental hallmark of cancer.

CHAPTER 5

Cancer cell death

Amanda S. Coutts, Sandra Maniam,
and Nicholas B. La Thangue

Introduction to cancer cell death

A defining feature of cancer cells is their uncontrolled proliferation and ability to overcome cell death mechanisms [1]. As most cancer treatments rely on the induction of cell death pathways, understanding how cancer cells circumvent these pathways is important in the development of novel therapeutic agents. Morphologically and biochemically, at least three types of cell death have been defined: apoptosis (type I), autophagy (type II), and necrosis (type III). This chapter will outline these three types of programmed cancer cell death and detail some of the specific pathways involved, highlighting the clinical relevance where appropriate.

Apoptosis

Apoptosis is a ubiquitous, energy-consuming form of cell suicide triggered and orchestrated by a defined set of molecular events. The term apoptosis was first used in 1972 by Kerr, Currie, and Wyllie, who described the main morphological features [2]. Thirty years later, Brenner, Horvitz, and Sulston received the Nobel Prize in Physiology and Medicine for unravelling some of the fundamental aspects of the biology of apoptosis using the nematode *Caenorhabditis elegans* as a model system [3]. Apoptosis can be triggered by either mitochondrial-dependent mechanisms or by ligand binding to cell surface death receptors (Figure 5.1). As such, apoptosis can be stimulated by a variety of internal and external stimuli and can be divided into the intrinsic and extrinsic pathways [4].

Caspases

Caspases are a family of cysteine proteases which orchestrate apoptotic execution pathways through proteolytic cleavage of target proteins. Caspases are initially synthesized as inactive precursors (procaspases) that are rapidly converted to active proteases upon induction of apoptosis. The caspases can be divided into two groups: initiators (caspase-8, -9, and -10) and effectors (also known as executioners; caspase-3, -6, -7). The caspases activate each other via cleavage leading to amplification of the signalling cascade. Of note, caspase-8 is essential for the extrinsic apoptosis pathway, while caspase-9 is necessary for the intrinsic signalling pathway. Both of these pathways converge on caspase-3 which is the predominant effector caspase involved in the cleavage of signalling components that effect the morphologic changes associated with apoptosis [5].

Hallmarks of apoptosis

Caspases cleave a number of cytoplasmic and nuclear substrates resulting in many of the morphological features associated with apoptosis. Proteolysis of cytoskeletal and nuclear proteins results in cell and nuclear shrinkage, leading to membrane blebbing as a consequence of a weakened cytoskeleton. One of the first biochemical hallmarks of apoptosis to be identified was the degradation of genomic DNA into ladder fragments as a result of endonuclease-mediated chromatin cleavage. Other classic hallmarks of apoptosis are condensed chromatin and nuclear fragmentation [6]. The cells eventually fragment into apoptotic bodies which are consumed by phagocytes with a minimal production of pro-inflammatory cytokines [6].

Intrinsic apoptosis

The intrinsic apoptosis pathway is tightly regulated by the Bcl-2 (B-cell lymphoma 2) family of proteins and is mainly activated by internal stimuli emanating from cellular damage sensors or physicochemical alterations produced by stressed cells (e.g., reactive oxygen species (ROS) or DNA damage; Figure 5.1). Mitochondria play a fundamental role in the intrinsic pathway of apoptosis by releasing key effector proteins such as cytochrome c and SMAC (second mitochondria derived activator). The release of effector proteins is a consequence of compromised integrity of the mitochondrial outer membrane by a process known as mitochondrial outer membrane permeabilization (MOMP). This release initiates caspase activation in the cytosol leading to caspase-mediated proteolysis of target proteins [6].

The Bcl-2 family members are grouped into two classes (Figure 5.1); the anti-apoptotic (e.g., Bcl-2, Bcl-xL, Bcl-w, and Mcl-1) and the pro-apoptotic (e.g., Bax, Bak, PUMA) proteins. The two pro-apoptotic family members Bax and Bak have been shown to be required for activation of the intrinsic apoptotic pathway [7]. Upon activation, Bax and Bak oligomerize within the outer mitochondrial membrane. The oligomers form pores in the mitochondrial outer membrane leading to MOMP [8]. Anti-apoptotic members bind to and inhibit Bax and Bak. Additional pro-apoptotic members, (BH3 only proteins such as PUMA, Bid, and Bad; Figure 5.1), can promote MOMP by binding to and activating Bax and Bak or by inhibiting the anti-apoptotic members.

Thus, key control of MOMP occurs through interactions between pro- and anti-apoptotic Bcl-2 family members to control
(A)   **Extrinsic and intrinsic apoptosis pathway**

Fig. 5.1 Apoptosis pathways. (A) Extrinsic and Intrinsic apoptosis. The extrinsic pathway is initiated by binding of ligands to death receptors, leading to the recruitment of adaptor proteins and caspase-8; This results in dimerization of caspase-8 which cleaves and activates the effector caspases. Intrinsic apoptosis stimuli activate Bcl-2 pro-apoptotic proteins such as Bax and Bak which promote MOMP. Following MOMP, soluble (blue circle) and insoluble (black circle) proteins are released to the cytosol. Cytochrome c binds to Apaf-1, inducing formation of the apoptosome which recruits procaspase-9; activated caspase-9 cleaves and activates executioner caspases leading to apoptosis. SMAC and OMI neutralize the inhibitory effect of IAP. AIF and endonuclease G translocate to the nucleus where they promote DNA fragmentation in a caspase-independent fashion. Promising clinical targets are labelled in green boxes. (B) Bcl-2 family proteins. The Bcl-2 family is comprised of anti-apoptotic and pro-apoptotic proteins that contain conserved functional Bcl-2 homology (BH) domains. The pro-apoptotic proteins can be subdivided into multi-domain and BH3-only proteins.

Bax and Bak oligomers leading to MOMP and release of proteins, like cytochrome c, into the cytosol. Once released into the cytosol, cytochrome c forms a complex referred to as the apoptosome which also contains caspase-9 and Apaf-1 (apoptotic protease activating factor 1). Caspase-9 is activated within the apoptosome, leading to cleavage and activation of the so-called executioner (or effector) caspases-3, -6, and -7 (Figure 5.1).

During apoptosis SMAC is also released from the mitochondria where it can activate apoptosis by relieving IAP (inhibitor of apoptosis protein) mediated inhibition of caspases [9]. MOMP also releases caspase-independent effectors such as apoptosis inducing factor (AIF) and endonuclease G. These proteins translocate to the

nuclear compartment where they promote DNA fragmentation and chromatin condensation [7].

Extrinsic apoptosis

The extrinsic pathway is activated via the binding of extracellular ligands to transmembrane death receptors and is mediated by members of the tumour necrosis factor (TNF) receptor superfamily (Figure 5.1; [10]). There are a number of well-characterized death receptors known to mediate apoptotic signalling including TNFR1 (TNF receptor 1), Fas, and TNF-related apoptosis inducing ligand (TRAIL) receptor 1 and 2 (TRAIL-R1/2) [11]. The death receptors

contain a death domain (DD) in their cytoplasmic tail which facilitates the recruitment and assembly of multi-protein signalling complexes.

Ligand binding to the death receptor results in the recruitment of adaptor proteins (such as FADD (Fas-associated DD) and TRADD (TNFR1-associated DD) to form the death-inducing signalling complex (DISC) [12]. The adaptor proteins, in turn, recruit procaspase-8/-10 and DISC to mediate autocatalytic processing of caspase-8/-10 which in turn stimulate the effector caspases-3, -6, and -7. Active caspase-8/-10 is also known to cleave the pro-apoptotic Bcl-2 family member Bid, leading to mitochondrial cytochrome c release, highlighting just one of the many instances of cross-talk between the cell death effector pathways.

Apoptosis in the clinic

Activation of apoptosis in tumour cells is a promising strategy for cancer treatment and most cancer treatments rely on general activation of apoptotic pathways for their efficacy. Because of the key role of Bcl-2 family members in MOMP, they are considered to be important clinical targets in anti-cancer therapy [13]. Inhibitors of anti-apoptotic Bcl-2 proteins and IAPs are under evaluation in preclinical settings as hopeful anti-cancer agents. For example, Genansense® (oblimersen) is a Bcl-2 antisense oligonucleotide that targets Bcl-2 mRNA leading to its degradation and thus reduction of cellular Bcl-2 protein. Genansense has shown promise in clinical trials (e.g., [14, 15]). Please refer to www.clinicaltrials.gov for more information. Small molecule BH3 mimetics, which would lead to Bax and Bak oligomerization, are also considered as promising therapeutics for anti-cancer treatment. To date, several including navitoclax (ABT-263) are undergoing clinical trials [16].

The use of TRAIL ligand (or monoclonal antibody) as a potent tumour cell-specific stimulator of apoptosis has been intensively studied as it appears to induce apoptosis in tumour cells, but not normal cells. Several clinical trials have shown promise, although many human tumours appear to be resistant to TRAIL-induced apoptosis. It may be that combination treatments that sensitize tumours to TRAIL will show more therapeutic potential [17, 18].

Necrosis

Necrosis is a well-characterized form of cell death and was until recently thought to be largely accidental. While necrotic cell death is often associated with injury and trauma, such as ischaemia or exposure to toxins, it is also becoming increasingly clear that programmed necrosis (referred to hereafter as necroptosis) is an important cell death mechanism. Increasing evidence suggests that necroptosis relies on the induction of a variety of specific genes and signalling pathways (for example, see [19]).

Features of necrosis

Unlike apoptotic cells, necrotic cells do not fragment into discrete bodies. Instead, the induction of necrosis is associated with cell rounding, organelle and cell swelling, and a lack of chromatin condensation. This leads to an eventual increase in cell volume and rupture of the plasma membrane. In contrast to apoptosis, necrotic cell death typically proceeds in the absence of caspase activation and often promotes an inflammatory response.

Receptor-mediated necroptosis

Initially, the idea that necrosis was a type of programmed cell death was put forward based on the findings that TNF could cause cell death that resembled both apoptosis and necrosis. While caspases can mediate death-receptor-mediated apoptotic cell death (described above), in certain cell types treatment with ligands of death receptors (e.g., FasL, TRAIL, and TNF) is able to trigger cell death in the absence of caspase activity. Morphologically, this type of cell death was shown to resemble necrosis in that the cells and nuclei swelled (with an absence of DNA fragmentation characteristic of apoptosis), and was subsequently named necroptosis [20].

TNF-induced signalling can have multiple cellular outcomes (such as survival, apoptosis, and necrosis) dependent on distinct signalling complexes. Binding of TNF to its receptor, TNFR1, results in the formation of a signalling complex that contains a variety of proteins (Figure 5.2). Importantly, formation of a receptor-interacting protein kinase (RIP)1/3 complex (necrosome) has been shown to be required for death-receptor-mediated necroptosis in apoptosis-deficient conditions [21]. The activity of this complex is thought to orchestrate the switch between apoptotic and necrotic cell death as the active complex can only form in the absence of functional caspase-8. This is because caspase-8 can cleave and inactivate RIP1/3 leading to apoptosis; but in its absence, RIP1 and RIP3 are phosphorylated and activated within the complex, resulting in downstream signalling events to execute necroptosis.

RIP1 and RIP3 have been shown to be regulated by a variety of mechanisms. For example, IAP can ubiquitinate RIP1, resulting in the formation of a membrane-associated complex that favours cell survival via NF-κB signalling pathways (complex I). In the absence of IAPs, complex I detaches from the cell membrane and recruits FADD and caspase-8 in a RIP1-dependent fashion to form complex II (the DISC complex). Thus, RIP1/3 activity within this complex will be regulated by caspase-8 activity to orchestrate the switch between apoptosis or necroptosis.

Mediators of necrosis

Various agents such as pathogens, oxidative stress, ionizing radiation, DNA damage, and calcium overload can trigger necrotic cell death [22]. While in some cases the importance of RIP1/3 in this process is clear, precisely how necroptosis is executed downstream of RIP1/3 activation remains unclear.

Energy metabolism has been linked with necroptosis. Adenosine triphosphate (ATP) levels are an important determinant of whether cell death occurs via necrosis or apoptosis. This is because apoptosis demands energy in the form of ATP (which is immediately targeted by caspases), while necrosis can result from (and is thought to result in) ATP depletion. Activation of RIP3 can also result in the recruitment of metabolic enzymes to the RIP1/3 complex, leading to increased glycolysis and production of ROS. This suggests that ROS signalling may be involved in mediating necroptosis, and studies have shown that inhibition of ROS production can limit necroptotic cell death [23, 24].
Fig. 5.2 TNF-induced necroptosis. TNFR1 activation results in recruitment of a TRADD containing complex I. IAP within this complex ubiquitinates (Ub) RIP1 leading to NF-κB signalling and cell survival. In the cytosolic complex II, FADD recruits and activates caspase-8 leading to cleavage of RIP1/3 and activation of apoptosis. In the absence of caspase-8 activity (e.g., Z-VAD-fmk), RIP1/3 are phosphorylated (p) and activated leading to necroptosis.

More recently, a complex containing RIP1 that is distinct from the TNF-induced complex, called the ripoptosome [25, 26], has been identified. This complex contains RIP1, FADD, and caspase-8, and, depending on the cell context, can promote apoptotic or necroptotic cell death. Interestingly, these studies suggest that this complex forms primarily in transformed cells, highlighting its potential importance in tumour cell death.

Necroptosis and cancer

Necrosis is commonly observed in human tumours and is also associated with chemotherapies and radiotherapies [21]. Importantly, the presence of necrotic cells can be a byproduct of other types of cell death and may not necessarily reflect the presence of programmed necrotic cell death. Currently there are no clear biomarkers for necroptosis, and in general necrotic cell death is identified by the absence of markers of apoptosis or autophagy. Several studies have examined necroptosis in the absence of apoptosis to identify signalling pathways that can impact on necroptosis [20, 27]. Interestingly, SMAC can inhibit IAPs, leading to the activation of RIP1, and small molecule mimetics of SMAC have been shown to prime apoptosis-resistant cells for necroptotic cell death in vitro [28]. It is likely that similar molecules may have clinical potential and could be exploited to target human cancers. As researchers

gain a better understanding of the signalling molecules involved in programmed necrosis, this will no doubt open up therapeutic options and allow the development of compounds that effectively modulate necroptosis in a therapeutically beneficial manner.

Autophagy

Autophagy ('self-eating') is a catabolic process whereby cytosolic components and organelles are degraded in order to recycle key cellular materials. Autophagy is a constitutive process required for proper tissue homoeostasis but can be rapidly regulated by a variety of stimuli (e.g., nutrient starvation, pathogens, DNA damage, and hypoxia). Under normal conditions, cells undergo a basal level of autophagy, allowing the breakdown and recycling of long-lived or aggregated proteins, and damaged organelles. During times of metabolic stress and nutrient depletion, autophagy is an important mechanism by which cellular material is recycled to provide the biomaterials necessary for survival. For this reason autophagy is often thought of as a mechanism of tumour cell growth and survival, but unrestrained autophagy has been suggested to be an effective cell death inducer. At least three forms of autophagy have been described: macroautophagy, microautophagy, and chaperone-mediated autophagy, but in this chapter we will hereafter be using autophagy to relate primarily to macroautophagy.

Formation of the autophagosome

The formation of the autophagosome begins with the formation of a double membrane phagosome (Figure 5.3). In mammalian cells the origin of the phagosome is not entirely clear, but studies suggest it may derive from the endoplasmic reticulum, mitochondria, golgi, and the plasma membrane [29]. The phagosome elongates and encloses to engulf cytoplasmic constituents as it matures into the autophagosome. The autophagosome eventually fuses with the lysosome (which contains a variety of degradative enzymes) to become a mature autophagolysosome able to degrade and recycle its components.

Autophagy-related genes (Atgs)

Autophagy was first described in yeast cells (with over 30 autophagy-related genes described [6]), but is a well conserved process and many of the initial observations in yeast have been shown to be relevant to autophagy in mammalian cells. The formation of the autophagosome is a rapid process that requires a tightly regulated set of at least 18 mammalian proteins comprising several different complexes (Figure 5.3; [30, 31]). Signals feed into autophagosome formation via the ULK complex (unc-51-like kinases) which, along with Atg9, is recruited independently to the autophagosome formation site. These are required for the recruitment of the class III phosphatidylinositol-3-kinase (PI3K) complex containing Beclin 1 (Atg6). Beclin 1 is an important initiator of mammalian autophagy, originally identified as a Bcl-2 interacting protein. Upon starvation, Bcl-2 is released from Beclin 1, allowing Beclin 1 to activate autophagy via formation of a complex containing vacuolar protein sorting 34 (Vps34; a class III PI3K), Vps15/p150 and Atg14L (Barkor). Vps34 within this complex generates phosphatidylinositol 3-phosphate (PI3P) which is important for formation of the autophagosome.

Two ubiquitin-like complexes are involved in autophagosome elongation and maturation (Figure 5.3). The first involves the ubiquitin-like Atg12, which conjugates with Atg5 in a process requiring Atg7 and Atg10. This complex then interacts with Atg16L and associates with the phagosome. The second is the LC3 (Atg8/microtubule-associated protein 1A/B light chain 3; LC3-I)
Fig. 5.3 Autophagy regulation and autophagosome formation. Numerous stresses activate autophagy signalling, leading to alterations in mTOR activity within the mTORC1 complex. Inhibition of mTOR under nutrient-replete conditions leads to activation of the ULK-containing complex and the Beclin 1 complex, both of which are required for phagosome formation. The phagosome elongates and matures, steps requiring the Atg12-5 and LC3 complexes. Atg12 is conjugated to Atg5, which requires Atg7 and Atg10; this complex interacts with Atg16L and associates with the phagophore. LC3-I is cleaved by Atg4 and lipidated to form LC3-II, which associates with the autophagosome. Closure of the phagophore resuts in the formation of the double-membrane autophagosome which can fuse with the lysosome, leading to degradation of cellular cargo.

family complex. Atg4 cleaves LC3-I which is then conjugated to phosphatidylethanolamine (PE) to form (LC3-II), allowing its association with the autophagosome. LC3-II remains bound to the autophagosome until it is recycled during lysosomal degradation and is thus considered one of the most reliable markers of autophagy.

Control of autophagy

mTOR

A variety of stimuli have been demonstrated to result in autophagy, including hypoxia, nutrient depletion, endoplasmic reticulum stress, and DNA damage. The most important regulator of autophagy is the serine-threonine kinase mTOR (mammalian target of rapamycin) pathway (Figure 5.3). Under normal growth conditions, when nutrients are replete, mTOR is active and acts to suppress autophagy. Rapamycin, for example, targets and inhibits mTOR, leading to induction of autophagy.

mTOR forms two complexes in cells (mTORC1 and 2) and it is only mTORC1 that is sensitive to inhibition by rapamycin. Numerous signalling pathways converge on mTORC1, including the PI3K/Akt, Ras proto-oncogene/mitogen activated protein kinase (MAPK), and AMPK (adenosine monophosphate protein kinase) signalling pathways (Figure 5.3). These pathways act upstream of mTORC1 to control its activation state. Active mTORC1 binds to the Atgs ULK1/2 within the ULK complex, leading to their phosphorylation and inhibition of autophagy (Figure 5.3). When nutrient levels are depleted, for example, AMPK is activated and will inhibit mTORC1 to result in enhanced autophagy. Conversely, in nutrient-replete conditions, active mTORC1 will stimulate protein synthesis and cell growth [32].

Dual role of autophagy in cancer

Autophagy is often seen in dying cells, which has led to the supposition that autophagy was responsible for the cell death, but how this occurs is currently unclear. In experimental systems, long-term starvation of cells has demonstrated that autophagy can lead to cell survival, calling this view into question. It has also been proposed that autophagy can result in the digestion of organelles necessary for survival, such as mitochondria. Indeed, when large enough numbers of mitochondria are removed by autophagy (a process termed mitophagy) cell death ensues. Certainly in a few situations autophagy has been shown to be directly responsible for the induction of apoptosis, for example during development of the salivary gland in *Drosophila* [33].

Although non-apoptotic cell death accompanied by autophagy has been well described in human cancer cells, it has been suggested that detection of autophagy in dying cells is the result of an unsuccessful attempt to cope with stress, rather than a bona fide death mechanism [27]. Indeed, the role of autophagy in cancer is currently unclear and autophagy is thought to play a paradoxical role in cancer, acting as both a survival and a death mechanism [21]. The tumour-suppressive nature of autophagy was first demonstrated by the finding that monoallelic loss of the autophagy regulator Beclin 1 could promote tumorigenesis in mice [34]. In human cancers monoallelic loss of Beclin 1 has also been observed. For example, roughly 75% of ovarian cancers and 50% of breast cancers are thought to be Beclin 1 haploinsufficient [21].

Conversely, autophagy can provide a survival advantage for tumour cells due to their high energy demand [35, 36]. Moreover, inhibition of autophagy can synergize with chemotherapy, supporting the notion that autophagy can play a protective role in cancer cell survival [35]. It may be that the genetic background and/or stage of the cancer plays a role in whether autophagy can promote or inhibit tumour cell death [37]. Moreover the situation is further complicated by the fact that there is substantial cross-talk between autophagy and apoptosis (e.g., the anti-apoptotic protein Bcl-2 can bind and inhibit Beclin 1).

mTOR hyperactivation has been found in several human cancers. Rapamycin is a natural inhibitor of mTOR, but rapamycin and several of its analogues have had limited clinical success [38]. This had led to attempts to develop more effective mTOR inhibitors (e.g., dual PI3K/Akt and mTOR inhibitors) but their clinical efficacy has yet to be demonstrated. The late-stage autophagy inhibitors chloroquine and hydrochloroquine have been evaluated in humans as they are commonly used anti-malaria drugs. Autophagy inhibitors in combination with other therapies could provide a more effective means to target human tumours [37]. Indeed, clinical trials evaluating hydrochloroquine along with other cytotoxic agents are currently underway (<www.clinicaltrials.gov>).

Conclusion

Given that the fundamental goal of cancer treatment is selective tumour cell killing, understanding the mechanisms responsible for tumour cell death is of primary clinical significance. It has been 40 years since the initial characterization of apoptosis, long assumed to be the only mechanism of programmed cell death. In the last decade it has become apparent that non-apoptotic programmed cell death mechanisms play vital roles in normal physiology as well as in disease states [9]. Moreover, as researchers further characterize the mechanisms and effectors involved in these pathways, it is becoming increasingly clear that there is extensive cross-talk between these pathways. Unravelling the complexities behind cell death will allow refinements in treatments tailored to specific tumour types, taking into account the genetic pathways and the primary modes of cell death involved.

Therapies aimed at inducing apoptosis in cancer cells have been clinically exploited as have biomarkers that can be used to predict the efficacy of such therapies. A long-standing issue with cancer therapy is the development of resistance to treatment. There are a plethora of genetic and epigenetic changes in tumour cells that can circumvent apoptotic pathways; as such, understanding and developing therapies that can target other death-signalling pathways could have great clinical significance. Indeed, as necroptosis seems to function in the absence of apoptosis, it may be an important target in apoptosis-deficient cancer cells. Therapies that can block the growth-favouring aspects of autophagy while enhancing apoptotic and necrotic death may also be of benefit. Further, the double-edged nature of autophagy requires a more comprehensive understanding of its outcome in human cancers. Indeed, much research is aimed at identifying autophagy response biomarkers but a clearer understanding of the outcome of autophagy in human tumours must be gained.

Given the complexity involved in the variety of cell death mechanisms, the challenge in oncology is how to harness these different modes of cell death in order to effectively eliminate cancer cells.

CHAPTER 6

Angiogenesis

Yull E. Arriaga and Arthur E. Frankel

Introduction to angiogenesis

Blood vessels arose in vertebrates to improve supply of oxygen, nutrients, and immune defence cells to different tissues and organs [1]. The initial vascular architecture is assembled in a process called 'vasculogenesis'. The process employs deposition of embryonal angioblasts next to each other to create the initial capillary network. Subsequently, angiogenesis is used to expand the vascular network within growing organs. Different organs provide organ-specific signals and markers to the endothelium [2]. Angiogenesis is critical both in vertebrate vegetative functions and immune defence and employs unique tissue-specific pathways to meet organ needs. Not surprisingly, such an important system is regulated by many cell and molecular components. Co-option of the angiogenesis process by tumours is critical for their survival and pathology since uncontrolled growth alone fails without nutrients and a permissive extracellular environment. The discovery of the role of angiogenesis in cancer growth began with microscopic histology in the nineteenth century followed by the discovery of pro-angiogenic molecules and their receptors with molecular biology tools at the end of the twentieth century. Ultimately, protein and small molecular weight inhibitors of one of the pro-angiogenic factors were used to successfully palliate patients with a number of metastatic cancers.

History

Virchow and other German pathologists noted exuberant vessel proliferation in tumours in the 1880s [3]. In the 1920s, Lewis observed markedly different vascular patterns among different tumour types [4]. Ide and Algire reported tumour hypervascularity in the 1930s and 1940s [5, 6]. Several decades later, Ehrmann and Greenblatt identified a filterable molecule produced by tumours that triggered endothelial proliferation [7, 8]. Based on this work, Folkman hypothesized in 1971 that inhibitors to pro-angiogenic factors would 'starve' tumours and be a new class of targeted cancer therapeutics [9]. In the following decade, Folkman's lab optimized microvascular endothelial culture conditions that permitted an in vitro assay for the search for endothelial growth factors. Subsequently, numerous investigators evaluated fibroblast growth factor and tumour growth factor beta and other molecules, but none met the rigorous requirements for induction of endothelial growth in its presence and loss of endothelial growth in its absence. Finally, in the late 1980s, the endothelial mitogen, vascular endothelial growth factor (VEGF), was purified and characterized by Ferrara and colleagues from pituitary follicular cell conditioned media [10]. VEGF met Koch's postulates—its presence enhanced angiogenesis and its absence by genetic or immunologic means inhibited angiogenesis. Ferrara's group then synthesized blocking monoclonal antibodies [11]. Other groups established the VEGF receptors (VEGFRs) as a family of tyrosine kinases and developed small molecular weight tyrosine kinase inhibitors (TKIs) [12]. Clinical studies in the last decade were associated with US Food & Drug Administration approval of the anti-VEGF antibody, bevacizumab, for metastatic colorectal carcinoma (CRC), metastatic non-small-cell lung carcinoma (NSCLC), metastatic renal cell carcinoma (RCC), and glioblastoma and approval of the VEGFR TKIs—sunitinib, sorafenib, pazopanib, and axitinib for metastatic renal carcinoma. Sunitinib and sorafenib were also approved for gastrointestinal stromal tumours (GIST) and hepatocellular carcinoma (HCC), respectively [13]. Regorafenib was approved for metastatic colorectal carcinoma (CRC) and for GIST. While encouraging, these VEGF-VEGFR targeted agents have produced modest several-month improvements in disease-free survival and overall survival. Currently, there are several hundred clinical trials of novel anti-angiogenesis compounds and new predictive biomarkers based on an improved understanding of the biology. Hence, a deeper understanding of angiogenesis should be fruitful to cancer scientists, pharmacologists, and physicians.

Biology

Angiogenesis is an orchestrated, elegantly controlled series of steps as diagrammed simplistically in Figure 6.1. The steps are listed temporally and include (a) tumour cell release of pro-angiogenic factors and attraction of stromal fibroblasts and macrophages, (b) endothelial tip cell selection with extension of filipodia, loosening of the endothelial cell junctions, degradation of the extracellular matrix, migration towards the tumour, pericyte detachment from vessel wall, and increased permeability of the endothelial cell layer with deposition of a provisional extracellular matrix-ECM scaffold, (c) endothelial stalk cell proliferation with intercellular junctions, (d) lumen formation, (e) tip cell fusion, (f) blood flow, and (g) phalanx cell quiescence with production of basement membrane and coverage by pericytes.

The molecular machinery for the changes in the endothelium, stromal cells and extracellular matrix employs multiple reactions influenced by time and space. Because of the inherent lack of organization in the tumour microenvironment, the resulting vascular network is only partially functional, generating the disparate vascular patterns found in different tumour types and incompletely handling the nutritional needs, waste removal, and immune cell repair of normal tissue wounds. The tumour vessels are dilated,
Fig. 6.1 Sprout induction. (A) The initiation of blood vessel formation. The presence of VEGF (blue gradient) activates the endothelium (yellow cells) of existing blood vessels. A VEGF/notch-dependent regulatory mechanism ensures the selection of a limited number of tip cells (green) by blocking tip cell formation in the immediate neighbours (via lateral inhibition). Tip cells sprout towards the VEGF gradient, and the adjacent stalk cells follow the guiding tip cell and proliferate to support sprout elongation. (B) VEGF/notch regulatory feedback during tip cell selection. The activation of VEGFR2 (pink) by VEGF (blue circles) induces the expression of the notch ligand DLL4 (D; blue). The subsequent activation of notch (N; red) by DLL4 in contacting cells reduces their expression of VEGFR2 and DLL4, thereby making them less sensitive to VEGF-mediated activation and limiting their ability to activate notch signalling in neighbouring cells. The expression of other tip cell enriched genes, such as UNC5B and PDGFB is reduced in stalk cells, whereas the expression of the non-signalling VEGF decoy receptors VEGFR1 and soluble (s) VEGFR1 is increased, further reducing the likelihood of VEGFR2 activation in these cells. Furthermore, jagged1 (J1; yellow), which is selectively expressed in stalk cells, competes with DLL4 in cis for binding to notch receptors on tip cells. Jagged1 binds, but does not activate the notch receptor, thereby preventing notch activation in the tip cells. (C) VEGF signalling during sprouting. Soluble VEGFR1 (sVEGFR1; brown) produced by the cells immediately next to the outgrowing vessel branch sequesters VEGF molecules, thereby creating a corridor of higher VEGF levels perpendicular to the parent vessel. This corridor might act to optimize spreading of the vascular network and to avoid contact with nearby emerging sprouts.

tortuous, hyperpermeable, and show heterogeneity within the tumour bed [14]. Despite the complexity, some of the major chemical pathways have been identified [15, 16].

Tumour tissues—tumour cells and stromal cells—over-express VEGF-A proteins including splice variants VEGF121, VEGF165, VEGF189, and VEGF206 [17]. VEGF transcription is induced by local hypoxia or VHL mutation with stabilization of HIF1α [18],

local inflammation with stabilization of NFκB [19], and/or as a product of multiple activated oncogenes [20]. A VEGF gradient develops in the tumour tissue with soluble and heparan sulfate matrix bound VEGF molecules. In addition, both tumour and stromal cells (fibroblasts and macrophages) from the hypoxic and inflammatory tumour microenvironment produce other pro-angiogenic peptides including VEGF-C, placental growth

factor (PlGF), fibroblast growth factor (FGF), Bv8/PK2—a homologue of endocrine-derived VEGF, IL-8, SDF-1, and PDGF-C [21–27].

The endothelial VEGF receptor VEGFR-2 is composed of extracellular immunoglobulin repeats and intracellular tyrosine kinase domains [28]. After VEGF-A binds VEFGR-2, the receptor homodimerizes, autophosphorylates at tyrosines 951, 1054, 1059, 1175, and 1214, and activates downstream FAK, Src, PLCγ, AKT, and p38 MAK kinase [29]. The endothelial cell converts to a 'tip cell' with filipodia, enhanced migration, decreased intercellular adhesions, increased vascular permeability, induction of Delta-like ligand 4 (DLL4), and Fringe glycosyltransferase [29]. Neuropilins NRP1 and NRP2 act as VEGF co-receptors. The tip cell Notch receptor becomes glycosylated by Fringe. Tip cells release ANG2 that causes pericyte release, express matrix metalloproteases that degrade the basement membrane, and permit escape from the bloodstream of proteins facilitating a pro-angiogenic ECM.

The neighbour 'stalk' endothelial cell has Notch receptors [28]. After binding the tip cell DLL4, Notch is cleaved by ADAM10/17/presenilins; the released Notch intracellular domain (NICD) complexes with transcription factor FBPj/CBF1 and Mastermind-like proteins; transcription occurs of Notch-related ankyrin repeat protein-NRARP. NRARP triggers transcription of cell proliferation genes, lymphoid enhancer-binding factor 1 (LEF1)/β-catenin-dependent Wnt-mediated intercellular adhesion genes, Jagged1 inhibitory Notch ligand gene, VEGFR1 decoy VEGF-A receptor gene and downregulates transcription of VEGFR2/VEGFR3 genes. NRARP also promotes NICD degradation thus limiting the time duration of the 'stalk' and 'tip' phenotypes. This time duration is fine-tuned by acetylation and deacetylation of NICD by SIRT1. These temporal controls determine the branching pattern of the vessels.

Blood vessel lumen formation occurs by different processes in different tissues [30]. In cases of large capillaries with constant perfusion, stalk cells retain the apical-basal polarity when they bud from the larger vessel. In other cases, lumen formation requires a series of discrete steps [28, 31]. Stalk multicellular rods first establish basal surface β1-integrin binding to ECM collagen/fibrin. This causes RAS-interacting protein 1 (RASIP1), RHOA GTPase-activating protein 29 (ARHGAP29), and partitioning defective 3 (PAR3) to transfer to the basal area and trigger basal redistribution of junctional proteins including zonula occludens 1 (ZO1), claudin 5, VE-cadherin and CD99. CD34 and podocalyxin (PODXL) move to the apical surface where their sialic acid negatively charged electrostatic repulsion generates a lumen. Protein kinase C-PKC phosphorylates moesin and binds filamentous actin-F-actin to PODXL. RHO-associated coiled-coil kinase-ROCK links non-muscle myosin II to the apical F-actin, and actomyosin contraction occurs, which expands the lumen. In addition, exocytic vacuole trafficking to the apical surface aids lumen expansion. Tip cells fuse by VE-cadherin formation of adhesion junctions first at filipodia and then throughout the cell interface [30]. Macrophages can assist in the process.

Once the capillary sprouts with lumens have fused, blood flow ensues. Blood flow activates the shear stress-responsive transcription factor Kruppel-like factor 2 (KLF2), which transcribes miR-126 [15, 28]. miR-126 represses SPRED1 and PIK3R2, which are MAPK and PI3K inhibitors, respectively. The signal pathway activation promotes vessel integrity.

Finally, the new vessel matures and quiescent 'phalanx' cells produce basement membrane and recruit and interact with pericytes [15]. Molecularly, phalanx cell TGFβ binds pericyte TGFBR2/endoglin/Alk-1 to enhance pericyte proliferation and differentiation. Phalanx cell PDGFB binds pericyte PDGFRβ for cell recruitment. Phalanx sphingosine-1-phosphate (S1P) reacts with pericyte and phalanx S1PR and triggers N-cadherin-containing phalanx-pericyte junctions. Phalanx DLL4 binds pericyte Notch3 and enhances mural and endothelium maturation. Pericyte ANG1 binds phalanx TIE-2 and prevents phalanx cell VE-cadherin internalization. Phalanx nitric oxide synthetase and thrombomodulin maintain vessel patency. Phalanx VE-cadherin dephosphorylates VEGFR2 maintaining quiescence. Phalanx intracrine VEGF prevents cell apoptosis. Pericyte FGF binds phalanx FGFR and preserves adherens and tight junctions. Phalanx cells also produce PAI-1 and TIMPs to preserve the basement membrane. Further, phalanx prolyl hydroxylase domain proteins (PHDs) respond to tissue oxygen to adjust cell shape via HIF2α signalling.

Clinical applications

Efficacy

Only a few anti-angiogenesis compounds have been FDA approved for use in cancer as shown in Table 6.1 and previously reviewed [32]. The humanized anti-VEGF-A antibody bevacizumab in combination with chemotherapy is used for metastatic colorectal carcinoma (CRC) and non-small-cell lung carcinoma (NSCLC), in combination with interferon-2α for metastatic renal cell carcinoma (RCC) and as monotherapy for recurrent glioblastoma multiforme (GBM). Food and Drug Administration (FDA) approved indications of bevacizumab in cancer therapy are shown in Table 6.2.

The VEGFR TKI sunitinib is used as a single agent for metastatic RCC, pancreatic neuroendocrine tumours, and imatinib-refractory GIST. The VEGFR TKI sorafenib is given for metastatic RCC and HCC. The VEGFR TKI pazopanib is used for metastatic RCC. The VEGFR TKI axitinib is given for metastatic RCC. The VEGFR TKI regorafenib is used as a single agent for chemotherapy refractory metastatic CRC and as third-line therapy for metastatic GIST.

Sunitinib monotherapy improved median PFS and OS by 6 and 4.6 months, respectively, versus interferon-α in the metastatic RCC NCT00083889 trial [33]. Similarly, sunitinib improved median PFS versus placebo by 5.5 months in the imatinib refractory GIST SUN1112 study [34]. OS data is not mature. Finally, sunitinib improved median PFS versus best supportive care by 5.9 months in the pancreatic neuroendocrine tumour NCT00428597 trial [35]. Again, OS data is not available but the sunitinib death hazard ratio was 0.41.

Sorafenib monotherapy for metastatic RCC yielded an improvement in median PFS and OS of 2.7 months and 3.5 months, respectively, versus placebo after censoring for placebo crossovers in the TARGET trial [36]. Sorafenib monotherapy versus placebo for HCC showed an improved median PFS based on radiologic progression and OS of 2.7 months and 2.8 months, respectively, in the SHARP trial [37].

Pazopanib achieved an improvement in median PFS improvement of 5 months versus placebo in metastatic RCC patients in the VEG105192 trial [38]. OS data were not mature.

Table 6.1 US FDA-approved anti-angiogenesis agents

Agent	Disease	Rr (%)	Pfs improvement (Mo)	Os Improvement (Mo)	References
Bevacizumab	CRC	ND	1.4, 2.6, 4.2	1.4, 2.6, 4.7	[82] [83] [84]
	NSCLC	ND	1.7	2	[85]
	RCC	ND	4.8	2, 0.9	[86] [87]
	GBM	23	4	ND	[88]
Sunitinib	RCC	ND	6	4.6	[33]
	GIST	ND	5.5	ND	[34]
	NET	ND	5.9	ND	[35]
Sorafenib	RCC	ND	2.7	3.5	[36]
	HCC	ND	2.7	2.8	[37]
Pazopanib	RCC	ND	5	ND	[38]
Axitinib	RCC	ND	2	ND	[39]

Axitinib compared to sorafenib as second-line therapy for metastatic RCC produced a two-month improvement in median PFS in the AXIS study [39]. Again, OS data were not available.

Anti-VEGF/VEGFR therapies are not completely cross-resistant. Patients may respond to a second TKI after progression on the first TKI [40, 41].

Lack of efficacy of bevacizumab as adjuvant therapy for micrometastatic disease

The National Surgical Breast and Bowel Project (NSABP) C-08 study was a prospective randomized open label multi-institutional phase III clinical trial which evaluated the safety and benefit of adding bevacizumab for 12 months to adjuvant chemotherapy with infusional 5 fluorouracil (5-FU), leucovorin and oxaliplatin (FOLFOX) after complete resection of the primary tumour in patients with high-risk stage II and stage III colon cancer [42]. In this study, patients who received adjuvant bevacizumab plus FOLFOX for treatment of micrometastases had a significant but transient improvement in disease-free survival (DFS) after the first 15 months of follow-up (hazard ratio: 0.62; p <.001). The early improvement in DFS in patients who received bevacizumab plus FOLFOX was lost with longer follow-up. At a median follow-up of 35.6 months there was no statistically significant difference in DFS in patients who received bevacizumab plus FOLFOX compared to those who received adjuvant FOLFOX without bevacizumab. Another prospective randomized study, the AVANT clinical trial, evaluated the safety and efficacy of adjuvant bevacizumab for 12 months added to adjuvant FOLFOX or to adjuvant capecitabine plus oxaliplatin (XELOX) in patients with resected high-risk stage II or stage III colon cancer [43]. Like the NSABP-C08 study, the goal of the AVANT clinical trial was to evaluate the role of adjuvant bevacizumab in the treatment of micrometastatic disease. The AVANT study did not show a significant improvement in DFS in patients who received adjuvant bevacizumab plus FOLFOX or XELOX. The lack of DFS and overall survival (OS) benefit of adjuvant bevacizumab added to standard chemotherapy in patients with high-risk stage II and stage III colon cancer after complete resection of the primary tumour is in contrast with the significant improvements in DFS and OS seen in patients with metastatic CRC, metastatic NSCLC, and GBM treated with bevacizumab plus chemotherapy.

To date, results from prospective randomized clinical trials in patients with solid tumours without gross metastases do not support the use of adjuvant bevacizumab for the treatment of micrometastases after complete resection of the primary tumour. The underlying molecular mechanisms explaining the lack of benefit of adjuvant bevacizumab for the treatment of micrometastatic disease are unknown. Angiogenesis signalling pathways might be different in the primary tumour, micrometastases, and macrometastatic lesions. Effects of bevacizumab on the primary tumour and on gross metastatic lesions include:

- inhibition of neoplastic blood vessel formation
- inhibition of vessel co-option
- decreased intratumoural vascular density
- normalization of intratumoral pressure

Table 6.2 Approved indications of bevacizumab for metastatic malignancies

Malignancy	Clinical benefit
Colorectal cancer (CRC)	Improvement in median overall survival-OS and median PFS: - Bevacizumab plus irinotecan/bolus 5-flourouracil-5FU/leucovorin-IFL, AVF2107 trial [82] - Bevacizumab plus infusional 5FU/leucovorin/oxaliplatin-FOLFOX, N016966 trial [83] - Bevacizumab plus infusional 5FU/leucovorin/oxaliplatin-FOLFOX4 in patients previously treated with a fluoropyrimidine and irinotecan. E3200 trial [84]
Non-small-cell lung cancer (NSCLC)	Improvement in median overall survival-OS and median PFS: - Bevacizumab plus carboplatin/paclitaxel, E4599 trial [85]
Renal cell carcinoma- RCC	Improvement in median overall survival-OS and median PFS: - Bevacizumab plus interferon-2α, AVOREN trial [86]; CALGB90206 trial [87]
Glioblastoma Multiforme-GBM	Improvement in median PFS: - Single agent bevacizumab (monotherapy), AVF3708 study [88]

- normalization of abnormal neoplastic blood vessel
- enhanced delivery of cytotoxic chemotherapy to cancer cells
- enhanced sensitivity of tumour endothelial cells to the cytotoxic effects of chemotherapeutic agents
- direct cytostatic effects in tumour cells.

The effects of adjuvant bevacizumab on micrometastases may be different when compared to the anti-angiogenic effects of bevacizumab demonstrated in primary tumours and in macrometastatic lesions.

Toxicities

The VEGFR inhibitors have distinct side effects compared to cytotoxic chemotherapy and require different management. The antibody and small molecule TKIs show slightly different side effect patterns.

Bevacizumab produces haemorrhage, wound healing complications, gastrointestinal perforation, arterial thromboembolism, bleeding, congestive heart failure (CHF), hypertension (HT), proteinuria/nephritic syndrome, infusion reactions, and reversible posterior leukoencephalopathy syndrome (RPLS) [44]. Bevacizumab avoidance in patients with haemotypsis, squamous NSCLC, or full anticoagulation will reduce bleeding events; bevacizumab avoidance 60 days before until 30 days after surgery will reduce wound healing complications; cautious bevacizumab use in patients with active intra-abdominal inflammation, large tumours, or prior abdominopelvic irradiation will reduce GI perforations; guarded bevacizumab use in patients >65 years old or with a history of arterial thromboembolism reduces arterial thromboses; vigilant bevacizumab use in CHF/prior anthracycline/chest wall irradiation patients should impact the frequency of CHF; bevacizumab use with blood pressure monitoring and addition of antihypertensive therapy will impact HT toxicity; bevacizumab use with urine protein regular measurements will avoid severe proteinuria/nephrotic syndrome; and finally, attention to rare infusion reactions or RPLS with appropriate intervention will avoid these life-threatening side effects.

The spectra of VEGF TKI toxicities are similar but show different frequencies of events for the different molecules [45]. Sorafenib most often produces hypertension, hand-foot syndrome, rash, anaemia, fatigue, diarrhoea, arterial thromboembolism, nausea, hepatotoxicity, hypocalcaemia, haemorrhage, elevated lipase, hypophosphatemia, and alopecia. Sunitinib also produces hypertension, hand-foot syndrome, rash, anaemia, fatigue, diarrhoea, arterial thromboembolism, nausea, hepatotoxicity, and a greater incidence of CHF, prolonged QT, myelosuppression, mucositis, asthenia, vomiting, and hypothyroidism. Pazopanib has a significant rate of proteinuria, hepatotoxicity, hypothyroidism, hyperglycaemia, and wound healing complications. Axitinib has commonly hypertension, fatigue, nausea, vomiting, hypothyroidism, proteinuria, diarrhoea, anorexia, and hand-foot syndrome. Rare complications of VEGFR TKIs are RPLS, intracranial haemorrhage, renal thrombotic microangiopathy, and mesenteric vein thrombosis [46]. Patient management includes monitoring of blood pressure, urine protein, TSH, liver functions, blood sugar, calcium, phosphate, ECG, and cardiac ejection fraction with dose adjustments and medications as needed. Palliative treatments are given including topical care for hand-foot syndrome, topical lidocaine for mucositis, hydrocortisone cream for rash, loperamide for diarrhoea, and ondansetron for nausea.

Economics

A six-month course of bevacizumab, sorafenib, sunitinib, pazopanib, and axitinib cost US pharmacies $54K, $51K, $54K, $39K, and $54K, respectively. These calculations do not include pharmacy markups, clinic visits, and monitoring laboratory tests [47].

Predictive tests/biomarkers

It is questionable that improvements in PFS and OS derived from the use of small molecule anti-angiogenic multikinase inhibitors in cancer therapy result from their anti-angiogenic effects. Blockade of the VEGF pathway or other angiogenesis signalling pathways by multikinase inhibitors may not result in tumour shrinkage [48]. The clinical benefit of anti-angiogenic multikinase inhibitors is modest. Fundamentally, these agents have a cytostatic effect in cancer cells and their anti-neoplastic effects may be indirect. These agents induce tumour endothelial cell apoptosis which in turn may result in tumour cell apoptosis, inhibition of tumour cell proliferation, and inhibition of distant metastatic spread. Their systemic effects on trafficking and function of haematopoietic progenitor cells and effector immune cells may result in tumour regression or growth [49, 50]. Patient selection with pre-treatment or early post-treatment predictive assays would improve benefit, reduce unnecessary exposure to toxicities, and reduce societal and patient costs. Patients with post-treatment grade 3 or 4 toxicities—HT, hypothyroidism, hand-foot syndrome—have the highest response rate, PFS, and OS [51–53]. Pilot, unconfirmed predictors of improved response/PFS/OS include pre-treatment low plasma IL-8 and SDF-1α, post-therapy decreased forward volume transfer constant-K^{trans}, and reverse reflux rate constant-K_{ep} using dynamic contrast enhanced (DCE) MRI, and post-therapy high plasma PlGF, IL-8, and low plasma MMP-2, bFGF, sTIE2, sVEGFR1, IL6, and SDF-1α [54–56]. In additional preliminary studies, in RCC elevated tissue carbonic anhydrase IX and in metastatic breast cancer (MBC) elevated tissue CD31 and PDGFRβ predict higher response rates to sorafenib and bevacizumab, respectively [57–58]. Genotype VEGF-2578AA/1154AA and IL8-251A TT are associated with MBC and ovarian cancer response to paclitaxel plus bevacizumab and cyclophosphamide plus bevacizumab, respectively [59–60]. All these potential biomarkers require confirmatory studies.

Anti-VEGFR agents in development

Current clinical trials of anti-angiogenesis and anti-tumour vascular drugs in cancer include at least four categories of studies. First, approved anti-VEGFR agents are tested in new indications and in association with biomarkers. Second, second-generation anti-VEGFR agents are being tested in phase III clinical trials.

Bevacizumab: additional indications

Bevacizumab produced improvements in PFS and OS in subsets of ovarian cancer and MBC patients. Addition of bevacizumab to carboplatin plus paclitaxel in high-risk ovarian cancer patients—FIGO

stage IV or FIGO stage III with >1cm residual disease after debulking—yielded five-month and eight-month improvements in PFS and OS, respectively, in two studies [61, 62]. Neoadjuvant chemotherapy with the addition of bevacizumab for triple negative MBC yielded a higher rate of pathologic complete response than neoadjuvant therapy lacking bevacizumab [63, 64]. Bevacizumab plus chemotherapy given to gastric, breast, and pancreas cancer patients with elevated plasma soluble low molecular weight isoforms of VEGF-A yielded improvements in PFS and OS compared to treatment without bevacizumab [65]. These disease states are excellent candidates for further phase III clinical trials leading to US FDA approval.

Approved VEGFR TKI additional indications

Pazopanib showed clinical efficacy in HCC with 73% of patients showing PR or stable disease [66]. A phase III randomized placebo controlled trial of pazopanib in patients with angiogenesis-naïve non-adipocytic soft tissue sarcomas showed an improvement in PFS of 3 months compared to placebo [67]. Sunitinib plus irradiation produced a partial remission in a chondrosarcoma patient [68]. These VEGFR TKIs may obtain additional approvals for these disease states after confirmation of safety and efficacy in phase III clinical trials.

Second-generation VEGFR TKIs

AEE788, brivanib, motesanib, OSI-930, tandutinib, vatalanib, BIBF1120, tivozanib, and cediranib have shown sufficient activity to merit randomized phase II/III studies in different malignancies. AEE788 is a HER1/2 and VEGFR TKI in clinical testing in solid tumours—NCT100118456 and GBM-00116376 [69]. Brivanib is a FGFR and VEGFR TKI with activity in sorafenib-refractory HCC evidenced by a disease control rate of 46%, a median PFS of 2.7 months, and a median OS of 9.8 months [70]. Motesanib is a VEGFR and PDGFR TKI tested in NSCLC with carboplatin and paclitaxel [71]. OSI-930 is a KIT and VEGFR TKI in a phase I evaluation—NCT100513851 [69]. Tandutinib is a FLT3 and VEGFR TKI with activity in prostate cancer and AML [72]. Vatalanib is a PDGFR and VEGFR TKI with activity in GIST and high serum LDH colorectal cancers [73]. BIBF1120 is a PDGFR, FGFR, and VEGFR TKI undergoing clinical testing in ovarian cancer and NSLCL [74, 75]. Tivozanib is a VEGFR TKI active in RCC [76]. Cediranib is a VEGFR and PDGFR TKI with activity in RCC [77]. Several other TKI cross-react with VEGFR, but their predominant and clinically important inhibition is likely for other receptors—vandetanib for RET and cabozantinib for MET [69]. Many of these compounds will be approved in different subsets of cancer patients enhancing 'personalized or precision medicine'.

Protein anti-VEGF/VEGFR agents

Two proteins modify VEGF signalling and are in late stage clinical trials. Aflibercept is composed of the second immunoglobulin domain of VEGFR-1, the third immunoglobulin domain of VEGFR-2, and the constant region of human IgG1 antibody. Aflibercept binds VEGF-A, VEGF-B, and PlGF. When combined with FOLFIRI, the combination extended PFS by 2.2 months and OS by 1.5 months in CRC compared to FOLFIRI alone in the VELOUR trial [78]. Aflibercept combined with docetaxel yielded seven partial remissions and 32 stable disease among 54 advanced solid tumour patients for an overall disease control rate of 72% [79]. Epistaxis, proteinuria, dysphonia, and HT occurred in >50% of patients. Ramucirumab is a human antibody reactive with VEGFR-2. Fifteen of 37 advanced solid tumour patients showed a partial remission or stable disease lasting >6 months on ramucirumab [80].

Novel anti-angiogenesis agents in clinical studies

As described above, there are additional critical signalling pathways that modulate angiogenesis. These have recently become targets for clinical tests of new anti-angiogenesis treatments. These targets include PlGF, PDGFR, VEGFR1, NRP-1, DLL4, ANG1/2, and S1P. Anti-angiogenesis agents that are not VEGFR directed are in phase I and phase II trials. A summary of anti-angiogenesis monoclonal antibodies and recombinant peptide proteins in clinical trials are presented in Table 6.3.

Small molecule vascular disrupting agents (VDAs) in clinical development

The modest results with anti-angiogenesis compounds may be due to several reasons including multiple pro-angiogenic hormones, pathways, and participating cells, unacceptable toxicities to normal blood vessels, promotion of metastases by slight increases in tumour tissue hypoxia, and reduced potency on established tumour vessels. An alternative approach is to target mature tumour blood vessels with a vascular disrupting agent (VDA). VDAs depend upon differences in intracellular or surface molecules between tumour and normal vessels. A small molecule VDA modifies intracellular tumour vessel functions leading to cell death or endothelial dysfunction. A number of small-molecule VDAs have reached the clinic and some are in various stages of testing in solid tumours. A summary of small-molecule VDAs in clinical trials are presented in Table 6.4.

In summary, a few small-molecule VDAs are continuing in development. The class appears to have modest efficacy, but, in selected cases, may be combined with cytotoxic chemotherapy or other therapies due to non-overlapping toxicities.

Ligand-directed VDAs in clinical development

Ligand-directed VDAs contain a peptide ligand which binds cell surface tumour endothelial antigens and an effector domain which produce vessel injury or thrombosis [80]. The ligand improves the tumour endothelial specificity of the VDA. Ligands include cyclic peptide mimetics and monoclonal antibodies. Effector domains include Fc fragments, radionuclides, or cytokines. Different tumours employ different angiogenesis pathways, and hence different ligands and targets may be optimal for different patient tumours. A summary of ligand-directed VDAs in clinical trials are presented in Table 6.5.

Table 6.3 Anti-angiogenesis monoclonal antibodies and recombinant peptide proteins in clinical trials

Agent	Class	Target	Effects and clinical trials
TB-403	Humanized antibody	PlGF	◆ Interruption of PlGF signalling to VEGFR1 ◆ Expected activity in tumours over-expressing PlGF and unresponsive to VEGF inhibition ◆ Phase I study in advanced solid tumours [89]
MEDI-575	Fully human antibody	PDGFR	◆ Expected activity in tumours unresponsive to VEGF inhibition ◆ Two phase I studies in advanced solid tumours ◆ Ongoing studies in NSCLC and GBM [90]
Icrucumab or IMC-18F1	Fully human antibody	VEGFR1	◆ Effects on tumour cell, endothelial cell, circulating haematopoietic cell, macrophage, and stromal cell VEGFR1 ◆ Safe at pharmacologically active dose levels in advanced solid tumours [91] ◆ Ongoing phase II studies in breast and bladder cancer
MRNP1685A	Fully human antibody	NRP1	◆ Safe in inter-patient dose escalation study [92, 93] ◆ Phase IB study in combination with bevacizumab plus paclitaxel in NSCLC [94]
OMP-21M18	Humanized antibody	DLL4	◆ Induces hyperproliferation of non-functional tumour vasculature leading to tumour ischaemia ◆ Study as single agent in advanced solid tumours [95] ◆ Ongoing studies in combination with carboplatin plus pemetrexed in NSCLC and with gemcitabine in pancreas cancer
Sonepcizumab	Humanized antibody	S1P	◆ Inhibition of SIP binding to S1PRs inhibits endothelial cell communication with pericytes ◆ Phase I study in advanced solid tumours [96]
REGN910	Fully human antibody	ANG2	◆ Ongoing phase I study in advanced solid tumours [97]
AMG 386	Recombinant peptide-Fc fusion protein	ANG1/2	◆ Binding of ANG1/2 blocks interaction with TIE2 [98] ◆ twenty-two ongoing clinical trials as single agent or in combination with chemotherapy, bevacizumab, or small-molecule TKIs: GBM, CRC, gastric/oesophageal adenocarcinoma, RCC, HCC, ovarian carcinoma, triple negative breast cancer

Table 6.4 Small molecule vascular disrupting agents (VDAs) in clinical trials

Agent	Effect	Clinical studies
Vadimezan, DMXAA or ASA404	Induces tumour endothelial cell apoptosis	◆ Flavonoid vascular disrupting agent [99] ◆ Increases intratumoral TNF-α concentrations ◆ Ongoing study with carboplatin plus paclitaxel in SCLC
Fosbretabulin or combretastatin A-4 disodium	Binds tubulin	◆ Inhibits microtubule assembly, destabilizes cytoskeleton, disrupts adherens junction complexes, increases tumour vessel permeability, blocks tumour blood flow [100] ◆ Single-agent studies in advanced solid tumours [101] ◆ Phase II study of carboplatin/paclitaxel/bevacizumab +/−ß fosbretabulin in NSCLC [102] ◆ Ongoing study of bevacizumab +/− fosbretabulin in ovarian cancer
OXi4503 or combretastatin A1 diphosphate	Binds tubulin	◆ More potent than fosbretabulin ◆ Phase I studies in advanced solid tumours [103]
Ombrabulin and crolibulin	Microtubule-directed agent	◆ Ongoing studies in sarcoma-ombrabulin and anaplastic thyroid cancer-crolibulin
ABT-751	Binds tubulin	◆ Sulphonamide vascular disrupting agent ◆ Phase I and phase II single-agent studies in advanced solid tumours [104, 105]
Plinabulin	Binds tubulin	◆ Depolimerizes microtubules ◆ Phase I studies with and without chemotherapy in advanced solid tumours [106, 107]
Solblidotin or TZT-1027	Binds tubulin	◆ Cytotoxic dolastatin-10 analog ◆ Inhibits microtubule assembly ◆ Three phase I studies in advanced solid tumours and NSCLC [108–110]
ADH-1	Vascular disrupting agent	◆ Cyclic pentapeptide N-cadherin antagonist ◆ Two phase I studies in advanced solid tumours [111, 112]

Table 6.5 Ligand-directed VDAs in clinical trials

Agent	Class	Clinical studies
Bavituximab	Anti-β2-glycoprotein 1 mouse-human chimeric antibody	◆ Single-agent study in advanced solid tumours [113] ◆ Four studies in combination with chemotherapy showed efficacy: ◆ With docetaxel, second line—MBC [114] ◆ With carboplatin/paclitaxel, first line—MBC [47] ◆ With carboplatin/paclitaxel—NSCLC [115, 116] ◆ Ongoing studies: in combination with cabazitaxel-castration resistant prostate cancer-CRPC, with paclitaxel—triple negative MBC, with sorafenib—HCC, with gemcitabine-pancreas cancer
Cilengitide	Cyclic RGD-containing pentapeptide. Blocks αvβ3/αvβ5-ECM interaction	◆ Study in recurrent GBM [117] ◆ Study in combination with temozolomide+radiotherapy, first line for GBM [118] ◆ Randomized phase III trials +/− chemotherapy: GBM—CENTRIC trial, H&N carcinoma—ADVANTAGE trial ◆ Ongoing NSCLC—CERTO trial
Intetumumab	Fully human anti-αv monoclonal antibody	Three studies: melanoma, angiosarcoma, and castration-resistant prostate cancer [119, 121]
PF 04605412	Fully human anti- αvβ3/α5β1 monoclonal antibody	Ongoing phase I study in advanced solid tumours
GLPG 0187	Anti- α5β1 peptidomimetic	Ongoing phase I study in refractory solid tumours
E7820	Sulphonamide derivative-α2 integrin inhibitor	Ongoing randomized study in combination with irinotecan in CRC
TRC105	Anti-endoglin human/murine chimeric IgG1 monoclonal antibody	◆ Studies in advanced solid tumours [122, 123] ◆ Dramatic responses in CRC, ovarian cancer and endometrial cancer ◆ Ongoing studies in combination with chemotherapy: MBC, HCC, CRPC, and other solid tumours
J591	Anti-PSMA murine monoclonal antibody conjugated to different radionuclides	◆ Conjugated to ^{111}In: ◆ Study in advanced solid tumours [124, 125] ◆ Tumour vasculature selectively and safely targeted ◆ Conjugated to ^{177}Lu: ◆ Remissions reported in CRC [126] ◆ Ongoing study in non-prostate metastatic solid tumours
^{131}I-L19SIP	L19 anti-ED-B FN human antibody Fv fused to CH4 and radiolabeled with ^{131}I	◆ Two phase I studies [127, 128] ◆ Ongoing studies in combination with radiotherapy or chemoradiotherapy for brain metastases and NSCLC
L19IL2	L19 anti-ED-B FN human antibody Fv fused to IL2	◆ Studies in RCC [129] and other solid tumours ◆ Study in combination with dacarbazine-melanoma [130] ◆ Ongoing studies in combination with dacarbazine-melanoma and with gemcitabine-pancreas cancer
NGR-hTNF	NGR peptide coupled with human tumour necrosis factor α	◆ NGR selectively binds CD13 on tumour endothelial cells ◆ Studies in advanced solid tumours, mesothelioma, CRC, and HCC [131–134] ◆ Randomized phase II study evaluating combinations with chemotherapies—NSCLC [135] ◆ Studies in combination with doxorubicin-refractory solid tumours, SCLC, and ovarian cancer [136–138] ◆ Studies in combination with capecitabine/oxaliplatin-refractory CRC and with cisplatin-solid tumours [139, 140] ◆ Ongoing studies in combination with doxorubicin for platinum-resistant ovarian cancer, study in soft tissue sarcoma and randomized phase II study in combination with standard chemotherapy—NSCLC ◆ Ongoing randomized phase II study-relapsed mesothelioma and maintenance therapy—mesothelioma

Conclusion

Angiogenesis consists of an orchestrated series of steps leading from vessel sprouting, tube and lumen formation, vessel fusion, and, finally, quiescence. How these steps and their associated molecular components relate to non-physiologic, tumour angiogenesis is still being defined. Several anti-angiogenic drugs have reached the clinic. They all target the VEGF/VEGFR signalling pathway. They provide modest clinical benefit, but at a cost of significant and sometimes life-threatening toxicities. Progress is occurring with application of new predictive biomarkers to extend anti-VEGF-A/VEGFR

approved drugs to new indications and more appropriate patient subsets. New, more selective VEGFR TKIs and novel protein drugs modifying VEGF–VEGFR interactions are likely to be approved soon for routine cancer care. Other components of tumour angiogenesis have been targeted, including ANG1/2 and S1P, and led to disease control. Ligand-directed VDAs—particularly antibodies to PS-β2 glycoprotein, endoglin [81], and CD13—have shown safety and excellent clinical activity. With enhanced understanding of vascular biology and advances in targeted therapy design, medical oncology practice will see an expanding role for tumour endothelial directed therapies.

CHAPTER 7

Invasion and metastasis

Andrew P. Mazar, Andrey Ugolkov, Jack Henkin,
Richard W. Ahn, and Thomas V. O'Halloran

Introduction to invasion and metastasis

Malignant (from Latin *malignus* = born to be bad) cancer has three characteristic features: anaplasia, invasiveness and the capacity to metastasize. Invasion involves the capacity of malignant cells to escape the primary tumour and to access a means of dissemination such as the lymphatics or the circulation (intravasation). Metastasis (from Greek *meta* = beyond; *stasis* = a standing still) is defined as dissemination of cancer cells from a primary malignant tumour to another part (or organ) of the human body followed by growth of the disseminated tumour in another organ site distant from the primary tumour. Benign tumours are not capable of invasion or metastasis [1]. Although most malignant tumours can metastasize, there are two exceptions: glioma (malignant tumours of the glial cells in the brain) and basal cell carcinoma (malignant tumours of the skin) [1]. Glioma and basal cell carcinoma are highly invasive tumours and can become locally advanced but they rarely form metastases [1].

Cancer invasion

Malignant tumours grow by progressive invasion and destruction of adjacent benign tissue. Proteases that are expressed or recruited by cancer cells such as matrix metalloproteinases (MMPs), cathepsins, plasmin, and urokinase plasminogen activator can break down extracellular matrix (ECM) adjacent to tumour cells as well as basement membrane that surrounds blood vessels to promote invasion [2, 3]. In addition, the transformed metabolism of cancer cells supports destruction of adjacent normal cells, further facilitating the invasive process [4, 5]. In contrast to normal cells, many malignant cells rely on anaerobic glycolysis even in the presence of abundant oxygen (Warburg effect) [6, 7]. Because anaerobic metabolism is energy inefficient, it is compensated by increased glucose uptake by cancer cells [8]. This high consumption of glucose by cancer cells (up to 50 times higher than normal cells) [6, 7] was used as a basis to establish the positron emission tomography (PET) imaging technique to detect primary and metastatic cancer [9], which utilizes the positron-emitting radionuclide glucose analogue fluorodeoxyglucose (^{18}FdG). This inefficiency in ATP production might be thought to represent a significant competitive disadvantage for cancer cell survival. However, mathematical modelling of the tumour–host interface proposes that anaerobic glycolysis actually supports tumour cell invasion [10]. In cancer cells, glycolysis leads to increased excretion of protons that decreases the extracellular pH around the tumour leading to p53

mediated apoptosis of normal cells that are adjacent to cancer cells, impaired immune cell response, and loss of intercellular gap junctions. Cancer cells survive this low pH milieu because they are p53-mutant or p53-null.

The molecular mechanisms of cancer cell invasion through benign tissue and into lymphatic and blood vessels are still poorly understood. Can cancer cells migrate and invade independently within benign human tissue? Despite many years of investigation into cancer cell invasion and metastasis, this simple but critical question remains to be addressed. In vitro migration and invasion assays (e.g. Matrigel®, wound healing) indirectly support the theory of cancer cell migration and epithelial mesenchymal transition (EMT) [11, 12]. However, these in vitro systems are extremely artificial in that they do not recapitulate the tumour microenvironment faithfully. As investigators set up more complex systems that take into consideration the various cell–cell and cell–ECM interactions that occur within a tumour, many of the conclusions drawn based on older migration and invasion results are being called into question. For example, EMT is defined as a process of cell transdifferentiation from an epithelial to a mesenchymal phenotype characterized by loss of cell adhesion and repression of E-cadherin (a tumour suppressor) expression [12]. The concept of EMT is based on the developmental phenomenon in embryogenesis although none of the cells are defined as epithelial or mesenchymal at embryogenesis, and thus the extrapolation of what is observed during embryogenesis to tumour invasion is tenuous at best [13]. The reversibility of EMT has been proposed based on the obvious similarity in the E-cadherin expression pattern in primary and metastatic tumours although reversibility has not been demonstrated experimentally [14, 15]. The major mechanistic support for EMT occurring in the first place is based on microscopic images of 2D tumour section that provide the impression that small separated clumps of 'migrating' E-cadherin-negative cancer cells invade surrounding benign tissue (Figure 7.1). However, recent experimental results using more sophisticated systems that reconstruct a tumour in 3D (rather than just looking at a tumour section in a single plane) indicate that all cancer cells within a tumour specimen are interconnected, forming a 3D network of cancer cell invading roots resembling a 'hair ball' in which the space between microscopic invading roots of cancer cells is filled with benign cells (Figure 7.1). These observations suggest that cancer cell proliferation rather than EMT-mediated migration is a primary driving force of cancer invasion. Three-dimensional modelling of tumour
Fig. 7.1 The schematic presentation of EMT and 'invading roots' hypotheses in human cancer.

sections suggests that invading roots might penetrate venules at multiple points, budding and releasing proliferating cancer cells into the blood circulation, leading to metastasis. Thus, cancer cell invasion and seeding into blood circulation (metastasis) may be driven by continuous proliferation of cancer cells. This hypothesis is further supported by the fact that most proliferating cancer cells are typically located at the invasive front of a tumour (Figure 7.1). This 'invading roots' hypothesis can explain the clonal selection of metastatic cancer cells (located at invasive ends of roots). These metastatic cells, selected by their capacity to survive and proliferate in this harsh environment, would have evolved over thousands of generations of proliferation from the originating cancer cells.

Cancer metastasis

Cancer cell dissemination and formation of metastasis occurs in several ways: (1) lymphatic (lymphogenous) dissemination; (2) haematogenous dissemination; (3) direct dissemination to cavities and surfaces of the human body.

Lymphatic metastasis

The most common route of cancer cell dissemination for many carcinomas is the lymphatics [1]. Lymph node metastasis follows the routes of lymphatic drainage. In many types of cancer, regional lymph nodes represent barriers to further spread of cancer cells. There are numerous interconnections between the lymphatic and vascular systems suggesting the possible involvement of lymphatic spreading in haematogenous metastasis as well [1].

Haematogenous metastasis

Common sites of distant haematogenous metastasis are the liver, lungs, and bones (Table 7.1) [1]. Haematogenous spreading of cancer cells is typical for sarcomas but is also observed in certain carcinomas such as renal cell [1]. Cancer cells detach from the primary

tumour and intravasate into venous flow. These disseminated cells are then delivered to target organs to form metastases (Figure 7.2). There are two hypotheses to explain the process of haematogenous metastasis: 'mechanistic' (blood flow) and 'seed and soil' (organ microenvironment) originally proposed by Paget [16, 17]. These hypotheses complement each other to explain how metastasis develops. Mechanistically, the prevalence of certain metastatic sites depends on where the primary tumour is localized in the body. For example, the liver is the first organ through which venous blood flow from colon, gastric, and pancreatic cancer passes, so these types of cancer frequently metastasize to the liver (Table 7.1). Metastatic breast cancer cells are delivered by venous flow to the right heart, which delivers blood to the lungs. Metastasis to brain and bone is formed by cancer cells delivered with arterial blood. In this case, metastatic cancer cells (from the primary tumour) pass

Table 7.1 Common metastatic sites of human cancer

Type of cancer	Metastatic site
Breast	Lungs, liver, bones, brain
Prostate	Bones, lungs, liver
Colon	Liver, peritoneum, lungs
Lungs	Adrenal gland, liver, brain
Melanoma	Lungs, liver, brain
Pancreas	Liver, lungs, peritoneum
Kidney	Lungs, liver, bones
Ovary	Peritoneum, liver, lungs
Stomach	Liver, lungs, bones
Bladder	Bone, lungs, peritoneum
Endometrial	Lungs, liver
Fig. 7.2 Schematic illustration of sequential steps in the process of haematogenous metastasis.

through the pulmonary vascular system, or lung metastatic lesions release cancer cells to seed secondary metastasis in brain and bone as seen for breast and lung cancer.

The 'seed and soil' hypothesis suggests that seeding and growth of cancer cells is regulated by the biologically specific microenvironment of the target organ (soil) [16]. Indeed, it has been demonstrated in vivo that certain kinds of cancer prefer to metastasize to specific organs regardless of blood flow or vascular anatomy [16]. However, the 'seed and soil' hypothesis is also compatible with the mechanistic hypothesis of metastasis because tumour cells must reach target organs by flow and be trapped there, at which time the 'soil' determines whether those trapped cells will progress to true metastases. Wood et al. [17] were the first to demonstrate the development of haematogenous metastasis in vivo. V2 carcinoma cells (rabbit carcinoma) were injected into small arteries in the rabbit's ear, into which a chamber was inserted to observe the ear capillary network. V2 cancer cells were rapidly trapped in the capillaries and a thrombus formed within 30 minutes of tumour cell injection. Division of cancer cells started in 24 hours with subsequent invasion through the endothelium (extravasation) which became obvious by 48 hours after injection. A metastatic lesion was established 72 hours post injection. This study was the first to illustrate that the process of haematogenous metastasis consisted of a series of sequential steps (Figure 7.2). This was also the first study to suggest that metastasis is an inefficient process, later confirmed by Fidler and co-workers [18] and others, since the vast majority (99.9%) of circulating cancer cells were destroyed quickly. Since potential metastatic cells are detached from the ECM and are essentially anchorage-independent until they seed, many of these cells likely undergo anoikis, a form of programmed cell death, upon detachment at this stage of metastasis [19]. A variety of host factors (e.g. blood viscosity and turbulence, platelets, T-cells, natural killer cells, and macrophages) also contribute to the rapid death of circulating cancer cells [20].

Moreover, the passage of disseminated tumour cells through capillaries leads to cancer cell lysis by shear forces [20]. Because only a few cancer cells end up seeding a metastatic site, a recent hypothesis that micrometastases (defined as metastatic tumours that are not clinically detectable) arise from cancer stem cells has been proposed [19, 21]. This hypothesis is currently under investigation in a variety of laboratories looking at many different tumour types. One of the challenges to studying metastasis is the lack of good animal models that completely recapitulate the metastatic process. However, this is changing as investigators develop new approaches that utilize genetically engineered mouse models (GEMM) and patient-derived xenografts (which use fresh patient tumours implanted directly into mice) to study the metastatic process [22, 23].

Direct dissemination to body cavities and surfaces

Direct dissemination of cancer cells into body cavities occurs when cancer grows through the target organ and into a body cavity; for example, the penetration of the colonic serosal layer by colon carcinoma leads to peritoneal dissemination. Pleural effusions and peritoneal dissemination are the most common metastases to represent direct ways in which cancer cells spread into a body cavity [1], and peritoneal dissemination is a common feature of ovarian cancer.

Molecular pathways involved in invasion and metastasis

A detailed discussion of the molecular pathways implicated in metastasis is beyond the scope of this chapter. However, a representative list of these molecules and pathways is provided in Table 7.2 along with references that discuss them in detail.

Clinical implication of metastasis

The kinetics of metastasis development varies in different tumours. For example, breast cancer metastasis can arise 10 to 15 years after primary tumour resection [24], leading some investigators to hypothesize that metastatic cells in breast cancer lie dormant (see below). In contrast, pancreatic cancer often demonstrates a very short time (<1 year) between primary tumour detection and clinical manifestation of metastasis. In general, tumour size, depth of cancer cell invasion, and, in some cancer types, necrosis (which correlates with tumour size) are considered to be valuable clinical predictors of increased risk for metastasis. The larger and more invasive the primary malignancy, the greater the probability of metastasis. For example, gastric carcinomas with progressively more invasion to mucosal, submucosal, muscle, and serosal layers have an increasing incidence of lymph node metastasis (5%, 23%, 52%, and 82%, respectively) [25–27].

Malignant primary tumours in human vital organs (brain, lung, liver) can lead to patient death because of primary tumour growth; however, the majority of cancer deaths (>90%) occur in patients with metastatic disease [28]. Many of these patients do not die from their tumour burden but rather from complications associated with metastatic disease. For example, approximately 30% of cancer deaths are caused by cachexia [29], a wasting syndrome, which develops in advanced stages of cancer and is therefore associated with metastasis. Cachexia is characterized by anorexia, progressive

Table 7.2 A representative listing of molecules and pathways involved in metastasis

loss of body fat and muscles, weakness and anaemia [30]. Patients with cachexia have decreased survival due to a loss of total body protein, leading to significant impairment in respiratory and heart muscle function [30]. In contrast to starvation, providing extra calories does not reverse the loss of fat and muscle in cancer patients with cachexia; the mechanism of cachexia is not well understood. In other cases, metastasis leads to cancer-related death due to the failure of organs affected by progressive metastatic disease (lungs, liver, and brain).

Lung metastasis

Metastasis to the lung is common in different types of carcinoma (Table 7.1). Sarcoma metastasizes almost exclusively to the lungs [1] and the incidence of lymphoma metastasis to the lung is increasing as these patients live longer due to improvements in therapy [31]. In many cases, there are no lung-related symptoms when lung metastases are detected. However, the symptoms of lung metastases can include chest pain, bloody sputum, cough, and shortness of breath. Complications of lung metastases include pneumonia, bleeding, respiratory failure, collapsed lung, and formation of effusions.

Liver metastasis

The colonization of cancer cells in the liver leads to progressive liver damage. Liver metastases can block bile ducts, leading to jaundice and intoxication. Liver metastasis is generally not curable [32] although surgery and local and systemic treatment of metastatic lesions has led to improved clinical outcomes with five-year survival now approaching 25–40% when surgery and chemotherapy

are combined [33]. Life-threatening complications of liver metastasis include hepatic failure and bleeding.

Brain metastasis

Metastases in the brain are the most frequent intracranial tumours [34, 35]. Clinical symptoms of brain metastasis develop in up to 10% of cancer patients [35]. These include seizures, headache, and neurological deficits. Brain metastases originate from lung cancer (50%), melanoma (20%), and breast cancer (25%) [35]. Brain metastases are typically located in the cerebral hemispheres (80%), cerebellum (15%), and brainstem (5%). Multiple brain metastatic lesions are detected in most of patients at the time of diagnosis of brain metastasis. The development of novel therapeutic approaches for the treatment of brain metastases remains a challenging task because the blood–brain barrier (BBB) is often not penetrated by systemically delivered drugs, and patients with brain metastases are typically excluded from clinical trials testing novel anticancer agents. Most brain metastases are not curable, although palliation with radiation therapy is utilized to improve quality of life.

Bone metastasis

Bone metastases are detectable in over 50% of patients who die of cancer [36]. There are two types of bone metastases: osteoclastic (breast cancer, lung cancer, multiple myeloma, some prostate cancer) and osteoblastic (prostate cancer). Reciprocal interactions are observed between tumour and bone cells in osteoclastic (osteolytic) lesions where cancer cells secrete factors that activate osteoclasts leading to degradation of the bone matrix, which releases growth factors to stimulate cancer cells to secrete more of these factors [19]. Osteoblastic metastases activate osteoblasts, leading to abnormal bone formation. Clinical signs of bone metastasis include severe pain, bone fractures, anaemia, affected mobility, and spinal cord compression. Osteolytic metastasis can also lead to life-threatening hypercalcaemia.

Peritoneal dissemination (carcinomatosis)

The peritoneum is a common site for surface metastasis in ovarian and gastrointestinal cancers with median survival of <6 months once they occur [37, 38]. Peritoneal dissemination may not produce any unusual symptoms in its early stages. Ascites is a typical feature of progressing peritoneal dissemination and may cause abdominal pain, breathing problems, loss of appetite, nausea, and constipation. Cytological analysis of ascitic fluid is performed to confirm peritoneal dissemination.

Metastatic dormancy and outgrowth

Following complete remission or maximum apparent shrinkage of tumours post-treatment, micrometastases can already be expected to be established at various distant sites, and a fraction of these are in microenvironments which are or will become permissive for outgrowth. These micrometastases contain live tumour cells that have survived chemotherapy, and may remain dormant through the course of treatment and for prolonged periods thereafter. Even in patients who undergo curative resections of early-stage disease, some will have recurrent metastatic

disease suggesting that micrometastatic disease was already present at the time of surgery [39]. Since metastatic outgrowth is the major cause of cancer death, the mechanisms by which these cancer cells persist over long periods of time in ectopic sites is of great importance, because the characteristics which allow these cells to survive also enable their outgrowth as new conditions evolve, often with enhanced malignancy and resistance to treatment that is associated with relapse [40, 41]. Dormant tumour cells may have been refractory to treatment because they are not dividing or they may express active drug resistance mechanisms which protect them from therapy. Thus, a deeper understanding of the mechanisms underlying dormancy presents an unmet therapeutic opportunity. This would also allow development of probes which home to dormant cells to detect their specific locations in patients who harbour them.

Three categories of molecules may be classified according to their contribution to metastasis and some of these are summarized in Table 7.2: (1) molecules which initiate metastasis through imparting an advantage in cell escape and invasiveness; (2) molecules providing an advantage in survival at the ectopic microenvironment; and (3) molecules promoting progression at those sites ('soil') by enhancing angiogenesis, stromal contributions to metastatic progression, or immune evasion [42]. Metastases that arise soon after primary tumour ablation likely derive from disseminated tumour cells (DTC) which have spread recently from an advanced tumour, then progress linearly at their new location. Micrometastases that remain dormant for long periods may be recent DTCs which are halted in their new setting or they may have originated from an early stage of the tumour, and then progressed in parallel. Owing to selection pressure and genetic instability, parallel progression of the DTC predicts independent disparate accumulation of genetic and epigenetic changes. These would vary among DTC according to their times of original dissemination and according to the niche in which they land, leading to heterogeneity. Genetic diversity, growth rate, and death rate in the examination of patients and their metastatic samples in relation to primary tumour stage are consistent with the parallel progression hypothesis in cases of long-term dormancy [43]. In the period of dormancy where micrometastases are present but are not clinically apparent, the mechanisms responsible for tumour cell dormancy and ultimate outgrowth are not well understood. However, based on both experimental and clinical information, two general mechanisms have been postulated. In the first case, tumour cells are thought to exist in a quiescent solitary state that is resistant to therapies directed against rapidly dividing cells [44]. Thus, in the case of adjuvant treatment, these cells would survive. The conversion of quiescent solitary cells into progressive disease may depend on the rate of accumulation of genetic changes. In the second case, small tumour cell clusters do proliferate but are balanced by a rate of apoptosis that gives no net increase in tumour size. These may remain in a state of zero net growth for long periods of time. Dormant tumours that begin to progress may experience outgrowth that occurs more rapidly and can be attributed only to new additional genetic changes [45]. This suggests that other mechanisms contribute to metastatic progression once dormant tumour cells are activated, such as the regulation of dormancy through the interaction of micrometastatic tumour cells with their microenvironment ('soil').

Tumour microenvironment and metastasis

DTCs interact with ECM, and their survival and ultimate progression to metastatic disease may be influenced by cross-talk with stromal cells, endothelial cells (EC), and endothelial progenitor cells (EPC) during angiogenesis, and interactions (or suppression of interactions) with immune system cells. It is likely that all of these contribute to the escape of a micrometastasis from dormancy, and each probably represents new opportunities for therapeutic targeting. For example, in the microenvironment invasion model, the genetic alterations in a tumour cell initiate transient changes in stromal gene expression [46] through epigenetic or phenotypic changes, and these could contribute to the progression of metastasis. Conversely, the failure of tumour cells to engage their environment may lead to their quiescence. New 3D cell culture systems comprised of basement membranes depleted of growth factors have been used to recapitulate transitions to or from dormancy, showing how ECM components can first impose signals inhibiting growth. In these model systems, dormant metastatic tumour cells show a unique cytoskeletal organization with minimal adhesive interactions with the ECM, but the switch to proliferation is accompanied by internal cytoskeletal rearrangements in the tumour cell and new interactions with ECM associated with the formation of actin stress fibres. In this switch to proliferation, actin stress fibres are formed through β1 integrin signalling that leads to myosin light chain phosphorylation. This requires fibronectin (FN) secretion by the tumour cells, which then mediates the interaction to the α5β1 integrin [47], inducing the switch from quiescence to malignant growth. In fact, dormant cell lines in this model system could be induced to aggressive behaviour by the simple addition of FN to the 3D milieu. In another study looking at dormancy in a model of head and neck cancer, increased urokinase plasminogen activator receptor (uPAR) and its binding to α5β1 integrin led to increased fibronectin fibril formation and tumour cell proliferation, whereas down-regulation of uPAR led to reduced signalling via α5β1 integrin and induced dormancy. Assembly of fibronectin fibrils via the uPAR-α5β1integrin interaction activates the Ras/ERK pathway and abrogates growth arrest [48].

In general, normal tissue architecture, intact ECM components, and protease inhibitors are suppressive of cancer cell outgrowth. Myoepithelial cells, fibroblasts, and immune system cells such as macrophages likewise initially resist tumour progression. However, these cells exhibit plasticity and. under the influence of cross-talk with cancer cell signals in the complex stromal milieu described above, can become significantly altered to create a tumour-permissive or enhancing environment.

Premetastatic niche

For many years, tumour stromal cells were thought to be mere observers in cancer progression, with tumour cells being the major driver in cancer progression. An abundance of evidence now indicates that tumours are complex systems with cancer-associated fibroblasts (CAFs), endothelial cells, and immune cells acting in concert to promote cancer progression and metastasis [49]. Two distinct populations of cells contribute to the progression of metastatic disease: the first is comprised of resident stromal cells and includes fibroblasts and endothelial cells; the second is derived from bone marrow precursors and includes macrophage,

neutrophils, mast cells, myeloid derived suppressor cells (MDSC), and progenitor cells [50]. In many tumours, the microenvironment is characterized by a chronic inflammatory state with prominent infiltration of bone marrow derived cells, including neutrophils, lymphocytes, and macrophages. Over time, this chronic inflammatory state undergoes cross-talk with the tumour cells to promote the transformation of normal stromal cells to tumour-associated cells that further contribute to metastatic progression [51]. Many of the molecules and pathways listed in Table 7.2 are implicated in this pathway including chemokines, proteases, cell-surface adhesive proteins, and the tumour ECM.

The immune system has a dual role in the development of cancer and metastasis [52]. Under normal conditions, most immune cells are tumour suppressive. In the tumour microenvironment, immune cells can be recruited and co-opted by the tumour to promote local invasion, angiogenesis, and metastasis. Tumour-associated macrophages (TAM) are a key player in this process and a growing body of evidence supports the role of TAM in tumour invasion, tumour growth, tumour angiogenesis, and metastasis by producing chemokines and growth factors, secreting proteases, and directly interacting with other tumour cells [53]. Further, the role of TAM may depend on its local environment, with individual subpopulations of TAMs promoting angiogenesis or invasion [54]. TAMs are attracted to a tumour by colony-stimulating factor CSF-1 and their increased infiltration into a tumour correlates with poor survival. While class M1 macrophages may initially resist tumour expansion, recruited M2-type TAMs enhance progression, as they secrete matrix metalloprotease-9 (MMP-9), which releases matrix-bound VEGF-A to promote angiogenesis. Identification of unique TAM genes in M2 (not found in MI types) may provide targets for maintaining dormancy. Mast cells, another type of immune cell, are attracted to tumour by monocyte chemotactic protein (MCP-1) and are also associated with poor prognosis. Mast cells are an abundant source of VEGF, bFGF, and TNFα [55], which can drive angiogenesis.

Immune suppression has a principal role in the development of metastasis. Particularly important to this immunosuppression are myeloid derived suppressor cells (MDSC), which are present in tumours, peripheral blood, the lymph nodes, and bone marrow of cancer patients and preclinical cancer models [56]. MDSC are CD11b+ immature bone marrow derived cells that suppress CD4+ and CD8+ T-cells, increase regulatory T-cell levels, and inhibit natural killer cells. Since MDSC are a heterogeneous population of cells, eliciting their exact role has been challenging. Peripheral blood MDSC have been identified in many solid tumours, and increased peripheral blood MDSC is associated with advanced stage and certain chemotherapy regimens [57]. The combination of permissive stromal microenvironment and the recruitment of MDSC to this microenvironment generates a premetastatic niche that is favourable to the outgrowth of metastases. This premetastatic niche is characterized by the presence of the CD11b+MDSC that allows metastatic tumour cells to seed and proliferate through the suppression of the immune system.

In addition to TAM and MDSC, other critical intermediaries that regulate tumour progression include various bone marrow derived progenitor cells. Bone marrow (BM) is a rich reservoir of haematopoietic and other types of progenitor cells stem cells that are anchored to the endosteal surface. Once the premetastatic niche is seeded by tumour cells and metastatic outgrowth begins,

these tumours begin to secrete soluble growth factors which promote the mobilization of progenitor cells into the circulation, which are then recruited to the tumour via chemo-attractant gradients. Stress from tissue injury (e.g., surgical resection of tumour) or remodeling, such as occurs when tumour cells seed a niche, leads to release of angiogenic factors, including VEGF, which mobilize these stem cells to the circulation. VEGF interacts with its receptors, expressed on endothelial stem cells, and thereby promotes recruitment of these endothelial precursor cells (EPC), also called circulating endothelial progenitors (CEP) to neo-angiogenic sites [58]. It has been proposed that these EPC are initiators of tumour angiogenesis and required for metastatic outgrowth [59]. EPC are thought to merge with the wall of growing blood vessels and then differentiate into EC. EPC are key contributors to the growth of small tumours but appear less critical for angiogenesis once tumour vessels are more established [60]. In a direct study of full thickness skin wounds in mice, EPC were found to peak at day 3 following wound creation [61]. Thus, in patients undergoing surgical or radiation ablation of tumour, the trauma effect on EPC mobilization may lead to a period of days or weeks with enhanced angiogenic sensitivity to drive small-tumour outgrowth. This implies that brief anti-angiogenic treatment may be a reasonable anti-metastatic strategy following surgical cancer resection [62]. In addition, typical cancer treatment with cycles of chemotherapy delivered at the maximum tolerated dose (MTD), followed by rest periods for recuperation of damaged tissues, has actually been found to induce increased levels of circulating EPC and mobilization during these necessary pauses, mimicking the rebound of neutrophils after their ablation by chemotherapy. EPC arrival and integration at sites of minimal residual disease stimulates local angiogenesis and can facilitate tumour repopulation, and may also stimulate otherwise dormant tumours to grow. In lymphoma xenografts, MTD dosing of cyclophosphamide with 21-day rest cycles was compared with lower doses delivered more frequently and not including recovery periods. The latter 'metronomic' regimen gave a more durable tumour response with consistent reduction in EPC while the MTD regimen showed robust increases in EPC after the end of each treatment cycle, and rapid development of tumour resistance [63]. In a review of many similar model studies, it was concluded that anti-VEGF agents given before the post-chemotherapy EPC spike can effectively blunt the surge of EPC observed in the rest cycle and may therefore limit metastatic outgrowth at its earliest stages. Additional evidence to this effect comes from studies of paclitaxel, which induces EPC mobilization via release of CXCR4 stores from platelets. Tumour response to paclitaxel therapy was demonstrated to be superior in Id mutant mice, which can make all normal BM cells but lack EPC mobilization, compared to wild-type mice, consistent with EPC enhancement of malignancy [64]. Since MTD cyclic dosing of at least some chemotherapeutic drugs seems to create tumour rebound driven at least in part by a pro-angiogenic surge, several strategies are being examined to counter this clinically. One is to include anti-angiogenic therapy during rest cycles of chemotherapy [65], and metronomic dosing has already proven to be superior to MTD dosing in several cases [66]. Another is to include metronomic dosing in combination with an antiangiogenic agent (e.g., pazopanib), although such strategies may be most pragmatic when both agents are orally available since they will be taken daily [67, 68].

In addition to co-opting immune cells and recruiting BM-derived cells to promote metastatic progression, tumour cells alter the gene expression of fibroblasts in their microenvironment, which reciprocate in turn. Fibroblasts are highly abundant in the stroma of tumours. Xenograft studies indicate that about one-third of cancer-associated fibroblasts (CAFs) originate from recruited precursors from bone marrow. Secretion of TGFβ also 'educates' resident fibroblasts to become CAFs, and many of these show epigenetic changes that are significantly mediated by microRNAs (miRs). MiRs with 19 to 25 nucleotides regulate gene expression post-transcriptionally by hybridizing to complementary sites in untranslated regions of target genes, leading to inhibition of transcription, or increased mRNA instability, leading to more rapid mRNA degradation. These miRs may function as oncogenes or tumour suppressors. MiRs can also be shed in exosomes of the plasma membrane and taken up by neighbouring cells, a key method of cell–cell cross-talk. Different miRs are dysregulated in CAF derived from a variety of cancers. Thus, it is likely that CAF and tumour cells reciprocally influence each other via exchange of miRs in addition to signals mediated via adhesion, junctional contact, and proteases, as discussed above. Breast cancer cells (BCC) which have metastasized to the BM can be very aggressive and resistant to treatment, with poor prognosis, although BCC can remain dormant for many years before undergoing metastatic progression. However, this suggests that their coexistence with BM stroma is thus important. At least four miRs have been identified which are delivered to these cells from BM stroma and target the stimulatory chemokine CXCL12 (aka SDF-1, stromal derived factor-1). The miRs move from stroma to BCC with the aid of gap junction proteins like connexin 43 to down-regulate expression of the growth stimulatory chemokine to maintain quiescence. When these miRs eventually fail to be secreted, BCC can grow. Exogenous delivery of the most potent of these, miR-197, might represent a future approach to restoring lost dormancy as a maintenance strategy in the treatment of metastatic breast cancer [69].

Circulating tumour cells

Circulating tumour cells (CTCs) were first described in a report dating from 1869 [70] and have been extensively studied because of their presumed role in the dissemination metastatic disease. To date, circulating tumour cells have been identified in many tumour types including breast [71], prostate [72], colorectal [73], and others [74]. The presence of circulating tumour cells has been correlated with disease progression and decreased survival in breast, colorectal, and prostate cancers. The number of CTCs increases with disease progression and CTCs have been identified early in the course of disease, prior to the detection of metastatic disease, but not all patients with CTCs have metastatic disease. This suggests that the sub-population of CTCs that can establish metastasis is a fraction of the total isolated CTCs and that some CTC may simply be shed cells with no metastatic potential. The recent advent of single cell profiling of CTCs has demonstrated heterogeneity of CTCs in several metastatic cancer types including breast cancer and castrate-resistant prostate cancer [75, 76], which supports the hypothesis that not all CTCs are metastatic. A commercial assay (CellSearch®, Veridex®) for the isolation and quantitation of CTCs is FDA approved for metastatic prostate, breast, and colorectal cancer patients. However, routine evaluation of CTC burden (liquid

biopsy) is not yet recommended in NCCN or ASCO guidelines. Nevertheless, being able to study CTCs at the single cell level is expected to yield new insights into metastatic disease in the future.

Treatment of metastatic disease

Despite years of progress in cancer therapy, curative treatments are not available for the majority of patients with metastatic solid tumours. Curative therapies have only been identified in a few metastatic cancer types including testicular cancer, choriocarcinoma, and papillary thyroid cancer [77]. Reports of successful treatment of diffuse metastatic disease date back to the 1950s [78]. Choriocarcinoma, which occurs most commonly after a molar pregnancy, was the first tumour to be cured with a combination of chemotherapy, radiation, and surgery. Testicular germ cell tumours are the most common solid tumour in young men (ages 15–35) [79]. Combinations of cisplatin-based chemotherapy, surgery, and radiation therapy have drastically improved the prognosis of these tumours. Several subtypes of thyroid cancer that avidly uptake radioactive iodine are also curable after metastasis [80]. Treatment with radioiodine relies on the unique physiology of the thyroid follicular cell and is not beneficial for the treatment of other tumour types. The early success in treating the tumour types described above led to the hypothesis that other chemosensitive tumours would be curable after identification of an appropriate chemotherapeutic regimen, a prediction that unfortunately has not come to fruition [81].

Despite the limited progress towards the cure of patients with metastatic solid tumours, notable progress has been made in the treatment of subsets of patients with metastatic breast, colorectal, and prostate cancers. Newly developed molecularly targeted chemotherapy, aggressive surgical management of liver metastasis, and the development of new local-regional cancer therapies have all contributed to this end. These management strategies are described in detail elsewhere in this volume.

The development of molecularly directed breast cancer therapies has improved the prognosis of most breast cancer patients, including tumours that over-express the estrogen, progesterone, and HER2/neu receptors. HER2/neu overexpression was considered to be a poor prognostic factor for the 20–30% of patients where it is over-expressed. The development of trastuzumab (Herceptin®, Genentech), a humanized monoclonal antibody against the HER2/neu antigen (member of the ErbB/EGFR family) drastically improved the prognosis of this disease. Treatment with trastuzumab as a single agent results in complete or partial response in about 25% of patients with HER2 positive metastatic metastatic breast cancer [82], while combination therapy of docetaxel and trastuzumab increases the complete or partial response to 72% [83]. Despite this impressive efficacy, most patients eventually progress on trastuzumab therapy, though a minority (9% in a recent report) has a durable complete response of greater than five years [84]. This subset of patients suggests that further gains in the treatment of HER2-positive cancers are possible and include: the development of antibodies against additional EGFR family members with synergistic activity with trastuzumab; the development of a trastuzumab drug conjugate; and the development of HER2-targeted nanoliposomes containing doxorubicin.

The first site of metastasis is the liver for a majority of patients with colorectal cancer. Patients with metastatic colorectal cancer (MCRC) are treated with combinations of 5-fluorouracil and

oxaliplatin (FOLFOX) or irinotecan (FOLFIRI) [85]. More recently, monoclonal antibodies against VEGF and EGFR have been added to these regimens with increased progression-free survival. While many patients initially respond to chemotherapy, and patients may even achieve a complete clinical response from chemotherapy, recurrence and eventual disease progression is likely. Surgical resection of colorectal metastasis can be attempted if there is complete resection with adequate liver reserve and survival for these patients ranges at 30–50% at five years, though not all patients are surgical candidates [86]. Neoadjuvant chemotherapy can also be utilized to reduce disease burden prior to surgery. More recently, techniques have also been utilized to reduce metastatic disease burden prior to surgery and for palliation. These include transarterial chemoembolization or Y-90 brachytherapy [87].

While the prognosis of some cancer patients has improved, other solid tumours remain refractory to curative therapy. These include pancreatic, ovarian, lung, and many others. Many factors contribute to the dearth of effective treatment options for these therapies including poor drug delivery to metastatic tumour sites, development of resistance, and progressive immune dysfunction [88]. Pancreatic adenocarcinomas are difficult to treat because of their hypovascular and fibrotic nature [89]. This relatively low vascularity impairs drug delivery to pancreatic cancers, which is thought to contribute to the poor prognosis. Moreover, pancreatic tumours are often asymptomatic and patients are frequently inoperable because of invasion of local structures and liver metastasis by the time they present and their disease is diagnosed. However, even with optimal surgical management, the overall survival of pancreatic patients remains dismal.

Most newly diagnosed ovarian cancer and small-cell lung cancer patients respond to cisplatin-based therapies, but these tumours rapidly acquire resistance to these therapies [90]. These include increased expression of glutathione, increased activity of DNA-repair pathways, increased drug efflux through export proteins, mutations in target enzymes, and loss of apoptosis pathways and other mechanisms, all of which contribute to metastasis of these cancer types. Another factor that contributes to the failure of therapy is the late diagnosis of both small-cell lung cancer and ovarian cancer, given that both are asymptomatic until late in progression and no screening tests are available [91].

Evidence that adjuvant chemotherapy and adjuvant radiotherapy can prevent the development of metastatic disease supports the hypothesis that drugs are most effective at treating micrometastasis. The American College of Surgeons Oncology Group Z0011 trial demonstrated equivalent survival in early-stage breast cancer patients with positive lymph nodes who undergo lumpectomy with whole breast radiation and systemic therapy at the discretion of their physician combined with either complete axillary lymph node dissection or no further treatment [53]. This study suggests that micrometastatic disease in the setting of the breast can be successfully treated using the combination of radiation and chemotherapy.

There is substantial effort ongoing in both academia and industry to discover and develop new drugs to treat metastatic disease that are based on the explosion of new knowledge of the molecular pathways that drive metastatic progression. These include agents targeted at a variety of kinase targets and signalling pathways, epigenetic signalling, oncogenes, targeted chemotherapy, and novel cytotoxic agents. Some of these new drugs used in mid- and late-stage clinical trials are summarized in Table 7.3 (not intended

Table 7.3 A sampling of new drugs in development for metastatic cancer

Type of drug	Name	Target or mechanism of action	Indication
Kinase inhibitors	regorafenib	VEGFR, FGFR, RET, PDGFR	mCRC
	selumetinib	MEK	melanoma
	vandetanib	EGFR	NSCLC
	pazopanib	VEGFR-1, -2, -3, PDGFR	RCC
	ibrutinib	Bruton's tyrosine kinase	Mantle cell lymphoma
Epigenetic modulators	panobinostat	HDAC	various
	belinostat	HDAC	various
	SB939	HDAC	Prostate cancer
Targeted chemotherapy (ADC)	T-DM1	HER2 targeted cytotoxic agent	Breast cancer
Other targeted agents	Brentuximab vedotin	CD30	Various lymphomas
	ASG-5ME	SLC44A4	Pancreatic, gastric
	Lorvotuzumab mertansine	CD56	SCLC
	rilotumumab	c-Met	Gastric cancer
	figitumumab	IGF-1R	various
Novel cytotoxics	epothilones	Microtubule targeting agnets	various
	ARW501	DNA damage check point inhibitor	pancreatic
	S1	DPD inhibitor	various

to be all-inclusive but merely representative) with a brief description of their mechanism of action.

CHAPTER 8

Genetic instability

Jennifer Wilding and Walter Bodmer

Introduction to genetic instability

DNA integrity is constantly under threat from both exogenous and endogenous DNA-damaging agents as well as from errors that occur during DNA replication and the distribution of chromosomes between daughter cells during cell division. Complex mechanisms have evolved to identify and repair damaged or incorrectly copied DNA, and it is the disruption of these mechanisms that can lead to genetic instability and, ultimately, cancer.

Normal cells are estimated to make errors approximately once every 10^4 to 10^5 nucleotides, but the vast majority of these are corrected through proofreading and mismatch repair (MMR) mechanisms, resulting in a mutation rate of approximately 10^{-8} per base per cell division [1, 2]. In addition to errors during DNA replication, changes such as deamination, depurination, alkylation, oxidation, and DNA breaks induced by reactive oxygen species (ROS) can also result in errors in the DNA sequence (reviewed in [3]). Exogenous factors, such as UV light, ionizing radiation (IR), and chemical exposure add to the burden of DNA damage with which cells must cope. Repair pathways that specialize in the repair of DNA lesions or base pair mismatches include:

- nucleotide excision repair (NER)
- base excision repair (BER)
- mismatch repair (MMR).

Repair of double-strand DNA breaks is accomplished via recombinatorial repair pathways involving:

- homologous recombination (HR)
- interstrand cross-link (ICL) repair
- non-homologous end joining (NHEJ).

In addition to the repair of small-scale DNA damage, chromosomal integrity and ploidy are protected by pathways that regulate chromosome segregation and centrosome duplication during cell division.

This chapter will give a very brief summary of the main features of the major DNA damage response and repair pathways and the nature of the different types of genetic instability that have been observed in human cancers (Figure 8.1). We will discuss the difference between genetic instability arising in germline predisposition syndromes compared to genetic instability in sporadic cancers, and the meaning of these distinctions with regard to the ongoing debate over the necessity (or lack thereof) of genetic instability for the development and progression of all cancers. Finally, we offer an overview of some of the possible mechanisms through which sporadic cancers may become genetically unstable.

It is widely quoted that most cancers exhibit some form of genetic instability at either the nucleotide or chromosome level. Genetic instability at the nucleotide level includes microsatellite instability (MIN/MSI+/RER+) in addition to the comparatively seldom cited and poorly understood phenomenon of point mutation instability (PIN). Genetic instability at the level of the chromosomes is referred to as chromosome instability (CIN) and is characterized by the accumulation of structural chromosome changes. Aneuploidy describes changes in chromosome number, but the term CIN is often used to encompass a wider range of changes in chromosome number and/or structure.

Germline mutations in DNA repair genes commonly confer a much higher than normal risk of development of cancer in an affected individual (but only when they are homozygous). Given that germline mutations in DNA damage response genes give rise to cancers that are genetically unstable, and that most sporadic cancers are also perceived to exhibit genetic instability, it is tempting to speculate that genetic instability is a driving force for the development and progression of all cancers because it accelerates the accumulation of potentially oncogenic mutations. There has been much debate as to whether it is absolutely required for cancer development or whether the genetic instability is simply a byproduct/bystander effect of selection for some other crucial mechanism such as escape from apoptosis [4, 5].

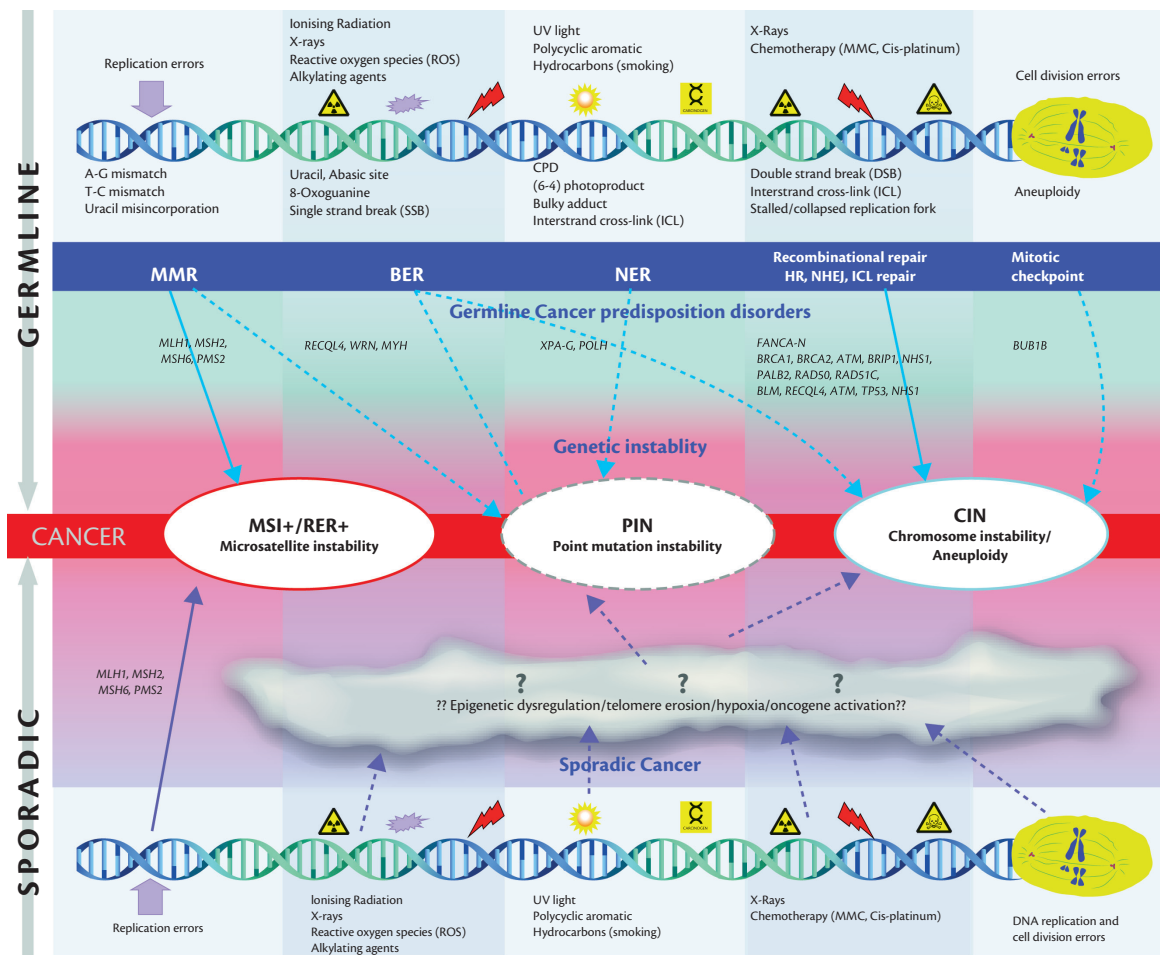
We can gain crucial insight into the nature of genetic instability by comparing its perturbation in inherited and sporadic cancers. Most heritable cancer predisposition syndromes are recessive, meaning that both copies of the DNA repair gene are mutated in every cell in these patients (Figure 8.2). No further event is needed to cause genetic instability in the cancer: the defect is present in all cells, hugely increasing the chance of developing the cancer through selectively advantageous mutations. However, it is important to note that heterozygote germline carriers for recessive cancer predisposing syndromes are not generally at any higher risk than the normal population of developing cancer. This is despite the fact that, in these cases, every cell harbours a mutation in one of the DNA repair genes and therefore has a theoretically much higher potential for genetic instability (through a single further somatic mutation in any cell). For genetic instability to arise through similar gene inactivation in a sporadic cancer requires two sequential inactivating mutations in a given DNA damage response or mismatch repair pathway gene in the same individual somatic cell. The crucial difference between the two is that while genetically unstable cancers arising in germline cancer predisposing conditions can be explained through mutation of DNA repair genes, these genes are rarely mutated in the sporadic cancers that exhibit similar modes of genetic instability [6–9].


Fig. 8.1 Pathways to genetic instability in germline and sporadic cancers. The figure illustrates from the top-down, the origin of DNA damage, the repair pathway affected, and the nature of resulting genetic instability arising through inactivation of respective pathways in germline cancer predisposing syndromes. The parallel mechanisms leading to sporadic cancers are illustrated from the bottom up. Whilst germline and sporadic cancers are subject to the same errors of replication and sources of DNA damage, with activation of the same damage response pathways and similar features of genetic instability, the genetic nature of the perturbation of the respective pathways is well characterized in germline cancers, but remains elusive in sporadic cancers. DNA repair mechanisms are differentially activated depending on the nature and location of the DNA damage. Solid lines linking affected DNA repair pathways to specific types of genetic instability indicate clearly defined and well characterized mechanisms, whereas dashed lines indicate an inferred mechanism through which the observed instability is achieved. Dashed outline for PIN indicates a less well-defined form of genetic instability.

Abbreviations: MMR, mismatch repair; BER, base excision repair; NER, nucleotide excision repair; HR, homologous recombination; NHEJ, non homologous end joining; ICL, interstrand cross link; UV, ultraviolet; MMC, mitomycin; CCPD, cyclobutane pyrimidine dimers; HNPCC, hereditary non-polyposis colorectal cancer; MAP, MYH associated polyposis; MSI+, microsatellite instability; RER+, replication error positive.

Perhaps we need to question whether or not it is fair to claim that most sporadic cancers display some form of genetic instability. It is important to point out that genetic instability is defined by an increase in *rate* (compared to normal) of generation and accumulation of mutations or changes in chromosome number or structure. The presence of large numbers of mutations or structural/numeric chromosomal changes provides no information regarding the rate at which they were generated nor whether they reflect a current state of genetic instability.

Is it really the case that cancers nearly always exhibit features of *instability*, or is the number of mutations/CIN/aneuploidy observed in any particular cancer more or less what could be expected simply from Darwinian selection of mutations that have occurred at no higher a rate than normal? The incidence of certain mutations that are selected for is necessarily much higher than would be predicted from the mutation rate alone. It is only the incidence of 'neutral' or

bystander mutations that should give some estimate of the mutation rate. Additionally, somatic mutation rates are not at all well defined. These are mostly based on mutations identified from a mixture of uncloned cells, where only mutations common to the majority of cells are detected (in contrast to the tumour, which is clonal) and so do not give valid estimates of the mutation rate [4]. There is, in fact, evidence that a sizeable proportion of at least some cancers do not display any form of genetic instability. For example, a subset of colorectal cancers termed MACs (microsatellite and chromosome stable) has been identified and accounts for up to one-third of all sporadic colorectal cancers [10–13]. This, in itself, argues strongly against a genetic requirement of instability for the development of cancer.

Results from recent whole-genome and -exome sequencing of individual cancers provide some further insight. For example, the recent TCGA study determined that more than 80% of 224
Fig. 8.2 Genetic mechansims leading to genetic instability in germline and sporadic cancers.
Abbreviations: HNPCC, hereditary non-polyposis colorectal cancer; AT, ataxia telangiectasia; BLM, Bloom syndrome; XP, xeroderma pigmentosum; FA, Fanconi anaemia; RER+/MSI+, replication error positive/microsatellite unstable.

colorectal cancers had acquired a median number of 58 non-silent mutations [14]. Does that number reflect a background of genetic instability? Without knowing the length of time each of those cancers has taken to manifest, it is hard to approximate a rate of mutation necessary to account for the observed numbers of mutations in any particular cancer. Further arguments against the requirement of genetic instability are supported by mathematical models, which show that genetic instability is not necessary for accumulation of the requisite number of mutations for a cancer to develop [15]. For example, lack of an increase in mutation rate (up to 1000 times higher in genetically unstable tumours) can be compensated for by a similar-fold increase in cell number such that the overall likelihood of accumulating each new mutation would be similar in a genetically stable tumour that has undergone clonal expansion [5]. In addition, the basic role of natural selection in the evolution of a cancer is often overlooked: the selective advantage conferred to the cell which acquires the initial inactivating mutation in one of the components of a DNA repair pathway cannot feasibly be related to the increase in mutation rate in subsequent progeny. Rather, there must be an advantage, such as escape from apoptosis, from which the initiating cell derives a selective advantage. It may well be that a basic requirement of all cancers is that in the early stages they overcome apoptotic signals, and that the simplest mechanism through which this can be achieved is via inactivation of DNA repair signalling pathways. Thus, even if genetic instability is present in a sporadic cancer, this may simply be a byproduct of the requirement for escape from apoptosis. Although the issue is key to understanding the role of genetic instability in cancer, this

chapter will not further attempt to address the question of how common true genetic instability is in sporadic cancers, but rather to give an overview of the types of genetic instability that may occur, and the mechanisms that might give rise to them in both sporadic cancers and those arising as a result of germline mutations in key genes.

Genetic instability at the nucleotide level

Mismatch repair pathway and microsatellite instability

The most clearly understood form of genetic instability at the nucleotide level in human cancer arises through inactivation of the MMR pathway. It is significant that it is the only form of genetic instability seen in a range of both germline and sporadic cancers that can be explained through the inactivation of the key genes in the relevant pathway.

MMR plays a crucial role in maintaining the fidelity of the genome by repairing DNA replication errors such as base–base mismatches and insertion/deletion loops that can occur during DNA synthesis. The MMR process is reported to improve the fidelity of DNA replication by 100- to 1000-fold and to reduce the replication error rate to one per 10^{10} bases [16]. The MMR system is comprised of several subunits including *MSH2* (mutS homolog 2) on chromosome 2p16, *MLH1* (mutL homolog 1) on chromosome 3p21, *MSH6* (mutS homolog 6) on chromosome 2p16, and *PMS2* (postmeiotic segregation 2)

on chromosome 7p22. These assemble to form two heterodimeric complexes: MSH2-MSH3 (MutSβ), which preferentially recognizes and binds to larger insertion/deletion loops, and MSH2-MSH6 (MutSα), which recognizes smaller insertion deletion loops as well as single base-pair mismatches [17–20]. MLH1 and PMS2 then heterodimerize and interact with the MSH2-containing heterodimers and recruit other proteins (including PCNA) required for the repair process.

Hereditary non-polyposis colorectal cancer (HNPCC), also known as Lynch Syndrome, is an autosomal dominant condition characterized by germline mutations in one of the DNA MMR genes. DNA repair is not impaired in the heterozygous state, but somatic alteration of the remaining copy of the normal gene results in the increased rate of accumulation of mutations in mono-, di-, and trinucleotide repeats throughout the genome.

Patients have an estimated 80% lifetime risk of developing colorectal cancer and an increased risk of developing a wide range of other malignancies including ovarian, gastric, brain, pancreatic, endometrial, biliary, small bowel, and urinary tract cancers [21]. Approximately 70% of germline mutations in HNPCC patients occur in either MSH2 or MLH1, whereas mutations in MSH6 are usually associated with an increased risk of endometrial cancer.

Loss of MMR function typically occurs through a combination of epigenetic silencing (promoter methylation) or mutation, coupled with loss of heterozygosity (LOH), of MLH1 and less frequently MSH2 or MSH6 [22, 23]. As a result, such tumours are replication error positive (RER+), which leads to the accumulation of insertion/deletion mutations in mono-, di-, tri-, and tetranucleotide repeats throughout the genome. The altered length of these microsatellite repeats is the 'phenotypic' manifestation of an inactive MMR, and is referred to as microsatellite instability (MSI+). This form of genetic instability in sporadic cancers has been described best in colorectal cancer and is found in up to 15% of sporadic colorectal tumours [23]. Crucially, MSI+ colorectal cancers tend not to exhibit genetic instability at the chromosome level (i.e. CIN) and often have diploid or pseudodiploid karyotypes. Most cancers that are MSI+ also show minimal evidence of widespread LOH (reviewed in [24]), whereas cancers with CIN show numerical chromosome alterations in addition to LOH and copy neutral LOH (LOH followed by reduplication such that while heterozygosity is lost, copy numbered is retained).

The underlying genetic instability in RER+ tumors (whether from sporadic or germline mutation derived cancers) results in a genetic profile that is distinct from RER– tumors and is characterized by mutation of 'susceptible' genes containing repeat sequences within their protein coding regions. In addition, studies in colorectal cancer have shown that deletions in regulatory, non-protein coding 3'UTR mononucleotide repeat sequences account for much of the mRNA expression profile differences seen between MMR proficient (MSI–/RER–) vs MMR deficient (MSI+/RER+) tumours [25].

This type of genetic instability is unique in that the genetic or epigenetic mechanisms involved in MMR inactivation are common to both sporadic cancers as well as cancers from patients harbouring germline mutations in one of the MMR genes. Thus MSI+ cancers always arise through inactivation of both alleles of one of the MMR genes.

Nucleotide excision repair (NER)

The NER pathway consists of 20 to 30 proteins that repair DNA damage caused by UV light as well as chemically-induced cross-links and bulky adducts. As with all DNA repair pathways, NER involves recognition of the damage, excision of the damaged nucleotides, and repair of the DNA strand. The NER pathway repairs complex lesions through the removal of approximately 30 bases. Exposure to UV causes two common mutagenic lesions, cyclobutane pyrimidine dimers (CPD) and pyrimidine (6-4) pyrimidone photoproducts (6-4PPs). If the lesion is in the transcribed strand of an active gene, it is repaired by the transcription-coupled repair (TCR) sub-pathway [26]. If the lesion falls within a transcriptionally inactive part of the genome, it is repaired by global genome repair (GGR) sub-pathway [27]. The two pathways differ in the mechanism by which damage is recognized but involve the same proteins for excision and resynthesis.

The first DNA repair disorder ever identified, xeroderma pigmentosum (XP), is an autosomal recessive disorder, which arises through inactivation of both copies of one of the XP genes active in the NER pathway. Diminished levels of the affected protein component of the NER pathway in these patients can reduce the level of DNA repair to 5% of normal. Individuals with XP are extremely sensitive to UV-induced cancers in addition to exhibiting neurological, ocular, and developmental abnormalities (reviewed [28]). The cells of XP patients are defective in their capacity to excise DNA cross-links and bulky adducts, and the persistence of these UV-induced lesions renders the genome vulnerable to their mutagenic effects. Skin cancers in these patients are characterized by high mutation rates at pyrimidine dimers and whilst they are genetically unstable at the nucleotide level and have been described as NER unstable (NIN), they tend not to exhibit gross changes in chromosome number (CIN) [29]. It is noteworthy that XP heterozygotes are not at an increased risk of developing cancer.

Base excision repair (BER)

The BER mechanism repairs DNA damage induced by metabolic processes such as methylation, deamination, reactive oxygen species (ROS) and hydrolysis [30]. Generally speaking, this pathway serves to repair and replace nucleotides with small chemical alterations. There are two BER pathways known as 'short patch' and 'long patch' depending upon the number of nucleotides replaced during repair. Both pathways are initiated by a specific glycosylase that recognizes the damaged nucleotide and releases it from the DNA leaving an apurinic or apyrimidinic (AP) site. An AP endonuclease or an AP lyase then nicks the DNA, and a DNA polymerase processes the nick and fills in the resulting gap. Finally, a DNA ligase completes the repair process by joining the newly synthesized 'patch' to the preexisting DNA strand.

At least 11 different human glycosylases have been discovered. Germline mutations in one of these, the *MutY* homolog *MUTYH*, lead to a cancer-predisposing syndrome called *MUTYH*-associated polyposis (MAP). Impaired function of MUTYH leads to the inability to repair G:A mismatches in DNA, leading to an increase of G:C to T:A transversions. MAP is an autosomal recessive disorder (the common variants are Tyr165Cys and Gly382Asp [31]), characterized by colorectal adenomatous polyps and a very high risk of the development of colorectal cancer in addition to a moderate risk for several extra-intestinal cancers.

The form of genetic instability in cancers from these patients is not, however, clearly defined, with reports of both aneuploidy as well as near diploid karyotypes.

Mouse models deficient for components of NER, BER, and MMR pathways provide important evidence for the roles of these genes in cancer. Mice deficient for individual components of both the NER and BER pathways do not generally result in spontaneous cancer phenotypes. In contrast, MMR deficient mouse models cause spontaneous cancers with nearly complete penetrance. Similarly, patients heterozygous for MMR gene mutations are tumour prone, whilst heterozygotes for BER gene mutations (and many other recessive cancer prone repair mutations) are not.

Point mutation instability (PIN)

This form of genetic instability has been described but is generally not widely accepted, perhaps because unlike MSI and CIN, there is no easy and standardized way to confirm the presence of PIN. Cancers with aneuploid karyotypes are easily identified as having CIN, whilst MSI can be inferred from the identification of a mutation or promoter methylation of one of the MMR genes, or confirmed by measuring changes in the repeat length of several widely used microsatellite loci. An increased rate in the accumulation of point mutations outside microsatellite repeats, diagnostic of PIN, would be difficult to confirm. This is especially true for sporadic cancers, where the genetic mechanisms underlying PIN are largely unknown. Cancer predisposition syndromes with germline mutations in genes affecting the NER and BER pathways lead to cancers that may be chromosome and microsatellite stable, but may accumulate mutations at the nucleotide level at an accelerated rate, and as such, could be considered to exhibit PIN. However, recent data from exome-capture DNA sequencing of 224 sporadic colorectal and rectal cancers identified cancers with two clear levels of mutation: the majority of cancers fell into a group with a median of 58 mutations versus a second group (13%) with a median of 728 mutations, which the authors designated as hypermutated cancers [14]. All but one of the 'hypermutated' cancers were mutated or epigenetically silenced at one of the MMR genes and 13 of them had an additional mutation in *POLE*, a DNA polymerase that together with another polymerase *POLD1*, has recently been found to predispose individuals carrying germline mutations within the proofreading domains to colorectal cancer [32]. However, only one of the hypermutated cancers had a *POLE* mutation where no concomitant mutation in an MMR gene was found. Using the standard definition of MSI+, which only tests for accumulation of mutations in five mono- or di- nucleotide repeat sequences, some of the hypermutated cancers with a mutant MMR gene other than *MLH1* were classified as microsatellite stable. It is possible that since most of these were mutant for MMR genes other than *MLH1* and that some also carried POLE mutations, the profile of accumulated mutations could be different in these cancers, and the genetic instability conferred by these genes would not be detected efficiently using the standard panel of five microsatellites. In fact, evidence from mouse models shows that the mutation spectrum arising from inactivation of *MSH3* is different from that in *mlh1* deficient mice, with around 40% of the frameshift mutations occurring outside of repetitive sequences [33]. If PIN existed as a separate entity from MSI+, high throughput sequencing studies should have revealed a group of cancers with no evidence of mutation in MMR genes, but with evidence of a higher than normal burden of point mutations. Thus, these two bodies of evidence [14] call into question the existence of a form of point mutation genetic instability distinct from that generated by inactive MMR in sporadic cancers.

DNA damage response (DDR) pathway

This is a signal transduction pathway that recognizes DNA damage and replication stress (accumulation and collapse of stalled DNA replication forks). It encompasses the recombinational repair of double strand breaks (DSBs), single strand breaks (SSBs), and interstrand cross-links (ICLs).

Almost all forms of replication-independent DNA damage require unwinding of double stranded DNA by helicases, cleavage of the DNA strand, and repair of the DNA by polymerases. In humans, DNA DSBs are repaired preferentially by a process called non-homologous end joining (NHEJ), which joins the broken DNA strands. Less commonly, homologous recombination (HR) uses genetic exchange with the homologous sister chromatid to repair the break, and this process involves a complex of proteins including BRCA1, BRCA2, and RAD51. During G0, most DSBs are repaired by one of two NHEJ pathways: the Ku-mediated and the more precise ataxia telangiectasia-mutated (ATM)-mediated.

The XRCC5/XRCC6 heterodimer (also known as KU) constitutes the DNA recognition component, which together with the catalytic subunit, DNA-PKcs, forms the DNA-dependent protein kinase (DNA–PK) complex required for repair of DSBs.

Epigenetic inactivation through promoter methylation of XRCC5 has been shown in approximately 20% of sporadic non-small cell lung cancers (NSCLCs).

Germline mutations in a range of genes involved in repair of DNA DSBs or DNA ICLs cause predisposition to a number of cancers including breast, ovarian, and leukaemia/lymphoma. These genes include: breast cancer susceptibility 1 (*BRCA1*), *BRCA2*, partner and localizer of *BRCA2* (*PALB2*), *BRCA1*-interacting protein 1 (*BRIP1*), *RAD50*, Nijmegen breakage syndrome protein 1 (*NBS1*), Werner syndrome helicase (*WRN*), Bloom syndrome helicase (*BLM*), RecQ protein-like 4 (*RECQLA4*) and the Fanconi anaemia (*FA*) genes [34–36]. Many of these proteins are components of the ataxia telangiectasia mutated (ATM) and ataxia telangiectasia and RAD3-related (ATR) signalling pathways. ATR responds to stalled replication forks and SSBs, whereas ATM is activated by DSBs. Both ATM and ATR signal through activation of the cell cycle checkpoint kinases CHK1 and CHK2, which phosphorylate chromatin-bound factors and promote fork stability and restart collapsed or stalled replication forks. This process is also dependent on several other factors including DNA helicases and translocases such as BLM, WRN and FANCM.

BRCA1 acts during the S and G2 phases of the cell cycle when it co-localizes with RAD51 at sites of DNA DSBs, and it is required for HR mediated repair of DSBs. There is also evidence that it is involved in other DNA repair processes, including transcription-coupled repair, NEJM and NER (reviewed in [37]).

Germline mutations in the FA genes (all but 2% of which are recessive) predispose affected individuals to a range of conditions, and the majority of patients develop haematological abnormalities, bone marrow failure, and eventually, acute myelogenous leukaemia. There are 15 genes in the FA family and they play a key role in the recognition and repair of ICLs and DSBs. Cells from people

with FA are defective in their ability to repair ICLs and are thus sensitive to drugs such as mitomycin-C, which treat cancer by causing DNA cross-links.

Poly(ADP-ribose)polymerase (PARP) proteins localize to sites of single (and double) strand breaks, where they recruit XRCC1 and induce structural changes in local chromatin that lead to the recruitment of other DNA repair proteins. The role of PARPs is particularly crucial in patients with *BRCA* mutations, where the repair of DSBs has already been compromised. Treating these patients with PARP inhibitors results in an effect called synthetic lethality, which arises when the combined inhibition of complementary pathways (one through homozygous inactivation of the *BRCA* gene in the cancer and the other through drug inhibition of another component of the DSB repair pathway) results in lethality not seen through inhibition of either pathway alone. Crucially, all non-cancerous cells within patients with germline mutations of *BRCA* genes retain one functional copy of the *BRCA* gene and are able to survive. Treatment of patients with *BRCA* mutations with PARP inhibitors has provided a substantial improvement to the outcome of these patients.

Genetic instability at the chromosome level

CIN and aneuploidy

Boveri proposed more than 100 years ago that cancer was caused by abnormal chromosome segregation [38]. Structural chromosome changes leading to CIN are generated most commonly through errors in the recombinational repair of DSBs and include translocations, inversions, deletions, and duplications. Numerical changes can occur as a result of errors within mitotic control pathways regulating chromosome segregation and centrosome duplication.

The factors underlying aneuploidy in sporadic cancers are poorly understood but several genes, including *MAD2* (*MXI1*), *BUB1B, BUB3*, and *CENPE* [39, 40], involved in the alignment and segregation of chromosomes during mitosis (reviewed in [41]), have been suggested to play a role in the formation of aneuploidy. *APC* [42], which is mutated in about 85% of colorectal cancers, has also been implicated in the genesis of aneuploidy in colorectal cancer. However, the fact that *APC* is also mutated in a large number of MMR deficient colorectal cancers where aneuploidy is not present suggests it is unlikely that *APC* plays a major role in the development of aneuploidy in colorectal cancer.

In yeast, more than 100 genes that can cause genetic instability at the level of the chromosome have been identified [43]. That disruption of these genes *can* generate a CIN or aneuploidy phenotype in model organisms does not necessarily mean that they are the cause of CIN or aneuploidy in human cancers. There have been reports of mutations in some of these genes in cancers, but the numbers are modest at best and can in no way account for the incidence of CIN or aneuploidy in human cancers. That these genes behave as typical tumour suppressor genes, requiring somatic inactivation of both copies of the relevant gene in sporadic cancers, may account for the low incidence of observed mutations in genes within these pathways in sporadic cancers. It may well be that genetic instability in sporadic cancers arises through some other mechanism with fewer steps and that, once again, CIN/aneuploidy is possibly just a side effect of selection for escape from one of the many tumour suppressive mechanisms employed by the cell.

Clearly, the lack of mutations identified in nearly all candidate genes studied to date indicates that the genetic and/or epigenetic factors that lead to CIN and aneuploidy in the majority of sporadic human malignancies have yet to be uncovered.

Mechanisms implicated in the development of genetic instability in sporadic cancers

If we accept that genetic instability is common in both sporadic cancers as well as those arising in patients carrying germline mutations for DNA repair pathways, we must also note that that the genetic instability in sporadic cancers clearly arises through a mechanism other than genetic or epigenetic inactivation of those genes associated with heritable cancer risk. There are only two possible explanations for this difference: genetic instability is required for development of cancer in general, but sporadic and germline-derived cancers reach this end through different mechanisms, or while genetic instability clearly occurs through genetic inactivation of key genes in DNA repair pathways in germline cancer predisposing conditions, the genetic instability seen in sporadic cancers is incidental and secondary to some other process. The mechanisms discussed below have all been implicated in the development of CIN in sporadic cancers. While it is clear that each of these plays a role in the development and progression of sporadic cancers, their causative role in the development of genetic instability in sporadic cancers remains unproven. They are therefore listed here to give a more complete overview of the currently held views that might explain genetic instability in sporadic human cancers. The assumption for each of these is that, if they provide a mechanism through which the rate at which genetic, epigenetic, or chromosomal changes could be generated (albeit transiently in some circumstances), they could be considered as mechanisms contributing to genetic instability.

Epigenetic alterations

Epigenetic alterations in cancer typically involve DNA hypermethylation of CpG dinucleotides (clustered into regions called CpG islands in the promoters of genes), which mostly result in the transcriptional inactivation of the associated genes [44]. Almost half of all genes are predicted to contain a CpG rich region that fulfils the criteria of being a CpG island [45]. Promoter methylation is a 'metastable' change affecting gene expression and may undergo selective pressure in tumorigenesis in just the same way as mutations. Thus, disruption of the epigenetic signature in cancer represents a theoretical alternative to genetic instability in providing a similar, heritable mechanism involved in the progression of cancer. This has been explored in the greatest depth in colorectal cancer, where the concept of a CpG island methylator phenotype (CIMP) was first described [46]; reviewed in [47].

The term refers to cancer-related aberrant methylation of CpG islands in the promoters of a range of genes, termed CIMP markers. Methylation of CIMP markers is broadly interpreted to indicate the presence of a disrupted methylation maintenance system and may be associated with more targeted methylation of tumour suppressor genes.

Telomeres

Telomeres protect the ends of chromosomes and stop them from being recognized by the DNA damage response machinery as DSBs.

Embryonic stem cells and adult tissue stem cells in humans express both the ribonucleoprotein (hTERC/hTR) as well as the catalytic component (hTERT) of the protein complex telomerase, which acts to maintain telomere length and protect cells from a type of cell cycle arrest known as replicative cell senescence (see [48, 49] for recent reviews). Most other somatic cells only express one ribonucleoprotein subunit, and lack hTERT expression. Consequently, they are unable to maintain telomere length during replication and eventually undergo replicative cell senescence. Cells with shortened telomeres which have become resistant to senescence have been shown to undergo chromosome fusion and develop CIN [50]. It has been shown that about 85–90% of human cancers express active telomerase [51]. It is unclear whether this is due to reactivation via re-expression of the catalytic subunit, or whether the cancers arose from a stem cell or early progenitor cell in which telomerase was already active. However, there is evidence that some early cancers and pre-cancerous cells undergo telomere loss-induced crisis and end-to-end chromosomal fusions, which can generate unstable dicentric chromosomes and potentially lead to CIN [52].

Hypoxia

Hypoxia is a common feature of developing cancers as they outgrow existing blood supply and before angiogenic stimuli lead to new vasculature. There is emerging evidence that hypoxia and cyclical hypoxia and re-oxygenation result in the induction of genetic instability and increased mutation frequencies [53, 54] through transcriptional repression of MMR genes including *MLH1, MSH2,* and *MSH6* [55, 56]. Hypoxic conditions have also been reported to result in oxidative base damage [57, 58], gene amplification [59], and DNA over-replication [60].

Recent studies have suggested a mechanism involving DNA replication stress which may account for the genetic instability (most commonly in the form of CIN) seen in sporadic cancers [61, 62]. Unresolved DNA replication forks, also known as DNA replication stress, can arise through any mechanism that interferes with the normal progression of DNA replication forks, including changes in the levels of dNTPs or proteins involved in dNTP synthesis, DNA synthesis, or damage to the DNA itself. If unresolved, stalled replication forks can lead to DSBs and complex chromosomal rearrangements (CIN) (reviewed in [3, 62, 63]).

Oncogene-induced DNA replication stress model

The oncogene-induced DNA replication stress model arose from the observation that early precancerous lesions tend to have an increase in the number of DNA DSBs thought to be caused by stalled DNA replication forks, in addition to constitutive activation of the ATM-CHK2 DNA damage response pathway [64, 65]. Importantly, this occurs in the absence of mutation of any of the DNA damage repair pathway genes such as *TP53*.

It was subsequently shown that activating mutations in several oncogenes including *RAS, MYC, CCNE1* (cyclin E), *CDC25A*, and *E2F1* are capable of inducing DSBs, LOH, and genetic instability in various animal model systems ranging from human to mouse and even yeast [64, 66–69]. Thus, the oncogene-induced DNA replication stress model argues that *RAS* and other oncogenes cause collapse of DNA replication forks and DSBs in early and precancerous

cells, which then provides selective pressure for the loss of DNA checkpoint genes like *TP53* in order to escape apoptosis.

Although there is some evidence for oncogene induction of this mechanism, and although the model would provide an explanation for why nearly all sporadic cancers are thought to have genetic instability in the absence of mutations in DNA repair pathway genes, there is currently no understanding of the mechanism by which the presence of activated oncogenes might cause DNA replication stress. There are also clear examples where precancerous lesions, such as colorectal adenomas, are not commonly aneuploid.

Conclusion

It is now undisputed that cancer arises as a result of the sequential accumulation of genetic and epigenetic changes, each of which is selected for in a Darwinian evolutionary process because they provide a selective advantage to the developing cancer. It is also clear that disruptions of the mechanisms that have evolved to maintain the fidelity of the genome result in increased rates of mutation and can accelerate tumorigenesis. It is widely accepted that many if not most cancers harbour some form of genetic instability, either manifested through CIN and aneuploidy, or via inactivation of MMR with resultant MSI. These observations have led some to hypothesize the existence of a mutator phenotype. The mutator hypothesis argues that genetic instability is present in precancerous lesions and drives tumour development by increasing the spontaneous mutation rate [70]. The key assumption with this argument is that spontaneous mutation rates are not high enough to give rise to the mutations that are selected for in the outgrowth of a cancer. The counter-argument is that mutation rates are large enough if selection is properly taken into account [4]. In hereditary cancers, genetic instability facilitates the accumulation of critical mutations in oncogenes and tumour suppressor genes, and these cancers almost certainly fulfil the requirements of the mutator hypothesis in that genetic instability occurs early in the development of the cancer and results in an increased rate of accumulation of spontaneous mutation. However, the germline cancer predisposition syndromes are almost always autosomal recessive and do not, in the heterozygous state, affect genome stability. If genetic instability were selected for in cancer, one might expect that individuals who are heterozygotes for mutations in repair genes associated with diseases like AT, BLM, XP, and FA would carry a much higher risk of developing cancers (through the single further step of somatic inactivation of the second allele) in the same way that individuals heterozygous for mutations in MMR genes have a 100% risk of developing colorectal cancer. But this is not found to be the case, strongly suggesting that the selective advantage conferred by MMR deficiency is not due to the increased mutation rate per se, but rather due to the acquisition of some phenotype directly related to growth and survival, such as resistance to apoptosis.

The key issue with genetic and epigenetic changes that increase genetic instability is whether their selective advantage is due solely to their effect on mutation rate, or whether it is due to a more direct effect, and that the increase in mutation rate is a bystander effect. The rationale for the argument against the mutator hypothesis rests on the fundamentals of natural selection; any selective advantage must be conferred in the first change that does not yet increase the mutation rate. Exhaustive studies of sporadic cancers have failed

to identify common mutations in DNA repair and mitotic checkpoint genes in a wide range of cancers (reviewed in [63]; [14, 71]). The low frequency of these mutations in sporadic cancers has confounded expectations and argues against the mutator hypothesis for sporadic cancers [4, 14].

DNA repair mechanisms generally result in activation of apoptotic pathways once a critical level of damage accumulates [72, 73]. This protective mechanism allows the cell to attempt repair, but in the event that the damage cannot be repaired, activation of apoptosis ensures that fidelity is retained. It then stands to reason that part of the role of the protein complexes involved in recognition and repair of damaged DNA is simultaneously to recruit and activate apoptotic pathways. Thus, inactivation of one or more of the components of DNA repair is likely also to affect the ability to escape apoptotic signals resulting from accumulation of excessive levels of damage. This escape from apoptosis would provide the most likely selective advantage conferred to a cell in which somatic inactivation of a DNA damage repair gene occurred.

It has yet to be determined whether transient telomere deficiency, epigenetic dysregulation, cycles of hypoxia and re-oxygenation, the oncogene-induced DNA-damage model, or some combinations thereof are responsible for CIN in sporadic human cancers. Similarly, there is no clear answer to the question of whether genetic instability in sporadic cancers is simply a common byproduct of, for example, the selective pressures against apoptotic signals that arise from activation of repair pathways in the face of DNA damage. Experimental and theoretical evidence do not support the concept of genetic instability as a universal and required driving force for all cancers, but where it is evident in sporadic cancers, we still have some way to go before we fully understand the underlying mechanisms.

CHAPTER 9

DNA repair after oncological therapy (radiotherapy and chemotherapy)

Ekkehard Dikomey, Kerstin Borgmann, Malte Kriegs,
Wael Y. Mansour, Cordula Petersen,
and Thorsten Rieckmann

Introduction to DNA repair

Normally, tumours are treated by combined modalities among which radiotherapy is of great importance. To achieve maximal tumour control, all malignant cells need to be killed. With ionizing irradiation, this is mostly achieved via non- and mis-repaired DNA double-strand breaks (DSBs) finally resulting in lethal chromosome aberrations.

Induction and repair of DNA damage

Induction and repair of double-strand breaks

Exposure to ionizing irradiation leads to numerous types of DNA lesions with about 30 DSBs per diploid cell per 1 Gy X-ray. In tumour cells this number may vary by a factor of two with substantial impact on the cellular radiosensitivity.

The repair kinetics of X-ray-induced DSBs are characterized by a biphasic curve finally approaching a constant plateau (Figure 9.1). There is a fast exponential component with a half-time ranging between 5 and 30 minutes, mostly associated with the repair in euchromatin, and a slow component with a half-time of 2–5 hours representing repair in heterochromatin. The final plateau represents the number of non-misrepaired and probably also misrepaired DSBs [1, 2]. Differences in the repair kinetics, especially in the final plateau, indicate defects either in damage response, chromatin organization, repair pathways, or repair regulation.

Initial DNA damage response

Upon induction of DNA damage, cells react with a complex DNA damage response (DDR). DSBs will be detected, marked and processed for repair. As a part of DDR, cell proliferation will be regulated to give more time for repair before entering highly sensitive cell cycle phases such as S phase and mitosis [3]. ATM kinase and MRN complex (Mre11, Rad50, Nibrin) play a critical role in the recognition of DSBs initiating phosphorylation of the histone 2AX for up to one to two megabase pairs. This phosphorylated histone, generally termed as γH2AX, recruits MDC1, which serves as a platform that stimulates the recruitment of other repair proteins forming so-called repair foci which can easily be detected via immunofluorescence.

Mechanisms of DSB repair

DSBs can be repaired by several distinct pathways that differ not only in the underlying mechanism and proteins involved but also in the preferred DNA structure needed (Figure 9.1). Mammalian cells have evolved three main DSB repair pathways: non-homologous end joining (NHEJ), homologous recombination (HR), and single-strand annealing (SSA). NHEJ is the central pathway, which requires no sequence homology and, hence, can act on DSB with different structures and also in all cell cycle phases [4]. The central unit of NHEJ is the DNA PK complex composed of the heterodimer Ku70/80 and the catalytic subunit PKcs, which keeps the two DSB ends together. Final ligation is then performed by Artemis and Pol μ together with XRCC4, LigIV and XLF [5].

HR is active only in late S and G2 phase [6], where the sister chromatid (the most appropriate homology sequence) is available (Figure 9.1). Rad51 as the central HR player forms a nucloprotein filament, which invades the sister chromatid and searches for homology. HR is specifically required for repairing one-ended DSBs which are generated when single-strand breaks run into the replication fork. Repair of such lesions by HR prevent their dissociation and thereby strongly guarantee genomic stability of the DNA [6].

When NHEJ is defective, mammalian cells may rejoin DSB via an alternative end-joining mechanism (Alt-NHEJ) which requires PARP1, XRCC1, and LigIII. Alt-NHEJ is error-prone and is characterized by slow kinetics. Interestingly, Alt-NHEJ has also been shown to mediate both intra-chromosomal joining for class switch recombination (CSR) and inter-chromosomal translocation junctions, and may therefore strongly contribute to an oncogenic transformation.

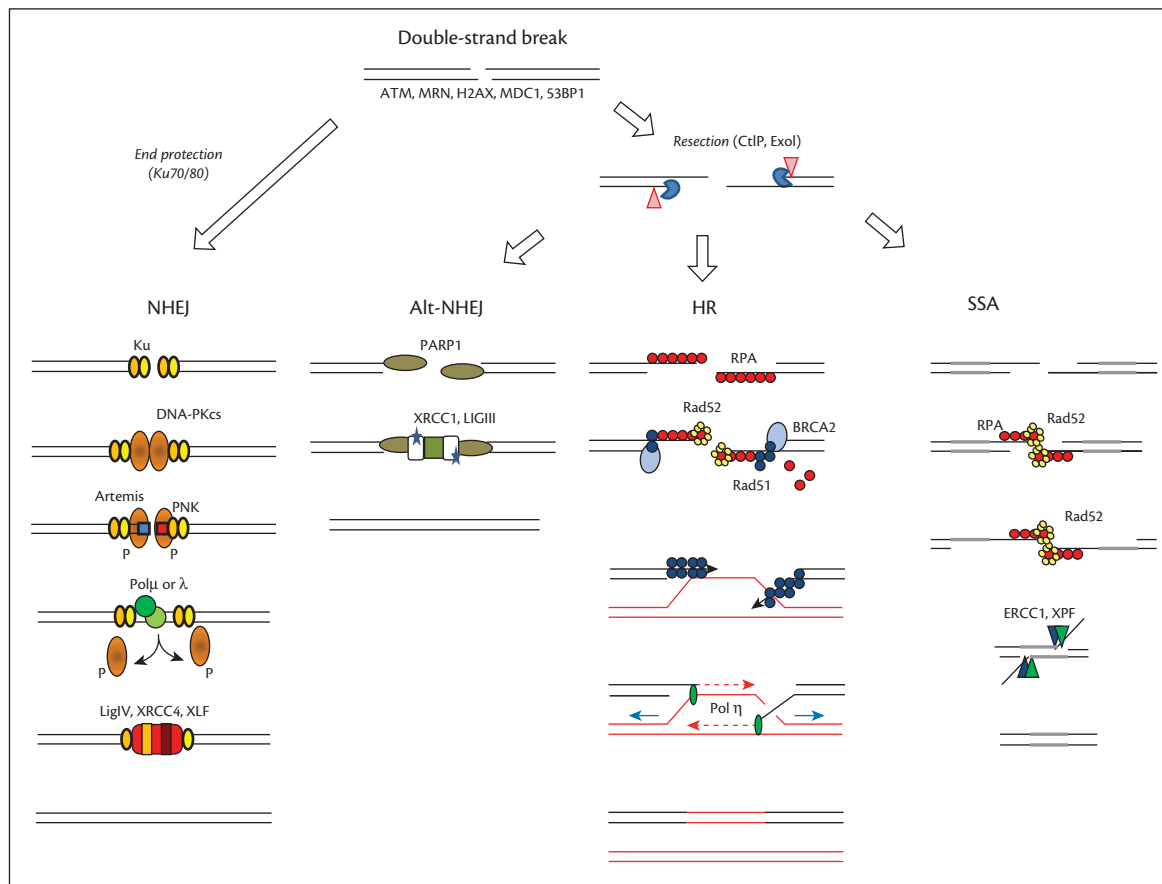
SSA is stimulated when a DSB is generated between two repetitive sequences of 20 to 50 base pairs. An extensive resection of the DSB ends is required for SSA before homologous sequences are identified by Rad52 (the central SSA player) followed by the removal of the overhanging ends [7].


Fig. 9.1 Repair pathways of radiation-induced DNA double-strand breaks in mammalian cells.
Abbreviations: NHEJ, non-homologous end joining; Alt-NHEJ, alternative non-homologous end joining; HR, homologous recombination; SSA, single-strand annealing.

With kind permission of Springer Science+Business Media

A functional hierarchy has recently been reported to exist between these three repair pathways to ensure fast and accurate repair of a DSB by canonical/classical NHEJ, which dominates over the other two pathways [8]. However, in many tumours this hierarchy is disturbed so that these two pathways are more active.

Targeting DSB repair

To enhance tumour radiosensitivity aiming to increase tumour cure, DSB repair is considered to be an optimal target, because it is the main determinant of the cellular radiosensitivity.

Radiochemotherapy

Radiochemotherapy is a main regimen for many tumors. Radiotherapy is combined with chemotherapy in an adjuvant or neo-adjuvant regimen but also may be given simultaneously. However, for most of the conventional drugs used there is rarely a synergistic effect observed but mostly only an additive effect, even for the often applied combination of radiation and cisplatin.

Molecular targeting

The great knowledge about the DSB repair mechanisms and their regulation achieved in the last years has paved the way in developing new specific targets to inhibit DSB repair in tumour cells to increase cellular radiosensitivity.

Epidermal growth factor receptor

The epidermal growth factor receptor (EGFR) is often over-expressed in tumours, and is known to regulate DSB repair. This receptor can be targeted either by specific antibodies (AB) such as cetuximab or tyrosine kinase inhibitors (TKI) such as erlotinib or gefitinib. A first clinical study with advanced head and neck tumours has demonstrated that at least cetuximab can be used in combination with radiotherapy (RT) to improve local tumour control [9]. Surprisingly, no such increase was seen when RT was combined with a TKI.

The mechanisms leading to this cetuximab-mediated improved tumour control are not yet fully understood. Cetuximab was found to suppress DSB repair by blocking both NHEJ and HR. However, an even stronger effect was seen for erlotinib, for which no cellular radiosensitization was seen. These data might indicate that the inhibition of DSB is only transient and might not result in an increased cell inactivation, because EGFR inhibition also blocks cell proliferation. Probably these cell cycle effects leading to premature senescence are more important for EGFR targeting [10].

Recent research focuses on downstream targets of EGFR such as the MAPK signalling pathways, which are known to regulate DSB repair. Probably, targeting of these two signalling pathways is more effective, because it cannot be compensated by other signalling cascades.

Due to its abundant expression in tumours, the EGFR may also be used for immunotherapy by applying radio-labelled AB. This approach specifically induces DSBs in tumours heavily over-expressing EGFR which are known to be highly resistant [11]. When combined with external irradiation, tumour control is already achieved with fairly low doses.

PARP-1

The poly (ADP ribose) polymerase 1 (PARP-1) plays an essential role in base excision repair (BER). As a consequence, upon suppression of PARP-1 by specific inhibitors more single-strand breaks or base damage will collide with replication fork leading to the formation of one-ended DSB (see "Mechanisms of DSB repair"). In cells with normal HR activity, these lesions are still repaired efficiently. However, in tumours with deficiency in HR, these lesions are not repaired. Therefore, targeting of PARP-1 will then lead to grossly increased lethality in HR-deficient tumours [12]. This concept, also termed as 'synthetic lethality', is considered to be a very promising tool specifically to inactivate tumour cells, because an HR defect is often seen in malignant cells [13].

PARP-1 is also involved in the Alt-NHEJ (see "Mechanisms of DSB repair"), which is known to be active in tumour cells. Therefore, when tumour cells using Alt-NHEJ are damaged either by radiation or specific chemicals such as cisplatin, inhibition of PARP-1 would lead to an enhanced cell killing. To apply this approach successfully in cancer therapy, biomarkers need to be established to allow identification of tumours which use Alt-NHEJ or are defective in HR.

HPV

Recent data indicate that in addition to cervix carcinoma, other types of tumour are also induced by a high-risk human papilloma virus (HPV) such as oropharyngeal squamous cell carcinoma (OSCC). Surprisingly, this tumour reacts much better to RT and RCT, when compared to HPV-negative head and neck tumours [14]. This higher local control was shown to be mediated by an extensive G2 block and an elevated level of residual DSBs [15]. When this G2 block is suppressed by specific inhibitors, a radiosensitization is seen in most HPV-negative OSCC, but not in normal human fibroblasts.

Chk1 und Chk2

In most tumours, the G1/S checkpoint is not active because p53 is mutated. As a consequence, these tumours especially rely on intra-S-phase as well as the G2 checkpoint, to prevent cell proliferation and to provide more time for efficient DSB repair. Both intra-S-phase and G2 checkpoints are initiated either by ATM or ATR, depending on the type of damage induced, which will then activate Chk1 and Chk2. There are several inhibitors available targeting either or both of these kinases which are already used in the clinics. These inhibitors are known to suppress DSB repair and with that specifically enhance tumour cell radio- as well as chemo-sensitivity [16, 17].

Prediction by DSB repair

Given its central role in cellular radiosensitivity, DSB repair may also be used to predict tumour response. Several tools are available reporting either directly or indirectly specific DSB repair capacity.

DSB repair foci

DSB repair foci, as measured by immunofluorescence, are considered an optimal parameter to determine specific repair capacity. For most tumour cell lines, an excellent correlation was reported between the residual number of DSB repair foci measured 24 hours after irradiation and cellular radiosensitivity [18]. It should, however, be noted that a difference in repair capacity of 1% has already been shown to have a strong effect on cell survival [19]. This technique may also be applied for tumour tissue slides irradiated both *in situ* or ex-vivo [18, 20]. However, there are still numerous problems to be solved such as hypoxic regions as well as contamination by normal tissue before this technique can be used in a daily clinical routine.

Immunohistochemistry

Beside many other factors, DSB repair capacity is also determined by the expression level of key repair proteins. Substantial variations in the amount of repair proteins have been reported in tumours both intra- and inter-individually. Among several proteins studied, the broadest variation has been reported for the heterodimer Ku protein, which is involved in NHEJ. For this protein, a clear and highly significant association was seen with an elevated expression leading to a high DSB repair capacity resulting in a poor prognosis after radiotherapy [21]. Such an analysis via immunohistochemistry may also include other proteins showing only an indirect effect on DSB repair such as EGFR and survivin [22, 23]. It should, however, be considered that this technique only allows determination of the relative amount of the protein present.

Gene expression

DSB repair capacity may also be estimated by gene expression analysis. This can be done either by a whole genome analysis or by specifically derived DSB repair tools. There are several studies showing an excellent correlation between a specific gene expression profile and tumour radiosensitivity [24, 25]. Surprisingly, however, these profiles did not include DSB repair genes.

Conclusion

There has been great improvement of our understanding about DSB repair and its regulation both in normal tissue as well as in tumours. These data revealed that tumours deviate in many aspects of DSB repair: the DNA damage response, the expression of DNA repair proteins, its hierarchy as well as its regulation. These deviations will allow us to establish new targets to specifically block DSB repair in tumours. One of the main objectives to achieve in the next few years is to establish tools allowing determination for each tumour its specific DSB repair defect, which can then be targeted by a specific therapy either in combination with RT or RCT.

CHAPTER 10

Biology of cancer and metastasis stem cells

Andreas Trumpp and Irène Baccelli

Introduction to biology of cancer and metastasis stem cells

Over the past 20 years, the concept of the cancer stem cell (CSC) has emerged after identification and characterization of CSC-enriched populations in several distinct cancer entities (Table 10.1) [1–3]. Although the concept remains controversial [4–6], new observations from clinical studies and basic research including transplantation experiments, in vivo lineage tracing experiments as well as clonal analysis of tumours have led to a more comprehensive CSC model of tumorigenesis, disease recurrence, and metastasis formation. The CSC concept is expected to contribute to the development of better therapeutic approaches to target residual disease, and break chemotherapy resistance and metastasis. The chapter is an updated and extended version of our recent review [7].

Historical background

Paget's landmark review on cancer in 1889 proposes that cancer might not be initiated by an accumulation of black bile produced by the stomach and the spleen (as initially proposed by Hippocrates and Galen), but rather by the encounter of a 'seed' (cancer cell) with an appropriate 'soil' (microenvironment). Indeed, as early as 1937, Furth and Kahn could demonstrate that one single mouse leukaemic cell is able to seed and form a new tumour in a healthy recipient mouse. The clonality of human cancers assessed by genetic markers was also demonstrated later on, confirming that cancers can arise from one transformed initiating cellular clone [8].

A clonal evolution model or multistep carcinogenesis model has subsequently been proposed to explain cancer development [9]. This model proposes that cells acquire tumorigenicity by accumulating mutations or genetic alterations, which occur stochastically in all neoplastic cells. This ultimately leads to the development of tumours, from benign to highly aggressive, depending on the type and number of newly acquired genetic alterations. For instance, this model has been thoroughly described for colon carcinoma [9].

However, accumulating evidence indicates that neoplastic cells do not always acquire tumorigenicity stochastically. Instead, tumours are often hierarchically organized, as are adult tissues [2, 10]. This was first demonstrated in mouse squamous cell carcinoma, where, by DNA lineage tracking, Pierce and colleagues could document the hierarchy between non-differentiated cells giving rise to well differentiated cells. The differentiated progeny was no longer able to form tumours in secondary recipients, contrary to non-differentiated cells. This observation, among many others, marked the beginning of the CSC research field [2, 10].

The classical concept of cancer stem cells

Adult regenerating tissues (such as the skin, the gastrointestinal mucosa or the haematopoietic system) are hierarchically organized [11–13]. At the top of the cellular organization, normal adult stem cells maintain tissues during homoeostasis and facilitate their regeneration, for example in response to infection or to cell loss due to injury or chemotherapy. These physiological stem cells are defined by their functional properties: they have the life-long capacity to self-renew (ability to give rise to a new stem cell following cell division), are multipotent, and can reversibly enter quiescent or even dormant states and resist cytotoxic drugs [11, 13–15]. Similar to regenerative tissues, many tumours follow a hierarchical organization and, like physiological stem cells, CSCs are defined by a series of functional traits [2, 10, 16] (Figure 10.1).

Universal CSC functional traits

At the helm of tumour hierarchy

First, CSCs can generate all cell types present in a tumour. Located at the top of the tumour hierarchy, CSCs can self-renew and also generate non-CSC progeny, which form the tumour bulk (differentiated progeny). Hierarchical organization of tumours, governed by CSCs, have been reported for many tumour types including germ cell cancers, leukaemia, breast cancer, brain cancer, colon cancer, pancreatic cancer, melanoma, and several others [7] (Table 10.1).

Unlimited self-renewal potential

In striking contrast with their differentiated progeny, CSCs can undergo unlimited self-renewing divisions. Typically, the presence of human CSCs within a cell population is experimentally addressed by serial transplantation of tumour cells into immunocompromised mice or rats (Table 10.1). Although considered state of the art, this assay has limitations and only imperfectly recapitulates the in vivo situation found in patients. Indeed, the immunocompromised mouse models lack an adaptive immune system (neither mouse nor human) and express cytokines/chemokines and other environmental components of mouse origin, such as the tumour vasculature. Furthermore, the detection and enumeration of functional CSCs by these methods remains highly assay-dependent, as several different immunocompromised mouse strains and many methods of tumour dissociation and implantation exist [34, 38, 39]. Nevertheless, human CSCs cannot be simply reduced to technical artefacts due to their detection in xenografts. Indeed, mouse CSCs have also been

Table 10.1 Identification of human primary tumour CSC biomarkers using in vivo assays. Studies reporting the existence of enriched human CSC populations are listed. In the first five columns, the main parameters influencing the efficiency of tumour engraftment are listed. *From left to right*: the tumour entity, the type of immunocompromised mouse strain used, the route of transplantation of human tumour cells, preconditioning of the recipient mice, treatment of mice during the assay, and whether the tumour cells were mixed with matrigel upon transplantation. In the next four columns, the main results of these studies are summarized. *From left to right*: the frequency of the identified CSC-enriched population observed in the given tumour entity, the biomarkers identified for this CSC-enriched population, the minimal number of tumour cells expressing these biomarkers able to give rise to a human tumour, as well as the reference of the corresponding study [7]

Cancer	Animal	Type of injection	Treatment of recipient mice	Injection with matrigel	% of csc-enriched population in tumour	Biomarkers	Minimal # of biomarker + cells to obtain a tumour	Reference
ALL (B-ALL)	NOD/SCID/ IL2rγc−/− newborns	intravenous	sub-lethal irradiation	no	82.50%	CD34+/CD19+	$2-6.10^4$	[17]
AML	NOD/SCID	intravenous	sub-lethal irradiation	no	0.75%	CD34+/CD38-	2.10^5	[1]
AML	NOD/ SCID, NOD/ SCID/β_2m−/− and NOD/SCID/ IL2rγc−/−	intravenous and intra-bone	IVIG of CD122 pre-treatment and sub-lethal irradiation	no	0.076 % (*)	CD34+/CD38- (*) or CD34+/CD38+ (**) (in samples with lowest CD34+/ CD38- fraction)	$7.5\ 10^3$ (*) or 10^6 (**)	[18]
AML	NOD/SCID	intra-femoral	IVIG of CD122 pretreatment and sub-lethal irradiation	no	0.06% to 0.00009% of bulk	NA	NA	[19]
Bladder	Rag2γcDKO	intra-dermal	NA	yes	3–36.3%	CD44	100	[20]
Breast	NOD/SCID	mammary fat pad	VP–16, oestrogen pellets	no	11–35%	ESA+/CD44high/ CD24low-neg	200	[21]
Breast	NOD/SCID	humanized mammary fat pad	oestrogen pellets	yes	3–10%	ALDH1+	500	[22]
BREAST ctcs	NOD/SCID/ IL2rγc−/−	intra-femoral	oestrogen pellets	yes	1%–44%	CD44+/MET+/ CD47+	1000 blood CTCs	[23]
Brain	NOD/SCID	intracranial	NA	no	6–29%	CD133+	100	[24]
Colorectal	NOD/SCID	renal capsule	sub-lethal irradiation	yes	1.8–24.5%	CD133+	100	[25]
Colorectal	NOD/SCID	subcutaneous	NA	no	2.60%	ESAhigh/CD44+	200	[26]
Colorectal	NOD/SCID	subcutaneous	NA	yes	3.50%	ALDH1+	25 serially passaged	[27]
Head and neck squamous cell carcinoma	NOD/SCID and Rag2γcDKO	subcutaneous	NA	yes	10–12%	CD44+	5000	[28]
Liver	SCID	intra-hepatic	NA	no	2.50%	CD45-/CD90+	10^3	[29]
Lung	SCID and NUDE	subcutaneous, after in vitro expansion	NA	yes	0.4–1.5%	CD133+	10^4	[30]
Lung	NOD/SCID/ IL2rγc−/−	subcutaneous	NA	yes	median 15%	lin-/CD166+	≤500	[31]
Melanoma	NOD/SCID	subcutaneous	NA	no	1.6–20.4%	ABCB5+	10^5	[32]

Melanoma	NOD/SCID/ IL2rγc−/−	subcutaneous	NA	yes	NA	NA	1 (in 28% of cases)	[5]
Melanoma	NUDE, (NOD/ SCID, NOD/SCID/ IL2rγc−/−)	subcutaneous	NA	yes	8–11%	CD271+	1000	[34]

Table 10.1 Continued

Cancer	Animal	Type of injection	Treatment of recipient mice	Injection with matrigel	% of csc-enriched population in tumour	Biomarkers	Minimal # of biomarker + cells to obtain a tumour	Reference
Ovarian	NUDE	subcutaneous	NA	yes	0.20%	CD44+cKIT-CD117+	100	[31]
Ovarian	NOD/SCID	subcutaneous	NA	yes	0.5% - >70%	CD133+	100–500	[35]
Pancreatic	NOD/SCID	subcutaneous and intra-pancreatic	NA	yes	0.2–0.8%	ESA+/CD44+/CD24+	100	[36]
Pancreatic	NUDE	intra-pancreatic	NA	no	3.6 cells per high power field	ESA+/CD133+	500	[37]

Abbreviation: CTC, circulating tumour cells isolated from the blood of patients.

reported in syngeneic mouse models of leukaemia, breast cancer, and skin cancer, providing strong evidence that CSCs govern many tumour types [7].

In addition to transplantation experiments, in vivo lineage tracing methods have been developed and used in syngeneic mouse tumour models and lentivirally marked human tumour xenografts to assess the fate of individual CSCs as well as the clonal composition within tumours (reviewed in [40]). For example, clonal analysis of human colon cancer xenografts revealed long-term transient as well as dormant clones. The latter ones only appeared in secondary and tertiary transplants suggesting that there is a significant fluctuation during the progression of tumour growth over time. Interestingly, slow-cycling dormant clones showed the highest resistance to chemotherapy showing that the clones that drive initial tumour growth might be distinct from the ones that reinitiate growth and relapse after therapy. Importantly, these data demonstrate that tumour heterogeneity is not exclusively the consequence of genetic heterogeneity, but also caused by epigenetically distinct tumour cells following the cancer stem cell model [15, 41].

Other CSC functional traits

Quiescence or slow-cycling states

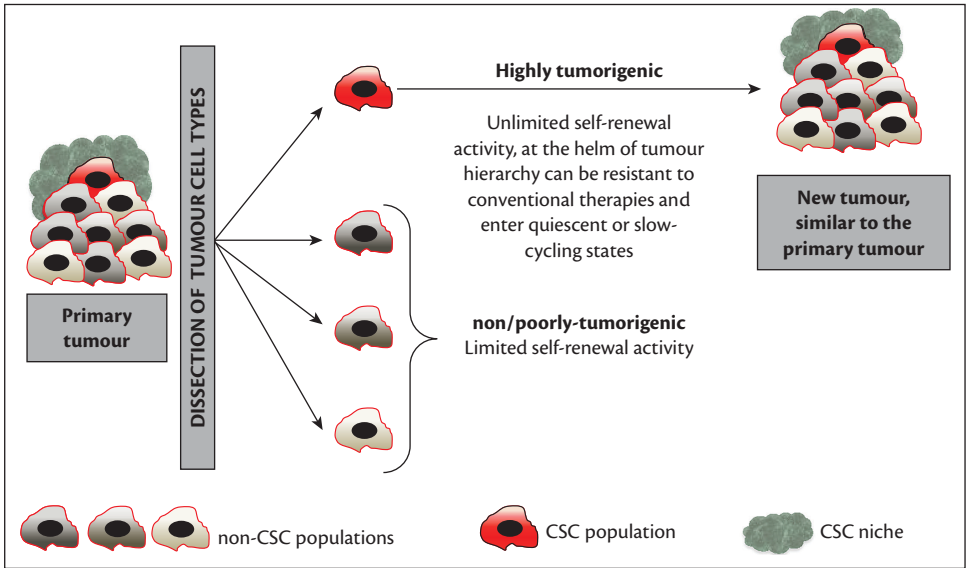
Although cellular quiescence does not seem to be a universal feature, some CSCs have been reported to shuttle between quiescent, slow-cycling, and active states, in a way similar to the behaviour of many adult stem cell types [14, 42–45]. For example, the presence of quiescent leukaemic stem cells (LSCs) has been reported in a mouse model for acute myeloid leukaemia (AML) [46]. Moreover, using clonal tracking techniques, delayed-contributing CSC clones were identified both in AML and in colon carcinoma, suggesting the existence of long-term quiescent/dormant pools of human CSCs [15, 41]. In line with these findings, a report showed a strong correlation between the number of slow-cycling breast cancer cells, as measured by retention of the membrane dye PKH26 in mammosphere cultures and the frequency of CSCs, assessed by tumorigenicity assay in mice. Of major importance, quiescence or slow-cycling states might render CSCs less likely to be responsive to conventional chemotherapy, which mainly targets cycling cells.


Fig. 10.1 The classical 'cancer stem cell' (CSC) concept. Tumours are heterogeneous and hierarchically organized entities. Upon dissociation and transplantation into an immunocompromised animal, human CSCs can be functionally distinguished from non/poorly tumorigenic cell populations by their ability to reinitiate and grow a similar heterogeneous tumour in vivo.

Moreover, quiescent normal stem cells can re-enter the cell cycle after injury in order to repair a tissue [14, 42, 46]. In agreement with this stem cell feature, it has been hypothesized that potential reactivation of quiescent CSCs might induce tumour relapse, which sometimes occurs decades after completion of therapy [47].

Increased resistance to conventional therapies

Similar to physiological stem cells, some CSCs were reported to exhibit remarkable resistance to chemotherapies. For instance, breast CSCs were found to accumulate in women with locally advanced tumours after cytotoxic chemotherapy had eliminated the bulk of the tumour cells [48]. Similarly, in chronic myeloid leukaemia (CML), BCR-ABL-driven LSCs are resistant to tyrosine kinase inhibitors (TKIs) such as imatinib, whereas these compounds eliminate the rest of the leukaemic cells, often even achieving a complete molecular response (undetectable levels of BCR-ABL mRNA by RT-PCR) [49, 50]. Accordingly, during STOP trials, in which TKI treatments are discontinued, tumour relapse was observed in the majority of patients. This was most likely caused by new tumour cell production by resistant CML-LSCs, as the relapsed 'non-LSC' leukaemic cells remained sensitive to the initially used TKI [51, 52]. Another case of resistant CSCs was reported for myelodysplasia carrying a 5q deletion. While the majority of tumour cells were efficiently targeted by treatment with the immunomodulator lenalidomide, leading to a complete clinical and cytogenetic remission, most patients relapsed due to the outgrowth of remaining resistant CSCs [53].

CSC resistance might first of all be caused by increased drug efflux capacities, mediated by expression of multidrug resistance (MDR) transporters [54]. Indeed, cancer cells named 'side population', due to their ability to efflux the fluorescent dye Hoechst, have been reported to be highly enriched for both normal and cancer stem cells [55]. Second, aldehyde dehydrogenase-1 (ALDH-1), a cytosolic enzyme involved in the catalysis of aldehyde oxidation, was reported to be specifically active in several CSCs [56]. In a retrospective study, ALDH-1 activity was significantly higher in breast cancer metastatic cells, which developed resistance to cyclophosphamide, compared to sensitive cells [57]. This suggests that ALDH-1 might also play a role in cytotoxic drug resistance. Third, genotoxic treatments like ionizing radiation might be evaded by CSCs due to increased DNA damage check point response and DNA repair capacities, as observed in CD133-expressing glioblastoma CSC-enriched populations compared to CD133-negative populations [58]. Last, CSCs might counterbalance the radiation-induced reactive oxygen species (ROS) production by increased expression of free radical scavengers, as reported for murine and human breast CSCs [59]. This ability might selectively protect CSCs from ROS-mediated DNA damage and hence explain their resistance to irradiation. Importantly, in vitro studies of drug-sensitive tumour cell lines suggest that cancer cells might transiently and reversibly acquire drug resistance, indicating that drug resistance might not always be a stable trait [60].

The CSC niche

The tumour microenvironment is composed of diverse immune cells, stromal cells, as well as extracellular components [61, 62]. CSC functional traits might be sustained by this microenvironment, termed 'niche' [63]. For instance, vascular endothelial cells maintained self-renewal and promoted tumorigenicity of glioma CSCs in a mouse xenograft model [64]. Hypoxia, notably via the hypoxia-inducible factor 2-alpha (HIF2α) increased glioma CSC self-renewal and

tumorigenic capacities [65]. Moreover, inflammatory cells and molecules such as interleukin 6, secreted by infiltrating immune cells in the tumour, enhanced the proliferation of colitis-associated CSCs [66].

The CSC niche might not only regulate CSC traits but might also directly provide CSC features to non-CSCs. For instance, tumour-associated myofibroblasts enhanced self-renewal of colorectal CSCs via HGF production but also strongly enhanced the in vivo tumorigenicity of non-CSCs through their secreted factors [67]. Extracellular matrix proteins such as periostin and Tenascin-C are critical for the outgrowth of breast cancer metastatic cells in the lung, possibly by coordinating the interaction with neighbouring cells and by enhancing signalling mediated by growth-promoting signalling factors [63].

In leukaemia and in prostate carcinoma cancer, cells could hijack existing physiological stem cell niches. Although physiological stem cell niches are known to play important roles for quiescence maintenance and resistance to stress-inducing treatments [68, 69], the influence of the tumour niche on CSC function at the cellular and molecular levels still remains to be elucidated.

Origin of CSCs

Importantly, the CSC concept has to be separated from the 'cell of origin' question: as outlined above, CSCs are defined by a series of functional tumour-propagating traits. However, the tumour 'cell of origin' defines the cell type from which the disease is derived, meaning the cell type first hit by an oncogenic mutation. However, this 'cell of origin' does not necessarily immediately acquire a CSC phenotype [70]. Having said this, CSCs might indeed originate from stem cells, as they are already capable of almost limitless self-renewal. For instance, embryonic stem cells can form teratomas when transplanted subcutaneously in recipient mice.

Nevertheless, CSCs can also originate from more differentiated progenitors that acquire stemness traits by accumulation of genetic or epigenetic abnormalities. For instance, progenitors derived from stem cells that already carry initiating genetic mutations acquire further mutations during differentiation that will finally lead to transformation. This would mean that the 'cell of origin' for the first mutation is a stem cell, but that the CSC that drives the tumorigenic clone would be a more differentiated progenitor. Such a scenario has been reported for chronic myeloid leukaemia (CML). Although the BCR–ABL fusion protein is the first event and is present in haematopoietic stem cell (HSC)-like CML cells (suggesting that the 'cell of origin' of the disease is a normal HSC), advanced-stage LSCs during blast crisis were found to be in a state similar to granulocyte/macrophage progenitors (GMPs) [71]. Similarly, in AML, the AML–ETO fusion protein is present in HSCs ('cell of origin' of the disease) but the functional leukaemic stem cells were detected in a Thy1-progenitor cell state. However, in acute promyelocytic leukaemia (APL), the MLL–AF9 fusion protein was not detected in HSCs, but when introduced in mouse GMPs, it could induce leukaemia, indicating that both the 'cell of origin' and the leukaemic stem cells were found in progenitors rather than in HSCs [72].

Recent work on induced pluripotent stem cells (iPS) has demonstrated that contrary to all expectations, the acquisition of self-renewal and pluripotency starting from any cell type can be achieved by activation of as little as four transcription factors [73]. Importantly, this reprogramming process requires the transient repression of p53 and INK4a, two of the most frequently mutated tumour suppressor loci in human cancers [74]. Similarly, loss of the same tumour suppressors causes an activation of a self-renewal

programme in normally non-self-renewing haematopoietic progenitors; consequently, these cells start to behave as haematopoietic stem cells in vivo despite maintaining a progenitor phenotype. Thus, these cells do not de-differentiate, but rather acquire self-renewal potential after loss of tumour suppressors [75]. These data raise the possibility that the accumulation of mutations in certain oncogenes and tumour suppressors may lead to a process that may be described as a partial reprogramming, with the acquisition of self-renewal activity paralleling the development of CSC activity. Indeed, in vitro reprogramming of human skin fibroblasts by stable expression of hTERT, H-RasV12 and SV40 LT and ST antigens leads to the generation of cells with CSC properties, able to form hierarchically organized tumours in mice [76]. Similarly, experimentally induced expression of the depolarization-inducing transcription co-activator TAZ [77] as well as experimentally induced expression of epithelial to mesenchymal transition (EMT)-inducing transcription factors TWIST or SNAIL [78] was reported to provide CSC-like properties to non-CSC cells.

Identification of cancer stem cell biomarkers

The cancer stem cell concept proposes that one of the major parameters to evaluate therapy efficacy is the quantification of remnant CSCs within minimal residual disease and not of gross measurement of tumour regression, as is typically used in clinical drug trials. Therefore, one major aim in the field is to identify reliable and specific CSC biomarkers for each tumour type.

Bonnet and Dick identified LSCs in AML by limiting dilution transplantations in non-obese diabetic/severe combined immunodeficient (NOD/SCID) mice as CD34+/CD38- leukaemic cells, closely resembling normal HSCs [1]. However, in the meantime, examination of a large set of AML patients revealed that functional CSC clones reside within several distinct immunophenotypically defined cellular compartments, showing significant inter-patient heterogeneity [19].

For solid tumours, a first leap forward was achieved in 2003, when Michael Clarke and colleagues reported the identification of breast CSCs within the EPCAM+/CD44+/CD24$^{low-neg}$ population of mammary pleural effusion and tumour samples. As few as a hundred EPCAM+/CD44+/CD24$^{low-neg}$ cells were able to reinitiate the original tumour in NOD/SCID mice, while 10,000 cells with an alternate phenotype were not [21]. Subsequently, breast cancer metastasis-initiating cells (MICs) were identified in the blood of hormone receptor-expressing luminal breast cancer patients. These EPCAM+/CD44+/MET+/CD47+ cells had the potential to initiate new metastasis after transplantation into immunocompromised mice, directly demonstrating that an often small proportion of circulating tumour cells had MIC activity [23].

Following these landmark publications, CSCs were identified in many more solid and haematopoietic human tumours as summarized in Table 10.1. Importantly, several reports indicate the existence of CSC-enriched populations displaying different, sometimes non-overlapping, sets of markers for the same tumour type. For example, only 1% of breast cancer cells simultaneously express both reported CSC phenotypes EPCAM+/CD44+/CD24$^{low-neg}$ and ALDH–1+. This discrepancy might be due to several different reasons. First, differences in methods could be responsible for these differences [34, 38]. Second, several CSC clones may co-exist within primary tumours [19] and the research groups may have detected different CSC populations. Third, functional CSC clones might reside within several immunophenotypically defined

cellular compartments [19, 79]. Last but not least, cancer entities are rarely uniform. For instance, during the last few years, various genome-wide gene expression profiling efforts combined with biomarker and clinical approaches have led to the sub-classification of breast cancers into increasing numbers of molecular subtypes [80, 81]. The mutational patterns vary between the different subtypes and this genetic heterogeneity is likely paralleled by a heterogeneous CSC complexity. Different CSC phenotypes might thus be associated with genetically diverse cancer-subtypes.

Therapeutic targeting of cancer stem cells

Studies on AML show that the signature of functionally validated LSCs is a good predictor for poor patient survival independent of any biomarker [19]. These data strongly suggest that therapeutic targeting of CSCs should be relevant for patients. However, many technical hurdles still need to be overcome.

Targeting CSC biomarkers

CD44, a transmembrane glycoprotein involved in cell–cell and cell–matrix adhesion is expressed on many tumour CSCs (Table 10.1). Altering CD44 function by a specific antibody inhibited AML-LSC proliferation in xenograft studies probably by inhibiting LSC-niche interactions [82]. However, universal targeting of CD44, which is also expressed by many adult stem cells, might be deleterious for patients. Undesirable effects might be evaded by targeting different isoforms of CD44 specifically expressed by tumour cells, such as CD44v6 [83]. However, severe skin toxicity has been reported in a phase I clinical trial of bevatuzumab (an anti-CD44v6 antibody) in the case of head and neck squamous cell carcinoma [84]. Nevertheless combination of the immunoconjugate bevatuzumab–mertansine with external beam radiotherapy provided improved local tumour control with possible targeting of CSCs [85].

More recently, successful eradication of AML-LSC was described by targeting of CD123 (interleukin-3 (IL3) receptor alpha chain), using a blocking antibody in xenografted mice. However, since CD123 is also expressed by normal HSCs, there is a risk of severe side effects. Targeting ABC transporters expressed by CSCs has also been explored [86] but was put on hold after realizing that these transporters play pivotal roles in blood-brain-barrier maintenance as well as in adult stem cell maintenance.

Targeting CSC molecular pathways

Based on the hypothesis that cancer cells might be more dependent on the activation of oncogenic pathways than their normal counterparts, a phenomenon termed 'oncogene addiction' [87], pharmaceutical companies have applied major efforts to target signalling pathways activated in CSCs and cancer cells in general. For instance, the NFκB pathway has been successful targeted and allowed selective eradication of AML and final phase (blast crisis) CML-LSCs. Guzman and colleagues treated in vitro leukaemic cells with parthenolide, a drug known to directly bind IκB kinase (IKK) as well as to modify p50 and p65 subunits. This pretreatment induced higher levels of ROS, which lead to a decrease of CD34+CD38– leukaemic populations and an impaired capacity of leukaemic cells to engraft in NOD/SCID mice, suggesting that mainly LSCs were targeted [88]. Similarly, inhibition of NOTCH signalling using gamma-secretase inhibitors in CD133 expressing medulloblastoma CSCs led to the diminution of CD133+ cells and correlated with impaired tumour engraftment in vivo [89]. Last, but not least, inhibition of the TGFβ

pathway by bone morphogenetic proteins (BMPs) was reported to lead to the differentiation of brain CSCs and successive cure of the disease in a xenograft model, providing a first proof of principle for the possible efficacy of a 'differentiation therapy'.

Sensitization to therapy

A number of studies have aimed to sensitize CSCs to therapy. For instance, in colon cancer IL4 blockade successfully primed CSCs to chemotherapy. In glioblastoma, a CHK kinase inhibitor increased the radiosensitivity of CSCs [58]. In addition, recent reports showing that dormant and chemotherapy-resistant normal stem cells can be activated and simultaneously sensitized to chemotherapy-mediated killing might provide a strategy to target dormant CSCs [42, 46]. Here a sequential treatment scheme would be used in which dormant CSCs would first be 'primed' and activated, followed by chemotherapy leading to complete elimination of the tumour including the initially dormant and resistant CSCs. Such a strategy was successfully applied in mouse models of AML and CML [46]. However, activation of dormant cancer stem cells may harbour the risk of disease progression and requires a highly efficient therapeutic option for the second phase, such as tyrosine kinase inhibitors in case of BCR-ABL driven CML. Finally, in a mouse model of APL, LSCs expressing PML-RARα (promyelocytic leukaemia-retinoic acid receptor alpha) could be forced out of self-renewal into differentiation by cooperative treatment of arsenic, cyclic AMP, and retinoic acid, leading to LSC clearance and impressive remission in patients [90].

Novel strategies to target CSCs

Some new hope might arise from the development of bi-specific or tri-specific antibodies that are able to specifically target cell populations. For instance, T-cell recognition via an anti-CD3 antibody can be combined with cancer cell recognition via an additional antigen-binding site such as EPCAM (catumaxomab) or HER2 (ertumaxomab) [91, 92].

In addition, high-throughput screening of drugs selectively inhibiting CSCs, rather than other tumour cells, has been successfully used to uncover compounds such as salinomycin. This antibiotic drug targets putative breast CSCs (grown as mammospheres in culture), as well as CLL LSCs, probably via inhibition of the Wnt pathway [93]. However, the toxicity of this molecule on physiological stem cells remains unexplored.

Last, but not least, recent discoveries concerning specific CSC biological properties might lead to the development of novel targeting strategies: for instance, glioma stem cells were found to be mechanistically distinct from their less tumorigenic counterparts regarding production of nitric oxide via nitric oxide synthase-2 (NOS2). NOS2 inhibition successfully slowed down tumour growth in a xenograft glioma model [94]. Similarly, glycine decarboxylase activity was found to be critical for non-small-cell lung CSCs suggesting that glycine metabolism might be a novel anti-CSC target [31]. However, in both cases, general toxicity of such treatments has not yet been thoroughly investigated.

In summary, therapeutic applications deriving from CSC studies are less straightforward than was initially anticipated, notably due to the large overlap in molecules expressed by CSCs and their respective normal stem cells that has so far hampered their use in the clinic due to collateral toxicity [95]. Nevertheless, without the efficient eradication of CSCs, a long-term cure for many cancer patients appears unreachable. Innovative efforts will therefore be required from the field to achieve this goal in the not too distant future.

Dynamic model of CSCs

Given the pace of research in the field and the diverse nature of the results, the classical view of CSCs needs to be updated. In this section, we introduce a more dynamic model for CSCs and integrate recent results into this model.

Multiple genetic CSC clones within one tumour

Recent studies in which several subregions of the primary tumour and metastases of pancreatic and kidney cancers were sequenced revealed an unexpected degree of intra-tumour heterogeneity [96–98]. This often highly underestimated heterogeneity may result from the fact that CSCs are genetically unstable. Indeed, in colon cancer such genetic instability was reported, leading to the formation of new CSC clones deriving from an initial 'parental' CSC clone [99]. In addition, two landmark studies in human ALL studied the genetic architecture of LSCs over time and following successive transplantations in xenografted mice. Both studies showed that several LSC clones co-exist within single patients. During disease progression, after therapy, and following serial xeno-transplantation, different LSC clones can take over and initiate new tumours [100, 101]. This might explain, at least partially, the observed 'acquired resistance' to targeted therapy observed in some patients. That is, after successfully targeting sensitive CSC clones, already present resistant clones may take over, mimicking an acquisition of resistance to the applied treatment. As a consequence, tumours might not be faithfully represented by single-headed hierarchical structures bur rather might resemble more oligarchic structures, displaying multiple heads: if one head, i.e. a CSC clone, is cut off (by targeted therapy, for instance), another one might take over, repopulating the tumour. Thus, dynamic hierarchies might exist within a single CSC clone and its progeny (intra-CSC clone hierarchy), but also between different genetically diverse CSC clones that compete with each other (inter-CSC clone hierarchy) (Figure 10.2A).

CSCs need not be rare

CSCs do not need to be rare, as shown by Kelly and colleagues using leukaemia and lymphoma genetic mouse models [4]. Indeed, CSC-enriched populations have been reported to represent extremely variable proportions of bulk tumour cells, ranging from 0.2% to 82.5% (Table 10.1). Moreover, the frequency of CSCs might increase during tumour progression, as recently shown by in vivo limiting dilution assays of grade 1 and grade 3 breast tumours [102].

During the last few years, the idea that CSCs must be rare, which is based on our knowledge of physiological stem cells, has often led to a questioning of the CSC hypothesis. For instance, it was reported that melanoma stage III to IV tumorigenic cells are very abundant, representing up to 30% of the tumour bulk. Moreover, the screening of a very high number of cell surface markers failed to distinguish these tumorigenic cells from other tumour cells [5]. From these results it was proposed that melanoma does not follow a CSC model but rather a stochastic model, where tumorigenicity is a random feature distributed among all tumour cells [103].

Although this is certainly possible, there are also alternative explanations to these observations. The difficulty of finding any relevant biomarkers for stage III to IV tumorigenic melanoma cells might be technically explained by the temporary loss of surface proteins due to the use of trypsin. Without using this enzyme, CD271 could be identified as a melanoma CSC marker by two other groups [33, 34].
Fig. 10.2 The dynamic CSC concept. (A) Although early-stage tumours might be governed by a single CSC clone, advanced-stage tumours might contain several distinct but related clones, either arising from the initial CSC clone or from its differentiated progeny via mutations or via induction by the CSC niche. Targeted therapy and/or chemotherapy eliminate(s) the tumour mass including possibly some of the CSCs. At least one resistant CSC clone is then responsible (possibly after acquiring additional mutations) for tumour relapse. (B) Advanced-stage tumours contain several distinct but related CSC clones. Some acquire enhanced self-renewal capabilities with simultaneously decreased differentiation. During tumour progression, the CSC clones compete with each other, leading to the dominance of at least one CSC clone with the subsequent loss of differentiated tumour progeny. Over time, this leads to a flattening of the hierarchical structure and to a selection of the most aggressive CSCs. Late-stage tumours may thus be comprised almost exclusively of aggressive, multiresistant CSCs, a situation similar to the one proposed by the stochastic model. (C) Carcinoma CSCs display a dynamic phenotype during systemic dissemination: they are able to at least partially lose epithelial traits through epithelial to mesenchymal transition (EMT). Probably only a subset of such disseminating CSCs is able to survive in the systemic circulation, extravasate, reacquiring epithelial features (MET), to seed in a new microenvironment and to initiate metastasis. All three scenarios illustrated in (A), (B), and (C) occur in parallel and/or during different phases of tumour progression. © Baccelli I, Trumpp A, 2012. Reproduced with permission from *The Journal of Cell Biology*, The evolving concept of cancer and metastasis stem cells, Volume 198, Issue 3, pp. 281–293, doi: 10.1083/Jcb.201202014

Alternatively, late-stage melanoma might consist of several distinct CSC clones displaying different cell surface biomarkers that are all highly malignant. These CSC clones might even differ from patient to patient, as described for ALL [100, 101]. Moreover, a likely scenario is a high selection and enrichment of CSC clones, which have retained little or no differentiation capacity. In this scenario, the initial hierarchy in the tumour is steadily decreased and flattened, leading to late-stage tumours composed almost exclusively of heterogeneous CSC clones (Figure 10.2B).

Plasticity of CSC phenotype

In recent years, the EMT process, in which epithelial polarized adherent cells are converted into mesenchymal-like depolarized migratory tumour cells, has been linked to the CSC phenotype and function in breast, pancreatic, and colorectal tumours. CSCs were found to express EMT-inducing transcription factors such as TWIST, SNAIL, and SLUG and, vice versa, EMT-undergoing cells were found enriched for CSC activities compared with cells

not undergoing EMT [104]. The process can be controlled by a ZEB1/mir200 feedback loop mechanism (maintaining stemness), itself controlled by p53 [105]. Overall, these findings suggest that epithelial markers might be down-regulated in carcinoma CSCs and would therefore be missed in typical screens, which generally exclude cells lacking epithelial markers such as EPCAM. Furthermore, they underline the fact that epithelial CSCs might strongly modulate their phenotype during tumour progression: for example, a CSC detected in an early-stage primary tumour might have a completely different phenotype from the one of a CSC circulating in the blood (Figure 10.2C). As a consequence of this plasticity, some of the reported CSC biomarkers might be relevant in some stages of tumour progression but obsolete in others.

Generating a dynamic concept of CSCs

These recent data and others suggest a more complex and dynamic CSC model integrating the three main additional features.

First, tumours are by definition genetically unstable entities. Therefore, the cellular composition of a tumour in an early-stage disease, at relapse, or at late stages may display significant genetic differences including genetic heterogeneity. The available data suggest that in early neoplasms only a single or very few CSC clones drive tumour growth. During disease progression, new CSC clones can arise either from existing CSC clones or from the differentiated progeny via mutation-mediated partial reprogramming. After eradication of the majority of tumour cells by chemotherapy and/or targeted approaches, one or a few CSC clones may survive and expand, leading to a change in the clonal and cellular composition of the relapsing cancer (Figure 10.2A).

Second, the different genetically distinct CSC clones may also compete with each other, leading to the selection of CSC clones with high self-renewing activity and simultaneous loss of differentiation capacity. This would provide an explanation for the observed flattening of the cellular hierarchy within advanced-stage tumours, which creates a situation similar to what is proposed by the stochastic model (Figure 10.2B). Third, CSC biomarkers can be unstable, as indicated by studies on EMT in solid tumours (Figure 10.2C). Thus, reported CSC biomarkers might only be relevant for a given tumour stage and therefore need to be validated for each case in conjunction with functional analyses.

Importantly, this dynamic CSC model suggests that only complex combinatorial treatments are likely to be efficacious to target late-stage tumours or metastasis. First, mutations that are commonly present in all clones have to be identified, for instance, by whole-genome sequencing of various regions within a single tumour mass [96, 106]. The associated deregulated pathways of these common mutations present in all subregions (likely including the various tumour subclones) need then to be targeted by pathway-specific strategies. Second, these strategies need to be complemented by therapies targeting additional CSC-specific features (see above) to eliminate not only the non-CSC parts of each tumour clone, but also the various CSCs present in advanced-stage tumours or metastasis.

CSCs and metastasis-initiating clones (MICs)

Metastasis might be initiated by a subset of CSC clones

Systemic dissemination and metastasis is responsible for most cancer-related deaths. To date, human MICs have not yet been prospectively identified. However, several lines of evidence indicate

that MICs might be found within subpopulations of CSCs. First of all, carcinoma CSCs possess tumour-initiating capacity, which is a mandatory trait for the establishment of secondary tumours in distant organs. Second, they express EMT markers [105], suggesting that they are able to migrate, as well as making them likely candidates for metastasis-initiating activities.

More specifically, several reports suggest that MICs might be comprised within CSC populations: CD44+ breast cancer cells (comprising a breast CSC phenotype) were proposed to have enriched metastatic activities in xenograft studies [21, 23]. Similarly, CD44+CXCR4+ cells, a subfraction of the putative pancreatic CSCs present at the invasive front of cell-line-induced pancreatic tumours, were reported to be enriched for metastatic capabilities [37]. Along the same lines, CD26, in combination with the CSC marker CD133 has been proposed as a marker for colorectal MIC-enriched tumour populations in primary tumour xenograft experiments [40].

MICs might be late-stage disseminating CSC clones

MICs might disseminate at an early stage during tumour progression or might derive from late-stage disseminating CSC clones [107]. Through mapping of the genetic evolution of both pancreatic primary tumours and metastases by next-generation sequencing, two recent studies identified the genealogy of metastatic clones [96]. Both studies suggest that even if both primary tumours and metastases consist of heterogeneous clones, additional driver mutations are present in the metastasis-initiating clones compared to the clones present in the primary tumours. In addition, metastatic clones were evaluated to be arising rather late within primary pancreatic tumours [96], even if the dissemination process itself might start rather early [108], suggesting that functional MICs are typically disseminating from advanced-stage tumours rather than from early-stage primary tumours.

MICs must be found among disseminating tumour cells

Since metastasis results from the successful dissemination of primary tumour cells into a distant organ, MICs should be found among disseminating tumour cells. These include circulating tumour cells (CTCs) as well as disseminated tumour cells (DTCs), found, respectively, in the blood or in the bone marrow of carcinoma patients. In the case of many carcinomas and in particular for breast cancer, the presence and/or number of DTCs or CTCs are linked to poor clinical outcome [109, 110]. Interestingly, variable proportions of CTCs and DTCs have been reported to display CSC phenotypes by immunocytochemistry or flow cytometry [23, 110]. However, the detection methods for carcinoma CTCs remain controversial. This is due to the use of EPCAM and cytokeratins (CKs) as positive selection markers, as they are not specific to tumour cells, but rather detect epithelial cells. Moreover, these epithelial proteins might be down-regulated during EMT-mediated dissemination. Indeed, in breast cancer CTCs simultaneously express mesenchymal and epithelial markers. Moreover, during disease progression and in response to therapies, reversible shifts between these cell fates have been observed, suggesting that EPCAM-based detection methods may miss many CTCs in breast cancer patients [111]. In a mouse model for pancreatic ductal adenocarcinomas, less than 40% of genetically YFP-labeled CTCs expressed CK19 or EPCAM, suggesting that a large proportion of CTCs undergo EMT and lose expression of epithelial markers. Further, more than 40% of

the detected YFP-labelled CTCs expressed the previously reported pancreatic CSC markers (CD44+/CD24+) and showed high clonogenicity in vitro, suggesting that at least some of the detected CTCs have self-renewing potential [108].

Functional in vivo analyses of different subfractions of human CTCs or DTCs using xenograft assays are required to test whether phenotypic disseminating CSCs are indeed functionally involved in metastasis initiation. Recently, it could be demonstrated that primary CTCs isolated from metastatic hormone receptor positive breast cancer patients can initiate new bone, liver, and lung metastasis after transplantation into immunocompromised mice [23]. These MICs expressed cell surface receptors previously implicated in tumour and metastasis, including CD44, the receptor tyrosine kinase and HGF receptor MET, as well as CD47, an inhibitor of macrophage activity. Presence of these MICs correlated with poor clinical outcome, suggesting that these cells are causatively involved in metastasis formation. These cell surface receptors may serve as biomarkers and may offer new possibilities for the detection and targeting of MICs [23].

The metastasis-initiating cell model

MICs likely arise from subpopulations of late-stage CSC clones, hence the relevance for characterizing CSCs, even in late-stage tumours. In addition to the functional capacities of CSCs, MICs have to display metastatic capacities, meaning that they must disseminate, survive in the systemic circulation, extravasate at the metastatic site and seed and grow in the new environment. Several metastatic clones might co-exist during dissemination, exhibiting different site-specific migration and seeding capacities (Figure 10.3). Indeed, Massagué and colleagues have proposed that, in the context of breast cancer, different metastatic populations can be distinguished according to their capacity to metastasize to the bone, the lung, or the brain in patients with systemic disease [112]. This appears to be related to their capacity to directly or indirectly generate a metastatic niche [63].

Summary

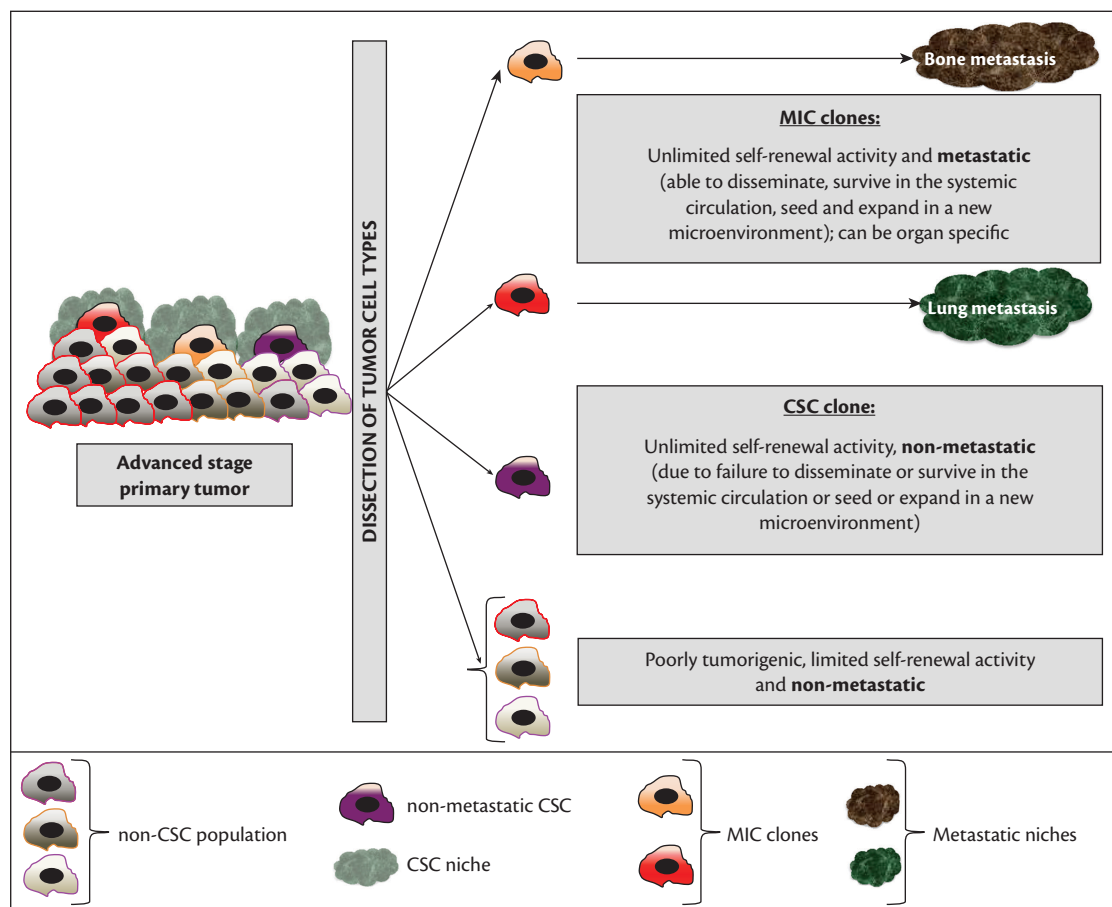
CSCs are a specific subset of transformed cells that are able to sustain primary tumour growth following a hierarchical pattern. Strong evidence for the existence of such cells exists in many cancer types, although the model may not be appropriate for all cancer types and/or all stages. Like any model, the CSC concept needs to be constantly adapted to the currently available data and is thus steadily evolving. Recent findings uncovering high intra-tumour genetic heterogeneity have led to the observation that several CSC-controlled clones can co-exist and compete with each other within a tumour. Furthermore, CSCs may have unstable phenotypes and genotypes,


Fig. 10.3 The 'metastasis-initiating cell' (MIC) concept. Advanced-stage primary tumours are heterogeneous and multihierarchical structures. Upon dissociation and transplantation in immunocompromised hosts, MICs can be functionally distinguished from CSC clones by their metastatic ability in vivo (dissemination, survival in the systemic circulation, extravasation, seeding, and expansion in a new microenvironment, termed 'metastatic niche'). MICs are adapted descendants and therefore subpopulations of CSCs with metastatic capacity and possibly organ specificity.

which makes it difficult to identify reliable and robust biomarkers and develop associated targeted therapies. In addition, cell-extrinsic factors provided by the CSC niche might provide yet another dimension to the complexity of CSC regulation. Importantly, most cancer-related deaths are a consequence of metastasis development rather than due to growth of the primary tumour. Therefore the better characterization of MICs will become pivotal in the future, in order to prevent and target so far insufficiently treatable metastatic disease. Importantly, the identification of CSCs is also therapeutically relevant for late-stage tumours since MICs in the blood or in distant tissues are likely a subset of CSCs. Evolving the CSC concept will help to focus research towards developing improved therapies by lowering the risk of tumour recurrence and allow the development of targeting strategies for fatal late-stage cancers.

CHAPTER 11

Biomarker identification and clinical validation

Richard D. Kennedy, Manuel Salto-Tellez,
D. Paul Harkin, and Patrick G. Johnston

Introduction to biomarker identification and clinical validation

With a few notable exceptions, most cancer therapy is given in a 'one size fits all' manner depending on the anatomical site involved and basic histopathology. In addition, drug dosage has been calculated from clinical trials using toxicity as an endpoint. Although these approaches have been quite successful in the past, an improved understanding of cancer at a molecular level has questioned how we develop novel drugs and how we select appropriate patients in the clinic.

Studies in solid and haematological cancers have demonstrated that cancers originating from a single anatomical site can represent complex diseases with several molecular subtypes. For example, breast cancer comprises at least five distinct diseases, which have different clinical outcomes and respond to therapies differently. This heterogeneity in diseases may explain why single-agent chemotherapy drugs rarely exceed 30% response rates and why the attrition rate in clinical trials remains high in cancer medicine.

A better knowledge of cancer biology has also led to therapies that target specific molecular pathways. These drugs are highly unlikely to work in the context of an unselected patient population and are also often very expensive. It is clear that some strategy will be required to select appropriate patients for these therapeutic approaches. In addition, these drugs do not result in the toxicities associated with conventional cytotoxic agents, such as bone marrow suppression, making the endpoints in dose escalation studies more challenging.

Biomarkers that allow personalization of treatment to a patient's specific disease offer a solution to these issues. The USA National Institute of Health defines a biomarker as: 'a characteristic that is objectively measured and evaluated as an indicator of normal biologic processes, pathogenic processes, or pharmacologic responses to a therapeutic intervention' [1]. There are many cancer-related biomarkers that have been published in peer-reviewed articles; however, very few have made an impact on patient care. This is largely due to a failure to demonstrate clinical validity. In this chapter we aim to explain the process of biomarker discovery and delivery with a view to helping the practising physician and translational researcher appreciate what constitutes a valid biomarker suitable for clinical use.

Types of biomarker used in cancer management

The biomarkers used in cancer management can be categorized into seven major groups that cover the spectrum through from identification of patients at risk to treatment decisions (Figure 11.1). Each of these is discussed in more detail below.

Biomarkers of cancer risk

These are typically inherited somatic mutations in tumour suppressor genes that can be detected by sequencing or sequence-specific PCR approaches using normal cells (often white blood cells). They predict a high risk of developing cancer within an individual's lifetime. Examples are mutations within the BRCA1 or BRCA2 gene that predict increased risk of breast and ovarian cancer [2, 3], mutations in the mismatch repair genes MSH2, MSH6, and MLH1 that predict increased risk of colorectal cancer, ovarian cancer, and endometrial cancer (hereditary non-polyposis coli [4]) and mutations in the p53 gene that predict increased risk of breast, connective tissue and brain tumours (Li-Fraumeni syndrome [5]). These markers are used to inform primary screening approaches such as regular mammography, ultrasonography, or colonoscopy as well as surgical prophylaxis.

Tumour markers

These biomarkers help the clinician to estimate the amount of viable tumour in a patient either as an adjunct to imaging approaches or as a sensitive test for small levels of disease below radiological detection. They can also, in some circumstances, be used as diagnostic tests, although most are relatively non-specific and should not be used alone. Typically, they are glycoproteins that are expressed from tumour sites and can be measured by ELISA assays. Examples are CA-125 for ovarian cancer, carcinoembryonic antigen (CEA) for colorectal cancer, prostatic specific antigen (PSA) for prostate cancer, CA19-9 for pancreatic cancer, beta-2 microglobulin for lymphoproliferative diseases, paraproteins for multiple myeloma, alpha-fetoprotein (AFP) for hepatoma, beta-human chorionic gonadotrophin (beta-HCG) for choriocarcinoma and beta-HCG/alpha-fetoprotein for germ cell tumours. Recently, technology has been developed that can isolate and

quantitate circulating tumour cells in patients with solid tumours. This technique promises to be a further approach to estimating tumour response in the future [6].

Prognostic biomarkers

These biomarkers are used to estimate the outcome for a patient, usually in terms of disease-free, progression-free, or overall survival in the absence of a specific treatment. For example, high tumour grade is a prognostic factor associated with a higher chance of disease relapse in many cancer types. The presence of metastatic disease in the regional lymph nodes in breast or colorectal cancer patients has been a useful prognostic biomarker and has guided treatment towards adjuvant chemotherapy after surgery. More recently, the multigene OncotypeDx® breast cancer test has been shown to estimate the likelihood of disease recurrence following surgery in early oestrogen receptor positive breast cancer in the absence of adjuvant cytotoxic chemotherapy [7]. Those at high risk of recurrence have been shown to benefit from the addition of chemotherapy. Similarly, it has recently been reported that the presence of microsatellite instability in stage II colon cancer may indicate a biomarker of good prognosis and therefore indicate no requirement for adjuvant chemotherapy [8]. The National Cancer Institute–European Organization for Research and Treatment of Cancer working group on cancer diagnostics have published **Re**porting recommendations for tumor **mark**er prognostic studies (REMARK criteria, Box 11.1) [9].

Predictive biomarkers

These estimate the likelihood of a patient benefiting from a specific therapy either in terms of an objective response or in terms

of disease-free or overall survival. A number are already used in the clinic to guide treatment (Table 11.1). Predictive markers can be used to improve drug development in two major ways. First, in early first-in-man studies, predictive biomarkers can be used to select patients thought likely to benefit. This is often referred to as a 'trial enrichment strategy'. The development of drugs that show no activity in these enriched populations may be halted in favour of more active compounds. An example was the selection of BRCA1 and BRCA2 mutant patients for first-in-man studies with single-agent olaparib, a PARP inhibitor [10].

The second application is the selection of patients that show superior outcomes to conventional therapy in drug registration studies (usually phase III). In this context the biomarker effectively becomes part of the treatment as it is required prior to administering the drug (referred to as 'on-label') and its validation falls under the appropriate regulatory authority such as the EMA or FDA. An example would be the on-label use of FDA-approved HER2 tests for patients receiving trastuzumab.

Pharmacogenomic markers

Although the response to cancer treatment often depends on tumour-specific molecular factors, naturally occurring genetic variations in normal somatic cells can also influence outcome. Single nuclear polymorphisms (SNPs) are base variations in genetic sequences, which occur in over 1% of the population. They can lead to altered metabolism of cancer drugs that increase or decrease their activity, and can therefore have important clinical consequences. Examples of SNPs that result in decreased metabolism are those in dihydropyrimidine dehydrogenase (DPD) which increase toxicity with 5 fluorouracil [11], in UDP-glucuronosyltransferase

Box 11.1 REMARK criteria

Introduction

1. State the marker examined, the study objectives, and any pre-specified hypotheses.

Materials and methods

Patients

2. Describe the characteristics (e.g., disease stage or comorbidities) of the study patients, including their source and inclusion and exclusion criteria.

3. Describe treatments received and how chosen (e.g., randomized or rule-based).

Specimen characteristics

4. Describe the type of biological material used (including control samples) and methods of preservation and storage.

Assay methods

5. Specify the assay method used and provide (or reference) a detailed protocol, including specific reagents or kits used, quality control procedures, reproducibility assessments, quantitation methods, and scoring and reporting protocols. Specify whether and how assays were performed blinded to the study end point.

Study design

6. State the method of case selection, including whether the study design was prospective or retrospective and whether stratification or matching (e.g., by stage of disease or age) was used. Specify the time period from which cases were taken, the end of the follow-up period, and the median follow-up time.

7. Precisely define all clinical endpoints examined.

8. List all candidate variables initially examined or considered for inclusion in models.

9. Give rationale for sample size; if the study was designed to detect a specified effect size, give the target power and effect size.

Statistical analysis methods

10. Specify all statistical methods, including details of any variable selection procedures and other model-building issues, how model assumptions were verified, and how missing data were handled.

11. Clarify how marker values were handled in the analyses; if relevant, describe methods used for cutpoint determination.

Results

Data

12. Describe the flow of patients through the study, including the number of patients included in each stage of the analysis (a diagram may be helpful) and reasons for dropout. Specifically, both overall and for each subgroup extensively examined report the numbers of patients and the number of events.

13. Report distributions of basic demographic characteristics (at least age and sex), standard (disease-specific) prognostic variables, and tumor marker, including numbers of missing values.

Analysis and presentation

14. Show the relation of the marker to standard prognostic variables.

15. Present univariate analyses showing the relation between the marker and outcome, with the estimated effect (e.g., hazard ratio and survival probability). Preferably provide similar analyses for all other variables being analyzed. For the effect of a tumor marker on a time-to-event outcome, a Kaplan–Meier plot is recommended.

16. For key multivariable analyses, report estimated effects (e.g., hazard ratio) with confidence intervals for the marker and, at least for the final model, all other variables in the model.

17. Among reported results, provide estimated effects with confidence intervals from an analysis in which the marker and standard prognostic variables are included, regardless of their statistical significance.

18. If done, report results of further investigations, such as checking assumptions, sensitivity analyses, and internal validation.

Discussion

19. Interpret the results in the context of the pre-specified hypotheses and other relevant studies; include a discussion of limitations of the study.

20. Discuss implications for future research and clinical value.

(UGT) which result in toxicity with irinotecan [12] or in thiopurine s-methyltransferase (TPMT) that predisposes to severe toxicity with 6-mercaptopurine [13]. SNPs may also result in decreased drug activation leading to loss of drug efficacy such as those affecting CYP2D6 that decrease the activity of tamoxifen [14].

Pharmacodynamic biomarkers

These biomarkers are used to measure the effect of a drug on its specific target and are used in dose optimization studies. This approach has become increasingly important as modern therapies that are targeted to specific molecular pathways are unlikely to have the same toxic effects observed for conventional DNA-targeted treatments. This can mean that traditional dose escalation to grade 3–4 toxicity may result in a drug dosage far

Table 11.1 Examples of predictive biomarkers used in routine clinical practice

Biomarker	Technology	Disease	Drug	References
BCR-ABL translocation	FISH	Chronic myeloid leukaemia	Imatinib	[25]
BRCA 1/2 mutation	Sequencing	Breast and ovarian cancer	Olaparib	[26]
BRAF mutation	PCR/sequencing	Melanoma	Vemurafenib	[27]
CD20 expression	Immunohistochemistry	B Cell lymphoma	Rituximab	[28]
C-kit mutation	PCR/Sequencing	Gastrointestinal stromal tumour	Imatinib	[29]
EGFR mutation	PCR/sequencing	Non-small-cell lung cancer	Gefitinib	[30]
EML4-ALK translocation	PCR/FISH	Lung adenocarcinoma	Crizotinib	[31]
HER2 amplification	Immunohistochemistry/in-situ hybridization	Breast Cancer	Trastuzumab	[32]
KRAS mutation	PCR/sequencing	Colorectal cancer	Cetuximab, panitumumab	[33, 34]
Oestrogen receptor Expression	Immunohistochemistry	Breast cancer	Tamoxifen, anastrozole	[35]

in excess of that required for complete inhibition of the pathway of interest. Pharmacodynamic (PD) markers allow investigators to find an appropriate biologically active drug dosage that may be well below toxic levels. This can make the treatment more tolerable to patients, save on the amount of drug administered with economical benefits, and reduce the likelihood of additive toxicity if the drug is combined with other more conventional cytotoxic therapies.

Ideally, the PD marker is measured in the tissue of interest and is directly related to the drug's mechanism of action, such as dephosphorylation of tumour PRAS40 for AKT inhibitors [15]. Alternatively, markers of proliferation such as tumour expression of Ki67 can be used to demonstrate drug activity as has been reported for aromatase inhibitors in breast cancer treatment [16]. In some studies, peripheral tissue has been used to demonstrate drug activity such as eyelash bulb H2AX expression for PARP inhibitors [10] or peripheral blood white cells for histone deacetylase activity following administration of HDAC inhibitors [17].

Radiological approaches are also being investigated as PD markers in cancer drug development. For example, dynamic contrast enhanced MRI and contrast-enhanced ultrasound have been used to measure tumour blood vessel response to anti-angiogenic agents [18, 19].

Biomarkers of physiological processes

The measurement of physiological processes such as renal function, liver function, and bone marrow function by electrolyte, metabolite, and blood cell and platelet counts is an important biomarker in cancer patient management. The clinician can potentially give or withhold treatment based on these measurements so it is essential they are measured with the same quality and their limitations understood as much as in the case of other cancer biomarkers.

Biomarker discovery

Biomarker discovery can either be hypothesis driven, where an investigator knows the likely molecular pathway that influences patient outcome, or investigational, where a biomarker is discovered in an unbiased fashion. An example of a hypothesis-driven approach would be where a drug is known to target a specific molecular pathway that can be affected by a cancer-related mutation. Examples are the use of activating BRAF mutations as predictive biomarkers for BRAF inhibitors or activating EGFR mutations as predictive biomarkers for EGFR-targeted therapies. A pure investigational approach may be taken where it is unclear which pathways are responsible for patient outcome such as the DNA-microarray-based discovery of a 70-gene prognostic test for early breast cancer (Mammaprint®) [20].

Biomarker discovery study designs

Biomarker discovery can be performed using three main approaches.

Preclinical model systems

Human cell lines and animal model systems can be used in the laboratory to model how a tumour may behave and respond to treatment in specific molecular contexts. This has the advantage that very specific questions around the biological relevance of a biomarker can be asked using single agent drugs. Preclinical systems, however, can also be misleading, as cancer behaviour can often be influenced by the immune system and tumour–stromal interactions. For example, human cell lines may demonstrate overexpression of genes that are unique to the artificial Petri dish environment and xenograft models for anti-angiogenic agents may not adequately model the biological pathways active in human tumours.

Retrospective archived tissue analysis

In this approach, archived material is analysed for biomarker discovery. This may be particularly useful in the case of prognostic biomarkers as the clinical follow-up and outcome data for a specific patient may be available. In addition, with the standard approach to tumour archiving there may be large numbers of samples available among clinical centres, particularly if formalin-fixed paraffin-embedded tissues are used. In the case of predictive

markers for novel therapies, however, it is unlikely that archived material will be available. Archived tumour material may also demonstrate degradation over time, introducing 'noise' to the analysis [21].

Prospective biomarker discovery

This may be the most appropriate approach when discovering a biomarker for a novel drug agent as material from responding and non-responding patients can be analysed to look for differences at a molecular level. One difficulty, however, may be the adequate powering of the study. Considering the heterogeneity that can occur in cancer, it is likely that at least 20 to 30 samples each from responding and non-responding patients will be required. If a drug agent has an expected response rate of 10% in a general population, 300 patients would need to be recruited to get 30 tissue samples from responders, which may be impractical. Novel adaptive trial designs may help to deal with this issue (Figure 11.2). Another problem is that novel agents are often combined with conventional drugs as part of a clinical trial. This makes it very difficult to identify biomarkers that are specific to the agent in question rather than for the combination of agents.

Given the importance of retrospective and prospective tissue collections in biomarker discovery and validation (see below), it is essential that those centres involved in such activities pay special attention to the quality of their retrospective and prospective biological collections. This is done through the establishment of institutional biobanks, which are tailored to provide samples for biomarker discovery and/or validation of the best possible quality and following the strictest ethical frameworks. In many instances, the quality of an institution's biobank is an indicator of the quality of its biomarker discovery programme.

Important issues with biomarker study design

Balancing for confounding factors

In the process of identifying a biomarker, samples from two populations with different outcomes are compared for molecular differences. These populations must be properly balanced for factors that may result in molecular differences independent from outcome or due to known prognostic or predictive factors. For example, if there is an over-representation of female patients in one of the sample sets then the biomarker may predict gender rather than outcome. If one sample set is predominantly comprised of high-grade tumours whereas the comparator is comprised of low-grade tumours, it is likely the resultant biomarker will predict outcome but this will have no clinical utility above standard histopathological examination. Examples of other factors to be considered for balancing between datasets are age, ethnicity, tumour stage, type of surgery, and concomitant medication.

Reagent effects

Many laboratory reagents are manufactured for research use only. They do not have the quality standards applied that would be expected for diagnostic tests and therefore demonstrate considerable variation between batches. This can result in considerable variation in biomarker results depending on which batch of reagent is used. For example, two batches of antibody may vary in concentration resulting in different immunohistochemical staining for the same sample. Ideally, this issue is dealt with by using GMP (good manufacturing procedure) grade reagents. Alternatively, the laboratory may choose to test every batch of new reagents to ensure correct performance or pool several batches of reagent to average out any batch-specific effects.

Population effects

When developing a biomarker it is important to ensure that it applies to the population in which it will be used. For example, a biomarker of response to androgen ablation in prostate cancer in a Caucasian population may not apply to an Afro-Caribbean population due to differences in prostate cancer biology between the groups.

Centre effects

A biomarker that is discovered using tumour material from one clinical centre may not work for patients from other centres. Factors such as centre-specific approaches to surgery, specific tumour fixation protocols, physician-specific chemotherapy regimens, and user biases on the assessment of tumour response may lead to a biomarker that only works in a centre-specific context. Ideally, biomarkers should be developed using tumour material and clinical data collected from multiple centres. In addition, each centre should provide samples representing the two populations of interest such as responders and non-responders.

Laboratory operator effects

Biomarkers that are discovered by a single laboratory operator risk validating only in the hands of the same individual. Biomarkers should be developed using defined standard laboratory operating procedures and, as much as possible, automated laboratory systems to prevent user-specific variation in protocols. In addition, samples for biomarker discovery should be randomized between several operators to remove the influences of any one individual.

Biomarker substrates

With the exception of radiological biomarkers, most cancer biomarkers are measured using biological materials. Examples are listed in Table 11.2. To date, many biomarkers have been measured using tumour material but this can raise some practical issues. First, tumour material may be difficult to biopsy. Patients with liver or lung metastases may require a surgical procedure that could be potentially harmful and is likely to reduce recruitment to biomarker-focused clinical studies. Alternatively, tumour material from an original diagnostic resection may be used but this may not be representative of the current disease in patients who have undergone tumour-cell selection by multiple courses of chemotherapy. Less invasive approaches to biomarker measurement, such as using circulating tumour cells, free plasma DNA/RNA/miRNA, urine, saliva, or faeces are being developed to try to circumvent these issues.

Important practical considerations for biomarker discovery

Sample practicality

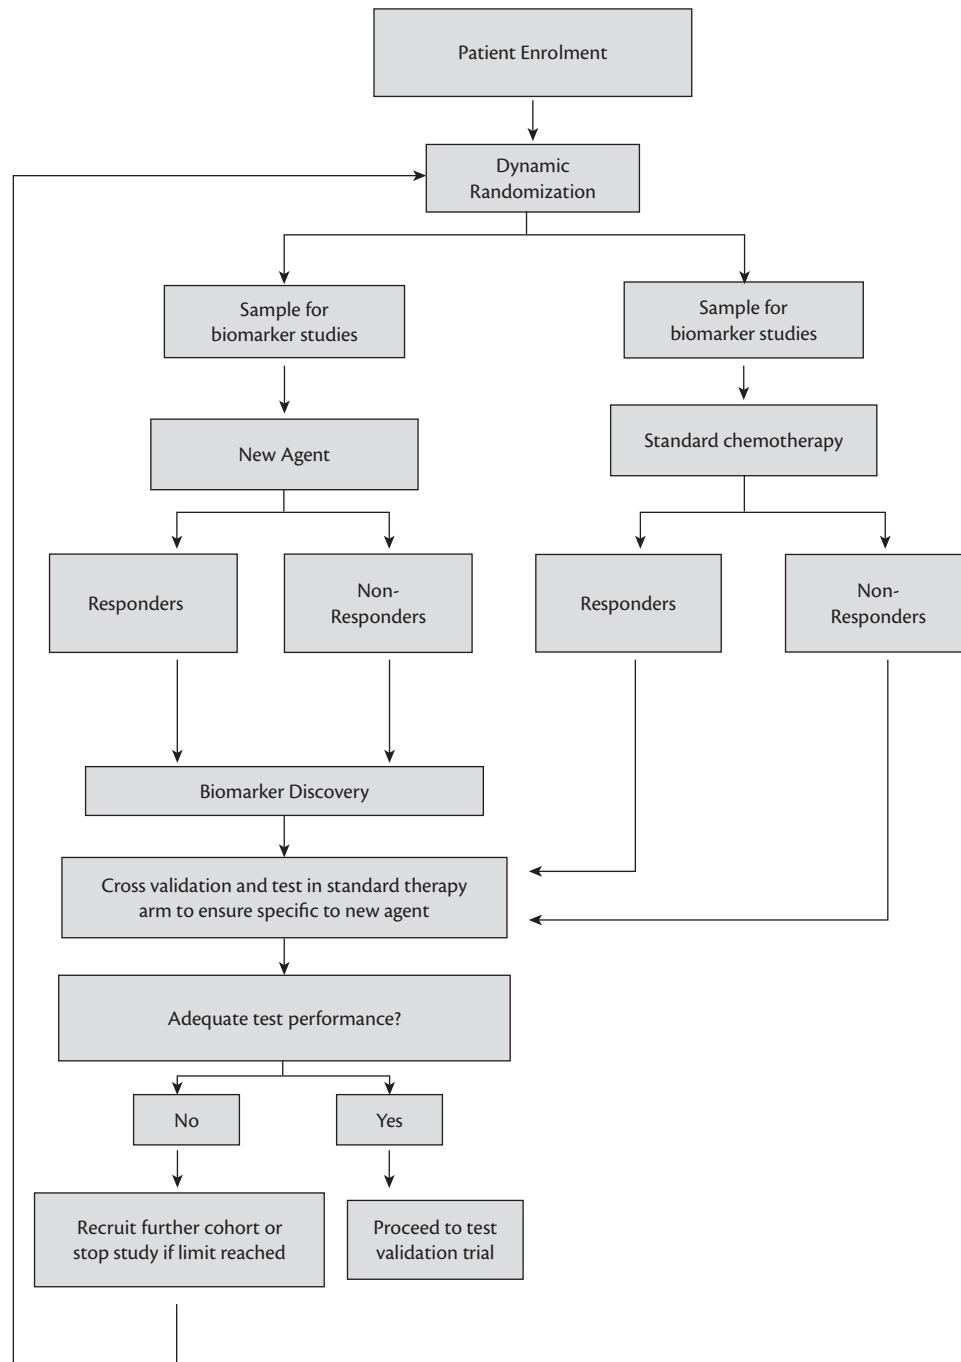
Although a technology may be very successful in discovering a potential biomarker in the research laboratory it may not be


Fig. 11.2 An example of an adaptive trial design for biomarker discovery.

practical for every day use in the clinic. For example, a requirement for fresh frozen tumour tissue will necessitate a change in clinical practice, as the surgeon will need to have liquid nitrogen available in the operating theatre for every tumour. Similarly, DNA-damage-induced repair foci detected by immunohistochemistry in irradiated fresh tumour biopsies are a good measure of DNA damage response and may guide the use of DNA damaging chemotherapy or PARP inhibitor treatment [22]. It is unlikely, however, that a process could be put in place where every tumour is harvested at the time of surgery and irradiated. Certain technologies such as mass spectrometry or full genome sequencing may

also be excellent for biomarker discovery but are at this moment too laborious and time consuming for use in a regular diagnostic lab.

In addition, a biomarker strategy that requires invasive sampling techniques that could result in significant patient morbidity or mortality is unlikely to succeed as a diagnostic in routine clinical practice.

Technology

A list of potential technologies for biomarker discovery and delivery are given in Table 11.3. Some technologies may be excellent for research purposes but may not be suitable for biomarker discovery.

Table 11.2 Biomarker sample sources

Source	Analytes	Biomarker	Advantages	Disadvantages
Tumour	DNA mRNA miRNA Protein metabolites	Predictive Prognostic Pharmacodynamics	Direct measure from disease of interest Often collected in diagnostic process	May be inaccessible Biopsy may not be representative of whole tumour due to heterogeneity May be large normal or stromal cell component
Blood	DNA mRNA miRNA Protein metabolites	Risk assessment Tumour markers Prognostic Predictive Pharmacogenomic Pharmacodynamic Physiological	Easy to obtain Allows serial measurements	Technology may not be sensitive enough to detect analyte Can be difficult to differentiate tumour-specific analytes from those due to non-specific disease-related effects Renal and liver function may affect levels of some biomarkers For PD markers, effects on blood cells may not represent tumour effects
Mucosa/Skin biopsy	DNA RNA miRNA Protein metabolites	Pharmacogenomic Pharmacodynamic	Easy to obtain Allows serial measurements	Uncomfortable For PD markers drug may have different penetration or biological effect in mucosa compared to tumour
Excreted/ Secreted Urine/Faeces/ Saliva	DNA RNA miRNA Protein metabolites	Risk assessment Tumour markers Prognostic Predictive Pharmacogenomic Pharmacodynamic Physiological	Easy to obtain Non-invasive Allows serial measurements	Technology may not be sensitive enough to detect analyte Can be variation due to dilutional effects Urine biomarkers may be affected by altered renal function Bacterial contamination may affect some assays
Eye lash/hair bulb	DNA RNA Protein metabolite	Pharmacodynamic	Easy to obtain No-invasive Allow serial measurements	Best suited for Immunohistochemistry/ Immunofluorescence Very small amounts of material for DNA/RNA/metabolite analysis. Drug effect on replicating cells in hair bulb may not represent tumour

Problems can arise where a platform is not properly quality controlled, leading to variable results and a loss of precision. For example, a poorly maintained q-PCR machine may generate highly variable results, which are discordant from a high-quality platform. These issues may not be immediately apparent in a research environment where a drift in biomarker results over time would not be detected. Ideally, technologies used for biomarker discovery should be properly maintained, run using standard operating procedures, and tested for variance over time. This is why there is currently a tendency to encourage biomarker discovery work in laboratories that adhere to diagnostic standards. Once a biomarker has been discovered, the appropriate delivery platform for the clinic will need to be selected. These may be distinct from the technologies used in the original biomarker discovery and more suited for diagnostic laboratory purposes. The technology should be cost effective, manufactured to FDA medical device standards in the USA or CE marked in Europe, compatible with a fast turnaround time (preferably under one week), and easy to use in a general hospital laboratory setting. Examples of these technologies are ELISA, Immunohistochemistry, and q-PCR. Occasionally more complex biomarker technologies such as DNA microarrays or DNA sequencing can be delivered from a central laboratory as a service, providing the test is not cost prohibitive, can be delivered in a realistic timescale, and fulfils the regulatory quality standards.

Table 11.3 Biomarker technologies

Analyte	Discovery technology	Clinical delivery
DNA	DNA microarray Sequencing (Sanger/Next Generation)	Polymerase Chain Reaction (PCR) Sequencing In-Situ hybridization
RNA	cDNA microarray Sequencing	Reverse transcriptase PCR (RT-PCR)
Protein	2D Gels Mass spectometry Protein Microarray	Immunohistochemistry Enzyme-linked immunosorbent assay (ELISA)
Metabolites	Mass spectrometry Nuclear magnetic resonance (NMR) Spectroscopy	ELISA Chemical/colourmetric assays

Expense

A biomarker with excellent performance characteristics that is discovered using an expensive technology but cannot be moved to a less expensive platform may not be successful. A cost versus patient benefit analysis will need to be adequately compelling to encourage reimbursement from national health or insurance schemes.

Cancer biomarker validation

It is an absolute necessity that a cancer biomarker is adequately validated prior to being used in patient management. Depending on the risks associated with its use there are various levels of validation expected under guidance from the EMA in Europe, and the FDA and CLIA legislation in the USA. These requirements are complex and evolving and readers seeking more detailed guidance are advised to contact these authorities. Some attempts are now being made to standardize these requirements globally due to the complexity of running international biomarker-focused clinical trials.

There are, however, some underlying basic principles in the validation of all biomarkers. These can be described as analytical validation, clinical validation, and evidence of clinical utility.

Analytical validation

The analytical characteristics of a biomarker must be known. These can be described as follows.

Precision

This is a measure of the repeatability of a biomarker result. Obviously an assay that gives differing results each time it is used for the same sample will be of limited use to a clinician. Specific factors that can cause low precision are inadequate operator training, variability in reagent batches due to poor supplier quality control, choice of a technology with inherent variable results such as phosphoantibody analysis on IHC, or poor maintenance of laboratory equipment. Another factor that may affect precision that is somewhat unique to cancer biomarkers delivered from tumour tissue is the effects of stroma and normal tissue on the result. Some tumour samples can have large amounts of fibrous tissue that may give a different biomarker signal to the malignant cell content. This effect can be reduced by macrodissection or microdissection of tumour material to standardize malignant cell content.

Accuracy

This is a measure of how close the assay result is to the known truth. In many cases the truth may be the results from a reference laboratory or as reported using the gold standard technology. Factors that may affect accuracy are improper sample handling prior to analysis, or a suboptimal operating procedure or technology. Another issue that can affect accuracy is the timing of tumour biopsy. A biomarker result measured from an original diagnostic tumour sample may be very different from the result from the same patient's tumour that has undergone selective pressure from chemotherapy or radiotherapy. Ideally, for predictive biomarkers, the assay should be performed immediately prior to starting the agent in question.

Detection limits

This is a measure of the amount of material that is needed in order to give an accurate result. For example, in the case of tumour material at least 20% of the specimen needs to be viable malignant cells in order to detect a mutation by conventional sequencing [23].

Reportable range

This is a measure of the expected normal population distribution of the assay result. This may be important when the target population for a drug is defined on a population basis such as the top quartile of patients expressing the highest level of a specific gene or protein. It also allows the laboratory to detect outlying results that could be due to the wrong sample type being submitted, sample handling errors, or diagnostic laboratory error.

Reference range

Most biomarkers have a predefined cutoff of what constitutes a positive or negative result. In the case of mutations this is straightforward, but for biomarkers with a continuous numerical result it can be more complicated. Most cutoffs in continually variable assays are set at the optimal sensitivity and specificity for the assay as defined from clinical trials. For multivariate assays, such as q-PCR or DNA-microarray measurement of several mRNA transcripts, the cutoff is usually a score from a computational algorithm. The software that is used for this calculation must also be validated and demonstrated to be consistent.

Internal controls

Appropriate internal positive and negative control samples must be developed for biomarker assays. These allow the laboratory to know if a technical problem has developed with the assay. This could be a simple operator mistake causing a sudden failure of control results or could be a reagent or equipment problem that could result in a gradual drift in results. To detect the latter, diagnostic laboratories will typically record and plot control results over time and apply statistical algorithms, such as the Westgard rules, to alert operators to an issue [24].

Clinical validation

For a biomarker to be useful it must have adequate clinical performance. The performance for a biomarker that dichotomizes a population into two groups, such as into predicted responder or non-responder or into predicted recurrence or non-recurrence at a defined time point, can be described in the terms of sensitivity, specificity, negative predictive value, and positive predictive value. Sensitivity is a measure of how well the assay detects true positive patients whereas specificity measures how well it excludes true negative patients. Negative and positive predictive values are dependent on the distribution of true positive and negative patients in a patient population and measure the proportion of subjects with a positive or negative test result respectively who are correctly diagnosed.

Some biomarkers predict a particular outcome on a time-to-event basis, such as disease-free or overall survival. This may be appropriate where there is no logical time point to act as a cutoff for a dichotomized approach. An example is early-stage oestrogen receptor positive stage breast cancer where recurrence events can continue beyond ten years. In such cases the biomarker performance may be best measured in terms of a hazard ratio with confidence limits.

It is absolutely essential that biomarker performance metrics be validated on a patient cohort completely independent from those used for assay discovery. This is to prevent 'over-fitting', where artificially high performance characteristics are observed for an assay applied to the same population used to discover it.

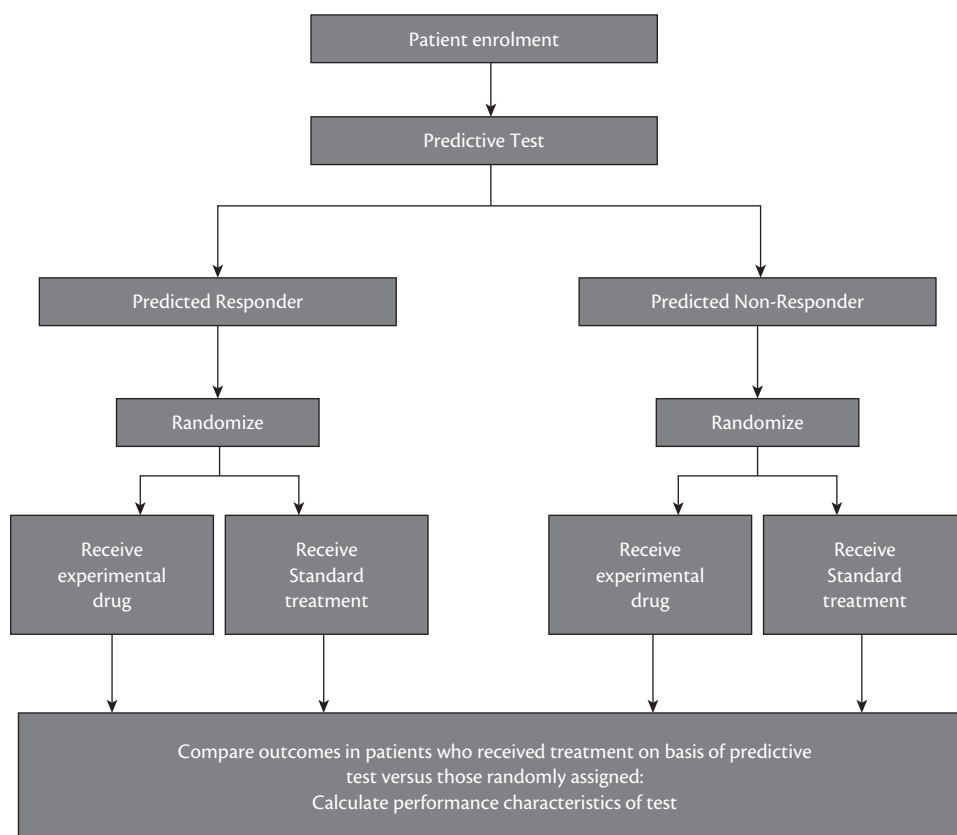
The appropriate design for biomarker validation studies is a subject of much debate, as some require large numbers of patients and are consequently very expensive. Most designs, however, can be classified as a prospective treatment interaction design, a prospective treatment stratified design, or a retrospective validation design (Figure 11.3). Prospective designs are usually required for the


Fig. 11.3 A treatment interaction biomarker validation study design.

validation of predictive biomarkers for novel therapeutic agents as no archived tissue is available. Retrospective validation can be performed on archived tissue where this is available and this approach may be particularly useful for prognostic tests where patient outcomes are known. It is important, however, that the material has been collected in a standardized manner consistent with how it will be collected in clinical use.

Clinical utility

An important consideration for a cancer biomarker before implementation is how it is likely to alter patient management. For example, it could be argued that for a cancer with a poor prognosis and few treatment options, a predictive biomarker would have to be extremely specific before a clinician would elect not to offer treatment. Assuming that the biomarker is not a regulatory prerequisite for offering a drug (on-label), a clinician may simply decide to offer chemotherapy to a patient with measurable disease and reassess after a few weeks rather than pay for an expensive predictive test. Obviously, in the case of adjuvant chemotherapy, this approach would not work, and a predictive test may be more important.

For the pharmaceutical industry, an important consideration will be how well a novel drug performs in the context of a biomarker when compared to the standard treatment arm in a registration study. If the combination of biomarker and drug demonstrates an improved outcome, the test will become 'on-label' and effectively become part of the drug therapy. In this case clinicians will be expected to perform the assay before offering the novel drug.

Quality control of biomarkers

Once a biomarker has been validated and entered clinical practice there must be system for quality control to protect patients from erroneous results. Unfortunately, this is often overlooked when biomarkers are measured in an academic environment. Quality control can take the form of internal and external activities. Internally, control sample results can be measured to ensure there is no drift in results. A random selection of samples should be rerun every few months to ensure consistency in reporting. Operators must all have demonstrable training and adhere to standard operating procedures. Equipment must be maintained to high standards and reagents must be batch tested to ensure no changes in specification. These activities are part of the core review of agencies to certify a laboratory adequate for diagnostics. Indeed, the quality of the laboratory's internal quality control scheme is a measure of its overall quality, although it can increase substantially the cost of the final laboratory test.

External quality control takes the form of formalized comparisons of results to reference laboratories and audits from approved bodies such as UKAS and the College of Pathologists.

Conclusion

With the development of targeted therapies, it is inevitable that oncology will be an increasingly biomarker-dependent discipline. The adoption of biomarkers is likely to benefit patients who will receive treatments that are more likely to work and are less likely to result in needless toxicity. Health care providers will also benefit,

as limited resources will be better targeted towards successful outcomes. Similarly, health insurance companies and national health services will be better able to pay for expensive new therapies, as fewer patients will be considered eligible for them. Finally, the appropriate use of pharmacodynamic, predictive, and prognostic biomarkers in clinical trials will identify ineffective therapies earlier in the development process and will improve the likelihood of successful agents reaching the clinic.

There are, however, challenges to the adoption of biomarkers in the clinic. First, it is unclear who should pay for their development. As discussed earlier, the validation process can require large clinical studies. To date these have been paid for by pharmaceutical and diagnostic companies. It could be argued that insurance companies and health services would benefit from adoption of these approaches and should become engaged in their development. In addition, there can be a perception in some pharmaceutical companies that biomarkers may limit the market for some drugs by selecting patient subgroups. Although this may be true, a non-biomarker-driven approach opens the possibility that a competitor may capture the market with an on-label predictive test, which may restrict the patient numbers but also demonstrates superior therapeutic responses.

In the next few years it is likely these issues will be resolved and the use of biomarkers will become increasingly commonplace in everyday clinical practice. When this occurs it will be the responsibility of every oncologist to ensure that these assays are properly validated and have the appropriate level of quality control so that patients gain the maximum benefit.

CHAPTER 12

Cancer, immunity, and inflammation

Campbell S.D. Roxburgh and Donald C. McMillan

Introduction to cancer, immunity, and inflammation

In recent years, the failure of the somatic mutation hypothesis of cancer progression to provide meaningful improvements in outcome in non-hereditary cancers has given way to a more complex paradigm in which host inflammatory responses are central. There is also now persuasive evidence that inflammation is key to tumourigenesis (reviewed in [1]) via DNA damage, stimulation of angiogenesis and proliferation, and inhibition of apoptosis. Indeed, inflammation is now considered a key hallmark of cancer [2]. However, the present chapter will focus on the role of immunity and inflammation in established cancer.

Work carried out in a number of common solid tumours including breast, gastrointestinal, urological, and lung cancer have been important in the current understanding of the importance of immunity and inflammation in tumour growth and progression, and it is clear that such findings are likely to be of importance in most sporadic cancers.

There have long been suspicions that dysregulated immune and inflammatory responses promote the progression and dissemination of established cancers [3]. For example, Dvorak [4] proposed that a 'tumour is a wound which does not heal'. Further, in patients with gastrointestinal tumours there have been repeated clinical observations that patients presenting as emergencies (with blood loss, obstruction, or perforation) or who develop an anastomotic leak following surgery have poorer cancer survival compared with those who did not, independent of tumour staging (e.g., [5–7]).

Cancer-associated alterations in patient immune and inflammatory responses are complex but are clearly linked. To examine such associations some arbitrary divisions have been made to differentiate various aspects of these responses. One rational approach would be to consider local responses in the tumour microenvironment and systemic responses in tissues distant from the tumour. Within these divisions it is then reasonable to consider innate, humoral, and adaptive responses (see Figure 12.1). By examining these responses and the mediators that link local and systemic immune/inflammatory responses it is possible to identify key mediators that can be targeted in future work. Finally, it is possible to comment on whether the up-regulation or attenuation of these responses may be important for disease progression and survival in patients with colorectal cancer.

Local immune and inflammatory responses

It is increasingly apparent that tumour progression is not a tumour-cell autonomous process [8]. There are a multitude of complex interactions between the host immune response and the tumour that dictate oncological outcome. As tumour cells proliferate and neoplasms grow in size, up to 90% of the tumour can consist of stroma and inflammatory cells [9]. In addition, tumour microsatellite instability status, CpG island methylator phenotype, and intra-tumoural HLA expression appear to be associated with tumour inflammatory cell infiltrate. This is consistent with a pronounced inflammatory cell infiltrate being more common in early-stage disease, degrading with increasing tumour size or T stage presumably reflective of tumour escape. Therefore, the tumour microenvironment plays a crucial role in determining disease progression, representative of the host–tumour interface where immune cells interact with each other and tumour cells.

With reference to the local immune and inflammatory response, more than 100 studies over the last 40 years have reported that immune cells in the immediate tumour microenvironment play an important role in determining survival in a number of common solid tumours [10, 11]. Recent work confirms that a pronounced tumour inflammatory infiltrate predicts good outcome and it has been proposed this may be used routinely to predict survival.

Klintrup and co-workers determined that, through a simple routine assessment of the entire immune/inflammatory reaction at both the invasive margin and in the central part of the tumour, a high-grade infiltrate was associated with improved recurrence-free and cancer-specific survival in colorectal cancer [12]. When the components of this inflammatory cell infiltrate were examined, a high-grade infiltrate was mainly composed of macrophages, lymphocytes, neutrophils, and plasma cells whereas a low-grade inflammatory cell infiltrate was almost exclusively composed of macrophages such that the macrophage count was similar in both high- and low-grade Klintrup scores [13]. Similar results have been reported in primary operable breast cancer [14].

Therefore, in general, where present an effective anti-cancer adaptive immune response is associated with improved outcome and where absent, other forms of innate myeloid derived cellular immune responses predominate and appear to be associated with poorer outcome. However, it is also increasingly clear that there is

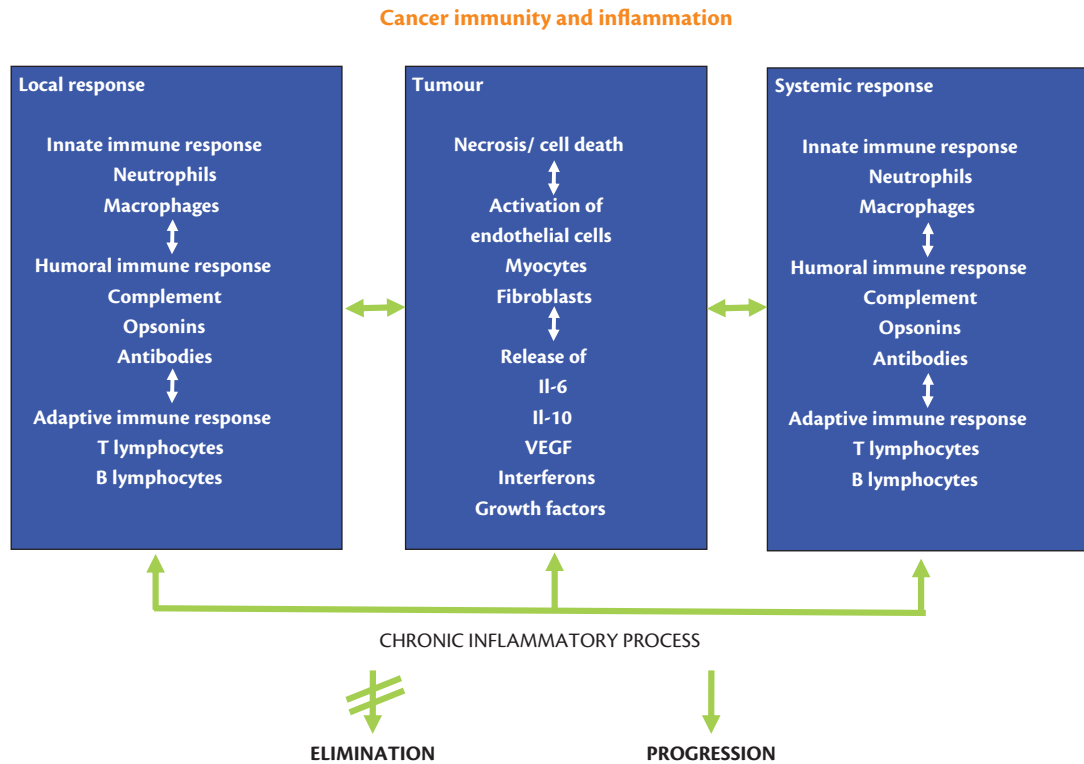
Cancer immunity and inflammation


Fig. 12.1 Cancer immunity and inflammation.

significant plasticity of these myeloid and lymphoid-derived cells exerting different pro- and anti-tumour effects as a result of signals from the tumour microenvironment. As a consequence, depending on the tumour, microenvironment (including stroma, immune cell type, and polarization and humoral immune responses) can act to attenuate or to promote tumour growth and spread. In particular, pro-tumour stromal responses are varied but can contribute to the production of factors that create an inflammatory microenvironment resulting in prolonged tumour cell survival, tissue remodelling, angiogenesis, increased proliferation, and increased metastatic potential [15, 16]. This area is currently the subject of intensive investigation.

Local innate immune and inflammatory response

The innate immune response comprises the immediate or front-line response to tissue injury or pathogens. Myeloid cells, including granulocytes, macrophages, mast cells, dendritic cells, and natural killer cells are known to be important in this response. It is generally non-specific and through chemokine and cytokine release acting on stromal cells, including fibroblasts, results in wound healing and tissue repair. In the acute setting, dendritic cells also act as antigen-presenting cells responsible for lymphocyte recruitment generating the adaptive component of the immune response. However, within the tumour microenvironment, host and tumour factors can act chronically to activate the innate response and there is a failure of resolution. The key cell types that are known to be involved include macrophages/monocytes, granulocytes, and mast cells, all of which are involved in tissue repair and can produce growth factors that act directly on

cancer cells or confer mitogenic capabilities (EGF, TGFβ, TNFα, interleukins, and chemokines).

With reference to cancer-associated inflammation, macrophages appear to be an important innate cell type. Higher relative densities of tumour-associated macrophages (TAMs) are associated with poorer prognosis in a variety of common solid tumours and targeting them has recently been associated with improved chemotherapeutic outcomes [17, 18]. There are two main subsets of macrophages; those exposed to pro-inflammatory Type 1 cytokines including IFNγ, IL6, IL12, iNOS, and TNFα are classically activated or M1 polarized and demonstrate anti-tumour activity. In contrast, macrophages exposed to IL4 and prostaglandins are termed alternatively activated or M2-polarized macrophages. These M2 phenotypes appear to make up the majority of TAMs and play a role in angiogenesis and metastasis. For example, M2 TAMs specifically produce chemokines including CCL17 and CCL27 that recruit non-cytotoxic T-cells (Th2 and T regulatory cells T_{regs}). Furthermore, M2 cells can produce CCL18 capable of attracting naïve T-cells. A tumour microenvironment composed of M2 macrophages, T_{regs} and naïve T-cells is likely to create lymphocytic anergy with ineffective anti-tumour responses compounding pro-tumour effects of M2 polarized cells [19].

However, the published literature on the association between tumour macrophage infiltration and cancer outcomes is inconsistent and high TAMs have been reported to be associated with both improved and poorer outcomes [10–20]. These results may reflect heterogeneity of macrophage function, including M1/M2 subtypes, and this has not been specifically examined in the majority of studies. Nevertheless, recent studies including M1 and M2 markers have related high M2 density to improved outcome (e.g., [21]). Therefore, it may be that the tumour microenvironment plays

a key role in regulating macrophage function since macrophages are predominantly located at the invasive margin and around areas of necrosis.

Neutrophils have been reported to contribute approximately 15–20% of the inflammatory cell infiltrate in colorectal cancer and are also associated with increasing tumour necrosis (e.g., [13, 22]). A number of studies have reported that increasing tumour neutrophil infiltration was associated with improved survival. However, this may be confounded by the observation that many inflammatory cell types increase together and are associated with improved survival [23], and therefore any association of a particular immune cell type with improved survival is not necessarily causal.

Mast cells are other innate immune cells capable of degranulation of pro-inflammatory mediators. For example, in six out of the seven published studies in colorectal cancer, high numbers of mast cells were associated with improved survival particularly when present at the invasive margin. Similarly, four out of six studies reported lower recurrence and improved survival with higher dendritic cell (DC) counts or densities [11]. In addition, although eosinophils make up a small proportion of tumour inflammatory cell infiltrates (approximately 2%), based on five of six published studies, high numbers when present are associated with improved outcome [11]. Finally, natural killer cells when present in increasing numbers are associated with an improved prognosis in patients with colorectal cancer. Again, the above relationships may be confounded by the fact that many inflammatory cell types increase together [23].

Local humoral immune and inflammatory response

Despite the current intense interest in immune and inflammatory responses in the tumour microenvironment there has been little work to investigate the importance of the components of the humoral immune and inflammatory response in patients with cancer. The humoral response can be considered to include the complement pathways, opsonins, and antibodies, and these are intimately linked to promote tumour cell lysis and phagocytosis. Indeed, there is good evidence from animal models to indicate their importance in determining innate and adaptive immune responses in the tumour microenvironment and the likelihood of tumour progression (e.g., [24–26]). Therefore, there is a considerable and pressing need to translate such findings from animal work into patient investigation of the tumour microenvironment.

Tumour stroma and local immune and inflammatory response

Given the increasing recognition of the tumour microenvironment in determining immune cell and inflammatory responses (see above) there is increasing interest in the role of the stroma in determining tumour growth and spread. De Wever and Mareel [27] proposed that changes in the stroma drive the key hallmarks of cancer, invasion and metastases. In particular, the appearance of myofibroblasts, cells sharing characteristics of smooth muscle cells and fibroblasts, was associated with increased cancer cell invasion. Indeed, they proposed that induction of apoptosis in these cancer-associated myofibroblasts may be a useful therapeutic target since the tumour microenvironment is similar to that of wound

healing, including the presence of myofibroblasts. Furthermore, consistent with the concept that 'tumour is a wound that does not heal', myofibroblasts do not disappear by apoptosis as in wound healing. More recently, this insight has been applied to the prediction of outcome in patients undergoing surgery for colorectal cancer. Higher numbers of stromal myofibroblasts, identified using specific staining, have been reported to be associated with shorter disease-free survival, independent of tumour stage [28]. Similar associations, independent of tumour stage, have been reported using routine H&E slides and calculating the proportion of tumour cells to stroma [29]. However, the relationship between the proportion of stroma and nature of the inflammatory cell infiltrate is not, as yet, clear.

Local adaptive immune and inflammatory response

The adaptive immune cells infiltrating the tumour are largely composed of T and B lymphocytes (TILs). Indeed, the association between a pronounced lymphocytic infiltrate and improved survival within breast and gastrointestinal tumours has been appreciated for more than 30 years [10, 11]. More recently, there has been interest in identifying subsets of TILs within tumours with CD3+, CD8+, CD45RO+, and FOXP3+ and to establish their prognostic value. Polarization of helper T lymphocytes (CD4+) towards a Th1 or Th2 type response appears to be key to determining the relationship between adaptive immune response and the tumour [30]. Generally, an effector cytotoxic T-cell (CD8+) or Th1 CD4+-type response is associated with a good outcome in many common solid tumours, and conversely infiltrates of T-regulatory lymphocytes (FOXP+) and a Th2 CD4+ response are associated with poorer outcome.

Th1-type responses appear to be driven mainly by CD4+T lymphocyte secretion of IFNγ, TNFα, IL2, and IL12. Th1 responses improve immune surveillance by the up-regulation of antigen presentation on MHC I and II molecules of antigen-presenting cells. In addition to recruiting CD8+ cytotoxic T lymphocytes, Th1 CD4+ lymphocytes also have cytotoxic capabilities through release of cytokines and cytolytic granules [30]. The primary effector cell of the Th1 adaptive immune response is the CD8+ cytotoxic T lymphocyte that recognizes antigens after exposure associated with humoral leukocyte antigen (HLA) class I proteins. After exposure to tumour antigen/HLA complexes, CD8+ cells clonally expand and have strong cytotoxic capacity, releasing cytolytic granules (perforin and granzyme B).

In contrast, Th2 CD4+ lymphocytes appear to release mediators including IL4, IL5, and IL10 that act to inhibit cytotoxic T-lymphocyte responses inducing T-lymphocyte anergy or unresponsiveness. The main role of the Th2 (CD4+) polarization appears to be the clonal expansion of B lymphocytes and the consequent production of antibodies. B lymphocytes have a role in mediating and regulating immune responses and also act as antigen-presenting cells to stimulate T-lymphocyte responses. However, their role in cancer is not as well established as that of T lymphocytes. Indeed, there remains ongoing controversy given that they may have pro and anti-T-lymphocyte effects effects in differing tumour microenvironments. For example, in a study examining the constituent cell types of the generalized lymphocytic/inflammatory cell infiltrate in colorectal tumours (Klintrup–Makinen Score), B lymphocytes

(assessed as plasma cells on H&E) were found to comprise 10% of all cell types and were significantly related to improved survival [13].

Another adaptive cell type of increasing interest is the T regulatory (CD4+ CD25+ Foxp3+) lymphocytes. T-regulatory lymphocytes are known to suppress the activity of CD8+, natural killer cells, and dendritic cells [31] through mechanisms including increasing immunosuppressive cytokines including IL10 and IFN-γ and direct cytolytic activity [32, 33]. A higher density of tumour T-regulatory-lymphocyte infiltrate has been associated with poorer survival in a variety of common solid tumours. However, for example in colorectal cancer, several studies have described contradictory results with higher density of FOXP3+ associated with improved survival in several studies [11]. The paradoxical role of FOXP3+T-cells in colorectal cancer has been hypothesized to relate to the possibility that T-regulatory lymphocytes also play an anti-microbial role in dampening pro-tumour inflammation due to bacterial translocation across the gut mucosal barrier [34]. Again, these reports may simply reflect that many inflammatory cell types increase together, and the independence of such an association with improved outcome requires further investigation.

A recently described subset of helper T lymphocytes is the Th17 group which is also capable of exerting pro- and anti-tumour activity based on surrounding mediators and site [35]. They exert their effects through secretion of IL17, IL21, and IL22. Pro-tumour effects may include stimulation of angiogenesis and recruitment of myeloid cells.

The concept of suppressor cells that undermine cytotoxic T-lymphocyte responses was developed in the 1980s by Schreiber and co-workers. A group of cells expressing CD11b and Gr-1 are now known as myeloid derived suppressor cells (MDSCs). MDSCs lack markers of mature myeloid cells (e.g., F4/80) and have high potential to suppress immune responses in common with M2 macrophages [36]. The two subsets of MDSCs are polymorphonuclear or monocytic MDSCs. MDSCs can suppress CD8+T lymphocytes through MHC dependent and independent mechanisms inhibiting IFNγ release. MDSCs and M2 macrophages foster an immunosuppressive microenvironment, coordinating recruitment of CD4+/FOXP3+ T_{regs} targeting CD8+ T lymphocyte apoptosis in addition to increasing metastatic potential [37]. In colorectal cancer, few studies have examined the prognostic value of MDSCs; however, increasing intra-tumoral MDSCs have been related to advancing disease stage and as a result have been hypothesized to be associated with disease progression.

Clearly, if such work is to have clinical relevance there is a need to have routine assessment tools that can be simply reported and understood. However, the routine assessment of the tumour inflammatory cell infiltrates and their use to predict outcome in patients with cancer is in its infancy and such tools are in rapid development. A relatively simple but subjective assessment of the tumour cell infiltrate was introduced as part of the Jass classification in the mid-1980s [38]. However, the reproducibility of the assessment was repeatedly questioned and the assessment was not incorporated into routine practice. More recently, an H&E based assessment of peri-tumoral inflammation (Klintrup–Makinen score, 12) has also consistently demonstrated tumour stage-independent prognostic value with lymphocytes as the predominant cell type [10–12]. In addition, over the last decade, many adaptive immune cell markers have been studied using immunohistochemistry. The evidence is strongest for CD3+, CD45RO, and CD8+T lymphocytes. In particular, a high CD8+ density at the invasive margin and within colorectal tumours has been consistently reported to predict improved oncological outcome in over 30 clinical studies [10, 11]. This knowledge has led to the development of several CD8+T lymphocyte-based prognostic scores including the Immune Score described by Galon and Pages based on CD8+and CD45RO+(memory T-cell), recently superseded by the immunoscore based on CD3+ (generic T-cell marker) and CD8+ [39].

It may be that tumour necrosis, as a result of a tumour outgrowing its blood supply, becoming relatively hypoxic and inducing the up-regulation of cellular stress genes in the tumour and the inflammatory cell infiltrate, is important in the induction of immune and inflammatory responses. Indeed, it has been postulated that the combination of inflammation and necrosis provides an environment in which the epigenetic regulation of genes, cell death, cell proliferation, and mutagenesis occurs [3]. At sites of chronic inflammation, cells are continuously dying as a consequence of hypoxic stress, an event in turn promoting growth and proliferation of the local epithelium. The apoptotic to necrotic conversion that is associated with unscheduled cell death and the subsequent release of necrotic mediators is recognized not to be a 'clean' death, but instead stimulates inflammatory pathways [3, 40]. These inflammatory pathways are now recognized to be important for angiogenesis, stromagenesis, and the promotion of epithelial proliferation, all of which are required for tumour growth.

In summary, most innate and adaptive immune cell types have been reported to play a role in tumour immune responses. Taken together the evidence suggests that a strong coordinated cytotoxic T-cell (adaptive) response is associated with improved cancer survival. However, when such a response is absent, other immune cell types, in particular M2 macrophages, MDSCs, Th2 CD4+cells, and FOXP3+T-cells, are associated with poorer cancer survival. As the tumour increases in size and disseminates there is a degradation of lymphocytic anti-tumour responses and development of T-cell suppressor responses (M2 macrophages and MDSCs). Therefore, a pronounced tumour inflammatory cell infiltrate appears to primarily reflect a down-regulation and up-regulation of the innate and adaptive immune systems, respectively, in the tumour microenvironment. In order that the above information is consolidated into the routine assessment of patients with cancer, standardized measurements of the tumour inflammatory cell infiltrate are required.

Systemic immune and inflammatory response

With reference to the systemic inflammatory response, more than 100 studies have reported the prognostic value of the systemic inflammatory response using blood biochemical or haematological markers, such as elevated C-reactive protein concentrations, hypoalbuminaemia or increased white cell, neutrophil, lymphocyte, and platelet counts or their combinations, such as the Glasgow Prognostic Score and the neutrophil:lymphocyte ratio (NLR), in patients with cancer [41–43]. For example, since the initial work a decade ago that the combination of C-reactive protein and albumin, the Glasgow Prognostic Score (GPS), had independent prognostic value in patients with cancer, there have been more than 60 studies (>30,000 patients) that have examined and validated the

use of the GPS or the modified GPS (mGPS) in a variety of cancer scenarios [42]. Similarly, over 60 studies (>37,000 patients) to date have examined the clinical utility of the NLR to predict patient outcomes in a variety of cancers [43].

Consistent with this is that there are significant associations between these systemic inflammatory response markers [44]. There is also robust evidence of their prognostic value in other gastrointestinal cancers and lung cancer. It is becoming clear what the optimal thresholds for these systemic inflammatory response markers are and the optimal combination of these markers for the prediction of survival [45]. Due to the simplicity and reliability of these markers, this is an area currently subject to intensive investigation and consolidation. It is, therefore, of interest to consider what these markers of the systemic inflammatory response might reflect in terms of the tumour–host responses.

Systemic innate immune and inflammatory response

The circulating innate immune cells, according to number, include neutrophils, monocytes/macrophages, mast cells, dendritic cells, basophils and eosinophils, and natural killer cells. Increased numbers of these circulating cells are associated with a non-specific response to infection or cell injury.

Accounting for the majority of circulating white cells, elevated numbers of circulating neutrophils are associated with increasing tumour stage and poorer survival in a variety of common solid tumours including colorectal cancer (e.g., [44, 45]). Furthermore, the role of neutrophils in effectively stratifying patient response to treatment is becoming clearer [46]. For example, circulating neutrophils above the upper limit of normal were independently associated with poorer outcome in patients with metastatic colorectal cancer treated with FOLFIRI or XELOX plus anti-VEGF. Further, in similar patients receiving palliative chemotherapy, a neutrophil/lymphocyte ratio >5 was independently associated with poorer survival [43]. Therefore, an elevated pretreatment neutrophil count appears to be a strong independent predictor of poor outcome in patients with cancer [46, 45]. Moreover, it would appear that neutrophils, similar to other inflammatory cells, are capable of polarization of N1 and N2 phenotypes, a matter that is currently the subject of investigation [46].

In addition, although they are less numerous, elevated numbers of circulating monocytes have been reported to be associated with increasing tumour stage and poorer survival in colorectal cancer [44]. Unlike tumour cell infiltration, little work has been carried out to examine the relationship between the phenotype of such circulating monocytes and cancer outcome. However, it is clear from work in other disease states that monocytes leave the bloodstream and migrate into tissues where, following conditioning by the local inflammatory milieu, they differentiate into macrophage or dendritic cell populations. Although passage of monocytes is essential for effective control of infections, such monocytes also contribute to the pathogenesis of inflammatory disease states [47] and possibly cancer.

Few studies have examined the associations between circulating mast cells, dendritic cells, basophils and eosinophils, and natural killer cells and survival. The acute phase proteins, including the prototypical C-reactive protein, rise during a period of infection, tissue injury, or necrosis. In response to such stimulus, circulating C-reactive protein concentrations may rise up to 50,000-fold. The increase in circulating concentrations is principally due to factors released by macrophages such as IL6. As its half-life is constantly circulating, concentrations of C-reactive protein are mainly determined by the rate of production in the liver. C-reactive protein is considered to be part of the innate immune response since it is thought to assist in complement binding to foreign and damaged cells and enhances phagocytosis by macrophages (opsonin-mediated phagocytosis). Indeed, there is evidence that neutrophils and macrophages have Fcγ receptors that can be activated by C-reactive protein. In addition, some tumours types stain for C-reactive protein [48]. Furthermore, Yang and co-workers [49] reported that, in myeloma cells, C-reactive protein can activate membrane-bound Fcγ receptors and in turn activate PI3K/Akt, ERK, and NF-kB pathways and inhibit caspase cascade activation resulting in increased tumour cell proliferation and inhibition of apoptosis. It is also of interest that circulating C-reactive protein concentrations were directly associated with tumour size and necrosis [50]. Therefore, it may be that C-reactive protein plays both an indirect and a direct role in tumour progression that ultimately leads to its strong association with poorer cancer-specific survival in patients with cancer.

Systemic humoral immune and inflammatory response

It is of interest that circulating concentrations of a number of the molecules that are associated with the activation of the components of the humoral immune and inflammatory response in patients with cancer have been reported to have prognostic value independent of tumour-based factors. These include the pattern-recognition molecules, complement C3a (e.g., [51, 52]), C-reactive protein (see above), mannose-binding lectin and complexes MASP-2 [53, 54], and antibodies [55–57].

Given that the function of the humoral immune and inflammatory mediators is to connect local and systemic response, these are ideally suited to sense tumour immune surveillance. It is therefore surprising that these molecules have not been subject to more investigation and exploited as prognostic and therapeutic markers. Again, there is a considerable and pressing need to extend and consolidate such findings into routine investigation of patients with cancer.

Mediators linking local and systemic immune and inflammatory responses

There are a number of plausible mediators linking local and systemic inflammatory responses. For example, Kantola and colleagues [58] have reported the pattern of alterations of 13 serum cytokine concentrations between >80 normal controls and patients newly diagnosed with colorectal cancer. Compared with controls, the presence of colorectal cancer was associated with a significant increase in IL6, IL7, IL8, IL12, IFN-gamma, MCP-1, and PDGF-BB. Sex, tumour site, and N stage had little association with the serum cytokine alterations reported. Furthermore, increasing T stage was only associated with a significant increase in IL6, IL8, and MCP-1; increasing grade was only associated with a significant increase in IL6 and IL8; while the presence of metastasis was associated with a significant increase in IL4, IL6, IL7, IL8, MCP-1, and PDGF-BB. In contrast, the presence of a systemic inflammatory

response, as evidenced by the modified Glasgow Prognostic Score (mGPS), was significantly associated with IL-1ra, IL6, IL7, IL8, IL9, IL12, IFN-gamma, IP-10, MCP-1, MIP-1B, and PDGF-BB. Taken together, these results would suggest that circulating IL6 and IL8 concentrations may link the tumour with the systemic inflammatory response. With reference to the inflammatory cell type, few inflammatory cells, with the exception of monocytes/macrophages, can produce such a spectrum of cytokines and growth factors, in particular IL6. These findings are consistent with the hypothesis that tumour necrosis (which increases with T stage) plays an important in both linking local and systemic inflammatory responses in patients with colorectal cancer [50].

It has long been recognized that tumour-associated macrophages localize to hypoxic regions of the tumour microenvironment. Therefore, it is plausible that the relative density of macrophages (perhaps M2) determined by the tumour microenvironments is important in the local and systemic production of IL6 and the nature of local and systemic immune and inflammatory responses [59]. Alternatively, recent work has suggested that an accumulation of myeloid-derived suppressor cells in the tumour microenvironment may be important in these observations.

Systemic adaptive immune and inflammatory response

The circulating adaptive immune cells, according to number, primarily include T and B lymphocytes. Increased numbers of T lymphocytes, in particular CD4+ and CD8+ subpopulations, are associated with a specific response to an antigen. Therefore, it is somewhat surprising that little in vivo work has been carried out to examine the relationship between circulating T lymphocyte subsets and outcome in patients with cancer, particularly since blood measurements are more readily available to assess and to monitor patient response to treatment.

Small studies have shown that in addition to increased circulating neutrophil counts there is a significant reduction in the percentage of CD3 T lymphocytes and in the numbers of CD4+ T lymphocytes but no difference in CD8 T lymphocytes in those patients who have colorectal cancer compared with controls and subsequently develop recurrence following curative surgery [60, 61]. More recently, small studies examining peripheral blood regulatory T lymphocytes (CD4+CD25+Foxp3+) in patients with colorectal cancer have reported that increased numbers of these immunosuppressive cells [62] are associated with increasing tumour stage and inflammatory cell infiltration, and are not normalized on resection of the tumour [63]. Therefore, an alteration of circulating T-lymphocyte subpopulations appears to be a feature of common solid tumours and is consistent with impaired immune function at the systemic level. However, further work is clearly required in this area.

In summary, work on routinely available markers of the systemic inflammatory response is now being consolidated in the form of systemic-inflammation-based prognostic scores such as the GPS and the NLR, primarily reflecting activation of the innate immune and inflammatory response. However, to date little work has been carried out to characterize the phenotype of circulating innate and adaptive immune cells. Nevertheless, the systemic inflammatory response appears primarily to reflect an up-regulation and down-regulation of the circulating innate and adaptive immune processes, respectively.

Therapeutic intervention in immune and inflammatory responses

There is great interest in potential strategies to manipulate immune and inflammatory responses in cancer for therapeutic gain. Generally speaking, this will involve restoration of a targeted anti-tumour-cell mediated immune response. Potential strategies that may improve oncological outcome include targeting both local and systemic innate and adaptive immune responses: for example, at a local level, repolarization of tumour-associated neutrophils and macrophages towards N1 and M1 phenotypes, respectively, and inhibition of myeloid-derived suppressor cell activity, as well as repolarization towards Th1 anti-tumour cytotoxic T-cell responses and suppressing T-regulatory cell activity. Other promising future strategies may include specific immune cell depletion or inactivation, and, at a systemic level, maintaining cell-mediated adaptive immune responses and suppressing development of non-specific innate cellular responses such that the host systemic inflammatory response and its associated detrimental effects on body composition and quality of life and survival are abrogated. Such therapeutic goals may be achieved using non-selective anti-inflammatory agents or using highly selective agents subtly to attenuate targeted mediators or pathways of the immune and inflammatory responses to cancer.

Non-selective agents

Aspirin and non-steroidal anti-inflammatory drugs including cyclooxygenase-2 inhibitors have been described as potential chemotherapeutic agents, most commonly in colorectal cancer. There is consistent evidence of a chemo-preventative reduction in colorectal cancer incidence and mortality, based on epidemiological studies [64].

With reference to advanced cancer, NSAIDs have been shown to attenuate the systemic inflammatory response and moderate cachexia [65]. In contrast, it is only relatively recently that a potential benefit in patients with early-stage colorectal cancer has been realized, with NSAID users less likely to present with recurrence. Indeed, emerging evidence of as much as a 40% reduction in recurrence and mortality in patients undergoing curative surgery for colorectal cancer makes the concept of the use of NSAIDs as adjuvant treatment in high-risk disease more compelling [66, 67]. Several prospective randomized trials are under way to determine the role of aspirin/NSAIDs as adjuvant therapy in colorectal cancer [67].

Several mechanistic pathways, including a myriad of COX-dependent and independent pathways, have been implicated in the direct and indirect effects of aspirin/NSAIDSs on tumour cells, the tumour microenvironment, and innate and adaptive immune responses: for example, the inhibition of several signal transduction pathways including Wnt/β-catenin and nuclear factor-kappa B (NF-κB). Recently, in the context of randomized trial data, patients with mutated PIK3 in their tumours where shown to have increased survival compared with the non-mutated form [68], and a reduced risk of cancer with NSAIDs in patients with mutations within the NF-κB pathway [69]. In addition, there is good evidence of their effect on platelet function and some evidence that NSAIDs may play a role in enhancing cytotoxic T-cell activity preventing cancer-associated immune suppression [70].

Nevertheless, for those patients likely to benefit from NSAIDs there is a clear need to identify treatment markers of immune and inflammatory response.

The 3-hydroxy-3-methylglutaryl coenzyme A (HMG-CoA) reductase inhibitors, commonly known as statins, are primarily used in the treatment of hypercholesterolaemia and atherosclerotic cardiovascular disease. However, they are known to have a number of pleiotropic effects on cell proliferation, angiogenesis, inflammation, and endothelial cell function. A number of epidemiological studies have reported a reduction in risk of colorectal cancer with statin use[71]. In particular, there is evidence from clinical trials of a 90% reduction in risk of inflammatory bowel-disease-related colorectal cancer [72].

Statins have a variety of actions that may potentially alter immune and inflammatory responses in cancer. For example, in cardiovascular disease prevention trials there are clearly identified anti-inflammatory effects, with down-regulation of pro-inflammatory cytokines and increased cardiovascular risk reduction in patients with elevated serum inflammatory markers [73]. Furthermore, favourable effects on organ rejection following heart and renal transplant suggest a potent immunomodulatory effect, potentially through a direct effect on MHC class II expression and subsequent T-cell activation [74].

Selective agents

With the increasing knowledge of the immune and inflammatory dysfunction in patients with cancer, specific and selective immunomodulatory agents are having an emerging role in oncological practice. In general, these include targeted agents aiming at specific manipulation of cytokines/chemokines or blocking cellular responses to encourage a rebalancing of immune and inflammatory responses. Novel methods of achieving this goal include the development of cancer vaccines and adoptive cell transfer.

The lead for such work has come from the newer treatments of chronic inflammatory diseases in non-cancer conditions. There have been therapeutic successes in targeting pro-inflammatory cytokines such as IL6 and TNF-α. To date, anti-IL6 immunotherapies (siltuximab) have been employed in phase II trials for ovarian and renal cancer with some promising results including stabilization of disease and attenuation of systemic inflammatory responses.

Further, monoclonal antibodies with specific effects on host–tumour immunity encouraging cytotoxicity include ipilimumab (anti-CTL-4), an immunostimulatory antibody that has been shown to enhance anti-tumour immunity and also counter the immunosuppressive inflammatory response created by the tumour in melanoma. The trial of ipilimumab in melanoma patients published in 2010 was the first ever positive randomized phase III drug trial in melanoma. Other monoclonal antibodies which encourage antibody-dependent cellular cytotoxicity include rituximab, a CD20 antibody which has been used in lymphoma leading to B-cell depletion, and catumaxomab, an anti-CD3 EpCAM chimeric antibody which has been used in the treatment of malignant ascites.

A recent promising strategy is to manipulate adaptive T-cell function. Programmed cell death 1 (PD-1) protein is a T-cell receptor mediating T-cell inhibition and along with its ligands (PD-L1 and PD-L2) plays an important role in regulating T-cell responses. Blocking interactions between PD-1 and PD-L1 with anti-PD-L1 antibody has been shown in phase I studies of breast, ovarian, melanoma, lung, and colorectal cancer patients to improve anti-tumour T-cell activity with encouraging clinical results [75].

Finally, there has been recent interest in the use of autologous dendritic cell pulsed with tumour peptides and injected as a vaccine directly into tumour tissue. This technique has been observed in early human studies to provoke potential anti-tumour adaptive immune responses with increased CD4+ and CD8+ T-cells [76]. Sipuleucel-T is a novel dendritic-cell-based vaccine that has been employed successfully in castration-resistant metastatic prostate cancer. Autologous peripheral blood mononuclear cells and antigen-presenting cells are extracted from the patient, activated ex vivo with a recombinant fusion protein (PA2024) which consists of prostatic acid phosphatase, a common prostatic cancer antigen linked to granulocyte-macrophage colony-stimulating factor (GM-SF). This cancer vaccine is then delivered back into the patient resulting in stimulation of host CD4+ and CD8+T-cell responses targeting prostate cancer cells. To date, three phase III trials have reported positive improvements in survival with infusions of Sipuleucel-T [77].

In summary, along with the now widespread appreciation of the pivotal role of the immune/inflammatory responses in dictating human cancer outcome, there has been a recent rapid expansion of therapies aimed at manipulation of these responses. Broad-spectrum anti-inflammatory drugs have long been appreciated as playing a role in oncological progression; however, stratification using more accurate immune/inflammatory or molecular profiling may help to identify those patients who may derive greatest therapeutic benefit. Recently, there have been impressive results observed in melanoma and renal cell cancer. It remains to be determined whether the use of such immunotherapies will apply to most tumour types.

Conclusion

It is clear that immune and inflammatory responses, both local and systemic, are intimately linked and impact on cancer survival. However, the mechanisms by which these inflammatory responses are activated, maintained, and interact are not clear. An interesting concept is that a cell-signalling mediator such as IL6 or pattern recognition molecules may have a key role. It also may be, at least in non-hereditary disease, that inflammation becomes the key hallmark on which all the other hallmarks of cancer are dependent. Therapeutic intervention using non-selective anti-inflammatory agents is widely advocated and likely to become part of routine clinical practice in the near future. Selective therapeutic intervention directed at the immune and inflammatory responses in cancer is in its infancy.

CHAPTER 13

Cancer and metabolism

Cameron Snell, Kevin C. Gatter,
Adrian L. Harris, and Francesco Pezzella

Introduction to cancer and metabolism

It was recognized in the mid-twentieth century that tumour cells exhibited characteristic changes in metabolism, in particular the use of glucose for glycolysis rather than for oxidative phosphorylation in the presence of adequate oxygen. This metabolic switch, named after Otto Warburg, who first made this observation (the Warburg effect) [1] was originally hypothesized to be causative in the development of cancer. Tumour development is now known to be driven by the activation of cancer oncogenes and loss of tumour suppressors. However, we now recognize that mutations in some metabolic enzymes can indeed cause cancer and intermediate products of metabolism may be able to promote tumour progression.

Proliferating cancer cells have a high energy requirement, to maintain homoeostatic cellular processes in the setting of a neoplastic microenvironment. The shift in energy production to aerobic glycolysis, whilst being much more rapid, yields far less energy than oxidative phosphorylation (2 net molecules of ATP per glucose molecule for glycolysis compared to 36 for aerobic glycolysis) [2]. An increased demand for glucose by tumour cells is potentiated by hypoxia and Akt signalling, and is the basis for positron emission tomography (PET) positivity by increased uptake of the glucose analogue 2-fluorodeoxy-D-glucose (^{18}F-FDG).

There is some debate about the selective advantage that glycolysis affords tumour cells. Initially, it was thought that mitochondria were intrinsically defective in tumours, although more recently it has been recognized that mitochondria retain the capacity for oxidative phosphorylation and consume oxygen at similar rates to normal tissues [3]. The increased rate of energy production possible with aerobic glycolysis has also been proposed as a selection advantage. Alternatively, high rates of glycolysis may be co-selected with factors that promote the increased expression of hypoxia-related genes (such as those required for angiogenesis) as an oxygen-independent energy source. Finally, increased intermediate products of glycolysis can be shunted into biosynthetic pathways required for serine and nucleotide synthesis and lipid synthesis [4] (Figure 13.1).

A more complex picture of metabolic transformation in tumours, beyond the switch to aerobic glycolysis, has emerged over the last decade and is increasingly linked to specific disturbances in cell-signalling pathways [5]. Additionally, tumours with the same genetic perturbations develop different metabolic adaptations depending on the host-tissue in which they arise, suggesting the stromal environment plays a role in shaping the metabolic profile [6]. The increased growth and metabolic requirements of tumours also require a corresponding increase in the production of NADPH as a reducing agent in anabolic reactions and to maintain cellular redox balance.

Supporting tumour growth: from angiogenesis to metabolic reprogramming

Warburg raised two important questions regarding how tumour cells are supplied by glucose and by oxygen [1]. Folkman's work addressed the latter issue and answered the question of how cancer cells are supplied by oxygen by raising the hypothesis that 'tumour growth is angiogenesis-dependent' [7]. Subsequent work led to the recognition of angiogenesis as one of the hallmarks of cancer [8].

Lack of angiogenesis and metabolic reprogramming

Although robust evidence has been reached that angiogenesis is crucial in cancer, this is not always the case, and some tumours can grow in the absence of angiogenesis by co-opting pre-existing vessels [9].

Non-angiogenic growth was first identified histologically in lung cancer as neoplastic cells fill the alveolar spaces co-opting the pre-existing capillary network and producing a characteristic 'chicken-wire' appearance [9]. A gene expression signature for non-angiogenic non-small cell lung cancer (NSCLC) was published in 2005, derived by comparing the expression of mRNA transcripts by microarray in 12 non-angiogenic and 30 angiogenic tumours [10]. Sixty-two genes were found to separate the two types of tumour, 40 of which were more highly expressed in non-angiogenic tumours. Surprisingly, rather than classic angiogenesis-related genes, the differentially expressed genes were involved in mitochondrial metabolism, transcription, protein synthesis, and the cell cycle. This result suggests that response to hypoxia does not necessarily trigger neo-angiogenesis but could, according to the genetic background of the neoplastic cells, lead to metabolic reprogramming [10].

Sustained signalling promotes metabolic reprogramming

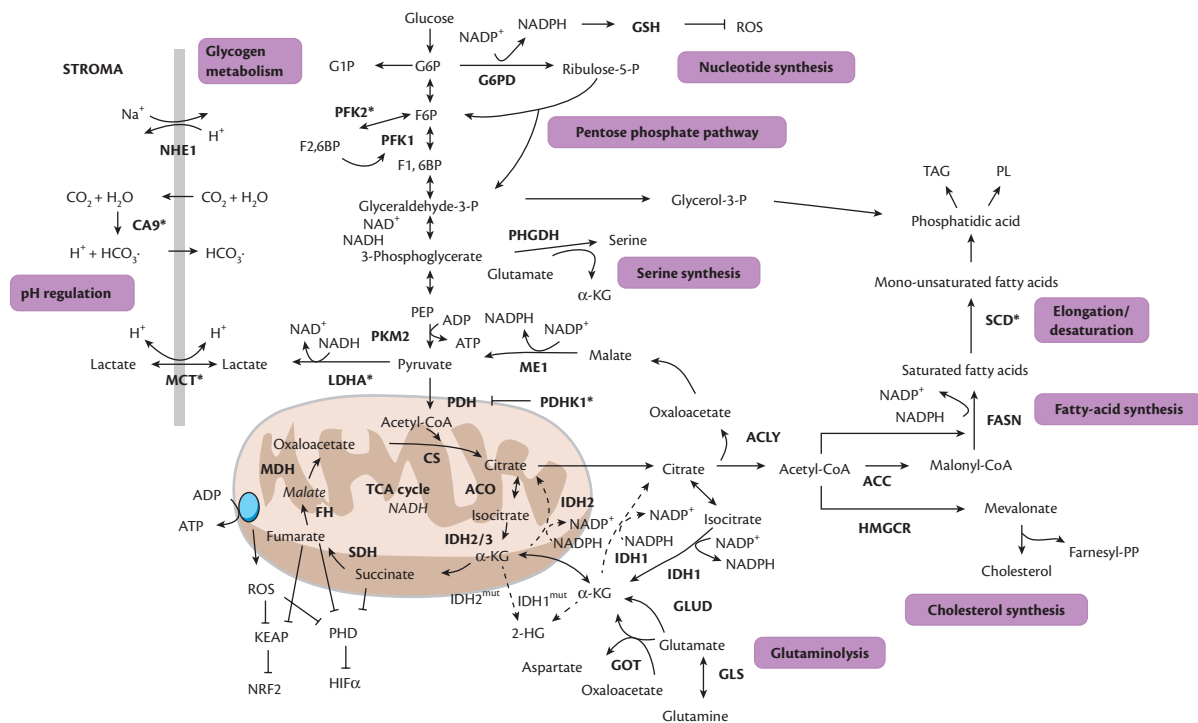
Cancer cells are driven by constant activation of growth signals, which are integrated into cellular adaptive responses in metabolism including increased glucose uptake, lipid, protein, and nucleic acid


Fig. 13.1 Overview of metabolic activities in cancer cells. The main metabolic pathways that contribute to the production of macromolecules in mammalian cells are nucleotide synthesis, the pentose phosphate pathway, serine synthesis, glutaminolysis, cholesterol synthesis, fatty-acid synthesis, and elongation desaturation. Glycogen synthesis and pH regulation contribute to cellular bioenergetics. The enzymes involved in these pathways are shown in bold, those induced in response to hypoxia are marked with an asterisk. Metabolic enzymes in the TCA cycle, fumarate hydratase (FH) and succinate dehydrogenase (SDH), can act as tumour suppressors. 2-hydroxyglutarate (2-HG) is produced from α-ketoglutarate (α-KG) by the mutant forms of isocitrate dehydrogenase 1 (IDH1) and IDH2 enzymes that are found in cancer (grey dashed arrow). Reductive carboxylation of α-KG by IDH1 and IDH2 produces citrate for lipid synthesis in hypoxic cells (black dashed arrow). Abbreviations: ACC, acetyl-CoA carboxylase; ACLY, ATP citrate lyase; ACO, aconitase; CA9, carbonic anhydrase 9; CoA, coenzyme A; CS, citrate synthase; FASN, fatty-acid synthase; F1,6BP, fructose-1,6- bisphosphate; F2,6BP, fructose-2,6-bisphosphate; F6P, fructose-6-phosphate; GLS, glutaminase; GLUD, glutamate dehydrogenase 1; GOT, glutamic- oxaloacetic transaminase; GSH, glutathione; G1P, glucose-1-phosphate; G6P, glucose-6-phosphate; G6PD, G6P dehydrogenase; HIF, hypoxia inducible factor; HMGCR, 3-hydroxy-3-methylglutaryl-CoA reductase; KEAP, kelch-like ECH-associated protein 1; LDHA, lactate dehydrogenase A; MCT, monocarboxylate transporters; MDH, malate dehydrogenase; ME1, malic enzyme 1; NHE1, Na+/H+exchange protein 1; NRF2, nuclear factor (erythroid-derived 2)-like 2; PDH, pyruvate dehydrogenase; PDHK1, pyruvate dehydrogenase kinase; PEP, phosphoenolpyruvate; PFK, phosphofructokinase; PHD, prolyl hydroxylases; PHGDH, phosphoglycerate dehydrogenase; PKM2, pyruvate kinase M2; PL, phospholipids; ROS, reactive oxygen species; SCD, stearoyl-CoA desaturase; TAG, triacylglycerides.

synthesis. Increased glutamine uptake and glutaminolysis are also characteristic of malignancies, and this serves to replenish TCA cycle intermediates used in biosynthetic reactions (Figure 13.2).

PI3K pathway

Growth factors usually activate receptor tyrosine kinases (RTKs) which then promote signalling through two pathways, the phosphatidylinositol 3-kinase (PI3K) and the Ras-Raf-MAP kinase (ERK) pathway. The PI3K is one of the most commonly mutated and activated pathways in tumour cells, often following inactivation of the tumour suppressor PTEN. Activation of downstream AKT integrates growth signals with increased metabolic requirements leading to higher glucose uptake by glucose transporters; it follows increases the activity of hexokinase and glycolytic flux. AKT1 signalling also strongly stimulates mTOR function by phosphorylating and inhibiting the negative regulator tuberous sclerosis 2 (TSC2) [11].

mTOR

Growth factors can promote the activation of mTOR beside the PI3K pathway. ERK signalling also phosphorylates TSC2 to inhibit it and promote mTOR activity. The convergence of multiple growth factor pathways, as well as the ability to sense free amino acids, supports mTOR as a key signal integrator and effector of metabolic control: its activation in cancer drives anabolism, energy storage, and consumption. It also activates translation, cell mass increase, and lipogenesis while inhibiting autophagy. There is mounting evidence that inhibition of autophagy promotes tumorigenesis, as mice deficient for the autophagy genes beclin and ATG4C are prone to developing tumours. mTOR is also able to promote the activity of hypoxia inhibitory factor (HIF), even under normoxic conditions [12].

AMPK

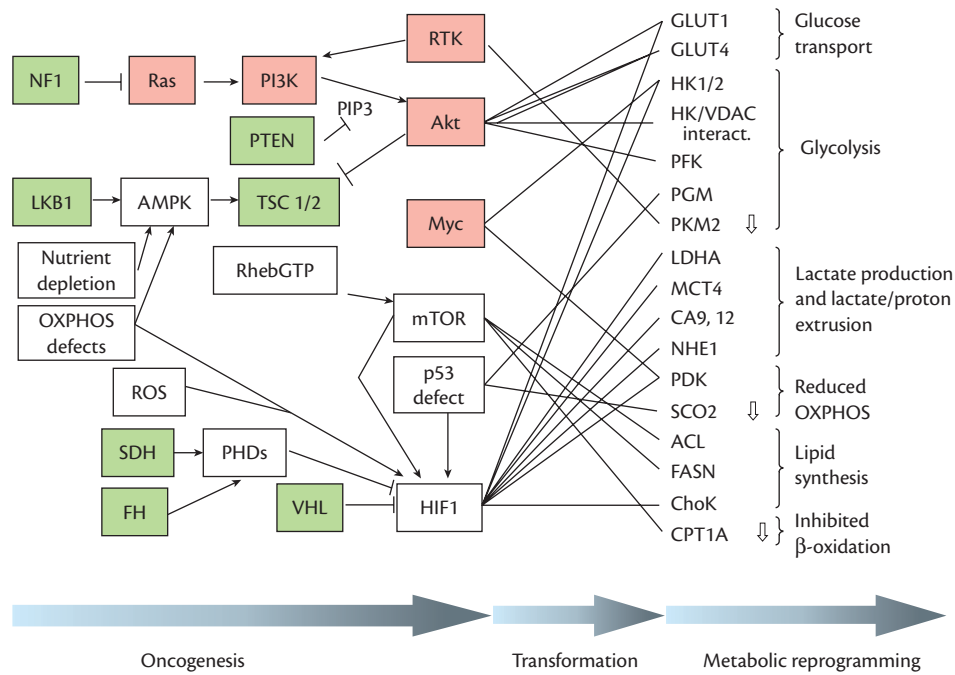
AMP-activated protein kinase (AMPK) is a crucial sensor of cellular energetic status, opposes the effect of AKT1, and is a potent inhibitor of mTOR signalling [13]. During periods of energy depletion or stress, AMPK is activated in response to increased AMP/ATP ratio, promoting oxidative phosphorylation and inhibiting cellular proliferation. In this way, exogenous growth signalling pathways must overcome the checkpoint role of AMPK activation in order to proliferate under conditions that are less energetically favourable (such as in hypoxia). Many tumours, therefore, decouple


Fig. 13.2 Molecular mechanisms of cancer-specific metabolic reprogramming. As a result of oncogenic gain-of-function events (pink) or the loss of tumor suppressors (green) affecting the PI3K/Akt/mTOR/HIF axis and/or inactivation of the p53 system, a stereotyped pattern of metabolic changes is induced, leading to cancer-associated alterations in metabolism. Note that arrows connecting different proteins do not necessarily indicate direct interactions.
Abbreviations: ACL, ATP citrate lyase; AMPK, AMP-activated kinase; CA9 and CA12, carbonic anhydrases 9 and 12; ChoK, choline kinase; CPT, carnitine palmitoyltransferase; FH, fumarate hydratase; GLUT, glucose transporter; HIF, hypoxia-inducible factor; HK, hexokinase; OXPHOS, oxidative phosphorylation; LAT1, L-type amino acid transporter 1; LDHA, lactate dehydrogenase isoform A; MCT, monocarboxylate transporter; mTOR, mammalian target of rapamycin; NF, neurofibromin; PDK, pyruvate dehydrogenase kinase; PFK, phosphofructokinase; PI3K, phosphatidylinositol 3-kinase; PIP3, phosphatidylinositol triphosphate; PGM, phosphoglycerate mutase; PHD, prolyl hydroxylase; PKM2, pyruvate kinase isoform M2; SCO2, synthesis of cytochrome *c* oxidase 2; SDH, succinate dehydrogenase; TSC, tuberous sclerosis complex; VDAC, voltage-dependent anion channel; VHL, von Hippel-Lindau ubiquitin ligase.
Reprinted from *Cancer Cell*, Volume 13, Issue 6, Kroemer G, Pouyssegur J, Tumor cell metabolism: cancer's Achilles' heel, pp. 472–482., Copyright © 2008, with permission from Elsevier, http://www.sciencedirect.com/science/journal/15356108

the activity of AMPK from growth signals, including by mutations in liver kinase B1 (LKB1), which is required for AMPK activity. The loss of LKB1, mutated in Peutz–Jeghers syndrome and sporadically in several other tumours [14], leads to increased mTOR and HIF1 activity and promotes the shift to glycolytic metabolism.

Oestrogen-related receptors

Oestrogen-related receptors (ERRs) have unique functions distinct from oestrogen receptors (ERs) although they share significant homology. There are three ERRs (ERRα, ERRβ and ERRγ), which do not associate with a known steroid hormone, and they are highly expressed in normal tissues with high-energy demands and many cancers. In breast cancer the expression of ERα is inversely related to the expression of ERRα. A high level of ERRα can promote glycolytic metabolic reprogramming, whereas ERRγ can sustain oxidative phosphorylation. ERR signalling is modulated by mitogenic signalling, and ERRα activity is promoted by EGFR and ERRB2 (HER2) signalling. ERRs are not affected by current hormonal therapies used in breast cancer [15].

Transcription factors orchestrate the metabolic switch

Hypoxia-inducible factors (HIFs)

A heterodimer of an unstable alpha subunit (in normoxia) and a constitutively present and stable beta subunit, HIF binds to DNA at specific locations called hypoxic response elements (HREs) and elicits a transcriptional up-regulation of genes required to respond appropriately to hypoxia. HIF1, the ubiquitously expressed isoform, promotes the transcription of genes encoding glucose transporters and most glycolytic enzymes increasing the capacity to perform glycolysis. HIF1 also prevents the entry of pyruvate into the TCA cycle by inducing the expression of pyruvate dehydrogenase kinase 1 (PDK1), altering the expressed isoforms of cytochrome c oxidase (from isoform 1 to 2) and inhibiting mitochondrial biogenesis. This causes reduced levels of oxygen consumption and a shift away from oxidative phosphorylation. HIF1 can be activated under normoxic conditions in tumours by oncogenic pathways such as PI3K and by mutations in VHL, succinate dehydrogenase, and fumarate hydratase [16].

MYC

High expression of the oncogene c-Myc is capable of immortalizing cells in vitro and it is overexpressed and amplified in approximately 30% of human cancers. Myc is a transcription factor capable of influencing expression of about 15% of all proteins, including a higher than expected presence of mitochondrial proteins. Oncogenic levels of Myc increase glutaminolysis leading to glutamine addiction of Myc-transformed cells [17]. In collaboration with HIF1, Myc can promote expression of several glycolytic enzymes and glucose transporters as well as lactate dehydrogenase A (LDHA) and PDK1 [18]. The relationship between HIF1 and Myc is complicated, and there is evidence that

the two can regulate each other's activity. One example is that HIF-1 can inhibit c-Myc activity, and thus inhibit mitochondrial biogenesis and respiration in hypoxia [19]. Myc also promotes the alternative splicing of the pyruvate kinase gene PKM leading to enhanced expression of the embryonic form PKM2 [20].

PKM2

Pyruvate kinase catalyses the rate-limiting step of glycolysis in which phosphoenolpyruvate is converted to pyruvate, producing ATP. The M2 isoform, up-regulated in many different types of tumour and highly proliferating tissues, can switch from a tetrameric to a dimeric form with lower activity [21]. This lower efficiency allows the accumulation of glycolytic intermediates for use in biosynthetic pathways, including the hexosamine pathway, glycerol synthesis, and the pentose phosphate shunt. High levels of Myc cause the expression of the M2 isoform and PKM2 interacts directly with HIF-1α, enhancing binding and transcription from HREs [22]. By increasing the transcription of proglycolytic genes such as *LDHA* and *SLC2A1*, PKM2 can promote a shift towards anaerobic metabolism.

Tumour suppressors contribute to increased glycolysis

Tumour suppressors also regulate glycolytic metabolism, and the loss of p53 can result in the Warburg effect, consequent to its role in maintaining expression of mitochondrial cytochrome c oxidase 2. P53 normally controls glycolysis through the TP-53-induced glycolysis and apoptosis regulator (TIGAR), increased expression of which inhibits glycolysis and increases the availability of glucose-6-phosphate [23]. P53 can also increase the amount of glucose-6-phosphate by inducing the expression of hexokinase II [24]. This metabolite is used in the pentose phosphate pathway and promotes the synthesis of nucleotides as part of the DNA damage response.

From the limited description of the metabolic consequences of high-frequency mutations in a wide variety of tumours as described, it is clear that metabolic derangements in cancer provide the conditions to support a high proliferative rate. This is not only through energetic supply, but also by promoting the accumulation of biosynthetic precursors for fatty acid, nucleotide, and protein synthesis. As a consequence of the ensuing cancer environment, tumour cells must adapt to survive in conditions of reduced oxygen and altered acid-base and redox balance.

Metabolic changes that support uncontrolled proliferation

Lactate and pH

The increased rate of glycolysis and conversion to lactate produces an acidic intracellular compartment and high concentrations of lactate. Regulation of intracellular pH is maintained in tumour cells by the Na^+/H^+ exchanger protein NHE1, required for tumour cell proliferation [25]. Carbonic anhydrase 9 (CA9], a target gene of HIF1, catalyses the conversion of carbon dioxide into bicarbonate at the extracellular aspect of the plasma membrane, promoting the removal of excess protons from the cell [26]. Lactate transport out of tumour cells is facilitated by the monocarboxylate transporters MCT1 and MCT4 which require the ancillary protein CD147 (basigin) for their

activity. Renal-cell tumours are particularly reliant on MCT4, secondary to aberrant activation of HIF1 by inactivation of VHL [27]. This leads to a pseudohypoxic state, resulting in a predominant glyocolytic metabolism which has a high requirement for efficient lactate export.

Hypoxia

Hypoxia promotes the stability and transcription activity of the HIF proteins which, as described previously, are efficient inducers of glycolytic metabolism. Other than effects on HIF, hypoxia also reduces the activity of mTOR and may reactivate autophagy and promote survival under stress, angiogenesis, metastasis, glycolysis and drug resistance.

Reactive oxygen species

Reactive oxygen species (ROS) are a set of radical species produced as a byproduct of metabolic processes. The mitochondrial electron transport chain is the main source of ROS and these can contribute to the cytoplasmic pool and affect cell signalling. Mitochondrial ROS can promote HIF stabilization [28], and inhibit PKM2 activity [29]. Consequent to this, the production of NADPH is increased through the pentose phosphate shunt, due to the increased availability of glycolytic intermediates. NADPH is required to maintain the activity of antioxidant systems including glutathione and thioredoxin. High levels of ROS are deleterious to the cell, causing macromolecular damage (including DNA), senescence, and apoptosis.

Metabolic genes with oncogenic or tumour suppressor activity

In addition to the contribution that alterations of oncogenes and tumour suppressor genes make towards driving metabolic transformation, it has been recognized that metabolic derangements can also actively participate in the transformation process.

Oncogenic mutation of metabolic enzymes

Mutations in IDH1 and IDH2 are commonly found in glioblastoma and always cause a single amino acid change (Arg132 in IDH1, Arg172 in IDH2). These characteristic changes lead to neomorphic enzyme properties promoting the conversion of alpha-ketoglutarate to 2-hydroxyglutarate [2-HG] [30]. 2-HG can modulate gene expression in tumours by inhibiting the DNA demethylase TET2 [31], leading to increased genome-wide CpG island methylation and repression of differentiation in astrocytes. Consequently, this metabolite can promote the development of poorly differentiated tumours by directing gene expression. These properties have led it to be named an 'oncometabolite'.

Mitochondrial enzyme tumour suppressor genes

Inherited mutations in the nuclear genes encoding mitochondrial proteins succinate dehydrogenase (SDHB, SDHC, SDHD) and fumarate hydratase (FH) lead to familial cancer syndromes and have implicated these genes as tumour suppressors [32]. Mutations in succinate dehydrogenase lead to accumulation in succinate, which inhibits the activity of HIF prolyl hydroxylases. The HIF prolyl hydroxylases hydroxylate HIF-α subunits in an oxygen-dependent manner, labelling it for VHL-mediated ubiquitination [33]. In effect, higher levels of succinate and fumarate lead to higher levels

of HIF signalling by inhibiting its degradation. This may provide the metabolic conditions conducive to oncogenic transformation.

Lipid biosynthesis is up-regulated in cancer

In order to support increased proliferation, tumour cells increase their rate of de novo fatty-acid synthesis. The expression of enzymes involved in lipogenesis is largely controlled by the sterol regulatory element binding proteins (SREBPs). The activity of SREBPs is regulated by AKT and is dependent on mTOR [34]. Increased lipid synthesis is required for the generation of structural lipids that are required for building biological membranes. Other lipids, such as triacylglycerols are used as an energy source, whilst others such as monoacylglycerol lipase may be a signalling molecule-inducing gene expression promoting invasion and metastasis [35]. The precise contribution of increased lipogenesis in tumours is not yet clear; however, SREBP1 expression correlates with breast cancer progression [36].

An increased rate of fatty acid synthesis in prostate cancer can occur in the absence of significant glucose uptake, making the staging of the disease problematic using ^{18}F-FDG PET. Increased fatty acid synthesis can be imaged using ^{11}C-acetate PET, enhancing patient management, and may also potentially be used to predict response to novel anti-fatty acid synthase inhibitors [37].

Glycogen synthesis in cancer

Despite the increased rate of glycolysis in tumours, many tumours and cell lines have been shown to accumulate glycogen. Glycogen accumulation performs a critical role, as inhibiting the breakdown by small molecule inhibition leads to apoptosis in pancreatic tumour cells. On the other hand, reducing the levels of glycogen phosphorylase, which leads to glycogen accumulation, leads to premature senescence of tumour cells and impairs tumour growth [38]. Tumoural glycogen maintains levels of NADPH and ROS, and potentially allows for regulation of substrate entry into the glycolytic pathway.

Potential strategies for targeting metabolic transformation

Metabolic reprogramming provides the opportunity for targeted drugs to selectively exert toxic effects on tumour cells. This may require tumour phenotyping to select patients who are most likely to benefit from therapies that target tumour metabolism [5]. As we have described, functional targeting of oncogenic pathways such as *PI3K* and KRAS, may reduce the downstream pathways that promote metabolic transformation as well as reducing growth of the tumour.

Metformin is an antidiabetic drug that is in widespread use and inhibits mitochondrial ATP production, causing activation of AMPK. This reduces the anabolic function of mTOR signalling and triggers autophagy. P53 loss sensitizes cells to the effects of metformin [39] and trials are currently underway evaluating whether metformin may be able to alter tumour metabolism in patients.

ERRα represents a new therapeutic target which may be able to reverse the global metabolic programming that occurs in tumours [15]. Drugs that reduce HIF signalling are also likely to be particularly efficacious given its central role in mediating increased glycolysis, angiogenesis, and metastasis.

One of the most convincing ways of targeting metabolism to produce anticancer effects is synthetic lethality. Lactate dehydrogenase A (LDHA) catalyses the conversion of pyruvate to lactate-producing NAD+, which itself is required for glycolysis. NAD+ can also be recycled from nicotinamide through the salvage pathway using the enzyme nicotinamide phosphoribosyltransferase (NAMPT). NAMPT inhibitors potentiate the effect of LDHA inhibitors [40]. In addition, NAMPT combined with genotoxic chemotherapy and radiotherapy may produce significant effect.

Conclusions

Although many tumours show a stereotypical altered metabolic phenotype with regard to enhanced glucose uptake, it is clear that a variety of metabolic pathways can produce this effect. Many of the metabolic pathways show commonality with hypoxic-induced changes. The changes are adaptive, allowing for strict ROS balance and biosynthetic function, and therapeutic strategies that interrupt these homoeostatic mechanisms may form the basis for future anti-metabolic treatments in cancer.

Aetiology and epidemiology of cancer

CHAPTER 14

Smoking and cancer

Jonathan M. Samet

Introduction to smoking and cancer

Historical perspective

The global impact of tobacco use on health is staggering. Worldwide, there are more than one billion users of tobacco products, including about 750,000 people who smoke cigarettes regularly [1]. The resulting burden of premature mortality, about 6 million deaths in 2011, makes tobacco use the world's leading cause of avoidable premature mortality [2]. Of the six million deaths, an estimated 2.12 million (33%) are from cancer [3]. This chapter provides a perspective on tobacco smoking as a cause of cancer, summarizing the evidence from epidemiological studies and reviewing a now extensive literature on how tobacco smoke causes cancer. It also covers the topic of tobacco control. In-depth reviews are available on these topics, such as Monographs 83 and 100E of the World Health Organization's International Agency for Research on Cancer (IARC), volumes 11 through 14 of the IARC Handbooks of Cancer Prevention, and the 2004, 2006, 2010, and 2014 reports of the United States Surgeon General.

Cancer has figured prominently in the identification of tobacco use as a major cause of disease worldwide. Although there were writings on the dangers of tobacco use for health centuries ago, the body of evidence that constitutes the foundation of understanding of tobacco as a cause of disease dates to approximately the mid-twentieth century. Even earlier, clinical case reports and case series had called attention to the likely role of smoking and chewing tobacco as a cause of cancer. The rise of diseases that had once been uncommon, such as lung cancer (Figure 14.1), was noticed early in the twentieth century and motivated studies to determine if the increases were 'real' or an artefact of changing detection. By mid-century, there was certainty that the increases were real and continuing, and the focus of research shifted to finding the causes of the new epidemics of 'chronic diseases' with an emphasis initially on lung cancer and coronary heart disease.

The rise of smoking had antedated the rise of lung cancer (Figure 14.1) and consequently smoking was among the postulated causes of the increase, but other factors were also considered. In initiating their pioneering case-control study of lung cancer in the late 1940s, Doll and Hill, the British epidemiologists, gave equal weight to smoking and to air pollution as possible causes of lung cancer. The key initial observations were made in epidemiologic studies of smoking and lung cancer with the earliest carried out in the late 1920s and 1930s [4]. Consistent results were reported from five case-control studies reported in 1950, all showing a strong association of cigarette smoking with lung cancer in men [5–9]. The case-control results were soon followed by confirmatory findings from cohort (longitudinal studies) including the landmark study of British physicians carried out by Doll and Hill [10, 11].

These initial observations sparked complementary laboratory studies on the mechanisms by which tobacco smoking causes disease. By the early 1950s cigarette smoke was known to contain benzo(a)pyrene, a recognized carcinogen, and in 1953, Wynder and colleagues reported that painting the shaved skin of mice with cigarette smoke condensate caused tumours [12]. The mounting evidence received formal review and evaluation by government committees, leading to conclusions that smoking caused lung cancer in the late 1950s and early 1960s, including the landmark reports from the Royal College of Physicians and the Advisory Committee to the US Surgeon General [13, 14]. Subsequent reports have led to a progressively lengthier list of cancers caused by smoking (Table 14.1). Even 40 years after the first Surgeon General's report, the 2004 report found the evidence for a number of malignancies sufficient to classify the associations as causal, including cervical cancer and acute myelogenous leukaemia [15], and IARC's Monograph 83 found the relationship to be causal for liver cancer [16]. The 2014 report of the US Surgeon General added colorectal cancer as causally associated with smoking [17]. These causal conclusions have long been critical in motivating aggressive tobacco control.

The issue of passive smoking and cancer has a briefer history. The 1972 report of the Surgeon General was the first to call attention to passive smoking in a chapter titled 'Public exposure to air pollution from tobacco smoke' [18]. The first major studies on passive smoking and lung cancer in non-smokers were reported in 1981, including the cohort study of Japanese women carried out by Hirayama which showed high lung cancer mortality among non-smoking women married to smokers compared with those married to non-smokers [19], and by 1986 the evidence supported the conclusion that passive smoking was a cause of lung cancer in non-smokers, a conclusion reached by the IARC, the US Surgeon General, and the US National Research Council. This conclusion has had widespread public health impact, serving as a key driver for smoke-free indoor environments including public places and workplaces. Research continues on passive smoking and other cancers, particularly for breast cancer—a still controversial topic [20].

Mechanisms of carcinogenesis

Tobacco smoke components

Tobacco smoke is a rich mixture of particles sufficiently small to reach the bronchioles and alveoli and of gases. Fresh tobacco
Fig. 14.1 Tobacco use and lung cancer mortality, US, 1900–1997 (per 100,000 and age-adjusted to 1970 US standard population).
Reproduced with permission from Hecht SS and Samet JM, Cigarette Smoking, pp. 1521–1551, in Rom WM (Ed.), *Environmental and Occupational Medicine*, Fourth Edition, Wolters Kluwer/Lippincott Williams & Wilkins, Philadelphia, USA, Copyright © 2007

smoke is reported as containing about 7000 distinct chemicals, including numerous known carcinogens, such as benzo(a)pyrene, tobacco-specific nitrosamines, benzene, polonium, and toxins [21]. These components contribute directly and indirectly to carcinogenesis. Tobacco smoke has high oxidative potential and causes inflammation in the lung and systemically. Tobacco smoke components move from the lungs into the circulation and reach throughout the body, thus leading to tissue doses of carcinogens, not only at the site of absorption, but to most organs of the body. The liver is a site of carcinogen metabolism and activation and the kidneys and bladder are involved in the excretion of carcinogens.

Tobacco smoke contains numerous known carcinogens, including many that have been evaluated for carcinogenicity by IARC [16, 22]. Broad classes of carcinogens include polycyclic aromatic hydrocarbons (PAHs), N-nitrosamines, aromatic amines, volatile aldehydes, and phenolic amines. The PAHs result from incomplete combustion and include benzo(a)pyrene, one of the first carcinogens identified in tobacco smoke. They act locally and bind to DNA. *N*-nitrosamines are a large class of carcinogens that includes the tobacco-specific nitrosamines *N*-nitrosamines 4-(methylnitrosamino)-1-(3-pyridyl)-1-butanone (NNK) and *N'*-nitrosonornicotine (NNN). The N-nitrosamines are potent systemic carcinogens and NNK causes lung and other tumours in animal models. Aromatic amines, also combustion products, include recognized human bladder carcinogens in occupational settings, 2-naphthylamine and 4-aminobiphenyl. Some other carcinogens in tobacco smoke are formaldehyde, catechol, and 1,3 butadiene,

and the leukemogen benzene. Diverse metals and the radionuclide ^{210}Po are also present in cigarette smoke.

The doses of carcinogens and other tobacco smoke components received can be assessed using biomarkers. Cotinine, a major nicotine metabolite, is a widely used biomarker for active and passive smoking that can be measured in blood, urine, saliva, and hair [16]. The doses of cigarette smoke carcinogens resulting from inhalation of tobacco smoke are reflected in levels of these carcinogens or their metabolites in the blood and urine of smokers. Certain biomarkers are associated with exposure to specific cigarette smoke carcinogens, such as urinary metabolites of the tobacco-specific nitrosamine NNK and haemoglobin adducts of aromatic amines. Levels of these biomarkers can be used as highly specific indicators of exposure to tobacco smoke carcinogens, while nicotine or its metabolites (particularly cotinine) are used as indicators of exposure to tobacco smoke generally, both for active and passive smoking. For example, the NNK metabolite, NNAL, can be measured in the urine of active smokers and of passive smokers [23].

Tobacco smoke and carcinogenesis

Figure 14.2 provides a general schema for the causation of cancer by the carcinogens in tobacco smoke. There are both specific and non-specific pathways by which smoking is thought to cause cancer. The figure begins with initiation of cigarette smoking and addiction; it is the maintained contact with tobacco smoke carcinogens consequent to addiction that leads to the very high risk of cancer in those who smoke daily throughout their lives, the general pattern of the addicted smoker. However, the sustained, but

Table 14.1 Cancers caused by active smoking, as identified by the United States Surgeon General or by the World Health Organization's International Agency for Research on Cancer (IARC)

Cancer type	Highest level conclusion available for active smoking	
	US Surgeon General	**IARC**
Bladder and ureter	Causal	Causal
Brain (adults only)	Suggestive of no causal relationship	–
Breast (women only)	Suggestive but not sufficient to infer causal relationship [17]	Positive association
Cervical	Causal	Causal
Colorectal	Causal [17]	Causal
Endometrial	Reduced risk in postmenopausal women	Evidence suggesting lack of carcinogenicity (postmenopausal)

Prostate	Suggestive of no causal relationship	–
Sinonasal	–	Causal
Stomach	Causal	Causal
Thyroid	–	Evidence suggesting lack of carcinogenicity

Source: data from US Department of Health and Human Services, *The Health Consequences of smoking: A Report of the Surgeon General*, US Department of Health and Human Services, Atlanta, Georgia, USA, 2004; International Agency for Research on Cancer (IARC), *Tobacco Smoke and Involuntary Smoking*, IARC Monograph 83, International Agency for Research on Cancer, Lyon, France, Copyright © 2004 and International Agency for Research on Cancer (IARC), *A Review of Human Carcinogens, Part E: Personal Habits and Indoor Combustions*, Monograph 100E, International Agency for Research on Cancer, Lyon, France, Copyright © 2012.

lower-level exposures of passive smokers are also sufficient to cause cancer. The figure highlights the multiple processes that lead to uncontrolled cell growth and malignancy and the multiple points in these processes at which tobacco smoke components contribute to carcinogenesis. Emphasis has been given to DNA binding and mutations but research also shows that tobacco smoke contributes to increased cancer risk through epigenetic mechanisms.

For many tobacco smoke carcinogens, metabolic activation is needed and genetic determinants of rates of activation may modify the risk of cancer in smokers [21]. The metabolic activation of cigarette smoke carcinogens by cytochrome P-450 enzymes has a direct effect on the formation of DNA adducts. There is consistent evidence that a combination of polymorphisms in the CYP1A1 and GSTM1 genes of the cytochrome P-450 system leads to higher DNA adduct levels in smokers and higher relative risks for lung cancer than in smokers without this genetic profile. Tobacco-specific carcinogens form adducts and lead to mutations in oncogenes and tumour suppressor genes. Smoking has been found specifically to increase the frequency of DNA adducts of cigarette smoke carcinogens such as benzo(a)pyrene and tobacco-specific nitrosamines in

the lung and other organs, and to cause DNA damage and mutations in key oncogenes and tumour suppressor genes, including *TP53* and *KRAS*. There is also evidence showing that smoking leads to the presence of promoter methylation of key tumour suppressor genes such as *P16* in lung cancer and other smoking-caused cancers. More recent research is more specifically characterizing the pathways by which smoking causes cancer. For example, the 2010 report of the Surgeon General found that smoke constituents, such as nicotine and NNK, can activate signal transduction pathways directly through receptor-mediated events, allowing the survival of damaged epithelial cells that would normally die.

Epidemiology of smoking and cancer

Overview

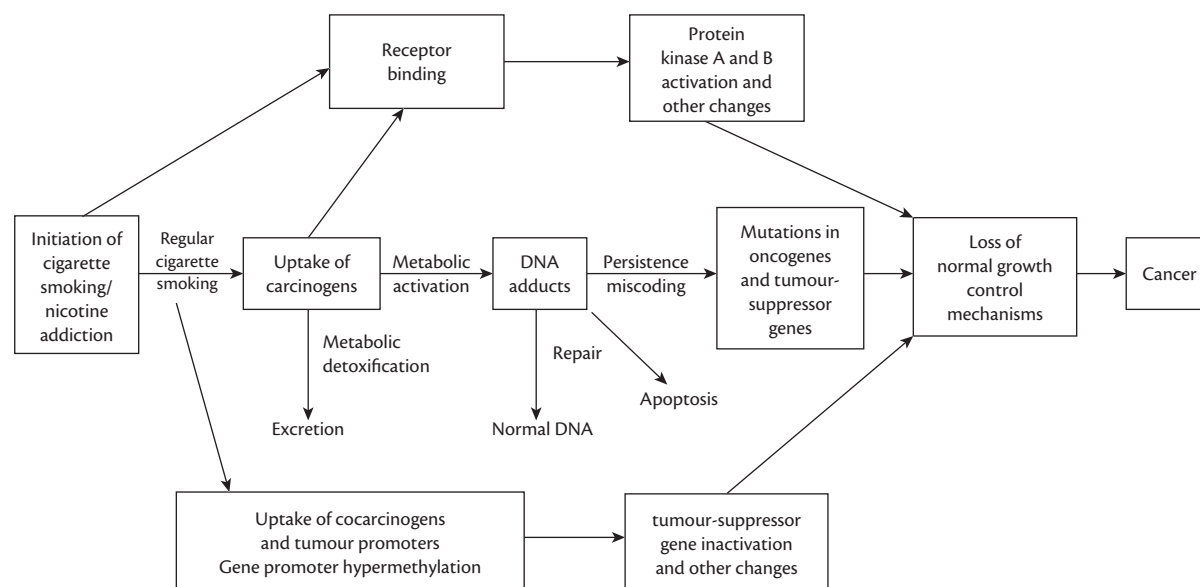
Smoking causally increases risk for multiple cancer sites (Table 14.1). Table 14.2 provides relative risk estimates for cancer death for major sites in the two cohort studies of the American Cancer Society, Cancer Prevention Study (CPS) I (1959–1965) and CPS II (1982–1988) [15]. Several general findings are notable: (1) the


Fig. 14.2 Link between cigarette smoking and cancer through carcinogens in tobacco smoke.
Reproduced from US Department of Health and Human Services, *How Tobacco Smoke Causes Disease: The Biology and Behavioral Basis for Smoking-Attributable Disease: A Report of the Surgeon General*, US Department of Health and Human Services, Atlanta, Georgia, USA, 2010.

relative risks for current and former smokers compared to never smokers are remarkably high for some sites, such as lung and laryngeal cancer; (2) former smokers uniformly have decreased relative risks in comparison with current smokers; (3) relative risks have tended to be lower in females than in males; and (4) relative risks tended to increase for females over the two decades between the two studies. Findings of more recent studies suggest that relative risks have continued to rise as more recent cohorts of women have started to smoke at a similarly young age as men and smoked with the same intensity.

Lung and laryngeal cancers

The impact of smoking on lung cancer in the twentieth century in the US can be seen in Figure 14.1. Cigarette smoking was rare in the early part of the twentieth century, as was lung cancer. Smoking increased due to mass production of cigarettes, increased advertising, pervasive availability of cigarettes by military personnel during World War I, and increased use by women at the time of World War II. Cigarette smoking peaked in the 50s and 60s, and began to decline after the wave of studies documenting its risks appeared and the publication of the first Surgeon General's Report in 1964. Mortality due to lung cancer in men can be seen to follow the curve for smoking prevalence by about 30 years, beginning to decrease in the mid-1990s. Lung cancer became the most common cause of cancer death in US women, surpassing breast cancer in 1988, and only now has the overall lung cancer death rate reached a plateau.

Lung cancer was the first cancer causally associated with cigarette smoking and the epidemiological data for lung cancer illustrate the power of smoking as a cause of cancer, the variation in risk with duration and amount of smoking, and the beneficial consequences of smoking cessation. Recent studies show about a 20-fold increase in risk of lung cancer in current smokers, compared with non-smokers and the relative risks are now comparable in male and female smokers in western countries. The strongest determinant of lung cancer in smokers is duration of smoking, and risk also increases with the number of cigarettes smoked, but not so steeply as for duration of smoking. Thus, earlier age of initiation of smoking greatly increases lung cancer risk. Cessation of smoking at any age avoids the further increase in risk of lung cancer caused by continued smoking, but the risk of ex-smokers for lung cancer remains elevated for years after cessation, compared to the risk of never smokers, and even with long-term successful quitting it does not return to the risk of the never smoker (Table 14.2).

Smoking increases the risk of all major histologic types of lung cancer [16]. Initially, the association of smoking with adenocarcinoma of the lung was weak, but in more recent decades that association has become stronger. In fact, changes in cigarette design are postulated as causing the shift in histological types of lung cancer over recent decades with adenocarcinoma replacing squamous cell carcinoma as the most common type of lung cancer caused by smoking in the US and elsewhere. The design changes are postulated to have led to deeper inhalation of smoke and greater doses of tobacco-specific nitrosamines which are linked to adenocarcinoma.

Lung cancer has multiple causes other than cigarette smoking but in populations with early age of initiation and average consumption of about 20 cigarettes per day, approximately 90% of lung cancer cases are due to cigarette smoking. For some occupational and environmental causes of lung cancer, such as asbestos and radon, synergistic interactions are well documented [16].

The general patterns are also similar for laryngeal cancer (Table 14.2). However, for laryngeal cancer, smoking interacts synergistically with alcohol consumption, greatly increasing risk for those who both smoke and drink alcohol heavily [16]. Risk patterns and synergism with alcohol are similar for cancers of the oropharynx and oesophagus as well and the comparable epidemiological patterns for these upper airway and digestive sites have led to the introduction of the concept of 'aerodigestive tumours'.

Table 14.2 Age-adjusted relative risks of death from smoking-related cancers from the Cancer Prevention Study (CPS) I and CPS-II

Disease category (ICD-9 code)	CPS-I (1959–1965)				CPS-II (1982–1988)

Other cancers

Cigarette smoking is causally associated with diverse other cancers (Tables 14.1 and 14.2). Similar to lung cancer, for these sites risk increases with smoking duration and number of cigarettes smoked, and cessation avoids further increases in risk. However, the magnitudes of the relative risks are substantially lower than for lung cancer (Table 14.2). For some sites, the evidence has long been sufficient to support a causal association, including cancers of the oral cavity, oesophagus, and urinary bladder. The evidence has also become sufficiently strong to causally link smoking to cancers of the stomach, pancreas, and kidney. For some of these sites, there has been careful attention to other factors and aetiological research has controlled for such factors, for example alcohol and carcinoma of the oesophagus, and explored the combined effects of smoking with these other factors [16].

For several sites, there are other strong causal agents, for example hepatitis B virus infection and hepatocellular carcinoma, and smoking has been causally linked to their aetiology only after epidemiological research fully clarified the role of smoking in the context of these other factors. The IARC identified smoking as a cause of hepatocellular carcinoma after summarizing epidemiological studies showing that the association with smoking was not arising from confounding by the other causal agents, particularly alcohol consumption. Additionally, there was a positive relationship with indicators of dose and a decline of risk after cessation. Similarly, cigarette smoking is a cause of cervical squamous cell carcinoma, accelerating the development of cervical malignancy in women with human papilloma virus, the apparent cause of most cases of cervical cancer. Myeloid leukaemia in adults is also causally related to cigarette smoking. Cigarette smoke contains benzene, a known leukomogen. The 2014 report of the US Surgeon General found the relationship of smoking with colorectal cancer to be causal [17].

For some cancer sites, the evidence is suggestive of a causal association but not yet judged conclusive. The most controversial findings relate to breast cancer for which the overall association with active smoking has been previously null. The breast tissue of smokers is exposed to tobacco smoke carcinogens, but smoking alters estrogen metabolism to a profile that may lower breast cancer risk [15]. Epidemiological studies have explored whether particular subgroups of smokers may be at increased risk, as defined by clinical characteristics, genotype for carcinogen metabolism, or risk factor profile. The evidence remains mixed. However, several groups have classified active smoking as a cause of breast cancer [24, 25]. The 2014 Surgeon General's report, based on an exhaustive evaluation of the literature and meta-analysis found the evidence to be suggestive of a causal relationship [17]. For prostate cancer, mortality, but not incidence, is increased in cigarette smokers [15].

Other types of tobacco use

Cigar and/or pipe smoking are strongly related to cancers of the oral cavity, oropharynx, hypopharynx, larynx, and oesophagus, with the risk being similar to that of cigarette smoking [26]. Dose-response relationships have been documented. Cigar and/or pipe smoking are causally associated with lung cancer and possibly with cancers of the pancreas, stomach, and urinary bladder [27].

Bidis, smoked by millions in India, Bangladesh, and other countries in Asia, are comprised of flakes of tobacco rolled within a leaf and held together by a string [1, 28]. Typically, they are made at the local level, but distributed widely. Toxicological and biomarker studies document a profile that indicates a potential for

risks comparable to those in smokers of cigarettes. Although the evidence is limited, epidemiological studies show increased risk for aerodigestive cancers in bidi smokers.

Passive smoking and cancer

Secondhand smoke (SHS) inhaled by never smokers has also been causally linked to lung cancer. Secondhand tobacco smoke is a mixture, mainly of the smoke generated between puffs, called sidestream smoke, and a minor portion of mainstream smoke constituents exhaled by a smoker. Although the levels of certain carcinogens in sidestream tobacco smoke are greater than in mainstream smoke per gram tobacco burned, SHS is diluted by air and the carcinogen dose received by a nonsmoker exposed to SHS is substantially less than that received by an active smoker.

Epidemiologic studies of secondhand tobacco smoke and lung cancer have typically found relative risks between 1 and 2. Over the decades since the first studies, meta-analyses have been repeatedly carried out. The 2002 evaluation by IARC compiled more than 50 studies of involuntary smoking and lung cancer risk in non-smokers. The IARC Monograph 83 concluded that there is a significant and consistent association between lung cancer risk in spouses of smokers and secondhand tobacco smoke exposure, with the excess risk being about 20% in women and 30% in men. Workplace exposures to SHS also increased lung cancer risk in non-smokers, by 12–19%. The findings of subsequent meta-analyses have been similar; a 2007 report based on 22 studies found that workplace exposure was associated with a 24% increase in risk [29].

The literature on SHS exposure and breast cancer is mixed and controversial, in part because of the inconsistent findings on active smoking, unlike lung cancer. The association of SHS exposure with breast cancer risk is strongest in case-control studies of premenopausal breast cancer, but less clear in cohort studies and for postmenopausal breast cancer. As for active smoking, several groups have concluded that passive smoking is a cause of breast cancer [24, 25], but neither IARC nor the US Surgeon General have yet reached this conclusion (Table 14.1).

Global burden of smoking-caused cancer

The global burden of smoking-attributable premature death is over six million annually, of which 2.1 million, or one-third of the total burden, are from malignancy. Not surprisingly, the number is greatest for lung cancer at 1.1 million [3]. Other leading sites include the oropharynx, oesophagus, stomach, and liver. In high-income countries, about half of the cancer burden is attributable to smoking; that percentage is currently lower in less developed countries, but anticipated to rise, absent effective tobacco control [30]. For passive smoking, 603,000 premature deaths are attributable to SHS exposure worldwide [31].

Tobacco control

Tobacco control has had a lengthy evolution that has been closely linked to the increasing evidence on the health effects of active and passive smoking and on what tobacco control modalities are efficacious [32, 33]. Historically, the initial findings on lung cancer and smoking were followed by efforts to educate the public about the risks of smoking with the expectation that they would stop. Since then, we have learned that tobacco control requires far more complex approaches that acknowledge the hierarchy of factors that determine the use of tobacco and the interplay of these factors across the lifecourse, as health is damaged by smoking from conception on. At each age, the emphasis of tobacco control shifts, moving from ending maternal smoking during pregnancy and SHS exposure during childhood, to preventing initiation, and then to promoting successful cessation. Additionally, tobacco control efforts need to be dynamic in time, changing as the tobacco industry attempts to counter any tobacco control measures.

Figure 14.3 provides a hierarchical model that is useful for framing tobacco control [34]. At the lowest level, emerging evidence shows that genetic factors figure in determining liability to addiction and risk for disease in smokers. Intermediate levels are also relevant: the roles of family and peers in initiation are well established. The broader neighbourhood, municipal and state and national levels are also critical in establishing both positive and negative pressures for tobacco use and in setting the critical 'cultural norm' around smoking. The cultural norm may be that smoking is acceptable as in present-day China where cigarettes have well-established roles in social interactions, or unacceptable as in much of the US today, where workplaces and public places are generally smoke-free. Advertising bans, pack warnings, and taxation rates—potentially determined at multiple governmental levels—also affect the environment for smoking and tobacco control. The global level is ever more relevant as the tobacco industry has consolidated into a limited number of multinational companies, including Philip Morris International, British American Tobacco, Japan Tobacco International, and Imperial Tobacco/Altadis [2]. The largest producer is China National Tobacco Corporation, a state monopoly that manufactures more than 90% of cigarettes consumed by China's 300 million smokers.

The industry has a critical role, as the 'root cause' of the tobacco epidemic. Considered in the classic epidemiological triangle of agent, vector, and host, the tobacco industry is the vector that conveys tobacco to people, the host. It also contributes to setting the environment by advertising and promoting its addicting product. We have learned that the industry also attempted to affect the environment around smoking by paying for placement of smoking in movies [35]. Viewing of smoking in movies has been causally linked to increased tobacco use [35]. Notably, the industry is an 'adaptive' vector that changes strategies in a dynamic way to target by host characteristics (age, gender, and race) and to counter efforts at tobacco control. The need to address the industry broadly is reflected in control measures that directly address its activities, including regulation, litigation, and the World Health Organization's Framework Convention on Tobacco Control (FCTC) [36].

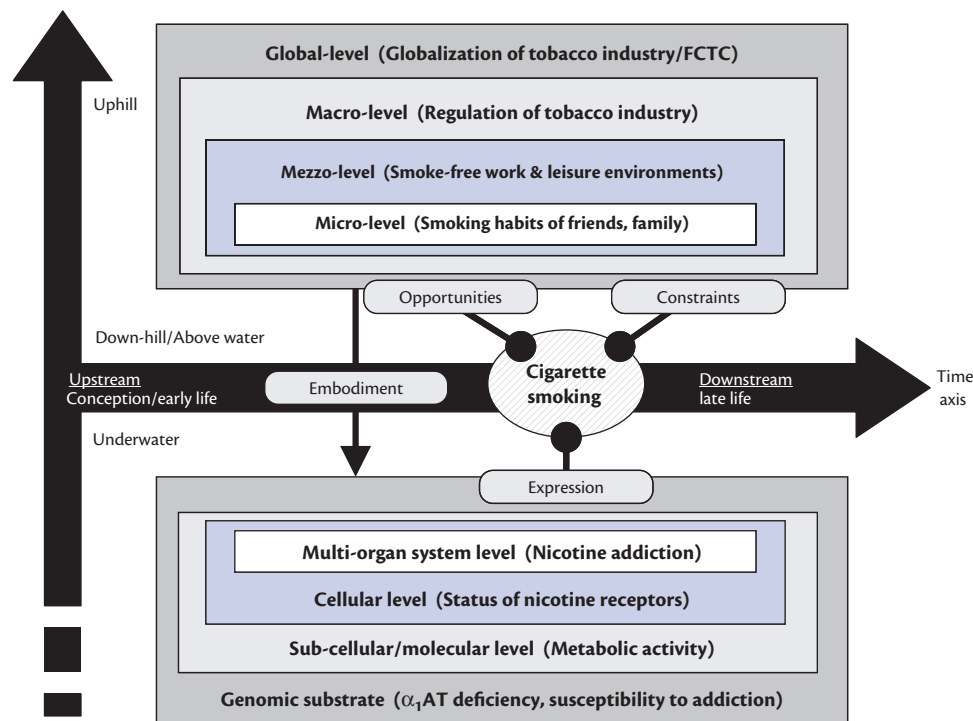
Over time, approaches to tobacco control have evolved such that they incorporate a package of interventions. This evolution reflects the expanding understanding of the impact of various tobacco control strategies. For example, the finding that passive smoking caused lung cancer motivated the implementation of smoking bans in public places and workplaces and initiated a change in social norms around smoking that moved smoking from being viewed as acceptable to unacceptable. As noted by Surgeon General Koop in the preface to his 1986 report, 'The right of smokers to smoke ends where their behaviour affects the health and well-being of others' [37]. Approaches to smoking cessation became more effective when nicotine was identified as addicting, nicotine replacement therapy and other pharmacological approaches were introduced,


Fig. 14.3 Axes of time and nested hierarchical structures for tobacco control.

and stronger behavioural approaches were introduced. Research and experience also documented the need to raise taxes, to use aggressive counter-marketing to denormalize smoking, and to protect children from the reach of the tobacco industry. Most importantly, decades of evidence shows that a multicomponent strategy is needed that targets non-smokers to keep them from smoking and that encourages and supports smokers to quit. Recent experience in New York City, for example, shows that an aggressive, multifaceted programme can have rapid impact. Following implementation of a smoking ban, tax increases, hard-hitting anti-smoking campaigns, and an active cessation programme, smoking prevalence fell from 21.6% to 19.2% between 2002 and 2003, signifying a reduction of approximately 140,000 smokers during this period [38].

Many nations have implemented tobacco control programs. Most importantly, there is now the FCTC, ratified and in force for most nations of the world, although not for the US and Indonesia. Many universal elements of national tobacco control policy are core provisions of the FCTC. Key provisions include a comprehensive ban on tobacco advertising, promotion, and sponsorship; a ban on misleading descriptors such as 'light'; and a mandate to place rotating warnings that cover at least 30% of tobacco packaging and encouragement for even larger, graphic warnings. The FCTC also urges countries to implement smoke-free workplace laws, address tobacco smuggling, and increase tobacco taxes. The FCTC has now been in place for more than five years and progress is slowly being made in implementing its components [39].

Building on the FCTC process, the WHO released its first 'Report on Control of the Tobacco Epidemic' entitled 'MPOWER' in 2008 [40]. MPOWER is a comprehensive tobacco control strategy intended to provide a programmatic counterpart to the FCTC. MPOWER includes six key tobacco control measures including

Monitoring the epidemic, **P**rotecting non-smokers from exposure to SHS, **W**arning smokers of the health effects of smoking with strong, effective health warnings, **E**nforcing advertising bans, and **R**aising the price of tobacco products. The WHO is tracking implementation of MPOWER and coverage of the world's population by its provisions. To date, its reach is still limited, although increasing coverage of the world's population by its elements can be anticipated [41]. Fortunately, global tobacco control has benefited greatly from funding from the Bloomberg Family Foundation and the Bill and Melinda Gates Foundation, first made available in 2007 and now slated to continue through 2016. These funds have supported capacity building in tobacco control, policy advocacy, regulation, and surveillance.

Cancer, smoking, and oncology

This brief review highlights the role of tobacco smoking as the leading cause of avoidable death from lung cancer. As for all health professionals, oncologists should be actively supportive of tobacco control at all levels—from local to global. In providing patient care, they need actively to promote cessation for those patients who smoke after diagnosis. These individuals are at high risk for a second malignancy, particularly at a site of smoking-caused cancer, and smoking has unfavourable consequences for outcome (see [42], for example, with regard to early-stage lung cancer). In a study of people treated for cancer at Roswell Park Cancer Institute, continued smoking after diagnosis increased both overall mortality and disease-specific mortality [43]. Unfortunately, smoking status has received little attention in cancer clinical trials and survey data for the US show that about 15% of adult cancer survivors are current smokers [44, 45].

The 2014 report of the US Surgeon General includes a comprehensive review of the evidence on smoking and cancer outcomes. Four notable conclusions for oncologists were reached [17]:

1. In cancer patients and survivors, the evidence is sufficient to infer a causal relationship between cigarette smoking and adverse health outcomes. Quitting smoking improves the prognosis of cancer patients.

2. In cancer patients and survivors, the evidence is sufficient to infer a causal relationship between cigarette smoking and increased all-cause mortality and cancer-specific mortality.

3. In cancer patients and survivors, the evidence is sufficient to infer a causal relationship between cigarette smoking and increased risk for second primary cancers known to be caused by cigarette smoking, such as lung cancer.

4. In cancer patients and survivors, the evidence is suggestive but not sufficient to infer a causal relationship between cigarette smoking and (1) the risk of recurrence, (2) poorer response to treatment, and (3) increased treatment-related toxicity.

These conclusions provide a powerful rationale for oncologists to address smoking by their patients. Oncologists should have skills in smoking cessation and monitor and address smoking cessation by their patients. They see them during multiple 'teachable moments' and they should be prepared to intervene with strategies, both pharmacologic and non-pharmacologic, of proven efficacy [46].

Summary

Tobacco smoking, as well as its use in other products, is the leading cause of avoidable premature mortality, including from cancer, worldwide. For some sites, such as lung cancer, risks are remarkably high in cigarette smokers and smoking has been linked to malignancy of most organs. Thus, tobacco control provides a tremendous opportunity for cancer prevention. A global public health treaty, the World Health Organization's FCTC, calls for the ratifying nations, now numbering 176, to implement a set of effective tobacco control policies [36]. The FCTC has now been in force for more than five years, creating a global tobacco control movement.

For oncologists, emerging evidence points to clinical implications of smoking with regard to therapy and outcomes in cancer. As for all clinical encounters, smoking needs to be assessed routinely and cessation counseled vigorously for cancer patients who are smoking. The American Society for Clinical Oncology advocates engagement of oncologists in smoking cessation as well as tobacco control generally [47]. The literature suggests that smoking cessation after the diagnosis of cancer improves prognosis.

CHAPTER 15

Viruses

Chris Boshoff

Introduction to viruses

Viral infection accounts for 15% of all human cancers. Seven viruses are known to be implicated in human malignancy (Table 15.1). The immune system is crucial in controlling oncogenic virus-infected cells, as is exemplified by the increased incidence of virus-induced cancers in immunosuppressed individuals. Oncogenesis is a multifactorial process and only a fraction of infected individuals will develop a tumour, particularly in the absence of immunosuppression. Tumour viruses establish long-term persistent infections in humans, with malignancy an accidental side effect of viral replication.

Animal and human oncogenic viruses have played crucial roles in our understanding of cancer biology. In particular, the discoveries of both oncogenes and tumour suppressor genes were made possible by studying animal oncogenic viruses. The discovery of the Rous sarcoma virus in 1911, an avian retrovirus, and other animal oncoviruses led to the eventual discovery of viral oncogenes (e.g. src, ras, and myc), and subsequently a plethora of human proto-oncogenes. The tumour suppressor protein p53 was discovered by studying the oncogenic functions of simian virus large T antigen (SV40-T). SV40-T interacts and abrogates the activity of p53, resulting in uncontrolled cellular proliferation.

Herpesviruses

Over 100 herpesviruses have been identified. Herpesviruses share a common virion architecture and become latent and persist for life in their hosts. They are large (100–140 kbp) DNA viruses with circular, double-stranded genomes. Latent viral genomes take the form of circular episomes.

Epstein Barr virus (EBV)

EBV is the prototype of gammaherpesviruses. In vitro, EBV infection of primary B lymphocytes induces transformation into permanent cell lines (lymphoblastoid cell lines, LCLs).

EBV-infected B lymphocytes are highly immunogenic and elicit powerful cytotoxic T-lymphocyte (CTL) responses. EBV-specific CTLs target human leukocyte antigen (HLA) class 1-associated peptides derived from the EBV latent proteins.

Although EBV is a highly transforming virus, only a small number of EBV-infected individuals develop an EBV-driven neoplasm, and despite the targeting of EBV-infected B cells by CD8+T-lymphocytes, EBV persists in B-lymphocytes. These two apparent paradoxes are explained by the down-regulation of all growth-promoting viral proteins, which include those known to elicit CTL responses in persistently infected B-lymphocytes. Only EBNA-1 (EBV nuclear antigen 1) is expressed in these cells. EBNA-1 is essential to maintain the stability of the viral episome, does not evoke an immune response, and does not induce cell proliferation.

Burkitt's lymphoma (BL)

The recognition of BL and of its associations with malaria and EBV infection is one of the great achievements of twentieth-century medicine. Post-World War II, the Irish surgeon Denis Burkitt studied a peculiar lymphoma common in African children, with a specific geographical distribution. His lecture tours brought him into contact with Anthony Epstein who suspected an infective agent was the culprit. Epstein used electron microscopy to discover EBV.

Only EBNA-1 is expressed in BL cells. These cells thus represent the resting persistently infected B cells in the circulation. However, BL cells are in cell cycle and rapidly proliferating due to the universally present translocation of the *c-myc* gene. This translocation brings *c-myc* under the control of an immunoglobulin enhancer. This translocation induces resting EBNA-1-expressing B cells to proliferate.

Nasopharyngeal carcinoma (NPC)

EBV enters epithelial cells from permissively infected lymphocytes trafficking through lymphoid-rich epithelium. The establishment of infection in epithelial cells could be the trigger for NPC development. EBV latent membrane protein-1 (LMP-1) is expressed in NPC and induces NF-κB, and consequently cell proliferation. Epidemiological data indicate that consumption of large quantities of salted fish (e.g., in South East China) is a co-factor.

Hodgkin disease (HD)

The finding of clonal EBV genomes in Reed–Sternberg cells and the restricted pattern of latent viral gene expression in nearly 30–50% of all HD cases suggest that EBV is not simply a passenger in HD. A positive association between a history of infectious mononucleosis and subsequent HD further supports a causal role.

Post-transplant lymphoproliferative disorder (PTLD)

PTLD represents one of the most common complications of immunosuppression following organ transplantation. Predisposing factors include primary EBV infection at or postdating transplantation, and high cumulative doses of immunosuppressive drugs.

Table 15.1 Infection and human cancer

Year when association with cancer was first established, or pathogen discovered	Discoverer/s	Agent	Viral Transcript involved in oncogenesis/ mechanism of oncogenesis	Neoplasm
1964	Epstein, Achong, Barr	Epstein–Barr virus	EBNA1-6 Latent membrane proteins (LMPs) Viral microRNAs	Burkitt's lymphoma, Hodgkin's disease, HIV-related lymphoma, Post-transplant lymphoproliferative disease, Nasopharyngeal carcinoma, *Leiomyosarcoma
1967–1968	**Blumberg, Okochi, Prince, Vierrucci	Hepatitis B virus	Hepatocyte regeneration	Hepatocellular carcinoma
1980	Gallo	Human T-cell leukaemia virus 1	Tax	T-cell leukaemia/lymphoma
1983	Zur Hausen	Human papillomavirus	E6, E7	Cervical and vulvar carcinoma, Anal carcinoma, Penile carcinoma, Oropharyngeal carcinoma
1989	Houghton	Hepatitis C virus	Hepatocyte regeneration	Hepatocellular carcinoma
1994	Chang and Moore	Kaposi's sarcoma-associated herpesvirus	viral cyclin LANA viral FLIP viral microRNAs	Kaposi's sarcoma, Multicentric Castleman's disease, Primary effusion lymphoma
2008	Chang and Moore	Merkel cell polyomavirus	Large T, Small T	Merkel cell carcinoma

*HIV-infected children with EBV positive leiomyosarcoma have been described.

**Between 1967-1968, Blumberg, Okochi, Prince, and Vierrucci reported that the Australian antigen is involved in the development of hepatitis B.

EBV+ lymphoproliferative disorders also occur in congenital immunodeficiencies, for example X-linked lymphoproliferative syndrome. Phenotypically, PTLD resembles in vitro transformed B lymphocytes, i.e. LCLs, where the tumour cells express all the latent viral proteins. Tumour cells are able to proliferate due to a lack of CTL responses in the immunocompromised host.

CD20 is frequently expressed on the tumour cells and immunotherapy against this antigen (e.g., anti-CD20 antibody rituximab) is an effective treatment option. Treatment also includes the infusion of EBV-specific CTLs.

AIDS-associated lymphomas

Up to 50% of HIV-related systemic lymphomas and 100% of brain lymphomas contain EBV DNA. PCR detection of EBV in the cerebrospinal fluid helps in the differential diagnosis of CNS lesions in HIV-infected individuals.

Kaposi's sarcoma-associated herpesvirus (KSHV)

For over 100 years, Kaposi's sarcoma (KS) remained a rare curiosity, until it emerged as a defining feature of the acquired immunodeficiency syndrome (AIDS). In 1872, the Hungarian dermatologist Moriz Kaposi published case histories of male patients in Vienna with *idiopathic multiple pigmented sarcomas* of the skin. *Classic KS* occurs predominantly in elderly male patients of Southern and East European ancestry. In some equatorial African countries, KS existed prior to HIV (*endemic KS*).

KS can develop after organ transplantation (*post-transplant or iatrogenic KS*). In 1981, two rare diseases in young men, KS and *Pneumocystis carinii* pneumonia, heralded the AIDS pandemic and *AIDS-KS* is today the most common form of KS.

Chang and colleagues [1] employed molecular techniques to identify sequences of a new herpesvirus (KSHV, or human herpesvirus-8 (HHV-8)) in AIDS-KS biopsies.

Kaposi's sarcoma (KS)

KSHV DNA is present in all four epidemiological forms of KS. Seroepidemiological surveys show that general populations at risk of developing KS have a higher prevalence of KSHV infection (Figure 15.1).

KSHV infects endothelial cells, and KSHV-encoded proteins provide a growth advantage to these cells and facilitate their escape from host immune responses. KSHV induces cytokines and other inflammatory molecules in the tumour microenvironment, promoting cell proliferation and angiogenesis.

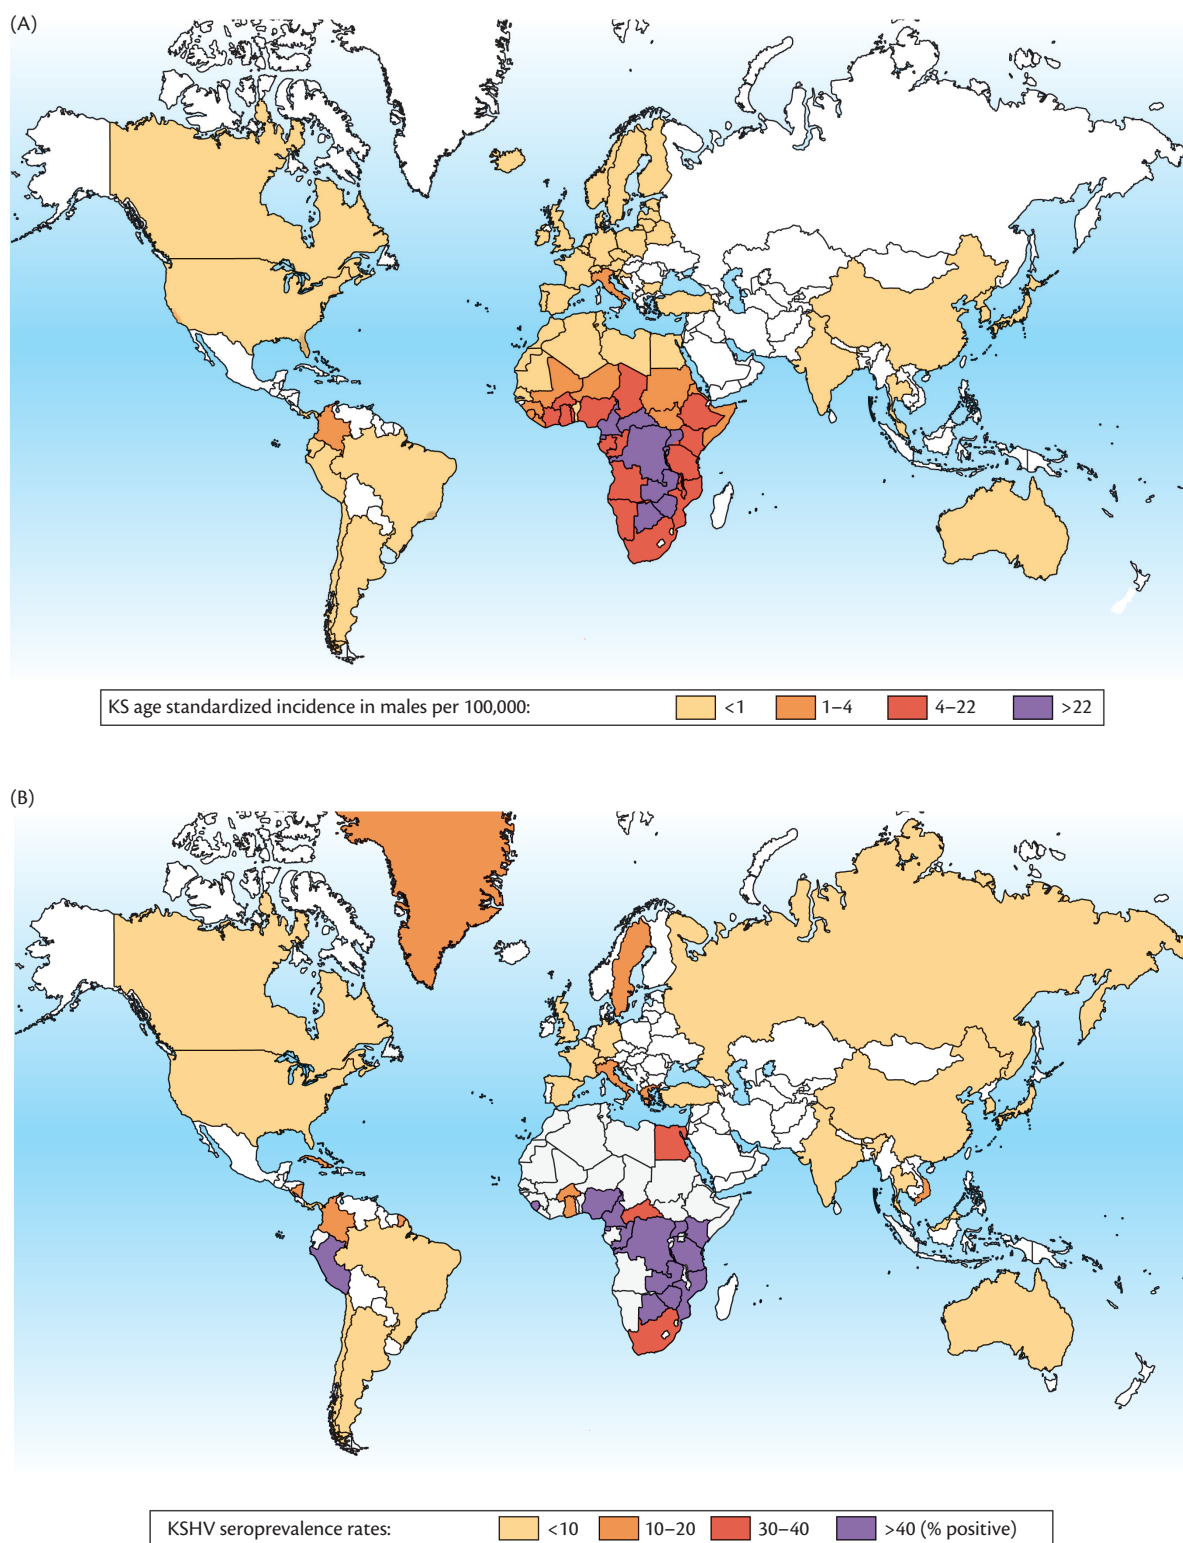
The introduction of anti-HIV therapy has led to a decline in the incidence of AIDS-KS and also in the resolution of KS in those


Fig. 15.1 Geographical prevalence of KS and seroprevalence of KSHV. (A) The standardized incidence of Kaposi's sarcoma (KS) is depicted for males. (B) KSHV seroprevalence rates were compiled from multiple studies.

already affected. This indicates that cellular immune responses are important in the control of KSHV infection and in KS pathogenesis. Post-transplant KS also regresses when immunosuppression is discontinued.

Multicentric Castleman's Disease (MCD)

MCD is a lymphoproliferative disorder associated with multiple organ involvement, especially spleen and lymph nodes with weight loss and fever. MCD is mostly diagnosed in HIV-infected individuals and is associated with increased circulating IL6 levels. KSHV DNA is found in up to 50% of MCD cases. Treatment includes cytotoxics, anti-CD20, or anti-IL6 antibody therapies.

Papillomaviruses (HPV)

The papillomaviruses are small (~8 kbp) DNA viruses with circular, double-stranded genomes. Over 100 distinct HPVs have been identified to date. The majority of infections result in a benign tumours (warts). Cells are usually infected at the terminal stages of epithelial cell differentiation and lysed, so virus-induced proliferation is self-limiting and does not progress to transformation. However, a number of HPV types (oncogenic subtypes) can induce cancer.

An infectious aetiology for cervical cancer was suggested by the observation that the most important risk factor is the number of sexual partners. Zur Hausen first hypothesized that this malignancy is caused by HPV, and in 1983 he and colleagues identified HPV sequences in this tumour. HPV-16 is found in nearly 60% and HPV-18 in 20% of cervical cancers. Other HPV types are also associated with cervical cancer.

A key step in cervical cancer progression is the accidental integration of viral DNA sequences into the genome of cells in the basal layer, i.e. the cells in which papillomaviruses normally persist. As a result, as the cells move upwards from the basal layer to the surface, replication to new virions can no longer occur, and progress of the virus infectious cycle has been interrupted. Integrated viral DNA retains the capacity to express HPV early genes (E6 and E7) which directly drive cellular proliferation. Secondary somatic genetic changes occurring in these latently infected cells give rise to malignancy.

Some HPV types (e.g., 16, 18, 31, and 33) are termed high risk because they are found in lesions that progress to malignancy. Other types, such as 6 and 11, are termed low risk, only rarely giving rise to tumours. E6 and E7 abrogate the activities of the tumour suppressor proteins P53 and pRb, respectively. Cells from a particular aggressive cervical cancer removed in 1951 (named HeLa cells after the patient **He**nrietta **La**cks) became a common source of human cancer cells. After decades of HeLa cells growing in laboratories, these cells remain dependent on HPV-18 E6 and E7 expression (i.e. oncogene addiction).

The implementation of a successful vaccine against the high-risk HPV types is poised to transform the incidence of cervical cancer and also the increasing incidence of HPV-associated oral cancer.

Human T-cell leukaemia virus 1 (HTLV-1)

In 1977 it was reported that a range of certain T-cell leukaemias in Japanese patients can be described as one syndrome: adult T-cell leukaemia (ATL)/lymphoma. Gallo and colleagues [2] discovered a virus with reverse transcriptase activity from a T-cell lymphoma cell line. This was the first isolated human retrovirus and therefore termed HTLV-1. Hinuma (1982) and colleagues demonstrated that retrovirus particles from an ATL cell line are identical to HTLV-1. Epidemiological studies showed that HTLV-1 and ATL co-localize in Japan, coastal regions of central Africa, in the Caribbean basin and in Taiwan.

HTLV-1 is transmitted from mother to child, either via infected maternal T lymphocytes across the placenta or via breast milk. HTLV-1 is also transmitted sexually or through blood products. Up to 6% of those infected develop ATL. The incubation period between infection and malignancy is 20–40 years, indicating that additional secondary somatic mutations are required. In vitro, HTLV-1 immortalizes and transforms primary human T lymphocytes.

HTLV-1 is a typical retrovirus: two copies of an RNA genome of 9000 nucleotides encode the *gag, pol*, and *env* genes surrounded by short terminal repeat sequences. One region of the HTLV-1 provirus encodes two additional genes expressing the proteins Tax and Rex. Tax is a transcriptional activator, promoting the transcription of viral and cellular proteins involved in cell proliferation including IL2 and IL2 receptor, both of which are required to initiate T-cell division, PDGF, and NF-κB. Tax is the principle oncogene involved in oncogenesis.

Adult T-cell leukaemia (ATL) is a malignant proliferation of CD4+T cells with high expression of the IL2 receptor. Circulating antibodies to HTLV-1 are present in >90% of patients and their spouses. Skin involvement, lymphadenopathy, hepatosplenomegaly, hypercalcaemia and lytic bone lesions are frequent. Few patients survive >6 months.

HTLV-1-infected tumour cells are clonal and each cell in the transformed lymphocyte clone contains virus integrated into the same site; however, this site varies from patient to patient. This indicates that HTLV-1 does not initiate malignancy by insertional mutagenesis.

There is currently no vaccine against HTLV-1.

Hepatitis B virus (HBV)

HBV belongs to the hepadnavirus group, which includes viruses of woodchucks and squirrels. These agents contain a DNA genome that is partially double-stranded and partially a single strand. The virion core enzymes convert the partially single-stranded DNA to a complete, double-stranded DNA helix. The entire genome is then transcribed, producing an RNA that is a full-length copy of the viral DNA. The longest RNA transcript acts as a template for a reverse transcriptase that is also the DNA polymerase. Reverse transcriptase copies the RNA template into a complementary DNA strand. This viral enzyme is blocked by reverse transcriptase inhibitors, which are currently being used to treat HBV infection.

Today, the most important routes of transmission in the West are through needle sharing among drug users and by sexual transmission. The responses in individuals undergoing a primary infection with HBV vary significantly: mild or subclinical infections being the most common. Up to 10% of adults with HBV infection do not clear the virus, but continue to synthesize viral antigens, developing chronic hepatitis.

Hepatocellular carcinoma (HCC)

The incidence of HCC correlates with the worldwide prevalence of HBV and persistence. The risk of developing liver cancer is 100 to 200 times greater for HBsAg carriers than for non-carriers.

Chronic HBV infection leads to the continuous production of viral antigens and attack of infected cells by the immune system with subsequent liver cell regeneration, and repeated immune attack of newly infected cells. Continuing hepatocyte division leads to an increased risk of mutations. Epidemiological studies indicate that the consumption of food contaminated with the fungus aflatoxin might act synergistically with HBV infection to induce HCC.

A successful recombinant vaccine against HBV was developed in the 1980s. In countries with effective universal vaccination programmes, for example Taiwan, the incidence of HCC has been dramatically reduced.

Hepatitis C virus (HCV)

HCV was first described in 1989. It is estimated that over 170 million people are globally infected. The 2–3% seroprevalence in the UK and USA is towards the lower seropositivity incidence. HCV is a single-strand RNA virus of 9400 bases, associated with acute and chronic hepatitis and liver cirrhosis. Virus replication is dependent on a viral-encoded RNA polymerase, which does not have proofreading capability, resulting in numerous genetic variations of the virus within an infected individual. This impacts both on viral replicative fitness, as well as on the selection of virus resistance to mechanism-based antivirals.

Most patients with haemophilia who were treated with blood products prior to the use of virus-inactivation procedures were infected with HCV. HCV infection is also more common among intravenous drug users.

Hepatocellular carcinoma (HCC)

Compared with HBV or HCV mono-infections, co-infections are associated with a higher risk of HCC. In HBV and HCV low-endemic areas (e.g., Sweden), these viruses play a minor role in the pathogenesis of HCC, compared to alcohol-related cirrhosis. The incubation period between infection and cancer is up to four decades. The high turnover of hepatocytes due to the ongoing cycle of liver injury and regeneration associated with cirrhosis predisposes to somatic mutations and eventual malignancy.

Current therapy for HCV infection includes pegylated interferon, usually co-administered with ribavirin, a nucleoside analogue. More recently, protease inhibitors have been developed, which may cure selected patients. Two viral enzymes, the NS3/4A serine protease and the NS5B RNA-dependent RNA polymerase, are being targeted with small molecules to develop mechanism-based therapeutics. An HCV vaccine is not yet available and may be difficult to develop because of the high variability of viral proteins.

Therapy for HCC includes surgical resection, radiofrequency ablation, transarterial chemoembolization, molecular targeted therapy (e.g., sorafenib), and chemotherapy. Orthotopic liver transplantation offers an effective treatment strategy for HCC, even in the setting of HCV or HBV cirrhosis. HCC recurrence is uncommon after transplant in properly selected patients and disease-specific long-term survival approaches 90%.

Merkel cell polyomavirus (MCV)

Polyomaviruses are small (~5400 base pair), non-enveloped, double-stranded DNA viruses. MCV is genetically related to the African green monkey lymphotropic polyomavirus. MCV encodes characteristic polyomavirus genes including the large T antigen and small T antigen. MCV T antigens have similar features to the T antigens of other polyomaviruses, known oncoproteins, and is expressed in human tumours.

Although MCV is a ubiquitous human virus, its mode of transmission is unclear. In human cancer, Merkel cell carcinoma (MCC), the virus is unable to replicate, because the viral T antigen is mutated, leaving the T antigen unable to initiate the DNA replication needed to propagate the virus. Therefore, MCC can be considered a 'dead-end host' for MCV.

Merkel cell carcinoma (MCC)

This aggressive skin tumour was originally described in 1972. It presents as a painless nodule on the skin, often in the head or neck region, and metastasizes early. Eighty per cent of MCC cases have MCV integrated in a monoclonal pattern, inferring that infection is present in a precursor cell prior to clonal expansion. The tumour usually develops on sun-exposed skin and ultraviolet light could be a co-factor. MCC development is modified by the immune system, as the incidence is increased significantly in immunosuppressed individuals. As with other virus-induced cancers, it is likely that additional somatic mutations act in concert with the viral T antigens to precipitate MCC.

Summary

- Up to 15% of all human cancers are caused by viruses.
- The incubation period between infection and malignancy can be decades.
- Virus-driven malignancies often require co-factors.
- Virus-driven cancers are more common in immunosuppressed individuals.
- Viruses may be either direct (e.g., HPV, EBV, HTLV-1), or indirect (e.g., HCV, HBV) oncogenic agents.
- Patients with cirrhosis resulting from any cause, including HBV or HCV, have a greater risk of developing liver cancer (hepatocellular carcinoma).
- Cervical cancer is one of the most common cancers in sub-Saharan Africa.
- Universal vaccination against HPV and HBV will have a major global impact on cancer incidence.

Glossary

Episomenon: Integrated viral or bacterial circular DNA; DNA element that is not incorporated into the genome.

Insertional mutagenesis: Mutagenesis of DNA by the insertion of one or more bases of DNA (virus or other), e.g., integrating a provirus near a normal cellular proto-oncogene, resulting in activation of the proto-oncogene and cellular transformation.

Latency: Life-long persistence of virus, where only of fraction of viral proteins are expressed; ability of a virus to remain dormant or *latent* within a cell.

Orthotopic: Relating to a tissue transplant grafted into its normal place in the body.

Plasmablast: Pre-terminally differentiated B-cell; precursor of a plasma cell.

Proto-oncogene: Cellular gene that has the ability to induce cellular proliferation and transformation; normal gene that can become an oncogene due to mutations or over-expression.

Reverse transcriptase (or RNA-dependent DNA polymerase): An enzyme (DNA polymerase) that converts or transcribes an RNA template into a complementary DNA strand. For example, the RNA genome of HIV is converted by the HIV-encoded *reverse transcriptase* into virus DNA that integrates into the host genome.

Somatic mutation: DNA alteration or mutation that occurs in the host genome after conception (therefore not a germline mutation).

Transcriptional activator: Protein that binds to DNA and stimulates the activation of nearby genes.

Transform/transformation: Process by which normal cells become malignant or acquire the properties of cancer.

Tumour suppressor protein (or anti-oncogene): A protein that can block cellular transformation, and therefore prevent cancer; loss or mutation of a tumour suppressor protein (e.g., p53) can predispose to cellular transformation.

Virion: Virus particle; virus structure.

CHAPTER 16

Chemical carcinogens

Paula A. Oliveira

Introduction to chemical carcinogens

The word carcinogenic was initially defined as the ability of a compound to unchain the process of cancer development in man and animals under suitable conditions, by acting on one or several organs or tissues [1]. With the discovery of the diverse mechanisms implicated in carcinogenesis, this description is now incomplete [2]. From an experimental point of view, a chemical compound is considered carcinogenic when its administration to laboratory animals induces a statistically significant increase in the incidence of one or more histological types of neoplasia, compared with the animals in the control group which were not exposed to the compound [3]. Humans can be exposed to chemical carcinogens when they are present in food, air, water, their workplace, etc. Chemical carcinogens can be classified as natural chemicals, synthetic compounds, or mixtures of both that are synthesized or used for industrial, agricultural, or commercial purposes. According to Irigaray and Belpomme [4] chemical carcinogens should be classed as either chemicals of endogenous origin, i.e. chemicals that result from human/animal natural metabolic intermediates, or exogenous chemicals. These authors also consider exogenous chemicals to be more prone to causing cancer than endogenous natural molecules. Only exogenous chemicals will be considered in this chapter, since exogenous chemical carcinogens may be the major contributors to human cancer.

Exogenous chemical carcinogenesis is a very complex multifactorial process throughout which gene–environment interactions involving exposure to chemical carcinogens and polymorphisms of cancer-susceptibility genes add further complexity. There are currently hundreds of individual chemical compounds shown to induce cancer and many thousands of additional chemical compounds are suspected carcinogens. Despite the fact that many lists of human chemical carcinogens have been published, they differ widely because of the strength of the accepted evidence provided. The problem behind their identification in humans is due to the lengthy latent periods involved (potentially over 20 years) between exposure to these agents and the first appearance of cancer. This chapter is concerned with main types of exogenous chemical carcinogens, how they are classified and their mode of action, absorption and metabolism, as well as the principal tests available for evaluating their carcinogenicity.

A historical perspective on the identification of chemical carcinogens

The history of the identification of chemical carcinogens is based on epidemiologic observations and animal experiments that identified cancer-causing chemicals. Chemical carcinogenesis was first suggested by clinicians some 200 years ago. According to Hayes [5], it was the English surgeon Percivall Pott who in 1775 first documented the causal association between contact to chemical substances and neoplastic development. This author described the incidence of neoplasias in the skin of the scrotum of London chimney sweeps as a result of repeated localized contamination with soot. Also in the eighteenth century, John Hill observed a high percentage of cancerous alterations in the nasal mucosa of snuff users and related it to the localized long-term exposure to snuff. In 1895, Rehn reported a high incidence of urinary bladder cancer in workers in the European dye industry. More recently, observations were made concerning the induction of angiosarcomas in patients exposed to contrast material use for radiological imaging studies [1, 6–10].

Based on these observations, in the early twentieth century several researchers conducted the first experimental studies on chemical carcinogenesis using laboratory animals. The primary investigational work was carried out in 1915 by Katsusaburo Yamagiwa and Koichi Ichikawa [11]. They rubbed rabbits' ears with coal tar and latter observed the development of malignant tumours at the site. These results were used to confirm epidemiologic observations of scrotal and nasal mucosa tumours by Pott and Hil,l respectively. In the meantime, other researchers evaluated the effects of several chemical carcinogens on the urinary bladder, liver, kidneys, pancreas, and lungs using laboratory animals. Later, Beremblum and Shubik [12] studied carcinogenesis on the skin of mice. By applying polycyclic aromatic hydrocarbons and croton oil, they described two phases in cancer development: initiation and promotion. For the first time, chemical carcinogens were being classified as initiators and promoters according to their involvement in each phase. In 1954, Foulds [13] individualized a third stage, termed progression, to account for all post-initiation events that occur during carcinogenesis after promotion. The overview of DNA as genetic material by Avery, MacLeod, and McCarthy [14] and the description of the structure of DNA by Watson and Crick [15] showed that DNA was the cellular target for chemical carcinogens and that mutation was the key to understanding mechanisms of cancer development.

The above described experimental studies, allied with epidemiological studies, have shown an apparent relationship between the induction of cancer in humans and rodents and exposure to chemical compounds. However, human life is led under very different circumstances from experimental procedures. While the process of carcinogenesis is analogous between man and animals in experimental situations, the various chemical compounds to which humans are exposed during their lives can modify the speed of cancer development and the occurrence of mutations, the speed of cell

growth and the phenotypical expression of the mutated genes. On the other hand, the individual's relative levels of vulnerability and protection mechanisms have their own part to play, which modifies each of the neoplastic stages.

Carcinogenic classification and their mode of action

Carcinogenic classification is by no means consensual [2, 16] and is in most cases based on the carcinogen's mode of action. Since chemical carcinogenesis comprises the three sequential and successive steps—initiation, promotion, and progression—according to the involvement of carcinogenic chemicals in each of the steps, several authors classify chemical carcinogens as initiators, promoters and progressors [17, 18].

Tumour initiators are those carcinogenic compounds capable of inducing an initial driving DNA mutation, using numerous mechanisms, in a dividing cell, via direct or indirect mutagenesis, so that an initial clone of mutated cells can emerge [4]. Initiators are chemicals that are DNA reactive, either directly or following metabolic activation. They can induce DNA changes such as interruptions of the DNA chain, errors in DNA repair, or elimination of a base repair. Examples of carcinogenic initiators include alkylating agents, polycyclic aromatic hydrocarbons, aromatic amines, metals (cadmium, chromium and nickel), aflatoxins, and nitrosamines.

Chemical carcinogens classified as promoters accelerate or promote the transformation process when applied repeatedly after initiators. Promoters can also act as initiators at the same time, though promoters are usually not initiators when used in isolation at the same dosage at which they promote. The promoter has to be present for weeks, months, and years in order to be effective and its effectiveness depends on its concentration in the target tissue [19]. Some promoter agents are specific to a particular tissue, but others can act on several tissues at the same time [20, 21]. Promoter compounds do not interact directly with DNA and unchain biological effects without being metabolically activated [19, 20, 22, 23]. They may induce some alterations in initiated cells, such as the alteration of cell-surface sensitivity to various growth factors, alteration of cell-surface glycoproteins and glycolipids, alteration of cell morphology, increased phospholipid and glucose metabolism, stimulation of DNA synthesis and cell proliferation, increased production of free oxygen radicals, the induction of disproportionate DNA replication within one cell cycle via gene amplification, and preventing apoptosis [4, 18]. Initiators require the application of promoters to induce cancer development in experimental models. However, in studies of chemical carcinogenesis with prolonged exposure and using high doses, almost all promoter agents induced neoplasias without the prior application of initiators [3, 24]. Examples of this are exposure to phenobarbital, benzene, and asbestos, which, even without the previous use of initiator agents, lead to neoplastic development [25, 26]. The following are some examples of chemical carcinogens classified as promoters: diethylstilbesterol, cyclamates, phorbol 12-myristate 13-acetate, and saccharin.

Chemical carcinogens can also be classified as progressors. These agents are chemical compounds that move mutated cells on from the promotion to progression phase, i.e. they enable premalignant mutated cells irreversibly to obtain the phenotype of fully malignant cells. Progressor agents include alkylating agents, arsenic salts, asbestos, and benzene [4, 17]. Complete carcinogens are capable of triggering all three stages of carcinogenesis.

Other authors classify chemical carcinogens according to the function of their mechanisms of action, and according to their involvement with DNA as being genotoxic and non-genotoxic (mitogenic and cytogenic) [7, 19, 23, 27, 28]. Genotoxic carcinogens are chemicals, or their metabolites, that have the capacity to directly react, or interact with DNA or genetic material to generate DNA adducts and subsequently mutations, chromosomal aberrations, and/or changes in chromosome number [29, 30]. They exhibit a direct analogy among their structure and activity, are mutagenic in in vitro assays, are active in high doses, and could affect various animal species and injure diverse organs [3, 28, 31]. DNA adducts are covalent bonds established with macromolecules, and if not removed prior to DNA replication, these adducts can result in mutations. If such mutations occur in critical oncogenes or the tumour suppressor genes that control cell proliferation, cancer development may follow [32]. Adduct repair is coordinated by numerous enzymes and is controlled by different genes. It can be done via the excision of bases, or nucleotides, recombined repair or mismatched repair and direct-damage reversal [33–36]. The detection of adducts suggests that chemical carcinogens were absorbed, metabolized, and distributed by tissues, thus fleeing from the body's detoxification and repair mechanisms [8, 37, 38]. Adduct detection can be done by techniques such as immunohistochemistry, immunoassays with ^{32}P, gaseous chromatography associated with mass spectrometry, and HPLC associated with fluorescent spectroscopy [39].

Non-genotoxic carcinogens have been shown to act as promoters and do not require metabolic activation. Little is known about this group of carcinogens but evidence from known non-genotoxic carcinogens suggests that in a high proportion multiple pathways need to be changed for cancer induction to occur [40]. As their name implies, they do not react directly with DNA, do not raise adducts, and are negative on mutagenicity tests carried out in in vivo and in in vitro studies, while genotoxic events may occur but are secondary to another biological activity [19, 28, 23, 30, 41]. Non-genotoxic carcinogens have a huge diversity of mechanisms of cancer induction including receptor-mediated endocrine modulation, non-receptor mediated endocrine modulation, tumour promotion, induction of tissue-specific toxicity and inflammatory responses, immunosuppressants, and gap-junction intercellular communication inhibitors. The diversity of modes of action for each non-genotoxic carcinogen, their tissue specificity, and their lack of genotoxicity makes their detection and description very difficult [40]. Non-genotoxic compounds potentiate the effects of genotoxic compounds, do not demonstrate a direct association among structure and activity, and their action is conditioned by their concentration. They are tissue- and species-specific [2, 25, 28, 33, 42]. Non-genotoxic carcinogens are classified as mitogenic and cytotoxic in regard to whether their activity is mediated by a receptor or not [2, 43, 44]. Mitogenic compounds induce cell proliferation in target tissues through interaction with a precise cellular receptor [44]. Cytotoxic carcinogens cause cell death in vulnerable tissues followed by compensatory hyperplasia [19, 28, 45]. The more nearby cells augment the number of cell divisions through regenerative events, the more likely it is that they will end up being prematurely recruited for the cell cycle and that the time available for DNA repair will be inferior—this increases the probability of mutations occurring [25, 43]. On the other hand,

necrotized cells are destroyed by the immune system and endogenous chemicals such as reactive oxygen species (ROS), reactive nitrogen species (RNS), and proteolytic enzymes are produced [18, 46, 47]. When production of these ROS and RNS exceeds the cellular anti-oxidant capacity, it may cause lipid peroxidation, oxidative DNA damage, oxidative damage to RNA, oxidative damage to proteins, and DNA mutations [18]. Mitogenic compounds should be present in adequate concentrations in order to promote their action. In contrast, the action of cytotoxic compounds is independent of their concentrations [2, 19].

In 2004, Bolt et al. [16] suggested the separation of genotoxic compounds into two groups: those which react with DNA, and those which are genotoxic at a chromosomal level. Compounds which react with DNA are subdivided into three different groups: initiators (with unlimited doses), borderline, and weak genotoxic (they act via a secondary mechanisms). In 2006, Butterworth [29] classified chemical compounds that can act on chromosomal structure and induce aneuploidy and changes in chromosome number as clastogenic. Since then, DNA damage at the chromosome level is being studied as an essential part of chemical carcinogenesis [48]. In 2011, Cohen and Arnold [49] suggested a refinement of chemical carcinogen classification into those chemicals that increase the risk of cancer that are non-DNA reactive and do so by increasing the number of DNA replications in the target cell population (increased cell proliferation) and those chemicals that are DNA reactive. According to these authors, this classification allows us to make the distinction between classes of chemicals based on their ability to generate DNA reactivity. To this day, this is the basis for the classification of chemical carcinogens and forms the basis for the distinction of potential risks to humans in regulatory decision-making.

According to their chemical structure chemical carcinogens can be classified as polycyclic aromatic hydrocarbons, alkylating agents, aromatic amines/amides, aminoazo dyes, carbamates, halogenated compounds, natural carcinogens, metalloids and hormones. In Table 16.1 they are brought together under the following headings: group, compound, mechanism of action, and affected organs/cancer type.

Table 16.1 Chemical carcinogenic agents

Group	Compounds	Major origins	Mechanism of action	Affected organs/ Cancer type
Polycyclic aromatic hydrocarbons	Benzo[a]pyrene [50]	Charcoal broiled foods Cigarette smoke	DNA adducts	Skin, lungs, stomach
	Dimethylbenz[a]anthracene [31]	Diesel exhaust Residential heating	DNA adducts	Liver, skin
Alkylating agents	Nitrosamides (N-ethyl-N-nitrosurea; N-methyl-N-nitrosurea; N-methyl-N-nitro-N-nitrosoguanidine) [51]	Chemical solvents	DNA adducts, methylation and ethylation reactions	Liver, lungs, kidneys, brain
	Nitrogen mustards (chlorambucil, cyclophosphamide) [31]	Cancer chemotherapy	DNA adducts, DNA strand breaks, DNA alkylation	Leukaemia Nasal tumors
	Ethylene oxide; propylene oxide vinyl chloride [52]		DNA adducts	Liver tumours, lung tumours, tumours from the hematopoetic system
Aromatic amines/amides	Aniline dyes, 2-naphthylamine, benzidine, 2-acetylaminofluorene [53]	Oil refining, synthetic polymers, dyes, adhesives and rubbers, pharmaceuticals, pesticides, explosives, cigarette smoke, hair dyes, diesel exhaust, burning/pyrolysis of protein-rich vegetable matter	DNA adducts	Liver, urinary bladder
	4-Aminobiphenyl [31]	Industrial exposition, cigarette smoke	DNA adducts	Urinary bladder
Aminoazo dyes	o-Aminoazotoluene; N,N-dimethyl-4-aminoazobenzene [54]	Dyes and pigments	Adducts with DNA and haemoglobin	Liver, lungs, urinary bladder Lungs, liver
Carbamates	N-methylcarbamate esters: propoxur [55]	Insecticides	Chromosome aberration, gene mutation, cell transformation	Experimental results showed liver, kidneys and testes degeneration
Halogenated compounds	Trichloroethylene, methylene chloride, chloroform, chloroisoprene, trichlorobenzene [56]	Industry involved in the production of polymers, pesticides, and fire retardants	Somatic mutations, modification of cell cycle pathways	Experimental results showed kidney, liver and lung cancer

Table 16.1 Continued

Group	Compounds	Major origins	Mechanism of action	Affected organs/ Cancer type
Natural carcinogens	Aflatoxin B1 [57]	Food contamination (grains, nuts, peanut butter) by *Aspergillus flavus*	Forms adducts with guanine, react with RNA and proteins	Liver cancer
	Asbestos [31]	Environmental media (air, water and soil); human activities (product manufacture, construction activities and transport)	Mutagenecity	Mesothelioma, lung cancer
	Ptaquiloside [58]	*Pteridium aquilinum*	DNA adducts	Urinary bladder
Metals	Arsenic [59, 60]	Natural and anthropogenic sources (drinking water, gold mining activities, etc.)	Cell cycle checkpoint dysregulation, DNA damage response, abnormal chromosomal segregation, defects in cell cycle checkpoints, disabled apoptosis, telomere dysfunction, altered chromatin structure	Skin, lungs, liver, lungs, prostate, kidneys, urinary bladder
	Cadmium [59]	Burning of coal and tobacco	Interferes with antioxidant defence mechanisms, inhibit apoptosis	Lungs, nasal cavity, breast
	Nickel [59, 61]	Industrial processes	Oxidative stress, recombination and repair of DNA	Respiratory cancer
	Chromium [62]	Industrial processes	DNA adducts, oxidative DNA damage	Lungs and nasal cavity
Hormones	Ethinyl estradiol [63]	Medicinal exposure	Cell cycle	Uterus and prostate
	Estradiol [64]	Medicinal exposure	Cell cycle	Breast
	Tamoxifen [65]	Medicinal exposure	Cell cycle arrest	Breast
	Estrogen [66]	Medicinal exposure	Cellcycle	Breast cancer, endometrial cancer, ovarian cancer

Absorption and metabolism of chemical carcinogens

Following exposure, chemical carcinogens may be absorbed in a number of ways (ingestion, inhalation, skin absorption, injection, or other possible contamination routes) and distributed across several tissues (Figure 16.1). Absorption depends on the physicochemical properties of the substance. Substances absorbed orally pass through the liver and only then they are distributed in the body; those absorbed in the lungs are distributed by the blood prior to reaching the liver at a later stage [67, 68]. Those chemical carcinogenic compounds classified as direct act directly on DNA, causing mutations and forming DNA adducts without being metabolized. These chemicals are also defined as activation-independent carcinogens and ultimate carcinogens. It has been estimated that approximately 25% of all carcinogens are direct carcinogens [4]. The relative carcinogenic strength of direct-acting carcinogens depends in part on the relative rates of interaction between the chemical and genomic DNA, as well as competing reactions with the chemical and other cellular nucleophiles. The relative carcinogenic activity of direct-acting carcinogens is dependent upon such competing reactions and also on detoxification reactions. Chemical stability, transport, and membrane permeability determine the chemical's carcinogenic activity. Direct carcinogens are typically carcinogenic at multiple sites and in all species examined [69].

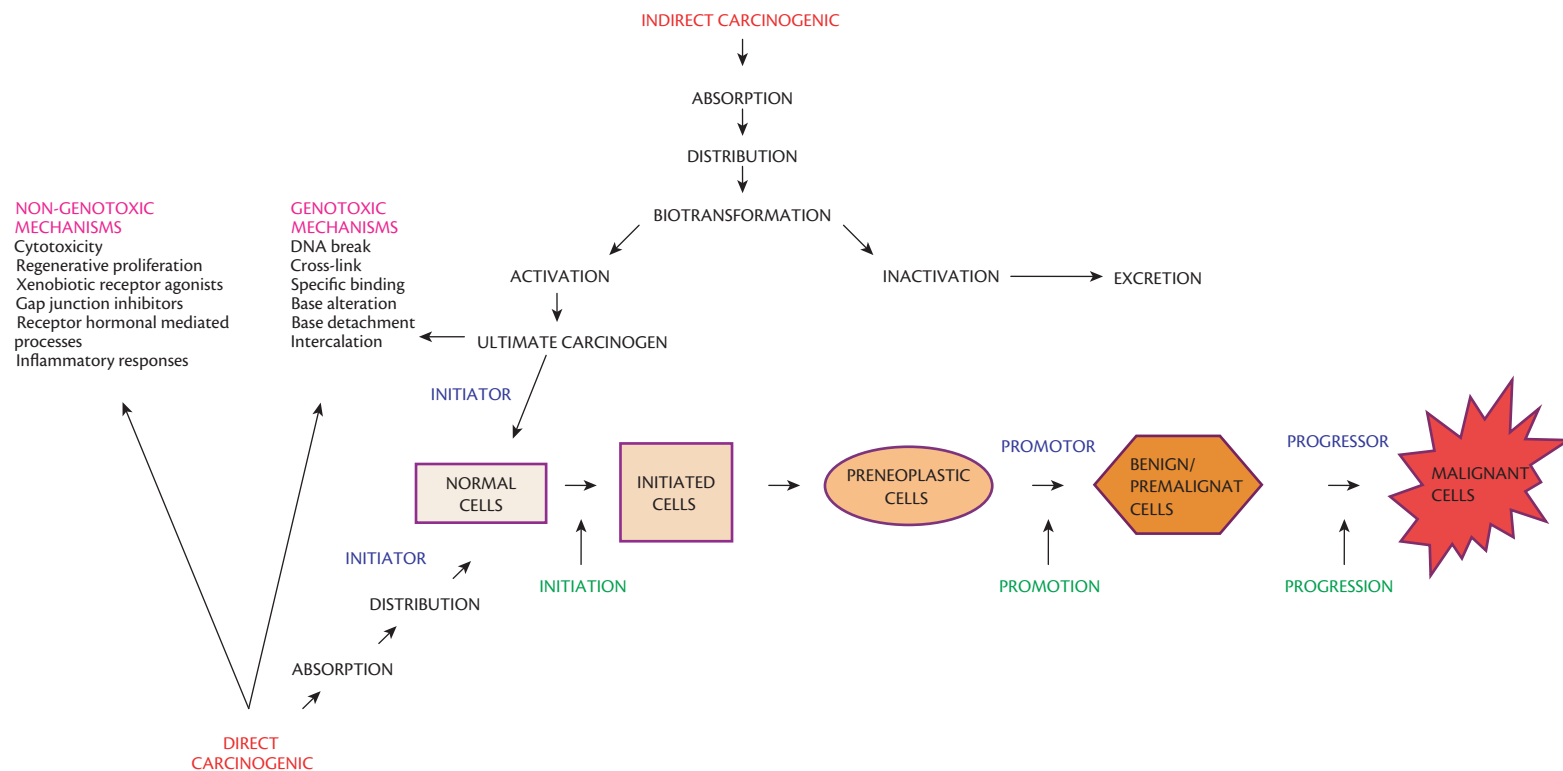
On the other hand, most chemical carcinogens, approximately 75% of them, require metabolic activation to be carcinogenic and are labelled as indirect, procarcinogens or indirect-acting genotoxic carcinogens [31, 70]. The terms procarcinogen, proximate carcinogen, and ultimate carcinogen have been coined to classify the parent compound (procarcinogen) and its metabolite form as well as the intermediate (proximate carcinogen) or final form (ultimate carcinogen) that reacts with DNA. The final form of the carcinogen is most likely to be the chemical species that results in mutation and neoplastic transformation. Indirect-acting genotoxic carcinogens usually produce their neoplastic effects, not at the site of exposure (as seen with direct-acting genotoxic carcinogens) but at the target tissue where their metabolic activation occurs. Metabolic activation occurs mainly in the liver at the plain endoplasmic reticulum, where the cytochrome P450 is abundant, and/or in other enzymes located in urothelium, skin, gastrointestinal system, oesophagus, kidneys, and lungs. The final product is an electrophilic compound that directly interacts with proteins, RNA, and DNA to form adducts [71]. The P450 system not only activates chemical carcinogens but also other drugs. Although some of these metabolic processes lead to activation in reactive electrophiles, many actually lead to inactivation of the chemicals by increasing aqueous solubility and leading to their increased excretion either in urine or in faeces [49]. Thus, exposure to any chemical initiates competing metabolic pathways for activation versus inactivation [49, 72]. The


Fig. 16.1 Absorption and metabolism of chemical carcinogens.

specificity of the activation systems of diverse tissues is dependent on genetic polymorphisms, which control the expression and distribution of the P450 enzyme, and the resulting susceptibility to cancer development. Metabolic pathways are equally important for both humans and animals, although qualitative and quantitative differences among them do exist. These have led to incorrect interpretations when animal models are used in the research and analysis of carcinogenic properties of chemical compounds [38, 41, 73].

Testing for carcinogenicity

Experimental assays with animal models and in vitro assays as well as epidemiological studies allow the recognition of carcinogenic chemical compounds and the analysis of many aspects of chemical carcinogenesis.

Animal models

Animal models should reflect the exposure to carcinogens or the genetic predisposition that is present in at-risk humans. In addition, pathological lesions should reflect the molecular changes and histological characteristics seen in human cancers [74]. The standard approach to carcinogenicity testing is to conduct two-year bioassays in small laboratory rodents (rats and/or mice). However, this kind of assay uses large numbers of animals, is time-consuming and expensive and is also fraught with sources of controversy regarding the relevance of the mode of action to humans or the dose used in the study compared with human exposure levels [49, 75]. The uncertainty in the extrapolation of results is particularly high for non-genotoxic carcinogens. This is because non-genotoxic carcinogens are likely to have a dose-response curve that is not linear and that includes a threshold. Furthermore, they could induce cancer in animals via a mechanism that is not applicable to humans. Achieving a positive result in a conventional assay only indicates that there is a potential hazard. Its significance for human health will depend on other factors, several of which need additional studies [76].

In vitro assays

In vitro models can be used to identify and to study chemical carcinogens. In vitro assays use prokaryotic, human, and animal cells, mimic some key stages of in vivo multistep carcinogenesis, measure induction of phenotypical alterations, have differing levels of complexity, and can overcome the ethical aspects related to animal experiments, as well as being faster, more cost-efficient and reduced reliance on animals. In vitro models have been shown to have a good concordance with rodent bioassay results, detecting both genotoxic and non-genotoxic carcinogens [77]. However, we do not have appropriate cell lines available which appropriately mimic the in vivo response, all the metabolic activation and inactivation processes are not maintained in vitro, and current in vitro approaches are unable to address the frequent occurrence of organ interactions that are implicated in many toxic end points. The first test described to evaluate the carcinogenic properties of chemical compounds in vitro was the malignant transformation of Syrian hamster embryo cells [78]. In 1970 the Ames test emerged. This test semi-quantitatively analyses a chemical's capacity to induce mutations in *Salmonella typhimurium* in a culture medium improved by using microsomatic enzymes [79]. Between 70% and 90% of identified chemical carcinogens showed positive results on the Ames test. Due to the high correlation that exists between mutagenicity and carcinogenicity, the Ames test is currently still used to assess the carcinogenic potential of chemicals.

Epidemiological studies

Global epidemiological studies have identified environmental and occupational chemicals as potential carcinogens. Epidemiological studies are retrospective and unless a big number of individuals are studied their levels of sensitivity is low [80, 81]. Epidemiological advances in the identification of chemical carcinogens are limited for two main reasons. First, only relatively high risks can be detected and, second, epidemiological surveys are based on observations of the effects resulting as a consequence of exposure that took place many years before.

Other methods

Computational approaches for genotoxicity prediction have existed for over two decades. The carcinogenic capacity of a chemical substance can be given using software that thoroughly reproduces man's physiological and metabolic procedures and relates them to the molecular configuration of the substance being evaluated [82, 83]. These chemical characteristics are correlated to the molecular structure of chemical, physical, and toxicological properties [84, 85].

Statistical learning methods have been explored as a new advance in genotoxicity prediction without any restrictions on the features of structures or types of molecules. As an alternative to focusing on specific structural characters or a particular group of related molecules, these methods classify molecules into genotoxic positive or non-genotoxic agents, based on their general structural and physicochemical properties, regardless of their structural and chemical types [86].

CHAPTER 17

Radiation-induced cancer

Klaus R. Trott

Introduction to radiation-induced cancer

The first case of a radiation-induced cancer in a radiology technol-ogist who suffered from severe atrophic skin damage (roentgeno-derm) was demonstrated in 1904. Since then, ionizing radiations have been established as one possible cause of cancer. Numerous radiologists in the first three decades of the twentieth century developed radiation-induced malignancies: either skin cancers as a consequence of late skin damage or leukaemia. The full extent of the risk of radiation carcinogenesis and its dependence on dose and exposed organ was only assessed after the long-term follow-up studies of the survivors of the A-bombs in Hiroshima and Nagasaki were established.

Molecular mechanisms of radiation carcinogenesis

Radiation-induced DNA damage preferentially causes deletions. Therefore, it is generally assumed that the inactivating mutation of tumour suppressor genes is the most probable mechanism of the induction of cancer by low radiation doses and that a single radia-tion track traversing the nucleus has a finite probability, albeit very low, of generating the specific DNA damage that results in cancer growth. This hypothesis supports the assumption that cancer risk increases proportionally with radiation dose without threshold [1]. Yet, the conclusion that this mechanism excludes the possibility of a dose threshold has been debated very controversially. Other biolog-ical mechanisms such as low-dose hypersensitivity which may spe-cifically eliminate cells harbouring DNA damage, and non-targeted radiation effects such as radiation-induced genomic instability, bystander effects, and immunological surveillance mechanisms may modify the consequences of direct radiation-induced trans-forming mutations. The complex mechanisms elicited by initial processes continue to be the subject of radiobiological research [2].

The A-bomb survivor lifespan study, cancer mortality, and cancer incidence

The dramatic experience of the people of Hiroshima and Nagasaki in 1945 initiated a programme for life-long follow-up of all A-bomb survivors. This is arguably the largest, most comprehensive, and most detailed epidemiological study ever performed. The results of this study are the main data source on which rules and regulations of radiation protection are based.

The Life Span Study (LLS) comprises 120,321 people, including about 54,000 atomic bomb survivors who were within 2.5 km of the hypocentre at the time of the explosion. Of the study population

52% was still alive in 1999, including >85% of the nearly 50,000 individuals who were children or adolescents in August 1945.

For >90% of the total study population, detailed information was collected by Japanese interviewers on their exact location at the moment of explosion. The dose assessment (called the DS 86) is based on Monte Carlo calculations of track passage from the source in the exploding bomb through the air and the buildings to the body of the individual, calculating mean organ doses for different critical organs.

The most significant long-term health damage observed in the LSS is a dose-dependent increased mortality from cancer [3]. Among the 44,771 deceased members of the LLS cohort with dosi-metric information, there were 9335 deaths from cancer and 582 deaths from leukaemia. By analysing the relationship with radia-tion exposure, it was concluded that until 1997, 440 cancer deaths (4%) and nearly 100 leukaemia deaths (15%) have been attribut-able to the radiation exposure. Significant dose relationships were found for death from leukaemia and carcinoma of the stomach, colon, lung, breast, oesophagus, bladder, ovary, and liver. Since, at the time of the last analysis nearly 50% of the cohort was still alive, it is not possible to make well-founded statements on the life-time risk of dying for people who were young at the time of exposure.

The publication of cancer incidence data 1958 to 1998 [4] is the most comprehensive and detailed analysis of the late carcino-genic effects of radiation. Of the 17,448 cancer cases observed in this study, 7851 occurred in individuals who had received a dose of >0.005 Gy and thus were considered exposed. Of these 853, i.e. 11%, were attributable to the radiation exposure. For a person aged 70 exposed to 1 Gy at the age of 30, the excess relative risk (ERR) was 0.47 for all cancers combined (0.58 for females and 0.35 for males).

The Chernobyl accident

The Chernobyl accident in 1986 was the most severe accident in the civil use of nuclear energy, so far. In the aftermath, many thousands of rescue workers, called liquidators, who were spread all over the former Soviet Union, were concerned about possible health dam-age from the radiation they had been exposed to during and after the accident. It was impossible to set up a comprehensive research programme such as after the Hiroshima and Nagasaki bomb explo-sions which covered all affected people. However, several epide-miological studies have been initiated and continue to provide important information on health consequences which complement the information gathered from the bomb survivors [5]. The liquida-tor studies as well as studies of populations living in areas of radio-active contamination from accidents and bomb tests will provide important comparisons of radiation risks in people with different

background cancer rates and from low dose rate radiation exposure with those in Japanese bomb survivors.

The most important findings in the populations exposed by the Chernobyl accident relate to the massive epidemic of thyroid cancer among the young which, until 2002, has affected nearly 5000 people who were under 17 in 1986. The data could be well fitted to a no-threshold linear dose response relationship with an eightfold increase of risk after 1 Gy thyroid dose. The highest risk was in children under 4 years at exposure. In young adults, the risk was much lower. The Chernobyl thyroid cancer cases provide a unique opportunity for studying specific molecular alterations caused by radiation since >90% of cancers occurring in those born between 1980 and 1986 are radiation-induced, whereas <10% of those occurring in those born after 1987 are radiation-induced. So far, few of the patients have died from thyroid cancer or treatment-related complications; the overall prognosis appears good [5].

Patients treated for benign diseases

Up to the 1960s, more patients were treated with radiotherapy for non-cancer diseases than for cancer. Although the number of indications has been reduced, it is still employed in the treatment of a variety of painful degenerative joint disorders. Doses are less than 10% of those given to treat cancer; results are usually fast and persistent. Some of these treatments are regarded as obsolete today; for example, for conditions such as ankylosing spondylitis pharmacological treatment options are available which are more convenient to doctor and patient. Moreover, some treatments used in the past were associated with a significantly increased risk of leukaemia and cancer [6, 7] analysed the mortality of 14,554 patients irradiated for ankylosing spondylitis between 1935 and 1954. Among the 1582 recorded deaths, the most striking finding was a tenfold increase in fatal leukaemia: 52 patients, compared to five expected. Post-partum mastitis was a very successful indication for low-dose radiotherapy. If irradiated early, one or two 0.5 Gy fractions will abolish the inflammation within a day or two, no abscess develops, no antibiotics or surgery are required, and breast feeding can be resumed quickly. Yet in most countries, this indication for radiotherapy has been abandoned as the extraordinary radiosensitivity of the breast of young women with regard to cancer induction became apparent. Shore et al. [8] studied 601 American women who had been irradiated between 1940 and 1957 for acute post-partum mastitis with a median dose of 3.5 Gy. After a mean follow-up of 30 years, they observed 56 women with breast cancer, whereas according to observation of the patients' sisters, only 32 would have been expected.

These observations led to the recommendation that indication, planning, and performance of radiotherapy for selected non-malignant diseases should be made with the same care as definitive radiotherapy for cancer, limiting field sizes, avoiding critical organs, and reducing radiation to the lowest effective dose.

Radon exposure of hard rock miners or in homes

The publication of a report in 1879 on lung diseases among the miners in Schneeberg (Saxony, Germany) is a milestone in the history of occupational medicine. Härting and Hesse [9] proved that miners working underground died from lung cancer, usually after about 20 years working underground. By cleaning the air by forced ventilation and the introduction of wet drilling, the cancer rate was significantly reduced within ten years. Lung cancer was caused by the exposure of the miners to the radioactive decay products of radon gas which attach to aerosols in the air, and are inhaled and deposited on the bronchial epithelial, irradiating the epithelial stem cells with α-particles.

Several large cohort studies of uranium miners confirmed the early findings. All types of lung cancer are increased in the uranium miners. There is a supra-additive interaction between exposure to radon and cigarette smoking, with silica dust in the mines also contributing to the cancer risk. The results of these studies suggest the possibility that exposure to radon in houses may cause lung cancer in the general population. Radon concentrations in houses vary by orders of magnitude and in some regions with special geological features they can reach values which cause concern. In several European countries and in China large case control studies on the contribution of radon exposure to the lung cancer risk have been performed. In the German study [10], nearly 3000 cases of lung cancer and 4200 controls were investigated. In addition to a comprehensive interrogation, radon concentration measurements were performed in current and previous homes. As expected, the most important risk factor for lung cancer was cigarette smoking. Despite this strong influence of smoking, a clear dependence of relative risk on radon concentration in homes was observed, as was also the case in studies in Finland, Sweden, and the UK. The overall excess lung cancer risk at a radon concentration of 100 Bq/m^3 was 10%. The excess risk from radon was found to exist for smokers as well as for non-smokers, with the risks interacting in a multiplicative way. Up to 10% of all lung cancers may be caused by radon in homes.

Second cancers after cancer therapy

During the typical follow-up period of a patient treated for cancer with radical radiotherapy, many patients will present with a second cancer. The frequency varies between <1% and >10%, depending on age and sex. Results of epidemiological studies demonstrate that after radiotherapy, the increased lifespan of cured patients, and not direct radiation effects, is the most important underlying cause leading to second cancers.

The International Commission on Radiation Protection (ICRP) developed a method to estimate the risk of radiation-induced cancer from the occupational and environmental exposure of workers and the general population which has been also widely used in estimating risk of second cancers after radiotherapy of first cancers. Yet the ICRP [1] strongly advised against using this method to estimate the risks of radiation-induced cancer after radiotherapy since the dose distributions within and between organs are completely different. Second cancer risks estimated this way are orders of magnitude higher than those derived directly from epidemiological investigations on radiotherapy patients. The risk of radiation-induced second cancers should be estimated by the comparison of second cancer rates in patient cohorts who were cured from their first cancer by either radiotherapy or by surgery. This method avoids the influence of competing risks from underlying genetics and lifestyle which may differ between cancer patients and members of the general population. However, important information can also be derived from studies on the topographical relationship of primary and second cancer in symmetrical organs, in particular in

patients with a primary breast cancer and a secondary lung cancer. Moreover, studies on second cancers after radiotherapy of young people and their comparison with age-matched healthy populations provide information after very long follow-up, but interpretation is difficult because of strong genetic susceptibility factors influencing risks. A comprehensive review by the National Council of Radiation Protection of the USA has been summarized by Travis et al. [11].

Carcinoma of the prostate

The results of the large cohort study on more than 120,000 prostate cancer patients registered in the SEER program who either had surgery or radiotherapy [12] demonstrate the extent of the problem for clinical radiotherapy well.

Of the approximately 17,000 prostate cancer patients who survived more than five years after radical radiotherapy, 1185 (7%) developed a second cancer. More than 1000 of those second cancers (>85%) are due to the increased lifespan after cure from the first cancer. Just about 120 to 150 of those second cancers among 51,584 prostate cancer patients (0.3%) are related to radiotherapy, in particular:

◆ approximately 50 cases of bladder cancer;
◆ approximately 15 cases of cancer of the rectum;
◆ approximately 50 cases of lung cancer;
◆ approximately 12 cases of leukaemia.

The most important message of the prostate cancer study is that half of all radiation-induced second cancers occur in the high-dose organs (bladder, rectum) and the other half in the organs exposed to low doses (lung). It is likely that different mechanisms are involved in the high- and low-dose organs. The mechanisms of low-dose radiation carcinogenesis have been explored in radiation protection research [13]. On the other hand, high radiation doses may lead to chronic radiation injury characterized by microvascular damage, parenchymal atrophy and chronic inflammation, a typical pre-cancerous lesion.

Breast cancer

Patients treated with post-operative radiotherapy for breast cancer receive significant radiation doses of more than 5% of the target dose to the contralateral breast. Since second cancers in the contralateral breast occur more frequently than expected and comprise nearly half of all second cancers in women with breast cancer, a causal relationship with the radiation exposure from the treatment of the first cancer was suggested. A case control study by Stovall et al. [14] embedded into the WECARE Study with 708 women with asynchronous bilateral breast cancer and 1399 women with unilateral breast cancer (controls) demonstrated that women <40 years of age who received >1Gy to the specific quadrant of the contralateral breast had a 2.5-fold greater risk for contralateral breast cancer than unexposed women. No excess was observed in women >40 years of age. It is particularly in young breast cancer patients that the dose to the contralateral breast should be carefully controlled.

Patients treated with post-operative radiotherapy for breast cancer receive very different doses to the ipsilateral compared to the contralateral lungs. Darby et al. [15] reported that among 115,165 women treated for breast cancer using radiotherapy 482 women died from lung cancer for which the affected side was clearly defined in the records. Of the cases, 283 (59%) were ipsilateral and 199 (41%) were contralateral. From these findings an absolute risk of 0.6% of radiation-induced lung cancer was estimated. Grantzau et al. [16] analysed the long-term risk of second primary solid non-breast cancers in the Danish national population-based cohort of more than 46,000 patients treated according to national guidelines of the Danish Breast Cancer Cooperative Group for early breast cancer between 1982 and 2007. About half received post-operative radiotherapy and were compared to those not receiving radiotherapy. Altogether, 2358 second cancers had occurred during the follow-up. The hazard ratio was not increased for sites distant from the treatment field; however, it progressively increased with duration of follow-up for sites in the thorax, in particular the lungs. The estimated attributable risk of developing a secondary cancer in the thorax (excluding contralateral breast) translates into one radiation-induced second cancer in every 200 women treated with radiotherapy.

Hodgkin lymphoma

Dores et al. [17] reported results of a large international study on 32,591 Hodgkin lymphoma patients with 2861 patients followed up for more than 20 years and 1111 patients for more than 25 years. Mean age at treatment was 37 years. Second malignancies developed in 2153 patients (7%) which, compared to the age- and sex-adjusted general population, was an increase of more than a factor of 2. The risk of late-developing solid cancers was particularly increased after radiotherapy while second leukaemias were mostly related to chemotherapy. The highest absolute excess second cancer risk was for cancers of the lung and breast. The authors calculated a 25-year cumulative risk of treatment-induced second cancers of 11.7%, most of which was related to radiotherapy.

In their review of late effects after treatment for Hodgkin lymphoma, Swerdlow and van Leeuwen [18] concluded that the substantial increase in solid tumour risk with time since diagnosis necessitated careful, lifelong medical surveillance of all patients. In particular, women treated with mantle field irradiation before the age of 30 are at greatly increased risk of breast cancer and follow-up of these women should include yearly mammography; however, the efficacy of these measures has not yet been demonstrated.

Paediatric malignancies

The chances of children with cancer being cured and having a near normal life-expectancy have reached a level unimaginable 30 years ago. But the price for this progress has been high. Neglia et al. [19] investigated a cohort of 13,581 children from the Childhood Cancer Survivor Study register in the USA who survived at least five years. After a mean latency of 12 years, 298 second malignancies were observed. Whereas the risk of secondary leukaemia (altogether 24 cases) increased to a peak after five to nine years, the risk of solid second cancers, in particular breast, thyroid, and CNS was significantly elevated during the entire follow-up period of up to 30 years. The study of de Vathaire et al. [20] specifically looked at the impact of radiotherapy on childhood solid malignancies on the risk of second cancers. They analysed the second cancer risk in 4400 three-year survivors treated in France and the UK, 3109 (71%) of whom received radiotherapy. For 2831 (91%) of these children, individual radiation doses at 151 points of the body were determined, based on the individual treatment plans using a

computer phantom. Of these, 113 patients (4%) developed a solid second malignant tumour. Twenty-five years after treatment of the primary malignancy, the cumulative risk was 5%; five years later it approached 8%. In 543 patients who had already attained an age >30 years, 16 second cancers were diagnosed while only 3.3 were expected, a fivefold increase. Diallo et al. [21] analysed the anatomical relationship between the location of fatal second cancers and the anatomy of the planning target volume (PTV) for sarcomas, brain tumours, breast cancer, and thyroid cancer. Of fatal second cancers, 50% were sarcomas, nearly 90% developed in or close to the PTV while the majority of central nervous system tumours occurred at a distance from the PTV. Tukenova et al. [22] reported that sarcomas occurred earlier than carcinomas but stayed constant after 20 years while the rate of carcinomas continued to increase steadily with increasing follow-up time.

In a study on 102 second cancers among 930 children treated for Hodgkin disease, Constine et al. [23] reported a threefold higher risk for female children treated for Hodgkin disease than for males of developing second cancers. This is mainly due to the high rate of cancers of the breast, but also of thyroid carcinomas and of sarcomas in females. These three cancer types comprise three-quarters of all second cancers in female Hodgkin survivors. Second cancers after childhood cancer radiotherapy are a particularly serious problem in female patients.

Conclusion

In a comprehensive analysis of data stored in the US Surveillance, Epidemiology and End Results Cancer Registries, Berrington de Gonzalez et al. [24] determined the proportion of second cancers which are attributable to radiotherapy treatments in 647,672 adults who survived their first cancer for more than five years and were followed up for another seven years. Of these 60,271 (9%) developed a second solid cancer between five and 12 years after treatment of the first cancer. The relative risk of second cancer and the proportion of cancers attributable to radiotherapy were calculated by comparing cancer rates for patients receiving radiotherapy versus patients not receiving radiotherapy in the definitive treatment of 15 types of first malignancy. In total, an estimated 3266 excess solid cancers could be related to radiotherapy in these five-year survivors, i.e. 8% of the total second cancers diagnosed in the cancer survivors who had received radiotherapy. The authors estimated that for every 1000 patients treated with radiotherapy there were an estimated three excess cancers by ten years after first cancer diagnosis which increased to five excess cases by 15 years. Over half of the excess cases occurred in organs likely to have received >5 Gy. The risk of radiation-induced second cancers is much greater in young and very young cancer patients. Increased cancer rates may persist lifelong.

All estimates of treatment-related second cancers made above are inevitably based on retrospective analyses of results from treating patients many years ago, yet the situation has changed dramatically in radiation oncology during the last two decades. Today, patients rarely receive radiotherapy alone. In particular, studies in patients treated as children with chemotherapy plus radiotherapy demonstrated that both treatment modalities increase the risk of secondary malignancy in cured patients, both regarding leukaemias and solid cancers. Therefore, the risk of cancer induced by the combination of chemotherapy, radiotherapy, and novel molecular agents cannot be predicted from the results of these studies on past patients, and the combinatory effects need to be closely watched in future.

CHAPTER 18

Aetiology and progression of cancer

Role of body fatness, physical activity, diet, and other lifestyle factors

Fränzel J.B. van Duijnhoven and Ellen Kampman

Introduction to aetiology and progression of cancer

The occurrence of cancer varies across the world. Among men in more developed regions, prostate cancer is most common, followed by lung and colorectal cancer [1]. Among men in less developed regions, lung cancer is most prominent, followed by stomach and liver cancer. Among women, breast cancer is the most frequently occurring form of cancer in developed regions of the world, followed by cancer of the colorectum and the lung. In less developed regions, breast cancer is also the most common type of cancer among women, followed by cervix uteri, lung, and stomach cancer. Migrant studies, in which people moved from one part of the world to another, have shown that cancer rates among these populations change rapidly over generations and become comparable to the cancer rates of the host country [2–6]. These observations indicate that in addition to genes, lifestyle, including diet and physical activity, is important in the aetiology of cancer.

In 1981, Doll and Peto estimated that about 35% of all cancer deaths are attributable to dietary habits [7]. A similar conclusion is drawn in the policy report of the World Cancer Research Fund (WCRF) in collaboration with the American Institute for Cancer Research (AICR) which appeared in 2009: about a quarter to a third of all cancers in higher-income countries and about a fifth to a quarter in lower-income countries could be prevented through eating healthily, being physically active, and maintaining a healthy weight [8]. This report was built on evidence from their second expert report *Food, Nutrition, Physical Activity and the Prevention of Cancer: A Global Perspective* [9]. In addition to the influence of lifestyle factors on the occurrence of cancer later in life, the second expert report also acknowledged that research on lifestyle factors during and after cancer is important, because the number of people that are diagnosed with cancer as well as those who survive cancer is increasing.

This chapter describes the evidence on the role of body fatness, physical activity, diet, and other lifestyle factors[1] in the aetiology as well as the progression of cancer, it discusses what proportion of cancer cases is attributable to these factors, and it provides evidence-based recommendations for the general public.

Development of cancer

Body fatness

As greater body fatness strongly and consistently increases the risk of many types of cancer, it is one of the most important risk factors for cancer as a whole. The evidence that it causes cancer of the breast (after menopause), colorectum, pancreas, oesophagus (only adenocarcinomas), endometrium, and kidney is convincing, whereas it is probable for gallbladder cancer [9–11]. In contrast, greater body fatness probably protects against breast cancer before menopause.

It is not only the amount of fat tissue, but also the location of fat tissue within the body that is important in the development of cancer. Greater abdominal (central) fatness is convincingly associated with an increased risk of colorectal cancer and it probably also causes breast cancer (after menopause), pancreatic cancer, and endometrial cancer [9–11].

The mechanism behind these associations is thought to run via increased circulating concentrations of hormones and growth factors, such as sex hormones, insulin, and insulin-like growth factor, which are involved in carcinogenesis [12, 13]. In addition, body fatness is characterized by elevated levels of pro-inflammatory factors, which can promote cancer development [12, 13].

Although estimates of population attributable fractions vary between studies according to the methodology used, the number of cancer cases that are attributable to body fatness also differ by type of cancer and by population (Table 18.1; [9, 14]). For example, about 34–38% of endometrial cancers are estimated to be attributable to body fatness in the UK, which is regarded as a high-income country, whereas it is about 18% in China, which is considered to be a low-income country. For colorectal cancer, 7–13% is estimated to be attributable to body fatness in the UK and 3% in China.

Given the high impact of body fatness, WCRF/AICR as well as the American Cancer Society (ACS) recommend individuals to achieve and maintain a healthy weight throughout life [9, 15]. A healthy weight is best achieved by choosing diets based on foods with low-energy density, avoiding sugary drinks, and being physically active throughout life.

Physical activity

Physical activity consistently reduces the risk of colon cancer and probably also protects against postmenopausal breast cancer and endometrial cancer. In addition to the beneficial effect of physical activity on body fatness, this may be due to its favourable influence on endogenous steroid hormone metabolism and immune function [16].

Around 3–12% of colorectal cancer cases are estimated to be preventable by being physically active on a regular basis in the UK, while it is around 7% in China (Table 18.1). It is advised to adopt a physically active lifestyle [9, 15]. This means building regular moderate, and some vigorous physical activity into everyday life, and diminishing the time spent sitting.

Diet

Plant foods

In general, plant foods are assumed to protect against cancer, as most diets that decrease the risk of cancer mainly contain foods of plant origin. The observed inverse associations between plant foods separately and the development of cancer, however, are relatively weak and are still debated [17].

The evidence that has currently been established is the following: a relatively high consumption of non-starchy vegetables, which includes green, leafy vegetables, cruciferous vegetables, and allium vegetables, probably protects against cancer of the upper-gastrointestinal tract (mouth, pharynx, larynx, oesophagus, and stomach) [9]. Allium vegetables alone probably also protect against stomach cancer, whereas garlic specifically has been shown to decrease the risk of colorectal cancer [9, 11]. The consumption of

fruits probably decreases the risk of cancer of the mouth, pharynx, larynx, oesophagus, lung, and stomach.

Foods containing dietary fibre, which also includes vegetables and fruits, is convincingly protective against colorectal cancer [11, 18].

In addition to dietary fibre, the beneficial effects of vegetables and fruits may be due to specific vitamins or other bioactive compounds, such as carotenoids including beta-carotene and lycopene (coloured vegetables), folates (green leafy vegetables and brassica), glucosinolates (brassica), and allyl sulphides (garlic and onions). Non-starchy vegetables and fruits are also typically low in energy density; thus a diet high in these products probably also protects against weight gain.

For cancers of the mouth, pharynx, and larynx, around 34% and 17% in the UK and 12% and 30% in China are estimated to be attributable to non-starchy vegetables and fruit, respectively (Table 18.1). Consuming an adequate amount of fibre is thought to prevent around 12% of colorectal cancer cases in the UK (Table 18.1).

The consumption of plant foods is encouraged by both the WCRF/AICR and ACS [9, 15]. WCRF recommends eating at least five portions/servings (at least 400 g or 14 oz) and ACS advises at least 2.5 cups of vegetables and fruits each day. In addition, they both promote the consumption of unprocessed cereals (whole grains) and limit the consumption of refined grain products.

Animal foods

Animal foods typically include meat, poultry, fish, eggs, as well as milk and other dairy products. The evidence for most of these foods in relation to the development of cancer is limited, with the exception of meat and milk.

Red meat, which includes beef, pork, lamb, and goat, as well as processed meat, meaning meats that are preserved by smoking, curing, salting, or the addition of chemical preservatives (e.g., ham, bacon, pastrami, salami, and sausages), are convincingly associated with an increased risk of colon as well as rectal cancer [11].

The exact mechanism by which red and processed meat increases colorectal cancer risk is unclear [11]. Factors that may play a role in colorectal carcinogenesis are specific mutagens, such as heterocyclic amines and polycyclic aromatic hydrocarbons, which are formed when meat is cooked well done at a very high temperature or over a direct flame (e.g., grilling, frying, or barbecuing). A specific component in red meat that may also be involved in the carcinogenic process is heme iron. This compound, which gives meat its red colour, may act through two different pathways: (1) it catalyses the peroxidation of fat in the gastrointestinal tract, which produces cytotoxic and mutagenic alkenals; (2) it induces the production of carcinogenic N-nitroso-compounds in the gastrointestinal tract. These latter N-nitroso-compounds can also be formed when nitrates and nitrites are added as preservatives to processed meats during the curing process.

Around 5% and 10% of colorectal cancers in the UK and 7% and 1% in China are estimated to be attributable to red and processed meats, respectively (Table 18.1). The guidelines to prevent cancer emphasize diminishing the consumption of red meat [15] (less than 500 g a week according to WCRF/AICR [9]) and limiting [15] or even avoiding [9] the consumption of processed meat.

Although the evidence on milk and the development of cancer is not limited, it is conflicting [9]. On the one hand, the consumption of milk probably protects against cancer of the colon and rectum, which is thought to occur at least in part due to a higher consumption of dietary calcium. On the other hand, diets high in calcium are probably associated with an increased risk of prostate cancer.

Based on these findings, it may be hypothesized that calcium both has an inhibiting as well as a promoting role in the carcinogenic process, which may differ by cell type.

Calcium may reduce colorectal carcinogenesis by binding to secondary bile acids and fatty acids, which prevents them from exerting their proliferative effects on colonic epithelial cells. In addition, calcium may directly influence the colorectal carcinogenic process by inducing differentiation in normal cells and apoptosis in transformed cells [9]. The mechanism of calcium in prostate carcinogenesis is proposed to involve vitamin D. A high intake of calcium down-regulates the formation of 1,25 dihydroxyvitamin D, which may result in increased cell proliferation in the prostate [9].

Due to these conflicting results, the proportion of cancers that can be prevented by drinking or not drinking milk cannot be determined and no recommendations are provided.

Alcohol

Alcoholic beverages cause several types of cancer. A high consumption of alcoholic drinks is convincingly associated with cancer of the mouth, pharynx, larynx, oesophagus, and breast (before and after menopause). It is also convincingly a cause of colorectal cancer in men, whereas it is probably a cause for colorectal cancer in women, and for liver cancer [9].

It is not the type of alcohol drink that is consumed that is important but the total intake of ethanol. The primary metabolite of ethanol, acetaldehyde, as well as other reactive metabolites, may be carcinogenic. In addition, alcohol may influence the production of prostaglandins, lipid peroxidation, and the generation of free-radical oxygen species. It also may act as a solvent, thereby enhancing penetration of carcinogens into cells, and it may change folate metabolism, with unfavourable effects on DNA-synthesis and DNA-methylation [9, 15, 19].

In the UK, 21–51% of oesophageal cancer is estimated to be attributable to alcohol consumption, whereas it is 11% in China (Table 18.1). If only the evidence on cancer was taken into account, all amounts of alcohol should be avoided. However, as low to moderate intake of alcoholic drinks is associated with a reduced risk of coronary heart disease, both the WCRF and the ACS recommend consuming no more than one drink for women and two drinks for men, per day, when alcohol is consumed [9, 15].

Preservation, processing, and preparation of foods

Some methods of food preservation, processing, and preparation may affect cancer risk. The strongest evidence exists for processed meat (described under 'Animal foods'), for salt and salt-preserved foods, and for foods that are contaminated with aflatoxins, such as cereals (grains) and pulses (legumes) [9].

It is the overall amount of salt that is consumed in itself and with salt-preserved foods that probably causes stomach cancer. Aflatoxins are produced by some moulds when the above-mentioned foods are stored too long in warm temperatures. These aflatoxin-contaminated foods cause liver cancer.

In the UK, 14–24% of stomach cancers are estimated to be attributable to salt intake, while there are no estimates for the impact of aflatoxin-contaminated foods on the total number of liver cancer cases (Table 18.1). WCRF/AICR recommends avoiding

salt-preserved, salted, or salty foods to ensure an intake of less than 6 g (2.4 g sodium) a day. In addition, they suggest not eating mouldy grains and legumes.

Other lifestyle factors

Dietary supplements

The findings for dietary supplements in the development of cancer are inconsistent [9]. Some studies have observed decreased risks for certain types of cancer, while others did not find any association or even reported an increased risk for particular forms of cancer. These results are based on specific populations which received specific doses of supplements. More research is needed to determine the role of high as well as low doses and natural as well as synthetic forms of supplements. In addition, combinations of different vitamins, minerals, or other compounds may be relevant when investigating supplements. For now, the use of supplements for the general population to prevent cancer is not recommended. The consumption of foods instead of dietary supplements is advocated as the best source of nutrients [9, 15]. However, in specific groups and in specific situations, the use of dietary supplements may be advisable. An example is the use of vitamin D for people who are not exposed to enough sunlight or those who are not able to synthesize a sufficient amount of vitamin D from sunlight [9].

Breastfeeding

There is strong and consistent evidence that lactation, breastfeeding by the mother, protects the mother against breast cancer at all ages thereafter [10]. This may be due to the fact that the lifetime exposure to menstrual cycles is shortened, which influences hormone levels and thereby influences breast cancer risk [9]. In addition, cells with potential initial DNA damage may be removed because of the strong exfoliation of breast tissue during lactation and the immense epithelial apoptosis at the end of breastfeeding, which may reduce breast cancer risk. For women with babies it is therefore recommended to breastfeed for at least six months after the baby is born [9].

Progression of cancer

In contrast to the enormous amount of original research studies that have been performed on the role of body fatness, physical activity, dietary and other lifestyle factors in the development of cancer, relatively few well-designed investigations have focused on the influence of these lifestyle factors on survival from cancer [9]. This new area of research, however, is now expanding. Most studies have focused on outcomes in breast, colorectal, and prostate cancer patients, as these are most prevalent in high-income countries. In addition to the fact that these are specific populations, these investigations are limited because there is a lot of heterogeneity in the type of exposure and especially the timing of exposure. Body fatness, physical activity, diet, and other lifestyle factors may have a different impact when patients receive treatment than when patients have finished their treatment. To make sure that changing these lifestyle factors is not harmful for patients at any time, the influence of lifestyle factors should first be evaluated in observational studies before feasible and effective intervention trials can be planned and conducted among cancer survivors.

The major challenge in conducting studies among cancer patients in combination with the lack of homogeneous studies in this field makes it difficult to draw firm conclusions for the cancer population at large [20, 21]. Since there is hardly any consistent scientific evidence available, the current recommendation for patients who have finished treatment is to aim to follow the guidelines to prevent cancer [9]: achieve and maintain a healthy weight, engage in regular physical activity, and adopt a healthy diet [9, 22].

Conclusion

The important involvement of body fatness, physical activity, diet, and other lifestyle factors in the development of cancer has been established and evidence-based recommendations for the general public have been set. The focus of investigations on lifestyle factors in the development of cancer will now be directed towards refining this knowledge: for instance, by unravelling the underlying mechanism and identifying the most relevant bio-active compounds, specific dietary patterns, or susceptible subgroups. The current recommendations to maintain a healthy weight, to adopt a physically active lifestyle, and to consume a healthy diet should help to reduce the number of persons that will be diagnosed with cancer worldwide. For the people who are diagnosed with cancer, however, evidence-based guidelines to improve their progression and quality of life still need to be determined. To define these guidelines, future research will be devoted to the role of body fatness, physical activity, diet, and other lifestyle factors in cancer progression.

Note

1 Given the overwhelming body of evidence on smoking in relation to cancer and other diseases, the importance of not smoking and avoiding exposure to tobacco smoke is now generally acknowledged and is, therefore, not part of this section. See Chapter 14 'Smoking and cancer'.

SECTION 3

Principles of oncology

Practice points for surgical oncology

Petra G. Boelens, C.B.M. van den Broek, and Cornelis J.H. van de Velde

Introduction to surgical oncology

Surgical oncology remains the cornerstone of curative oncology treatment for most solid cancers. Historically, surgery was the only cure for cancer for a long time. If a tumour was mobile, thus movable by the surgeon on palpation, it could be taken out. With respect to modern surgical oncology, it has become far more innovative and complex. Nevertheless, surgical removal of solid cancer still offers the best chance of long-term survival over all other treatment modalities for most cancers.

Precision diagnosis using high-tech imaging techniques such as ultrasound, MRI and CT-scanning, and sometimes PET/CT, can personalize the surgical approach. Cancer surgery especially has benefited from advances in imaging. Cancers are nowadays clinically staged as either resectable or potentially resectable or unresectable, depending on patient characteristics such as fitness and comorbidity, preferences, TNM stage, and appearance on imaging. As expected, enhanced pre-operative staging has implications for treatment options. For example, MR-based staging of rectal cancer is very accurate in T-staging and definition of mesorectal fascia (MRF) involvement [1], separating good prognosis patients from poor prognosis, and determining who should receive upfront treatment with radiation and/or chemoradiation therapy. MR-based restaging in rectal cancer after primary treatment with radiation or chemoradiation defines response and definitive surgery.

Minimal invasive surgery such as laparoscopic techniques in colorectal surgery were introduced and showed to be safe with respect to long-term oncological outcomes [2–4]. For the direct post-operative period, benefits of laparoscopic surgery are lower risk of mortality and morbidity and shorter hospital stay. In the field of breast cancer, breast-conserving surgery in combination with post-operative radiation therapy versus mastectomy is similar in long-term survival in numerous randomized trials [5, 6]. Some studies also describe significant benefit in body image and satisfaction with breast-conserving therapy in comparison to mastectomy, although decreasing in time due to late effects of radiation therapy; others have seen that body image problems did not differ at two years after any type of surgery. Shared decision-making between the surgeon and patient has a role in achieving long-term satisfaction by the treatment choice that fits the patient the best according to her preferences. Decision aids, web-based or digital, assist in this aim.

In some fields, a more extensive surgical resection results in better outcome such as the Dutch D1D2 trial: the standardized extended (D2) lymphadenectomy leads to better results than standardized limited (D1) lymphadenectomy in patients with resectable primary adenocarcinoma of the stomach. After a median follow-up of 15 years, D2 lymphadenectomy had lower locoregional recurrence and gastric-cancer-related death rates than D1 surgery. Of note, the D2 procedure was associated with more post-operative mortality, morbidity, and reoperation rates. Because a safer, spleen-preserving D2 resection technique is currently available in high-volume centres, this modified D2 lymphadenectomy is the recommended surgical approach for patients with resectable (curable) gastric cancer [7].

Perioperative care has become better over time; therefore, surgeons are less hindered by age, stage, comorbidity and advanced disease for deciding on surgical management. In case of resectable liver metastases of colorectal cancer, the sequence and timing to treat the primary or metastases with surgery or systemic therapy play a role in treatment [8]. Chemotherapy and radiofrequency ablation (RFA) may be options to consider in borderline resectable disease.

Cancer care now involves a wide spectrum of systemic therapies with pre- or post-operative, induction, and/or palliative treatment(s). Specifics about these are elaborated in other chapters of this textbook. Consequently, managing cancer is increasingly a multidisciplinary alliance. Dedicated health care professionals from all different disciplines should discuss all the possible options of treatment at several decision points in time before sharing this with the patient. Presentation of a patient with cancer in a multidisciplinary team (MDT) is the preferred approach.

History of surgical oncology

The earliest surgical operations in human history were carried out in prehistoric times (2000 BC) in several parts of the world—in Europe, in Asia and particularly in Peru, where well-preserved mummies endure. Many of these mummies have a hole in the skull which is the product of trepanning (also known as trephining or trephination) which was thought to be helpful in releasing evil spirits. Surgery in the old days was obviously a risky business.

With regards to surgical oncology, in the Greek and Roman empires people such as Hippocrates started to recognize and treat cancers. The introduction of general anaesthesia (nitric oxide and

ether to start with), antisepsis (principles discovered by Lister, Semmelweis, and Pasteur), and many surgical pioneers (such as Moore and Halsted for introducing radical breast surgery, Kocher for the approach in thyroid surgery, and Miles for the abdominoperineal resection for rectal cancer) were at the base of modern surgical oncology. In the last decades, many advances have been made toward better surgical oncological outcome and better quality of life.

Cancer surgery and resectability

Although it sounds very logical that resectability means that a tumour can be resected, it is a bit more complex than that. Final determination of resectability requires a multifaceted evaluation of tumour anatomy by imaging, existence of local and/or distant disease, age, comorbidities, functional status, and sometimes results of laboratory tests to determine the risk–benefit profile of surgery. This evaluation may take more than one outpatient visit to complete for the patient and at least one MDT discussion to decide on treatment strategies. Moreover, if upfront non-surgical treatment is considered; restaging might reveal additional surgical options.

Now, with diverse types of high-tech imaging techniques within reach, the definition of resectability is far more complicated. For example, what is resectable pancreatic cancer? According to the cancer staging systems this would be cancer not associated with disease outside the pancreas. The anatomic extent of the primary cancer is pre-operatively and primarily determined by CT scan; this means there should not be tumour extension into the major blood vessels (such as branches from the celiac trunk, common hepatic artery, superior mesenteric vein or artery, or portal vein) or adjacent organs. Until recently, tumours that appeared to involve any of the major abdominal blood vessels were considered unresectable because survival following surgical procedures that required resection and reconstruction of these vessels was poor. In some centres, however, pancreatic tumours are resected with the involvement of major blood vessels, with good long-term outcome. It should be recognised that this can only be done in expert centres.

In cancer surgery, outcome is generally measured by comparing survival and disease-specific outcomes. It has become more accepted to implement other measures of quality such as quality of life, infectious complications, body image, or cosmetic outcome as outcome measures. The preferences of the patient in these processes are important to sustain long-term satisfaction with the choices that were made.

Age and comorbidity

In Western countries, the fastest growing part of the population is people aged 65 years or older, and the highest incidence of colorectal cancer is among those aged between 70 and 80 years old. In recent years, the focus on elderly colorectal cancer patients has increased. It is important to realize that the elderly population forms a very heterogeneous group of patients. Not only can calendar age be very different from biological age, but the definition of elderly also varies widely from ≥65 years to ≥80 years in different studies. Calendar age alone is, therefore, not the primary influence on outcome; rather, the combination of comorbidities and decreased physical reserve to recover from adverse events that may occur may determine the outcome for elderly patients. This is also

referred to as biological age. Hence, calendar age itself should not be a contraindication for more aggressive or adjuvant treatment. Comorbidities, on the other hand, are of critical importance in the care of a patient.

However, comorbid conditions do not alone determine post-operative outcome in elderly patients; fitness or frailty must also be taken into account. Unfortunately, there is scarce information available on pre-operative conditions of fitness at advanced age, including factors such as 'frailty', age-related muscle loss (sarcopenia), and malnutrition. These factors indicate which elderly individual is more vulnerable in encountering adverse outcome. Hence, identifying 'frail' octogenarians is of utmost importance to acquire a realistic prognosis of cancer surgery. Currently, instruments developed for this are unfortunately both time-consuming and rather impractical.

Malnutrition is highly prevalent in elderly populations; approximately one-third to one-half of hospitalized patients are malnourished at the time of admission, which leads to higher post-operative morbidity rates. This suggests that consideration of the perioperative nutritional status is especially important in elderly patients.

Staging and restaging

Staging cancer is the process of establishing the anatomical location, size, and depth of the tumour growth, the locoregional extent in adjacent organs, and the spread of cancer either to lymph nodes or distant organs. Staging is important in planning a surgical approach (if possible) and to gather information about prognosis. Usually, a higher stage is associated with worse outcome and has varying potentials for treatment. It is important that staging is discussed in a multidisciplinary board, because all treatments are based on anatomy and stage.

The TNM classification is one of the most commonly used staging systems. This system has been accepted by the International Union Against Cancer (UICC) and the American Joint Committee on Cancer (AJCC). Most medical facilities use the TNM system as their leading classification for cancer reporting. MDTs are encouraged to discuss clinical TNM stage and pathology TNM as pre-operative and post-operative bases for treatment regimes.

The TNM system gives information about the extent of the tumour (T), the extent of spread to the lymph nodes (N), and the presence of distant metastasis (M). For example, the T stage of the primary tumour will be described as TX when the primary tumour cannot be evaluated or is unknown and T0 if there is no evidence of a primary tumour. If the primary tumour is an in situ carcinoma, it is called Tis (pre-invasive cancer), and the following are sequential in size T1, T2, T3. T4 indicates growth into an adjacent organ, including the skin. Regional lymph nodes (N) are classified according to the same method: NX—regional lymph nodes cannot be evaluated; N0—no regional lymph node involvement; and N1, N2, N3—involvement of regional lymph nodes in ascending numbers (number of lymph nodes and/or extent of spread). For distant metastasis (M), the methodology is similar and describes as: MX–distant metastasis cannot be or are not evaluated; M0—no distant metastases are present; and M1—distant metastases are present.

With the development of pre-operative therapies—radiation therapy, chemotherapy or biologics—the initial staging will be part

of the comparison of the restaging after induction or pre-operative treatments on therapeutic effects or response and give information about final surgical outcome and prognosis. Restaging is usually less accurate because of biological changes to the tissue such as fibrosis which makes pathology difficult to interpret. MRI, for example, is the standard restaging modality for rectal cancer and breast cancer. In some fields—pancreatic cancer, ovarian cancer, and hepatic malignancies—PET-CT could assist in monitoring therapy for staging and restaging.

Anatomical surgery

The best option on long-term survival and reduced local recurrence is precise surgery if possible; the tumour needs to be confined to a resectable organ or organ part or en bloc with draining lymph nodes.

Some sites in the body have very delicate and clear surgical landmarks of the tissue to be resected (thyroid cancer, rectal cancer, pancreatic cancer) while other areas are less clearly defined anatomically such as breast tissue or liver parenchyma.

The aim of oncological surgical resections is a clear margin around the tumour. If there is extension of the tumour in the surrounding tissue, this is called locally advanced disease, which requires a different surgical approach. Locally advanced disease does not always adhere to anatomical landmarks. It is imperative for surgeons to know the anatomy of the tumour at hand. Nerves, vessels, and adjacent organs should be respected if not involved in the tumour process.

A clear margin of one millimetre equals complete resection in most cancers, although a larger margin reduces the risk of local recurrence. For instance, in breast cancer, Halsted introduced the radical mastectomy (surgical removal of the breast, pectoralis major, and minor muscles en bloc with a full axillary lymph node dissection). In 1983, Maddox et al. compared the Halsted radical mastectomy to the modified radical mastectomy (not resecting the muscles) and had similar results on ten-year survival, although local recurrence was lower after radical mastectomy [9]. In the same period, breast preservation (wide local excision of the breast mass with locoregional irradiation) was studied, and nowadays it is very well established that breast preservation can result in equal long-term outcome when compared to mastectomy. With local treatment, pathological exam of the surgical margins became important. Before the 1990s, only margins where tumour tissue was suspected when checked macroscopically were investigated microscopically. From 1990 and beyond, margins were evaluated more intensively, but evaluations were not standardized.

A 2 mm free margin is regarded sufficient in breast cancer. Proximal and distal margin are terms used, for example, in colon cancer, which depend on the vascular supply of the segment of the colon that needs to be resected.

In rectal cancer, the border surrounding the mesorectum (the fatty tissue around the serosal layer of the rectal wall harbouring the locoregional draining lymph nodes), the mesorectal fascia (MRF), is best described by a pre-operative MRI, measured in millimetres towards the tumour. This is the clinical differentiation between clinical T3 and T4 disease and will give the best prediction of whether a negative circumferential resection margin (CRM) will be possible. A CRM >1 mm is associated with better survival and a lower incidence of local recurrence [1, 10].

Prophylactic surgery in hereditary cancer CRC

About 3–5% of colorectal cancers are of hereditary origin. If there is clinical suspicion of polyposis or Lynch syndrome, the patient should be referred to a specialist in human genetics for genetic testing. Clinical suspicion is based on clinical criteria or on molecular screening in the context of a suggestive personal or family history.

Lynch syndrome (LS/hereditary non-polyposis colorectal cancer [HNPCC]) is the most common hereditary colorectal cancer syndrome and is estimated to account for 3–5% of all CRC cases. LS is caused by mutations in DNA mismatch repair (MMR) genes which are inherited in an autosomal dominant pattern and are associated with accelerated development of cancers. Life-time risk for colorectal and endometrial cancers approaches 70–80% and 40–60%, respectively. At-risk family members who undergo screening colonoscopy have a reduced risk of developing HNPCC-related cancers and lower mortality. It is recommended that colonoscopies with polypectomies and endometrial biopsies with transvaginal ultrasonography are repeated frequently in Lynch syndrome. With surveillance intervals of one to two years, members of families with Lynch syndrome have a lower risk of developing CRC than with surveillance intervals of two to three years.

Familial adenomatous polyposis (FAP), which is caused by mutations in the adenomatous polyposis coli (APC) gene, is characterized by the development of multiple adenomas in the rectum and colon starting during the second decade of life. Individuals with FAP carry a 100% life-time risk of CRC. Cancer prevention—including prophylactic colectomy-- and maintaining a good quality of life are the main goals of management, and regular and systematic follow-up and supportive care should be offered to all patients.

Important topics in hereditary colorectal cancer syndromes that are open for discussion are which patient must be treated earlier, ideal timing for surgery, and the extent of surgery. In FAP patients, by the late teens or early twenties, colorectal cancer prophylactic surgery is advocated. The recommended options are total proctocolectomy and ileoanal pouch (IPAA) or ileorectal anastomosis (IRA) for attenuated FAP.

Desmoid tumors are rare non-metastasizing fibromatoses that can occur in association with familial adenomatous polyposis. Desmoids have a prevalence of 10–26% in FAP and are usually a major source of morbidity and one of the most common causes of death in these patients. An interaction between female gender and early (<18 years) colectomy of patients developing desmoids has been investigated, with a hazard ratio (HR) of 2.5.

Breast and ovarian cancer

Although a family history of breast and/or ovarian cancer is common in women diagnosed with breast or ovarian cancer, less than 10% of all breast cancers and less than 15% of ovarian cancers are associated with inherited genetic mutations. The majority of hereditary breast and ovarian cancers are associated with mutations in two genes, breast cancer type 1 and 2 susceptibility genes (BRCA1 and BRCA2). Less commonly, breast cancer is due to other hereditary cancer syndromes, such as Li-Fraumeni and Cowden syndromes, which are related to mutations in the TP53 and PTEN genes, respectively.

Women with BRCA1 and BRCA2 have markedly elevated risks of breast cancer and ovarian cancer, with a lifetime risk of breast cancer of 50 to 85% and a 15 to 40% chance of developing ovarian cancer. There is also an increased risk of a second breast cancer diagnosis. Men with BRCA1 and BRCA2 also have an increased risk of breast cancer and prostate cancer. Whereas the increased lifetime risk for men with BRCA1 of breast cancer and prostate cancer is undefined, the lifetime risk of breast cancer of men with BRCA2 appears to be under 10%, and the lifetime risk of prostate cancer is elevated five- to sevenfold. Besides breast, ovarian, and prostate cancer, patients with mutations in the BRCA2 gene have elevated risks of other cancer types, such as pancreatic cancer.

Patients with hereditary breast and ovarian cancer are counselled to initiate screening considerably earlier than average risk patients due to the early age of diagnosis. Expert recommendations include clinical breast examination two to four times annually beginning at age 25, with annual MRI and mammography screening from the age of 30. Twice per year, screening for ovarian cancer using transvaginal ultrasound and serum CA-125 levels should begin at age 35. Besides prophylactic mastectomy, bilateral salpingo-oophorectomy should be offered at completion of childbearing. For men, clinical breast examination semi-annually is advised, as well as a baseline mammogram and appropriate prostate cancer screening.

Other hereditary disorders

MEN1 is a rare heritable disorder classically characterized by a predisposition to tumours of the parathyroid glands, anterior pituitary, and pancreatic islet cells. In patients with MEN1, known MEN1 carriers, and family members whose risk has not been eliminated by DNA testing, clinical vigilance should be maintained for symptoms or signs that could be due to MEN1-associated tumours. These include symptoms of nephrolithiasis, amenorrhoea, galactorrhoea, erectile dysfunction, peptic ulcer disease, diarrhoea, and neuroglycopenic or sympathoadrenal symptoms from hypoglycaemia. We typically measure serum calcium annually to detect asymptomatic hyperparathyroidism, which may be treated surgically.

CDKN2A mutations, also known as FAMMM syndrome (familial atypical multiple mole/melanoma syndrome), is an autosomal dominant genodermatosis characterized by multiple melanocytic nevi, usually more than 50, and a family history of melanoma. This syndrome is associated with a wide variety of other tumour types and may be among the most common mutations in human cancer. Besides melanoma, families with CDKN2A mutations appear to have an increased risk of exocrine pancreatic cancer. This is more specifically in families with CDKN2A mutations that impaired the function of p16. Screening for melanoma in those susceptible to FAMMM should begin at age 10 with a baseline total body skin examination including scalp, oral mucosa, genital area, and nails, as family members may develop melanoma in their early teens.

There are currently no successful screening methods to detect early, operable pancreatic carcinoma. The anatomic location of the pancreas and late-presenting, often non-specific, initial symptoms of pancreatic cancer hinder the ability to detect masses at an early, resectable stage. However, promising results have been seen with the use of endoscopic ultrasound (EUS) and endoscopic retrograde cholangiopancreatography (ERCP) in clinical trials evaluating high-risk families. These tests are not currently considered standard of care, and patients and families at high risk for a pancreatic cancer, such as those with FAMMM syndrome, should be referred for consideration of clinical research screening programs.

Minimal invasive surgery

Laparoscopy

Laparoscopic surgery is a minimal invasive surgical modality that has increased its acceptance in oncological surgery in the last decades in some surgical fields. It is a keyhole technique that requires small incisions and the use of a laparoscope. To work with the laparoscope, a pneumoperitoneum is necessary to elevate the abdominal wall to create viewing and working space; to obtain this, carbon dioxide is insufflated intra-abdominally. In 1902, the first laparoscopic procedure was reported in dogs and in 1910 in humans. Prior to 1990, the only specialty performing laparoscopy regularly was gynaecology. In general surgery the laparoscopic cholecystectomy was the first accepted procedure. Conceptually, the laparoscopic approach is intended to minimize post-operative pain and reduce recovery times, while maintaining an enhanced visual field for surgeons. Disadvantages are loss of tactility, range of motion, poor depth perception, and a longer learning curve and operation time. Late conversion to open surgery is mostly due to complications such as bleeding or perforation and can bring the patient into a worse position than open surgery. From the societies (e.g., EAES) strict recommendations have been made to train professionals in laparoscopic techniques in order to optimize surgical quality. Due to improved patient outcomes in the last two decades, laparoscopic surgery has been adopted by various surgical subspecialties including gastrointestinal surgery, gynaecologic surgery, and urology. Based on numerous prospective randomized controlled trials, the approach has proven to be beneficial in reducing post-operative morbidities such as wound infections and incisional hernias, and is now deemed safe when applied to surgery for cancers such as cancer of the colon. Moreover, it renders similar outcomes with respect to overall survival and disease-specific survival. It should be taken into account that patient selection remains crucial; obesity, tumour extension to other organs or vessels, and previous abdominal surgeries increase the complexity or impossibility of laparoscopy [2–4].

Laparoscopic and/or thoracoscopic techniques have been developed for oesophageal cancer surgery, colon cancer, lung cancer surgery, rectal cancer surgery (confined to the rectal wall T2–T3 a/b), liver surgery, pancreas resection, adrenalectomy, nephrectomy, and even for breast cancer and small thyroid cancers.

Newer techniques include single incision laparoscopy (SIL) only using one port to execute the surgical procedure. Robotic approaches are used for prostatectomy and pelvic lymphadenectomy in expert centres and are ergonomically friendly for the surgeon but are still costly. Natural orifice transluminal endoscopic surgery (NOTES) is an experimental surgical technique whereby 'scarless' abdominal operations can be performed with an endoscope passed through a natural orifice (mouth, urethra, anus, etc.), then through an internal incision in the stomach, vagina, bladder, or colon, thus avoiding any external incisions or scars. This is not in widespread use yet.

Local treatments

There are many local treatments for early or palliative for advanced and borderline resectable cancer, usually at a risk of being less safe or not treating micrometastases in locoregional lymph nodes. Many techniques are still experimental and there is little hard evidence to promote them; expert centres could be consulted for advice.

TEM rectal cancer

A minimally invasive procedure called transanal endoscopic microsurgery (TEM) is indicated for removal of benign or premalignant rectal tumours and early-stage rectal cancers (T1). A full thickness excision is performed from the rectal wall and the mesorectum with the draining lymph nodes left in situ. Of course, there are many benefits of minimizing rectal cancer surgery, such as no abdominal scars, better sexual and urinary function, and less surgical complications.

However, it should always be noted that unknown lymph node metastasis (in pT1 approximately 8%) are not treated; TME surgery is recommended when the pathology report reveals high-risk features such as lymphovascular invasion, tumour stage more than T1sm2, poor differentiation grade, or incomplete resection. Follow-up is recommended frequently with endoscopy, CEA, and additional imaging and/or biopsies in case of symptoms.

Polypectomy, ESD, EMR, and EMA in colon cancer

For early colon cancers, advanced techniques such as endoscopic mucosal resection (EMR), endoscopic submucosal dissection (ESD), or even endoscopic mucosal ablation (EMA) are available. However, there are no data currently available showing long-term safety and equivalence with regards to oncologic outcomes. The main hesitation in using these endoscopic techniques for early colon cancer is that submucosal cancer invasion and/or lymph node involvement cannot be endoscopically recognized. Early colon cancer is defined as cancer that has progressed in the mucosa and/or submucosa, with or without lymph node involvement. Early colon cancer generally has a very good five-year prognosis and is traditionally treated surgically. Assessing the risk of lymph node metastasis should include a pathology exam with description of histological features such as moderate/poor differentiation, lymphatic invasion, positive margins, and depth of submucosal invasion. In contrast to their advice on surgical resection, expert groups are debating that surgery for early colon cancer without lymph node metastasis is unnecessary with respect to post-operative risks.

RFA in liver surgery

Local treatment in liver surgery has been developed to avoid large resections with its accompanying morbidity for borderline or unresectable disease. Of course, not all tumours or patients are suitable for these approaches. Because cryosurgery, using liquid nitrogen, or a probe that is very cold, to freeze and kill cancer cells is not being widely performed, this section will focus on RFA. RFA can be carried out percutaneously or during laparotomy. In RFA, a needle is inserted into the liver, usually under the guidance of ultrasonography or CT. Once it has been placed within the tumour, a rapidly alternating current (radiofrequency energy) is produced that destroys the tumour. It cannot be used for very large lesions or lesions that are on top of blood vessels. It can potentially leave small islands of remaining tumour cells, and is therefore regarded as a second-best choice after primary resection.

Laser surgery

Laser surgery uses a powerful beam of light, which can be directed at specific parts of the body, without making a large incision, to destroy cancer. For example, in the digestive system, a laser is often used to remove colon polyps (e.g., EMA). Laser surgery has been used to treat abnormal tissue, carcinoma in situ, and early cancer of the cervix, vagina, and vulva, to name a few.

Hyperthermic Intraperitoneal Chemotherapy (HIPEC)

Isolated peritoneal carcinomatosis in advanced colorectal cancer represents a special biologic entity with poor prognosis with systemic chemotherapy alone or with no intervention. Current data, including one randomized controlled trial and numerous prospective and retrospective studies, suggest a role for colorectal surgery and HIPEC in a multimodal treatment regimen that may improve PFS as well as OS for selected patients with peritoneal carcinomatosis. In the randomized trial, after a median follow-up of 21.6 months, the median survival was longer in the experimental arm than in the control arm (22.4 months versus 12.6 months, hazard ratio 0.55, 95% CI 0.32–0.95). The mortality rate was 8% in the HIPEC group, and the most severe toxicity was due to small intestinal leakage and sepsis.

HIPEC can be performed with acceptable morbidity and low mortality in specialized centres. Nevertheless, pre-operative patient selection is crucial for the success of the combined treatment concept. Main selection criteria are good general health status, limited intraperitoneal tumour dissemination (peritoneal cancer index, PCI < 20), limited small bowel disease, and no extra-abdominal metastasis [11].

Perioperative care

Fast track surgery

Fast track protocols in surgery were designed to minimize surgical complications by providing a multimodal approach, implementing as far as possible evidence-based tools to achieve early recovery after major surgery [12, 13]. This was first carried out for patients undergoing colectomy. ERAS (enhanced recovery after surgery) focuses on the following elements: improving patient education, reducing pain, reducing nausea and vomiting, stimulating normal diet, and getting the patient out of bed as soon as possible. Implementation of ERAS has resulted in a large reduction in length of hospital stay (see http://www.erassociety.org/). It takes teamwork from the patient, surgeon, anaesthesiologist, general practitioner, and nurses to make such a protocol work.

Surgical checklists and safety

Perioperative surgical checklists are mandated by many hospitals, as determined by the reduction in morbidity and mortality seen as a result of the use of the World Health Organization's Surgical Safety Checklist. Implementation of checklists has been associated with a reduction in surgical complications and mortality in hospitals with a high standard of care [14, 15].

Curative and palliative surgery

Curative surgery

Surgery gives the best chance to cure cancer; this means that all tumours should be removed during surgery. Curative surgeries remove partial or total organs of origin and in some cases the draining lymph nodes that might contain (micro)metastases.

Palliative surgery

The aim of palliative surgery is mainly to reduce pain or symptoms for the patient. The surgery may not necessarily aim to eradicate any or all cancer tissue in the patient. In fact, palliative surgery is often deemed to be worthwhile and feasible by cancer specialists when the disease is not responsive to any type of curative treatment. A successful palliative surgery may not only make the patient's life more comfortable, but may in some cases also prolong the patient's life. Palliative surgery which removes cancer tissue is recorded as cancer-directed surgery. Palliative surgery, such as a nerve block procedure to interrupt pain signals in the nervous system, or a stent placement to alleviate obstruction, etc., which does not remove cancer tissue is recorded as non-cancer-directed surgery. Deviating stoma formation can be done through a small incision to decompress an ileus due to obstructing colon or rectal carcinoma. A double bypass is an example of a palliative procedure ensuring the passage of food while a pancreatic cancer or duodenal cancer is obstructing the proximal intestines.

Locally advanced disease

In locally advanced disease, it is always advisable to ensure that a patient is sent to the appropriate referral centre for this specific cancer. The opportunities to be cured by surgery are higher in expert high-volume centres. In expert centres, experimental studies might offer the up-front non-surgical therapies to downsize the tumour and result in as much organ-sparing surgery as possible.

Local relapse and salvage treatment

In breast cancer, local recurrences can be operated by excision, salvage mastectomy, or salvage axillary clearance. Recurrent rectal cancer can be operated by wide excision and stoma formation, which can be very large resections with concomitant blood loss and post-operative recovery, yet still offering the best possibility for secondary cure. If a peri-anastomotic recurrence happens in colon cancer, this has a relative better prognosis than, for instance, peritoneal metastases. Salvage treatment should always be discussed in multidisciplinary teams and/or referral centres should be consulted to obtain the best treatment strategy.

Timing of Surgery

Upfront Surgery vs up-front systemic therapy vs up-front radiation or CRT therapy

Over the past decades, additional treatments for cancer have been introduced. Overall, surgery remains the cornerstone of cancer treatment in most cases. The addition of radiotherapy, chemotherapy, and the combination of radiotherapy and chemotherapy, has been investigated in many cancer types. The timing of these additional treatments has been under discussion.

In case of non-metastatic rectal cancer, patients could receive pre-operative radiotherapy or pre-operative chemoradiation, depending on the size and location of the tumour, whether the circumferential margin is threatened, and the possible malignant lymph nodes found on imaging. Pre-operative radiotherapy or chemoradiation is preferred over post-operative treatment, since the toxicity, local control, and compliance are better when pre-operative treatment is given. When pre-operative radiotherapy is chosen, the timing of the surgery to follow it is investigated at this point. In the Dutch TME trial, pre-operative radiotherapy is followed by surgery within ten days of the first fraction of radiotherapy [16, 17]. Several studies have suggested that an interval of more than three days between radiotherapy and surgery could lead to worse survival. The ongoing Stockholm III trial is investigating whether delayed surgery, with an interval of four to eight weeks between radiotherapy and surgery, is feasible, safe, and introduces downstaging of the tumour [18]. Pre-operative chemoradiation is preferred when downstaging of the tumour is needed. The timing between pre-operative chemoradiation and surgery is still under discussion, as it seems that the longer the interval, the more downstaging is achieved. In certain cases, this could lead to pathological complete responses, which are associated with excellent long-term outcome.

In breast cancer, adjuvant therapies for patients with a higher risk of recurrence are chemotherapy, hormonal therapy, or targeted drugs like trastuzumab. Tumour grade, stage, hormone receptor status, Her2 status, and lymph node status are factors involved in the decision for additional therapies. Many randomized trials report equivalent outcomes of neoadjuvant systemic therapies in comparison with adjuvant [19, 20]. The main benefit is to downsize the tumour and make it possible to discuss breast-conserving therapy (wide local excision combined with radiation therapy).

Specific procedures in surgical oncology

Sentinel node

In breast cancer, it has been established that the sentinel node (SN) procedure is very relevant for lymph node staging in clinically non-metastasized patients and plays a crucial role in the decision tree for initiation of adjuvant therapy. Even in patients with a biopsy of DCIS (ductal carcinoma in situ), a sentinel node is advised in the following situations: indication of mastectomy due to the large size of the DCIS, a small DCIS with risks of harbouring an invasive part such as in patients younger than 55 years of age, solid lesion on mammogram, or moderate or poor differentiated DCIS in the biopsy.

A sentinel node in melanoma is recommended for nodal staging of patients without clinical apparent metastases and in melanoma thicker than 1 mm. The recommendations are derived from studies showing no clinical relevance if there are already metastases because of a median survival of seven months, and in thin melanoma a very low incidence of lymph node metastases. From Dutch studies, five-year survival appears to be about 90% if the sentinel node is negative, in contrast to 65% when it is positive in clinically non-metastasized patients. It has a clear relevance in nodal staging in clinically non-metastasized melanoma. The evidence for additional lymph node dissection when the SN (sentinel node) is positive is still under investigation; no or weak differences in survival or disease-specific survival are currently described.

Two recent meta-analyses have acknowledged that a sentinel node procedure in patients undergoing resection for colorectal cancer has low sensitivity and little clinical relevance.

Role of the Multidisciplinary Teams (MDT)

Due to the difficult biology of cancer and the many specialties involved in the treatment, potentially suboptimal care could be given quite easily. In an ideal situation, patients would receive optimal treatment from an expert specialist, coordinated by one case officer. Over the past two decades, there has been growing recognition that shared decision-making was needed for optimal cancer care. Therefore, multidisciplinary care has become an integral part of cancer care in many Western countries. MDT meetings were established to ensure that care delivery is consistent with the best available evidence. The presence of different specialists means that consideration of the full range of therapeutic modalities is available for each patient. There is clear evidence that MDT meeting result in changes in patient management. And although limited, evidence indicates that MDTs are associated with improved patient outcomes for many cancer types, probably due to influencing various aspects of patient care. These factors include adherence to guidelines, nurse education, increased surgical volume and experience, and improved interdisciplinary working. Although multidisciplinary care is considered standard practice in many countries, access to such care still varies among countries and hospitals. The importance of good communication cannot be overstated, and is likely to become more rather than less important as cancer is determined to be a greater number of biomarker-determined disease subtypes. Both the European CanCer Organisation (ECCO) and the European Society of Surgical Oncology (ESSO) have as part of their mission the encouragement of true multidisciplinary cancer care.

Cancer management in Europe

Reflecting on cancer management in Europe, the EUROCARE-4 (EUROpean CAncer REgistry-based study on survival and CARE of cancer patients; http://www.eurocare.it/) analysis showed improved survival for all cancers and for all major cancer sites [21]. To collect good data on cancer management is demanding and time-consuming; however, these data are imperative to generate information on the quality of care. To give insight on variation between hospitals or countries, it is important to define best practices to learn from and to study subgroups of patients, such as the elderly, who are excluded from or underrepresented in randomized controlled trials. Large epidemiological research has been providing us with crude annual incidences and outcome comparisons of almost all cancers in Europe. The limitations of these studies are that they rely on completeness and quality of data from the available sources, mostly national cancer registries, and that not all countries have a national coverage of registry of patients with cancer.

Striving for multidisciplinary care is the vision of ECCO and ESSO. This means integrating the expertise and insights of the different professions and stakeholders that constitute the oncology community to achieve the best possible patient outcomes—taking into consideration the trends that impact on cancer, the complexity of the disease, and the specificity of each cancer patient.

A lot has changed in quality assurance in surgical oncology in many European countries as a result of introducing quality-control indicators and delivering voluntary or obligatory registries and audit structures. The improvements in cancer care have been spectacular. The next part of the chapter is dedicated to European surgical registries and audits and their results.

A history of cancer registries

Since the beginning of the twentieth century, cancer registries have provided population-based, comparative survival statistics for cancer patients. The task of the first population-based registry in Denmark, which started in 1943, was outlined as the collection of data in order to serve as a basis for individual follow-up of patients. The goal was to obtain reliable morbidity statistics with a view to an accurate estimate of therapeutic results and variations in the incidence of malignant neoplasms. From the mid-1940s, cancer registries were started up in a number of countries.

In 1989, EUROCARE was funded, based on collaboration between the Istituto Nazionale Tumori (Milan, Italy), the Istituto Superiore di Sanità (Rome, Italy) and a large number of population-based cancer registries from 12 European countries. EUROCARE is a cancer epidemiology research project on the incidence and survival of European cancer patients. It aims to describe any differences between populations, and if so, how large they are, how they evolve and how reliable the survival estimates are [22]. This project was the first to compare cancer survival rates among populations.

A comparison of the survival of patients diagnosed with cancer among different populations may be profoundly difficult to interpret, as longer survival may depend on either later death or earlier diagnosis (adding 'lead time'). In order to compare survival rates among different registries, it is necessary to have standardized information on disease stage at diagnosis, on the actual diagnostic procedures used for staging, and on treatment. These items are usually not available from population-based cancer registries.

Quality assurance in surgical oncology

Currently, quality assurance is a hot topic, although it is relatively new in surgical oncology. Audits have achieved excellent results at the national level, but differences between countries remain and cannot be easily explained. To reduce those differences by identifying and spreading best practice, ECCO and ESSO have initiated an international, multidisciplinary, outcome-based quality improvement programme, the European Registration of Cancer Care (EURECCA). EURECCA was founded in 2007 for rectal cancer; now, there are subgroups for colon and rectal cancer, breast cancer, oesophago-gastric cancer, and hepato-pancreatico-biliary cancer.

Surgical outcome showed large variation among centres. Surgery is steadily shifting from being a craft to becoming a transparent and well-defined skill. Training, specialization, knowledge, teamwork, and continuous quality improvement are considered mandatory for surgeons of the twenty-first century.

Since the beginning of the 1990s, several surgical audits have been set up in Europe. Initially, most of the audits were for rectal cancer, because of its poor outcome and variation both among hospitals and individual surgeons. Using audits, the Nordic countries

were able to improve outcome in rectal cancer patients and showed that this process reduces healthcare-related costs.

Registries and audits of cancer in Europe

In the last two decades, there have been several European surgical audits. An audit is a quality instrument that collects detailed clinical data from different healthcare providers, which can be adjusted for baseline risk and subsequently fed back to individual hospitals or surgeons. In this way, 'best practices' can be identified, communicated, and broadly adopted.

Rectal cancer surgical audits

Most audits were initially set up for rectal cancer, as mentioned above, because of poor outcome and remarkable variation among hospitals and individual surgeons. Later, most rectal cancer audits expanded with the registry of the outcomes of colon cancer. Between 1993 and 2009, eight surgical (colo)rectal audits were performed in Europe. The oldest is the Norwegian Rectal Cancer Project started in 1993. Outstanding results were achieved after four years: the proportion of applied TME surgery increased from 78% to 92% and the local recurrence rate dropped from 28% to 7%. Moreover, they proved to be very cost effective. Currently, the audit is called the Norwegian Colorectal Cancer Project because colon cancer has also been incorporated. After the excellent results of the Norwegian Rectal Cancer Project, several other countries initiated audits on (colo)rectal cancer, including the Swedish Rectal Cancer Registry, the Danish Colorectal Cancer Database, the National Bowel Cancer Audit Programme (NBOCAP) from the UK, the International Quality Assurance in Colorectal Carcinoma from Germany, Poland, Italy, and Lithuania, the Project on Cancer of the Rectum (PROCARE) from Belgium, the Spanish TME project, and the Dutch Surgical Colorectal Audit.

EURECCA colorectal aims to improve care for patients with colorectal cancer in Europe by forming a European platform for sharing the data of registries and audits in order to be able to learn from them, and to form a core dataset in Europe. More information can be found at www.canceraudit.eu.

Breast cancer audits

Several projects have shown that the quality of breast cancer care can be improved by auditing as well. To illustrate, EUSOMA (the European Society of Mastology) is the organization representing breast cancer specialists in all disciplines in Europe. It promotes dedicated breast units by accreditation/certification, covering all aspects of breast cancer care, and developing guidelines and recommendations in order to form a basis for auditing [23].

Volume of procedures and outcome

It has been suggested that preventable surgical deaths may have been related to inadequate experience with the surgical procedures involved [24]. In the absence of better information or criteria that describe surgical quality, task forces aiming to improve surgical safety and surgical quality have embraced the volume norm. High-risk elective procedures in high-volume centres should reduce the risk of operative death [25].

An inverse relationship between volumes of surgical procedures per hospital and surgical outcome is at present relevant to many surgical cancer treatments. Hospitals are divided between high and low volume depending on the procedure. The surgeon and procedural volume have an effect on post-operative mortality and long-term survival.

Ever since the manuscript of Birkmeyer et al. [25] was published, a large number of studies on the effect of hospital volume on outcomes after gastrectomy have been published. Nowadays, centralization of gastric cancer surgery is implemented in the UK, Sweden, Finland, Denmark, Sweden, and the Netherlands. As in the Netherlands, oesophagectomies had already been centralized before; there will be also be upper gastrointestinal (GI) centres in other countries. This enables the formation of dedicated upper GI MDTs. Beside upper GI cancers, many other cancer surgery types are currently being centralized, such as pancreatic cancer surgery, hepatic surgery, breast cancer surgery, and colon and rectal cancer surgery.

Using hospital volume as the sole basis for referral to improve outcome has been criticized. Low-volume hospitals can have excellent outcomes, and vice versa. Studies on the surgeon's volume have been performed, but sometimes with contradictory results. It has been suggested that centralization combined with auditing is more effective in comparison with centralization alone. With auditing, providers of care are being monitored, and their performance is being benchmarked against others.

Shared decision-making

In cancer management, it is important that all steps are carefully discussed with the patient and that the physician listens and takes notice of the patient's preferences in the treatment. In 'shared decision-making' (SDM) clinicians and patients make decisions together using the best available evidence. This sounds logical, but not all surgeons have been trained to elucidate patients' preferences in the same session that diagnosis and treatment are discussed or even when the operation is scheduled. It has been postulated that physicians do not always choose according to the patient's preferences but substitute their own views [26]. In a study of 150 patients with prostate cancer facing radiation therapy, physicians were asked to judge which patient would choose which dosage if given the possibility of choosing between two dosages of radiation. Patients were provided with a decision aid (DA), clearly showing all the benefits and risks of each dosage scheme. Physicians proposed the preference that the patient would choose and then the actual patient preferences were compared. Physicians tended to underestimate the patients' decision-making preferences and made the assumption that patients would choose the less toxic treatment [26]. It might not just be the patient who needs counselling but also the physician who needs to be modernized in information flow to and from the patient.

In order to illustrate this important issue, given that we know that breast conserving therapy and mastectomy result in similar long-term outcomes, we raise the question as to whether patients diagnosed with early breast cancer, given the choice of breast-conserving or mastectomy, would make a high-quality choice [5]. Women diagnosed with breast cancer were given up-to-date, complete information about the risks and benefits of breast-conserving surgery and mastectomy in a controlled, supportive setting. After going through DA, the women completed exercises in explicit values clarification. Women were afterwards seen by a surgeon who endorsed a shared and informed

decision-making process. Collins reported high knowledge scores, significant associations between patient values and treatment choice, and low decisional conflict [27]. In this study, a third of the women chose mastectomy, the more radical and potentially mutilating procedure [27]. Self-possession and peace of mind as a result of breast removal and having avoided radiation were rated significantly higher by participants choosing mastectomy. Other features and outcomes, such as avoiding local recurrence, did not differ between those choosing mastectomy over breast-conserving surgery.

A recent Cochrane meta-analysis concluded that using DAs improves the knowledge of patients about the intervention options relating to their disease and reduces decisional conflict [28]. Implementation of a web-based DA for breast cancer surgery increased patients' readiness to make a decision about their surgery, and was reinforced by having the surgery option at hand [29]. For an example of a website with a DA relating to surgery of the breast in breast cancer, see www.bresdex.com.

CHAPTER 20

Practice points for radiation oncology

Annekatrin Seidlitz, Stephanie E. Combs, Jürgen Debus, and Michael Baumann

Introduction to radiation oncology

Radiotherapy is an indispensable treatment modality in modern oncology with curative potential in a wide spectrum of malignancies. About half of all cancer patients today receive radiotherapy during the course of their disease either with curative or palliative intent. The proportion of cancer patients treated by radiotherapy is steadily increasing as a consequence of outcomes which are equivalent to surgical approaches in several tumours, increased use of function-preserving approaches in oncology, better access to radiotherapy, and other factors. Radiotherapy is often combined with surgery or cytostatic drugs; increasingly, combinations with molecular targeted drugs are being introduced in clinical practice. In contrast to systemic treatment approaches, curative radiation therapy aims to obtain permanent local or locoregional tumour control by eradicating all macroscopic or microscopic tumour in the irradiated volume. Because of the spatial distribution of dose, radiotherapy is highly dependent on imaging information. Throughout its history radiotherapy has been an interprofessional approach integrating clinical oncology, medical physics and technology, and radiation biology. Progress in all of these fields has contributed to today's high efficacy of radiotherapy [1]. Technological developments in treatment machines, imaging, and information technology for rapid treatment planning allow delivery of highly conformal radiation dose distributions which cover the tumour and spare surrounding normal tissues. These technologies have been rapidly translated into clinical practice. Radiotherapy regularly uses model-based approaches to individualize treatment based on imaging information and radiobiological data on tumour control (TCP) and normal tissue complication (NTCP) probabilities. This personalized radiation treatment is expected to be enhanced in the coming years beyond anatomical and clinical data by relevant biomarkers, particularly bioimage-based information.

The scope of this brief chapter cannot be to give a comprehensive overview of the foundations and practice of radiooncology; excellent textbooks are available for this [2–5]. Rather, we focus on some important basic principles, practice points, and developmental strategies which are of relevance to the non-radiation oncologist which might be of use for discussions in the multidisciplinary setting.

Aim of radiotherapy and therapeutic window

The aim of radiotherapy is to achieve uncomplicated local or locoregional tumour control by permanently inactivating all cancer cells in the irradiated volume without inducing severe normal tissue reactions. This concept was laid out by H. Holthusen in the 1930s [6]. After variable threshold doses, steep and usually sigmoid-shaped increases of TCP and NTCP are observed. If, for a given radiation treatment technique and schedule the TCP curve is located left of the NCTP curve, uncomplicated local tumour control initially increases, with the effect on the tumour reaching a maximum before it falls again when the NTCP also increases. The therapeutic window depends therefore on the relative position of the TCP and NTCP curves as they reflect the overall radiosensitivity of a given tumour versus the surrounding normal tissue. The aim of clinical radiotherapy is to prescribe for an individual patient a dose close to the maximum of uncomplicated local tumour control. This almost always means that some risk of severe normal tissue reactions has to be accepted, which has important implications for informed consent discussions and for follow-up of patients after treatment. The aim of research in radiation oncology is to broaden the therapeutic window by either increasing the radiosensitivity of tumours or by making normal tissues more radioresistant or, optimally, both.

Radiation effects on tumours

Radiotherapy given alone or in combination with drugs is highly effective in permanently inactivating cancer stem cells (CSC). CSCs are defined functionally as cells that have the ability to expand and form a recurrent tumour after high dose irradiation [7]. Cancer cells as well as normal cells can be radiation-inactivated through several mechanisms. Generally speaking, unrepaired or not correctly repaired DNA damage is underlying radiobiological radiation-induced cell kill. Of particular importance is the presence of oxygen directly at the time of irradiation, as free oxygen may fix DNA damage which otherwise is scavenged. Thus, cells irradiated in the presence of oxygen are more sensitive than cells irradiated under hypoxic conditions (oxygen effect) by a factor of approximately three. This effect is clinically highly relevant as many tumours

contain a large proportion of hypoxic cells [8]. As DNA damage frequently occurs in every cell of the body, different efficient repair mechanisms have evolved during evolution (see Chapter 9 'DNA Repair after Oncological Therapy' in this volume). Unrepaired DNA double-strand breaks or clusters of such damage are considered to be the most important DNA damage leading to cell death after radiotherapy. The leading mode of radiation-induced cell death is mitotic cell death (or mitotic catastrophe) caused by severe chromosome damage which results in the inability of the cell to divide correctly in the next (or one of the next) M-phase of the cell cycle. Autophagy as well as direct radiation-induced cell necrosis play a minor role in the inactivation of non-haematological tumour cells. Direct cellular necrosis does not significantly contribute to radiation-induced cell kill, but may play a role as an unregulated process of cell destruction due to ischaemia and inflammation. Apoptotic cell death plays a major role after irradiation of haematopoietic and lymphatic neoplasm and some normal tissues but only a minor role in the majority of solid tumours. Radiation-induced senescence is one of the central mechanisms in normal tissue reactions like fibrosis, as will be explained later.

Permanent local control after radiotherapy is only achieved if all CSCs are inactivated by radiation or killed by the host (e.g., immune reactivity) or if surviving CSCs are remaining in a permanent dormant state [9]. If one or more CSCs survive irradiation and escape inactivation by the host, recurrence will occur. Radiobiological studies indicate that inactivation of CSC is an exponential function of dose and that after the high radiation doses typically applied in curative radiotherapy on average only few CSCs survive (see Figure 20.1A). This has important implications, as drugs which often have only relatively weak effects on CSCs may show significant anti-tumour effects when combined with radiation.

Selected key points of general importance for multidisciplinary oncology which can be derived from the radiation dose-effects on CSC include the following:

Geographic miss needs to be avoided

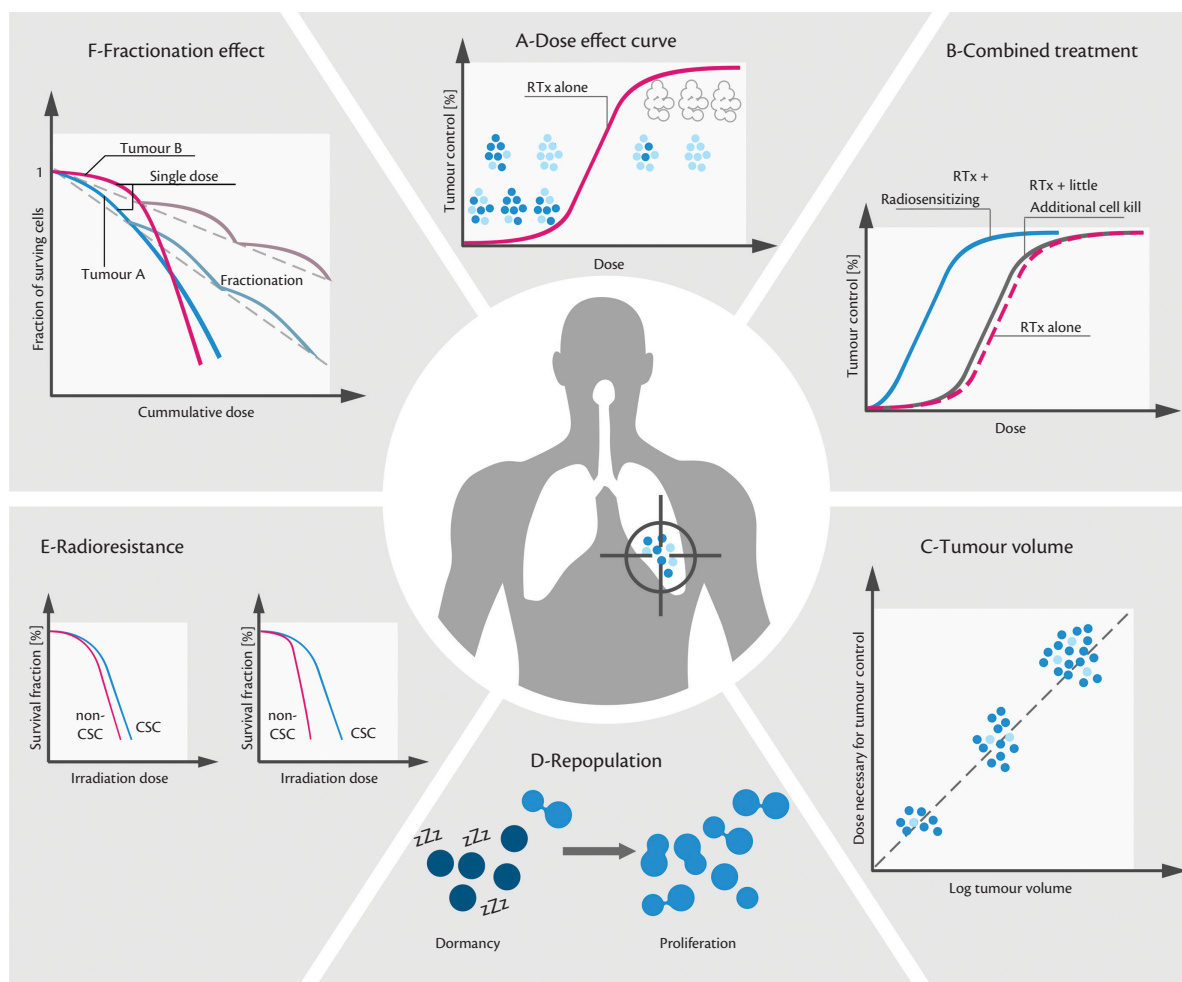
As a single surviving CSC may cause a recurrence and radiation dose response relationships in general are steep, it is of the utmost importance to ensure that all tumour cells are covered by the prescribed dose. While this may sound trivial, it certainly is not, given the severe limitations of imaging technologies to define small tumour extensions and microscopic disease, the motion of tumours and normal tissues during the treatment series and individual fractions, and changing anatomy during treatment (e.g., weight loss related decrease of fatty and soft tissues, tumour growth or regression). Much of the


Fig. 20.1 Radiobiological mechanisms underlying tumour control after radiotherapy. For explanation see text.

recent technological advances in image-guided radiotherapy, with increasing use of in-room imaging equipment, are aimed at minimizing these problems. It is also important to understand that scientific evaluation of local tumour control after radiotherapy requires detailed knowledge of the site of recurrence and the dose applied to this site (Figure 20.2). Only from such data can information on, for example, the radiosensitivity of a given tumour be derived.

The dose necessary for permanent local eradication of a tumour increases with the logarithm of the number of CSCs present in the tumour

In a given tumour site and histology, tumour volume is a clinically valid approximation of CSC number [9, 10]. Frequently, lower doses are therefore prescribed to areas with low tumour burden, such as subclinical or microscopic residual disease, compared with macroscopic tumours of different volumes. Because of exponential radiation cell kill, the dose levels needed to eradicate tumours of different volumes do not increase linearly but on a logarithmic basis (Figure 20.1C). This leads in clinical practice to relatively small differences in prescribed dose which, for example on tumour boards, are often found counterintuitive by oncologists not trained in radiobiological principles. A clinically particularly important example is macroscopic incomplete resection of tumour ('removal of bulk'). Even if 90% of the tumour is resected, the radiation oncologist has to apply almost or exactly the same dose to the residual tumour, as if it has not been resected, because logarithmic cell kill 90% removal corresponds generally to about 2 fractions of 2 Gy. Thus, while the effect of macroscopic incomplete resection is small or nil, there may be added unwarranted treatment effects on normal tissues from surgery and radiotherapy. Notable exceptions include situations where due to (incomplete) resection, the radiation volume can be importantly reduced or critical normal tissues, such as the optic nerve, can be excluded altogether from the treatment volume. It is obvious that such approaches require detailed interdisciplinary discussion and treatment planning before administering therapy. On the other hand, because of the steep dose-response relationships, relatively small escalations in total dose to macroscopic tumours may lead to significant increase of local tumour control rates. This is one of the reasons underlying the enthusiasm of radiation oncologists toward highly conformal precision techniques because these may allow escalation of the total dose without exceeding (volume-dependent, see below) normal tissue tolerance.

Regression of tumours after chemotherapy may not allow significant reduction of total radiation dose

Another important clinical practice point originating from the exponential cell kill of radiation is that partial regression of tumours after drug treatment, even if impressive, usually does not allow a significant reduction in the radiation dose to the tumour. In addition, regression after induction treatment may importantly disturb the relationship of volume and CSC number if the drugs applied are mainly effective on non-CSCs [7]. As there are currently no clinically suitable tests for CSC survival after induction treatment,
Fig. 20.2 Individual and scientific evaluation of treatment outcome after radiotherapy requires detailed knowledge of the site of recurrence and the dose applied to this site. 18Fluor-deoxyglucose uptake in recurrent tumours detected by PET-CT in two patients treated with identical radiochemotherapy for advanced head and neck cancer was superimposed to the original treatment plans. (*Upper panels*) 36 m after end of treatment of a T4 N2 carcinoma of the tongue a recurrence was detected within the former high-dose region. (*Lower panels*) 6 m after treatment recurrence was diagnosed in a region formerly spared from radiation for normal tissue protection in a patient with T2 N3 carcinoma of the piriformal sinus. While the tumour in the upper panels was resistant to the treatment, no statement on resistance is possible for the second tumour.

reduction of radiation doses based on regression after drug treatment may potentially jeopardize local control and should therefore be reserved for the clinical research setting. However, one potential advantage of induction chemotherapy is that the radiation target volume may be reduced after response to the drugs.

The dose necessary for local control of tumours of equal size depends on the density and radiosensitivity of CSC

It is well recognized that the radiosensitivity of different tumour entities differs widely. While lymphomas and germ cell tumours are often exquisitely radiosensitive, sarcomas and high-grade gliomas are usually highly radioresistant. The most frequent tumour entities, squamous cell or adenocarcinomas, range between these extremes [11]. In addition to these differences of radiosensitivity among tumour entities there is also vast heterogeneity of radiosensitivity between tumours of the same histology and size in different patients (intertumoral heterogeneity). Recent research indicates that even different subvolumes of the same tumour in the same patient may differ in radiosensitivity (intratumoral heterogeneity). It is obvious that knowledge of the radiosensitivity of individual tumours obtained from predictive tests before the start of treatment would provide an opportunity to better tailor the treatment to individual patients. Currently several such tests are under preclinical and clinical investigation. Radiobiological mechanisms that may underlie differences in radiosensitivity of tumours of equal volume include:

◆ CSC density/total CSC number to inactivate

◆ intrinsic cellular radiosensitivity of CSC and repair capacity of CSC during fractionated radiotherapy. Radiosensitivity of some CSC may differ from non CSC (Figure 20.1E–F)

◆ repopulation of CSC during treatment (Figure 20.1D)

◆ hypoxia and other microenvironmental factors may increase radioresistance of CSC.

Combination of irradiation with drugs will increase local tumour control only if the drugs kill additional CSCs or if they radiosensitize CSCs

Figure 20.1B illustrates that combination with radiosensitizing substances or drugs which directly kill CSC can shift the dose-response curve for local tumour control to the left, i.e. may achieve a higher curative potential for the same radiation dose. This can be clinically very important if the radiation doses applied cannot be further escalated because of risk of normal tissue complications and if at the same time no (or little) overlapping toxicities exist between the drugs and radiation for the dose-limiting normal tissue [12]. A large number of clinical trials have corroborated this strategy in the past decades, and simultaneous drug plus radiation treatment is today more the rule than the exception. Different mechanisms have been shown to underlie the improvement through combined modality treatment, most importantly independent kill of CSCs. However, direct cellular radiosensitization or more indirect mechanisms such as reduction of repopulation or the improved oxygenation status of CSCs may improve local control after combining radiotherapy with drugs. Further exploitable mechanisms of combined radiochemotherapy include spatial cooperation (i.e.

radiation to kill the macroscopic tumour bulk and chemotherapy to destroy micrometastases) or modification of treatment volumes in sequential approaches [13]. It should be noted, however, that particularly in the field of molecular targeted drugs many combinations with radiation have shown more pronounced tumour regression and longer growth delay but no impact on local tumour control. Such drugs obviously are effective on the bulk of non-CSCs in the tumour but ineffective at killing CSCs in the context of radiotherapy (Figure 20.1B). As it has been shown that novel drugs might also modulate the radiation response of normal tissues in both directions, it will be important carefully to investigate if the therapeutic window can be broadened by new approaches.

Radiation effects on normal tissues

The radiosensitivity of organs at risk depends on the types of tissue of which they are composed, their structure, function, pre-existing defects, and remaining potential for compensation. In addition, the different parameters of radiotherapy, including beam quality, total dose, dose per fraction, time interval between fractions, dose per week, overall treatment time, volume irradiation, and spatial dose-distribution, have significant impact on radiation effects in normal tissues (as well as in tumours). The challenge of radiation treatment planning is to minimize the risk of normal tissue damage while fully covering the tumour. To facilitate this complex and dynamic process the radiation oncologist utilizes data derived from detailed long-term observation of irradiated patients. Through the use of appropriate radiobiological and biostatistical methodology, data with high spatial resolution on normal tissue effects are correlated with dose-volume-fractionation parameters under consideration of clinical parameters, for example on pre-existing damage. From these data NTCP-curves are established that will then be used in a model-based approach in the radiation treatment planning of future patients. Although considerable inter-patient heterogeneity exists in the risk of a given normal tissue reaction after the same treatment, NTCP curves tend to be significantly steeper than TCP curves due to more extensive intertumoral heterogeneity. In general, it is useful to differentiate between two broad classes of normal tissue effects in radiotherapy, i.e. early and late effects.

Early radiation-induced normal tissue reactions

Early (or acute) normal tissue reactions occur during radiotherapy and usually resolve within weeks or a few months after treatment. The underlying radiobiological mechanism is the kill of stem or precursor cells with subsequent cell depletion in tissues with high turnover. Typical examples include haematological effects, mucositis, dermatitis, or hair loss. Incidence and severity and to some extent time of onset of early radiation-induced normal tissue reactions increase with:

◆ increasing total dose

◆ increased dose-intensity (weekly dose), i.e. short overall treatment times

◆ increased volume

◆ additional damage, e.g. simultaneous cytotoxic therapy

Early side effects cannot only importantly compromise the patients' wellbeing but may also cause treatment interruptions or dose limitation, thereby potentially decreasing the chance of local tumour control.

Intermediate late reactions

Radiogenic pneumonitis and demyelination disorders of the central nervous system such as Lhermitte's syndrome are examples of intermediate late side effects of radiotherapy. Radiobiological parameters are neither typical for early or late reactions. For example, the risk of pneumonitis increases after both short overall treatment times and high doses per fraction.

Consequential late effects

Consequential late effects are defined as late effects occurring after particularly severe early normal tissue reactions and, while follow the radiobiology of early normal tissue reactions, show the typical time course and morphology of late normal tissue reactions.

Late radiation-induced normal tissue reactions

In contrast to early effects, late normal tissue reactions occur months or even years after completion of radiotherapy, and are usually irreversible and often even progressive. Typical examples include subcutaneous or lung fibrosis, telangiectasia, necrosis, vascular stenosis, or damage of nerves and radionecrosis of CNS tissue. Fibrosis, for example, is often already fully expressed after one or few years, while coronary stenosis is an example of a late damage often occurring a decade or later after end of treatment. For a long time it has been assumed that, much as early normal tissue damage, late effects are caused by cellular depletion. Long turnover times of target cells were assumed to be the cause of clinical delay of damage. While this radiobiological mechanism remains part of the explanation of the clinical time course, it is now known that molecular events in cells, tissue and potentially even the whole organism cascade over long time intervals and contribute to the development of subclinical and overt late damage. Incidence and severity of late radiation-induced normal tissue reactions increase with:

◆ increasing total dose

◆ increased dose per fraction

◆ short time intervals between fractions

◆ increased volume

◆ additional damage, e.g. simultaneous cytotoxic therapy, trauma, or infection to irradiated tissue.

Today the radiation dose applied to the tumour is usually limited by the risk of late normal tissue reactions. Late NTCP can only be considered during prescription and treatment planning, which relies on continuous evaluation of detailed clinical data of patients treated in the past [14, 15].

Secondary malignancies

Ionizing radiation is well recognized as a potential cause of secondary malignancies. This issue is reviewed in detail by K. Trott in Chapter 17 'Radiation' in this volume.

Management of radiation-induced normal tissue effects

The management of side effects requires a high level of expertise. Early reactions need intense supportive care during radiation treatment to prevent treatment interruption or other unwarranted modifications of treatment. Patients with early normal tissue reactions should always be seen by their radiation oncologists who needs to review whether these are expected based on the treatment plan or, if unexpected, will re-review the parameters of radiotherapy. The radiation oncologist also recommends supportive measures to ameliorate the symptoms as well as for skin care, nutrition, and pain control during treatment. Suspected late normal tissue damage also needs to be evaluated by the radiation oncologist because such damage occurs only in irradiated volumes and usually follows closely the biological effective radiation dose distribution. Not infrequently, radiation damage is assumed by other healthcare professionals to underlie a new lesion or symptom in a patient previously treated by radiotherapy, while this is judged to be extremely unlikely after expert review, necessitating further diagnostic evaluation. Last but not least, the radiation oncologist should be involved in cases of further treatment such as surgery (or even surgical dental care) when this affects pre-irradiated tissues. This enhances the pre-therapeutic assessment of the risk of complications, and frequently allows modification of the procedure. Even on histopathological exam it is not possible to determine if a tumour has been induced by radiation. Therefore, suspected radiation-induced tumours should be reported to the radiation oncologist. As late normal tissue reactions are the main dose-limiting factor in modern radiotherapy, detailed follow-up of patients with analysis of outcome is the only option for the radiation oncologists to further refine model-based radiation treatment planning. Therefore, long-term follow-up of patients is established good clinical practice in radiotherapy, and in some countries even mandatory by law.

Utilizing radiobiological knowledge: dose per fraction, overall treatment time, volume

Fractionation in curative treatment is aimed at broadening the therapeutic window

Early in the twentieth century, both radiation treatment with a high-dose single irradiation or few fractions (German school) and treatments with a large number of fractions (French school) were in use in radiotherapy [1, 16]. Fractionated radiotherapy with 2 Gy per fraction and five fractions per week to different total doses (dependent on tumour entity, size and location) over several weeks became an international standard for many decades (so-called conventional fractionation, CF) and probably continues to be the most often applied fractionation schedule [17, 18]. Some centres, particularly in the UK and in Canada, applied somewhat higher doses per fraction to lower total doses in a shorter overall treatment time on a routine basis. Such schedules would be categorized as moderately hypofractionated and accelerated radiotherapy. Treatment with single doses or few fractions were reintroduced to curative clinical radiotherapy in the context of modern stereotactic ablative radiotherapy approaches. From a radiobiological point of view, fractionated radiotherapy has the following main advantages compared to single-dose treatments or radiotherapy with few fractions [19, 20]:

◆ Early normal tissue damage depends significantly on overall treatment time, that is on dose-intensity (dose per week). Thus, fractionated treatments over longer treatment periods lead to less early normal tissue reactions and are better tolerated by the patients. The downside is that CSC may repopulate the tumours during treatment which decreases the change of permanent local tumour control. Such repopulation has been demonstrated for a variety of tumours, most notably squamous cell carcinoma of the

head and neck, lung, and other sites but at a lower magnitude for prostate cancer, for example.

- Late normal tissue damage increases with increasing dose per fraction, while this is not the case for many tumours. Thus, application of higher number of low-dose fractions widens the therapeutic window between tumours and late-responding normal tissues, given that the time interval between the fractions is long enough (usually six to eight hours; for some tissues even more). The downside here is that there are notable exceptions among tumours. For example, the probability of locally controlling breast cancer and likely prostate cancer at the same total dose increases with dose per fraction; however, there might be significant intertumoral heterogeneity.

- Tumours often contain large proportions of hypoxic radioresistant CSCs while there is little or no hypoxia in surrounding normal tissues. Radiation first kills the sensitive cells but, dependent on dose and the proportion of hypoxic cells, these will dominate the overall effect. During fractionated radiotherapy, hypoxic tumour cells may reoxygenate, which would enhance the therapeutic effect.

Over the past decades modified fractionation schedules have been developed based on the following radiobiological principles.

Accelerated radiotherapy (AF)

AF entails application of the total dose in shorter overall treatment time. AF that counteracts CSC repopulation has been shown in a number of randomized trials (HNSCC and lung cancer) to increase locoregional control at the same total dose as used for CF, or to result in equivalent local tumour control at decreased total radiation doses. With AF, early normal tissue reactions are increased, while late normal tissue reactions are either constant or slightly increased. The latter may be the consequence of too short time intervals between fractions or very intense normal tissue reactions leading to consequential late effects. A very important lesson learned from AF clinical trials is that overall treatment times in curative radiotherapy should not be prolonged beyond prescription [21, 22]. Evidence is emerging that for concurrent radiochemotherapy the impact of overall treatment time on local tumour control is less than for radiotherapy given alone.

Hyperfractionated radiotherapy (HF)

HF is the application of doses per fraction less than 2 Gy (usually 1.1–1.3 Gy, two fractions per day). HF intends to decrease late normal tissue damage, thereby allowing an increase in the total dose to the tumour. This finds support in randomized trials on HNSCC; however, late normal tissue damage was usually not reduced to the anticipated extent. HF is often combined with AF, allowing an increase in total dose or a decrease in late normal tissue reactions and at the same time counteracting repopulation.

Moderate hypofractionation

In tumours with potentially high repair capacity, such as breast cancer, moderate hypofractionation, with, for example, 3 Gy per fraction, can achieve the same local tumour control at lower total dose, that is at a lower number of fraction. Whether this approach widens the therapeutic ratio is still under debate. Notably, moderate hypofractionation is usually also accelerated and thereby might

also counteract repopulation of CSC. Moderate hypofractionation has, among techniques, an emerging role in particle therapy.

Single-dose treatment or hypofractionation

Single-dose treatment of hypofractionation doses per fractions of 3 Gy or more is regularly used for palliative treatments where total doses are low (e.g., 10 x 3 Gy, 4 x 5 Gy, 1-2 x 8 Gy) and life expectancy is usually short. It also is used clinically on a routine basis for high-precision stereotactic radiotherapy to small tumours using high, so-called ablative doses.

High-precision conformal radiotherapy

As outlined above, all CSCs have to be inactivated to achieve local tumour control. For this the gross tumour volume (GTV) has to be identified and delineated in the treatment plan ([23, 24], see Figure 20.5D). The tumour position often changes during a single fraction (e.g., respiratory motion in lung cancer) or between fractions. This can today be taken into account by image-guided daily set-up, by motion control, or by 4D CT based treatment planning (iGTV). Furthermore, there are microscopic tumour extensions or microscopic deposits of tumour cells which cannot be depicted by imaging but need to be defined by statistical experience (e.g., from resection specimens) in the so-called CTV (clinical target volume: [23, 24], see Figure 20.5D). Further margins need to be added, for example, for physical beam characteristics and remaining geometrical and motion uncertainties (planning target volume, PTV: [23, 24], see Figure 20.5D). In earlier times, generous margins were applied to account for all these uncertainties. However, both early and late NTCP increases with increasing high-dose volume (and to some extent also with low-dose volume). Thus, high-precision radiotherapy, which conforms the dose to the tumour and spares as much sensitive normal tissue as possible, reduces the risk of normal tissue damage substantially and widens the therapeutic window as long as all tumour tissue is covered. Conformal radiotherapy has also allowed substantial escalation of the doses applied over the past decades, thereby significantly improving local tumour control rates.

Essentials of physics and technology in radiotherapy

Most radiation treatments are given as external beam radiotherapy (EBRT) using megavoltage photons. These are applied either using cobalt 60 units or, much more frequently today, linear electron accelerators (linacs). In linacs, high-energy electrons are stopped at a target, thereby generating X-rays with maximum photon energies typically from 4 to 20 MV. Particle therapy with protons, carbon ions, or other ions is emerging as a new clinical treatment modality, but currently is available at only a few centres worldwide. Figure 20.3 compares the depth dose distribution of different beam qualities. Electrons have an energy-dependent finite range in tissue and are therefore mainly suitable for treatment of superficial tumours where they can spare underlying deeper normal tissues. Megavoltage X-rays of different energies show an energy-dependent build-up region at the entrance surface before they reach their dose maximum at the depth of a few centimetres. This build-up reflects the energy transfer onto secondary electrons which is of great clinical importance for sparing skin
Fig. 20.3 Depth dose distribution of different beam qualities. For further explanation see text.

and superficial structures. Introduction of megavoltage beams into clinical radiotherapy between the 1950s and 1970s because of their depth-dose characteristics has been a major technological breakthrough compared to lower energy X-rays used before.

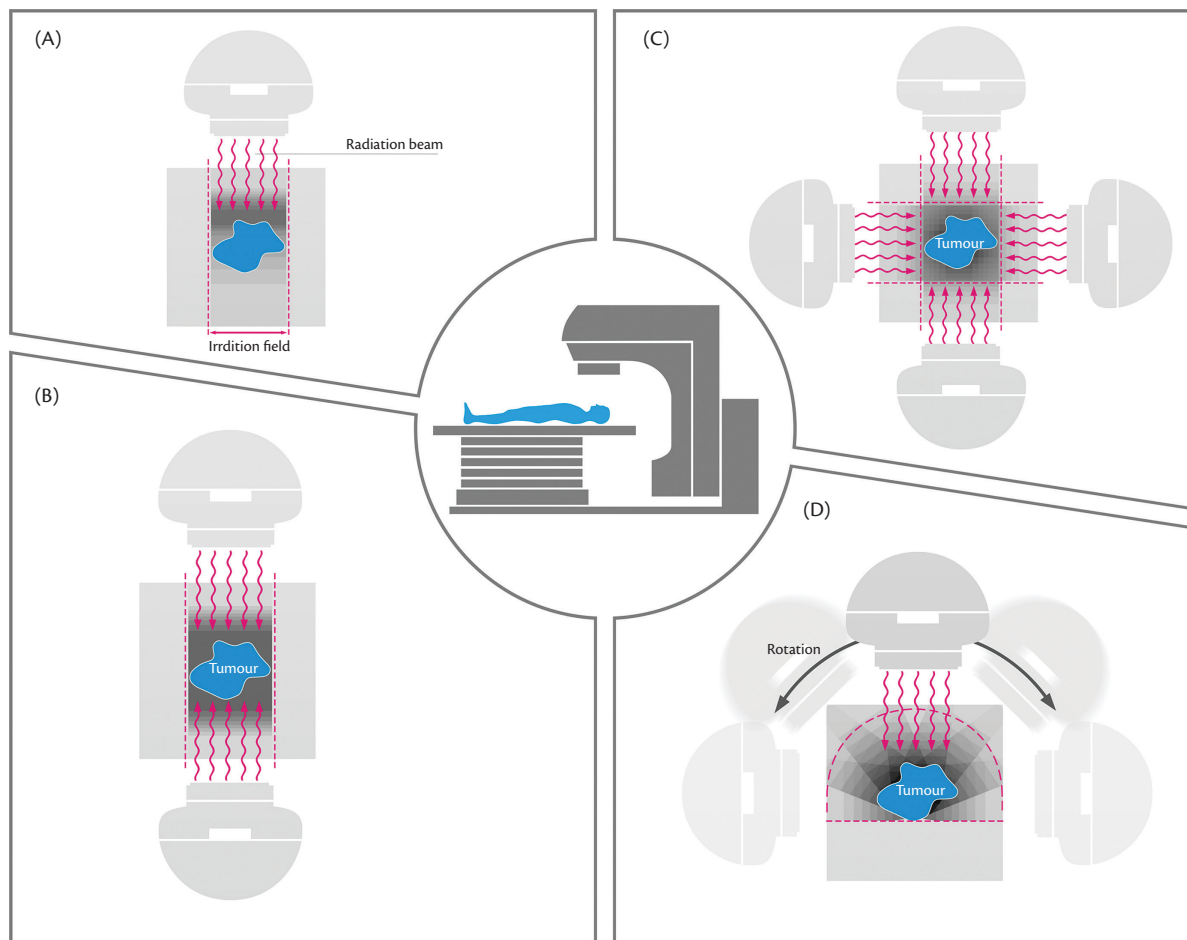
These orthovoltage X-rays did not have skin-sparing effects and therefore frequently resulted in dose-limiting skin reactions. For photon beams there is an energy-dependent decrease of dose behind the dose maximum. In contrast, protons and heavier ions have a lower entrance channel dose. At the end of the range, a large portion of their energy is deposited over a very small distance, resulting in the so called Bragg peak. The range of the particles in tissue and thereby the depth of the Bragg peak depends on the beam energy. Thus, compared to photon beams, particle beams show an inverted dose distribution which can be utilized for improved protection of normal tissues. For treatment with photons, normal tissues before and behind the tumour will always be irradiated to relatively high doses (Figure 20.4); this is not true for particle beams where dose to normal tissues behind the tumour can be effectively avoided. To spare dose to normal tissues while achieving relatively homogeneous dose distribution in the tumour, photon beams in clinical practice are almost always applied using several fields from different directions (Figure 20.4). This concentrates the high-dose region to the tumour (crossfire irradiation), but at the cost of smearing lower doses to larger volumes of normal tissues. Arc treatments extend this concept to an extreme by delivering the radiation practically through an infinite number of fields. Stereotactic body or brain radiotherapy also uses this concept, utilizing either arcs or a high number of fields to treat small tumours with very steep fall-off of dose to the periphery. To


Fig. 20.4 Dose distributions for different beam arrangements. With increasing number of treatment fields the conformality of the high-dose region to the tumour increases, while low doses are smeared to larger volumes.

achieve conformality while blocking tissue that is not intended to be irradiated from that direction, radiation fields are shaped by individual customized metal blocks or, today, by motorized multileaf collimators (MLC) which may assume essentially each shaping geometry (Figure 20.5A and 20.5B). As the leaves of MLC can be moved during treatment, it is also possible to modify the dose in the different segments of each field, which is utilized in intensity-modulated radiotherapy (IMRT), showing further improved conformality of photon beams (Figure 20.5C). Particle beams may be conformed to the target volume by passive scattering using scatter foils, collimating-apertures, range shifter and compensators to shape the field and spread out the Bragg peak. Alternatively, the Bragg peak may be actively scanned over the tumour volume allowing for intensity-modulated proton therapy. With usually only few fields, particle beams may achieve in several clinical situations advantageous dose distributions compared to even optimal photon therapy (Figure 20.6). In particular, the irradiated volume which receives low or intermediate radiation doses may often be significantly reduced and some structures may be spared altogether. This advantage explains the enthusiasm to introduce these beams more widely in clinical practice where they are currently already considered to be superior to photon beams in, for example, paediatric CNS cancers and tumours located at the base of skull. While the biological effects of protons are usually considered similar to those of photons (exceptions are currently under intense radiobiological investigations), heavier ions are biologically more effective, particularly in the Bragg peak, which may potentially gain further advantage of such beam qualities. However, as pointed out later in this chapter, many practical issues still need to be solved and appropriate clinical trials must be performed before the value of particle beams relative to photon beams may soundly be assessed for a wide range of tumour sites [25]. In contrast to EBRT, brachytherapy uses radioactive sources that are positioned directly into cavities (e.g., cervix cancer, see Figure 20.7]) or interstitially inserted in the tumour (e.g., prostate cancer). Brachytherapy delivers very high doses in the proximity of the source with a rapid fall-off to the periphery.

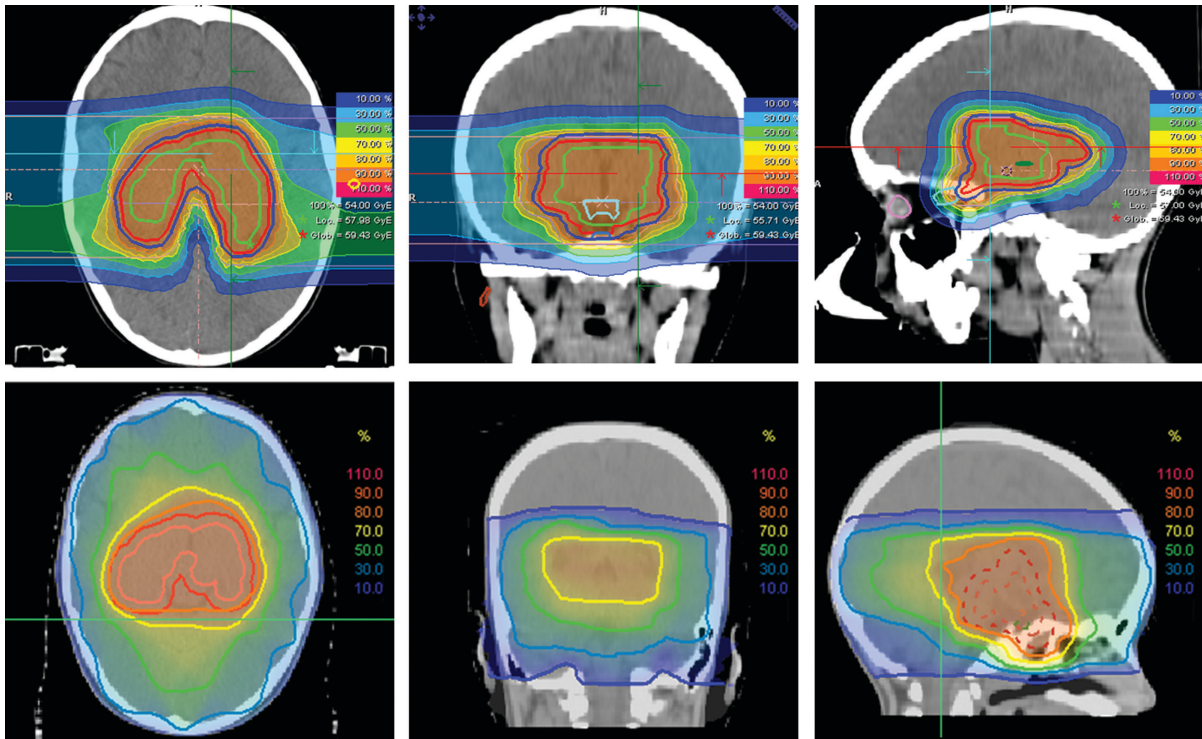
Treatment planning today is performed using fast computerized treatment planning systems (TPS). Target volumes and normal tissues at risk are usually defined on the basis of CT images in treatment position for conformal planning in three dimensions of the appropriate beam number, beam direction, beam quality,
Fig. 20.5 (A, B) Use of multileaf collimator (MLC) to conform the shape of the irradiation field to the shape of the tumour and to spare critical structures. (C) By motorized movement of leaves during irradiation, inhomogeneous doses within each field for intensity-modulated radiotherapy (IMRT) can be generated. (D) Target volume terminology according to the International Commission on Radiation Units and Measurements ICRU [23, 24].


Fig. 20.6 Comparison of the dose distribution of proton therapy with two entrance fields (*upper panels*) to intensity-modulated photon radiotherapy (IMRT) with seven entrance fields (*lower panels*) in a 5-year-old girl with brain stem glioma. Considerably larger volumes of normal brain are irradiated to lower doses with photon therapy than with proton therapy.

and energy. Vast advances have been seen over the past decades in developing very fast algorithms which allow the optimal dose distribution for each patient to be defined with great precision. Two-dimensional treatment planning or standard radiographic simulation can still be reasonable, especially in the palliative set-up.

Advanced treatment techniques of particular importance for current clinical practice include the following:

Intensity-modulated radiation therapy (IMRT)

Usually optimized by means of so-called inverse dose planning, IMRT may significantly enhance conformation of the dose to the target volume compared to standard forward-planned 3D conformal radiotherapy (3DCRT). It is particularly beneficial in tumours with complex irregular shapes, for example concave tumours located around critical normal tissues. IMRT is widely considered an established standard for cancers of the prostate, head, and neck or lung, for example. However, while the distribution of high doses is more conformal for IMRT, greater volumes of normal tissues are irradiated to lower doses compared to 3DCRT. Application of IMRT is therefore not generally advantageous to 3DCRT, and the optimal planning approach for specific sites and for the individual patient's anatomy needs expert assessment.

Simultaneous integrated boost (SIB)

IMRT allows the application of a SIB (higher dose to the GTV or suspected areas of radioresistance) in parallel to the application of

lower doses to areas which do not require such high doses (e.g., volumes of suspected microscopic disease). Whether this approach leads to improved clinical outcome (in particular with regard to late radiation damage) needs to be explored further.

Image-guided radiotherapy (IGRT)

State-of-the-art in-room imaging equipment allows higher precision of patient set-up and of radiotherapy application [27]. Inter- and intrafractional movement of tumours and normal tissues as well as changes in anatomy during treatment increase the risk of missing part of the target. Control of the geometric in-treatment position directly in the treatment room by on-board kV radiography or in-room CT and, very recently, also MRI significantly enhances the precision with which radiotherapy may be applied, allowing the use of narrower margins. Advanced radiotherapy approaches such as IMRT or SBRT require combination with IGRT to meet their potential. Motion control, for example by breath holding techniques, abdominal compression, jet ventilation under general anaesthesia, gating (turning the beam off when the target volume moves out of a predefined window setting) or tracking (the beam follows the moving tumour) may be used to further decrease margins in specific clinical settings. Four-dimensional CT may register images over time, thereby providing an exact time–space resolution of movement. This may be utilized by 4D treatment planning where integral GTV or CTV are defined as the basis for beam selection.

Stereotactic brain or body radiotherapy (SBRT)

Because of the steep dose gradient that can be achieved using SBRT techniques, small tumours or metastases may be treated to very high biological doses (ablative doses) in a single session or using few fractions. For ablative single-dose irradiation the term radio-surgery is also used. Usually the use of EBRT for SBRT is limited to a few small tumours or metastases. SBRT to ablative doses has been shown to be a valid alternative to surgical procedures, for example in early lung cancer or lung metastases. An emerging role for SBRT is treatment of oligometastases with locally curative doses.

Workflow of radiotherapy

Today radiotherapy is usually an integral part of an overall multidisciplinary workflow in oncology, with the radiation oncologist being involved at several steps. This is because Multidisciplinary Teams (MDTs) give superior clinical results. A simplified workflow is outlined in Figure 20.8.

Clinical assessment of the patient and steering of diagnostic procedures

It is the opinion of the authors of this chapter that each oncologist who treats patients, independently of discipline, should be educated expertly to steer basic workup and staging of patients, and that institutional guidelines or multidisciplinary clinics should ensure that this is performed to the same standards for all patients. Basic evaluation needs to be supplemented by specialist assessment, for example in making decisions on the applicability of radiotherapy or specific radiotherapy techniques.

Fig. 20.8 Synopsis of the standard workflow in radiation oncology.

Multidisciplinary case discussion in tumour boards

Discussions should be performed as soon as all necessary information on patient characteristic and tumour histology, localization, and stage is available and certainly before treatment is initiated. Further multidisciplinary discussions are frequently necessary after completion of individual treatment steps in the multidisciplinary workflow, for example after completion of neoadjuvant radiochemotherapy before surgery.

Informed consent discussion and prescription of radiotherapy

Before start of treatment planning, the radiation oncologist informs the patient in detail about the recommended radiotherapy procedure, its goal, and relevant early and late normal tissue reactions. Alternative treatment options should also be covered and, if appropriate, discussions with specialists from other disciplines should be offered. As the basis for the treatment planning process, the radiation oncologist prescribes the details of the radiotherapy schedule to the target volume (e.g., total dose, dose per fraction, overall

treatment time, beam quality) and specifies constraints of dose to critical normal tissues.

Patient set-up and imaging in treatment position

The patients need to be positioned for radiotherapy precisely, reproducibly, and as convenient as possible. The choice of the optimal treatment portals must anticipate later treatment planning and application, and endeavour not to compromise them. Various individual customized materials are used for positioning, such as thermoplastic masks for fixing the head, and body casts for immobilization of the trunk or extremities. Skin marking with robust stain or tattoos is essential to match the patient's position within the therapy room via a laser alignment system. CT imaging in treatment positions is performed.

Delineation of target volume and normal tissues at risk

Treatment planning is today usually performed based on CT in which the Hounsfield units represent the electron density of the tissue which is directly related to absorption of the beam in the tissues of the individual patient. For complex delineations, for example, requiring high contrast of soft tissues planning CT can be matched with MRI. Matching with PET images may provide important information on metabolic activity, allowing improved definition of tumour versus normal tissues. Once all pre-planning imaging has been done, the radiation oncologist delineates the target volumes ([23, 24], see Figure 20.5D: GTV, CTV, PTV) and normal tissues at risk of radiation damage in the planning CT images.

Generation of treatment plans

Treatment plans are usually generated by the dosimetrist or by the medical physicist, using sophisticated treatment planning software. Often alternative plans for comparative analysis are provided. Although algorithms for radiation treatment planning have become significantly faster over the last few years, generation of an optimal treatment plan may still need several days, in particular in complex clinical situations or when very advanced radiotherapy techniques are being used. Treatment plans have to be reviewed for tumour coverage and sparing of normal tissues as well as robustness to possible deviations, and must be signed off by the radiation oncologist and the medical physicist, who have to work closely together for optimal results. Quantitative analyzing tools supporting the evaluation, such as dose-volume histograms for all delineated structures, are implemented in all modern treatment planning systems. However, particularly when several critical normal tissues need to be considered, the decision for the optimal treatment plan may be extremely difficult. At this stage it may also be necessary to adapt the prescribed dose or the intended target volume or, infrequently, to re-start the process accounting for different patient positioning or a change of treatment strategy. When the final treatment plan has been decided upon, further quality assurance by the medical physicist is required as well as the production of auxiliary materials. In many instances, the application of the treatment plan is simulated before treatment using kV radiographic equipment with the geometry of the treatment machine, a dedicated CT simulator, or at the treatment machine itself using onboard imaging equipment.

Irradiation is delivered over weeks requiring periodically verification

Radiotherapists (or radiotherapy technologists or radiotherapy assistants) treat the patient under supervision of the radiation oncologist and medical physicist at the treatment machine. In many instances, treatments are given daily over several weeks. Because of this long duration, ongoing treatment monitoring and set-up verification is necessary. There are many sources of uncertainty during treatment. These may be patient-related (e.g., weight loss, variable filling of bowel or bladder) or attributed to the treatment application. The latter include incorrect positioning, variations in field or rotational settings, deviations in isocentre position, errors in collimator alignment or shape of blocks, varieties of treatment couches between simulator and accelerator, deviations in the in-room alignment system, light beam incongruence. Systematic errors usually have more severe consequences (e.g., if the tumour is partly missed) while random errors may wash out during the treatment. However, in settings requiring the highest precision these random errors may also have significant consequences. A number of monitoring and verification procedures are used during the course of radiotherapy to detect inaccuracies and errors during treatment and correct for them. Adaptive radiotherapy techniques (often requiring re-planning) are also being increasingly implemented to correct for changes in patients' anatomy. In addition, patients are closely monitored during treatment by the radiation oncologist for side effects of radiotherapy on normal tissues, which often require supportive measures and sometimes modification of the treatment.

Follow-up after radiotherapy

After the end of treatment patients need to be followed up for tumour control as well as for evaluation of normal tissue reactions, and data should be included in registers for quality assurance and for scientific evaluations. Follow-up is frequently integrated in multidisciplinary clinics, but evaluation of normal tissue effects requires special expertise and detailed comparison with dose distributions, necessitating the participation of the radiation oncologist in follow-up.

Workflow for oncological emergencies

Oncological emergencies including neurological deficits caused by metastases in the vertebrae or superior vena cava syndrome need consultation of the MDT, including a radiation oncologist, within hours. Diagnostic procedures and the start of treatment must be performed without delay. When the decision is made for radiotherapy, simple techniques are often applied in such situations, at least for the initial treatments.

Emerging directions

Particle therapy and other very high-precision (bio-) image guided technologies

As outlined above, these technologies can apply high doses at lower normal tissue toxicity, which may significantly further improve outcome in those tumours that still recur frequently. They may potentially also allow for a reduction in the number of radiation fractions, which may decrease the time for the patient at the treatment centre

and may spare resources. While protons are considered to be associated with a comparable relative biological effectiveness (RBE) as photons, heavier charged particles such as carbon ions have the potential to modulate the biological effect of radiotherapy due to the higher RBE produced by the specific and severe radiation damage of high-LET beams. This RBE can vary depending on several factors, but mostly ranges between 2 and 5 [26]. It must be noted, however, that the potential of very high precision beams can only be exploited if the whole chain of radiotherapy is optimized: most importantly, pre-therapeutic imaging, treatment planning, and in-room monitoring, in particular accounting for additional range uncertainties compared to photon beam treatment. Continuously adapted radiotherapy which considers tumour size, location, and movement as well as the position of normal tissues at each treatment day is another promising strategy to increase the therapeutic window of radiotherapy but requires substantial further technological improvements such as ultra-fast recalculation of treatment plans, enhanced in-room imaging, and automated fast non-rigid registration technologies. Emerging integrated imaging-therapeutic facilities include among others, MR-Linac hybrids.

Large databases and automated clinical decision-support systems

Because the spatial distribution of dose is an important determinant of radiation response in tumours and normal tissues, and because the exact distribution of dose may be highly variable even for patients with well-matched anatomy and tumours, large-scale databases (including imaging information, dose plans, and spatially resoluted follow-up information) are powerful tools for developing prediction models for radiotherapy. Clinical decision-support systems based on the predictive and prognostic data of several sources can be utilized substantially to enhance a variety of steps in radiotherapy planning and application, including prescription, delineation, or treatment plan optimization. Overall, this requires the implementation of intense multi-institutional networks to generate databases of the necessary size and quality as well as powerful analysis tools [28].

Biological individualization in radiation oncology

Today radiotherapy is a highly individualized treatment modality for cancer, with dose-volume prescriptions based on individual anatomy and utilization of model-based parameters for TCP and NTCP on an individual patient basis. Dose distribution is a powerful surrogate marker for radiation effects in both tumours and normal tissue. Technological advances over the past few decades, together with careful clinical studies and clinical-radiobiological analysis have been the basis for these achievements. Further advances in individualized radiotherapy are expected from integration of this technology with modern biology. A number of putative predictive biomarkers for radiosensitivity of tumours are currently under preclinical and clinical evaluation. Examples include determination of residual DNA double-stand breaks after irradiation by measurement of γH2AX foci which closely correlate with cellular radiosensitivity, determination of the extent of tumour hypoxia, and re-oxygenation by bio-imaging using PET and hypoxia-specific tracers such as 18F-misonidazole, or high-throughput methodologies such as whole exon sequencing which may provide a broader spectrum of markers indicating radioresistance. Only one predictive biomarker for radiosensitivity would add significantly

to the stratification and individualization already established in radiotherapy today. Because of the spatial distribution of dose, predictive bio-imaging methodology is widely being considered as particularly relevant for radiotherapy. Further considerable promise for individualized approaches in radiation oncology bears the combination with specific drugs which either overcome radiobiological mechanisms of radioresistance (e.g. hypoxic cell sensitizers in hypoxic tumours or DNA repair inhibitors in tumours with high capacity for repair of radiation induced double-strand breaks). Such treatment combinations require application according to predictive biomarkers for development of individualized approaches. Monoclonal antibodies against the epidermal growth factor receptor (EGFR) have been the prime example of successful radiosensitization by targeting a specific molecule in combination with radiotherapy; however, to date no reliable biomarker is available for this approach, excluding a biological-driven individualized application.

Novel study design

A challenge for oncology in general is to develop study designs which can cope with individualized treatment approaches, i.e. an increasing number of treatment strata of patients with a decreasing number of eligible patients for such studies per centre. This is further complicated by the fact that the number of potential treatments rapidly increases and that frequently (though sometimes unintentionally) different parameters are variable in the same trial (e.g., in a study testing a new drug combined with radiotherapy, dose distribution may be very heterogeneous; see Figure 20.2). These trends necessitate formation of large study networks (for prospective as well as retrospective data) as well as substantial investments in quality control and new biostatistical assessment techniques.

CHAPTER 21

Principles of chemotherapy

David J. Kerr, Daniel G. Haller, and Jaap Verweij

Introduction to principles of chemotherapy

The treatment of cancer is one of the best settings for a multidisciplinary approach to treatment in medicine. Surgery and radiotherapy are frequently still the primary choice of treatment for patients with malignant tumours. However, since 60–70% of patients with cancer will develop metastatic disease during their lifetime despite local control of their cancer, for most patients cancer may be considered a systemic disease, requiring systemic treatment. In addition, along with radiation and surgery, systemic therapy is frequently given as part of primary treatments with curative intent. The development of systemic therapy over the last few decades has therefore created an important role for medical oncologists in the care of patients with cancer. One of the dominant reasons for the emergence of medical oncology as a subspecialty was the significance of the toxicity associated with conventional cytotoxic drugs. Classically, these agents have steep dose response curves and narrow therapeutic ratios, and therefore a small increment in dose can lead to a large increase in toxicity. Famously, the French philosopher René Descartes declared, 'Cogito ergo sum,' (I think, therefore I am), and we may be able to modify this statement to justify the emergence of medical oncology in the early days to 'Veneno, ergo sum,' (I poison, therefore I am). The types of systemic treatment available to the medical oncologist are continually expanding with newly emerging pharmacological and biological therapies that have clinical activity. We can predict that the role of medical oncology will become increasingly important in the near future.

Every medical oncologist must be aware of the scientific rationale for choosing specific drugs, combinations of drugs, or combinations of different types of treatment. This chapter summarizes the basis of chemotherapy, and addresses important issues in the development of new approaches using molecular targets in a more sophisticated way to try to obtain tumour cell kill, dormancy, or enhanced immune rejection of the cancer.

Principles of chemotherapy

In the majority of patients with cancer, chemotherapy will be considered for use at some time during the course of their illness, aiming either at cure, prolongation of life, or palliation, depending on tumour type, stage, and the relative fitness of the patient.

In an ideal world, the design of chemotherapy regimens should be based on specific knowledge about cell cycle kinetics, pharmacokinetics, biochemical–pharmacological factors, and bioinformatic analysis of the consequences of inhibition of signal transduction pathways. However, this is often still trumped by empirical knowledge of the responsiveness of specific tumours to specific drugs, and a more traditional disease-oriented approach to anticancer drug development. Although much has been made of the remarkable insights that cell and molecular biology has given the oncology community and a belief that it would be possible to treat cell targets and pathways rather than specific tumour types, it has become clear that a 'driver mutation' in, for example, lung cancer may not operate in the same way in colorectal or breast cancer, given the differing mutational landscape in these diverse tumour types. This lends greater weight to the computational statisticians' attempts to model what the consequences of inhibition of pathway X are on pathway Y, and how different resistance escape mechanisms might operate depending on the constellation of background mutations.

Mechanism of action of commonly available drugs

Anthracyclines

Anthracyclines (doxorubicin, daunomycin, epirubicin, daunorubicin) are anti-tumour antibiotics used in cancer chemotherapy derived from the Streptomyces bacteria and have three mechanisms of action:

- inhibits DNA and RNA synthesis by intercalating between base pairs of the DNA/RNA strand, thus preventing the replication of rapidly-growing cancer cells
- inhibits topoisomerase II enzyme, preventing the relaxing of super-coiled DNA and thus blocking DNA transcription and replication
- creates iron-mediated free oxygen radicals that damage the DNA and the lipid domain of cell membranes.

Vinca alkaloids

Vinca alkaloids (vincristine, vinorelbine, vinblastine, vindesine) are antimitotic and antimicrotubule agents that were originally derived from the periwinkle plant Catharanthus roseus. The principal mechanisms of cytotoxicity relate to their interactions with tubulin and disruption of microtubule function, particularly of microtubules comprising the mitotic spindle apparatus, leading to metaphase arrest.

Taxanes

Taxanes (docetaxel, paclitaxel, nab-paclitaxel) are diterpenes produced by the plants of the genus Taxus (yews). The principal mechanism of action of the taxane class of drugs is the disruption of microtubule function. Microtubules are essential to cell division,

and taxanes stabilize GDP-bound tubulin in the microtubule, thereby inhibiting the process of cell division—a 'frozen mitosis'. Thus, in essence, taxanes are mitotic inhibitors. In contrast to the taxanes, the vinca alkaloids destroy mitotic spindles. Both taxanes and vinca alkaloids are together named spindle poisons.

Alkylating agents

Alkylating agents (nitrogen mustards—cyclophosphamide, ifosfamide, melphalan, chlorambucil; nitrosoureas—carmustine, lomustine, streptozocin; alkyl sulphonate—busulfan). Their principal mechanism of action is to allkylate the N7 residue of the guanine which can crosslink nucleobases in DNA double-helix strands. This makes the strands unable to uncoil and separate, leading ultimately to apoptotic cell death. The anti-tumour antibiotic, mitomycin, isolated from Streptomyces caespitosus can also be considered an alkylating agent as it is activated to produce a species which crosslinks guanine residues in the sequence 5'-CpG-3'.

Bleomycin

Bleomycin is a glycopeptide antibiotic produced by the bacterium Streptomyces verticillus which induces DNA strand breaks by generating superoxide free radicals.

Platinum-based agents

These include cisplatin, carboplatin, and oxaliplatin. Platinum-based agents also bind N7 guanine and can cause intra- and interstrand DNA crosslinks, inhibiting DNA synthesis and inducing programmed cell death.

Antimetabolites

Antimetabolites (purines, pyrimidines, anti-folates) are chemicals that inhibit the use of a naturally occurring metabolite that is essential for the cell's normal economy; for example, DNA and protein synthesis. Such drugs are often similar in structure to the metabolite with which they interfere. Purine analogues (mercaptopurine, thioguanine, fludarabine, pentostatin, and cladribine) are antimetabolites that mimic the structure of metabolic purines and that therefore inhibit DNA synthesis. Pyrimidine analogues (5-fluorouracil, gemcitabine, floxuridine, cytosine arabinoside) are antimetabolites that mimic the structure of metabolic pyrimidines and that inhibit DNA and RNA synthesis. Antifolate analogues (methotrexate, pemetrexed) are drugs that impair the function of folic acids. A well-known example is methotrexate. This is a folic acid analogue, which, owing to structural similarity with it, binds and inhibits the enzyme dihydrofolate reductase (DHFR), and thus prevents the formation of tetrahydrofolate. Because tetrahydrofolate is essential for purine and pyrimidine synthesis, methotrexate inhibits production of DNA, RNA, and proteins (as tetrahydrofolate is also involved in the synthesis of amino acids serine and methionine).

Topoisomerase inhibitors

Topoisomerase inhibitors (topo 1—irinotecan, topotecan; topo 2—etoposide, amsacrine, teniposide), inhibit the two enzymes that regulate the overwinding or underwinding of DNA and lead to single and double-strand DNA breaks that can induce apoptosis.

Hormonal agents

Hormonal therapy involves the manipulation of the endocrine system through exogenous administration of specific hormones, particularly steroid hormones, or drugs which inhibit the production or activity of such hormones (hormone antagonists). Because steroid hormones are powerful drivers of gene expression in certain cancer cells, changing the levels or activity of certain hormones can cause cytostasis, or cell death.

Aromatase inhibitors

At menopause, oestrogen production in the ovaries ceases, but other tissues continue to produce oestrogen through the action of the enzyme aromatase on androgens produced by the adrenal glands. Aromatase blockade reduces oestrogen levels in postmenopausal women, causing growth arrest and/or apoptosis of hormone-responsive cancer cells. Letrozole and anastrozole are aromatase inhibitors which have been shown to be superior to tamoxifen for the first-line treatment of breast cancer in postmenopausal women, and exemestane is an irreversible 'aromatase inactivator' which is superior to megestrol for treatment of tamoxifen-refractory metastatic breast cancer. Analogues of gonadotropin-releasing hormone (GnRH) can induce chemical castration, complete suppression of the production of oestrogen, progesterone and testosterone from the reproductive organs via the negative feedback effect of continuous stimulation of the pituitary gland by these hormones. Leuprolide and goserelin are GnRH analogs which are used primarily for the treatment of hormone-responsive prostate cancer.

Oestrogen receptor antagonists (SERM)

Tamoxifen is a partial agonist, which can actually increase oestrogen receptor signalling in some tissues, such as the endometrium. Raloxifene is another partial agonist SERM which does not seem to promote endometrial cancer, and is used primarily for chemoprevention of breast cancer in high-risk individuals. Toremifene and fulvestrant are SERMs with little or no agonist activity.

Antiandrogens

Antiandrogens are a class of drug which bind and inhibit the androgen receptor, blocking the growth- and survival-promoting effects of testosterone on certain prostate cancers. There are steroidal antiandrogens and 'pure' antiandrogens. The steroidal antiandrogens include megestrol. The 'pure' or nonsteroidal antiandrogens include bicalutamide, flutamide, and nilutamide.

Cell signalling inhibitors

This broad classification underpins the remarkable insights that cell and molecular biology have yielded over the past two decades that have resulted in druggable targets, several of which are used as biomarkers to select chemosensitive patient subpopulations.

Anti-angiogenic inhibitors (bevacizumab, aflibercept, sorafenib, sunitinib, pazopanib and everolimus)

Angiogenesis requires the binding of signalling molecules, such as vascular endothelial growth factor (VEGF), to receptors on the surface of normal endothelial cells. When VEGF and other endothelial growth factors bind to their receptors on endothelial cells, signals within these cells are initiated that promote the growth and survival of new blood vessels. Angiogenesis inhibitors interfere with various steps in this process; for example, bevacizumab is a monoclonal antibody that specifically recognizes and binds to VEGF, preventing it from activating its receptor. Other angiogenesis inhibitors, including sorafenib, regorafenib, and sunitinib, bind to receptors

on the surface of endothelial cells or to other proteins in the downstream signalling pathways, blocking their activities. Ramucirumab is a fully human monoclonal antibody (IgG1) being developed for the treatment of solid tumors. It is directed against the vascular endothelial growth factor receptor 2 (VEGFR2). By binding to VEGFR2, it works as a receptor antagonist blocking the binding of vascular endothelial growth factor (VEGF) to VEGFR2. VEGFR2 is known to mediate the majority of the downstream effects of VEGF in angiogenesis.

Growth factor receptor inhibitors

Aberrant expression of the epidermal growth factor receptor (EGFR) system has been reported in a wide range of epithelial cancers. In some studies, this has also been associated with a poor prognosis and resistance to the conventional forms of therapies. These discoveries have led to the strategic development of several kinds of EGFR inhibitors, which comprise the anti-EGFR monoclonal antibodies cetuximab and panitumumab, and the small molecule EGFR tyrosine kinase inhibitors gefitinib and erlotinib. Human epidermal growth factor receptor 2 (HER2) is the target of the monoclonal antibody trastuzumab, which is effective only in cancers where HER2 is over-expressed.

One of the difficulties in classifying signal transduction inhibitors is that they often have multiple targets and it may be impossible to be precise about the dominant mode of action. Some of the main pharmacologic types are:

- multitargeted tyrosine kinase inhibitors which include erlotinib, imatinib, gefitinib, dasatinib, sunitinib, nilotinib, lapatinib, sorafenib, crizotinib, regorafenib
- proteasome inhibitors, such as bortezomib
- mTOR inhibitors, such as temsirolimus, everolimus
- histone deacetylase inhibitors, such as vorinostat (SAHA)
- hedgehog pathway inhibitors, such as vismodegib.

Cellular principles of chemotherapy

For cytotoxic treatment, the following characteristics of tumour growth are important in determining outcome:

- cell cycle time
- tumour doubling time

- growth fraction
- tumour size, or the number of cells in the population.

Decades ago, Skipper et al. [1] found that the doubling time of proliferating murine cancer cells is constant, forming a straight line on a semilog plot. Death of the animals resulted when the malignant cells reached a critical fraction of body weight. Since other experiments [2] had shown that a single surviving cell leads to treatment failure, and there is still no evidence that normal levels of host defence are capable of eliminating a few remaining tumour cells, for a given amount of chemotherapy survival was related to tumour size at the time of diagnosis (Figure 21.1).

These studies were performed in model systems, often using murine leukaemic cell lines, showing logarithmic (exponential) growth. All of the cells were in cycle and dividing, with no cells in a resting phase, and the cell number doubling at a tumour-specific rate. While knowledge based on these model characteristics is important, the rules only apply to the cells in the proliferation compartment. Unfortunately, only a few human cancers have a large proportion of such responsive proliferating cells. In most tumours there is a large non-proliferating compartment; therefore, these model systems, though important in their time, are not truly representative of the kinetics of human solid tumours [3].

Most human tumours are diagnosed when they are relatively large and kinetically and genetically heterogeneous. Due to a variety of factors such as poor vascularity, hypoxia [4], and competition for nutrients, they exhibit decelerating growth at this stage. Larger tumours contain a high fraction of slowly or non-dividing cells (termed G0 cells) and as a consequence the growth fraction is low. Therefore, in treating human tumours, the fractional cell kill hypothesis probably does not apply as well as in animal tumour models. Non-proliferating cells are less sensitive to antineoplastic agents, particularly because they have time to repair the damaged DNA. As many antineoplastic agents are most effective against rapidly dividing cells, the cell-kinetic situation at tumour diagnosis is unfavourable for treatment with most drugs.

Unlike the tumour models used by Skipper, and related to the fact that the proliferating cell population is distinct from the non-proliferating population, human tumours are thought to follow a different growth pattern. Attempts have been undertaken to describe human tumour growth by mathematical models. Two available models are the so-called Gompertzian growth model and the exponential growth model. The primary distinction between the two models is that in Gompertzian growth kinetics
Fig. 21.1 Cancer dynamics.

the growth fraction of the tumour is not constant but decreases exponentially with time. Exponential growth implies that the time taken for a tumour to double its volume is constant. A significant problem is that most tumours only become clinically manifest by approximately 10^9 tumour cells (equating approximately to a size of 1 cm^3, representing the last part of the tumour's growth curve). Thus, estimating growth curves of human primary tumours based on multiple time points of tumour volume appeared to be difficult, if not impossible. Overall, the available data suggest that the Gompertzian growth model (sigmoid in shape on a log scale) is the most probable model (it is interesting to reflect that Gompertz was an economist and developed his models around how industrialized economies behaved).

Apart from cell-kinetic heterogeneity, genetic and biochemical heterogeneity of human tumours may also reduce the likelihood of cure. Although most human tumours evolve from a single clone of malignant cells [5], more recent studies have shown that this homogeneity does not persist during further stages of tumour growth, presumably as a result of further somatic mutations of the original tumour line. When non-homogeneous tumour cells are exposed to drugs, sensitive tumour cells will be destroyed while resistant cells will survive and proliferate [6]. As a result, tumour cell kill tends to decrease with subsequent courses of treatment, as resistant cells are selected. Paradoxically, normal tissues never change their level of sensitivity to chemotherapy, emphasizing an important difference in relative genetic stability.

Pharmacological principles of chemotherapy

The scheduling of drug treatments is based on both practical and theoretical considerations. Intermittent cycles of treatment are used to allow periods of recovery of normal tissues. This strategy aims at re-treatment with full therapeutic doses as frequently as possible, in keeping with the fractional cell kill hypothesis, but also allowing the normal tissues to recover from the unintended effects of cytotoxic treatment. The outcome of chemotherapy will obviously largely depend on the overall intrinsic sensitivity of the treated tumour.

Fractional cell kill means that a given drug concentration applied for a defined time period will kill a constant fraction of the total cell population, independent of the absolute number of cells. In other words, each treatment cycle kills a specific fraction (percentage) of the remaining cells. Since this fraction is never 100%, a single drug

administration will never be sufficient to eradicate a tumour completely. Therefore, treatment results will also be a direct function of the drug concentration and exposure time and the frequency of repeating treatment. Drug concentration and exposure time will be dependent on pharmacokinetic (PK) factors such as drug absorption, metabolism, and elimination (Figure 21.2). These will have to be considered in general in determining the dose, schedule, and route of drug administration. In addition, inter-patient variations in PK parameters are usually large and this may be one reason for the inconsistency in responses of 'sensitive' tumours.

The bioavailability of a drug describes the proportion of a dose of a drug that enters the systemic circulation (e.g., for intravenous 5-FU this would be 100% compared to 10–25% for oral 5-FU). For drugs taken orally that are intended for systemic action, a significant proportion of a given dose may not even enter the systemic circulation. This may be due to poor absorption from the gastrointestinal (GI) tract, or metabolism in the gut wall or liver (called first-pass metabolism).

Various processes are involved in drug elimination, although hepatic and renal processes are the most important. The liver is the main organ of drug metabolism. There are generally two types of reaction (Phase I and Phase II) that have two important effects:

◆ Make the drug more water soluble—to aid excretion by the kidneys.

◆ Inactivate the drug—in most cases, the metabolite is less active than the parent drug, although in some cases the metabolite can be as active, or more so, than the parent (e.g., irinotecan, tamoxifen).

Phase I metabolism involves oxidation, reduction, or hydrolysis reactions. Oxidation reactions are most common and are catalysed by cytochrome P450 isoenzymes located primarily in the liver. Phase II metabolism involves conjugation reactions, such as glucuronidation (such as UGT1a1) or sulphation, which produce more water-soluble compounds, enabling rapid elimination.

The main route of excretion of drugs is the kidney. Renal elimination is dependent on multiple factors that include:

◆ glomerular filtration rate (GFR)

◆ active tubular secretion (may involve P-gp)

◆ passive tubular secretion.

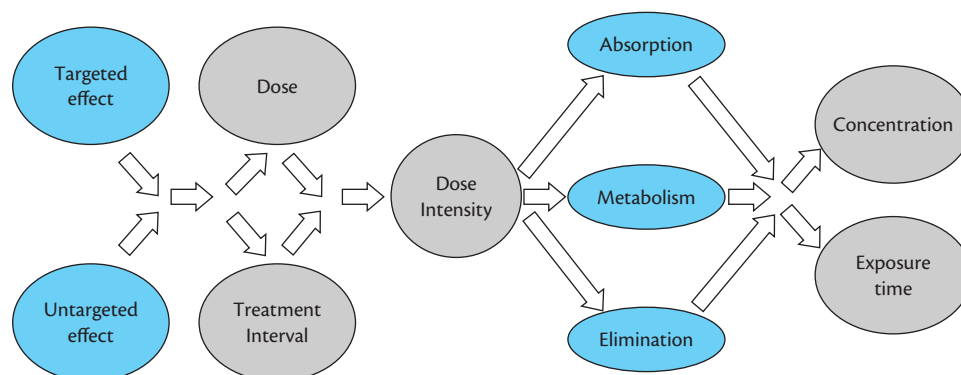
If a drug is metabolized mainly to inactive compounds (e.g., 5-flourouracil), renal function will not greatly affect the elimination.


Fig. 21.2 Pharmacodynamics in cancer chemotherapy.

If, however, the drug is excreted largely unchanged (e.g., carboplatin), or an active metabolite is excreted via the kidney (e.g., morphine), changes in renal function will influence the elimination, and dose adjustments may be necessary.

Effect of hepatic and renal impairment

Impaired liver function can affect the pharmacokinetics and pharmacodynamics of many anticancer drugs (e.g., anthracyclines, taxanes, vinca alkaloids, and 5-FU). Reduction in hepatic blood flow and a potential fall in the number and the activity of hepatocytes can alter liver function and impact on drug clearance. A reduced synthesis of albumin can result in reduced drug–protein binding, thereby affecting the volume of distribution. Cholestasis can affect the biliary excretion of drugs and metabolites. Patients with impaired hepatic function may also develop a degree of renal impairment due to decreased renal plasma flow and GFR. Unlike impaired renal function, there is no simple test that can determine the impact of liver disease on drug handling. A combination of factors needs to be considered before such impact can be assessed, which include liver function tests (LFTs), diagnosis, and physical symptoms.

In general, the metabolism of drugs is unlikely to be affected unless the patient has severe liver disease. Most problems are seen in patients with jaundice, ascites, and hepatic encephalopathy. As such, doses of drugs should be reviewed in the following situations:

- hepatically metabolized drug with narrow therapeutic index
- there is a significant involvement of the cytochrome P450 system (CYP3A4/5 is highly susceptible to liver disease, while CYP2D6 appears relatively refractory)
- international normalized ratio (INR) >1.2.
- bilirubin >100micromol/L
- albumin <30g/L
- signs of ascites and/or encephalopathy.

The elimination of several cytotoxic drugs and their metabolites is dependent upon renal function (capecitabine, carboplatin, cisplatin, methtrexate). Impaired renal function, coupled with rising urea plasma concentrations, induces changes in drug pharmacokinetics and pharmacodynamics. Implications for drug therapy include:

- increased risk of undesirable effects and toxicity through reduced excretion of the drug and/or metabolite(s)
- increased sensitivity to drug effects, irrespective of route of elimination, (e.g., antipsychotics)
- increased risk of further renal impairment (e.g., NSAIDs).

Many of these problems can be avoided by simple adjustment of daily dose or frequency of administration. The dose nomogram for carboplatin is an excellent example of this. In other situations, however, an alternative drug may need to be chosen.

Pharmacogenetics

If it were not for the great variability among individuals, medicine might as well be a science and not an art.

William Osler

Pharmacogenetics is the study of how variation in an individual gene affects the response to drugs which can lead to adverse drug reactions, drug toxicity, therapeutic failure, and drug interactions. Genetic variability can affect an individual's response to drug treatment by influencing pharmacokinetic and pharmacodynamic processes (e.g., variations in genes that encode cytochrome P450 isoenzymes, drug receptors, or transport proteins can determine clinical response). Pharmacogenetics can aid in the optimization of drug therapy through the identification of individuals who are likely to respond to treatment, or those who are most likely at risk of an adverse drug reaction. For example, with tamoxifen the active metabolite, endoxifen, is produced by a reaction involving CYP2D6. Patients with a PM phenotype are at risk of therapeutic failure with tamoxifen. Drugs that inhibit CYP2D6 will also mimic the PM phenotype and should be avoided. Warfarin bleeding effects are more common with CYP2D9 polymorphisms; patients with mutations in UGT1a1 reduce metabolism of irinotecan and are associated with more toxicity.

Dose intensity

Most cancer chemotherapeutic agents in vitro and in vivo exhibit a steep dose-response curve. Consequently, it is considered desirable to administer them in humans at the highest possible dose-intensity, since in theory even small reductions in dose would lead to substantial reductions of tumour cell kill. The importance of dose intensity in tumour responsiveness in humans was first suggested in heavily criticized retrospective analyses performed by Levin and Hryniuk [8] and others [9]. These investigators suggested dose response correlations for 5-fluorouracil in colon cancer, cisplatin in ovarian cancer, doxorubicinin in breast cancer, and vincristine in Hodgkin's disease. Subsequently, for some of these, prospective randomized trials of a relatively small sample size have supported or refuted the concept.

It is generally accepted that the most important measure of drug exposure would be the area under the curve in a plot of local tumour drug concentration against time.

Obviously, there is a hierarchy ranging from simple plasma levels of unbound and activated drug (where appropriate) to activated drug concentrations within the target tumour cell. Unfortunately, there are scarcely any data from humans to suggest that plasma drug levels do correlate with tumour levels and response.

Locoregional drug administration

Regional perfusion with antineoplastic drugs can generate higher than expected drug concentrations in the body compartment which harbours the dominant tumour burden.

1. Direct intrathecal administration of drugs such as methotrexate or cytarabine enables a higher local dose in a sanctuary site.

2. Hepatic artery or portal vein infusion in theory allows an increased drug concentration to liver primary or secondary tumours [10].

3. Intra-arterial perfusion can be used for metastatic and primary liver cancer, limb melanomas and soft tissue sarcomas.

4. Intraperitoneal chemotherapy is effective for ovarian cancer [11–13].

Dose intensification using local administration in uncontrolled studies has suggested improved response rates. However, with the exception of intrathecal therapy in acute lymphocytic leukaemia, hepatic arterial infusion for metastatic colorectal cancer, and intra-peritoneal therapy for ovarian cancer, none of the regional methods has been reported in randomized trials to produce a longer survival than conventional systemic methods of drug administration.

An increase of the dose per administration

The dose per administration can be increased without changing the intervals between administrations. One such method to increase tumour cell kill is to use doses of chemotherapy that cause pro-longed bone marrow suppression and to rescue the host either with autologous bone marrow harvested before treatment or with allo-genic marrow from a histocompatible donor.

With the use of high-dose chemotherapy, new dose-limiting tox-icities to organs other than bone marrow emerge, such as nitrosou-rea toxicity to lung, kidneys, or liver [14]. For this reason, its use is still limited to certain classes of drugs. To date, marrow-ablative chemotherapy in humans has only been shown effective in leukae-mias and lymphomas, tumour types with high growth fractions and intrinsic sensitivity to chemotherapy.

Shortening treatment intervals

This method has been used, especially in solid tumours, as another way of increasing dose intensity. The introduction of drugs such as the 5-hydroxytryptamine-3 antagonist anti-emetics and the haematopoietic growth factors has greatly facilitated this approach. Although weekly [15] or biweekly administration of relatively high doses of drugs previously given at three- to four-week intervals seems feasible and yields interesting results in uncontrolled trials, it is too early to conclude if the resulting increases in dose intensity produce an increase in cure rate (an exception may be in the use of dose-dense adjuvant chemotherapy for breast cancer).

Principles of combination chemotherapy

As a consequence of somatic mutations, tumour cell kill tends to decrease with subsequent courses of treatment, as genetically resistant cell types are selected out.

For this reason, single-agent treatment is rarely curative. Therefore, and for a variety of other reasons discussed here, cancer chemotherapy is most frequently given as a combination of differ-ent drugs. Favourable and unfavourable interactions between drugs must be considered in developing such combination regimens. These interactions may be pharmacokinetic, cytokinetic, or bio-chemical, and may influence the effectiveness of the components of the combination. The theoretical and sometimes proven superi-ority of combination chemotherapy over single-agent treatment is derived from the principles listed in Box 21.1.

When any drugs are administered in combination, three out-comes are possible: additive, subtractive, or synergistic effects. With additive effects, the drugs act completely independently of each other, presumably through non-overlapping biochemical pathways, and have no pharmacokinetic interactions which alter the quantum of drug reaching its active site. For subtractive or negative syner-gistic effects, one drug interferes with the other to reduce efficacy. This could be competition at the active site, altered pharmacokinet-ics inducing one of the enzyme systems responsible for the other

Beware of drug-drug interactions

---

drug's metabolism, or the unexpected consequence that inhibition of a biochemical pathway might have on up-/down-regulation of the target kinase of the companion drug. Synergy is defined as an interaction between drugs where the effects are stronger than their mere sum and may be driven by both pharmacokinetic and pharmacodynamic interactions. The best way of demonstrating true synergy is to use the Chou–Talalay method for drug combina-tion. This is based on the median-effect equation, derived from the mass-action law principle, which is the unified theory that provides the common link between single entity and multiple entities, and first-order and higher-order dynamics. It is possible, therefore, to apply stringent equations in the preclinical setting, both in vitro and in vivo to empirical cytotoxic drug combinations to determine whether true synergy can be documented and therefore used as a piece of supporting evidence to take specific anticancer drug com-binations into the clinic.

Activity as a single agent

Drugs with at least activity as a single agent should be selected. Because of primary resistance (see later), which is frequent for any single agent even in the most responsive tumours, complete response rates of single agents rarely exceed 20%.

Different mechanisms of action

Drugs with different mechanisms of action (and toxicity profiles) should be combined. The various anticancer agent classes have different targets in the cell. Thus, even if a certain target cannot be exploited in a given tumour cell, another target might. Even if tumours are initially sensitive, they usually rapidly acquire resist-ance after drug exposure. This is probably due to selection of pre-existing resistant tumour cells in the biochemically heteroge-neous tumour cell population. In other words, the chemotherapy destroys the sensitive cell population, but is less effective against the non-sensitive population of cells that is subsequently able to con-tinue expanding. In addition, cytotoxic drugs themselves appear to increase the rate of mutation to resistance, at least in tumour mod-els [16]. The use of multiple agents with different mechanisms of action enables independent cell killing by each agent. Cells that are resistant to one agent might still be sensitive to the other drug(s) in the regimen, and might thus still be killed. Known patterns of cross-resistance must be taken into consideration in the design of drug combinations.

Different mechanisms of resistance

Drugs with different mechanisms of resistance should be com-bined. Resistance to many agents may be the result of mutational changes unique to those agents. However, in other circumstances a single mutational change may lead to resistance to a variety of
Fig. 21.3 P-glycoprotein: action and inhibition. The blocking agent binds to the cytoplasmic binding site of the drug, inhibiting its efflux.

different drugs. The number of potential mechanisms of resistance is continually increasing and is partly drug dependent.

The most investigated form of multidrug resistance is the one mediated by increased expression of the P170 membrane glycoprotein (PGP). Primary (intrinsic) over-expression of this protein has been identified in tumours derived from healthy tissues in which the protein also occurs [17]. Secondary (acquired) over-expression has also been found following chemotherapy in various diseases. PGP mediates the efflux of drugs such as anthracyclines, vinca alkaloids, epipodophyllotoxins, and various others, all derived from natural resources. PGP-mediated active efflux results in decreased intracellular drug levels, resulting in decreased cell kill. Agents that compete for the protein such as calcium-channel blockers, cyclosporin, and various synthetically produced drugs can, at least in models, reverse the effect of PGP (Figure 21.3). The clinical relevance of this type of resistance and its reversal is still unclear.

For several of the classic alkylating agents (cisplatin, cyclophosphamide, melphalan) resistance appears to be related to enhanced repair of drug-induced DNA damage.

There are many other mechanisms of resistance, including alterations in target proteins (e.g., dihydrofolate reductase with altered affinity for methotrexate) and carrier-mediated drug uptake (e.g., reduced folate). In the heterogeneous human tumours, there are frequently various mechanisms of resistance that play a role. Reversing only one of these is unlikely to yield a major impact. Resistance reversal is therefore pursued in only limited numbers of tumours. Because of the presence of drug-resistant mutants at the time of clinical diagnosis, the earliest possible use of drugs that are not cross-resistant is recommended to avoid the selection of double mutants by sequential chemotherapy. Adequate cytotoxic doses of drugs have to be administered as frequently as possible to achieve maximal kill of both sensitive and moderately resistant cells. Less desirable alternatives are the use of different regimens in alternating cycles of therapy or the use of multiple cycles of one regimen given to the point of maximal response, followed by a second regimen.

Different dose-limiting toxicities

If possible, drugs with different dose-limiting toxicities should be combined. In the case of non-overlapping toxicity it is more likely that each of the drugs can be used at full dose and thus the effectiveness of each agent will be maintained in the combination. Unfortunately, for many cytotoxic agents the side effects frequently involve myelosuppression. If there is overlapping myelotoxicity,

arbitrary scales of dose adjustment according to bone marrow toxicity can be used, or haematopoietic growth factors can be added to reduce the risk related to myelosuppression. Clearly, drugs that have low bone marrow toxicity, such as vincristine, cisplatin, and bleomycin, are favoured to combine with myelosuppressive agents. Drugs with renal or hepatic side effects in theory can alter the elimination of other agents through these routes and therefore must be used with caution in combinations. For example, cisplatin causes renal toxicity and is known to alter the pharmacokinetics of other agents (such as methotrexate or bleomycin) that depend on renal elimination as their primary mechanism of excretion.

Cell cycle-related and biochemical interactions

Cell cycle-related and biochemical interactions between drugs can also be used to design combinations. Examples of drug interactions are listed in Box 21.2.

Provided that the drugs used are active in a particular disease, knowledge of cell kinetics can be used to consider initiation of therapy with agents that are not specific for cell cycle (the alkylating

agents and nitrosoureas), first to reduce tumour bulk and second to recruit slowly dividing cells into active DNA synthesis. Once the latter is achieved, therapy can be continued within the same cycle of treatment with agents specific for cell cycle phase (such as methotrexate or the fluoropyrimidines) that mainly affect cells during periods of DNA synthesis. Further, repeated courses with S-phase-specific drugs, such as cytosine arabinoside and methotrexate, that block cells during the period of DNA synthesis, are most effective if they are administered during the rebound rapid recovery of DNA synthesis that follows the period of suppression of DNA synthesis [18]. For cytosine arabinoside, for instance, this occurs approximately ten days after the first treatment with this agent.

An example of biochemical interaction suggesting a rational combination of drugs is shown by the example of leucovorin (5-formyltetrahydrofolate) enhancing 5-fluorouracil, by ternary stabilization of its metabolite (fluorodeoxyuridine monophosphate) with thymidylate synthase [19].

Adjuvant and neoadjuvant systemic therapy

Drug therapy is also used to benefit patients who exhibit no evidence of residual disease after initial therapy, but are at high risk of relapse (adjuvant therapy), or those with bulky primary disease to reduce this bulk preceding local therapy (neoadjuvant therapy).

Adjuvant therapy

There are two major reasons why adjuvant chemotherapy might be considered: (1) the high rate of recurrence after surgery for some, apparently localized tumours and (2) the failure of systemic therapy or combined modality treatment to cure patients with clinically apparent metastatic disease. These issues may in turn be related to the following three points. First, once the tumour bulk is reduced to clinically undetectable levels with local therapy, the number of cells yet to be destroyed by subsequent chemotherapy is relatively small, in contrast to the large numbers of cells in the case of clinical metastatic disease. According to the principles of log cell kill in the first situation, the likelihood of completely eradicating the remaining tumour cells is much higher than in the latter (Figure 21.4).

Second, as mentioned earlier, there is evidence from tumour models that supports the hypothesis that tumours are most sensitive to chemotherapy at their earliest stages of growth. This is thought to be related to their high growth fraction (most cells are in active progression through the cell cycle), shorter cell cycle times, and therefore greater fractional cell kill for a given dose of drug [20]. Once tumours progress to clinical detectability, their growth fraction falls, the cell cycle time lengthens, and they become much less sensitive to treatment.

Third, there is a relationship between tumour bulk and tumour cell resistance. The probability of the occurrence of resistant cells in a tumour population is a function of the total number of cells present and mutation rates. Therefore, subclinical (occult) tumours rather than clinically detectable tumours are more likely to be cured by chemotherapy.

On the other hand, there are obviously potential disadvantages of adjuvant chemotherapy that have to be taken into account. They relate to immediate, short-, and long-term side effects of such treatment. Since a significant fraction of patients receiving adjuvant treatment is already cured by the primary surgical procedure they would therefore experience needless toxicity and risks if treated with adjuvant therapy. The immediate side effects obviously relate to potentially lethal infectious complications from neutropenia, bleeding, and less hazardous—but very inconvenient—side effects such as alopecia and nausea and vomiting.

Late complications such as carcinogenicity and permanent sterility assume greater importance, but neither risk has been adequately quantified for all drugs and combinations. The risks of other late effects such as bone marrow hypoplasia from alkylating agents and nitrosoureas, the cardiotoxicity of doxorubicin, neurotoxocity of platins and taxanes, and pulmonary toxicity of bleomycin and the nitrosoureas should obviously not outweigh the potential benefits. In balancing these risks with the outcome as far as tumour eradication is concerned, adjuvant chemotherapy has become a standard of care in many cancers of childhood, the breast, the colon, and the ovary.

Neoadjuvant therapy

If chemotherapy is used as initial treatment, preceding a form of local therapy, it is called 'neoadjuvant therapy' or 'induction therapy'. Such neoadjuvant chemotherapy has attracted increasing attention in the treatment of some adult solid tumours. Factors
Fig. 21.4 The principle of adjuvant chemotherapy as opposed to treatment of measurable disease.

related to the response to neoadjuvant chemotherapy are similar to those that may affect adjuvant chemotherapy, namely growth rate, presence of drug resistance, and tumour mass. The potential benefits of neoadjuvant chemotherapy involve the control of the primary tumour as well as of potential micrometastases.

There are several potential advantages for control of the primary tumour [21, 22]. First, local reduction of the tumour may facilitate the use of more conservative surgery and/or radiotherapy. Second, administering chemotherapy prior to the local therapy avoids the potential of poor distribution and penetration of drug at the tumour site due to the compromised vascularity that may result from surgery and/or radiation therapy. Third, cytotoxic drugs can be combined concurrently with radiation therapy to increase the local control rate. Fourth, post-chemotherapy surgery offers a unique opportunity to assess the correlation between clinical tumour response measurements and actual pathological changes. Fifth, the response of the primary tumour to chemotherapy may reflect the response of micrometastases and therefore influence further patient management.

The disadvantages of neoadjuvant chemotherapy are similar to those mentioned for adjuvant chemotherapy. Additional disadvantages may be:

1. Selection of drug-resistant clones

2. An increase in toxicity from subsequent therapies

3. A failure of cytotoxic agents to reduce the primary tumour significantly, thereby possibly allowing further subclinical progression of disease

4. A loss of the advantage of attacking micrometastases after surgical resection of the primary tumour mass, when they may exhibit more favourable cell kinetics.

Conclusion

Despite the insights in tumour biology gained by modern molecular genetics, the broad principles governing medical oncology and the delivery of systemic anticancer therapy have remained intact over the past few decades. It is all about delivering sufficient quantities of the drug to its site of action and a molecular target which is differentially or uniquely expressed relative to normal tissue. We can respond to but not control the genetic background of the tumour, utilizing predictive and prognostic biomarkers [23, 24] but we can control drug dose and this must remain the cornerstone of effective medical oncology.

Multidisciplinary cancer care

David N. Church, Rachel Kerr, and David J. Kerr

Introduction to multidisciplinary cancer care

Given the complex biology of the disease and the many different medical specialties required to deliver a cancer management plan in keeping with current best practice, it is not surprising that cancer care has the real potential to become fragmented, arbitrary, and suboptimal. The ideal scenario would be one in which the patient moved seamlessly along the care pathway, receiving appropriate interventions from expert specialists as tumour type and stage demanded. This 'journey' would be coordinated by a case officer managing the various interfaces and streamlining communication so that the patient felt supported, informed and confident that each element was part of a cohesive whole. It might be worth pause for reflection now so that the reader might consider the situation in their own hospital, centre, or clinic and how far from or close to this ideal their own practice may be.

Certainly in the UK ten to 15 years ago there was a growing recognition, driven initially by the compartmentalization of cancer care, the length of waiting times for operations or access to radiotherapy, and the fact that the UK's cancer outcomes fell short of the major European nations and the USA that changes in the delivery of care were much needed [1, 2]. A major policy decision taken at that time was to promote multidisciplinary working as a key element in service improvement. The definition of multidisciplinary cancer care is variable [3–6], and may include multidisciplinary clinics [7–9], multidisciplinary protocols for diagnosis and treatment [10], and multidisciplinary team (MDT) meetings [11]. However, it is undoubtedly the last category that has had the greatest impact on working practices, as MDT discussion has become mandated for all new incident cases of cancer in the UK over the last two decades. The MDT is typically defined as a group of doctors and other health professionals with expertise in a specific cancer, who discuss each case before tailoring a personalized management plan. The specific composition of any MDT depends on the tumour type cared for, but most teams will involve one or several surgeons, radiologists, histopathologists, medical oncologistsand clinical radiation oncologists, palliative care physicians and clinical nurse specialists. Other health professionals, including clinical geneticists, physiotherapists, occupational therapists, psychologists, dieticians, speech therapists, and pharmacists, may also be involved.

Since their inception, MDTs have become progressively more site specialised, and although initially this was manifested predominantly as surgeons focusing their attention on particular tumour types in order to increase and refine their caseloads, over time there has been a shift to a tumour-specific focus for all team members. Clearly this raises issues for staffing and time commitments, and

begs the question as to whether there is sufficient capacity to support this degree of specialization. Irrespective of their composition, however, the importance of MDTs in many healthcare systems has increased substantially over recent years. In the UK, the proportion of cancer cases managed by an MDT has increased from less than 20% to greater than 80% over the last two decades [12], and multidisciplinary care is mandated by healthcare organizations in the UK, mainland Europe, the USA, and Australia [4, 13–15]. In addition to improved coordination and delivery of care, many other benefits of MDTs working for patients and healthcare professionals have been suggested. However, the organization of MDT care requires substantial time and cost commitments, and the cost-effectiveness of MDTs is difficult to ascertain. Furthermore, high-quality evidence of benefit of MDTs working on patient outcomes is at best scanty, for reasons discussed below. Nevertheless, the UK NHS cancer plan regards MDTs as an essential part of the management of common cancers, and has recommended the extension of multidisciplinary care to rare tumours.

Organization and delivery of multidisciplinary cancer care

The purpose of the MDT is to collate sufficient clinical, pathological, and radiological data to enable the team to make a consensus recommendation for the optimum modality and sequence of treatment. In general, the patient history is presented by either the clinician who made primary contact or the clinical nurse specialist who has been appointed the 'key worker' for the patient; the histopathologist reports the tumour characteristics (ideally using a nationally agreed proforma designed to capture validated prognostic factors in addition to conventional TNM staging); and the radiologist delineates the primary tumour and annotates the presence/absence of distant metastases (Figure 22.1). The MDT may request further information (e.g., MRI scan of liver if there is doubt on the CT scan about presence of hepatic metastases), but if there are sufficient data, a treatment plan is formulated and a referral to initiate treatment made to the primary clinician, who could be a surgeon, radiotherapist, medical oncologist, or palliative care specialist, depending on clinical circumstance. Coordination is essential as often the patient will have to meet new clinical teams situated in different areas of the hospital or even in a completely different centre. The roles of the MDT coordinator and the clinical nurse specialists are pivotal as, for the MDT to function effectively, the results of the discussions need to be disseminated to the relevant healthcare professionals, and to the patients themselves, accurately and expeditiously.

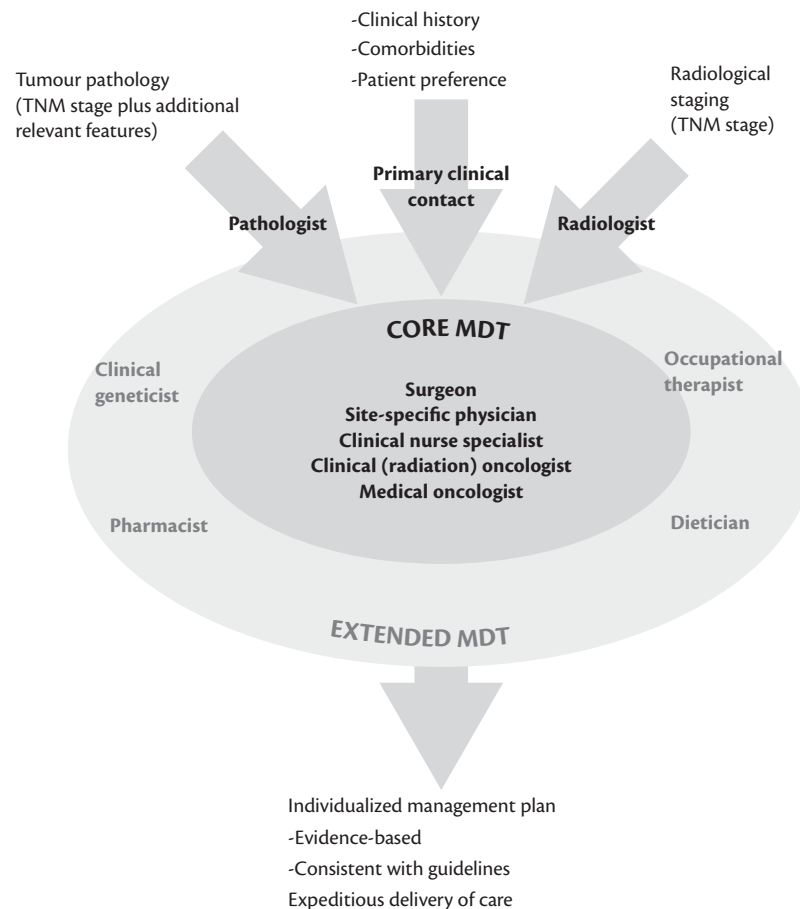
As mentioned, in response to the unacceptable delays in treatment for cancer of a decade ago, the NHS in the UK has mandated


Fig. 22.1 Organization of MDT meetings. The clinical history and other salient features are typically presented by the clinician who made primary contact with the patient, or the clinical nurse specialist (CNS). The tumour pathology is summarized by the histopathologist and the imaging findings presented by the radiologist. The MDT then discusses the case and a tailored management plan is formulated. This should be both evidence-based and consistent with national and international guidelines. By collecting many specialists together, the MDT should expedite delivery of care when compared with sequential referrals between specialists.

that all new cancer patients should be discussed by an MDT, and that this is subject to audit as a quality surrogate in an ongoing national programme. The frequency of MDT meetings varies with caseload and tumour prevalence, though MDTs for the common solid tumours (lung, breast, colorectal, and urogenital) tend to meet weekly. The implementation of MDT working has helped to reduce waiting times to more internationally acceptable figures and has also improved the patient experience of the cancer journey.

Potential benefits of multidisciplinary care

By pooling the expertise of healthcare professionals from various clinical specialities, MDTs aim to provide a personalized and optimum management plan for each case discussed. As a result, patients should benefit from expert diagnosis and staging, with secondary review of imaging and pathology resulting in improved diagnostic accuracy, particularly in uncommon cancers [16, 17]. The presence of different specialists should mean that consideration is given to the full range of therapeutic modalities available for each patient, rather than the preferred therapy of the primary physician or surgeon [18, 19]. This is of particular importance for complex cases, for patients with comorbidities and for cases where combined modality therapy—such as chemoradiotherapy—is indicated. For more

straightforward situations, MDT teamwork may facilitate closer adherence to evidence-based guidelines [20, 21]. In addition, MDT discussion should prevent inappropriate referrals and expedite care delivery compared with the traditional model of sequential consultations with different specialists.

More generally, the structure of MDT meetings is consistent with the application of peer review, and the teamworking required may help promote initiatives for service improvement [22]. The MDT provides an ideal forum at which to identify patients who may be eligible for clinical trials, and the presence of a research nurse at the MDT may help ensure that the option of study participation is available to all eligible. Improved data collection as a result of MDTs should facilitate audit and research. In response to a survey of MDTs in the UK in 2009, characteristics of effective MDTs have been published to serve as a model for MDT improvement [23, 24]. Intended benefits for patients from having their case managed by an MDT are summarized in Box 22.1.

In addition to directly improving patient care, participating healthcare professionals may also benefit from working in a MDT. Communication between different team members is also often better where they have a formal working relationship but within the structure of regular discourse and mutual support. For challenging cases, the reassurance of corporate decision-making may

Box 22.1.   Benefits of multidisciplinary cancer care

- Greater accuracy of diagnosis and staging
- Selection from a choice of treatments decided by a group of experts, rather than by one doctor
- Better coordination and continuity of care through all disease stages
- Treatment in line with locally agreed policies and national guidelines
- Provision of appropriate and consistent information, as the healthcare provider giving the information should be more aware of the team's strategy for care
- Greater consideration of patient's psychological and social needs.

be beneficial, although the legal position of such recommendations is unclear [25]. The open communication between professionals is also conducive to learning about novel treatments and clinical trials [26, 27].

Challenges for multidisciplinary care

A typical MDT meeting involves ten to 20 healthcare professionals, lasts between one and three hours, and may require substantial preparation for participants—particularly radiologists and pathologists who may have to review 20 to 30 cases beforehand. The average clinician may attend between one and three such meetings a week, and even the most cursory of calculations will demonstrate the significant time commitments that MDT working demands from members. Consequently, it is perhaps unsurprising that a common contributor to suboptimal MDT effectiveness is lack of attendance at meetings [28–30]. A study of breast cancer MDTs showed that while surgeons and clinical nurse specialists were present for the entire meeting 95% of the time, and pathologists and radiologists in 90–95% of cases, the proportion of clinical oncologists who attended the entire meeting was 70%, and medical oncologists were present throughout in only 44.1% of cases. Medical oncologists were more likely to attend the whole MDT meeting if it was held in a protected session (71% versus 54%), though only 28% of MDT meetings were in protected time. A subsequent study of breast cancer MDTs reported similar findings, and lack of attendance of core members has also been noted in colorectal and head and neck cancer MDTs [29–31]. Time pressures may also lead to challenges in ensuring each case is discussed in sufficient detail to permit the formulation of a detailed management plan. As a representative example, the Oxford colorectal cancer MDT comprises 12 to 15 consultants, four to six specialist nurses and two MDT coordinators, and discusses an average of 30 to 40 new patients each week in a 1–1.5-hour slot. The team is absolutely committed to joint working, but feels that the need to spend more time discussing more complex or difficult cases means that a 'tick-box' mentality is sometimes applied to straightforward cases.

The logistics of conducting an MDT meeting is in itself a substantial undertaking. Meeting rooms require information technology support to permit projection of imaging and histopathology, and in many cases to enable videoconferencing with other hospitals. The MDT coordinator plays a pivotal role in ensuring that correct meeting facilities are booked, that the necessary patient information is available, and that the result of discussions is accurately recorded and expeditiously disseminated to all those involved in the patient's care [18, 30, 32].

As a result of the staff and support costs, MDT working requires substantial investment, and it has been shown that funding strategies often underestimate the true costs of MDT service. A recent analysis collated all salary and support costs of breast MDTs in one UK cancer centre during 2009. During this period the MDT met 53 times and formulated treatment plans for 1315 patients from 2343 discussions. The total cost for the year was £114,948, translating to a cost per management plan of £87.41—similar to the NHS estimate of £85.62 for an average MDT decision. Staff costs comprised 86% of the total [33]. Though this likely represents a worthwhile investment, such evaluation is essential if the true value of MDTs to patient care is to be calculated.

As with any team, successful MDT working is also dependent on the ability of the group to perform well together, a characteristic dependent on both team composition and size [33]. The MDT chair should foster an environment in which all members are encouraged to contribute, with mutual respect for opinions that may differ, and constructive feedback provided on previous decisions [18, 34–37]. This aspect of MDT working is potentially at odds with the historical role of the clinician as largely autonomous care provider, and teams do not typically function well without guidance and training for members [20, 38]. To address this common deficiency, in the UK an MDT self-assessment programme, MDT-FIT ('feedback for improving team-working') is under development with the aim of improving MDT performance [39].

A further potential Achilles heel of MDT working is that central decision-making may be perfectly coordinated but delivery of the treatment plan may be fragmented. Although the ideal of patients moving smoothly along the care pathway from one specialty to another is entirely achievable, the many transitions along the route have the potential to lead to a rather disjointed and daunting experience for the patient at a time of maximum vulnerability. This risk is significantly reduced by the availability of a clinical nurse specialist or key care worker able to accompany the patient when they attend for primary and subsequent treatments in order to maintain continuity and ensure that patients do not get lost in the system. Although many clinical nurse specialists perform this function excellently, again, time pressures prevent them from providing this level of care and support as routine and in every case.

Evidence of benefit from the MDT approach

There are relatively few studies evaluating the effect of MDT working in any form, and those focusing on its effect on cancer outcomes are even less common. The logistics of organizing a randomized controlled trial comparing MDT working with non-MDT working would be challenging to say the least, and as MDT working is both common, and in many cases mandated, internationally such a study is highly unlikely to be performed. Consequently, most data are retrospective, with many before-and-after studies that run substantial risk of confounding due to improvements in care outwith the MDT during the study period. A systematic review of MDT effectiveness published in 2010 [6] identified two systematic reviews [40, 41], one abstract, and 18 original studies [42–58] analysing the effects

of MDT working on cancer survival. Of these, 12 studies (one prospective [57]) and six retrospective cohort studies [42–44, 46, 54, 58], five before-and-after series [47, 50–52, 56] reported statistically significant associations between multidisciplinary care and patient survival. However, significant methodological limitations, including heterogeneity of the definition of multidisciplinary care and a lack of comparison with control groups were common. Thus, it was possible that some of the benefit of MDT working was in fact due to confounding factors including biases in patient selection and improved survival secondary to improved treatments during the study period [6, 40]. Consequently, although the collective weight of evidence to date suggests that multidisciplinary care improves cancer survival, this cannot be authoritatively asserted at present. More controversial still is the evaluation of whether the costs of MDT working justify clinical benefits. Studies evaluating the effects of MDT working on treatment and outcomes for common cancers are discussed below and summarized in Table 22.1.

Breast cancer

MDT management of breast cancer is now standard in the UK and much of the developed world. However, despite early studies reporting that breast MDT cancer care was associated with frequent alteration of patient management plans [11, 59], shorter time to treatment, and greater patient satisfaction [7], a systematic review in 2006 found no evidence that MDTs were associated with improved survival for patients with breast cancer [40]. The authors concluded that while MDT care should in theory be associated with improvement in survival, there was a lack of high-quality evidence to support this.

An important recent report by Kesson and colleagues from Scotland has gone some way to correcting this apparently anomalous situation [60]. In 1995 MDT care was introduced in the Greater Glasgow health board area as part of an initiative to improve the quality of care, but not in areas managed by other health boards in the west of Scotland. Following this introduction, care in the intervention area applied common principles of MDT care—regular meetings, application of evidence-based guidelines and audit—while care in the non-intervention area remained organized along traditional lines, with surgeons unilaterally responsible for making decisions on surgery and adjuvant therapy. Following publication of national guidance on cancer care in 1999, the non-intervention areas also adopted MDT care, and the discrepancy ceased to exist. By comparing outcomes between areas before the introduction of MDT care (analysed time period January 1990 to September 1995) and during the intervention period (time period October 1995 to December 2000), the authors were able to address many of the limitations of previous studies, by defining the composition of an MDT at the outset, observing the effect of care where no other model was available, and including a contemporaneous comparison population to adjust for temporal improvements in survival. Before the introduction of MDTs, breast cancer mortality was 11% higher in the intervention area than in the non-intervention area (hazard ratio adjusted for year of incidence, age at diagnosis, and deprivation = 1.11; 95% confidence interval 1.00 to 1.20). After multidisciplinary care was introduced, breast cancer mortality was 18% lower in the intervention area than in the non-intervention area (0.82, 0.74–0.91). All cause mortality did not differ significantly between populations in the earlier

period, but was 11% lower in the intervention area than in the non-intervention area in the later period (HR 0.89, CI 0.82–0.97). Interrupted time series analyses showed a significant improvement in breast cancer survival in the intervention area in 1996, compared with the expected survival in the same year had the pre-intervention trend continued (P = 0.004). This improvement was maintained after the intervention was introduced. It would appear therefore, that multidisciplinary care was associated with improved survival and reduced variation in survival among hospitals. These results provide the most convincing evidence of benefit for patients with any tumour type from MDT care to date.

Lung cancer

The diagnostic workup for suspected lung cancers often requires multiple investigations, including imaging studies such as ^{18}FDG-PET, bronchoscopy, endobronchial ultrasound (EBUS), mediastinoscopy, and thoracoscopy, many of which are performed by different specialists. In addition, management is frequently multimodal and both the type and scheduling of treatment vary substantially depending on tumour histology and stage. Intuitively, MDTs would be expected to have substantial impact in this tumour type.

In an early effort to assess the effectiveness of MDT working in lung cancer, a pilot study to assess the feasibility and efficacy of referral to a central multidisciplinary diagnostic clinic for diagnostic workup compared with conventional investigation was conducted by investigators at the Royal Marsden Hospital in London. Reported in 2003, this showed that MDT review was associated with shorter time to initiation of treatment though on follow-up no difference in survival between groups was detected. Although the investigators confirmed the feasibility of the pilot, they noted that expanding the study to a size powered to detect survival change would require substantial commitment from patients and physicians [45]. Another study evaluated treatment and survival of patients with non-small-cell lung cancer (NSCLC) before and after the implementation of MDT care in a single centre in Scotland [50]. The pre- and post-cohorts were well matched for baseline variables. Adoption of MDT care was associated with significant increases in the proportion of patients treated with chemotherapy (23% versus 7%; P < 0.001) and in overall survival (6.6 months versus 3.2 months; P < 0.001). However, the before-and-after nature of this study might mean that improvements in systemic therapy and supportive care during the study period may have contributed to the results.

Both of these studies were included in a systematic review of the effect of MDT working on lung cancer outcomes published in 2008. Sixteen studies met the authors' inclusion criteria, including several in which the primary focus was not MDT care per se. Statistical pooling was not possible due to a clinical heterogeneity; however, only two publications, including the study by Forrest, reported improved survival [41]. Both were potentially confounded by the before-and-after design and the authors concluded that although MDT review may be associated with improved survival in lung cancer, the published evidence did not provide conclusive support for this at present. In an attempt to address these deficiencies by minimizing confounding due to temporal changes in management, Boxer and co-workers compared outcomes for 988 patients diagnosed with NSCLC between 2005 and 2008 in Southwestern Australia according to whether or not their cases were discussed

Table 22.1 Summary of studies evaluating the effects of MDT working

Tumour type	Intervention evaluated	Comparison group used	Study design	Sample size	Effect of MDT care on patient management	Effect of MDT care on survival	Notes	Reference
Breast cancer	Effect of introduction of MDT care in health board areas (intervention area)	Adjacent health board areas without introduction of MDT care (non-intervention area)	Temporally matched comparison before and after introduction of MDTs	N = 14, 358	Not reported	18% reduction in breast cancer mortality (HR 0.82, 0.74–0.91) and 11% reduction in all cause mortality (0.89, 0.82–0.97) in intervention area compared to compared to non-intervention area	Highest quality evidence of benefit of MDT care on cancer survival. Screen-detected cancers excluded to avoid bias. Survival improvement persisted after adjustment for confounders	[60]
	Receipt of multimodality treatment/high surgical caseload (>30 cases/year)	Patients not treated with multimodality therapy/low surgical caseload	Population-based retrospective cohort study (1979–1988)	N = 12,861	Patients treated by surgeons with high caseload more likely to receive adjuvant chemotherapy and hormone therapy	Receipt of multimodality therapy associated with improved survival	High surgical caseload likely to be associated with MDT working	[43]
	Receipt of multimodality treatment/high surgical caseload (>30 cases/year)	Patients not treated with multimodality therapy/low surgical caseload	Population-based retrospective cohort study (1989–1994)	N = 11,329	Patients treated by surgeons with high caseload more likely to receive chemotherapy	Management by surgeon with high caseload associated with five-year survival of 68% versus 60% for cases managed by surgeons with lowest caseload	High surgical caseload likely to be associated with MDT working	[46]
	Impact of Calman–Hine recommendations, including MDTs	Cases managed by surgeons with less adoption of MDT working	Population-based, retrospective cohort study	N = 12,961	Increased adherence of teams to manual of cancer service standards associated with greater use of postoperative radiotherapy following breast-conserving surgery (OR = 1.22, P = 0.05)	Trend towards improved survival with increasing surgical site specialization (HR = 0.93, 95% P = 0.1)	Study noted variable implementation of Calman–Hine recommendations	[53]
	Introduction of one-stop multidisciplinary clinic	Cases managed prior to introduction of multidisciplinary clinic	Single centre, before-after study	N_1 = 162 N_2 = 177	Significant decrease in time to initiation of treatment with MDT clinic (29.6 days versus 42.2 days; P = 0.0008). Improved patient satisfaction	Not reported	Authors note pivotal role of nursing coordinator in multidisciplinary care delivery	[7]
	Effect of MDT review on diagnosis/management plan	Nil	Single centre, retrospective review of during six-month period	N = 75	MDT revised treatment plans in 32 cases (43%)	Not reported		[11]
	Effect of MDT review on diagnosis/management plan	Nil	Single centre, retrospective review during one-year period	N = 149	Change in interpretation of imaging in 67 cases (45%) and to interpretation of pathology in 43 patients (29%). Alteration of management plans in 77 cases (52%)	Not reported		[59]

Lung cancer	MDT case discussion	Lung cancer cases not discussed in MDT during same period	Retrospective study of all patients with lung cancer diagnosed between 2005 and 2008	988	MDT case discussion associated with increased use of chemotherapy (46% versus 29%; P < 0.01), radiotherapy (66% versus 33%; P < 0.01) and palliative care (66% versus 53%; P < 0.01	No change in survival	Greater number of patients >80 years age in non-MDT group (25% versus 13%)	[61]
	Introduction of MDT meetings for non-small cell lung cancer	Cases before introduction of MDT meetings	Single centre, before-after study comparing two one-year periods (N_1: 1997, N_2: 2001)	N_1 = 117 N_2 = 126	Implementation of MDT working associated with increased use of chemotherapy (23% versus 7%; P < 0.001)	MDT care associated with improved survival: 6.6 versus 3.2 months (P<0.001)	MDT meetings contained respiratory physicians, medical and clinical oncologists, palliative care physician, radiologist and lung CNS	[50]
	Implementation of MDT meetings and appointment of specialist thoracic surgeon	Cases managed before adoption of MDT working and specialist surgeon	Before-after series	N_1 = 65 N_2 = 175	Significant increase in overall resection rate (23.4% versus 12.2%; P < .001) and operations in the elderly (18% versus 4%; P = 0.02)	No change in five-year survival (31% versus 32%)		[49]
	Central multidisciplinary two-stop clinic for patients with suspected lung cancer	Cases randomized to standard workup	Randomized, controlled pilot study	N = 88	Time to initiation of treatment significantly less in MDT group (three weeks versus seven weeks; P < 0.0025)	No difference in survival at two years	Authors noted that definitive trial would require substantial commitment for patients and clinicians	[45]
Gastrointestinal cancer	Impact of Calman–Hine recommendations, including MDTs for colorectal cancer	Cases managed by colorectal surgeons with less adoption of MDT working	Population-based, retrospective cohort study	N = 12, 358	Increased use of preoperative radiotherapy for rectal cancer with increase in team specialization (HR = 1.43, P < 0.04)	3% decrease in relative risk of death per 25% increase in team score (HR = 0.97, 95% CI 0.94–0.99)	Team score reflected implementation of Calman-Hine recommendations, including MDT care	[54]
	Impact of introduction of colorectal cancer MDT	Patients treated prior to implementation of MDT care	Before-after study (N_1: 1997–2002, N_2: 2002 to 2005)	N_1 = 176 N_2 = 134	Increased use of adjuvant chemotherapy after introduction of MDT care (31% versus 13%; P < 0.01)	Increased three-year overall survival for patients with stage III disease following MDT implementation (66% versus 58%; P–0.023)		[56]
	Impact of introduction of dedicated MDT with liver surgeon for metastatic colorectal cancer	Patients referred directly to specialist hepatobiliary unit	Prospective cohort study	N = 331	Frequency of preoperative chemotherapy not reported	Five-year survival greater for patients referred via specialist MDT (49.9% versus 43.3%; P = 0.0001)		[57]
	Impact of MDT on outcome for patients with oesophageal cancer	Patients treated prior to implementation of MDT care	Before-after study (N_1: 1991–1997, N_2: 1998 to 2003)	N_1 = 77 N_2 = 67	Greater use of radical radiotherapy (P = 0.001) and palliative chemotherapy and radiotherapy (P<0.001) following adoption of MDT working	Five-year survival in group managed by MDT 52% versus 10% for historical controls (P<0.001)	MDT comprised specialist surgeons, oncologist, radiologists, pathologist, gastroenterologists, CNS	[52]

(continued)

Table 22.1 Continued

Tumour type	Intervention evaluated	Comparison group used	Study design	Sample size	Effect of MDT care on patient management	Effect of MDT care on survival	Notes	Reference
	Impact of tertiary centre MDT review for pancreatic cancer	Nil	Prospective study of 203 cases in one-year period		Revision to radiological staging in 38 cases (18.7%), to pathological interpretation in 7 cases (3.4%). Alteration of management plan in 48 patients (23.6%)	Not reported		[62]
Urological cancer	Introduction of concurrent multidisciplinary clinic for low risk prostate cancer	Sequential specialist consultations	Retrospective multicentre study during one-year period	N = 701	Higher proportion of patients in MDT cohort managed with active surveillance (43% versus 22%; P<0.001)	Not reported	High rate of patient satisfaction from MDT clinic	[66]
	Effect of MDT meetings on patient management for urological cancers	Nil	Prospective single-centre study during six-month period	N = 124	Major change to diagnosis/staging* in 2 cases (1.6%), minor change in 5 cases (4.0%)	Not reported	Prior to MDT referring clinicians documented proposed management plans and comparison was made with MDT recommendation	[67]
	Central MDT discussion of selected urologic cancers	Local MDT discussion	Retrospective review of 87 cases during one-year period	N = 87	Change in management from local MDT plan recommended in 0/67 prostate, 4/19 (21.0%) bladder, and 1/1 renal cancer cases	Not reported	Referral to central MDT based on pre-defined criteria	[67]
Gynaecologic cancer	Management of ovarian cancer at multidisciplinary clinic	Patients not managed at joint clinic during same period	Population-based retrospective cohort (one-year period)	N = 533	Patients twice as likely to receive platinum-based chemotherapy (P < 0.001)	Five-year survival 35.3% versus 19.2% (P < 0.001)	130 patients of 479 assessable during study period seen at joint clinic. Improved survival unlikely to be due solely to chemotherapy use	[42]
	Management of ovarian cancer by multidisciplinary team at cancer centre	Patients treated at peripheral units	Retrospective cohort study	N = 287	Higher proportion of patients managed by MDT in cancer centre treated with postoperative platinum-based chemotherapy (98% versus 86%; P = 0.008)	Survival in cases managed in peripheral units significantly less than in those managed by MDT (HR 1.79; P = 0.02)	Service evaluation prior to introduction of management guidelines for ovarian cancer	[58]
	Tumour board discussion of gynaecologic cancers	Nil	Retrospective review during 3-year period (391 new cases, 68 recurrences)	N = 459	Major revision to diagnosis/staging* in 23 cases (5.0%), minor change in 9 cases (2.0%)	Not reported	Authors concluded tumour board review affects patient care	[71]

	MDT discussion of gynaecologic cancers	Nil	Retrospective review during one-year period	N = 509	Major revision to diagnosis/staging* in 30 patients (5.9%) and minor discrepancies in 16 cases (3.1%) Commonest alterations were recommendations for chemotherapy and surgery	Not reported	Authors concluded tumour board review affects patient care	[69]
	Tumour board discussion of gynaecologic cancers	Nil	Prospective analysis over one-year period	N=153	Major revision to diagnosis/staging resulting in change in management in 8.5% and minor change in 26.1%	Not reported		[80]
	Discussion of cases of uterine sarcoma at MDT meeting	Cases not discussed at MDT	Population-based retrospective cohort study	N = 87	Less use of adjuvant chemotherapy in patients discussed by MDT	No impact of MDT discussion on survival apparent		[30]
Head and neck squamous cell carcinoma (HNSCC)	Multidisciplinary clinic with surgeons and oncologists	Cases prior to adoption of MDT working	Retrospective audit—before-after (1: 1996–1997, 2: 1999–2000)	N_1 = 566 N_2 = 727	Not reported	MDT management associated with trend to improved two-year survival in first audit (P = 0.1) and significant improvement in second audit (P = 0.02)	Greater use of MDT working following publication of Calman-Hine report	[47]
Miscellaneous tumour types	Adoption of weekly MDT meetings as part of creating of dedicated cancer centre	Patients managed before MDT implementation, SEER data	Before-after series	N_1 = 5, 487 N_2 = 10, 548	Decrease in proportion of cases managed with surgery alone (36.9% to 31.0%; P<0.0001). Increase in proportion of patients treated with systemic therapy (24.6% to 42.1%; P<0.0001)	Increase in five-year actuarial survival for all tumour types (52% to 58%; P<0.0001]. Significantly improved survival for cancers of breast, lung, prostate, stomach, pancreas, oral cavity	Authors conclude multiple advantages to multidisciplinary team approach	[51]

Notes: * resulted in change in patient management.

in an MDT. Cases discussed at MDT had better documentation of disease stage and performance status, and these patients were also more likely to receive chemotherapy, radiotherapy, and palliative care referrals that patients whose cases were not discussed (P < 0.001 all comparisons). Despite this, no effect of MDT discussion on patient survival was evident [61].

Consequently, although MDT working clearly impacts on patient management in lung cancer, current data do not conclusively prove its benefit in improving patient outcome.

Gastrointestinal cancer

Several studies have examined the effect of MDT working on gastrointestinal malignancies. In an early study, Stephens and colleagues compared outcomes for 67 consecutive patients with oesophageal cancer treated after the adoption of MDT working in 1997 with 77 consecutive historical controls managed by individual surgeons previously [52]. Five-year survival was dramatically higher in the group managed by MDT (52% versus 10%, P<0.0001). Patients managed by MDT were significantly more likely to receive palliative chemotherapy and radiotherapy, though the proportion of patients treated with preoperative chemotherapy was not documented. Though it is likely that the improvement in outcome resulted from multiple factors, many of these are likely to have been secondary to the adoption of MDT working. The effect of MDT care on management of pancreatic cancer was examined in 203 patients treated at a tertiary centre multidisciplinary clinic between 2006 and 2007. MDT review of imaging led to a change in disease stage in 38 cases (18.7%), and in pathological interpretation in seven cases (3.4%). The treatment recommendation of the MDT differed from that previously planned for the patient in 48 cases [62]. Survival outcomes were not reported in this study.

In common with the examples cited above in breast and lung cancer, a multidisciplinary approach to colorectal cancer management can result in alteration in management [63]. A study performed by Burton and co-workers demonstrated that MDT discussion of staging MRI for rectal cancer cases reduced positive circumferential resection margins through improved preoperative treatment [64], and MDT management was associated with increased use of neoadjuvant therapy in a US study [63]. A large study examining the effect of the Calman–Hine recommendations on colorectal cancer care in Yorkshire in the UK ranked colorectal cancer teams according to how closely they adhered to the ideal MDT published in the UK manual of cancer standards, with increasing team score indicating closer adherence. The investigators found no significant link between increase in team score and the frequency of chemotherapy overall, or of preoperative radiotherapy for rectal cancers. However, for every 25% increase in team score a statistically significant 3% reduction in risk of death for all colorectal cancer patients was observed (HR = 0.97, 95% CI = 0.94–0.99) [54]. Although the large size of this study (12,358 patients) and its population-based nature strengthen these conclusions when compared to single-centre studies, the possibility that the improvements in survival may have resulted from factors other than MDT working remains. The multimodality management of liver metastases from colorectal cancer is a notable success of contemporary cancer medicine, and multidisciplinary care has been an integral component in this. However, specialist radiology and surgical review are required to identify cases suitable for curative resection and absence of these may result in patients being denied radical treatment inappropriately.

Therefore, in most large centres discussion of such patients at a specialist hepatobiliary MDT is recommended. A recent study retrospectively identified patients with colorectal liver metastases treated with palliative chemotherapy by oncologists without specialist hepatobiliary MDT review. Imaging prior to chemotherapy was reviewed by liver surgeons blinded to patient management [65]. Of 52 patients with liver-only disease, 33 (63%) were considered potentially resectable by the expert panel. Although this decision was based on purely radiological grounds, it is unlikely that all of these patients would have been unfit for surgery.

Urological cancer

Prostate cancer is a heterogeneous malignancy, the optimum management of which varies from active surveillance to radical prostatectomy or radical radiotherapy. Treatment recommendations for patients may vary according to care providers' biases, and a noteworthy recent study provides an interesting insight into the effects of multidisciplinary working on this. In this large retrospective study of men with low-risk prostate cancer, review at a concurrent multidisciplinary clinic (including a urologist, radiotherapist, and medical oncologist) was associated with a higher proportion of men selected for active surveillance and lower rates of treatment with radical prostatectomy or radiation than in patients seen by practitioners sequentially [66]. This difference was not due to temporal change in practice as all patients were treated in 2009, and the authors conclude that these results may have significant clinical implications. In contrast to these data, Acher and colleagues examined the frequency with which MDT review changed management plans for urology patients in a single centre over a six-month period. Prior to each meeting, referring surgeons completed a form for patients stating their proposed management plan, and this was then compared with the team decision made at the meeting. There was concordance between the two in over 98% of cases, and the authors concluded that it may be possible to reserve MDT discussion for challenging cases without compromising patient care [67]. Similarly, in a report analysing the importance of central MDT review (based on defined criteria) for urological malignancies, management was not changed in any cases of prostate cancer, while for bladder malignancies 4 out of 19 cases (21.0%) had a change in management [68].

Gynaecologic cancer

Several studies report that MDT review of gynaecological malignancies frequently results in change in diagnosis and staging [69–71]. Cohen and co-workers investigated the frequency with which pathological and radiological findings were altered by discussion at a specialist gynaecology MDT in New Zealand [69]. Discrepancies were classified as major if they resulted in a change in patient management, and minor if they did not. From 509 cases discussed during the one-year period analysed, 46 deviations were found (9%), with 30 major (5.9%) and 16 minor (3.1%) discrepancies. The most frequent changes to patient management were recommendations for chemotherapy and surgery. Similar findings were noted in an early study of the effects of multidisciplinary working for all cases of ovarian cancer diagnosed in Scotland in 1997, in which MDT management was associated with increased use of platinum-based chemotherapy. Notably in this study, MDT care was also associated with improved survival, with an effect beyond that explicable by the greater use of platinum-based treatment in this group [42].

Head and neck squamous cell carcinoma

Birchall audited cases of head and neck cancer in the southwest of England before and after the publication of the Calman–Hine report, which promoted MDT working (periods examined 1996/1997 and 1999/2000). Although two-year overall survival was unchanged between the two periods, in both audits MDT management was significantly associated with improved survival [47]. The proportion of patients treated with surgery, radiotherapy, and chemotherapy did not alter between the first and second audits; however, whether use of these treatment modalities was more common in cases managed by MDT is not reported.

Other evidence for effectiveness of MDT care

Although as discussed above, MDTs should improve communication and enhance coordination of treatment, few studies have addressed this. One audit of head and neck cancer found that although referral pathways appeared satisfactory, delays occurred due to waits for investigations, beds, and specialist treatments, particularly radiotherapy [29]. A further concern was that MDTs were frequently understaffed. Another questionnaire-based survey published in 2003 found that 62% of lead clinicians of colorectal MDTs stated that there were difficulties in running the MDT, with 32% lacking a dedicated MDT coordinator. The authors emphasized the essential role of MDT coordinators, and stressed the importance of mapping the patient care pathway to identify bottlenecks where delays occurred [30]. A study of breast cancer teams found that clinical performance was improved by the number of breast care nurses, and positively correlated with the workload of the MDT. This study also demonstrated that teams with a number of leaders were associated with greater effectiveness, while a single, clear leader negatively predicted innovation and effectiveness in audit and research. Interestingly, levels of psychiatric morbidity were lower for MDT members than those reported for other health teams and the NHS workforce in general [35], a finding mirrored by another report which found less psychiatric morbidity overall in MDT members than previously published rates for UK clinicians. However, this average is perhaps an oversimplification as the researchers found substantial variation within teams and high rates of emotional exhaustion in MDT leaders [72]. Although commonly postulated as an advantage of MDT working, evidence for an impact of MDT working on clinical trial recruitment is limited, though published data are consistent with increased frequency of clinical trial participation in patients identified as eligible by MDTs [26, 73, 74].

The future of multidisciplinary cancer care

Cancer is largely a disease of ageing, and the increasing proportion of the elderly who suffer malignant disease poses a particular challenge of MDT working. Although meetings are generally excellent at recording disease stage and pathological factors, documentation of other patient factors such as performance status and comorbidities is frequently variable and occasionally absent. A study of patients with upper gastrointestinal cancers discussed at MDTs found that in 15.1% of cases the MDT recommendation was not implemented. In 43.9% of these cases the discordance was due to comorbidity and in 34.2% to patient choice. The authors concluded that more information on comorbid disease was required for MDTs to make informed recommendations on patient care [75]. Other studies have reported that MDT treatment plans for patients were not actioned in 10–24% cases of colorectal cancer, and 4.4% of lung cancer cases [76] due mainly to a combination of comorbidities and patient refusal [21, 77]. Although validated scales such as the Charlson comorbidity index provide prognostic information for patients with cancer [78] they are not commonly used outside clinical trials. Incorporation of such indices into MDT discussion would substantially strengthen recommendations for the elderly, and is increasingly straightforward using the computer-based applications available. At the very least, a minimum dataset comprising performance status and concurrent illnesses should be available for each patient discussed.

Given the general acceptance that MDT meetings are integral to current best practice in oncology, attention is likely to focus on the refinement, standardization, and streamlining of MDT function. The application of modern information technology (IT) methodology promises significant improvements in all areas. The current MDT model of discussion of each case by core MDT members followed by formulation of an optimum management plan is typically accompanied by limited, if any, documentation of the factors decisions are based upon and little context between one patient and the next. To the external observer, particularly those from backgrounds in engineering and decision science, MDT meetings are in large part art and in small part science. Though the development of evidence-based checklists to structure MDT meetings [39] is a step in the right direction, it is possible to develop integrative software tools to record, display, and report the decision-making process and its outcome in a structured way. Such a system, MATE (Multidisciplinary meeting Assistant and Treatment sElector), developed at the Royal Free Hospital in London was designed to capture patient data including pathology and imaging results, identify patients eligible for clinical trials, and suggest evidence-based treatment recommendations. The developers performed a prospective evaluation through 2008 and 2009 during which MDT patient data was entered onto MATE, though the MDT were unaware of the treatment recommendations generated by the software. On analysis, the recommendations made by MATE displayed better concordance with clinical practice guidelines than MDT recommendations (97% versus 93.2%); in addition, the software identified 61% more patients eligible for clinical trials than the MDT [79].

It is likely that in the next few years MATE, and similar software, will be sufficiently adaptable to contain multifactorial analysis based on genomic data in addition to traditional prognostic factors in order to take advantage of the revolution in genomics which underpins personalized cancer medicine. The logical endpoint of this development will be a suite of software for the management of cancer patients, not only combining current patient data, but also able to display it within the context of a database of previous patients with annotated outcomes, and links to national cancer treatment guidelines and expert disease management systems. This will propel the MDT into an era in which clinical outcomes become the gold standard used to compare the quality of teams and hospitals and, when made publicly available, allow citizens better to choose the centres to which they would prefer referral.

Conclusions

There is clear evidence that MDT working results in change in patient management, and, though limited, outcome data are

consistent with a benefit for patients with cancer from MDT care. As discussed previously, the widespread adoption of MDT working internationally means that such a randomized controlled trial of MDT care is unlikely to take place, although prospective audits should help to confirm that the benefits of MDT working are being realized in practice.

Multidisciplinary care probably improves patient outcomes by influencing various aspects of care. These factors include adherence to guidelines and nurse education, increased surgical volume and experience, and improved interdisciplinary working. Although multidisciplinary care is considered standard practice in many countries, access to such care still varies. However, these results support the universal provision of cancer care by specialist, multidisciplinary teams. The importance of good communication cannot be overstated, and is likely to become more rather than less important as cancer is resolved into a greater number of biomarker-determined disease subtypes. While it is likely that MDTs will remain site-based for the foreseeable future, there will be increasing specializations around targeted molecular pathways as the application of high-throughput sequencing technologies to clinical samples becomes routine. Further work should address other cancer types, tease out which are the most important contributory elements of team-delivered cancer care, and address the issue of cost-effectiveness.

Principles of clinical pharmacology

Introduction to pharmacokinetics and pharmacodynamics

Michael Ong and Udai Banerji

Introduction to principles of clinical pharmacy

Pharmacology is the branch of medicine that studies the uses, effects, and modes of action of drugs. In oncology, principles of pharmacology have been critical in addressing the balance between therapeutic and toxic drug properties—a challenging matter considering that many anticancer drugs are dosed at or near their maximum tolerated dose (MTD) [1, 2]. Two major domains of pharmacology are pharmacokinetics—'what the human body does to a drug', and pharmacodynamics—'what the drug does to the body'. In this chapter, we give an overview of how studies of pharmacokinetics and pharmacodynamics have influenced and continue to guide the development of anticancer drugs in use today.

Pharmacokinetic analyses describe drug absorption, distribution, metabolism, and excretion (ADME) in the body. Pharmacokinetic studies aim to define a dose-response relationship for both therapeutic and toxic drug effects, and describe variation in drug exposure between individuals. A key pharmacokinetic concept is that drug response in individuals is related to drug concentration at the target site. Since intratumoural drug concentrations cannot be practically obtained in clinical practice [3], pharmacokinetic studies typically describe plasma drug concentrations over time as a surrogate measure of tumour exposure. Mathematical models can thereafter be formulated to describe and predict pharmacokinetic processes that take place following administration.

Drug pharmacokinetics are affected by both physicochemical drug characteristics [4] (cell membrane permeability, biotransformation, and protein binding) and physiological parameters [5] (body composition, gastrointestinal motility, organ blood perfusion, and urine flow). The array of influencing factors makes it unsurprising that most anticancer therapies carry substantial pharmacokinetic variability as high as tenfold between individuals [6]. This variability may be very significant since the majority of anticancer agents have narrow therapeutic indices—small differences between the minimum effective dose and the minimum toxic dose—potentially leading to suboptimal drug dosing in some patients or, conversely, toxic dosing in others [7].

Understanding of pharmacokinetics has a key influence on attempts to reduce the interpatient variability of drug exposure. Examples of important influences of pharmacokinetic studies on oncological practice include defining drug dosing by adjusting for patient body surface area [8–12] (e.g., paclitaxel) as drug clearance can increase as a function of body size; routine drainage of third-space fluids prior to administration of methotrexate to prevent drug-fluid distribution and increased late toxicity [13]; alkalinization of urine to promote renal excretion of high-dose methotrexate [14]; carboplatin dose calculation through estimation of renal function [15]; and understanding and reduction of drug–drug interactions as a result of cytochrome P450 activity [16] (see section on 'Absorption').

Pharmacodynamic analyses describe drug effects on the body and tumour, with key pharmacodynamic effects observed for anticancer drugs being host toxicity and tumour response. Host toxicity can be characterized using standardized criteria commonly utilized in clinical trials [17]. The severity of toxicity is important in defining the maximally tolerated dose of a drug. A common dose-limiting toxicity of conventional chemotherapy and, in particular, DNA-damaging and tubulin-binding agents has been myelosuppression [18]. It is possible to model myelosuppression in relation to pharmacokinetic parameters, clinical parameters, or pharmacodynamics biomarkers such as DNA adduct formation [19, 20].

However, pharmacodynamic assessments have evolved as advances in cancer biology have spurred the development of molecularly targeted drugs against the hallmark traits of cancer such as cell signalling and angiogenesis [21]. This paradigm shift towards targeted treatment has redefined the ways in which new anticancer drugs are developed and evaluated [22]. Sophisticated pharmacodynamic biomarkers in both normal and tumour tissues can be used to confirm an appropriate level and duration of target and pathway modulation [1]. Therefore, demonstration that a drug can modulate the biological target of interest and thereby invoke functional consequences represents an essential goal of pharmacodynamic assessments in modern clinical trials.

Pharmacodynamic biomarkers can assess drug effect at the target site (e.g., tumour) or at a surrogate site (e.g., platelet-rich plasma), and are broadly divided into 'proof-of-mechanism' biomarkers that demonstrate drug modulation of the intended target in the human

Table 23.1 Examples of types of biomarkers used to define doses and schedules of targeted agents

Type of PD Biomarker	Target	Biomarker	Drug
Proof-of-mechanism	ABL	p-CRKL	Imatinib
	m-TOR	p-S6	Everolimus
	HDAC	Acetylated histone	Vorinostat
Proof-of-concept	EGFR	Ki67	Gefitinib
	BRAF	FDG-PET	Vemurafenib
	VEGF	DCE-MRI	Bevacizumab

body; and 'proof of principle' biomarkers which demonstrate functional consequences of inhibiting a target (see Table 23.1). For example, the degree of p-ERK inhibition caused by the BRAF inhibitor, vemurafenib, is linked to its efficacy [23]. An increasingly important concept is that a biologically effective dose range exists that appropriately modulates the target and may be different than the maximally tolerated dose, as is the case for bevacizumab [24, 25].

Principles of pharmacokinetics and pharmacodynamics play crucial roles in the way drugs are developed and used as monotherapy or combination therapy. Integrating pharmacokinetic and pharmacodynamic information is challenging, but very informative, and aids in optimizing the dose and schedule of targeted anticancer agents. Understanding pharmacologic principles, combined with specific information regarding an individual drug and patient, underlies the individualized optimal use of anticancer drugs.

Pharmacokinetic parameters

Describing the time-course of a drug in an individual begins with serial sampling of plasma drug concentrations following drug administration. These concentrations are then serially plotted against time in a concentration-time profile, as shown in Figure 23.1. Pharmacokinetic parameters that can be directly derived from this profile include:

- **Cmax**: the peak drug concentration in plasma observed
- **Tmax**: the time to peak drug concentration

Concentration–Time Profile
Fig. 23.1 Examples of a pharmacokinetic profile of intravenous and oral drugs following linear pharmacokinetics.
IV, intravenous; PO, oral.

- **Half-life ($t_{1/2}$)**: the time it takes for half of the drug to be eliminated from the body;
- **Area under the curve (AUC)**: the mathematically integrated area under the concentration-time curve; expresses in a single value the person's overall exposure to drug.

These parameters are useful to describe the expected duration and extent of drug exposure, intrapatient and interpatient variation, and changes in drug exposure as a result of factors such as concomitant drug interactions or liver dysfunction. Half-life is useful to understand the rate of elimination or accumulation of a drug. A drug takes four to five half-lives after dosing to be 93–97% eliminated from the body. Conversely, if a drug is dosed regularly at intervals shorter than the half-life, concentrations will reach higher levels until a steady state is achieved, in which drug entry is equally balanced by drug elimination. Since drugs with a very long half-life (e.g., trastuzumab half-life is 6–16 days) may require a long time to reach steady state, a loading dose may be considered to achieve therapeutic levels faster [26]. Cmax and AUC are useful to describe drug exposure and may be associated with pharmacodynamic effects. For example, Cmax of pegylated liposomal doxorubicin is associated with stomatitis grade and leukocyte nadir [27]; a higher AUC of drugs such as cisplatin, docetaxel, and vinorelbine is associated with a higher response rate of solid tumours [7] and greater haematological toxicity [28, 29].

Absorption

Drug absorption is a key factor that affects the concentration time-course of a drug in the body. Traditional cytotoxic chemotherapies have been largely administered as intravenous agents, which achieve maximum plasma concentrations (Cmax) nearly instantaneously since absorption across membranes is not required. In contrast, many newer molecularly targeted anticancer agents are now developed in oral formulation [30]. Orally administered drugs undergo absorption through a dynamic transfer process from the gastrointestinal lumen, across the intestinal epithelium, and into portal blood. Cmax of orally administered drugs are not instantaneously achieved, may be lower than an equivalent intravenous dosage, and may take hours to peak (Figure 23.1).

A relevant concept for orally (and other non-intravenously) administered agents is bioavailability (F)—the fraction of the administered drug reaching the systemic circulation as intact drug compared with intravenous dosing:

$$\text{Bioavailability (\%)} = \frac{\text{AUC}_{\text{non-intravenous}}}{\text{AUC}_{\text{intravenous}}} \times 100$$

Absolute bioavailability compares exposure to drug in oral formulation compared to the same drug in intravenous formulation; relative bioavailability compares two products to each other, and is commonly used to show bioequivalence for a generic formulation to the original formulation. Typical bioavailability of commonly administered oral anticancer agents is depicted in Table 23.2.

Drug bioavailability may be affected by:

- **Drug physicochemical properties**: lower molecular weight, increased solubility, increased lipophilicity, and non-ionization

favour good oral bioavailability [4]. These characteristics promote passive uptake of drug from the gastrointestinal lumen, a rate-limiting step for absorption of most oral drugs [31].

- **'First-pass metabolism' by intestinal/hepatic enzymes**: oral, but not intravenous, drugs are subject to 'first-pass metabolism', in which metabolizing enzymes within enterocytes inactivate drug prior to the drug reaching the systemic circulation (e.g., 5-fluorouracil). Intestinal metabolism occurs mainly via phase I metabolic reactions (described in the 'Metabolism' section) performed by cytochrome P450 (CYP) 3A monooxygenases within enterocytes. Interestingly, grapefruit juice contains furanocoumarins that directly downregulate and inhibit intestinal CYP3A4, leading to less CYP3A4-mediated first-pass metabolism and potentially greater drug exposure and effect of oral drugs [32, 33].

- **Patient factors, including food-effects**: interpatient variation in the amount of gut surface area, gut transit time, and gastric/intestinal pH can all affect absorption of orally administered agents. Concurrent ingestion of food also affects drug bioavailability by affecting drug solubility and gastrointestinal physiology. For example, lapatinib bioavailability is increased fourfold with a high-fat meal and erlotinib 1.6-fold [34].

- **Active drug efflux into bowel lumen**: efflux transporters situated on the apical/luminal membrane of the intestine can limit oral bioavailability of drugs (e.g., paclitaxel [35]) by pumping drug out into the bowel lumen. Key intestinal efflux transporters include P-glycoprotein (P-gp; *ABCB1*), members of the multidrug resistance-associated protein (MRP; *ABCC*) family, and the breast cancer resistance protein (BRCP; *ABCG*).

Because the need for drug absorption alters ADME significantly, orally administered agents have characteristically greater pharmacokinetic variability than intravenous agents; this must be carefully considered with agents such as etoposide which can be administered by either route [36, 37]. A non-intravenous route should be avoided if bioavailability is poor or variable, particularly for drugs with narrow therapeutic indices [38].

Distribution

Drug distribution into extravascular tissues can occur once drug is delivered intravenously or absorbed via the gut into the intravascular space. The apparent extent of distribution of drug out into the extravascular tissues and away from the intravascular space (plasma) can be described by the volume of distribution (Vd):

Vd = Amount of drug in the body/concentration
     of drug in plasma at equilibrium

Vd theoretically relates the measured drug concentration in plasma to what volume would be required if the body was a uniform space in which drug was distributed. In general, larger Vd indicates greater diffusibility of the drug, but the numerical value of Vd does not relate to a specific physiological volume. Vd can be no less than that of the plasma volume (approximately 3 litres (L)/70 kilogram (kg) man), but can be far greater than that of the total body water volume (42 L/70 kg man). However, larger Vd does not necessarily equate to a higher degree of drug penetration into tumour

tissue; mitoxantrone, for example, has a high Vd because it is highly sequestered by DNA binding and entrapment in acid vesicles of normal cells, and has limited tumour tissue penetration [39]. Table 23.2 lists Vd for commonly administered anticancer agents.

Vd is affected by the following factors:

- **Drug physicochemical properties**: highly lipid-soluble, non-polar compounds are generally able to penetrate cell membranes and fatty tissues more easily with a greater drug distribution than more polar, water-soluble compounds [4]. Penetration beyond the blood–brain barrier (BBB) into the central nervous system (CNS) is largely determined by lipid solubility, and secondarily by molecular size [40]. Formulation can drastically affect drug distribution; pegylated liposomal doxorubicin has 600-fold lower Vd due to stable retention of drug encapsulated by liposomes in circulation [27].

- **Degree of protein binding**: generally, unbound (free) drug is considered to be 'active' and available to bind to receptors, undergo metabolism, and be eliminated from the body. Protein binding predominantly occurs with albumin and/or alpha1-acid glycoprotein. Theoretically, highly protein-bound drugs are susceptible to large increases in free drug fraction by drug-displacement interactions such as salicylates displacing protein-bound methotrexate [41].

- **Active drug efflux and 'pharmacokinetic sanctuaries'**: drug-efflux transporters can affect distribution by limiting transcellular drug entry at the BBB, blood–testis, and blood–ovarian interfaces. At the BBB, drug entry into the brain is limited by endothelial cell tight junctions blocking paracellular uptake, and luminal efflux transporters including P-gp that actively pump drug away from the CNS [42]. The BBB may be impaired in brain metastases, leading to better penetration of drugs traditionally thought to have poor CNS penetration such as paclitaxel and trastuzumab [43, 44]. Poor or suboptimal drug penetration into pharmacokinetic sanctuaries may require circumvention by alternative treatment modalities: intrathecal methotrexate or external beam radiotherapy in children's acute lymphoblastic leukaemia can prevent CNS relapse [45]; delayed orchiectomy is indicated for advanced germ-cell cancer initially treated with chemotherapy because of a relatively high incidence of residual germ-cell cancer or teratoma in the unresected testis [46, 47].

- **Third-space fluid distribution**: third-space fluid such as pleural effusions can influence drug kinetics, especially with drug properties such as methotrexate (MTX) where the Vd is relatively small (approximately 40 L) and protein binding is low (~50%) [13]; thus, drainage of effusions is recommended prior to administration because MTX may accumulate and exit slowly from third-space fluids, leading to prolonged half-life, drug exposure, and toxicity [48].

Metabolism

Drug metabolism is a critical step in the disposition of most drugs, and primarily occurs in the liver. However, enzymes involved in metabolism are also present in many tissues including the intestine and tumour. Drugs typically undergo enzymatic biotransformation by drug metabolizing enzymes into more water-soluble states to increase the rate of excretion through urine and bile. Usually these reactions transform drugs into inactive metabolites; in some cases parent drugs, such as capecitabine, are inactive (pro-drug) and

Table 23.2 Pharmacokinetic properties of commonly administered anticancer agents.

Class	Drug	Absorption				Distribution			Metabolism			Excretion

require metabolic activation [31]; while occasionally both parent drug and metabolites are active.

Drug metabolism reactions are broadly categorized into phase I reactions performed by cytochrome P450 (CYP) monooxygenases, and phase II reactions responsible for drug conjugation.

Phase I reactions non-synthetically form new or modify existing functional groups on a parent drug to improve water solubility and enhance reactivity for further metabolism or excretion. Phase I oxidation reactions are most commonly performed by CYP enzymes located in the hepatocyte endoplasmic reticulum. Over a hundred CYP enzymes are known, of which CYP3A4 and CYP2D6 have the greatest potential for drug metabolism. CYP3A4 alone accounts for 60% of all hepatic cytochromes, and is involved in the metabolism of many anticancer drugs [49]. Because CYP activity is dependent on concentration, degree of induction, and potentially functional genetic polymorphisms, substantial interpatient variability of CYP drug metabolism has been described [50].

A number of clinically significant drug interactions can occur on the basis of alteration of CYP function, and require careful consideration. For example, tamoxifen is converted into its active metabolites via CYP2D6, but antidepressants, beta-blockers and antipsychotic drugs can potentially inhibit CYP2D6 activity and thus tamoxifen bioactivation [51]. Warfarin is an oral anticoagulant whose more active enantiomer, S-warfarin, is metabolized almost exclusively by CYP2C9. A significant interaction occurs with concurrently administered capecitabine, resulting in exaggerated warfarin anticoagulant activity and the need for careful monitoring.

Non-CYP phase I enzymes may also catalyse drug oxidation, reduction, or hydrolysis and include ketoreductase, aldehyde dehydrogenase, carboxylesterases (CES), dihydropyrimidine dehydrogenase (DPD), and cytosine deaminase (CDA). A well-known, clinically relevant functional variant is DPD deficiency. DPD is the rate-limiting and most important enzyme in catabolism of 5-fluorouracil. Partial (3–5% of patients) or complete (0.1%) DPD deficiency may occur in unselected patients, potentially leading to myelosuppression, diarrhoea, mucositis, and neurotoxicity in those treated with 5-fluorouracil [52].

Phase II reactions predominantly occur in the hepatocyte cytoplasm, and are catalysed by the enzymes uridine diphosphate glucuronosyltransferases (UGT1 and UGT2), sulfotransferases, and glutathione S-transferases. Phase II reactions add large water-soluble polar groups to the parent drug or its oxidized metabolites to make compounds more hydrophilic and generally more inert. The reactions are synthetic in nature, and the polar groups that can be added include glucuronic acid, sulfate, acetate, glycine, glutathione, or methyl groups.

Phase II enzymes can be genetically polymorphic, with functional consequences. A well-known functional polymorphism is described for *UGT1A1*, the phase II metabolic enzyme responsible for glucuronidation of SN-38, the active metabolite of irinotecan. Patients with the *UGT1A1 7/7* genotype (10% in North America) have functional deficiency *UGT1A1*, leading to higher patient exposure to SN-38 and a higher risk of severe neutropenia and diarrhoea [53–55].

Excretion

Drugs and/or their metabolites are mainly eliminated from the body via the biliary tract or the kidneys.

Biliary excretion

Drugs may be secreted by hepatocytes into the bile via efflux transporters such as P-gp, MRPs, and BCRP. Generally, larger (>500 daltons), lipid-soluble, amphipathic, or acid-conjugated metabolites are secreted into the bile, whereas smaller compounds are excreted in the urine. Drugs with hepatic elimination may need dose adjustment in the setting of liver dysfunction as detailed in Table 23.2. Reabsorption of drugs via the enterohepatic circulation can occur, leading to prolonged drug exposure and pharmacological effect. For example, the active metabolite SN-38 undergoes enterohepatic recirculation as characterized by rebound increase in SN-38 levels after discontinuation of irinotecan infusion [56].

Renal excretion

Free, unbound drug may be filtered by the kidney glomerulus, actively secreted into the proximal tubule, or reabsorbed in the distal tubule of the kidney nephron; the net excretion rate by the kidney is the sum of these three processes. For example, methotrexate and pemetrexed are eliminated unchanged in the urine via glomerular filtration and active tubular secretion [57, 58]. Drugs with renal elimination may need dose adjustment in the setting of renal dysfunction as detailed in Table 23.2. Urine pH may alter the excretion of drug; for example, the excretion of methotrexate is improved by co-administration of sodium bicarbonate to alkalinize the urine [14]. Concurrent drugs may also affect renal excretion of drugs. Concurrent administration of ASA, NSAIDs, penicillins, cephalosporins, and probenecid appears to inhibit renal drug transporter functions [59], decreasing renal elimination of methotrexate and resulting in clinical toxicity [60]. Renal elimination of paclitaxel, etoposide, ifosfamide, methotrexate, and bleomycin may also be reduced by concurrent platinum chemotherapy [61].

Clearance (Cl) is a pharmacokinetic parameter that describes the efficiency of irreversible drug elimination from the body. A drug is considered to be eliminated by either metabolism or excretion of the parent drug. For example, a molecule that has undergone glucuronidation is described as having been cleared, even though the molecule itself may have not yet left the body. Clearance occurs mainly via the liver or kidneys, but drug may also be eliminated in expired air, sweat, or saliva.

In pharmacokinetic terms, Cl is expressed as the volume of blood from which a drug can be completely removed per unit of time (e.g., 100 mL/min):

$$\text{Clearance} = \text{Dose}/\text{AUC (estimated by } [0.693 \times V_d]/t_{1/2})$$

Clearance can be especially useful in optimizing dosing of patients because it describes the efficiency of drug elimination from the body. Clinical factors such as age, gender, race, nutrition, and organ function may be predictive of drug clearance; for example, it has been described that patients over the age of 70 have an approximately 30% decrease in clearance related to CYP enzyme activity [62]. Clearance of a parent drug (e.g., temozolamide or dacarbazine) may still yield active metabolites and it is important to consider the further metabolism and elimination of such compounds [63].

Pharmacokinetic models

Animal models are used to test toxicity and efficacy of an anticancer drug before it is administered to humans. Regulatory

requirements vary, but often a rodent and non-rodent species is tested. The first-in-human starting dose for evaluation in clinical trials is often calculated by allometric scaling [64]. Extensive pharmacokinetic-pharmacodynamic efficacy modelling is also conducted as a part of drug discovery for targeted agents to define a pharmacologically active dose range in these models. It is possible to relate findings in human trials to these animal models while making go/no-go decisions at the end of phase I studies.

Linear, one-compartment pharmacokinetic models treat the body as a 'well-stirred' single compartment in which drug distributes instantaneously. Drug metabolism/excretion occurs at a rate directly proportional to drug concentration: doubling of drug concentration will be met with doubling of drug metabolism/excretion. Functionally, this is relevant in the case where therapeutic drug concentrations only occupy a small proportion of the available metabolizing or transporting enzyme sites.

Multicompartment pharmacokinetic models account for the time of drug distribution between tissue and plasma by dividing the body up into compartments in which drug can distribute and/or eliminate. The pharmacokinetic behaviour of most drugs is best described using a two-compartment model, in which a central compartment (blood plus the extracellular spaces of well-perfused tissues) and a peripheral compartment (less well-perfused tissues into which the drug permeates more slowly) are defined. Notably in these models, an alpha phase will characterize the rate of distribution away from plasma, while a beta phase (terminal half-life) will characterize the rate of elimination from plasma [65].

Non-linear pharmacokinetics (zero-order kinetics) may occur because drug excretion, metabolism, or protein-binding processes become saturated at typical blood concentrations. In this situation, increases in drug are not met with increasing metabolism or transport. Drug concentrations in blood rise unexpectedly and potentially dangerously with increasing dosage. Paclitaxel has been described as following non-linear pharmacokinetics [66], likely resulting from an interaction with the Cremophor® excipient used to dissolve paclitaxel. Furthermore, doxorubicin given concomitantly with paclitaxel can exhibit non-linear pharmacokinetics as well, possibly as a result of saturation of biliary excretory mechanisms [67]. Drugs may exhibit linear pharmacokinetics at low doses but non-linear pharmacokinetics at high-doses, as is observed for cyclophosphamide [68].

Population pharmacokinetics is the study of the variability in plasma drug concentrations between individuals who receive standard dosage regimens and who represent the target patient population. Population pharmacokinetic models aim to account for observed inter-individual variation by quantification of covariates using specific patient parameters to determine the optimal dose for the individual.

Pharmacokinetic-pharmacodynamic (PK-PD) models can provide a means of exploring important pharmacological and toxicological properties of a drug by describing the time course of the pharmacological effect of a given dose. Three components are required for a PK-PD model: a pharmacokinetic model, characterizing the time-course of a drug and metabolite concentrations in plasma; a pharmacodynamic model, characterizing the relationship between concentration and effect(s); and a link model, which serves to account for the often observed delay of the effect relative to the plasma concentration.

Pharmacodynamic biomarkers

Proof-of-mechanism biomarkers

Biomarkers crucial to demonstrating the mechanism of action of an anticancer agent are considered to be 'proof-of-mechanism' biomarkers. The aims of such assays are to demonstrate that the drug is modulating its intended target in the human body. In the case of tyrosine kinase inhibitors, it could be measurement of activation of the downstream signal transduction pathway; for example, measurement of inhibition of ERK phosphorylation as a pharmacodynamic readout of the EGFR inhibitor, gefitinib [69], or the study of S6 phosphorylation as a readout of an m-TOR inhibitor such as everolimus [70]. While these markers often measure biomarkers downstream of the intended biological target, pharmacodynamic biomarkers could also include quantification of accumulation of an upstream biological protein; for example, the quantification of accumulation of corticosterone upstream of the intended CYP17 was used to help define the dose of the CYP17 inhibitor, abiraterone [71].

While proof-of-mechanism biomarkers may be used to tailor the dose and schedule of anticancer drugs in phase I studies, they are also crucial in go/no-go decisions to stop the development of a drug if toxicity-limiting dose escalation occurs at doses of drug which does not cause proof-of-mechanism biomarker modulation.

Proof-of-concept biomarkers

Proof-of-concept biomarkers study the functional consequences of inhibiting a target. An example of a proof-of-concept biomarker includes measuring volume transfer constant (Ktrans) via dynamic contrast-enhanced magnetic resonance imaging (DCE-MRI) to measure vascular permeability while evaluating an anti-angiogenic agent such as bevacizumab or axitinib [72]. As proof-of-concept biomarkers study downstream functional events on inhibiting a target, they are sometimes not specific to the target itself. For example, measurement of Ki67 to determine the reduction of proliferation could be used as a proof-of-concept biomarker for an EGFR inhibitor such as gefitinib [73] or the BRAF inhibitor, vemurafenib [74]. In some instances, a change in proof-of-concept biomarker can also be investigated for use as a predictive biomarker of response. For example, the use of 18-fludeoxyglucose positron emission tomography (FDG-PET) to study the pharmacodynamic effects of imatinib in gastrointestinal stromal tumours [75].

Tissues for pharmacodynamic biomarkers

The gold standard for performing pharmacodynamic biomarker assays remains cancer tissue. Depending on the tumour being studied or the platform being used to assess pharmacodynamic biomarkers, it is possible to perform multiple assessments of pharmacodynamic changes before and after treatment with an anticancer agent. Examples of instances where it is possible to study pharmacodynamic biomarkers in tumour serially include the study of phosphorylation of CRKL in circulating leukaemia cells after treatment with the tyrosine kinase inhibitor imatinib, or the study of Ktrans using DCE-MRI of tumour to assess the anti-angiogenic effects of a VEGFR inhibitor such as axitinib [72]. Limitations of pre- and post-tumour biopsies include (1) the fact that often only one pre- and one post-treatment samples are taken

due to safety considerations and therefore a sampling error may occur in relation to the time at which pharmacodynamic changes occur; and (2) the area of tumour sampled may not contain the biologically relevant drivers due to intra-tumoral heterogeneity [76]. Tumour biopsies are often performed in the later stages of a phase I study when it has been demonstrated that the drug has reached pharmacologically relevant plasma concentrations, and if appropriate assays are present to demonstrate modulation of proof-of-mechanism biomarkers in normal tissue. An exception to this rule is if the drug target itself resides in normal tissue, as in the case of ipilimumab, which modulates cytotoxic T-cell activation [77].

As multiple repeat sampling of tumour tissue is often not possible, pharmacodynamic biomarkers are often also assessed in normal tissue. It is often possible to sample normal tissue on multiple occasions, from which pharmacodynamic information may help to decide on scheduling of a drug. Commonly used tissues include peripheral blood mononuclear cells (PBMNCs) or platelet-rich plasma (PRP) to measure a diverse set of biomarkers such as p-ERK [78], p-AKT [79], acetylated histone H3 [80–82], and HSP70 [83], which are useful to study a variety of drugs targeting MEK, AKT, histone deacetylase (HDAC), or heat shock protein 90 (HSP90). Disadvantages of using PBMNCs and PRP are that the tissue being sampled consists of terminally differentiated and non-proliferating tissue which may not have relevant genetic abnormalities such as mutations in BRAF or amplified HER2. Normal tissue such as skin and hair follicles has the potential advantage that it demonstrates pharmacodynamic activity in extravascular space [69, 79, 81].

Technical aspects of pharmacodynamic biomarkers and validation

Pharmacodynamic biomarkers must be quantifiable across a dynamic range, taking into account the degree of normal variability in the patient sample being studied. If studying normal tissue, it is possible to look at variation in normal volunteers [84]. If studying tumour tissue, fortunately, interpatient variability may be partially controlled by the patient acting as their own control, i.e. the post-treatment samples are compared to pre-treatment samples. However, studies in variation of pharmacodynamic biomarkers in tumour may require multiple pre-treatment biopsies, or can be investigated using serial imaging [85]. Attention to the degree of reproducibility of the assay, and the processing and stability of samples once stored are crucial to valid interpretation of pharmacodynamic data [85].

Pharmacogenomics

Pharmacogenomics is the study of how an individual's genetic inheritance (his/her genome) or tumour genetics may affect drug pharmacokinetics and pharmacodynamics. Due to rapid advances in DNA sequencing techniques, individualized analysis of inherited germline DNA and/or tumoural DNA has become feasible and potentially useful for individualizing drug dosing and selection. However, interpreting the functional consequences of genetic changes such as single-nucleotide polymorphisms is complex because gene phenotypes are commonly polygenic (determined by multiple genes), and the outcomes of interest such as drug toxicity of irinotecan may not rely solely on a single genetic change such as a *UGT1A1* gene polymorphism [53–55]. Nevertheless,

pharmacogenomics is an increasingly studied field in oncology and carries great potential to inform individualized drug dosing and selection [86].

Conclusions

Pharmacokinetic principles crucially underpin the safe prescription and effective administration of anticancer drugs. Practices such as dose adjustments based on body surface area, clinical factors, and organ function have evolved out of pharmacokinetic studies in an effort to reduce interpatient variability to drug exposure. Further attention to variability as a result of oral administration of drugs, concomitant medications, drug formulation, and syndromes of host metabolic deficiency are important to an oncologist's routine practice. Individualization of drug doses based on these factors and assays such as therapeutic drug monitoring and pharmacogenomics can potentially identify patient populations with a high likelihood of toxicity [87].

Pharmacodynamic principles have become increasingly important to the development of molecularly targeted agents as our knowledge of cancer biology has evolved. Both proof-of-mechanism and proof-of-concept biomarkers allow demonstration of anticancer activity at pharmacological doses different to the maximally tolerated dose. Information from pharmacodynamic biomarkers potentially allows us to define drug dosing with wider therapeutic indices, optimal scheduling, and favoured combinatorial approaches [88, 89]. As new therapies targeting the hallmark traits of cancer are developed and evaluated, pharmacological principles will continue to increase in importance for optimizing anticancer drug delivery and minimizing toxicity [1].

Design and analysis of clinical trials

Daniel J. Sargent and Qian Shi

Introduction to design and analysis of clinical trials

Overall mortality rates for cancer patients have maintained a declining rate of more than 1% per year for the past ten years, with substantial contributions to this decline from four major cancers sites: lung, colorectum, breast, and prostate [1]. Recent exciting advances in genomics, proteomics, and computational power empower scientists with new tools to understand the causes and prognoses of cancer at the molecular level. Innovative targeted compounds are being developed with great potential to battle the disease. In the face of these advances, the high failure rates of late-phase clinical trials in oncology [2] are of substantial concern. In this chapter, we aim to present general concepts and principles, as well as current innovations and issues and future directions of design and analysis of clinical trials in oncology from a statistical perspective, with an expectation that adherence to these principles will ultimately increase clinical trial quality and reduce the phase III trial failure rate.

The intended audience of this chapter is a wide range of professionals in oncology research, especially those involved in clinical trials. We will not devote attention to mathematical theories of statistical design and analysis methods, but rather will provide a high-level overview on the relevant topics. Several excellent texts provide comprehensive discussions of the development and applications of statistical methods in clinical trials; we cite several such references.

Scientifically sound study design and conduct are fundamental and essential to the success of any research. This is particularly true for oncology therapeutic development in this new era of emerging personalized medicine. Successful clinical design and analysis are never easy tasks, which involve, but are not limited to, framing the right question based on high-quality scientific evidence, identifying the targeted disease population, selecting well-defined and most relevant endpoints, determining the cost-effective sample size and sampling schema, carefully controlling the impact of unknown or non-measurable confounders, formulating decision rules based on comprehensive operating characteristics assessment, prespecifying subgroup analyses and correlative studies, and building in continuous patient safety and therapeutic efficacy review.

Design of clinical trials

It is increasingly recognized among oncology researchers that collaboration with statisticians in the early stage of planning a study is not only valuable but critical. This is especially true for oncology clinical trials, to prevent costly mistakes in both financial burden to society and devastating losses to patients and their families. These mistakes can be due to methodological errors, underpowered studies with severe adverse effects, or misinterpretation of collected data. Optimal clinical trial design can simplify subsequent analyses by defining data collection processes appropriately, reducing bias and variability, and minimizing the influence of complicating confounders. In this way, stronger or more convincing evidence can be revealed by simple statistical analysis methods with fewer assumptions [3].

The section presents the principles, methodologies, and several illustrative examples related to the design of oncology clinical trials. Traditional or so-called standard designs will be presented, followed by two key elements of designing a clinical trial: endpoint selection and sample size determination. For additional technical background regarding clinical trial design and analysis, we refer readers to other sources such as Armitage and Berry [4] and Marubini and Valsecchi [5].

Traditional designs

A *clinical trial* is an experiment testing the safety and efficacy of a treatment or a medical procedure on human subjects through a rigorously defined protocol. This includes application of treatment, ascertainment of outcome(s), safety monitoring, decision rules, analysis plans, and specimen collection [3]. Clinical trials are generally classified as phase I, II, and III according to their primary aims and the stage in the timeline of drug development.

Phase I studies

Phase I studies are generally aimed at identifying the optimal dose level and treatment schedules based on an assessment of a new regimen's toxicity. In recent phase I studies, an extended cohort may be added to confirm the optimal dose level identified during the trial, to allow the generation of preliminary efficacy data, and to further define the basic clinical pharmacology of the drug.

A traditional and commonly used phase I design in oncology is the cohort-of-three design. The fundamental assumption is that treatment benefit and the toxicity are both increasing in a monotone fashion as the dose increases (e.g., with cytotoxic agents). Under this assumption, the balance between maximizing the treatment response and protecting patients from severe toxicities can be

achieved by identifying the maximum tolerated dose (MTD). The MTD is defined as the highest dose level at which the percent of patients experiencing dose-limiting toxicity (DLT) reaches the pre-specified acceptable limit. In the cohort-of-three design, the limit of this percent is set to be 1/3. In general, DLTs are defined as serious or fatal side effects of the new regimen.

Practical considerations require the study design to prespecify a small set of doses, optimally based on preclinical evidence, with patients treated adaptively according to the observed rate of toxicity at each of the previously studied dose levels. In the cohort-of-three design, three patients are treated at the starting dose level. If no DLT is observed, three patients will be treated at the next higher dose level. If more than one DLT is observed, three patients will be treated at the next lower dose level. If one DLT is observed, an additional three patients will be treated at the same dose level. The MTD will be considered as exceeded if two or more DLTs are observed out of three or six patients at a given dose level. The next lower dose level will be defined as the MTD as long as six patient have been evaluated on that level.

The cohort-of-three design has several appealing features: it is straightforward to conduct, decision-making of dose escalations is transparent, and there is no need for sophisticated computing programs. However, this design may require a long time and many patients to reach the MTD, with many patients treated at the suboptimal dose levels. For example, 56 patients were accrued during 38 months, and 13 dose levels were tested in a study assessing irinotecan for patients with advanced cancer [6]. In addition, multiple simulation studies have demonstrated that model-based approaches can more accurately determine the true MTD, perhaps with fewer patients [7]. In the modern era of therapeutic development of treating cancer, more than one-dimensional dose-finding strategies are needed for testing combinations of new standard compounds. Many novel therapies with cytostatic or targeted compounds do not share the same dose-response assumption of cytotoxic agents. Innovative designs which account for efficacy data in dose-finding decision-making may be more appropriate in many cases than traditional cohort-of-three phase I study design [8, 9].

Phase II studies

Phase II trials are aimed at quickly screening new treatments or regimens based on early evidence of their efficacy, as well as further characterizing the toxicity of a regimen. As opposed to phase I studies, a focused disease population (e.g., a particular tumour type with specific stage) is generally considered. Historically, single-arm designs were commonly used in this setting. As oncology research has advanced, a randomized design has become more frequent. Regardless of the design, these clinical trials are vital to determine if the new treatment should be tested in large-scale comparative (phase III) studies. In addition, the feasibility of the new treatment, including safety, administration, and cost, will be informed during this phase of development.

Single-arm phase II studies construct the design using two benchmarks of the underlying treatment effect based on historical data. For instance, if the response rate (RR) is used to measure the treatment effect, then the first benchmark is a clinically uninteresting rate, p_0. If the true RR of the new regimen is as low as p_0, then it is not worthwhile continuing evaluation. The second benchmark is the targeted rate, p_1 ($> p_0$). An RR which is as high as p_1 will

be considered to warrant a large-scale comparative trial. By pre-specifying acceptable type I and II error rates (explained in a later section), the required number of patients (i.e. sample size) and the number of responses (i.e. boundary of efficacy-decision rule) can be calculated.

For ethical considerations, it is desirable to minimize the number of patients treated with ineffective or inferior treatments. Stopping trials based on results of interim analyses is commonly applied. From a statistical perspective, there are two reasons for stopping a trial early—stop for superiority (i.e. efficacy) or stop for inferiority (i.e. futility). The first situation applies when there is overwhelming evidence that the experimental treatment is superior to historical control (or a concurrent control in a randomized two-arm study). Stopping for futility (i.e. lack of efficacy) implies that based on an interim analysis result it is highly unlikely that the trial will achieve the targeted treatment effect even if all patients are enrolled. Due to the small sample size of phase II trials, a substantially large treatment effect (usually beyond what is realistic) will need to be observed to meet the early stopping criteria for efficacy.

Simon's optimal two-stage design [10] is a widely used method for single-arm phase II trials in oncology. For a typical phase II study, for example, to test the null hypothesis that the RR of a regimen is at most 60% versus the alternative hypothesis that the RR is greater than 75%, Simon's design requires a maximum sample size of 71 patients to achieve 90% power at the significance level of 0.1. A planned interim analysis (i.e. the first stage) will be conducted when 34 patients are enrolled and the response data are available. If 21 or fewer responses are observed, the trial will be terminated early for futility. Otherwise, an additional 37 patients will be accrued. If the study proceeds to the second stage and more than 47 responses are observed, the new regimen may warrant further investigation. Other designs and further discussion can be found in many references [11–16].

One of the major drawbacks of the single-arm design is the lack of robust knowledge of historical success rates due to heterogeneity of study population, limitations of previous studies (poor design or data quality), or even lack of relevant studies. This has been considered to be one of the reasons that contribute to the high failure rate of subsequent phase III studies [17, 18]. An alternative to the single-arm design is randomized phase II studies. Randomized selection and screening designs have been proposed and used in oncology drug development. In a selection design, multiple experimental arms are tested. A 'winner' will be selected for a future phase III trial either based on the highest estimated success rate for the primary endpoint [19], or between multiple arms if the difference in treatment effect between the best arm and less optimal arm(s) is larger than a prespecified criterion [20]. In a screening design, the experimental regimen is compared to standard-of-care treatment in a head-to-head manner [21]. A screening phase II design is very similar to phase III randomized trial design, but with higher type II error rate and lower power.

Phase III studies

Phase III clinical trials are pivotal, designed to provide the definitive evidence to move a new regimen or modality into patient care, or to definitively refute the usefulness of the proposed new treatment. Under most circumstances, phase III clinical trials are designed to compare concurrent arms with randomized allocation

of patients. Randomization continues to be considered as a simple and reliable tool to prevent bias in allocating treatments in comparative studies, includes biases due to treatment selection based on patients' prognostic factors, and known/unknown (measured/unmeasured) confounding factors. For more practice and theory associated with randomization, we refer readers to the discussions by Lachin [22, 23].

There are two classes of design for phase III trials: the superiority design and the non-inferiority/equivalence design. In a randomized clinical trial (RCT) with a superiority design, the primary aim of the study is to show whether the new therapy is superior to an established therapy or placebo. Alternatively, if the alternative treatment is easier to administrate, costs less, or is less toxic than standard of care, showing superiority is not necessary; a definitive demonstration of non-inferiority is all that would be required [24–27]. Non-inferiority or equivalence trials are designed to show the alternative therapy is not inferior to or equivalent to an established therapy, respectively. The different aims of these two types of design lead to significantly different design aspects from a statistical perspective, such as the planning, analysis, and reporting of an RCT. Figure 24.1 illustrates the difference in specifications of null and alternative hypotheses comparing these designs.

Randomization is one of the fundamental principles for RCTs. It balances known and unknown prognostic factors. However, within a particular trial (especially a trial with small sample size), random chance may lead to imbalances with respect to important prognostic factors [28, 29]. To prevent the potential failure of randomization, randomization procedures can be implemented within subpopulations defined by different levels of patient baseline characteristics which influence prognosis. This is called *stratification* of treatment assignments. The patient characteristics (i.e. prognostic factors) are referred to as *stratification factors*. In addition to the benefit of assurance that compared groups are similar with respect to known prognostic factors, stratified randomization also protects against type I error [30, 31], increases power [32, 33], reduces sample size (especially for equivalence trials) [34], and facilitates subgroup analyses [35]. Generally speaking, fewer strata are better. With fewer stratification factors, the trial is more likely to avoid incomplete fills of blocks (*over-stratification*) and to assure equal distribution of stratification factor among treatment groups [36].

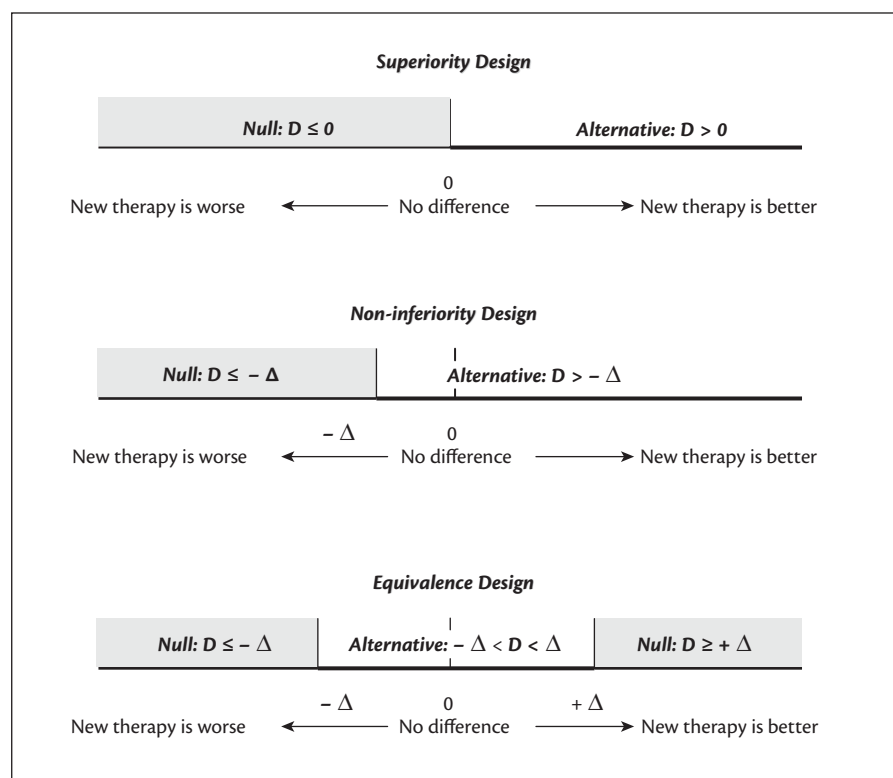
In randomized studies, blinding (or 'masking'), when possible, is another critical method for reducing bias. Blinding is a procedure that withholds information from specific groups of individuals [37]. For instance, patients are blinded to what treatment arm (intervention versus control) they are receiving. This is aimed to reduce the response bias associated with the psychological impact of being treated with an intervention perceived as superior to a control treatment. Blinding the treatment allocation to patients also prevents the attrition bias (i.e. dropout from control arm), non-compliance and co-intervention bias (i.e. patients in control group may seek out alternative interventions or obtain experimental intervention) [38]. Other groups that are commonly blinded are healthcare providers and outcome assessors. The knowledge of the treatment assignment of a patient may induce differences in the quality of patient–provider interaction, for example selective decisions to cross over from the control to the experimental


Fig. 24.1 The null and alternative hypotheses for superiority, non-inferiority and equivalence randomized clinical trials.

Note: D is the treatment effect (e.g., difference) between new therapy and control therapy. Δ is the non-inferiority and equivalence margin in non-inferiority and equivalence design, respectively.

intervention [37]. Blinding to outcome assessors helps prevent the tendency for evaluators to assess patients treated with the experimental intervention more favourably [39]. Using a placebo which is identical in appearance to the treatment drug is a common procedure for blinding in randomized trials [40, 41].

Endpoints

Types of endpoint

The primary endpoint(s) is one of the most critical elements in formulating the design, data collection, and statistical analyses plan of a clinical trial. It is a quantitative measurement implied or required by the primary objective(s) of a study, and will be determined in each study subject. The best endpoint is a clinical measurement reflecting the most relevant potential treatment effect of the new regimen that can be defined with rigorous mathematical and statistical properties. Many times, a clinical objective may imply more than one quantitative definition of an endpoint. For example, 'improve survival'—a common goal in oncology studies—might mean prolonged median survival, higher five-year survival rate, or a lower death rate specifically due to disease. These three quantitative definitions may require different methods or schedules of assessment, and need not yield the same sample size or analysis plan. In other instances, various study teams may define the same endpoint differently. For example, pre-operative morbidity could be defined as disease-specific, treatment-specific, or a composite; every primary endpoint must be clear and unambiguous.

The phase of clinical trials also affects the choice of endpoints. For example, the presence of a DLT during the first cycle of treatment is commonly used in phase I dose-finding trials. Short-term tumour-related measures (e.g., response status during treatment) may be a suitable primary endpoint for phase II screening trials. For confirmatory phase III oncology studies, overall survival, defined as time from randomization to death due to any cause, is a standard endpoint. From a statistical perspective, there are several types of endpoint that are likely to be used in various clinical trials. These include continuous endpoints (e.g., prostate-specific antigen level), dichotomous endpoints (e.g., response rate), or time-to-event endpoints (e.g., time to disease recurrence). Determining a proper endpoint that can be obtained reliably and repeatedly in a particular clinical trial is an essential task for the statistician and involves careful communication between the statistician and clinical investigators.

Surrogate endpoints

As mentioned in the previous section, overall survival (OS) is considered a standard clinical primary endpoint in phase III trials of life-threatening diseases, such as cancer. However, using OS as an endpoint frequently increases the duration or sample size of a clinical trial. For example, in early-stage cancer trials, sufficient power has to be achieved by extending patient follow-up or increasing the sample size due to a low death rate. This clearly hinders rapid development of effective therapies. To overcome this problem, using surrogate endpoints which are measured earlier, more frequently, more conveniently, or at less cost to replace the 'true' endpoint of OS seems to be an attractive solution.

There are various definitions of surrogate endpoints in the literature [42]. For example, the Biomarkers Definitions Working Group (BDWG) defines a surrogate endpoint as 'a biomarker that is intended to substitute for a clinical endpoint. A surrogate endpoint is expected to predict clinical benefit (or harm or lack of benefit or harm) based on epidemiologic, therapeutic, pathophysiologic, or other scientific evidence' [43]. A critical requirement of a valid surrogate endpoint is that the treatment effect observed on a surrogate endpoint should reliably predict the treatment effect on the clinical endpoint. This implies a stronger requirement for a surrogate endpoint than simply a significant correlation between it and the clinical endpoint.

There are two branches of statistical surrogate evaluation methodologies: a single-trial or a meta-analytic evaluation. In the single-trial approach, the 'proportion of treatment effect' (PTE) [44, 45] explained by the surrogate, has been the predominant approach. Recent innovative methods of evaluating surrogate endpoints using single-trial data have emerged, including the semi-competing risks paradigm [46] and the use of causal models [47]. On the other hand, work in the meta-analytic framework [48] and regression-based approaches [49, 50], based on multiple randomized trials, is frequently used to evaluate the potential time-to-event surrogate endpoints in oncology. Burzykowski et al. further developed the concept of a 'surrogate threshold effect' (STE) that estimates from existing trials the magnitude of a surrogate needed in a future trial to predict benefit on the true proposed endpoint [51]. Lassere has proposed [52] a biomarker surrogacy evaluation scheme to better enable integration of surrogacy into the clinical context.

In oncology studies, there has been a long history of utilizing surrogate endpoints. For example, tumour shrinkage or delayed tumour growth, improved levels of biomarkers, such as prostate-specific antigen (PSA) in prostate cancer, are considered as good prognostic factors for long-term clinical outcomes. Therefore, tumour response, time to progression or recurrence, and measures defined by certain forms of biomarkers over time are frequently used as primary outcomes in early phase clinical trials. Many times, these substitutes for the true clinical endpoint, such as OS, are used without any formal validation. However, as we gain a greater understanding of the validation conditions for surrogate endpoints, the process of formally evaluating a potential surrogate endpoint has been increasingly adopted. Shi and Sargent summarized recent applications of evaluating surrogate endpoints in oncology studies including colorectal, prostate, and breast cancer [42]. In the adjuvant colorectal cancer setting, Sargent et al. successfully validated three-year disease-free survival (DFS) as a surrogate endpoint for five-year OS [53]. In metastatic colorectal cancer, progression-free survival (PFS) has also demonstrated promising surrogacy [54], but such surrogacy was not established in advanced breast cancer [55]. No studies, to our knowledge, have successfully established strong surrogacy of tumour response for OS in any disease.

Power and sample size considerations

Errors and biases

In the statistical design of any clinical trial, control of possible error is a critical concept. Generally speaking, there are two types of error. One is random, which is purely due to chance. Another is systematic, known as bias, which describes errors that are not a consequence of chance alone [3].

We borrow Piantadosi's analogy to distinguish random errors and bias [3]: if the treatment effect in a clinical trial is the 'sound or signal' we aim to detect, then random errors can be considered to be the 'background noise', whereas bias is signal distortion. There are often a set of factors (well-known) that contribute to the possibility of bias. In many cases, these sources of bias can be understood well enough to be controlled. This is fundamentally different from random errors: pure random errors have no preferred direction. Clinically, averaging over a large number of observations or long enough time periods, the relative effect of random errors on treatment effect detection (hypothesis testing or parameter estimation) will be sufficiently small. However, bias cannot be reduced by averaging after repletion or taking additional observations. For controlling bias, randomization and stratification are two critical principles. Concurrent controls, objective assessments, active follow-up and endpoint ascertainment, and no post hoc exclusions are also critical considerations to reduce bias [3].

In a clinical context, although bias can arise in numerous ways, the critical ones are generally well understood and can usually be removed or reduced by good design and proper conduct of the clinical trial. However, due to sampling variability, subject heterogeneity, measurement error, and other sources of noise, the random error can never be completely eliminated. One aspect of the design of a clinical trial is to control and reduce the random error to an acceptably low level, while still maintaining the feasibility of conducting a trial ethically and financially. This goal is mainly achieved by the careful consideration of sample size calculations in respect of two types of error: false positive (type I) and false negative (type II) errors.

Significance level and power

Regardless of whether a design is based on hypothesis testing, significance testing, or confidence interval estimation, the statistical design of a clinical trial is centred on controlling type I and type II errors. A type I error is a 'false positive' result and occurs if there is no treatment effect or difference but investigators incorrectly conclude that there is. On the other hand, a type II error occurs when there is a treatment effect but investigators fail to detect it—a 'false negative' result. The significance level (frequently denoted as α) is the boundary of the acceptable type I error rate, i.e. the risk level the investigators are willing to accept that an observed significant treatment effect is not 'truthful' and instead due to chance. The significance level is usually set to be 0.05 in trials targeted to provide confirmatory results. For early phase studies (e.g., phase II), α can be as high as 0.2. The type II error rate usually is denoted by β. The value of $1-\beta$ is commonly known as power. The power of the study is the likelihood of concluding a treatment effect or difference exists when in fact it does.

For a particular design, the type I error rate and power depends on sample size, the null hypothesis regarding the treatment effect (e.g., no difference for a superiority design), the clinically meaningful effect size of the new treatment compared to standard care or placebo (alternative hypothesis), and the specific statistical model which depends heavily on the choice of the primary endpoint.

Study operating characteristics

When designing a clinical trial, the sample size and decision rules provide direct guidance for conducting the study. When a study is simple, for example without any interim looks, and a single primary endpoint, and a traditional design is considered, controlling type I and II error rates is straightforward. Many statistical software packages can perform the sample size/power calculations. If one or more interim looks are desired, then sample size calculations must be adjusted accordingly, as type I error rates are inflated due to multiple testing—multiple looks will increases the rate of positive findings purely by chance [3]. In some situations, the power will be also affected. Hence, a comprehensive evaluation of the proposed study design before launching the study is critical. From a statistical perspective, this consists of evaluating the study operating characteristics—calculations of probabilities of discovering the treatment effect and the likelihood of stopping the study early at interim looks under a range of assumptions of the true treatment effect. These assumptions usually range from no effect (null hypothesis) to the targeted clinical meaningful treatment difference (alternative hypothesis). In complex designs, simulation studies can be powerful tools to assess the study-operating characteristics. In these studies, the clinical outcomes can be generated based on design parameters under statistical models (the one chosen to determine the sample size and decision rules), and a designed study can be repeatedly 'conducted' and 'produce' the hypothetical outcome data a large amount of times (>1000). It is not uncommon for existing statistical designs to be inadequate or for their underlying assumptions to be unfit for the situation in hand. In these circumstances, simulation studies provide a flexible tool to perform sample size and power calculations and define optimal decision rules.

Advanced designs

Phase I cancer therapies are shifting from cytotoxic compounds to cytostatic or targeted therapies. The shape of dose-response curves of these new regimens is usually unknown. It could be monotone non-decreasing, non-linear, or increasing with a plateau. The traditional cohort-of-three design is not appropriate in such cases. The continual reassessment method (CRM) [56] is a novel alternative design for phase I dose-finding studies. CRM phase I design uses the statistical model to update the estimated the DLT rate of each dose level, and determine the dose level for the next patient after observing each patient's DLT status at a given dose level, with all previous patients' data incorporated. As therapies become increasingly targeted, with reduced off-target effects (i.e. toxicity), the primary goal of many phase I trials is also changing towards defining a biologically optimal dose (BOD)—a dose that has maximal efficacy with acceptable toxicity. Modified CRM designs to identify the BOD, and other newer phase I designs have been proposed and developed [57–59].

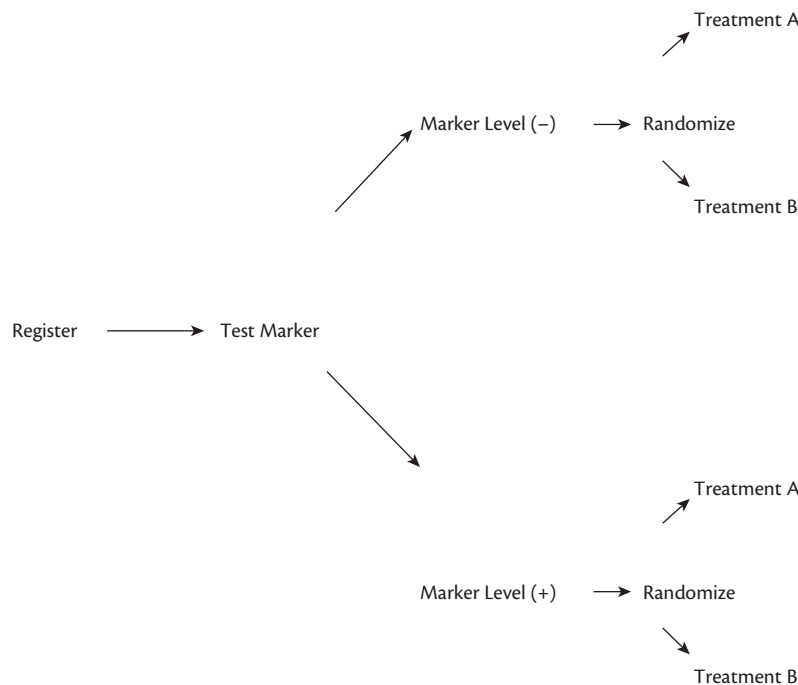
It is well recognized that the long time period and high cost of conducting clinical trials is problematic. One appealing novel design is to combine phase II and III stages by conducting phase II/III studies. Theoretically, by streamlining the plan and conduct of the study, and allowing the inclusion of phase II patients into the phase III analysis, efficiency can be enhanced. Although the overall type I rate and power need special treatment, by adjusting the sample size and carefully formulating the decision rules in both phase II and III components, there are several flexible approaches to apply this design. Different designs can be used in the phase II portion, including single-arm efficacy analysis (e.g., a phase II/III study testing FOLFIRINOX versus gemcitabine in metastatic pancreatic cancer [60]), screening design (e.g., CALGB-80802 [61]),


Fig. 24.2 Treatment-by-marker interaction designs as in [53].

and a selection design (CALGB-30610 [62]). Furthermore, different design aspects such as assessing multiple primary endpoints, mixtures of non-inferiority and superiority, or inclusion of multidimensional interim looks can be accommodated in this design (e.g., the Alliance intermediate risk rectal trial [63]).

To further streamline clinical trials, adaptive designs have been increasingly proposed. An important difference in adaptive design from traditional phase III randomized design is that this design can address more than one question through prespecified ongoing modification of the trial based on accumulating data [64]. Adaptations can include adding or dropping arms/doses, changing the proportion of patients randomized to each arm, adaptively defining an indication or responder population, and seamlessly transitioning between phases of clinical trials [65]. I-SPY2 [66, 67] is an example of an adaptive study aimed at prospectively identifying efficacious compounds in biomarker-defined patient populations. Multiple compounds from different drug companies and multiple biomarkers are being tested. Throughout the trial, the design algorithm continuously calculates the predictive probability of each regimen being successful in a 300-patient phase III confirmatory trial.

Based on the growing role of biomarkers in clinical trials, novel trial designs for validating prognostic and predictive biomarkers are in active development. The clinical utility of a predictive biomarker is to determine whether an individual patient will respond to a particular therapy or not, which can guide the individualized therapy [68]. Prospective designs include enrichment designs (only patients with biomarker-positive status will be studied) [69], treatment-by-marker interaction designs (patients with valid biomarker tests, both positive and negative, are randomized within each biomarker strata) [68, 70] (see Figure 24.2), marker-based strategy designs, and adaptive designs [68, 71].

Analysis of clinical trials

Among experiments in medical research, it is likely the case that clinical trials are the ones with the largest portion of effort expanded in the planning stage. A prospectively defined clinical trial protocol includes a carefully formulated statistical design, a well-planned assessment schedule and method for outcomes classification, well-established data monitoring and reporting programs, etc. As such, proper experimental design and execution tend to simplify the data analysis tasks, which in turn strengthen the evidence a clinical trial can deliver. Hence, analysis of clinical trial data can often follow basic and common statistical methods. For standard endpoints, depending on their nature, the commonly used statistical tests or regression techniques can be used to compare endpoints between groups and assess the associations between endpoints and other baseline factors, respectively. For example, the two sample t-test and chi-squared test are suitable to compare continuous and binary endpoints between treatment groups, respectively. Multivariate logistic regression is useful to assess the treatment effect on binary endpoints adjusting for confounders. When the primary endpoint is a time-to-event outcome (e.g. OS), log-rank and Cox proportional hazards models are used for simple comparison and association analysis, respectively. In addition, confidence intervals with a prespecified confidence level (e.g. 95% = $(1-0.05) \times 100\%$, where 0.05 is the significance level) are often used to give the interval estimate of the treatment effect. The length of the confidence interval provides an idea of the precision of the point estimate and strongly depends on sample size. The interpretation of a 95% confidence interval of a hazard ratio comparing overall survival times between two treatment groups is that, over the collection of all 95% confidence intervals that could be constructed

from repeated random samples, 95% will contain the true hazard ratio. We refer readers for further technical details to Armitage and Berry [4], Everitt [72], and Campbell and Machin [73]. Time-to-event endpoints (e.g., OS and time to recurrence) are frequently used in oncology studies. Readers can consult Kleinbaum [74] for complete introduction to the analysis of survival data.

Intention-to-treat principle

The findings of a clinical trial can be sensitive to how investigators handle imperfections in data, for example non-adherence to protocol treatment, missing and incomplete measurement, non-protocol-specified treatment cross-overs, eligibility errors, follow-up dropouts, etc. Among these data imperfections, treatment non-adherence has received a great deal of attention in the clinical trial literatures. This leads to the intention-to-treat (ITT) principle, as stated by Fisher et al. [75]: 'The analysis that includes all randomized patients in the groups to which they were randomly assigned, regardless of their adherence with the entry criteria, regardless of the treatment they actually received, and regardless of subsequent withdrawal from treatment or deviation from the protocol.'

ITT has become the preferred approach to analysing randomized clinical trials based on a consensus supporting ITT analyses from statistical and clinical perspectives. An alternative to an ITT analysis is the per-protocol analysis, where patients are analysed according to the treatment actually received, even if the randomization called for something else. Per-protocol analysis has been shown to be potentially misleading and may confuse rather than help the interpretation of results, since there might be confounders which are associated with patients' adherence or non-adherence to the treatment [76] such as other treatments, disease status, lifestyle, or other unknown factors. For these reasons, the ITT analysis has been suggested as the standard analysis for a randomized clinical trial by several authors [77, 78]. Lagakos et al. [79] also showed that the size of an ITT analysis is not distorted by early treatment termination, although a loss of power can occur. From a clinical standpoint, the reasons for exclusion of patients due to non-adherence are frequently associated with prognosis or can affect the treatment groups differently. Although per-protocol analysis may be a better method in some circumstances, for example a non-inferiority design, or if required by a certain biological question, it should generally not be considered as the primary analysis of a randomized clinical trial.

Control for multiple comparisons

Within a clinical trial, besides the primary endpoint, several secondary endpoints are also generally prospectively specified to address questions beyond the primary objective. In addition, there might be one or more correlative studies which examine the prognostic value of genetic, pathological, or imaging biomarkers, for example. In this sense, clinical trial data often lend themselves to exploratory or hypothesis-generating analyses. Multiple endpoint analyses lead to multiple uses of the same data, i.e. multiple comparisons. The major problem associated with multiple comparisons is the inflation of type I (false positive) errors. If a nominal significance level is set to be 5%, two independent comparisons will increase the overall type I error rate of detecting at least one significant result to 9.8%, and three comparisons will increase it to 14.3%. Multiple comparisons also frequently arise when subgroup analyses are carried out. Hence, investigators must be aware of these types of problems when performing exploratory analyses. A good practice in reporting these findings is to acknowledge the hypothesis-generating nature of the analysis and always carry out an independent validation study to confirm the results.

Controlling multiple comparisons refers to controlling the family-wise type I error rate. Depending on what inferences are intended, the family-wise error rate can be controlled in the *weak* or *strong* sense [80]. Weak control is appropriate only if one wants to make a statement regarding the global null hypothesis against any kind of alternative hypotheses (where the deviance lies is not important). However, in many cases, the specific differences among subgroups do matter. In this case, strong control should be applied. The Bonferroni adjustment is a widely used multiple comparisons correction, where the significance level is set to be the nominal level divided by the number of comparisons planned to be conducted. It has been shown that Bonferroni adjustment is too conservative, especially when multiple comparisons are correlated to each other. Improved methods include Holm [81] and Hommel [82] procedures (more powerful than Bonferroni method), fixed-sequential testing methods [83] (based on prespecified sequence of hypotheses), and resampling-based methods [84, 85] (which release the distributional assumptions of p-values). Furthermore, when a large number of tests are conducted (e.g., genetics studies), control of the false discovery rate [86] is a more powerful (i.e. more liberal) method.

Conclusions

In this chapter we addressed several key statistical issues associated with clinical trials. It should be recognized that a clinical trial is often a moving target. Decisions regarding modification and termination of a trial can (and will) be influenced by the advancing knowledge gained over the course of the study, both internally and externally. Communication and collaboration among the investigators and statisticians throughout the conduct of a trial are thus critical. Essential discussions between these experts involve the key questions to the practical planning and conduct of a study, including what the targeted disease population is, how 'success' is defined, what the clinical meaningful treatment effect is, and what the existing knowledge of the new regimen may be. With the discovery of genetic signatures and biological pathways, biomarker-directed therapy has an increasing role in oncology therapeutic research. Innovative clinical trial design is needed. By building an understanding of the principles and methods in clinical trial design with increasing experience with clinical trial principles, progress toward more effective therapeutic development can be accelerated.

CHAPTER 25

Medical ethics in oncology

Eric A. Singer

Introduction to medical ethics

The ethical practice of medicine is often taken for granted by physicians, our colleagues, and our patients. It is assumed that as members of a learned profession, doctors instinctively understand how to dissect complex ethical dilemmas and fulfil the expressed and implied standards of the Hippocratic tradition [1]. This is assumed despite the remarkable advances in both diagnostic and therapeutic technology that would make contemporary medical practice seem unrecognizable to physicians of 100 years ago, let alone the fifth century BC. Fortunately, the ethical underpinnings of medicine remain unchanged: alleviating suffering, avoiding harm, and a healing relationship based on trust [2]. The aim of this chapter is to examine several areas of ethics that are of particular concern to oncologists.

Ethics in oncology

For most practitioners, ethics was taught in medical school or at university prior to the decision to pursue career specialization; we were not yet oncologists or urologists or paediatricians. The fundamentals to which we were exposed should still serve us well, but it can be helpful to explore subspecialty-specific dilemmas that occur with increased frequency. Given the central role that clinical trials play in oncology, this chapter will highlight some of issues involved with human subject research and the sequelae of advances in translational research and novel therapeutics. The reader will also gain valuable knowledge from several other chapters within this text that focus on complementary topics including clinical trial design, health care economics, cancer screening and prevention, and palliative care and supportive oncology (see Chapters 24, 26–30, and 33–35).

Research ethics

Ethics is more often about balancing competing principles or goods than simply choosing between right and wrong or good and bad. In the realm of clinical oncology research, the desire to generate knowledge and identify new or improved therapies is a compelling good. However, research involving human subjects includes a genuine risk of harm. To help establish a framework within which to examine conflicts in research ethics, one can turn to a collection of international statements that were written in response to severe ethical lapses with the goal of preventing future abuses.

The Nuremberg Code, written in 1947 in response to the atrocities performed by Nazi doctors during World War II, emphasizes the primacy of obtaining voluntary consent from all research participants and the importance of using human subjects only when the research results will benefit society and are not otherwise obtainable [3, 4]. The Declaration of Helsinki, adopted in 1964 and most recently updated by the World Medical Association in 2008, focuses on physicians performing research with patients and states that 'the well-being of the individual research subject must take precedence over all other interests' [5]. The seventh update of the Declaration of Helsinki was updated in 2013. Readers are encouraged to visit the World Medical Association's website at <www.wma.net> to review the latest iteration of this important document, which is published on the website of the Journal of American Medical Association (JAMA). In the United States, the Belmont Report, issued in 1979, emphasizes the principles of respect for persons, beneficence, and justice when evaluating the ethical nature of human subjects research [6]. Despite the guidance offered in these and other codes of research ethics, there has not been a widely acknowledged, comprehensive framework that is universal in its applicability [7].

Requirements for ethical research

Emanuel and colleagues describe seven requirements for the conduct of ethical clinical research in their seminal paper published in 2000 [7]. These central tenets include: (1) social or scientific value; (2) scientific validity; (3) fair subject selection; (4) favourable risk–benefit ratio; (5) independent review; (6) informed consent; and (7) respect for potential and enrolled subjects. Table 25.1 defines each of these seven requirements, lists the supporting ethical framework for their inclusion, and describes the skill set needed to evaluate whether each requirement has been met.

Some of the advantages of this rubric are that the seven requirements for ethical human subjects research are applicable to studies performed in economically developed as well as developing countries; that they are relevant to trials examining diagnosis, treatment, or prevention in both oncology and non-oncology domains; and that they encapsulate the values and priorities of multiple international statements on the ethical conduct of research without having been created in response to a specific crisis or incident [7]. Despite these benefits, questions about research ethics persist. Several contemporary concerns include clinical cancer research involving phase I trials, placebo-controlled trials, and the use of mandatory research biopsies.

Phase I trials

The primary endpoints for phase I oncology studies are to characterize the safety, tolerability, and side effects associated with novel therapies. Response to treatment, such as reduction in tumour size or number, improvement in disease symptoms, or prolonged

Table 25.1 Seven requirements for determining whether a research trial is ethical

Requirement	Explanation	Justifying ethical values	Expertise for evaluation
Social or scientific value	Evaluation of a treatment, intervention, or theory that will improve health and well-being or increase knowledge	Scarce resources and non-exploitation	Scientific knowledge; citizen's understanding of social priorities
Scientific validity	Use of accepted scientific principles and methods, including statistical techniques, to produce reliable and valid data	Scarce resources and non-exploitation	Scientific and statistical knowledge; knowledge of condition and population to assess feasibility
Fair subject selection	Selection of subjects so that stigmatized and vulnerable individuals are not targeted for risky research and the rich and socially powerful not favoured for potentially beneficial research	Justice	Scientific knowledge; ethical and legal knowledge
Favourable risk–benefit ratio	Minimization of risks; enhancement of potential benefits; risks to the subject	Non-maleficence, beneficence, and non-exploitation	Scientific knowledge; citizen's understanding of social values are proportionate to the benefits to the subject and society
Independent review	Review of the design of the research trial, its proposed subject population, and risk–benefit ratio by individuals unaffiliated with the research	Public accountability; minimizing influence of potential conflicts of interest	Intellectual, financial, and otherwise independent researchers; scientific and ethical knowledge
Informed consent	Provision of information to subjects about purpose of the research, its procedures, potential risks, benefits, and alternatives, so that the individual understands this information and can make a voluntary decision whether to enrol and continue to participate	Respect for subject autonomy	Scientific knowledge; ethical and legal knowledge
Respect for potential and enrolled subjects	Respect for subjects by 1. Permitting withdrawal from the research 2. Protecting privacy through confidentiality 3. Informing subjects of newly discovered risks or benefits 4. Informing subjects of results of clinical research 5. Maintaining welfare of subjects.	Respect for subject autonomy and welfare	Scientific knowledge; ethical and legal knowledge; knowledge of particular subject population

*Ethical requirements are listed in chronological order from conception of research to its formulation and implementation.

survival may be assessed as secondary endpoints but they are not the driving factor behind phase I trials. Concerns regarding the ethics of phase I oncology trials have been debated for more than 30 years [8–14].

The fundamental issues in this debate centre on a potentially unfavourable risk–benefit ratio (limited likelihood of benefit despite a considerable risk of toxicity) and the adequacy of the informed consent process required prior to study participation [8]. Despite these ethical concerns, phase I trials continue to be a critical aspect of oncology drug development and many large cancer centres have dedicated phase I or developmental therapeutics teams whose primary goal is to engage in translational and early human cancer studies.

A favourable risk–benefit ratio is one of the seven requirements for ethical research [7]. While making such a determination is not always straightforward, allowing oncology patients, many of whom have advanced disease that has failed to respond to approved therapies, to consider participating in a phase I trial that is evaluating a drug that is supported by encouraging preclinical evidence is reasonable. The likelihood of direct personal benefit is small, but so is the expected benefit from using a third- or fourth-line standard chemotherapy for most malignancies. Additionally, the level of evidence supporting extended-line therapies is often weak as agents may lack a specific indication and are used off label. Lastly, these extended-line treatments come with definite toxicities that are often very similar to those expected in phase I trials. In fact, the American Society of Clinical Oncology (ASCO) in its statement on individualized care for patients with advanced cancer suggests that patients consider enrolling in a clinical trial so that they may 'gain access to promising new interventions when standard therapy has little to offer and to do so in a highly regulated setting that offers a chance to contribute to improvement in outcomes for future patients' [15].

Since direct patient benefit is not the primary goal of phase I oncology protocols, some critics contend that only patients who don't fully grasp the purpose of early oncology trials would be willing to enrol in them. Patients must mistakenly believe that the purpose of a given study is to provide them with personalized and effective cancer care rather than to generate medical knowledge that might help future patients. This scenario, which was first described in psychiatric research, is referred to as the therapeutic misconception [16, 17].

Pentz and colleagues sought to understand the prevalence of the therapeutic misconception among subjects enrolled in phase I oncology studies at an academic medical centre during the first month of trial participation [18]. Among research subjects they interviewed and surveyed, 68.4% of respondents (65 of 95 subjects) could not correctly describe that the purpose of phase I research is to produce generalizable knowledge rather than direct personal benefit and that the treatments provided on the trial were set by the protocol rather than individualized by their treating physician. When examining demographic factors that were associated with therapeutic misconception, these researchers found that lower education and lower family income correlated with an increased risk. However, they also noted that having limited treatment options was not associated with an increased likelihood of therapeutic misconception, indicating that cancer patients were not more likely to confuse the purpose and design of clinical research with standard treatment because of the lack of therapeutic choices. While there are numerous limitations to this small single-centre study, it demonstrates that the therapeutic misconception continues to be a challenge to the proper conduct of phase I research.

Rather than claiming that cancer patients cannot participate in phase I clinical trials because of the possibility of not understanding the purpose and methods of research, Wendler proposes a slightly different approach to dealing with the therapeutic misconception. While ensuring that potential research subjects understand the differences between standard clinical care and clinical research is important, he suggests that investigators focus their efforts on confirming that subjects understand the *specific facts* about the *specific protocol* they are considering [19]. This 'task-specific' approach concerns itself less with the general differences between routine clinical care and a clinical trial and instead works to have the research subject appreciate how his/her treatment, testing, follow-up, and potential for benefit/harm will change if an investigative approach is chosen over standard therapy.

The therapeutic misconception is a genuine problem in the conduct of ethical clinical cancer research, but as Pentz and colleagues and Wendler have shown, the fact that some patients have difficulty understanding or articulating the differences between clinical research and standard clinical care is not an insurmountable problem and should not result in a moratorium on early-phase oncology research. Increased attention to clear, readable, culturally competent informed consent documents, the use of patient/subject advocates, and attention to the specific differences between routine and experimental treatment in a specific protocol can help ensure that research subjects are choosing to enrol in clinical trials with the necessary information and for the right reasons [20].

Use of placebos

Prospective, randomized clinical trials are the foundation of modern oncology. However, when designing such a study, considerable attention must be paid to the comparison arm as well as the experimental arm. Should the comparison arm be the 'standard of care' or a placebo? The use of inactive controls in trials enrolling subjects with cancer diagnoses remains controversial.

Emanuel and Miller describe the placebo-controlled trial debate as one that focuses on two opposing and unwavering camps [21]. Proponents of placebo-controlled trials emphasize the methodological purity attainable when there is no active comparison arm. Since the purpose of clinical research is to create generalizable information, placebo-controlled studies are appealing in that the statistical analysis is much more straightforward and accurate. However, opponents of placebo use believe that an active control must always be used whenever one is available as a way of minimizing the risks of forgoing treatment for research subjects. Supporters of active controls often cite the Declaration of Helsinki, which requires new therapies always be tested against the best current therapy available [5]. In setting up these opposing 'orthodoxies', Emanuel and Miller offer a compromise as the best way forward. This middle ground permits placebo-controlled studies when there are strong methodological reasons for omitting active controls (assuming the study meets all seven criteria for ethical research listed above), it is clear that subjects who receive placebo will not suffer serious harm, and that the research protocol has adequate safeguards to minimize any risks associated with subjects receiving placebo rather than a standard, active therapy [21].

Within the realm of oncology trials specifically, placebo-controlled studies are ethically justifiable when studying a condition that has a high placebo response rate; that fluctuates in the severity of its symptoms; that has an unpredictable course; for which existing treatments are of little benefit or highly toxic; or in relation to which there is no recognized standard therapy for a specific disease state [22]. If one or more of these conditions are met, and a placebo is to be used, additional safeguards are required to ensure that those subjects randomized to receive placebo are not at an increased risk of death, serious harm, or severe discomfort [22]. The research protocol and informed consent process must clearly explain these safeguards and the likelihood with which subjects will receive the placebo.

Best supportive care should be offered to all research participants regardless of the study arm to which they are randomized, and a detailed supportive care management plan should be stipulated in the research protocol. The reader is referred to Chapters 32–34 in this volume for additional details about supportive oncology and palliative care. Similarly, careful selection of the clinical trial design, such as with a randomized discontinuation design, can help reduce the number of subjects exposed to placebo and allow crossover to the study drug or other standard therapies upon progression [23]. Detailed information about study design and analysis is available in Chapter 24.

Mandatory research biopsies

The growing emphasis on 'personalized' or 'precision' medicine has led to the inclusion of research biopsies in clinical trials with increasing frequency [24–27]. The purpose of these biopsies is to facilitate correlative science, such as identifying predictors of treatment response or resistance, and might be required at multiple time points during the trial. Increasing our understanding of biomarkers and targetable pathways is crucial to enhancing treatment options, but the vast majority of these benefits are years from fruition and are unlikely to benefit the research subject [28–31]. Therefore, the incorporation of mandatory research biopsies raises several questions pertaining to subject autonomy/informed consent and minimizing risks while maximizing potential benefits for trial participants [32, 33].

In order to examine the issue of mandatory oncology research biopsies with greater granularity, Peppercorn and colleagues describe three different types of biopsy: clinical biopsy; research biopsy for correlative science; and research biopsy for an integral

biomarker study [34]. A clinical biopsy is performed as part of the routine diagnosis of most malignancies and provides a direct benefit to the patient by helping to determine the type of treatment needed. Unused portions of a clinical biopsy can be used for correlative science with the patient's consent via a tumour bank or biorepository. A research biopsy performed to evaluate for an integral biomarker may or may not provide benefit to the research subject. In this scenario the utility of the integral biomarker is what is under investigation and the biopsy is necessary to determine if the biomarker is present in a tumour. The integral biomarker biopsy will determine the subject's eligibility to participate in a trial, which might provide a benefit. Lastly, a biopsy for correlative science provides an unclear benefit to the patient and will not be used to determine trial eligibility or to drive standard patient care. Correlative science biopsies may be exploratory or used to answer a specific hypothesis. The concern regarding mandatory correlative research biopsies arises from the requirement that subjects consent to future invasive procedures with potentially significant risks and no potential direct benefits in order to participate in a clinical trial now [35].

In order to further elucidate the risks associated with oncology research biopsies, Overman and colleagues examined the complication rates seen at their comprehensive cancer centre during a five-year period [36]. They identified 38 trials that required at least one mandatory research biopsy. Analysis of tumour tissue was a study endpoint in 95% of the trials. The primary reason for a research biopsy was for integral biomarker analysis or correlative science in 32% and 68% of the studies, respectively. In terms of complications from 745 biopsies, overall and major complication rates were 5.2% and 0.8%, respectively. However, among 211 thoracic or 189 abdominal/pelvic biopsies the complication rates increased to 17.1% and 1.6%, respectively. Overman and colleagues concluded by calling for improved informed consent documents that explicitly state the lack of benefit and investigative nature of non-integral biomarker biopsies and to provide organ or body-site-specific complication rates to help potential subjects understand the risks involved with research biopsies.

A recent position statement from ASCO provides five conditions that must be met in order ethically to justify the added risk associated with the inclusion of a mandatory research biopsy in a clinical trial [34]. These conditions include: (1) strong scientific rationale—a properly powered and independently reviewed protocol; (2) adequate informed consent—nature of the research, type of biopsy to be done, lack of direct benefit, and description of risk are clearly explained; (3) risk minimization—use of the least invasive technique targeting the safest site; (4) timing—combine research biopsies with other routine tests/procedures; (5) lack of other options—study cannot be performed without mandatory biopsies from all research subjects (e.g., analysing previously obtained tissue, using optional biopsies, or using another tissue source such as circulating tumour cells, etc.).

The need for correlative and translation science will continue to grow as the role of targeted therapies expands into new disease states. Likewise, clinical oncology research will continue to be possible because research subjects decide that the known risks and potential benefits of participating in cancer research have been minimized and maximized, respectively. Mandatory research biopsies are ethically permissible but must be considered the method of last resort and undertaken with great care so that research subjects are protected and empowered to make an informed decision.

Oncology drug shortages and the cost of cancer care

In addition to the myriad dilemmas pertaining to the ethical conduct of clinical oncology research, some of which are described above, there are two significant issues related to approved or standard of care oncology drugs that are occurring with greater frequency. The first is shortages of once readily available oncology medications and the second is the rapidly increasing cost of oncology treatments and technologies.

Managing oncology drug shortages

Becker and colleagues examined the incidence of oncology drug shortages at their urban, academic cancer centre from April to September 2010 and again in 2011 [37]. They found that 12 oncology drugs were in shortage in 2010 while the number increased to 22 in 2011. During the 2011 study period, nearly 10% of oncology patients had documented therapy changes due to the limited availability of chemotherapeutics compared to zero changes in 2010. In surveying their centre's oncologists, 30.4% felt these alternative regimens were less evidence-based and 34.8% believed they came with an increased risk of toxicity. While this is only an illustrative example, oncology drug shortages are a reality and a management plan should be developed in advance of an actual crisis [38].

Rosoff and colleagues logically state that the first step in dealing with an oncology drug shortage is to maximize efficiency and minimize waste [39, 40]. When this is inadequate to alleviate the shortage, they suggest using the 'accountability for reasonableness' process created by Daniels and Sabin to develop a rationing schema [41, 42]. Box 25.1 lists and defines the four ethical requirements of the accountability for reasonableness rationing system: (1) relevance, (2) transparency, (3) revision, and (4) enforcement.

Since the cause, duration, and scope of oncology drug shortages are constantly in flux, medical centres and oncologists should create their management strategies well in advance of an actual shortage. Table 25.2 describes factors that Valgus and colleagues believe should be considered when developing a response to oncology drug shortages. These factors include: (1) drug indication, (2) patient goals of care, (3) patient cycle of treatment, (4) presence of suitable alternative agents, (5) medical necessity, (6) informed consent, and (7) timing of the policy [43]. Rationing standard, conventional chemotherapeutics may seem jarring in the age of targeted therapies and novel biologics. However, failing to develop and implement a logical, just, prospective plan that includes the input of physicians, nurses, pharmacists, social workers, ethics committee members, and patient representatives is ill advised and could lead to suboptimal as well as unethical treatment decisions.

Cost of cancer care

In keeping with issues of access to cancer care, the costs of treatment are a significant barrier to many patients [44–47]. The proliferation of expensive targeted therapies, biologics, new radiation delivery methods, and robotic-assisted surgery has the potential to markedly increase the overall, as well as out-of-pocket, costs of cancer treatment. While this type of dilemma is largely dependent upon the type of healthcare system in which a patient finds him or herself, some of the ethical questions that arise have broad appeal. Namely, what should the role of the oncologist be in managing the

Table 25.2 Factors to consider when faced with an oncology drug shortage

Indication	**Approved indication versus off-label use**
	Patients being treated with a medication that has an approved indication for their condition should receive priority over off-label uses of a shortage drug.
	First-line versus subsequent-line
	Patients receiving first-line therapy should receive priority over patients getting second- and subsequent-line therapy.
Goals of care	**Curative intent versus palliation**
	Patients who may be cured of their disease should receive a shortage drug over those who are not curable or who are using the drug for palliation. Best supportive care should be offered to all patients regardless of goals of care, treatment indication, or line of therapy.
Cycle of treatment	**Ongoing regimen versus treatment plan being developed**
	Patients who have started a treatment regimen should receive a shortage drug over those who have not yet started therapy in order to avoid a situation where a patient receives the toxicity of therapy, and possibly that of another agent, but is not able to receive the potential benefit of a full course of the originally intended treatment.
Suitable alternatives	**Alternative approved and available versus not**
	Patients who may be treated with multiple regimens supported by high levels of medical evidence should be encouraged to choose the medication or combination of medications that avoids or uses the least amount of the shortage drug.
Ability to pay	Medical necessity should trump the patient's insurance status/financial resources when making allocation decisions. Drug hoarding, gray- or black-market purchases, price gouging, and bidding wars are unethical. Market forces certainly do affect healthcare and oncology, but they should not determine how healthcare providers handle oncology drug shortages.
Informed consent	Coping with a cancer diagnosis and treatment is extremely difficult when all recommended options are available. The stress, anxiety, and frustration our patients feel because of oncology drug shortages must be considered.
	In order for patients to make an informed treatment decision, oncologists must communicate:
	◆ what treatment is recommended
	◆ how a shortage will be managed
	◆ likely ramifications of a treatment disruption
	◆ whether alternative treatments, such as surgery, radiation, or another drug/regimen are available.
Policy timing	**Proactive versus reactive**
	Oncology drug shortages are a reality and will continue to challenge practitioners and patients alike. Congress and specialty societies are aware of the issue and working to lessen the likelihood of future events. However, each health system, medical centre, and practice must proactively develop plans for how to deal with oncology drug shortages.
	These plans, like those in place to manage a mass casualty incident, natural disaster, or a pandemic flu outbreak, should be informed by the best science available, be created with the input of diverse stakeholders (physicians, nurses, pharmacists, social workers, patient representatives, ethics committees, etc.), and be regularly reviewed and updated.

economic impact of a cancer diagnosis on the individual patient as well as the healthcare system as a whole?

ASCO's guidance statement on the cost of cancer care suggests a multifaceted approach to this problem [48]. It states that, on the individual patient level, oncologists must continue to strive to provide each patient with the best evidence-based care available. However, when competing therapies with similar efficacy and toxicity are available, it is reasonable to disclose this fact and allow cost to help inform treatment recommendations. Likewise, patients may reasonably decline a proven therapy, even one that might prolong their lives, because of the high associated out-of-pocket costs. As an oncology community, quality of life, cost-effectiveness, and survival metrics need to be incorporated into clinical trials whenever possible so that discussions about the cost of cancer care can be based on much more robust data than are presently available.

Oncology specialists may be asked to advise government health agencies, healthcare organizations, or insurance companies as these bodies set policy or make coverage determinations. Their recommendations should be based on the best science available,

transparent to all stakeholders, mindful of existing health disparities, and include a robust review/appeal mechanism. The previously described 'accountability for reasonableness' model can serve as a useful framework for this type of project as well [41–43] (Box 25.1).

Oncology ethics resources

Shuman and colleagues recently reviewed the ethics consultation databases of two comprehensive cancer centres [49]. They identified 207 adult oncology ethics consultations performed between 2007 and 2011 and found that the most common issues pertained to code status and advanced directives (25%), surrogate decision-making (17%), and medical futility (13%). Additionally, they identified communication problems and interpersonal conflicts in 41% and 51% of cases, respectively. Unfortunately, this chapter cannot address all of these topics in detail. However, additional resources are available.

Tenner and Helft have published an annotated bibliography of oncology ethics literature that will enhance the ability of novices

Box 25.1 Putting ethical priority setting into practice

Relevance

- Develop a rationale for each priority-setting decision.
- Use decision criteria based on your mission, vision, and values.
- Collect data/information related to each criterion.
- Consult with internal/external stakeholders to ensure relevance of decision criteria and to collect relevant information.
- Make decisions using a multidisciplinary group of informed stakeholders.

Transparency

- Communicate the decision and its rationale.
- Use an effective communication strategy to engage internal/external stakeholders around priority-setting goals, criteria, processes, and decisions.

Revision

- Incorporate opportunities for iterative decision review.
- Develop a formal decision-review process based on explicit decision-review criteria.

Enforcement

- Lead by example (i.e. ethical leadership).
- Evaluate and improve the priority-setting process.

and experts alike to handle the challenges of contemporary oncology practice [50]. Professional societies such as ASCO, the European Society of Medical Oncology, and the American Society for Bioethics and Humanities also have web-based content, position papers, and educational tracks at their annual meetings that can help augment practitioner knowledge and skill. Lastly, and perhaps most importantly, early ethics consultation can help address concerns or problems before they worsen and potentially place patients or research subjects at risk.

Conclusions

It is an exciting time to be an oncologist. However, despite the proliferation of novel treatments and the promise of precision medicine, conflicts between competing goods or obligations will continue to arise. This brief chapter has attempted to highlight several of the most common issues faced by oncology specialists in order to provide a framework for ethical reasoning. Readers are encouraged to examine the primary sources cited in this chapter so they may deepen their understanding of the ethical foundations of the practice of oncology.

Health economic assessment of cancer therapy

Jeffrey Peppercorn

Introduction to health economic assessment of cancer therapy

Our ability to deliver high-quality cancer care is increasingly influenced by our ability to understand and manage the costs of care. Delivery of cancer therapy requires both an effective intervention and the ability to provide access to the intervention for patients in need. Much of the research of recent decades has been devoted, appropriately, to developing effective interventions in a variety of cancer settings. However, it is now clear that providing access to these interventions to patients in need is a global challenge requiring providers and policy makers to address the costs of cancer care both in the clinic for individual patients and at the level of the healthcare system.

At the level of national healthcare systems, the costs of healthcare in general, and the costs of cancer care in particular, are high. High costs are threatening to undermine or actively undermining the sustainability of national budgets. In the United States in 2011 it was estimated that total healthcare expenditures reached $2.7 trillion [1]. By the year 2020, it is projected that healthcare costs will account for roughly 20% of the US Gross Domestic Product (GDP) [2]. While the US leads other nations in healthcare spending as a percentage of GDP, rising costs threaten national budgets in nearly all developed countries [3]. Though there are considerable differences in the ways healthcare is financed and administered in different nations, there is a common need to deliver high-quality care at sustainable costs.

At the level of the individual patient, there is again considerable variation in the cost of care on the basis of their disease and setting. Both the total cost of care for a given patient and the percentage of that cost, if any, that will be paid out of pocket directly by the patient varies by national system and insurance coverage. However, costs for an individual patient impact care in virtually all settings whether due to direct financial hardship, uncertainty of access due to personal wealth or health insurance status (in the US) or due to national policy regarding access to care in countries with national healthcare systems (UK).

This chapter will review recent estimates of the aggregate costs of cancer care, discuss methods for determining cost-effectiveness or value in cancer care, provide a framework for understanding the components of cost at the societal and individual levels, and discuss efforts to control cost while preserving or improving quality and outcomes.

What does cancer care cost?: the societal perspective

The magnitude of costs of cancer care can be measured in terms of total spending, percentage of national GDP, or in terms of the cost to care for a single patient. In the US, total healthcare spending for 2013 is estimated at 2.98 trillion dollars, accounting for 17.6% of the GDP [2]. This amount of spending as a percentage of GDP exceeds that of other developed countries, with the closest being the Netherlands at 12% and France at 11.8% [4]. Estimating the component of total healthcare spending attributable to cancer can be difficult, particular in a fragmented healthcare system, but the US National Cancer Institute estimates that total cost of cancer care in the US was 124.5 billion dollars in 2010 [5]. This represents less than 5% of total healthcare spending and is generally consistent with the percentage of total spending attributable to cancer estimated for other developed countries [6]. For example, though total spending is lower in the UK, the National Health Service estimates that 5.4% of total healthcare spending for 2010/2011 was devoted to cancer care, compared to 11% of spending for mental healthcare, and 7.2% for cardiology-related care [7].

Total spending is a very crude way to estimate where and why money is being spent in cancer care. Many streams of spending contribute to total costs, including hospital fees, physician services, ancillary services (nursing, physical therapy), drug costs, surgical costs, radiation therapy, and durable medical goods. In the US, the Centers for Medicare and Medicaid Services (CMS) provide a breakdown of spending by services and funding source, but a comparable breakdown spending on components of cancer care is not currently available. At the level of total healthcare spending for major categories of medical services, the US spent 37% on hospital care, 24% on physician services, 12% on prescription drugs, 7% on nursing home care, 5% on dental care, and 3% on home healthcare in 2011 [1].

In addition to considering costs of cancer care by service or intervention, we can attempt to break down costs by individual cancer. In 2010, in the US it was estimated that total spending was 16.5 billion for breast cancer, 14.1 billion for colorectal cancer, 12.1 billion for lymphoma, 12.1 billion for lung cancer, and 11.9 billion for prostate cancer, with lesser amounts for other malignancies. Thus, we appear to be spending the most money on the most prevalent cancers, as would be expected. To truly

understand costs at the public health level, however, we would need data on spending by intervention category or service for each of these diseases, and ultimately for each stage of disease. Obtaining data at this level of granularity is difficult, particularly in a healthcare system with multiple payers and limited public availability of data. However, this level of detail is needed to identify areas that may be experiencing higher than expected inflation, or where spending is not consistent with disease prevalence or clinical benefit. Effort to understand and control total spending without this level of detail should proceed with a large dose of caution.

Efforts to understand and control rising costs of care

Policy makers are concerned not just with the level of spending, but with the increase in spending, or what has been termed the 'cost curve'. A major objective in recent healthcare reform debates within the US, and indeed an objective worldwide, is to 'bend the cost curve' in a downward direction, or at least achieve a less steep upward slope over time to control the growth of spending. With projections that, by 2020, healthcare spending will to rise to 20% of GDP, or one-fifth of the entire US economy, there is legitimate concern about the impact this will have on other valued social goods such as education, housing, and even research to improve future delivery of healthcare. While oncology is only a small part of total healthcare spending by some estimates, there is concern that through a combination of higher incidence of disease, increased care delivery per patient, and rising costs for prescription drugs and other aspects of care that inflation in this area will contribute a disproportionate amount to increased healthcare spending and must be addressed now. Total oncology spending in the US is projected to grow from 27 billion in 1990 to 157 billion dollars by 2020, representing a staggering 600% increase in 30 years [8].

Identifying the factors and specific elements of spending that are responsible for the aggregate increases in cost can be challenging from available data. Using available data from the public system, Medicare, which covers care for older and disabled patients, Warren et al. found that between 1991 and 2002 the large increase in the spending for lung, colorectal, and breast cancer was driven by both utilization (the amount of care delivered) and charges for services and for hospital care. During this period, the percentage of patients with breast cancer receiving chemotherapy increased from 11% to 24% and the cost of chemotherapy increased from roughly $6,000 per patient to almost $13,000 [9]. In another study of Medicare spending, Dinan and colleagues found that PET scans and MRI utilization have increased across most types of cancer. Radiology may be a disproportionate driver of costs due both to innovation and relatively high margins on services. Between 1999 and 2006 the cost of imaging for cancer increased by 5.1% to 10.3% each year, while the cost of all cancer care increased by only 1.8% to 4.6% [10].

Rising aggregate costs of cancer care derive both from the cost of treating individual patients and from the number of patients who require treatment. Demographic, environmental, and behavioural factors that modify the risk of cancer in a population can have a large impact on societal costs of care. While cancer can strike at any age, it is predominantly a disease of older patients. Projected growth of the percentage of patients aged 50 years and older, and particularly an increase in the percentage of elderly patients in the population, are expected to translate into a dramatic increase in the number of patients with cancer unless there are countervailing advances in cancer prevention. Cancer is also rapidly becoming more common in developing countries as populations are living longer due to improvements in nutrition, successful treatment of infectious disease, reductions in infant mortality, and improvements in paediatric care [11]. In 1990, there were close to six million deaths from cancer estimated worldwide, but by 2010 roughly eight million cancer deaths occurred, a 38% increase [12]. In the US, due to a combination of changing demographics as well as success in management of cardiovascular disease, cancer has become the leading cause of death among those under age 85 [13].

Factors responsible for rising cancer incidence vary by nation. In China, dominant factors include chronic infection, including hepatitis B leading to liver cancer, and tobacco use [14]. In France, it is estimated that roughly 24% of cancer deaths are attributable to tobacco use, and obesity may contribute to 3% of cancer deaths [15]. There is concern worldwide, and particularly in the US, that rising levels of obesity will contribute to increases in cancer in addition to other adverse health consequences. In the US, more than one-third of the population is now characterized as obese. Among adult non-smokers in the US, close to 15% of cancers among men and nearly 20% of cancer among women are attributable to obesity [16]. From a policy perspective, prevention through modification of risk factors across a population may be one of the most effective means to control total societal costs without adverse impact on the quality of care for individuals diagnosed with cancer.

It should be noted that the societal costs of cancer care delivery are only a portion of the total economic consequences of cancer for society. The societal economic burden of cancer includes costs for care delivery, but also indirect costs caused by loss of economic productivity of individuals suffering the morbidity and mortality caused by cancer, as well as their family members who become caregivers. In Germany, for example, it was estimated that the direct cost of cancer care in 2004 was 12.1 billion euros [6]. The indirect cost, virtually all related to lost production due to cancer deaths, was estimated at 14.7 billion euros. In the US, a 2002 estimate listed direct costs of cancer care at $61 billion US dollars versus $110 billion in indirect costs [6]. Thus, in considering the costs of cancer care to society, we must consider not only the spending on care delivery but also the downstream impact of that spending. If spending on radiology leads to earlier diagnosis and improved treatment and outcomes, spending on a genomic predictor of recurrence leads to a decision to forgo systemic therapy, or spending on an expensive targeted adjuvant therapy improves cure rates, spending on some aspects of care may rise, but the overall economic impact may be favourable.

Impact of costs on individual patients

In addition to the impact of cancer care costs on societal budgets, the impact on individual patients can be considerable. In all settings, costs can impact the individual due to decisions made at the national level regarding coverage and access. In the majority of developed countries there is universal access to healthcare, but

there are differing thresholds and mechanisms for determining what aspects of healthcare are provided and how it is allocated.

In the US, pending the full implementation of the Affordable Care Act of 2010, there is no guarantee of access to cancer care (or any other care other than emergency room services). In this context, the impact of costs of care to individual patients can be extraordinary. For example, a one-year course of adjuvant trastuzumab therapy for HER2 positive breast cancer costs approximately $50,000. This figure, already greater than the median family annual income in the US, does not include the provider costs, costs of other chemotherapy typically given with trastuzumab, costs for surgery, pathology, radiation therapy, lab work, hospitalization, and many other aspects of care. The newly approved drug TDM1 for the same disease in the metastatic setting costs approximately $98,000 for a one-year course of treatment, again on top of other healthcare expenses incurred during this time. Given these costs, only those with adequate insurance coverage can be sure to gain the benefits of these interventions. Cost presents a true barrier to care.

The impact of the high costs of cancer care in the US has been demonstrated in multiple studies. Patients with no health insurance or even inadequate insurance tend to present later in the course of illness and to experience worse cancer outcomes, including death, compared to patients with adequate health insurance [17]. Unfortunately, in some studies the public insurance system for poor people, Medicaid, qualifies as inadequate with outcomes similar to no insurance at all [17]. In addition to 52 million uninsured patients in the US, it is estimated that 29 million are 'underinsured', meaning coverage is inadequate to guarantee access to quality healthcare as of 2010 [18]. Underinsured patients may forgo non-cancer-related medical care, reduce expenditures on food, clothing, and shelter in order to cope with the costs of cancer medication [19]. Some patients also report discontinuation of cancer therapy due to cost [18].

Oncologists report that cost impacts cancer treatment decisions and that discussions of costs of cancer care with patients are deemed important. However, in a 2008 survey conducted by Neuman and colleagues, 58% of physicians reported inadequate knowledge to discuss costs of care with their patients [20].

Measuring the value of cancer care

Given the issues and concerns noted above there is a need to ensure that resources committed to cancer care are well spent. This is true if the spending is from the state budget, from an insurance provider, or from the patient's own pocket. We need to be able to identify not only the medical risks and benefit of any potential intervention, but to assess the relative benefit compared to the resources expended, or the 'value' of care. Developing an operational definition of value is complex.

In determining value, we need to be able to identify and, to some extent, quantify the medical benefits, toxicities, and risks of an intervention and the direct and indirect costs associated with its use. We must then determine what threshold of cost for a given net clinical benefit is reasonable or worthwhile. We are generally most concerned with financial evaluation of those interventions (a diagnostic test, drug, procedure, or any other aspect of care) where there is some marginal clinical benefit that may or may not, in the context of cost, offer good 'value'. If the harms outweigh the clinical

benefits or the cost is negligible (such as information on diet or exercise), we don't generally need to take a hard look at value.

Assigning value implies that we can define the overall worth of an intervention and make choices between options that take into account the totality of benefits, harms, and costs, and to some degree, alternatives. In truth, there is no ideal formula or even a broad consensus on how value should be assessed in cancer care or at what threshold of benefits and costs an intervention becomes 'high value'. However, there are well-validated methods of assessing relative clinical benefit and cost that move us in the direction of defining value.

All methods to evaluate clinical benefit relative to cost have at their core a goal of allowing us to assess value and make decisions about whether a given component of care should or should not be provided. Assigning value is not equivalent, per se, to rationing, which can be defined as a programme of distribution for scarce goods and services according to a rational prespecified framework. However, assigning value can be fairly seen as a necessary step in guiding medical decision that considers financial costs and that predictably will result in some level of constraints on care on the basis of factors other than clinical benefit alone. In a world of infinite resources, we might consider only clinical factors and provide all interventions in any setting with possible marginal benefit. In reality, resources are not infinite, so that a policy of considering marginal benefit only is unsustainable, and we need to be able to assess value to guide medical decisions.

It should be noted that efforts to define a rational basis to make healthcare allocation decisions date at least back to the days of triage in the army of Napoleon. In this early example, concern was not the cost of care, but given limited supplies and medics, inadequate available care to meet the needs of all soldiers injured in battle. The utility of care to the patient (as distinct from the severity of the illness) was made a primary consideration for allocation, or rationing, of care. In modern medicine, outside of the solid organ transplant setting, we are more often concerned with financial scarcity. However, drug shortages in oncology have recently become more common, resulting in further consideration of explicit rationing in oncology [21].

One of the most common methods of assessing value in oncology is to perform a cost-effectiveness analysis. As the name implies, the goal is to determine the cost of an intervention and weigh this against the effectiveness for the outcome of interest. If the objective is survival in metastatic pancreatic cancer, then to determine the cost-effectiveness of systemic therapy interventions for this disease we would need to know their cost for a course of treatment and their impact on improving survival. Any clinical goal can be considered, from survival to disease response rate to relief of pain, as long as it can be quantified as a measure of effectiveness and it is clearly defined.

Continuing with this example, if we consider three available interventions, gemcitabine, gemcitabine + erlotonib, or the FOLFIRINOX regimen (consisting of 5 FU, leucovorin, irinotecan, and oxaliplatin), we might calculate a ratio of the cost in dollars per increased weeks in expected survival compared to survival and costs with symptom management alone (or placebo). This would allow us to consider the cost-effectiveness of each intervention discretely and to make value-based comparisons between interventions.

In this example, one can quickly see why a basic calculation of cost and one measure of clinical effectiveness—weeks of survival—may be

inadequate to fully assess value. What if a six-week extension in survival is at both a higher financial cost and at the cost of several months more of severe toxicity, such that the patient is alive but spending most of their time in bed feeling tired or nauseous? What if the cost of the intervention itself is modest but it requires expensive additional medications to treat side effects, or is likely to require prolonged hospitalization in a subset of patients? In addition, some distinguish the definition of 'efficacy', taken as the impact of an intervention of a clinical outcome in a near-idealized setting such as highly regulated randomized control trial versus 'effectiveness' defined as the impact of an intervention on the outcome of interest in a real-world broader population context. Either setting can be used in cost-effectiveness analysis, but it is important to be able to make the distinction and recognize that the 'effectiveness' of an intervention in practice is often somewhat less than its 'efficacy' in a clinical trial. Further complicating these issues, what if we wish to assess the cost effectiveness of first-line interventions for metastatic breast cancer or castrate-resistant prostate cancer in terms of impact on survival? How do we account for the impact of subsequent treatments or consider surrogate endpoints that may or may not correlate well with survival?

To address some of these challenges several steps have been taken to improve the methodology of cost-effectiveness assessment. First, one can try to define a meaningful outcome that considers not just longevity but also quality of life to facilitate meaningful comparisons in effectiveness among diverse interventions. Thus, instead of measuring survival alone in terms of weeks, months, or years, we can estimate gain in terms of quality-adjusted life years or 'QALYs'. What we gain in beginning to incorporate quality of life, however, we start to lose in the objectivity of our measurement because two individuals may have different definitions of what constitutes quality of life under different clinical scenarios. Because this calculation implies a measure not just of the intrinsic value of a clinical objective like survival time, but also of the subjective utility individuals assign to survival in differing conditions, calculation of cost-effectiveness involving QALYs is sometimes referred to as cost–utility analysis.

Often, one of the purposes of cost-effectiveness analysis is to compare the incremental benefit provided by a new expensive intervention to a standard less costly intervention. We want to ask if the marginal improvement in outcomes is 'worth it'. To do this, health economists use the incremental cost-effectiveness ratio or 'ICER'. The benefits of the interventions can be described in terms of QALYs or some other measure of outcome, the costs of a course of therapy identified, and the ratio of absolute difference in QALY over net increase in cost provides the ICER. To take a real-world published example, using the regimens for pancreatic cancer listed above, Tam and colleagues calculated the ICER for use of more effective but more expensive regimens. They determined utility of health states with pancreatic cancer by surveying physicians to calculate QALYs and used the pharmacy records from a Canadian cancer centre to determine cost. In Canadian dollars, the cost of a one-month course of gemcitabine was roughly $29,000 versus $41,000 with the addition of erolotinib versus $57,000 for FOLFIRINOX. Although gemcitabine plus erlotinib was cheaper, the ICER for this regimen was $153,631 per QALY versus $133,184 for FOLFIRINOX, suggesting that the latter, while more expensive in absolute terms, appears to provide better value [22].

In addition to the challenge of determining which outcome to use in measuring cost-effectiveness, determination of cost involves choices as well. First, cost can vary in some health systems depending on negotiations between payers and providers or manufacturers. It is important to distinguish between the charge for the intervention (the amount of money requested by the supplier) and the cost (the actual amount of money that changes hands). Second, one needs to consider whether to use the isolated cost of the intervention itself or the cost of the intervention and all associated ancillary care measures, such as drugs or hospitalizations, that might occur to treat symptoms or complications. Some studies use 'cost consequences' analysis to try to capture all associated costs with one plan of care over a longer timeframe to allow more financially realistic comparisons between two options. In such analyses, there remain questions over what time period should be used and what costs incurred during that period should be included.

As a 'consumer' of cost-effectiveness studies it is important for oncologists and policy makers to be aware of the many variables that can be considered in study design and the fact that such studies can be biased by these decisions. Some analyses of the field of cost-effectiveness research in medicine have found that there is bias among studies sponsored by the pharmaceutical industry, and more generally strong publication bias towards studies demonstrating favourable ICERs [23]. There has been a steep rise in the number of published cost-effectiveness studies over the past two decades, with variable quality [24]. The reader should carefully evaluate the underlying assumptions in the methodology, sources of data, and potential sources of bias.

Controlling costs

Determination of what constitutes good value in cancer care and how and whether cost control to ensure good value will be implemented differs by national healthcare system. A threshold of less than $50,000 per QALY gained is usually accepted as a clear measure of good value in most developed countries, although the exact threshold can vary [25]. Many cancer therapies that are used in the US do not meet this threshold and it has been suggested that a threshold of $100,000 per QALY or more may be more reasonable [21]. As might be expected, in nations where healthcare delivery, not just financing of healthcare, is a public service, there tends to be the greatest emphasis on ensuring that all care provided reaches a specified threshold of value, and the greatest means to enforce such care delivery.

In the UK, where the National Health Service is an example of both public financing and delivery of healthcare, the National Institute for Health and Clinical Excellence (NICE) explicitly evaluates both clinical effectives and cost-effectiveness of cancer care interventions. NICE provides the NHS with recommendations for which cancer therapy should or should not be provided on the basis of cost per QALY gained. In Canada, there is public funding for healthcare with universal access. Providers may be private or practice and government-funded hospitals. Many coverage decisions about healthcare resources are made at the level of the regional province. However, cancer therapy and other drugs are now subject to Common Drug Review by the Canadian Expert Drug Advisory Committee, which explicitly considers cost-effectiveness in its recommendations. Provinces are not required to follow the committee's recommendations but reportedly do so up to 90% of the time [26].

In Australia, there is universal healthcare with all citizens covered by one of 15 public insurance companies, with supplemental

private health insurance available for a price. Diagnostic studies and cancer treatment, including chemotherapy, are covered without cost to the individual by the public system [27]. In the Australian system, decisions about cancer drugs availability are guided by the Pharmaceutical Benefits Advisory Committee, which explicitly considers both effectiveness and cost. A therapy will only become available if there is a favourable review by the committee [26].

In contrast, the US Food and Drug Administration by statute may not consider cost when determining approval for new drugs and the Centers for Medicaid and Medicare (which provide public financing of healthcare for elderly, poor, and disabled Americans) may not consider cost in benefits coverage decisions. These policies leave little leverage to promote high-value healthcare and control costs. Thus, the 2010 Patient Protection and Affordable Care Act, in addition to attempting to establish near universal access to care, established the Patient Centered Outcome Institute to support development of an evidence base to guide policy makers' decisions on coverage and access. However, unlike NICE, this new agency was still prohibited from establishing a cost–benefit threshold for healthcare and (like those of NICE) its recommendations are non-binding [28].

In the absence of an agency that determines value or cost-effectiveness for cancer care, in the US efforts to control costs while maintaining quality have fallen to private payers and to the profession. One mechanism seen as promising is the promotion of guidelines or pathways of care. With a defined guideline for a clinical scenario, evidence-based care can be promoted and costs can be better predicted, which allows insurance companies to attempt to match premiums to expenses. Data from an insurance provider-sponsored study of lung cancer care demonstrated that following guidelines resulted in equivalent outcomes but at substantially lower cost (35% reduction in total costs of care) compared to standard practice [29].

At the level of the profession, the American Society of Clinical Oncology joined 26 other medical specialties in participating in the 'choosing wisely campaign' in which several practices were identified that can be eliminated with no detriment (or possible improvement) in quality and resulting cost savings [30]. One does not have to agree on a definition of value to decide that an intervention without proven benefit (particularly when it has been well studied) should be eliminated. The first five practices identified were: (1) Don't use cancer-directed therapy among patients with very poor performance status and/or no proven benefit from further intervention in the patient's setting; (2) Don't perform staging studies for asymptomatic patients with early-stage low-risk prostate cancer; (3) Don't perform staging studies in asymptomatic patients with early-stage breast cancer; (4) Don't use serum biomarker or imaging studies as part of routine surveillance for asymptomatic patients with breast cancer after initial treatment; and (5) Don't use white cell growth factors for patients with low risk of febrile neutropenia [30].

Further work is underway to provide additional examples. At this time, the impact of this campaign is unknown and the cost savings depend primarily on physician behaviour and discretion. However, perhaps in part as a result of markedly increased attention to cost and to high-value practice in the US media, and the resulting impact on decision-making by physicians and patients, healthcare inflation has already started to decline, prior to full implementation of healthcare reform [31].

Clinical discretion in cost control

In any healthcare system, there is balance between allowing for physician discretion in medical decision-making and controlling quality and costs through regulation, access to interventions, and reimbursement policies. Physicians have an active role to play in ensuring that care delivered meets high standards of effectiveness and efficiency. In keeping with the goals of promoting high-quality care and preserving physician discretion to provide needed care to individual patients, cost-effectiveness must be considered in clinic.

While determination of value remains complex, a framework for identification of interventions that can be eliminated without negative impact on quality has been proposed [3]. By attempting to eliminate interventions that are not evidence based, those that are duplicative, and those that would not be pursued if the patient was offered the opportunity to make an informed choice, we can eliminate some costs of care while improving quality.

Two challenges to providing cost-effective care in oncology are constraints on the clinician's time with a patient and physician awareness of the costs of therapy [3]. When seeing patients with advanced cancer, it can be easier and faster to propose and review an intervention than to engage in a longer conversation to assess the patient's preferences and discuss the option of palliative care alone [32]. Similarly, when evaluating a new symptom, an oncologist may find it easier to simply order an expensive scan than to take a detailed history and physical to guide evaluation rationally [33, 34].

Oncologists may be up to date on the latest interventions, which are often featured in scientific and lay press, but less aware of evidence suggesting areas where care can be safely limited. For example, two large randomized trials have demonstrated that for asymptomatic patients with early-stage breast cancer there is no proven utility to obtaining tumour markers or routine staging studies for surveillance [35, 36]. Despite this decades-old evidence, use of these tests continues in some practices, necessitating identification of this issue by ASCO as one clear way to reduce costs without detriment to quality, as noted above [37]. It is worth noting that in the context of the medico-legal landscape in the US, 'defensive medicine', or practice based on fear of lawsuits, may guide some care decisions. While several studies show minimal financial impact of defensive medicine, clinicians continue to report that legal considerations impact decisions in some settings [38–40]. In addition, financial incentives in the US likely contribute to over-utilization.

In addition to clinical discretion, patient demand likely contributes to over-utilization of cancer care, or at least some of the ancillary aspects of cancer care to some degree. While it is doubtful that anyone requests more chemotherapy or surgery than they absolutely need, in the realm of diagnostic tests, provider visits, and in some cases pursuit of high-cost interventions with marginal to negligible proven benefit, patient preference and insensitivity to cost may play a role. This is the flipside of the economic burden and barriers to care imposed by cancer on many patients, particularly in the US. If patients do not bear any responsibility for costs of care, they are likely to be more indifferent to costs to society, or value of care, and to focus on marginal clinical benefits alone. This is described as 'moral hazard', where one party of a medical decision is shielded from the financial consequences. Surveys of patients suggest that they are open to considering both effectiveness and cost in medical decisions, and may be willing to pay more

out of pocket for higher-value care [41]. Cost-sharing, in which patients pay a percentage of the costs of care through co-payments or deductibles, is increasingly seen in the US as a way to promote higher-value care. However, it is possible that cost-sharing indiscriminately reduces utilization of both low- and high-value care, requiring carefully analysis of the impact of cost-sharing when it is implemented.

Cancer care at the end of life

One aspect of cancer care that deserves special consideration in discussions of value is care at the end of life. Currently, many patients with cancer will ultimately die from their disease, and prevention of death is not an achievable goal. At some point, further disease-directed therapy becomes futile and, worse, potentially harmful to the patient. While we strive to define value in other aspects of cancer care, it is clear that resources devoted to disease-directed therapy past the point of potential for benefit are wasteful (as opposed to resources devoted to promoting quality of life and palliating symptoms). Unfortunately, studies suggest that a large portion of total spending for cancer care is for care delivered in the last weeks or days of life when this care may be both futile and inconsistent with the preferences of an informed patient [42–44]. This futile disease-directed care may have financial consequences for the patient's family and society and may compromise the patient's quality of life during the weeks prior to death as well as detract from a needed focus on palliative care [45].

Steps forward to understand and address the costs of cancer care

As outlined in this chapter, there is a need to consider the financial consequences of treatment decisions on our patients and for society. Regardless of the national healthcare system, there are constraints and tradeoffs in the resources that can be committed to healthcare and other societal goods, including cancer research itself. There may also be tradeoffs to consider among the care that can or should be provided to a single patient and our ability to provide care for all patients in need. Further research and public debate among interested and informed stakeholders is needed to guide rational policy and to promote quality care.

We need improve evaluation of the cost of cancer care in the clinic. We need to find efficient means to provide information on the direct and indirect financial impact of treatment decisions on patients and their families at the point of care. To the extent that we wish conversations over cost to enter the clinical encounter, we need to determine what the content and goals of these conversations should be, and what the impact will be on treatment decisions and on the patient's experience of cancer. It is clear that patients are interested in knowing how treatment decisions will affect them economically; it is less clear that they want conversations about the societal costs of care to enter the clinic or impact decisions.

At the policy level we need to strike the right balance between cost control, physician discretion, and allowing for patient autonomy where reasonable. In some areas of oncology, we have excellent evidence to guide practice. Support of guidelines through incentives, reimbursement, formulary policy, and other means can support quality care and control costs. In other areas, or in rare presentations of common cancers, evidence is limited and we may never have data from large randomized trials to guide practice. Patients in such settings require care that may not easily be reduced to a guideline or pathway, or best practices may be defined by rapidly evolving clinical literature that requires flexibility in the system to allow timely access to appropriate care. It is important for clinicians to be able to assess the clinical needs of individual patients and practice evidence-based medicine. It is also increasingly important to recognize that continued access to high-quality care and support for further innovation in oncology is now tightly linked to our collective ability to achieve sustainability in the healthcare system and promote high-value care.

SECTION 4

Population health

CHAPTER 27

Cancer control planning

Massoud Samiei

Background

Among the non-communicable diseases (NCDs), cancer is rapidly becoming a serious burden for the populations and health authorities in all low- and middle-income countries (LMICs). As the World Health Organization (WHO) stresses, there is no country in the world where cancer does not occur [1]. Despite all the progress made in cancer research and in the fight against cancer, it is a fact that the disease cannot be completely eradicated in the foreseeable future. A logical public health measure must therefore focus all efforts on preventing and confining the disease or, in other words, a systematic and coordinated approach is needed to reduce the impact of cancer on populations. Such an organized approach is called *cancer control*.

WHO places great emphasis on the rising impact of NCDs and cancer in LMICs, and the disproportionate suffering they cause in poor and disadvantaged populations [2]. The growing cancer epidemic in LMICs presents a major challenge to global public health. If present trends continue, more and more people will die prematurely and needlessly from cancer. Most countries are unable to cope with the current trends due to severely limited or non-existent resources and necessary medical infrastructure, which are needed to prevent, diagnose, and treat cancer. Even worse, few LMICs, if any, are prepared to deal with the increased cancer burden looming on the horizon. The cancer epidemic will certainly get worse with immense social and economic consequence unless more concrete and concerted actions are taken at global, regional, and country levels. In particular, with the rapid changes taking place in cancer risk and cancer burden in LMICs, there is an urgent need for governments to enact effective *cancer control policies* and *strategies* to facilitate the development of appropriate cancer control action plans [3]. Unfortunately, due to the absence of NCDs and cancer in the Millennium Development Goals, the international donor community still has difficulty considering cancer control a priority in LMICs; as a result, donor funding has been very limited for cancer control efforts.

The good news is that a clearer picture of the global issues of cancer is emerging and quite a number of evidence-based targets and cost-effective interventions for prevention and for reduction of morbidity and mortality can be identified for most common cancers [4]. It is for this reason that the establishment of a *national cancer control strategy* (or *policy*) to facilitate the planning and implementation of various activities to control cancer is strongly encouraged for all countries. More importantly, as some cancers are avoidable and others treatable when detected early, any systematic and organized measures to control cancer should be able to reduce cancer mortality and morbidity to improve the quality of life of cancer patients and their families. Even in low-resource countries, cancer control activities are necessary [1, 4].

As the resources are constrained everywhere and there are many competing healthcare priorities, effective plans with well-defined activities are needed to ensure that the limited resources are distributed in accordance with identified priority cancer control needs, and accessed equitably and sustainably. These actions should be systematic and form part of a holistic and coordinated approach, involving the public sector, non-governmental organizations (NGOs), academia, and the private sector. This should ensure that the selection and implementation of best practices in cancer prevention, early detection, treatment, and care are *resource-level appropriate* (that is, appropriate for the income level of the country) and are consistent with the country's prevailing social and cultural circumstances. Policy makers and cancer advocacy groups in LMICs should therefore consider *cancer control planning* and its financing and implementation a *public health necessity* and not an option [1].

The efforts described above are collectively referred to as a *national cancer control plan* or *programme* (NCCP). Other terminologies such as *cancer control strategy, comprehensive cancer control plan* or *population-based cancer control strategy/plan/programme* are also commonly used with the same meaning. Often, the words 'strategy', 'plan', and 'programme' are used interchangeably. In the context of cancer control, a *programme* is a collection of all national strategies and *plans* of action intended to reduce the impact of cancer in the *entire country and its population* relying on *all the resources* available during a determined period. An NCCP is described by the WHO as: 'a public health programme designed to reduce cancer incidence and mortality and improve quality of life of cancer patients, through the systematic and equitable implementation of evidence-based strategies for the prevention, early detection, diagnosis, treatment and palliation, making the best use of available resources' [5]. NCCPs provide a platform for the application of best evidence-based practices in cancer prevention and treatment. WHO emphasizes that the implementation of a carefully planned NCCP offers the most cost-effective means of achieving a tangible degree of cancer control, even where resources are limited [4]. The comprehensive cancer control approach also allows all stakeholders in a country to share with each other their skills, knowledge, and resources, so that the country can take advantage of all its potentials to more quickly and efficiently reduce the burden of cancer for all its population. Naturally, any intervention that is selected to be part of the NCCP must be economically feasible and, more importantly, culturally appropriate for the intended population and setting in mind.

Cancer control planning or NCD control planning?

It is important to take note of some recent developments concerning cancer and NCDs, which will have a bearing on future approaches to cancer control planning.

Although the growing burden of NCDs had been recognized since late 1980s, only in the past decade or so has there been increased attention to these diseases among health policy makers with growing concern about the severity and the magnitude of NCDs throughout the world. More significantly, health authorities worldwide have become aware about the increased prevalence of NCDs in LMICs and the cost of treating them, which has contributed to a widening of the healthcare gap between various sectors of society. As a result, the question of providing affordable means of treating the growing number of patients with cancer and other chronic diseases in LMICs, particularly in terms of medicine and health technology, has become increasingly prominent in the minds of policy makers and health authorities, in addition to concerns about the most feasible strategies for prevention and control. This has also become a priority for many United Nations (UN) agencies and active international organizations, but has been given a new emphasis following the comprehensive resolution approved by all UN member states in September 2011 on the prevention and control of non-communicable diseases [6], among which cancer is a leading cause of death. The matter has been given even higher urgency following the May 2012 World Health Assembly's decision to set *a global target of 25% reduction of premature mortality from NCDs by 2025* as a key target, amongst others, for the implementation of the UN resolution [7].

It is clear, therefore, that controlling cancer does not need to be at the expense of other diseases in LMICs or done in isolation. As a matter of fact, WHO underscores that 'National cancer control programmes evaluate the best ways to control and prevent cancer at country level. Governments who early on committed to address non-communicable diseases are already seeing progress in reducing cancer, diagnosing sooner and saving lives. Based on these successful examples, more countries should implement similar programme' [8]. The prevention and control of cancer should therefore be integrated into all major horizontal and vertical actions for other NCDs and all aspects of cancer control plans—from prevention to management of cancer and related research priorities—should be part of the national plans for strengthening the health system [9]. It is understood that strengthening health systems will make national efforts to reduce the burden of both communicable and non-communicable diseases more effective and sustainable. A recent WHO report on the global status of NCDs has put forward a series of interventions known to be effective, feasible, and affordable in any resource setting [10]. Primary healthcare (PHC) is identified as the best framework for implementing recommended interventions. The report highlights that NCCPs fit into the broader WHO framework to strengthen health systems with a major focus on PHC, and are part of the implementation of the *Action Plan of the Global Strategy for the Preventions and Control of NCDs*, which was endorsed by the World Health Assembly in May 2008 [2]. WHO has recently issued a new update of this Action Plan for 2013–2020 with the approval of its member states [11]. There are already a number of initiatives in various regions showing that this is the most feasible approach [9, 12, 13].

Elements of cancer control

Cancer control involves a number of key elements, which generally consist of four main components considered by WHO to be the cancer control priorities [1]: *prevention, early detection and screening, diagnosis and treatment*, and *palliative care*. Often, additional components are necessary which could be included in the NCCP, or within one of the above, especially where more resources are available. The most crucial among these are: a population-based cancer registry and surveillance system (to assess cancer burden, identify needs to support planning, monitor outcomes of all actions, and support cancer control evaluation); cancer advocacy and public education; survivorship and psychosocial support for patients and their families (more broadly called *cancer rehabilitation* aiming to help a person with cancer obtain the best physical, social, psychological, and work-related functioning during and after cancer treatment); and cancer research and clinical trials. Sometimes, other titles are used to describe the main components: for example, *primary prevention* (prevention), *secondary prevention* (early detection and screening), and *tertiary prevention, tertiary care*, or *cancer management* (diagnosis, treatment, and palliative care).

Whatever terminology is used, the important issue to note is that cancer control planning is about *all actions* that can reduce the impact of cancer and improve the quality of life for patients. Prevention, early detection and screening, diagnosis and treatment, palliative care, and psychosocial support are the components of cancer control that can reduce the burden of cancer. Advocacy and public education are essential prerequisites to inform and engage the population. Surveillance, research, monitoring, and evaluation are necessary to understand the causes of cancer, the effects of various interventions, and to analyse the country's cancer burden, as well as to measure progress for feedback into the cancer plan.

It is the responsibility of the health planners and policy makers to ensure that the NCCP planning process brings together all cancer stakeholders in the country to work on assessing strategic options and choosing those that are feasible, effective, and cost-effective bearing in mind the specific conditions of their country. Only then can they find the best combination of priorities and cost-effective interventions that will suit their resource setting and social and cultural boundaries to address cancer effectively within an overall national NCD strategy [10].

Naturally, very few countries will be able to have a comprehensive plan involving all cancer components right from the beginning. Experience from high-income countries suggests that cancer control capacity can develop in a step-by-step approach, starting with a few high-priority and implementable components (such as a focus on two to three common curable cancer sites, on risk factors such as tobacco control and banning public smoking, and on improved palliative care services). Later on, more components and interventions can be added as results are achieved and more resources become available. In most regions, perhaps the key indicator of progress would be a change of attitude and perception by the public about cancer as a non-preventable and non-curable disease, or that a cancer diagnosis is considered a death sentence [14, 15].

The planning process

The cancer control planning process can start when a country's national authorities decide to create a new cancer control plan or

update an existing one. The development of a national cancer control plan and programme involves a number of logical and systematic steps similar to any other strategic planning process. Experience shows that it is vital to follow these steps to arrive at valid and workable strategies and plans. WHO has published managerial guidelines for cancer control [1], and a set of six modules entitled 'Cancer Control: Knowledge into Action' on how to develop and implement an effective cancer control plan to combat cancer effectively [4, 16]. The Union for International Cancer Control (UICC) has also very useful cancer control planning guidelines and toolkits for NGOs [17, 18]. WHO and the International Atomic Energy Agency (IAEA) jointly have developed a self-assessment tool that can help kick-start the planning process [19]. More planning guidelines, toolkits, and assessment models are also available from other organizations [20–23]. These are essential references for all planning stages.

Pre-planning prerequisites

In order to develop a successful NCCP, leadership and the relevant stakeholders need to be identified early on in the process to form a *cancer control* or *NCCP planning group* so that all partners can participate and take ownership and responsibility for the programme. The most important early first step for the initiator of the cancer control planning process is, therefore, to identify and invite and engage all governmental and non-governmental national stakeholders and service providers, including the private sector and patient organizations (where active). The process must involve all stakeholders from the beginning to the end. This systematic approach is the only manner in which a country's health authorities will be able to establish an effective programme to translate cancer control knowledge into appropriate actions in line with existing resources and available capacity [4]. To be effective and have enough authority, the NCCP planning group in LMICs needs to be established under the auspices of the Ministry of Health, and act as a *Steering Committee for Cancer Control* in the country, led by a *Programme Coordinator* who would oversee the entire process from planning to implementation and evaluation.

During pre-planning, all participants in the process would benefit from a review of existing cancer control strategies, plans or programmes, and discussion on possible opportunities, feasible interventions, lessons learned, and areas needing more attention such as quality health data and equitable access to cancer control [4, 24–26]. They should also review the different approaches adopted in similar countries for planning and delivery of population-based cancer control, and their accomplishments or failures, to decide how best to proceed in line with their aspirations, commitment, political will, local conditions, capacity, and resources [4, 27–29]. One option that has proven critical for many countries is that governments may seek external technical support (available from several organizations, particularly WHO, IAEA, UICC, IARC, INCTR, and AfrOx) to advise their Ministry of Health and the cancer control group on all issues related to NCCP planning.

Next, the NCCP planning group must familiarize themselves with the various dimensions of the cancer problem in the country with planning and implementation methodologies based on existing cancer control guidelines and tools from WHO, UICC, and other sources as indicated above. Every country should also adopt some *guiding principles* and a *set of values* to direct and

help its policy makers and participants in the NCCP planning processes to remain within a defined framework when analysing the situation, selecting cancer control interventions, making recommendations, or taking decisions for any action. A list of such principles and values based on experience in some 50 countries is presented here:

1. *Management and coordination*: cancer control leadership is expected to create clarity and unity of purpose; encourage team building; ensure broad participation, ownership of the process and mutual recognition of the efforts made; and involves everyone in continuous learning.

2. *Performance*: a strong focus on quality and the development of a culture of measurement and quality assurance.

3. *People*: a strong focus on rights and entitlements of patients, their families, and care providers. People's needs must come first.

4. *Collaboration*: a greater emphasis on partnership with community and voluntary sectors.

5. *Equity*: addressing health inequalities among different population groups.

6. *Accessibility*: an affordable, timely, and equitable access for all sectors of the population to a comprehensive range of health services regardless of ability to pay.

7. *Gender and culture*: recognition of and respect for gender sensitivity, cultural diversity, and ethical values of communities targeted.

8. *Evidence based*: a system of planning and evaluating policy and service delivery based on needs assessment, scientific evidence, and appropriate health technologies.

9. *Sustainability*: support long-term sustainability of the healthcare system by dealing effectively with and reducing the rise in the number of cancer cases.

10. *Efficiency*: use public resources wisely and promote the efficient use of these resources throughout the cancer system.

11. *Integration*: use available resources in a more efficient, balanced, and equitable manner by adopting cancer control strategies that are *integrated* within the *healthcare system* (linked to NCD strategy or linked to other existing services such as palliative care). In addition, recognize the common risk factors and opportunities for collaboration and integrated actions simultaneously to reduce the incidence of other chronic diseases.

12. *Stepwise approach*: follow WHO recommendations to adopt *primary healthcare* (PHC) and a stepwise approach to planning and implementing interventions, based on local considerations and needs. (See, for example, the definition of and a discussion on the stepwise approach to palliative care [29].)

In addition to the above, the planning group should bear in mind that although many specific objectives of an NCCP are achievable within five to ten years, its aims of reducing significantly the incidence of cancer and mortality, and maximizing cancer survival, will require more than 20 to 40 years to materialize. Thus, the final plan can only be successfully implemented if there is an equally long-term commitment on the part of government and partners (stakeholders) to carry out all its elements with close attention

to realistic objectives, governance, resource allocation, financing issues, and regular monitoring and performance assessment.

Planning stages

Although WHO [4, 5, 19], the UICC [17, 18], the US Centers for Disease Control and Prevention (CDC) [20, 21], the IAEA [23, 31], and other organizations [32] have developed NCCP-related guidelines, toolkits, and needs assessment tools and models, as highlighted by a recent report from Imperial College London, there is no internationally agreed common format of an NCCP nor a commonly accepted framework to adapt them to local conditions [33]. In addition, no framework is available for NCCP evaluation or comparison, except for a few recent reviews where some criteria have been defined [33, 35]. As a result, a centrally maintained database on NCCPs and their performance worldwide does not exist, which would be ideal for measuring progress made in various regions. Additionally, there are significant differences across regions in the types of prevalent cancers, resources available for cancer control, organizational structure of healthcare system and service delivery, and existing cancer services, making it difficult to propose a single model for a cancer control plan and related interventions. As a result, the structure and framework of cancer plans will also vary; no single model will be suitable for all countries, although similarities in terms of goals, objectives, and planned actions are common among NCCPs.

The overall process can start following pre-planning consultations and the formalization of the planning group and its membership, and their familiarization with, and adherence to, the guiding principles outlined above as adapted in the country (which should preferably be issued by the Ministry of Health). The planning group must carefully review the country's epidemiological data, including data collected by cancer registries, where available, and then jointly set goals, objectives, strategies, and priorities for action considering the country's capacity and resources [4]. They should also work on mobilizing support for the implementation of the plan, and put in place an evaluation system to monitor implementation progress. Ideally, the planning group should be involved in implementation as well (and that is why it is essential for the planning group to be appointed formally by the Minister of Health as the *Steering Committee for Cancer Control* to have the overall responsibility for the entire process). The planning group might seek advice from others within the country or internationally in all stages of their work, but particularly in situation analysis [19, 23], and in comparative assessment of interventions and health technologies. This entire process might take as long as five to six years, a year or more to complete the plan, and normally a period of five years to implement each NCCP cycle. Time should also be allocated for evaluation of each plan and preparation of the next plan cycle.

Planning model

The model proposed here is a *hybrid* one, where the most relevant elements of models and cancer systems available [32, 33], and the actual experience in LMICs engaged in cancer control planning and implementation [31, 34] have been combined to present a more structured planning framework. To start with, the planning process can be summarized into ten major Steps, which are further divided in four set of activities as outlined in Figure 27.1.

As the planning moves forward, each set of Steps in Figure 27.1 represents a period of time and activities which can be considered as a response to two specific questions: one about cancer control status/situation, and the other about cancer control actions. These questions are outlined on the flowchart in Figure 27.2 for each set of Steps in similarly coloured boxes as in Figure 27.1 (the Steps corresponding to each *question* are also indicated in the boxes). It can easily be seen that the four *status/situation-oriented* questions (questions A to D) lead to the four *action-oriented* questions starting with a '*What*'. These four '*What*' questions form the basis for a planning model that was originally developed by a group of public health and cancer experts in the US and also adopted here [32].

Fundamentally, responses to questions A to D form the structure of an NCCP. During the preparatory stages of planning and drafting a consensus NCCP document, eight key questions in Figure 27.2 need to be answered by the Ministry of Health and the group assigned to the task. Arranging the original ten Steps into this set of questions somewhat simplifies the planning process for the planning group, although the responses will require extensive discussion. It is also clear from question D in Figure 27.2 that the process is not linear but cyclic and the process returns to question A once every few years (similar to *project life cycle* idea used in management [36]).

Based on the above analysis, cancer control planning and implementation can be looked at within a framework consisting of *four main* and *two intermediate stages*. The stages are linked in a cycle which can be presented graphically as depicted in Figure 27.3. The 'blue' boxes represent the main stages of the cycle from A to D (corresponding to boxes in Figure 27.2), and the 'orange' ones are intermediate stages highlighting the two key 'milestones' of the planning process; one after Stage C, the agreement on a 'Cancer Control Strategy', the completion of the NCCP formal document and the launching of the NCCP, and the other after Stage D, the evaluation report of NCCP and the revised NCCP for the next cycle. The central 'grey' box defines the vital prerequisites and the enabling conditions for the progress and success of the NCCP. This box is also the information centre for the NCCP, linking all cancer control data, inputs, activities, and outputs from all stages of the cycle.

Stage A: setting desired aims, goals, and objectives (What should be done?)

Here the NCCP planning group is established and a coordinator is nominated in partnership with stakeholders. To respond to the question 'Where does the country stand now in terms of cancer control?', they analyse all available cancer data to assess the magnitude of the cancer burden, the populations at risk, the risk factors, and any existing gaps in cancer control services. The minimum data needed is a reasonable estimate of all new cases per year, and reliable information on the proportion that may be curable after diagnosis. The top few cancers in the country for which effective prevention is available and those for which early diagnosis can be effective should be listed with estimates of number of people affected. Most LMICs will lack reliable data on cancer incidence, mortality, prevalence, and five-year survival from diagnosis, due to absence of population-based registries. (The only alternative is to rely on data published regularly by the IARC, which provides estimates of cancer incidence for most countries [37].) Special attention must be paid to cancer risk factors. Countries with a high percentage of young people (a triangular population pyramid with broad base) may not have a large cancer incidence but will have a significant prevalence of cancer risk factors [10]. A review of the common types of cancer can provide hints to what

1. Review of epidemiological data and prevailing cancers (if available from cancer registries or other sources), and country specific cancer risk factors

2. Assessment of existing infrastructure and services, and relevant gaps and needs

3. Setting measureable cancer control aims, goals and objectives

4. Agreement on possible strategies for cancer control, and *resource-level-appropriate* initial actions, activities, interventions, and related indicators (targets) for each objective

5. Estimation of timeline for achieving the specific objectives (5 years and beyond)

6. Agreement on 5-year priorities and the level and sources of financing

7. Development of implementation plan, and plans for raising additional funds

8. Selection of institutions responsible for delivering the NCCP components (and identification of potential partners)

9. Arrangements for management and implementation of the NCCP

10. Monitoring and evaluation of the results at the end of timeline, feedback to the management of NCCP, and revised NCCP for a new cycle (restart the Steps)

Fig. 27.1 The ten major Steps in cancer control planning.

the risks are (e.g., smoking and lung cancer, Hepatitis B infection and liver cancer) but a high-quality random population-based survey will usually be necessary to measure risk factor frequency and to help set priorities for prevention [27]. At the end of this Stage, the aims, goals, and optimal objectives of the NCCP are defined[1], which must be reviewed in the next two stages based on resource-level-appropriate strategies. The activities and outcomes of this stage are driven by *data*.

A) Where does the country stand now in terms of cancer control? (Steps 1–3)
• WHAT SHOULD BE DONE?

B) Where does it want to be in 5 years? 10 years? 20 years and beyond? (Steps 4–5)
• WHAT COULD BE DONE?

C) How can it get there and achieve the respective goals and objectives? (Steps 6–8)
• WHAT CAN BE DONE?

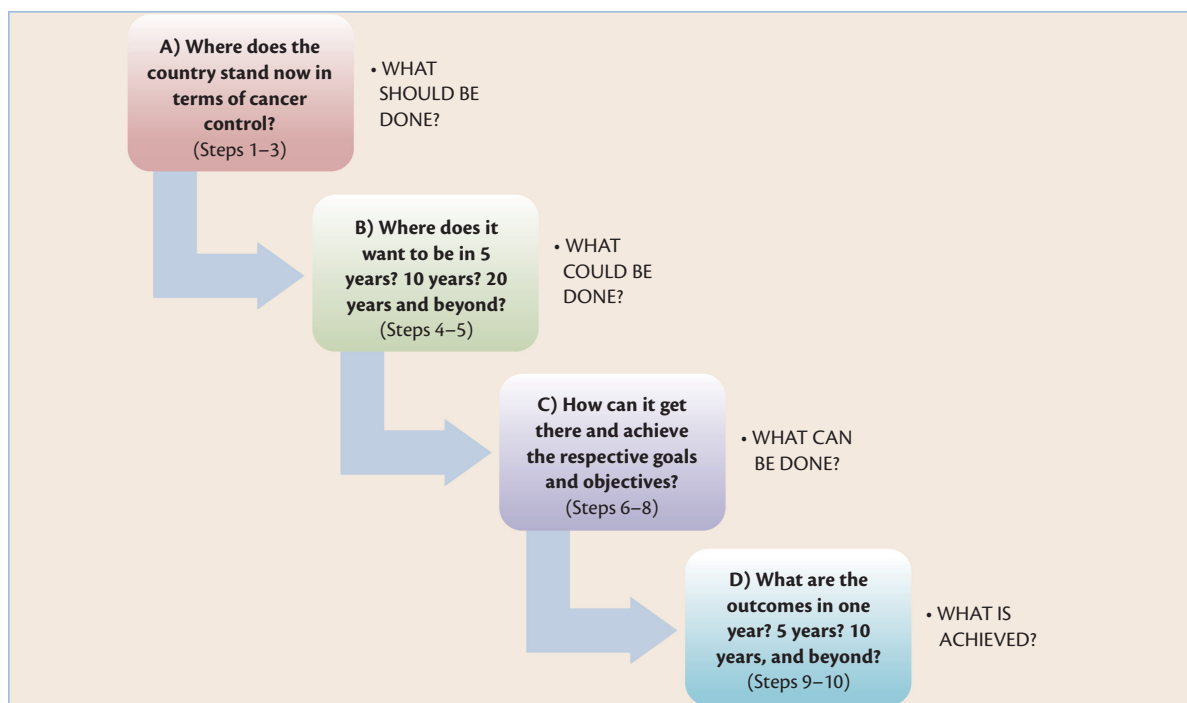
D) What are the outcomes in one year? 5 years? 10 years, and beyond? (Steps 9–10)
• WHAT IS ACHIEVED?


Fig. 27.2 The key questions driving the cancer control planning process.

Fig. 27.3 Cancer control planning life cycle.

Stage B: evaluating available strategies (What could be done?)

Based on the objectives set above, relevant strategies are evaluated in consultation with stakeholders to define the interventions and related improvements in healthcare infrastructures in order to respond to the question 'Where does the country want to be in five years, ten years, and beyond?' This stage is mainly *science driven* as it relies on current evidence-based interventions to find those most effective (and cost-effective) for a given setting. If expertise is required for reviewing scientific information and the costs of various interventions, outside experts could be invited through WHO, or other relevant organizations, to help.

Stage C: setting resource-level-appropriate priorities and strategies (What can be done?)

Here the NCCP planning group needs to respond to the question 'How can the country get there and achieve the desired goals and objectives?' In coordination with stakeholders, they must choose amongst possible strategies from Stage B those that are implementable and acceptable locally, and correspond to the country's available and possible additional resources (funds, trained professionals, equipment, and facilities) and the type of cancers targeted (the effectiveness and the costs of intervention strategies for prevention, early detection, curative therapy, and palliative care of common cancers vary substantially and need careful technical review) [9, 24–27].

Cancer control strategy and NCCP document

At the end of Stage C, most countries opt to produce a formal document to present the findings and recommendations of the planning group in the form of a *strategy* or *policy*. Some countries prefer to call such formal documents, when issued by the government, a *policy paper*, and when developed through a partnership of governmental and non-governmental entities, a *strategy*. In general, a strategy defines the overall character, mission and direction of a cancer control plan. Strategies are formulated and implemented with a view to achieving specific goals, but they do not say specifically how to arrive at that end. That is where *policy* is needed to provide direction to all involved on how goals will be achieved.

While the development of possible and feasible strategies (Stages A, B, and C above) and the implementation plan (Stage D) are the responsibility of the Steering Committee for Cancer Control, policy is the responsibility of the government.

This document is then approved and signed by the Minister of Health (or higher authorities to ensure longer-term commitment and political support) and endorsed as a formal document of the government. A well-formulated cancer control strategy (CCS) provides a solid platform and guidelines for implementing and maintaining cancer control measures and for making cancer control an integral part of the nation's healthcare programme. According to WHO, such a document may be defined as 'an explicit commitment by the government and its partners that provides objectives for a balanced cancer control programme, specifies the relative priority of each objective and indicates the resources and measures required to attain the objectives' [1]. An excellent example of such a document is the 2010 Cancer Policy Framework of the Newfoundland and Labrador province in Canada [38]. This document outlines the provincial government's response to the burden of cancer in the province by providing key policy directions that will be used to guide cancer control efforts and specific action plans in the province in the coming years.

NCCP Document

The NCCP planning group and their coordinator must also produce a written version of the NCCP (that is the CCS and its implementation plan), and have it agreed as a consensus document by all concerned and ratified by the Minister of Health. This formal document is vital for further action by the government and the planning group, and is also needed to ensure an efficient and effective management of the NCCP and its continuity. Additionally, an *NCCP communication strategy* needs to be discussed and documented to ensure full public and media understanding and support for the plan and its actions. These documents will later be the main reference for officially adopting the NCCP, launching it, and managing its implementation.

Although the NCCP formulation will follow each country's specific situation and needs, the structure of the written document will be generally similar everywhere, i.e. an assessment of the cancer burden in the country; definition of aims, goals, and objectives; identification of the priority needs of the country; the cancer control strategies adopted; setting of realistic performance indicators (targets) and timeline, identifying those responsible for each; and review of resources available within the health system and sources of future funding (for examples of NCCPs see the 'Further reading' list at the end of this chapter).

Stage D: implementing and evaluating (What is achieved?)

The last stage provides a response to the question 'What has been achieved in one year, five years, ten years, and beyond?' It is basically an *outcome-driven* stage for implementing in cooperation with stakeholders the strategies reviewed during Stage B and selected during Stage C to meet the objectives defined during Stage A. The first action is to develop an implementation plan and define the processes to manage, monitor, and evaluate it (an implementation plan is needed whether a CCS has been formally approved at the end of Stage C or not).

Stage D is the longest period within the cycle and is normally set to five years. As it involves the management of NCCP's implementation processes, it requires adequate administrative, financial and technical capacity at national level [1, 4].

Evaluation report and revised NCCP

After the implementation period, there is a year of NCCP review and evaluation of results to provide feedback for the new cycle. Monitoring and evaluation are crucial to measure what various stakeholders and partners who have been given responsibility for the implementation of agreed interventions and actions have achieved. In addition, any shortcomings or failures must be addressed with recommendations for the next cycle. The results are reflected in a report and then utilized for feedback into NCCP to adjust objectives, intervention strategies, and activities as necessary, and to secure the resources for the next five-year cancer plan. A *new Stage A and NCCP cycle* with an enhanced cancer control status and programme in the country can then begin.

The success of this model, apart from being dependent on the efficient organization of the entire process, the long-term government commitment, the effectiveness of the planning group (Steering Committee and its Coordinator), resources available, and the collaboration of all partners involved, depends greatly on the availability and functionality of a pool of data and knowledge for decision-making in all its stages (the enabling condition presented in the 'grey' box in Figure 27.3). The data should ideally be centrally maintained or compiled, as part of the cancer surveillance and information system, using a computerized cancer information system with oversight of the Steering Committee.

Challenges facing planners

In this short overview of cancer control planning steps and processes, it is not possible to highlight all critical issues and challenges that are most relevant for LMICs. A recent WHO survey on national capacity for NCDs [10] in 185 countries revealed major gaps in cancer control planning and services. WHO reports that 'even if countries developed cancer plans or policies, many countries are struggling to move from commitment to action. Often these plans are not integrated into wider national health and development planning. In addition, many countries lack institutional capacity, as well as decisive leadership to ensure adequate national funding for cancer control' [39].

To guide the professionals interested in the topic, it suffices to stress that experience with operational NCCPs shows that those with more *realistic objectives and strategies*, corresponding to the *level of resources available*, have accomplished more [4, 24]. In such NCCPs, priority is given to effective (and cost-effective) interventions and programmes that are *resource-level-appropriate* and beneficial to the largest part of the population. Beyond resources, effective NCCPs are those that are *managed* well by a dedicated team and its leader, namely the *Steering Committee* and the *Programme Coordinator*, particularly in terms of continuous monitoring, evaluation, and periodical adjustments during implementation [25, 27].

Until quite recently, one area of concern for developing cancer plans in LMICs was the lack of sufficient or consolidated evidence and information in some fields relevant to low-resource settings. Despite the progress made, the experience in many LMICs shows that cancer control planning groups and policy makers often face more complicated questions, especially technical ones, related to planning Stages A, B, and C, for which there

are not always readily available responses, either due to the lack of adequate scientific evidence relevant to their particular setting, or the lack of a clear or agreed definition of some of the terminology used in the cancer control literature. For example, to quote from an excellent reference on the subject [24]: 'What level of cancer incidence justifies a prevention or early detection programme? How do policy-makers know what specific approach or intervention is likely to succeed under their own circumstances? What is a comprehensive approach? What are necessary resources?' Alternatively, more specific ones as often discussed in cancer control conferences: What are the most appropriate screening approaches for common cancers? What are the right diagnostic and treatment technologies and infrastructure for the country? Or: How many professionals are needed to establish a reasonable cancer treatment service?

Fortunately, there have been a number of international initiatives and substantial scientific publications on cancer-control-related work and practice in the past decade, which are gradually shedding light on most of the 'What' and 'How' questions. For instance, the publication in 2006 of a set of guidelines by Breast Health Global Initiative intended to help policy makers and healthcare providers in LMICs adapt evidence-based, economically feasible and culturally appropriate practices, has strengthened efforts to improve breast healthcare and outcomes for women in LMICs through NCCPs [40]. Additional work has shed further light on *what's needed, what works*, and *how it should be done* [26, 29, 34, 41]. Further, there have been a few recent evaluations and reviews of existing NCCPs that are helpful in pinpointing some of the opportunities and key requirements for success [24, 33, 35, 42].

Finally, national efforts may be further enhanced or strengthened by being linked to global efforts spearheaded by international organizations (such as the HBV and HPV vaccination campaigns), in addition to seeking their assistance for situation analysis, NCCP planning, or certain plan implementation aspects (as mentioned above).

To learn more about best practices and cost-effective strategies in different settings, the most instructive approach is the review of existing NCCP documents of other countries and their reported experience. The online References and Additional resources provide an extensive list for further reference and reading. In addition to relevant material posted on the websites of organizations involved in cancer control as cited here, cancer control plans or strategies of a number of countries, including those of LMICs, can be found on the Internet, many of which can be instructive for anyone working on cancer control.

Note

1 The cancer control *aims, goals and objectives* need to be stated clearly in the NCCP document. As these terms could often be confusing in different languages, some examples are given below using WHO and other guidelines in the literature: Aims: (a) Reducing the overall incidence and mortality of selected cancers in the country, as well as improving overall survival and the quality of life of cancer patients and their families; Goals: (b) Preventing cancer and raising public awareness about the high priority cancers in the country and means of combating them; (c) Detecting cancers early and facilitating early access to treatment and follow-up; (d) Providing high quality cancer care for every patient diagnosed with cancer, with an emphasis on palliative care during the early stages of the plan; (e) Investing in expansion and improvement of existing services to cover larger populations; (f) Ensuring adequate availability of workforce, and facilitating education and training in cancer control components; (g) Ensuring cancer services are gradually available and accessible across the country at affordable costs; Objectives: (Objectives are country, burden and resource dependent and can be general or more specific. For each goal, there can be a number of objectives – and often for each objective, more specific ones are defined): (h) Reducing incidence of cancers caused by tobacco; (i) Reducing tobacco smoking rates among health care professionals and patients attending primary care clinics.

CHAPTER 28

Cancer prevention
Vaccination

Sarah E.B. Goltz and Julian Lob-Levyt

Introduction to cancer prevention vaccination

Since the development of the first successful vaccine—smallpox in 1796—vaccines have played a critical role in improving individual and public health globally. Few advances in medicine and science have had as substantial an impact on global morbidity and mortality as vaccines. Even in the lowest resource settings, vaccines have delivered important advances against disease. In the face of a growing global burden of cancer, the potential for vaccines to prevent, and possibly even to treat, cancers presents an important opportunity in cancer prevention, treatment, and control in all countries.

Over the past several decades, vaccine research and development have expanded greatly, resulting in an arsenal of powerful new vaccines that effectively protect against bacterial and viral causes of disease. Cutting-edge science has delivered new prophylactic vaccines that are unmatched in their safety and effective protection against disease. A new generation of highly effective prophylactic vaccines has been created through the novel use of adjuvants to boost immune response, and the development of conjugate vaccines that can provide high levels of individual protection and foster greater herd immunity.

The current growing interest and investment in cancer vaccines is particularly timely and important. The 2010 Global Burden of Disease Study revealed that a major epidemiological transition was well underway, particularly in low- and middle-income countries. This research illustrated a significant epidemiological shift that challenged assumptions that chronic diseases, including cancers, were limited to high-resource settings. This research showed a heavy burden of cancer and other chronic and non-communicable diseases in low- and middle-income countries [1]. Increases in smoking, dietary and lifestyle changes and toxic environmental exposure, together with longer life expectancy have contributed to the growing public health challenge of cancer worldwide. Increasingly, resource-poor health systems struggle to meet the need for cancer prevention, treatment, and control.

In the face of a growing global burden of cancer, vaccine solutions to prevent and possibly treat cancer are particularly relevant. Currently, there are three cancer vaccines. Two of these vaccines protect against cancer-causing viruses: hepatitis B virus (HBV) and the human papillomavirus (HPV). The third vaccine is a cancer treatment vaccine, which is an immunostimulant for late-stage prostate cancer. Other treatment vaccines are currently in development targeting other major cancers including bladder cancer, Hodgkin lymphoma, prostate cancer, and breast cancer. To date, these and others in development have yet to prove effective.

Current prophylactic cancer vaccines

Hepatitis B virus and liver cancer

Hepatitis B (HepB) is an infectious inflammatory illness of the liver caused by the HBV. Globally, more than two billion people are infected with HBV and more than 600,000 die each year from HepB [2, 3]. Transmitted sexually and through blood-to-blood contact, including mother-to-child transmission at birth, HBV is one of the most highly infectious viruses known today. HBV is 50 to 100 times more infectious than HIV [2].

HBV infection can cause both acute and chronic disease. Only chronic disease has been shown to cause cancer. Most individuals who are chronically infected with HBV are asymptomatic and remain unaware of their disease status. These individuals are particularly at risk both for spreading HBV and for suffering long-term health consequences, including cirrhosis of the liver and hepatocellular carcinoma (HCC). The likelihood of developing chronic infection—and thus, cancer risk—is directly related to the age at which an individual becomes infected with HBV [2].

In developing countries, perinatal transmission is a common route of infection often due to a lack of knowledge about the mother's status as a chronic carrier of the virus and poor management of mother-to-child transmission prevention protocols. If infected perinatally, infants are far less likely to develop acute illness than children over 5 years and adults. However, once infected, 90% of infants and 30–50% of children will develop chronic HepB disease [4]. Individuals with chronic HBV infection, often unaware of their HBV status, have a 15–25% risk of dying prematurely from HBV-related causes include hepatitis, liver cirrhosis, and HCC [5]. Research indicates that chronic HBV infection accounts for 75–80% of HCC in many parts of Asia [6], where as much as 66% of the total global burden of HCC exists [7].

Effective screening tests are available to diagnose HBV infection. Although no medical treatment is available for acute infection, chronic infection can be managed with medicines, where available and appropriate. Chronic HBV infection remains a leading cause of cancer in Asia, Amazonia, and Southern and Eastern Europe. In Asia, 8–10% of the adult population is chronically infected [8]. In Western Europe and North America, less than 1% of the adult population is chronically infected [2].

Hepatitis B vaccines

HepB vaccines are recommended in most countries for all infants, unvaccinated children under 19, and individuals at high risk for exposure, including health professionals, men who have sex with

men, intravenous drug users, diabetics less than 60 years of age, and haemodialysis patients [9, 14]. As HepB is relatively rare in the UK, the National Health Service does not provide universal infant and childhood vaccination. Only children of HBV-positive mothers and high-risk individuals are routinely vaccinated in the UK. However, in over 110 countries where infection rates remain high, universal childhood vaccination is the norm [15].

Today, there are multiple formulations of the Hep B vaccine. HepB is often included in combination vaccines targeting multiple pathogens with a single vaccine administration. Only one formulation, the single antigen vaccine, is used to prevent vertical transmission and it must be administered within 24 hours of birth. These have been registered and are in use worldwide. HepB vaccination is among the vaccines prioritized and recommended by the World Health Organization (WHO) and national authorities globally. According to the WHO, over one billion doses of Hep B vaccine have been administered worldwide since 1982. The strong safety profile of the Hep B vaccine has been confirmed through continual global monitoring and expert reviews [8].

When delivered in complete series, Hep B vaccination is known to be 95% effective at preventing HBV infection and the resulting disease. According to the WHO, HepB vaccination imparts immune protection for 20 years [2]. As chronic disease is most often a consequence of infection early in life, immune protection afforded by early vaccination has been deemed sufficient to establish lifetime protection and no booster is recommended. Findings from a follow-up study of individuals vaccinated as infants through Taiwan's universal Hep B vaccination programme demonstrate the vaccine's protective effect and a statistically significant decrease in HCC twenty years post-vaccination [11]. Where HCC was present among vaccinated adults, it was directly linked to incomplete or unsuccessful HBV vaccination and poor prevention of mother-to-child transmission [11].

The Hep B vaccine offers an important case study for what can be done to make life-saving vaccines affordable and accessible globally. For nearly a decade, Hep B vaccine was beyond reach of most low- and middle-income countries. Galvanized by a 1992 World Health Assembly resolution to universally recommend Hep B vaccination, the WHO led an international effort to quickly scale up availability of HepB vaccine in low- and middle-income countries. Both Gavi, the Vaccine Alliance (focused on providing access to vaccines in the world's poorest countries) and the Pan American Health Organization (PAHO, focused on providing technical support and cooperation in Latin American countries) have stepped forward to provide valuable technical, vaccine pricing, and procurement support for many low- and middle-income countries. Both organizations have been instrumental in expediting widespread uptake and reducing the costs of vaccines, including Hep B, for countries where the burden of vaccine-preventable diseases is highest.

The impact of these efforts is significant. The price of the vaccine has dropped dramatically from US$100 per dose in the early 1980s [12] to just over US$0.17 in 2013 [13]. As a result of lower prices and greater international support, between 1992 and 2011, the number of countries that routinely vaccinated for HepB rose from 31 to 179 [2]. Among these countries, China has made unprecedented strides to implement a nationwide effort to prevent perinatal transmission of HepB. With catalytic Gavi support for initial pilots, first dose at birth vaccination has increased from 64% to over 90% in less than one decade. This increase in coverage—achieved even in China's most remote areas—was accomplished by expanding affordable access to the vaccine for the government, while increasing awareness and demand for hospital-based delivery of HepB vaccine among mothers. A recent study indicates that the partnership between the Government of China and Gavi prevented 3.82 million chronic infections and 685,000 future deaths in the areas jointly targeted between 2002 and 2011 [14]. According to Gavi, today less than 1% of children in China are chronic carriers of HBV [15]. Since routine vaccination began, other countries have reported similar drops in chronically infected children (Figure 28.1) [2].[25]
Fig. 28.1 Hepatitis B vaccine introduction in high- and low-income countries.

Human papillomavirus and cervical cancer

The HPV group contains over 150 viruses. Over 40 of these viruses are transmitted sexually and can cause cervical, vaginal, vulvar, anal, oral, and throat cancers. HPV can also cause tumours in the head, neck, urethra, and penis. Infection with HPV is common and usually cleared by an individual's immune system. Only persistent HPV infection can lead to cervical and other cancers. Cervical cancer is the largest cancer killer among women in most low-income countries. Each year, approximately 500,000 women develop cervical cancer and 275,000 women die from the disease [16].

In developed countries, high rates and frequency of cytology-based screening and early and effective treatment for pre-cancerous lesions has led to a significant drop in cervical cancer mortality. The limited or failed replication of an effective cytology-based cervical screening system—reliant on sufficient pathologists and follow-up treatment and referral systems—has caused cervical cancer screening to stagnate in developing countries. In 2006, only an estimated 5% of women in developing countries were screened for cervical pathology, compared to 75% of women in developed countries [17]. Over the past decade, a robust international effort has been underway to address this disparity and identify new screening and early treatment tools that could make cervical screening programmes viable in all resource settings. These efforts have been successful in identifying promising new tools, but have yet to be taken to scale in most resource-poor settings. As such, the swift rollout of the HPV vaccine is essential in order to reduce the overall burden of cervical cancer in the coming decades.

HPV vaccines

HPV vaccines became available in 2006. Currently, there are three HPV vaccines available—a bivalent (Cervarix®), a quadrivalent (Gardasil®), and a nine-valent (Gardasil 9®), which was approved in the US in late 2014. All three vaccines are non-infectious recombinant vaccines and protect against HPV 16 and 18, the two types of HPV responsible for 70% of cervical cancer cases globally and most HPV-induced genital, head and neck cancers. The quadrivalent vaccine also protects against HPV 6 and 11, which cause 90% of genital warts [18]. Manufacturers of the bivalent and quadrivalent claim some degree of cross-protection against other oncogenic strains of HPV, including HPV 45 and 31 [19]. Both vaccines have excellent safety profiles [19, 20, 21]. A recent population-based study in Australia, where the quadrivalent HPV vaccine was introduced nationally to girls since 2007, validated clinical studies by showing reductions in infections from HPV 16 and 18 among women and indicating early protective effects of the vaccine against genital warts among vaccinated women and herd immunity among males [22]. Both vaccines are safe and can be administered along with other vaccines including HepB, diphtheria, tetanus, pertussis and poliomyelitis.

The novel nine-valent vaccine protects against cervical cancer from HPV 16, 18, 31, 33, 45, 52, and 58, as well as genital warts causing HPV 6 and 11. This vaccine protects against the HPV types responsible for 90% of cervical cancer. Unlike Cervarix® and Gardasil®, which are registered worldwide and recommended by the WHO, Gardasil 9® is only registered in the US.

In December 2014, the WHO expanded and updated its recommendations for HPV vaccine use through the publication of new guidelines. In these recommendations, the WHO underscored the importance of introducing HPV vaccination as a part of a comprehensive cervical cancer control strategy where cervical cancer

is a public health priority, would not compromise existing screening programmes for women, and is financially sustainable and cost-effective. As HPV exposure is common at sexual debut, HPV vaccination is recommended in early adolescence prior to first sexual contact. The WHO continued its recommendation that the vaccine be delivered to girls between the ages of 9-13 years of age. The dosing recommendations for girls vaccinated before the age of 15 was changed from a three-dose schedule to a two-dose schedule for both Cervarix® and Gardasil® at a six-month interval. Girls who were vaccinated with less than a six-month interval, or are immunocompromised, or are over the age of 15 should receive the three doses of the vaccine according to the original schedule of 0, 1–2, and 6 months. These guidelines do not incorporate any specific vaccination recommendations for the nine-valent vaccine, which has not yet been approved by the WHO.

While newly vaccinating countries exclusively targeting girls aged 9–12 can begin to focus on a two-dose schedule, the three-dose schedule will likely continue to be used in high-income countries where girls above the age of 15 are commonly vaccinated. In fact, many high-income countries have national HPV vaccine programmes that target girls up to the age of 26. In 2011 and 2012, several countries also expanded the registration of the quadrivalent vaccine to include protection for boys against genital warts and anal, oral, and throat cancers.

The UK, Australia, Canada, New Zealand, and the US were among the first countries to introduce HPV vaccine in 2007 and early 2008. Some countries initiated catch-up campaigns for girls and young women in order to maximize the potential benefit of the vaccine. These countries included Australia, Canada, Denmark, the Netherlands, New Zealand, and the UK [23]. In 2011 and 2012, several countries including Australia and the US included the vaccination of boys in their national HPV prevention efforts. In developing countries where adolescent health services are weak or non-existent, HPV vaccination programmes have the potential to act as a springboard for strengthened adolescent health programmes and services.

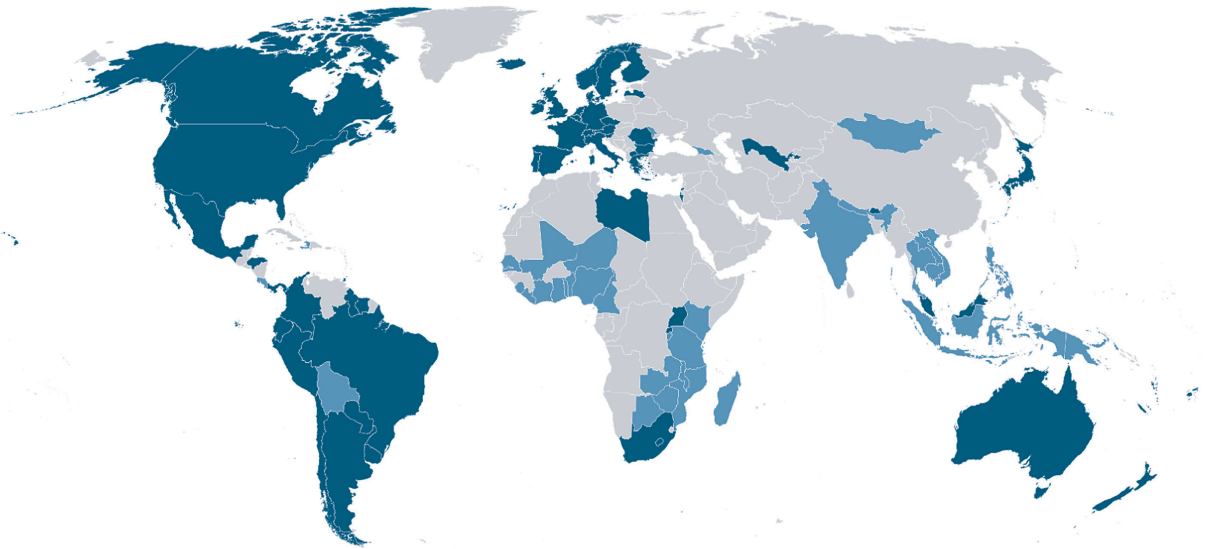
Unlike the HepB vaccine, which took several decades to scale in low- and middle-income countries, HPV vaccine has taken a much faster trajectory in all resource settings. As of September 2014, 73 countries and territories have included HPV vaccine in their routine immunization programmes and pilot programmes are underway in 37 countries (Figure 28.2) [24]. As with HepB, both Gavi and PAHO are providing critical technical and procurement support for HPV vaccine introduction. These organizations also had a significant impact on HPV vaccine price. Gavi has provided financial support to Gavi-eligible countries, allowing these vaccines to be affordable to the lowest-income countries. Gavi has secured a purchase price of $4.50 and will use its funds to purchase HPV vaccine and make these vaccines available to low-income country governments for a modest co-pay. Gavi expects to vaccinate more than 30 million girls by 2020 [25]. For middle- and low-middle-income countries in Latin America, PAHO's Revolving Fund has secured largely affordable prices for HPV vaccines. In 2013, these prices were as low as $13.08 for the bivalent and $13.79 for the quadrivalent for countries in Latin America. These vaccine prices are still far higher than HepB, but are following a similar trajectory over a shorter period of time and will need to come down further if they are to be truly affordable for the poorest and even middle-income countries [25].


Fig. 28.2 Global Progress in HPV vaccine introduction: September 2014. Dark blue: countries with national HPV vaccination programmes Light blue: countries with HPV vaccine pilot programmes.

Several emerging issues could hasten the already rapid uptake of HPV vaccine in the coming years. First, the recent WHO recommendations for countries vaccinating girls under the age of 15 to switch to a two-dose schedule will have a considerable positive impact on the cost and challenges associated with the introduction of this vaccine. Second, the recent approval of the nine-valent introduces the possibility that in the future girls vaccinated with vaccine that covers such significant oncogenic HPV types might not require screening as adults. Finally, as HPV vaccination becomes more commonplace and affordable, the question of whether national programmes should vaccinate boys will likely get more attention. HPV vaccine could become an important strategy to protect males against other HPV-related cancers, as well as reduce the spread of HPV infection from males to females.

Cancer treatment and vaccines

The use of vaccines for cancer treatment is an exciting and evolving area of biomedical innovation. While the HepB and HPV vaccines offer protection against viruses that can cause cancer, cancer treatment vaccines mount a direct attack on a cancer that has already developed. Treatment vaccines are intended to delay cancer cell growth, cause shrinkage of existing tumours, prevent cancer recurrence, or eliminate cancerous cells that were not killed by other forms of treatment [26]. Treatment vaccines present a particularly difficult challenge as cancer cells often adapt quickly to changes in their environment and may have defence mechanisms that weaken anticancer immune responses [26]. Current tumour cell vaccines under development are made from harvested DNA or cells collected from the diseased person or tumour. These cells are then altered chemically or genetically. In theory, once altered, the modified DNA or cells are injected back into the diseased person in order to trigger an immune response that will directly alter cancer cells or increase the immune strength of a cancer patient.

Despite considerable research and interest in this area, only one cancer treatment vaccine is currently approved and available. Sipuleucel-T (Provenge®) is a treatment vaccine for prostate cancer. It is currently only approved for use in the US and is used in men with metastatic disease. This treatment vaccine is used to prolong survival, not to cure or reduce disease burden. The vaccine's impact on overall survival rate has been approximately four months [27]. Studies are underway to understand if the vaccine could be effectively used to increase survival time in less advanced cancer patients.

Sipuleucel-T is an autologous vaccine—created for each individual patient—making widespread commercialization and cost important barriers to widespread use. Immune cells from the diseased patient are collected through leukapheresis. These cells are then used to develop each patient's unique dose of Sipuleucel-T, which is then delivered to the patient intravenously 3 times over 2 week intervals [26]. This vaccine is currently in use exclusively in the US. Its current cost and reliance on sophisticated technology to develop the vaccine puts it far beyond reach of low- and middle-income countries.

Other cancer treatment vaccine trials are underway including pancreatic, brain, lung, and breast cancers as well as multiple myeloma, leukaemia, and melanoma.

Innovative strategies to drive cancer vaccine development and access

As cancer rates continue to grow globally, novel strategies are necessary to encourage and support scientific and biomedical efforts to develop new cancer prevention and treatment vaccines. Over the past several years, a number of notable innovative financing mechanisms were developed to encourage the creation or purchase of new vaccines for low-income countries. The Advanced Market Commitment (AMC) was created to frontload investment in

vaccine research and development and to ensure earlier and afford-able vaccine access in the lowest income settings. The AMC was designed to 'pull' or trigger development efforts for new vaccines by securing international financing for yet-to-be-developed vaccine. The International Finance Facility for Immunisation (IFFIm) was a broader effort that sought to rapidly decrease vaccine-preventable childhood diseases by frontloading funding for vaccine procure-ment. By doing so, it demonstrated that a large, viable and sustaina-ble vaccine market could be built in least developed countries. Both mechanisms could serve as useful models to drive cancer vaccine research and secure markets that would make innovations in can-cer vaccines available in all resources settings.

CHAPTER 29

Cancer chemoprevention

Hans-Joerg Senn, Nadir Arber, and Dirk Schrijvers

Introduction to cancer chemoprevention

Cancer chemoprevention is defined as the pharmacologic intervention by specific substances (drugs or nutrient-components) with the process of carcinogenesis, in order to prevent the development of overt, invasive malignant neoplasms [1]. This preventive attempt is particularly challenging in cancer types which have a long subclinical developmental phase, because of their low cellular proliferation rate and their slow preclinical evolution, until they become clinically detectable and therapeutically as well as prognostically relevant. Therefore, only certain specific cancer types are presently the focus of clinical chemoprevention, especially those with rather slow evolution such as adenocarcinomas. Additionally, such efforts are directed only those for which there exist relatively mild and tolerable ways of pharmacological intervention in otherwise (still) healthy individuals with only a statistically elevated risk of developing certain types of cancer on the basis of either their genetic background and family history or else their professional and personal exposure.

This means that the list of cancer types in which cancer chemoprevention presently constitutes a valuable primary preventive option is still short and actually confined to breast and colon cancer (see Table 29.1), with some candidate neoplasms such as prostate cancer at the doorstep of wider clinical interest [2]. In addition, another major limitation is operative in hormone-dependent tumours such as breast and prostate cancer: the anti-endocrine pathway of interaction with carcinogenesis is only effective in individuals developing target-oriented, receptor-positive disease.

Chemoprevention in (invasive and non-invasive) breast cancer

Epidemiology and the importance of the problem

Breast cancer is the most common cancer type of European women with 425,147 cases being diagnosed in 2008 and an overall incidence rate of 66.7/100,000 women and 128,737 dying from breast cancer, with a mortality rate of 16.9/100,000 women [3]. Despite remarkable progress in the primary curative treatment of early, localized disease, the overall mortality of breast cancer on a worldwide scene has been increasing during recent years due to the growth in the incidence of invasive breast cancer in heavily populated Asian countries, mainly due to changing living habits and significant increase of the lifespan of their populations [4]. In addition, it has become increasingly evident that the realistic gains of long-standing efforts of secondary breast cancer prevention (nationwide mammography screening) on ultimate survival figures in the Western hemisphere remain lower than previously anticipated [5]. For this reason, hitherto rather marginalized attempts to prevent breast cancer development 'at the roots', i.e. primary chemo- or pharmacological prevention, will become increasingly important in the future. These chemopreventive efforts have been greatly enhanced during the last two to three decades by the uncontested success of post-surgical adjuvant chemo- and endocrine therapy results obtained in multiple clinical trials by international groups, which clearly show decreased relapse and increased overall survival rates as a result of adjuvant chemotherapy and adjuvant antihormonal interventions [6, 7]. It is therefore logical to apply these successful attempts to prevent cancer relapse to the situation of primary cancer development and its potential prevention.

Chemoprevention by anti-oestrogens (SERM's) and aromatase inhibitors

In the last 15 years, innovative efforts by the National Surgical Adjuvant Breast and Bowel Project (NSABP) in the US and others such as the International Breast Cancer Intervention Study System (IBIS) have made it possible to test this concept of chemoprevention by anti-hormones (first tamoxifen, later also raloxifene and other SERMs) in a series of important clinico-preventive trials. These trials resulted nearly uniformly in a remarkable decrease in the development of overt, invasive breast cancer as well as localized precursors (DCIS and LCIS) in women with an increased chance of developing breast cancer on the basis of their risk profile [8]. The actual decrease of developing overt cancer over a latent period of presently around ten years is 35–50%, figures that have been confirmed—and even surpassed—by similar prevention trials with newer SERMs (arzoxifene, lozofoxifene) or aromatase inhibitors by other international trial groups such as the IBS-I trial with tamoxifen [9] and the exemestane trial [10]. More such breast cancer chemopreventive trials, including simple 'non-oncological' compounds such as daily low-dose aspirin and the anti-diabetic compound metformin, are currently in progress, usually involving five years of medication to selected female populations with increased breast cancer risk (Table 29.2).

Problems and obstacles related to the concept of chemoprevention in breast cancer

Despite these encouraging preventive results, there is still much resistance in health politics— on the part of the medical profession and the public itself—to transferring these positive trial results to clinical reality. This true even in the US, virtually the only country in which breast cancer chemoprevention by anti-hormones such as

Table 29.1 Mechanisms of action for chemopreventive drugs

Agent	Tumour type	Target	Mechanism of action	Pathway
Tamoxifen	Breast cancer	Cell membrane	Blocks peripheral action of oestrogen (SERM = selective oestrogen receptor modulator)	Oestrogen receptor
Raloxifene	Breast cancer	Cell membrane	Blocks peripheral action of oestrogen (SERM)	Oestrogen receptor
Anastrozole Exemestane	Breast cancer	Aromatase enzyme	Inhibits biosynthesis of oestrogen (e.g., conversion of androgens to oestrogens)	Oestrogen receptor
Aspirin	Colorectal cancer	COX-1 and COX-2	Open, diverse	Prostaglandin PG)-Synthesis, NF-kappa-B
Celecoxib Ofecoxib	Colorectal cancer	COX-2	Inhibition of proliferation, induction of apoptosis, immune modulating, COX-2 inhibitor (Rofecoxib = withdrawn)	PG synthesis, Leukotriens synthesis NF-kappa-B
Finasteride	Prostate Cancer	5α-reductase	Inhibition metabolism dihydrotestosterone to testosterone	Androgen receptor
Dutasteride	Prostate Cancer	5α-reductase	Inhibition metabolism dihydrotestosterone to testosterone	Androgen receptor

tamoxifen and raloxifene is already approved by the drug regulatory agency the US-FDA. The reasons are multifold: involved females at risk—still healthy and not afflicted by disease pressure—dislike the prospect of five years of drug-induced, variable anti-oestrogenic side effects; the doctors involved do not like the idea of being seen to be responsible for causing side effects and doing potential harm; and the industry is afraid of costly legal interaction and liability suits on the part of (still) healthy individuals at risk, possibly resulting in detriment to their normal way of life as a result of taking potentially unnecessary or ineffective cancer-preventive drugs.

Nevertheless, the potential means for successful, long-term primary (chemo-) prevention of invasive breast cancer and its localized precursors (DCIS, LCIS) are in our grasp should medicine and society accept them on a broader scale. Meanwhile, even potentially more appealing, non-oncological, and less toxic drugs, such as the anti-diabetic metformin, hold promise for breast cancer chemoprevention [11]. Whether these pharmacological preventive interventions will finally lower not only the incidence but also the mortality

of breast cancer remains to be shown with longer follow-up in the future.

Chemoprevention in colorectal cancers (CRC)

Epidemiology and importance of the problem

CRC is the second and third, most common cause of cancer death among men and women, relatively, aged 40 to 79 years. There were 229,219 (203,185) cases diagnosed in 2008 with an overall incidence of 13.5/100,000 individuals in both sexes and 110,059 (102,110 in women) dying from CRC with a mortality rate of 10.0 (10.6 in women) [3]. On a worldwide basis, there were more than 1,200,000 new cases in 2012, with more than 600,000 deaths. The progression of adenomatous polyps to overt invasive cancer spans over more than a decade; hence, CRC provides a window of opportunity actively to prevent the disease by drug intervention [12]. Screening

Table 29.2 Results of randomized major trials with different chemopreventive agents (anti-oestrogens) against breast cancer

Agent	Trial	Number individuals	MFU months	RR (ER+)	Comments
Tamoxifen (20mg/d)	NSABP P-1	13,388	>108	0.38	Significant decrease in the development of invasive and non-invasive breast cancer in TAM-treated risk-women
	IBIS-1	7139	>96	0.66	
	Royal Marsden	2471	>158	0.61	
	Italian trial	5408	>132	0.77	
Raloxifene (60mg/d)	MORE/CORE	7705/4011	>96	0.24	Breast cancer was sec. endpoint, but raloxifene active (RAL versus TAM!)
	RUTH	10,101	>69	0.45	
	STAR-trial	19,747	>93	1.24	
Lasofoxifene (0.25 vs 0.5 mg/d)	PEARL-trial	8556	>72	0.19	Higher dose more active
Arzoxifene (20mg/d)	Generations	9354	>60	0.30	Highly significant breast cancer preventive effect
Exemestane	MAP-3 trial	4560	>14	0.35	Exemestane reduces risk for invasive breast cancer significantly

Abbreviations: MFU, median follow up; RR, relative risk; TAM, tamoxifen, RAL, raloxifene.

colonoscopy would represent an attractive and effective prevention option, yet it is a relatively expensive procedure that carries some risk, require expertise, and whose acceptance rate by healthy individuals is rather low. As the emphasis of screening is shifting more towards real prevention, colonic adenomas, as the premalignant lesions, has become an attractive target for chemoprevention. This latter intervention is most useful in high-risk subjects, such as those with familial adenomatous polyposis or HNPCC [13].

General ways of pharmacologically preventing CRC

In average-risk populations the picture is less convincing, although chemopreventive strategies have been extensively studied to reduce the incidence and recurrence of adenomas and to delay their progression to CRC. There are many agents with some proven but minor efficacy (e.g., calcium, curcumin, vitamin D, fibre, etc.). But in most cases the effect is controversial, and in the best-case scenario the preventive effect is less than 20% [13].

CRC prevention by non-steroidal anti-inflammatory drugs (NSAIDs)

NSAIDs have been proven to be promising and most attractive candidates for chemoprevention of CRC. The preventive efficacy of these agents is supported by a multitude of randomized animal trials, and by 67 out of 69 epidemiological studies [14]. All of them clearly demonstrate that NSAID consumption prevents adenoma formation and decreases the incidence of and mortality from CRC. The attractiveness of these drugs partly stems from their ability to influence multiple mechanisms and components of the carcinogenesis pathway, from initiation to progression. The consumption of NSAIDs is not at all free of toxicity [13].

There are at least three isoforms of the cyclo-oxygenase (COX) enzymes. COX-1 is constitutively expressed in normal tissues and protects intestinal mucosal integrity. COX-2 is an early-response gene that is highly inducible by neoplastic and inflammatory stimuli. COX-3 is a variant form of COX-1. COX enzymes are probably the most common therapeutic drug targets in human history. Three international multicentre, randomized, placebo-controlled studies (PreSAP, APC, Approve) were launched at the beginning of the 21st century to evaluate the efficacy and safety of COX-2 inhibitors in preventing the recurrence of sporadic colorectal adenomas. The trials lasted five years: threes year on-drug with an additional two years of follow-up off-drug. In all these studies, the use of COX-2 inhibitors was clearly associated with a significant reduction in the risk of adenoma recurrence, particularly of advanced adenomas, which carry the highest risk for malignant transformation [14–16]. However, worldwide attention predominantly centred upon unexpected cardiovascular side effects [17]. Thus, cardiovascular toxicity caused the early termination of all COX-2 trials and the use of these agents in chemoprevention.

CRC prevention using aspirin (ASA)

Aspirin was first synthesized 120 years ago. There is vast experience with its cardiovascular protective effects, and strong evidence demonstrating that low-dose aspirin prevents adenoma recurrence, reduces the incidence of CRC, and is even associated with lower CRC mortality. The effect is mostly seen in COX-2-expressing tumours, in the right colon, and if taken for at least a decade [19]. The risk–benefit balance for cancer prevention should be weighed up in conjunction with the benefits in prevention of the three major modern health catastrophes: other cancers, vascular illnesses, and Alzheimer's disease. ASA might be this 'magic bullet'. However, the ideal chemopreventive agent remains to be defined in the context of drug acceptance by the respective risk populations and of the principle of 'primum non nocere' (first: do no harm). Combinations of agents may be preferred, due to their potential of maximizing effectiveness, while limiting drug toxicity. Individualized approaches may emerge in the future, based on personal risk–benefit ratios by specific genetic profiles [20].

Chemoprevention in prostate cancer
Epidemiology and importance of the problem

Prostate cancer is the most common cancer type in European men with 370,733 being diagnosed in 2008, an incidence rate of 59.3/100,000 males, and 89,629 dying from prostate cancer, with a mortality rate of 12.0/100,000 [3]. Prostate cancer is a good candidate for chemoprevention due to its high prevalence, long latency, hormonal dependency, serum marker (PSA) for monitoring, and the existence of defined histological precursor lesions. Strategies for prevention include limiting accumulation of genetic damage with dietary antioxidants, anti-inflammatory agents, or hormonal manipulations. Several chemopreventive agents and strategies have been studied to decrease the incidence and development of this potentially lethal and invalidating disease.

Chemoprevention of prostate cancer by nutritional agents

Several nutritional treatments (selenium, vitamin E and D, lycopene, green tea, pomegranate, silymarin, phytoestrogens) have been studied in the prevention of prostate cancer. However, the interpretation of these studies has been hampered by their variable design and because their results were based on cohort, case-control, or only small randomized phase II studies [21]. Data from several randomized trials are available (Table 29.3), but so far none of these interventions have proven to be convincingly beneficial and ready for general use [22, 23], while vitamin E was even shown to increase the risk of prostate cancer [24].

Chemoprevention of prostate cancer by anti-inflammatory drugs

Inflammation is an important factor in the carcinogenesis of prostate cancer and several anti-inflammatory drugs have been tested as preventive agents [25]. However, studies were limited to cohort or prospective registry studies. No data of randomized phase III trials are available.

Chemoprevention by hormone-interfering drugs

Two phase III randomized trials with 5α-reductase inhibitors, finasteride in the Prostate Cancer Prevention Trail (PCPT) [26] and dutasteride in the REDUCE trial [27], in men aged above 50 years with a prostate-specific antigen (PSA) level within normal range and no suspicious prostate examination and/or a negative prostate biopsy, showed a decreased risk of prostate cancer development compared to placebo (a 24.8% relative reduction over a seven-year period in the PCPT and a 22.8% reduction in prevalence over a four-year period in the REDUCE) (Table 29.3). However, when

Table 29.3 Randomized chemopreventive phase III trials in prostate cancer

Author (year)	No. pts	Agent	Control	Outcome
Lippman (2008) Klein (2011)	35,533	Selenium; vitamin E; combination	Placebo	HR not different among groups; vitamin E significantly increased PC
Marshall (2011)	423	Selenium	Placebo	No difference in PC
Thompson (2003)	18,882	Finasteride	Placebo	24.8% reduction in prevalence over 7 years (P < 0.001); more high grade PC
Andriole (2010)	6,729	Dutasteride	Placebo	Relative risk reduction of 22.8% (P < 0.001) over 4 years; more high grade PC

Abbreviations: No, number; pts, patients; HR, hazard ratio; PC, prostate cancer.

prostate cancer was diagnosed, the median Gleason score (= differentiation grade) was higher in the treatment arm compared to the placebo arm, which might result in prostate cancer with a more aggressive behaviour. This should be discussed with men asking for primary prostate cancer prevention. Although much effort has gone into determining the role of primary chemoprevention in prostate cancer, it has not yet found its way into daily clinical practice in Europe, and only selectively in the US. Patients should be informed about the advantages and disadvantages of prostate cancer chemoprevention in order to make an informed personal decision [28].

Table 29.4 Selected chemopreventive trials in lung cancer

Setting	Phase	No. pts	Agents	Primary end point
Primary	**III**			
Smokers		29,133	BC/vitamin E	Harm/neutral
Smokers/asbestos		18,314	BC + retinol	Harm
Secondary	**II**			
Metaplasia		150	Etretinate	Neutral
Metaplasia		87	Isotretinoin	Neutral
Metaplasia		68	Fenretinide	Neutral
Sputum atypia		73	Vitamin B_{12} + folic acid	Neutral
Sputum atypia		755	BC + retinol	Neutral
Tertiary	**III (SPT)**			
NSCLC		307	RP	Neutral
NSCLC + HNC		2,592	NAC/RP	Neutral/neutral

Chemoprevention in lung cancer

Lung cancer is one of the most common cancers in Europe with an incidence of 391,000 new patients and 342,000 dying from lung cancer in 2008 [3]. Since smoking is involved in the majority of lung cancers, preventing people from starting smoking or helping them quit tobacco use is certainly the most effective method of prevention, although the realization of these aims at the political and personal levels is still difficult. In patient groups defined as 'high risk' due to a smoking history, cellular atypias in sputum, airflow obstruction, or a prior surgically cured non-small-cell lung cancer, several interventions have been tested [29]. But most trials have been negative, while some even showed the use of some chemopreventive agents caused harm, possibly due to the combination of smoking and the preventive agent itself (Table 29.4). At least at present, no chemopreventive measures are recommended in patients at high risk for the development of lung cancer.

CHAPTER 30

Population cancer screening

Andrew Evans, C. Simon Herrington,
and Robert J.C. Steele

Introduction to population cancer screening

Screening is the process whereby theoretically asymptomatic individuals are tested to diagnose a disease at an early stage of its development with the aim of improving treatment outcome. In cancer, this includes not only detecting early invasive disease but also, where possible, the detection of premalignant disease so that the screening process may have an effect on disease incidence as well as outcome. It is important to be absolutely clear that the primary aim of population screening is to decrease the burden of disease on large groups so that the screening test must be affordable, acceptable, and associated with minimal risk.

The criteria for effective population screening were first established by Wilson and Jungner [1] and these are itemized in Box 30.1. Although the detection of early disease may seem to have obvious benefits, screening is associated with biases that have the effect of making screen-detected disease appear to have a better prognosis than symptomatic disease irrespective of whether or not the outcome has actually been affected by the screening process. The terms used to describe these biases are volunteer bias, length bias, and lead time bias. Volunteer bias results from invitations to be screened being taken up more readily by people who are health conscious. In other words, people who accept screening invitations are more likely to experience a better outcome from their disease anyway; for example, they may be more likely to take exercise and less likely to smoke. Length bias is a consequence of intermittent screening tests tending to pick up slow-growing disease that is more likely to be associated with a good prognosis than more aggressive, fast-growing disease that is likely to present between screening episodes. Finally, lead time bias is an inevitable consequence of early diagnosis; detecting disease at an early stage of its development inevitably leads to an observed improved duration of survival simply by virtue of shifting the point of diagnosis forward in time.

To prove that screening is effective, these biases must be eliminated, and to do this, population-based randomized controlled trials (RCTs) are required. In these trials, it is essential that the group randomized to be offered screening be analysed as a whole, including those who do not choose to participate in the process and those who are diagnosed with interval cancers (cancers that are diagnosed after a negative screening test in the interval until the next screening invitation). The disease-specific mortality in this group must then be compared with that seen in a randomly selected control group which is not offered screening, and only if a significant improvement is seen in the test group can screening be considered to be unequivocally beneficial.

In the UK and in many other countries, screening is available for breast, cervical, and colorectal cancer. For breast and colorectal disease population-based RCTs have been carried out; this is not the case for cervical cancer, but the observed benefits accrued from the programmes already in place make it impossible to perform such studies.

Breast cancer screening

Breast cancer incidence has risen worldwide for many decades and the disease is particularly common in the Western world. In the UK a woman's lifetime risk of developing breast cancer is 1 in 7 and it is now the commonest cancer in UK women, although lung cancer is now the commonest cause of cancer death. Breast cancer cannot currently be broadly prevented and the disease shows a strong size/outcome relationship making screening for breast cancer attractive. The recent decrease in breast cancer mortality in the UK appears to be due to a combination of earlier presentation of symptomatic cancer, better treatment, and the introduction of mammographic screening. Mammographic screening is now widespread throughout the developed world, and its introduction followed the results of a number of RCTs, the first of which was the HIP study from New York which took place during the 1960s.

Screening modalities

The only screening modality which has been shown to reduce population mortality from breast cancer is mammography. Screening using clinical examination and breast self-examination has not been shown to be effective in reducing breast cancer mortality. In recent years, ultrasound screening has been shown to increase the number of small node-negative cancers detected in women with mammographically dense breasts, but the impact of this increased cancer yield on mortality is unknown. However, ultrasound screening is time consuming and has poor specificity. MRI is now widely used to screen women at high risk of breast cancer, particularly women with BRCA1 and BRCA2 mutations. Again, the effect of such screening on breast cancer mortality is not known [2].

The screening process

In the UK, women are invited for screening appointments either at static screening units or on mobile vans where mammograms are performed by specially trained radiographers or assistant practitioners. The mammograms are then double read by radiologists or advanced radiographic practitioners. Non-concordant results are commonly resolved by arbitration. Between 3.8% and 8.6% of women are recalled for assessment; of these, about one in seven women will have cancer [3]. When women are recalled they are assessed by a multidisciplinary team which can carry out further mammography,

Box 30.1 Principles of screening

1. The condition should be an important health problem.

2. There should be an accepted treatment for patients with recognized disease.

3. Facilities for diagnosis and treatment should be available.

4. There should be a recognizable latent or early symptomatic stage.

5. There should be a suitable test or examination.

6. The test should be acceptable to the population.

7. The natural history of the condition, including development for latent to declared disease, should be adequately understood.

8. There should be an agreed policy on whom to treat as patients.

9. The cost of case-finding (including diagnosis and treatment of patients diagnosed) should be economically balanced in relation to possible expenditure on medical care as a whole.

10. Case finding should be a continuing process and not a 'once and for all' project.

Fig. 30.1 Vacuum biopsy specimen X-ray of mammographic calcification.

Due to continuing criticisms of breast screening, which suggested that the overall mortality may be higher in those undergoing screening due to possible adverse effects of treatment, all-cause mortality was also assessed. This showed a relative risk of dying of any cause in the study arm of 0.98, which was of borderline statistical significance [5]. The precise mortality reduction attributable to screening is controversial as RCTs may underestimate the benefit of screening due to non-attendance and contamination (mammography occurring within the control group). Regular attendance for mammographic screening may result in a 63% reduction in breast cancer death for individual women [6].

Which age groups should be screened?

There is strong evidence from RCTs for a reduction in breast cancer mortality in women aged 55–69. Previous meta-analyses have supported the introduction of screening at age 50 but these data are based on ten-year age bands. Data analysis based on five-year age bands of screening women aged 50–55 has never shown a mortality benefit in this age group. The reasons for this are unclear but it has been suggested that this may be due to unusual behaviour of breast cancer in perimenopausal women.

There is no evidence from RCTs to support the screening of women over the age of 70, but the number of women over the age of 70 in these studies is small. Although the mammograms of older women are easy to read because of their low mammographic density and the incidence of cancer is high, there is an increased risk of over-diagnosis in this age group. A recent evaluation of service screening in northern Sweden showed significant mortality reductions for women aged 40–49 (RR 0.64 (0.43–0.97)) and women aged 50–69 (RR 0.70 (0.54–0.91)), but no mortality benefit was seen for women age 70–74 (RR 1.08 (0.58–2.03)) [7].

The most recent meta-analysis of RCTs screening women aged 39–49 at randomization has shown a statistically significant mortality reduction of 17% [8], and the Malmo [9] and Gothenburg [10] studies have both shown statistically significant mortality reductions in younger women. As breast cancer is only half as common in women in their forties compared with women in their fifties, some have suggested that presenting data in terms of percentage reduction in population mortality may be misleading. On the other hand, preventing breast cancer deaths in younger women will result in a larger number of life years gained and it has been shown that

ultrasound, clinical examination, and image-guided biopsy during a single appointment. Approximately 95% of invasive cancers and 90% of DCIS lesions are diagnosed preoperatively (Figure 30.1). Most benign lesions excised following screening are removed because of their uncertain malignant potential.

Quality assurance

For screening to be effective all the components have to be carried out to a very high level of performance. To ensure this, the performance of mammography, screen reading, non-operative diagnosis and treatment are subject to strict scrutiny against a set of national guidelines at both a unit and individual level. Performance of many of the components of screening has been shown to be related to volume. Therefore individuals involved in providing screening have to achieve minimum standards in terms of both quantity and quality [4].

The evidence for screening

Data from RCTs provide the strongest evidence of the efficacy of screening in reducing breast cancer mortality, and the most recent and highest quality RCTs of screening have been carried out in Sweden. The last overview of the Swedish trials included data from Malmo, Gothenburg, Stockholm, and the Ostergotland arm of the Two Counties study. Data from the Kopparberg arm of the Two Counties study was not included. Almost a quarter of a million women were included in these studies, with half being invited for screening and the other half making up the control group. The median trial time was 6.5 years and the median follow-up 15.8 years. The summated results indicated a 21% reduction in breast cancer mortality, with the largest reduction in women aged 60–69 (33%).

breast cancers arising in women in their forties account for 34% of life years lost to breast cancer.

The RCTs of screening were not originally designed to look at breast cancer mortality reductions in particular age groups and such subanalyses have been criticized. In particular, some of the screening episodes occurring in women aged 40–49 at randomization actually occurred when women were over 50. In addition, women in the control groups of these studies were not always screened at 50 or screened at all. Therefore, it is possible that part of the mortality benefit demonstrated in these women may be due to screening episodes over the age of 50. However, re-analysis based on age at diagnosis rather than randomization suggests that cancers detected by screening episodes before age 50 do impact on mortality. The UK Age Trial was the only RCT to perform all screening episodes before age 50 [11]. Participants aged 39–41 were randomly selected and were screened annually. The RR of breast cancer death in this study group was 0.83 (95% ci 0.66–1.04).

The low cancer incidence in women under the age of 50 results in the specificity of both recall and surgical biopsy being lower than that in older women. It has been said that there is reduced mammographic sensitivity in women in their forties; however, recent data suggest that the use of two views, high-film density and digital mammography [12], has substantially improved mammographic sensitivity in younger women. The most important obstacle to screening younger women is the short lead time of screening, the high frequency of screening required in younger women and the low incidence of breast cancer, which has led some to question the cost-effectiveness of screening in this age group. However, these disadvantages may be at least partly negated by the large number of life years gained per life saved.

Screening frequency

The lead time of screening is the time between mammographic detection and clinical presentation, and for screening to be effective the screening frequency has to be less than the lead time. The lead time achieved by mammographic screening is age dependent. For women under 50 the lead time of screening is just less than two years. The presence of this short lead time indicates the need to screen more frequently in women under the age of 50, so that the ideal screening interval is 12 months.

For women over 50 years the lead time of screening is between 3 and 4.5 years. Two-yearly screening should therefore be effective in this age group, as indicated by a recent analysis of pooled interval cancer data from six European countries. Interval cancer rates of 29% of the expected breast cancer incidence without screening in year 1 and 63% in year 2 [13] indicate that two yearly is the maximum screening interval that is appropriate. A recent analysis of interval cancer rates in the NHSBSP gave very similar results [14].

Over-diagnosis and over-treatment

Over-diagnosis and over-treatment imply the detection and treatment of cancers that would not become clinically apparent in the patient's lifetime or threaten life. Over-diagnosis probably occurs in about 10% of cancers detected when screening women aged 50–70 [15]. The rate is likely to be significantly higher when screening women aged over 70 years due to the decreased life expectancy and more indolent tumour profile in women of this age. Low-grade ductal carcinoma in situ (DCIS) and invasive tubular cancers are
Fig. 30.2 Mammographic image of DCIS manifesting as impalpable calcification.

currently being over-treated. A number of studies are now addressing this issue by suggesting either less invasive treatment or a watch and wait policy for such lesions.

Ductal carcinoma in situ (DCIS)

About 25% of the cancers detected by screening are DCIS. Such lesions are usually diagnosed following the stereotactic sampling of impalpable mammographic calcification (Figure 30.2). Detection and treatment of high-grade DCIS is likely to beneficial by preventing the development of high-grade invasive cancer within a few years, but low-grade DCIS has a very indolent clinical course with many lesions not progressing to invasive disease after many years follow-up. The detection and treatment of such lesions almost certainly involves a degree of over-diagnosis and over-treatment [16]. About 70% of screen-detected DCIS is high grade, 15% intermediate grade, and 15% low grade.

Prognostic factors for screen-detected invasive cancers

The three classical breast cancer prognostic factors are size, histological grade, and lymph node stage. However, these factors were derived from symptomatic breast cancer series and they have been found to be of less value in predicting the behaviour of small screen-detected cancers. Histological grade is a prognostic factor for screen-detected cancers as a whole but not for cancers under 15 mm in size. Lymph node stage has been found to be a powerful prognostic factor for screen-detected cancers including small lesions; however, node positivity is present in less than half of the women with small screen-detected cancers who die of their disease. A number of studies have found that the presence of lymphovascular invasion in the resected specimen is an important prognostic factor, especially in node-negative women.

In recent years a number of studies have shown that the mammographic features of breast cancer contain important prognostic information. Tabar has shown that mammographic comedo calcification indicates a poor prognosis for small screen-detected lesions [17, 18]. Mammographic spiculation has been found to indicate a good prognosis for screen-detected breast cancer. This is probably a reflection of the fact that screen-detected cancers with a basal phenotype, which carry a poor prognosis, are rarely spiculated [19].

Conclusion: breast cancer screening

Mammographic screening can reduce breast cancer mortality in women aged 55–69 and probably in women from age 40. The downsides of mammographic screening are false positive screening recall/surgical interventions, over-diagnosis, and over-treatment.

Colorectal cancer screening

Colorectal cancer continues to be the fourth most commonly diagnosed cancer worldwide, and the most important prognostic factor in colorectal cancer is stage at diagnosis. As symptoms have poor sensitivity for colorectal cancer [20], screening is the only reliable method of early detection, and in this section, the evidence regarding the performance of currently available screening tests, factors influencing the uptake, and the potential adverse effects will be addressed.

Guaiac based faecal occult blood testing (gFOBT)

Until recently, detecting blood in faeces has relied on the guaiac test but this is an indirect measure of haemoglobin, relying on its ability to react with peroxidase. Within a screening context, the sensitivity of gFOBT for cancer is probably in the region of 50% owing to its low analytical sensitivity for blood and due to the fact that cancers bleed intermittently. On the other hand, the specificity (percentage of disease-free individuals with a negative test) is around 98%, which, although not perfect, makes gFOBT suitable for population screening.

Now that immunological tests for blood in faeces are available gFOBT is becoming obsolete, but the original population-based trials of colorectal cancer screening utilized gFOBT. As the results of these trials proved that screening for colorectal cancer is effective, they are worthy of consideration [21]. Three studies comparing biennial unrehydrated Haemoccult II® with uninvited controls took place in England, Denmark, and Sweden, but the first to report was carried out in the US. Here, volunteers were randomized into three groups, including annual and biennial screening with rehydrated Haemoccult II® in addition to a control group. A further study from France also studied biennial gFOBT, but was not strictly randomized, but compared different regions, some of which were offered screening.

The trials from England, Denmark, Sweden, and France all demonstrated reductions in colorectal-cancer-specific mortality of between 15% and 18% with a positivity rate of around 2%. The American study achieved better results, owing to the use of a rehydrated gFOBT which gives a higher positivity, and, indeed, around 30% of the population randomized to screening underwent colonoscopy.

These five studies are of the utmost importance as they are the only controlled studies of population screening compared to no intervention. The consistent reduction in disease-specific mortality indicates that early detection of colorectal cancer is truly beneficial and population screening by gFOBT can be estimated to reduce colorectal cancer mortality by 16%, increasing to 23% when adjusted for uptake [21].

In the UK, the National Screening Committee advised a demonstration pilot of biennial gFOBT screening to determine whether or not the results of the randomized trials could be reproduced within the UK National Health Service. This pilot was successfully carried out in two areas of the UK, one in Scotland and one in England

[22], and as a result, the UK Health Departments have now rolled out screening programmes. The initial outcomes indicate that the national programmes should produce the expected results [23, 24]. These programmes involve sending out test kits and invitations in the post, and the completed tests are returned for analysis at central 'hub' laboratory.

Faecal immunochemical testing

Faecal immunochemical testing for blood (FIT) is specific for human haemoglobin and there are now several manufacturers who produce quantitative FIT that provides a measure of the concentration of haemoglobin in faeces. Thus, FIT has significant advantages over gFOBT.

Qualitative FIT may be used in concert with gFOBT in order to reduce the false-positive rate created by the non-specific nature of the guaiac test and this approach has been introduced into the Scottish Bowel Screening Programme [25]. However, although it reduces the numbers of negative colonoscopies it does not address the issue of low clinical sensitivity seen with gFOBT. For this reason, there has been major interest in using *quantitative* FIT as the first-line screening test.

In two recent studies, a quantitative FIT has been compared with the Haemoccult II® gFOBT. In the first, from France, 10,677 individuals undergoing screening were offered both gFOBT and FIT [26]. Using a cut-off of 20 ng Hb/ml, the gain in sensitivity produced by the FIT was 50% for cancer and 256% for high-risk adenoma. This, however, was offset by a decrease in specificity. In the second study from the Netherlands, 20,623 individuals between 50 and 75 years of age were randomized to either a Haemoccult II gFOBT® or a quantitative FIT [27]. For the FIT, a cut-off of 100 ng Hb/ml was used to trigger colonoscopy. The positivity rate of the FIT was 5.5% compared with 2.4% for the gFOBT. However, the number needed to scope to find one cancer was the same between the two tests, and the detection rates for advanced adenomas and cancer were significantly higher for FIT than gFOBT.

From the relatively limited amount of information available, it would appear that a low cut-off for quantitative FIT in the region of 50 ng Hb/ml will detect most, although not all, cancers but will miss a substantial number of adenomas, particularly those of small size. Of course, the price for detecting a higher proportion of cancers and adenomas is a higher false-positive rate and a higher colonoscopy rate.

Flexible sigmoidoscopy

Given that 75% of cancers arise in the left colon, it was proposed that flexible sigmoidoscopy (FS), with removal of all adenomas, would provide effective screening that would reduce the mortality *and* incidence of colorectal cancer. This hypothesis has been tested in three multicentre randomized controlled trials, one from Italy (SCORE) [28] one from the UK (Flexiscope®) [29], and one from the US (PLCO) [30] In all three studies, reductions in colorectal cancer mortality and incidence were observed, although the effects were largely restricted to left-sided cancers. The importance of these three studies is that they demonstrate beyond doubt that endoscopy and polypectomy can reduce the incidence of colorectal cancer and that FS is a credible candidate as a first-line screening test. Indeed, in England, 'once-only' FS is to be rolled out as a screening modality between the ages of 55 and 60, i.e. before FOBT screening starts.

However, uptake of FS screening poses a problem. Because the FS trials were performed in volunteers, the population uptake of FS could not be estimated. A Norwegian population-based randomized trial of FS achieved a participation rate of 67% [31], but a randomized study from the Netherlands comparing gFOBT, FIT, and FS achieved participation rates of 32.4% for FS compared with 49.5% and 61.5% for gFOBT and FIT [32]. On the other hand, a study from Italy found a similar participation rate for FIT and FS, although both were low at 32% of those invited [33]. It seems likely that both cultural issues and differences in level of deprivation are likely to be important in determining uptake of FS.

Colonoscopy

Colonoscopy would seem to be the ideal screening test; false positive results for neoplasia are not possible, the specificity is 100%, and the sensitivity is very high, albeit not 100%. In addition, colonoscopy is used widely for opportunistic screening and there is good epidemiological evidence that colonoscopy can reduce the incidence of colorectal cancer by means of polypectomy [34]. Despite this, the use of colonoscopy as a population-screening tool remains controversial, and although there are currently four randomized trials of colonoscopy screening worldwide, none of these have reported and there are relatively little data from which conclusions can be drawn.

It is interesting to note, however, that the effect of colonoscopy in reducing colorectal cancer mortality and incidence is less strong for the right side of the colon than the left [35]. This may reflect quality of colonoscopy; bowel preparation is often poorer in the right colon than the left colon and adenomas in the right colon are often flat and subtle when compared with the polypoid lesions seen on the left.

Radiology

There is increasing interest in CT colography as a screening tool. A recent randomized trial from the Netherlands which compared colonoscopy with CT colography found that uptake of CT colography (34%) was significantly better than with colonoscopy (22%), but that colonoscopy identified significantly more advanced neoplasia than was found on CT colography [36]. Interestingly, on an intention to screen basis, the diagnostic yield was similar for both strategies, but it should be noted that the uptake for both modalities was poor.

Uptake

Uptake is a crucial performance indicator for a screening programme. For gFOBT screening, population uptake generally ranges from 50% to 60% but, of course, the uptake required to produce a measurable reduction in incidence or mortality depends on the sensitivity of the test. As mentioned above, the type of test affects uptake, and most of the evidence indicates that gFOBT or FIT is more acceptable than flexible sigmoidoscopy which, in turn, is more acceptable than colonoscopy. Sociodemographic factors also have a profound influence on uptake. UK studies show that uptake of gFOBT screening falls with increasing deprivation and that women are consistently more likely to accept an invitation for colorectal cancer screening than men [37].

As uptake is central to the success of population screening, there has been great interest in interventions aimed at improving participation. Continuing to invite individuals for screening even if they do not accept the first invitation is the most obvious; a recent analysis of prevalence and incidence screening in Scotland demonstrated that the cumulative uptake of the first screening invitation rose from 53% to 63% over three biennial rounds [38]. Different forms of faecal testing also influence uptake; there is good evidence from randomized studies that the sampling method has an important effect as FIT seems to be more acceptable than gFOBT [39].

Endorsements by general practitioners and pre-notification have also been tested. Receiving the invitation from a family physician appears to be important [40], and comparisons of invitations with or without endorsement from a general practitioner have confirmed this [41]. Pre-notification is also effective as evidenced by randomized studies [42].

Adverse effects of screening

Any screening strategy is associated with false negative results leading to the development of interval cancers, defined as cancers that are diagnosed after a negative screening test in the interval before the next test date. It is held that a negative test result can falsely reassure people so that they ignore symptoms, creating a diagnostic delay—the 'certificate of health effect'.

A recent analysis of interval cancers in the Scottish gFOBT Programme found that interval cancers comprised about 50% of all cancers in the screened population in the first three rounds [43]. However, both overall and cancer-specific survival were significantly better for patients with interval cancers when compared to an equivalent population that had not been offered screening [43]. Thus, interval cancers have a relatively good prognosis when compared with cancers arising in the absence of screening, but it has to be accepted that, with gFOBT screening, high interval cancer rates occur.

This study raised two other concerns; namely that gFOBT screening tends to miss cancers in both the right side of the colon and the rectum and that it preferentially detects cancers in men when compared to women. The gender effect is almost certainly due to the fact that faecal occult blood testing is less sensitive for cancer in women than in men, and quantitative FIT testing has shown that faecal haemoglobin concentrations are higher in men than in women [44]. This suggests that differential cut-offs should be employed for male and female participants.

The issue of the effect of screening on 'all cause' mortality has created some controversy recently [45] and it has been suggested that screening programmes should be assessed on the basis of their effect on this parameter rather than on disease-specific mortality. It must be appreciated, however, that because colorectal cancer accounts for only 2% of all deaths, to demonstrate an effect on all-cause mortality would require a randomized trial that would be prohibitively large.

Conclusion: colorectal cancer screening

Currently, faecal testing for blood and lower gastrointestinal endoscopy are the only credible strategies for colorectal cancer screening, and there is good evidence from RCTs to support both strategies. Novel approaches, including faecal DNA markers, DNA methylation-specific RNAs, and specific protein panels are under investigation [46–48] and volatile compounds may also be useful [49]. None of these approaches have yet emerged as a practical solution, however, and refinement of the application of FIT and FS seems the most promising way forward at present.

Cervical cancer screening

Screening programmes aim to reduce mortality from invasive cancer by detecting and treating pre-invasive disease and/or early invasive tumours, but the purpose of screening is not to make a diagnosis; rather, it aims to reduce risk by identifying those who require further investigation to establish a definitive diagnosis, on the basis of which appropriate treatment can be undertaken. Cervical carcinoma, whether squamous cell carcinoma or adenocarcinoma, arises from well-defined pre-invasive (intraepithelial) lesions termed cervical intraepithelial neoplasia (CIN) or cervical glandular intraepithelial neoplasia (CGIN) respectively. These lesions, particularly CIN, can be sampled relatively easily as (1) they involve the surface of the cervix and (2) the cervix is easily accessible. These factors make cervical carcinoma particularly amenable to prevention through population screening. It is important to appreciate that cervical screening programmes are designed primarily to detect squamous epithelial disease and are less effective for the detection of glandular abnormalities, as these are both less consistently represented in cervical smears and more difficult to identify colposcopically. HPV testing may play a role in improving the detection of these glandular abnormalities.

The National Health Service Cervical Screening Programme (NHSCSP) was introduced in the UK in 1988. This programme is based on regular screening of women through a call-recall system, with subsequent investigation and management of women with abnormal smears using colposcopy and a range of treatment modalities. At the time of writing, the age range over which screening is provided in England and Northern Ireland is 25–64 years, with three-yearly screening from 25 to 49 and five-yearly screening from 50 to 64 [50, 51]. Over the age of 65, smears are only taken from women who have not been screened since the age of 50, or who have had abnormal smears that justify continued screening. In Scotland and Wales, screening commences at age 20, is undertaken at three-yearly intervals and finishes at 60 [52, 53]. In the Republic of Ireland, screening is offered to women aged 25 to 60: three-yearly from 25 to 44 and, if two consecutive results are negative, five-yearly from 45 to 60 [54]. Quality assurance of all elements, including cytology, colposcopy, and histopathology, against agreed auditable standards is important for the provision of a high-quality programme.

Cervical sampling and the investigation of abnormal cervical smears

Most cervical carcinomas, and pre-invasive cervical lesions, arise in the cervical transformation zone, where the native cervical columnar/glandular epithelium has been replaced, in response to cervical eversion after puberty, by metaplastic squamous epithelium. This zone can be sampled effectively by taking a cervical smear. Cervical smears can show a range of abnormalities that correlate with the nature and severity of the underlying lesion. Different terminologies are used to describe these abnormalities in different countries, although there is general agreement that there is a spectrum of abnormality ranging from the effects of human papillomavirus (HPV) infection through grades of cytological atypia to invasive carcinoma. In the UK, the term dyskaryosis is used to describe this atypia which is graded mild, moderate, and severe, terms that correlate broadly with the presence of CIN grades 1, 2, and 3, histologically. Glandular abnormalities are more difficult to detect but,

when present, are referred to as glandular dyskaryosis, which may indicate a CGIN lesion. In general, women with smears showing moderate or severe squamous dyskaryosis, or glandular dyskaryosis, are referred for colposcopy and further management, whereas those with mild squamous dyskaryosis or more minor abnormalities (termed borderline changes) are recalled for repeat smears at shorter time intervals than is routine.

Colposcopic examination involves both direct inspection of the cervix at low magnification and assessment of the effect of the application of both acetic acid (which turns epithelium with a high nuclear content white) and iodine (which stains glycogenated epithelium); in general, abnormal squamous epithelium is acetowhite and iodine negative. The colposcopist can choose to take biopsies from abnormal areas to determine the histological diagnosis, or to treat the lesion directly. This can be performed using either ablative methods such as laser ablation or cold coagulation, in which case biopsies should be taken prior to treatment; or by excision using loop excision of the transformation zone (LETZ), straight wire excision of the transformation zone (SWETZ) or needle excision of the transformation zone (NETZ). These latter procedures not only treat the lesion but also produce a tissue specimen for histopathological analysis.

Tissue biopsies and other excision specimens are used to determine the nature and grade of any lesion present and to assess whether the lesion has been excised. Excisional methods of treatment therefore carry the advantage that a histological diagnosis is reached on the entire lesion and hence, in particular, early invasive lesions can be identified and managed appropriately. Subsequent management of CIN and CGIN is determined by the grade and extent of the lesion but may involve further excision. All patients with high-grade lesions (CIN 2, CIN 3, high-grade CGIN) are followed up with regular cervical smears according to the relevant screening programme guidelines. The management of patients with invasive lesions, whether squamous cell carcinoma or adenocarcinoma, is discussed at the gynaecological oncology multidisciplinary meeting and is dependent on stage and, to some extent, tumour type.

HPV testing and vaccination

The recognition that HPV infection is necessary (but not sufficient) for the development of cervical carcinoma [55], and the development of effective prophylactic HPV vaccines [56, 57], is beginning to have an impact on the cervical screening programmes in the UK. A UK-wide HPV vaccination programme started in 2008, offering a bivalent HPV vaccine against HPV 16 and HPV 18 to all 12–13-year-old and 17–18-year-old girls. Girls aged 13–18 y were offered the vaccine over the subsequent two years as part of a catch-up programme. An accelerated catch-up programme was implemented at the end of 2008 such that all girls born on or after 1 September 1990 could be protected before the end of the academic year 2009/2010. The effects of the HPV vaccination programme are not yet clear; as it is a prophylactic vaccine, its efficacy is due to prevention of infection and hence, given the long lead time to development of CIN/CGIN and invasive carcinoma, it will be some time before any effects on mortality from cervical carcinoma will be measurable. Moreover, the effects of preventing infection by HPV 16 and 18 on the prevalence of other HPV types that infect the lower genital tract [58, 59] are not yet clear. It is of note that the vaccine changed from September 2012

to a quadrivalent formulation that includes HPV 6 and HPV 11 in addition to HPV 16 and 18 [60]. This extends the efficacy of the vaccine to the prevention of genital warts, the majority of which are caused by infection with these two HPV types.

The strong link between HPV infection and cervical carcinoma has also prompted consideration of HPV testing as an adjunct to cytology in cervical screening, where it may have a particular role in the triage of women with mild cytological abnormalities and as a 'test of cure' on follow-up after treatment [61, 62]. Although HPV testing can lead to an increase in colposcopy rate, this is balanced by returning up to a third of women with mildly abnormal smears to routine recall, reducing the number of cervical smears being taken from this group of women. This relates to the high negative predictive value of HPV testing, which is also relevant to its use after treatment as most women with a negative HPV test in this setting can be returned to routine recall rather than being managed conventionally with more frequent cervical smears and, potentially, further colposcopy. By carrying out HPV testing using a centralized model, these two applications have been shown to be cost-effective [63].

Conclusion: cervical screening

It is clear that cervical screening has reduced mortality due to cervical carcinoma. However, the introduction of HPV vaccination and HPV testing is likely to improve the programme still further by prevention of HPV infection and by the optimization of management and follow-up strategies [64]. However, continuous audit and research are needed to assess the impact of these changes on the primary objective of the programme, i.e. mortality reduction.

Prostate and lung cancer screening

Two other common cancers that have attracted a lot of interest from a screening point of view are prostate and lung cancer. Prostate cancer screening has been based on detecting raised blood levels of prostate-specific antigen (PSA), and to date there have been five randomized trials of good quality. A recent Cochrane systematic review incorporating these trials has concluded that prostate cancer screening does not significantly reduce either all-cause or prostate-cancer-specific mortality [65]. In addition, PSA testing is associated with substantial risk of harm owing to high false-positive rates, over-diagnosis and adverse outcomes after both transrectal ultrasound biopsies and radical prostatectomy for screen-detected cancers. Currently, therefore, population screening for prostate cancer screening cannot be recommended.

Lung cancer screening has received a lot of attention following the publication of a randomized comparison of low-dose CT or single-view chest radiography which demonstrated a significant reduction in lung cancer mortality in the group allocated to CT [66]. This was not, however, a population-based trial of lung cancer screening, as only those who had agreed to participate were randomized, and there was no control 'no screening' arm. Until the results of population-based trials are available no recommendations can be made, and great care must be taken to avoid the use of lung cancer screening as an alternative to smoking cessation.

CHAPTER 31

Familial cancer syndromes and genetic counselling

Henry T. Lynch, Carrie L. Snyder, and Jane F. Lynch

Introduction to familial cancer syndromes and genetic counseling

Genetic counselling is truly mandatory for patient education, surveillance, and management of all forms of hereditary cancer. Indeed, it has become the clinical bedrock for these disorders, wherein it has constantly been stimulated by the veritably logarithmic advances in molecular genetics with the identification of an increasing number of cancer-causing germline mutations. Table 31.1 lists known hereditary cancer syndromes, with the caveat that new syndromes and new information on known syndromes are constantly being recognized. This chapter represents more than 50 years of the authors' experience in diagnosing, DNA testing, and counselling thousands of families representing more than 100,000 affected and/or high-risk cancer-prone patients. Using colorectal cancer (CRC) as a model, Table 31.2 points out the magnitude of CRC and its familial and most common hereditary forms, both worldwide and in the US. Figure 31.1 shows the hereditary CRC syndromes that have been identified to date, as an example of the complexity of differential diagnoses.

Family history

The genetic counsellor's responsibility will be the compilation of a comprehensive cancer family history. Ideally, this will involve three or four generations of the proband's family covering both maternal and paternal lineages. It must include cancer of *all* anatomic sites, with verification whenever possible. Clearly, the family history is the linchpin in this effort. Figure 31.2 shows a modified nuclear pedigree which, when completed, will, in most cases, aid significantly in identifying a hereditary cancer syndrome should one be present in the family.

The genetic counsellor's role is exceedingly important, given substantial evidence that among the physician community the family history is often ignored or insufficiently recorded, thereby compromising an opportunity for identifying and targeting those patients who are at high risk for hereditary cancer syndromes and who would benefit from DNA testing, screening, and potential life-saving management. DNA testing will, therefore, enable more certainty for its diagnosis, with furtherance of targeted clinical translation, surveillance, and personalized medical management.

The discipline of evidence-based genetic counselling, particularly as it relates to genomic medicine, which encompasses the roles of medical geneticists with evidence-based genetic counselling, has been more clearly defined in terms of its service obligation for high-risk patients [1–3]. The genetic counselling discipline is clearly a challenging one which harbours an intense thirst among genetic counsellors for its clinical expansion given the incredibly rapid progress in the identification of an increasing number of patients with virtually all forms of hereditary cancer syndromes [4]. When there is germline mutation evidence in a patient/family, there will be a clear need to focus on its genetic counselling implications.

Berliner and Fay [5] have discussed genetic counselling recommendations with a particular bent towards their medical, psychosocial, and ethical implications relevant to the identification of individuals at risk for the hereditary breast-ovarian cancer (HBOC) syndrome and, in turn, embracing genetic susceptibility concerns, as developed by the Practice Issues Subcommittee of the National Society of Genetic Counselors' Familial Cancer Risk Counseling Special Interest Group. This knowledge is based upon an extensive review of the current literature dealing with cancer genetic risk assessment in addition to the professional expertise embodied in the genetic counselling discipline.

Personalized cancer medicine

Disease-related gene identification such as *BRCA1* and *BRCA2* in HBOC syndrome and the mismatch repair (MMR) germline mutations, namely *MLH1, MSH2, MSH6, PMS2*, and deletions in the *EPCAM* gene that silence MSH2 in Lynch syndrome (LS), provide the stimulus for a scientifically-based study design with a highly targeted focus on patients whose lifetime cancer risk, with considerations for differences in their heterogeneity and penetrance, can be more carefully defined than programmes which exist for their so-called sporadic counterparts. The power inherent in the identification of cancer-causing germline mutations harbours further advantage in that it provides benefit which can be effectively derived from individualized therapeutic development, all in concert with this personalized cancer medicine phenomenon. Therefore, with the help of pathologists, medical geneticists, medical oncologists, surgeons, genetic counsellors, and molecular genetic colleagues, we are now merging our cancer control efforts towards the development of newly-derived disease risk classifications in concert with innovative molecular-based cancer treatment. Clearly, this new molecular approach to cancer diagnosis, screening, and therapy means that we are in the midst of a new era for cancer control. Its ultimate success will be seen in the ability to identify family members who fit the particular hereditary cancer

Table 31.1 Hereditary cancer syndromes

Hereditary cancer syndrome	Organs affected	Genes	Frequency
Hereditary breast-ovarian cancer	Breast, ovary, possibly gastric and prostate cancer	BRCA1, BRCA2	exact is unknown; ~4–6% of breast and ovarian cancers
Lynch syndrome	Most commonly the colorectum, followed by the endometrium, ovary, uroepithelial tract, small bowel, stomach, pancreas, hepatobiliary tract, probably breast and prostate; skin in Muir-Torre variant, brain in Turcot variant	mismatch repair genes: MSH2, MLH1, MSH6, PMS2; also silencing of MSH2 by deletion in EPCAM gene	~3% of all colorectal cancer; ~2% of all endometrial cancer; other related cancers less common
Familial CRC type X	Colorectum	unknown	unknown
Familial adenomatous polyposis and attenuated FAP	Colorectum, desmoid tumour, hepatoblastoma, thyroid carcinoma, medulloblastoma	APC	1:6,000–1:13,000
MUTYH-associated polyposis	Colorectum	MUTYH	1.5% of individuals are heterozygous for this recessive trait
Hereditary juvenile polyposis	Colorectum, stomach, small bowel, pancreas	SMAD4, BMPR1A	1:15,000–1:50,000
Peutz–Jeghers syndrome	Breast, colon, pancreas, stomach, ovary (including sex-cord tumours), Sertoli-cell tumours, gall bladder, urinary bladder, genitourinary tract, respiratory tract	STK11	1:29,000–1:120,000
Cowden's syndrome	Breast, follicular thyroid, endometrium	PTEN	1:200,000
Bannayan–Riley–Ruvalcaba syndrome	Thyroid cancer, hamartomatous colon polyps	PTEN	rare
Gorlin syndrome	Basal cell, gastric hamartomas	PTCH	1:40,000–1:57,000
Multiple endocrine neoplasia I	Parathyroid, enteropancreatic endocrine, and pituitary tumours	MEN1	2:100,000
Multiple endocrine neoplasia II B	Medullary thyroid, pheochromocytoma, mucosal neuromas, ganglioneuromas, gastrointestinal hamartomatous polyps	RET	25% of all medullary thyroid carcinoma
Hereditary diffuse gastric cancer	Stomach, lobular breast cancer	CDH1	<3% of gastric cancer
Familial atypical multiple mole melanoma syndrome	Skin, pancreas	CDKN2A	~6%–8% of melanomas; ~5% of pancreatic carcinoma
von Hippel-Lindau	Kidney, liver, pancreas, renal cell carcinoma, pheochromocytoma, retinal and cerebellar hemangioblastoma	VHL	1:36,000
Li–Fraumeni	Sarcoma, breast cancer, brain tumours, leukaemia, lymphoma, laryngeal carcinoma, lung cancer, adrenal cortical carcinoma	P53	unknown
CHEK2 1100delC	Breast, colorectum	CHEK2	unknown
Neurofibromatosis type 1	Neurofibromas, optic nerve gliomas, iris hamartomas, neurofibrosarcoma, pheochromocytoma, duodenal carcinoid, neuroblastoma, ependymoma, rhabdomyosarcoma, and Wilms' tumour; in children: juvenile myelomonocytic leukaemia (juvenile chronic myelogenous leukaemia) and myelodysplasia.	NF1	1:3,000
Neurofibromatosis type 2	central nervous system tumours	NF2	1:35,000
Retinoblastoma	Intraocular	RB	1:13,500–1:25,000
Wilms' tumour	Kidneys, leukaemia, non-cancerous developmental anomalies	WT1, WT2	1:10,000
Ataxia telangiectasia	Breast cancer in heterozygotes; non-Hodgkin lymphoma, leukaemia, gastric cancer, medulloblastoma, glioma	ATM	1.4% of population carry recessive trait; disease incidence 1:30,000–1:100,000
Bloom's syndrome	Leukaemia, lymphoma, carcinomas of larynx, lung, esophagus, colon, breast, cervix, noncancerous anomalies	BLM	Unknown in general population; 1:48,000 among Ashkenazi Jews

(continued)

Table 31.1 Continued

Hereditary cancer syndrome	Organs affected	Genes	Frequency
Fanconi's anaemia	Myelodysplastic syndromes, leukaemia (usually acute myelogenous leukaemia), squamous carcinomas of the upper aerodigestive tract, cervix, vulva, and anus; hepatocellular carcinoma, possibly secondary to anabolic steroid treatment	*FA-A, FA-B, FA-C, FA-D, FA-E*	Estimated 1:300 are heterozygous for this recessive disorder
Werner syndrome	Sarcoma, melanoma, and carcinoma of the thyroid, stomach, liver, breast, and bile duct	*WRN*	1:50,000–1:100,000
Gastrointestinal stromal tumours	Sometimes malignant	KIT/PDGFRA	Hereditary component unknown
Hereditary prostate cancer	Prostate; possible involvement of other sites	Multiple proposed candidate genes	Unknown
Haematologic	Blood-related malignancies	Under investigation	Estimated 5% of the aggregate of haematologic cancers

syndrome's molecular-based diagnosis and thereby can become candidates for full participation in cancer control measures driven by genomic medicine [6, 7].

Demand for genetic counsellors

There is an increasing service demand for genetic counsellors but, unfortunately, the supply of individuals with this expertise is severely limited. Clearly, the need may vary in different geographical regions. A genetic counsellor in a specific geographic location may often be located by clicking on 'find a counselor' in the National Society of Genetic Counselors' website at http://www.nsgc.org.

It is clear that genetic counsellors must assume the role of the 'family teacher and cancer guardian' with responsibility for educating the proband and ideally his/her at-risk relatives. At a minimum, the educational plan must constitute the following:

1. Advice in lay terms about DNA, genetic testing, and its cancer risk significance.

2. Take-home message on screening and management benefits.

3. Legal protection against insurance/employment discrimination as embodied in the Genetic Information Nondiscrimination Act (GINA).

Contact at-risk relatives

Ideally, the counsellor will emphasize the importance of the proband's role to inform close relatives of their cancer risk status with practical input about their need to become committed to

the dicta of this educational process. For most, this will involve the sharing of cancer risk data, DNA testing, and its cancer control implications, so that close relatives can achieve potential lifelong benefit; they must also be made aware of sources of help, for example genetic counselling, medical geneticists, centres of genetic expertise, all in concert with knowledge and participation in this process with their family physicians.

Cancer germline mutations and patient benefit

Mutations may cause cancer in several ways. The main types of gene involved in hereditary carcinogenesis are oncogenes, tumour
Fig. 31.1 Circle graph depicting the marked genotypic and phenotypic heterogeneity in hereditary colorectal cancer syndromes.

Abbreviations: AC-1, Amsterdam Criteria 1; MMR, mismatch repair; FAP, familial adenomatous polyposis; AFAP, attenuated familial adenomatous polyposis; HBCC, hereditary breast and colorectal cancer; PJS, Peutz–Jeghers syndrome; FJP, familial juvenile polyposis; CD, Cowden's disease; BRRS, Bannayan–Ruvalcaba–Riley syndrome.

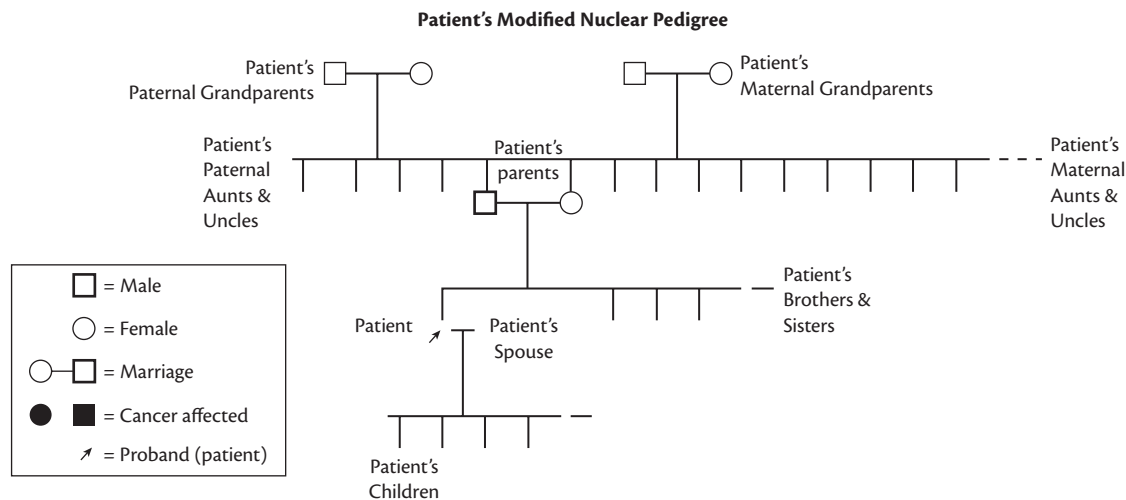
Patient's Modified Nuclear Pedigree


Fig. 31.2 Diagram representing a simple, modified nuclear pedigree for clinical use.

suppressor genes, and DNA repair genes. Oncogenes are genes that normally participate in cellular growth pathways, and that become abnormally activated in cancer. Tumour suppressor genes normally suppress cellular growth or cause cells to become differentiated, and are inactivated in cancers. DNA repair genes participate in repair of DNA damage and their inactivation leads to numerous mutations in target genes, including oncogenes and tumour suppressor genes. The 'two-hit' hypothesis of hereditary cancer indicates that when a person inherits an abnormal gene in one allele, an acquired mutation in the other allele will lead to cancer.

Germline mutations which predispose to some of the more common cancers, particularly in the case of the HBOC syndrome and *BRCA* mutations, and CRC with multiple extracolonic cancers in LS, prominently abetted by discovery of the MMR germline mutations, namely *MLH1, MSH2, MSH6*, and *PMS2*, provide excellent models for life-saving benefit from genetic counselling. These well-known and now time-honoured mutation discoveries took place in the mid-1990s [8–10]. Commercial laboratories providing sequencing data for these mutations rapidly emerged throughout the world as patient and physician knowledge expanded and became immersed in a brand new and indeed novel era of patient-centred genetic counselling. This process has rapidly evolved largely due to the cloning of these germline mutations.

Prior to these mutation discoveries, we had to rely solely on an individual's family history and the patient's position in the pedigree to estimate lifetime cancer risk. Thanks to prodigious clinical research on these mutations in patients/families, the cancer spectrum has been broadened in many hereditary cancer-prone syndromes. The vulnerable cancer sites may be extensive as with *BRCA2* mutations, which, in addition to breast and ovarian cancer, may show a pattern of cancer types involving an excess risk of male breast cancer, in addition to cancers of the colon, prostate, pancreas, and malignant melanoma. In the example of LS with MMR germline mutations one may find CRC and extracolonic cancers involving the endometrium, ovary, upper uroepithelial tract, small bowel, breast, prostate, adrenocortical carcinoma, sebaceous carcinomas in the Muir-Torre variant of LS, and glioblastoma in the Turcot's variant. Predictably,

we believe *other* cancers will ultimately be identified as being integral to these hereditary cancer syndromes. These findings, coupled with germline mutations segregating in the families, have allowed us to estimate patients' lifetime risk for these cancers. Importantly, this enables patients to make more informed cancer control decisions, in concert with advice from their physicians and genetic counsellors, about cancer screening, prophylactic (risk-reducing) surgery, or chemoprevention strategies such as tamoxifen as breast cancer chemoprevention in *BRCA* mutation carriers.

The carrier of a cancer-causing mutation may avoid cancer morbidity and mortality through engaging in a variety of preventive options. Non-carriers of a deleterious mutation can avoid the economic and emotional stress of a lifetime of preventive activities and will revert to general population cancer screening guidelines.

Psychosocial factors

Ideally, genetic counsellors must be prepared to work with the patient on the following potential psychosocial and economic issues:

1. Concern about insurance and employment discrimination.

2. The need for the counsellor and physician to keep active communication with the patient current.

3. 'Scapegoating' by family members, such as 'Why did you bring me into the world knowing our family cancer risk was so enormously high?'

4. Fear of manifesting cancer, particularly if found to harbour a cancer-causing mutation, which may be reflected by the query, 'Do I really want to know my molecular genetic test results?' In our experience in the context of our research protocols, at least 20% of our patients who have been tested for a deleterious mutation have declined to receive this information about their gene status, thereby generating an unresolved deep-seated emotional state of anxiety and apprehension about their germline status [11].

5. Emotional stress surrounding the need to tell loved ones about the family history, for example, a fiancé in advance of marriage.

This issue has implications for cancer's morbidity/mortality, long-term risk to progeny, and cost.

6. Finally, there may be lifelong anxiety with stress about cancer risk and the need to know how to cope more effectively with this distress.

Genetic counselling and risk reducing surgical options

Thanks to the high level of knowledge about cancer predictability and certainty in the case of the mentioned *BRCA* and MMR germline mutations, the past decade has opened up many opportunities for risk-reducing removal of organs that are highly vulnerable to cancer. Thus, in the case of carcinoma of the breast in *BRCA1* patients, studies by Hartmann et al. [12, 13] have shown high lifetime benefit of bilateral risk-reducing mastectomy (BRRM). Contralateral risk-reducing mastectomy (CRRM) increased by more than 150% from 1993 to 2003, based upon HBOC's natural history showing an excess of bilateral breast cancer in *BRCA* mutation carriers. However, Brewster and Parker [14] have shown that while this CRRM reduces the risk for contralateral breast cancer, there is nevertheless conflicting evidence as to why there is not reduced breast cancer mortality. Nevertheless, risk for distant metastatic disease outweighs risk of contralateral breast cancer [14].

Risk-reducing bilateral salpingo-oophorectomy (RRSO) provides an excellent opportunity for prevention of ovarian cancer (OC), which affects approximately 20% of patients with *BRCA2* and between 40–68% of those with *BRCA1* mutations. Identification and management of at-risk families harbours major public health implications, bridging gynaecologic and clinical genetic practice, given the fact that screening for OC is currently of unproven benefit [15]. An added benefit of RRSO is an approximate 50% reduction in breast cancer in *BRCA* mutation carriers, particularly when RRSO is performed premenopausally [16, 17]. We therefore recommend the option of RRSO in women with *BRCA* mutations who have completed their families and have been provided acceptable genetic counselling and referral to a knowledgeable gynaecologic oncologist [17, 18].

These clinical and molecular genetic considerations mandate the need for genetic counsellors to remain abreast of the multitude of new developments, including newly developed 'next generation' DNA sequencing (NGS) technologies which provide remarkable power for genome study [19, 20].

Family information service (FIS): maximization of personalized medicine

An FIS is a cost-effective, highly efficient way of educating and counselling all available and interested family members from a geographic catchment area in a single setting. It makes the best use of the physician's and genetic counsellor's time and effort, has group therapy potential, and patients welcome it. It has become an extremely valuable application of an expanded genetic counselling model, enabling effective communication with many family members who have gathered together as a group, particularly once a deleterious germline mutation has been identified in the family [21]. This approach to hereditary cancer education, DNA testing, and cancer control has many advantages:

1. It enables a physician, genetic counsellor, or other key members of the cancer genetics team, to explain fully what it means to be at increased cancer risk based upon the presence of a significant cancer family history and/or the presence of a cancer-causing germline mutation.

2. It provides an opportunity to cover highly pertinent aspects of cancer screening and management, with particular focus given to available, highly targeted cancer control approaches.

3. Through follow-up one-on-one discussions with family members, it provides an opportunity for the team to learn more about those family members in the pedigree who are in attendance at the FIS, versus those who either elected not to attend or simply had no knowledge of the fact that they were even part of the pedigree and thereby at heightened hereditary cancer risk. Those individuals who did *not* attend the FIS, but who may yet be at inordinately high cancer risk, and thereby could benefit immensely from appropriate education and individual personalized counselling, should be informed of the team's willingness to assist them. Their more genetically informed close relatives in attendance at the FIS may be in a position to help in this process [22].

4. This entire process allows for collection of consenting patients' DNA for genetic testing following genetic counselling where the pros and cons of germline mutation testing are presented in depth so that the patient can be fully informed about all facets of DNA testing. In this way, the patient will be in the best possible position to follow his/her wishes to provide written informed consent.

5. It supports those high-risk family members who may otherwise be reluctant to express concerns about some of the multifaceted issues involved in their cancer risk status and its assessment through DNA testing. They may be able to discuss more freely any emotionally threatening concerns which may not previously have been broached in a one-on-one genetic counselling session.

6. The FIS may be one of the most cost-effective and emotionally sound approaches known to the hereditary cancer educational process.

Logistics of the FIS

In preparation for the FIS, key family members will often volunteer to help inform their relatives about the objectives of the FIS, encourage their attendance, and identify a meeting place such as their physician's waiting room or their local hospital's outpatient department. These FISs often take place on a weekend when such facilities are less likely to be in use. Indeed, once a convenient time and place are decided, family members can set up individual appointments, should they wish to meet with the physician and/or genetic counsellors for individualized genetic counselling. If DNA had been previously collected and results of testing are available, coupled with informed consent, they can be given their results at the time of an FIS in a private one-on-one result disclosure session.

Importance of proband's close relatives

Rubin et al. [23] investigated whether CRC-affected patients were aware of the increased cancer risk to their close family members and whether sufficient help was delivered to them. Their findings, based upon 253 CRC patients showed that only 120 (47.7%) knew that their first-degree relatives were at increased risk for CRC. A mailed educational brochure, designed to improve their knowledge about

their familial cancer risk, did not improve their understanding. These authors [23] therefore concluded that the majority of patients lacked knowledge about their family members' risk and provided a clear indication that more effective educational tools were required. We believe that personal interaction with the family is an optimal way of providing so-called 'hands on' education during meeting with the family information service. Rubin et al. [23] summarize this in the rather terse statement that most CRC-affected patients simply do not know about their family members' risk.

In another study pertaining to cancer risk among probands' relatives, van Dijk et al. [24] investigated the extent to which medical specialists derive information from the family history in concert with the Amsterdam Criteria and Bethesda Guidelines in the case of LS, and subsequently apply recommended cancer control criteria to patients with CRC and a suspicion of LS. Their research involved 244 patients from the Netherlands who satisfied at least one of the Bethesda Guidelines. It was noteworthy that a complete family history was recorded for only 38 of the 244 patients (16%). Those patients with a more complete family history were more likely to be referred to the clinical genetic centre than those with an incomplete or absent family history (53% versus 13% and 4%, respectively; P = 0.0001) and were more likely to be analysed for microsatellite instability (MSI) (34% versus 6% and 1%, respectively; P < 0.001). These authors concluded that the family history is neglected in the majority of patients with CRC. Furthermore, MSI is pursued in only a small proportion of patients who meet the guidelines for this testing.

Tranø et al. [25] studied medical records of CRC patients in Norway and found a striking lack of attention to family history. Sixty-nine percent of patients had no family history recorded on the medical chart. The family history information of the 31.0% who did have it included in their medical record had not been clinically assessed, adding up to 0.0% whose records had been beneficially utilized.

This is not a new observation. Thirty years previous to the Tranø paper, a study was published in *JAMA* [26] that followed a similar design, although the earlier study looked at outpatient cancer clinic records of oncology patients: 'In most cases, the family history of cancer had been either omitted altogether, reported as negative despite substantial evidence to the contrary, or, if noted as positive, not pursued or acted on' [26].

This 1979 study found, as did Tranø's 2009 study, that interviews with the patients whose records had been studied turned up enough positive family histories to be of real concern, as did investigations during the intervening years [27–29].

What the genetic counsellor needs to know about Lynch syndrome

Box 31.1 provides a description of the natural history of LS. Clearly, this reflects the need for the genetic counsellor's knowledge base.

Cancer-prone pedigrees frequently present challenges to the physician/genetic counsellor due to their often diverse genotypic and phenotypic heterogeneity. Often, failure in their interpretation with ultimate problems in diagnosis may result from a lack of extension, reduced penetrance, or failure to search for genealogic and pathologic confirmation of cancer as well as non-cancer phenotypic features such as those so abundant in hereditary disorders such as familial adenomatous polyposis (FAP).

Figure 31.3 depicts a family with the classical phenotype of LS spanning six generations with four generations of affected family members. The proband (IV-3) was diagnosed with three different LS associated cancers: colon cancer at the hepatic flexure at age 53,

---

Box 31.1. Cardinal features of Lynch syndrome

- Autosomal dominant inheritance pattern seen for syndrome cancers in the family pedigree.

- Earlier average age of CRC onset than in the general population. Average age of 45 years in Lynch syndrome versus 63 years in the general population.

- Proximal (right-sided) colonic cancer predilection: 70–85% of Lynch syndrome CRCs are proximal to the splenic flexure.

- Accelerated carcinogenesis: tiny adenomas can develop into carcinomas more quickly, within two to three years in Lynch syndrome versus eight to ten years in the general population.

- High risk of additional CRCs: 25–30% of patients having surgery for a Lynch syndrome-associated CRC will have a second primary CRC within ten years of surgical resection if the surgery was less than a subtotal colectomy

- Increased risk for malignancy at certain extracolonic sites:
  - endometrium (40–60% lifetime risk for female mutation carriers)
  - ovary (12–15% lifetime risk for female mutation carriers)
  - stomach (higher risk in families indigenous to the Orient, reason unknown at this time)
  - small bowel
  - hepatobiliary tract
  - pancreas
  - upper uroepithelial tract (transitional cell carcinoma of the ureter and renal pelvis)
  - prostate cancer
  - breast cancer
  - adrenal cortical carcinomas
  - brain (glioblastomas in the Turcot's syndrome variant of the Lynch syndrome)
  - sebaceous adenomas, sebaceous carcinomas, and multiple keratoacanthomas in the Muir–Torre syndrome variant of Lynch syndrome.

- Pathology of CRCs is more often poorly differentiated, with an excess of mucoid and signet-cell features, a Crohn's-like reaction, and a significant excess of infiltrating lymphocytes within the tumour.

- Increased survival from CRC.

- The sine qua non for diagnosis of LS is the identification of a germline mutation in a mismatch repair gene (most commonly *MLH1, MSH2,* or *MSH6*) that segregates in the family, i.e. members who carry the mutation show a much higher rate of syndrome-related cancers than those who do not carry the mutation.

ureter cancer at age 56, and then kidney cancer at age 57. Sadly, one of his sons (V-4) developed colon cancer at age 19 and died from this at age 20. Endometrial and ovarian cancers are also expressed in this family in individuals III-1, III-4, III-12, IV-23, IV-24, IV-26, and IV-27. A deleterious *MSH2* mutation was identified within this family in 1995. Genetic testing and counselling of several family members ensued, with education regarding cancer control screening and preventive measures.

Figure 31.4 depicts a contrast to classical LS. Unfortunately, when the proband (V-2) in this family was diagnosed with CRC at the extremely early age of 19 she had no family history to alert her to this possibility. Upon her diagnosis, genetic counselling and testing was done which revealed an *MSH6* mutation. Once the family history was compiled, only a few cases of CRC were discovered on the proband's paternal lineage. Surprisingly, the proband's paternal grandmother (III-22) was found to be positive for the *MSH6* mutation. The grandmother had not been having frequent colonoscopies and yet, fortunately, has not been affected with CRC at the age of 80, giving an example of incomplete penetrance.

Figure 31.5 demonstrates the effectiveness of a multidisciplinary approach to identifying and properly recommending screening based on clinical features. The proband (III-5) was fortunate to have a very astute dermatologist recognize the association between sebaceous adenomas with the risk of CRC due to its association with LS. When the dermatologist diagnosed the proband with a sebaceous adenoma he immediately recommended that the proband have a colonoscopy 'right away'. The proband followed his recommendation and the first two colonoscopies were clear of lesions but the third colonoscopy, done five years after the sebaceous adenoma diagnosis, identified cancer in the ascending colon. If the proband had not been diagnosed with a sebaceous adenoma he would have never been alerted to his risk for developing CRC at such a young age, since the family history is negative.

Figure 31.6 depicts the pedigree of an extremely large family containing more than 700 individuals wherein 50 individuals manifested CRC [30]. The *EPCAM* mutation was identified in this highly extended kindred who was under study by us for more than 35 years [30]. Deletion in the epithelial cell adhesion molecule (*EPCAM*) gene results in hypermethylation and incomplete silencing of *MSH2* [31, 32] *EPCAM* mutation carriers may have phenotypic features that differ from carriers of *MSH2* mutations, namely an almost exclusive expression of site-specific CRC, and so a paucity of extracolonic cancers. However, it should be noted that the larger the deletion and the closer its proximity to the *MSH2* gene, the higher the risk of extracolonic cancers [33]. The breadth and size of the family shown in Figure 31.6 is testament to the potential impact of a single mutation event.

Missed opportunities for DNA testing, screening, and management: genetic counselling implications

Our experience and those discussed in the literature indicate that all too many patients at increased hereditary cancer risk experience confounding factors which contribute unnecessarily to their morbidity and mortality, collectively posing missed cancer prevention opportunities. This problem appears to be one that may be heightened among African Americans (AAs) and other minorities who,

unfortunately, sustain multiple healthcare disparities when compared with European Americans (EAs). One such example is that given by Hall et al. [34] which shows how screening has lowered CRC mortality but, nevertheless, compliance gaps persist among AAs (Table 31.3).

A large LS family studied by Hes [35], with 15 affected family members, provides an excellent example of this problem. This study indicated a deficit of awareness and knowledge about the natural history of LS and its screening and management implications among physicians as well as their high-risk patients. Soberingly, none of the family members underwent pre-symptomatic screening based upon their family history. We must conclude that in spite of the hereditary features indicating LS's natural history of its cancer phenotype, which should have led to referral of high-risk patients for genetic counselling and diagnosis, these were unfortunately totally ignored. Clearly, genetic counselling coupled with family support and encouragement could have diminished consequential high morbidity and mortality [35].

Maximum genetic testing benefit

Should we test all women with breast cancer?

Goodwin et al. [36] ask whether or not all women with breast cancer should be tested for the presence of a *BRCA* mutation, since the finding could be of major clinical significance. For example, information about prognosis can help women make better-informed decisions regarding treatment, risk-reducing surgery inclusive of risk-reducing bilateral mastectomy, and risk-reducing salpingo-oophorectomy. In an editorial on the Goodwin et al. paper, Narod [37] considers this to be an excellent reason to determine one's genetic status. For example, a patient with a *BRCA* mutation can then ask, 'If I develop breast cancer and it's identified by MRI screening, will its prognosis be so good that I'm nearly assured of a cure?' Clearly, if the answer is yes, risk-reducing surgery may be unnecessary. However, Narod suggests that we might test all patients with breast cancer soon after diagnosis, but recognizes fully that the test is expensive. He suggests that the simplest recommendation would be to test women diagnosed with breast cancer younger than 50 years old, as well as those with triple-negative breast cancer and women with a family history of early-onset breast and/or ovarian cancer. Hopefully, in the future the cost of genetic sequencing will decline and so it may be reasonable to test *all* breast cancer patients before a surgical and medical treatment plan is decided.

Should we test all CRC affecteds?

Hampel et al. [38] raise the same DNA-testing question for the identification of LS in all CRC affecteds; they give a resounding 'yes' based upon the evidence they have accumulated. Specifically, they investigated 500 consecutive patients with CRC and identified 18 (3.6%) that had LS. Of these 18, all had high microsatellite instability (MSI-H) while 17 (94%) were correctly predicted by immunohistochemistry (IHC). Their findings disclosed that one in 35 cases of CRC showed LS. These investigators also took the position that all endometrial cancer cases should be molecularly screened for LS [39]. They concluded that IHC is the preferred method to screen for LS.

Mvundura et al. [40] estimated the cost-effectiveness of genetic testing strategies to identify LS among newly- diagnosed CRC

Fig. 31.3 Pedigree showing a classical LS family, with colonic and extracolonic cancers.

patients using MSI and IHC, which appeared to be cost-effective from the perspective of the US healthcare system. Their findings showed that detection involved twice as many cases of LS as would be found by targeting younger patients. Ladabaum et al. [41] also provided further evidence of how widespread CRC testing for LS could yield substantial benefits at acceptable cost. The cost effectiveness depended upon the participation rate among relatives at risk for LS.

These findings, involving more comprehensive testing for HBOC and LS, will immediately define the need for appropriate

Table 31.3 CRC screening by race [33]

Test	AAs	EAs	P value
Faecal occult blood testing	49.0%	60.7%	0.035
Lower endoscopy	44.1%	58.5%	0.011
Any CRC screening	66.2%	76.3%	0.053

Abbreviations: AAs, African Americans; EAs, European Americans.

genetic counselling among those high-risk individuals who are identified as harbouring the respective HBOC and LS disorders. These data are presented in order to define better the emerging need for genetic counselling in an ever-widening array of hereditary disorders that are highly likely to be identified through rapidly emerging diagnostic genomic and computer-generated technology.

Direct-to-consumer (DTC) genetic testing

The genetic revolution which has impacted the practice of medicine and healthcare has made patients increasingly aware of genetic testing and its benefits. However, unfortunately, many physicians and patients are being misled by DTC test offerings of questionable accuracy and utility [42]. This results in patients' receipt of mundane information based on potentially important results but in the *absence* of appropriate genetic counselling by professionals. This problem has been addressed by the US General Accounting Office which concluded that such DTC tests were 'misleading and of little or no practical use' [43]. Risk profiles provided by such testing companies have been described as having 'no predictive value' and may falsely alarm or reassure consumers [44].

Fig. 31.7 Pedigree of AFAP family.

Genetic counselling featuring children and young adults

Several forms of hereditary cancer show early clinical and pathology manifestations, and so require genetic counselling of children and youth. The classic example is FAP. Lynch et al. [45] described a variant of this disorder known as attenuated FAP (AFAP).

When evaluating FAP in families, particularly in at-risk children, one must remain cognizant of patients with extremely early onset of colonic adenomas and CRCs as well as upper gastrointestinal fundic gland polyps and gastric adenomas in addition to a variety of other extracolonic tumours. For example, hepatoblastomas, although relatively rare, are more likely to involve FAP patients at an early age. It is noteworthy that among FAP-affected children younger than 10 years, the risk for FAP is more likely to occur at codon 1309 in the *APC* mutation, which leads to a more aggressive phenotype in which early risk-reducing colectomy can be indicated [46].

In one AFAP family, in addition to CRC, gastric cancer occurred, which was heavily influenced by the presence of numerous fundic gland polyps. The study involved more than two decades of investigation in which gastric cancer posed an early diagnostic problem since it was obscured by the multiple fundic gland polyps. The pedigree is depicted in Figure 31.7. Fear and anxiety were rampant among many of these high-cancer-risk patients, based upon the recognizable phenotype of precancerous multiple colonic adenomatous polyps coupled with a highly penetrant *APC* germline mutation.

We provided *APC* results to the children in this family [47] in a group FIS setting, since we reasoned that they would be more likely to express their concerns freely in such an environment. In the educational portion of the FIS, we emphasized that the colon was the major cancer-prone organ in FAP. Cancer control issues in the family were also emphasized.

Special attention was focused on a subset of this pedigree (Figure 31.7), in which progeny, namely individuals VI-6, VI-7, VI-8, VI-9, VI-10, of an *APC* mutation-positive mother (V-12) with a 426delAT *APC* mutation participated in an FIS [21] with disclosure of their *APC* testing results. Informed consent was obtained from non-minors, while among minors parental permission and the minor's assent for genetic testing and counselling were obtained. The importance of early average age of cancer onset and the need for surveillance among affected individuals was emphasized.

The first of V-12's progeny to receive *APC* results during the FIS was individual VI-10, an 8-year-old girl. She understood our discussion but appeared to realize that FAP was rampant throughout her family. After her blood draw, she asked her mother almost on a weekly basis if her test results were ready. Interestingly, however, she did not show any emotion save that for nervous giddiness and laughter when told that she was negative for the *APC* mutation. She did state that she was 'happy'.

The next to receive results was VI-8, an 18-year-old male. He had been born prematurely and had multiple medical problems. He was told he was positive for the *APC* mutation. His demeanour throughout was one of being strikingly negative and he repeatedly said 'I don't care' whenever the issue of *APC* results was discussed. He was informed of the importance of getting a baseline colonoscopy but appeared to be reticent about considering that option.

Conclusion: genetic counselling limitations

Genetic counselling is labour intensive, and remuneration for this service is severely limited by many insurance carriers, resulting in decreased physician involvement. Fortunately, much of this service is being provided by genetic counsellors who are highly experienced and knowledgeable about the natural history of hereditary cancer syndromes, germline mutation testing, as well as screening and management recommendations which are melded into the syndrome's natural history. They often have an educational background in psychology, which may contribute to preparing them for compassionately dealing with the emotional burden experienced by many patients when they learn about the lifelong consequences of harbouring a germline mutation and its potential need for a lifetime of targeted screening and management.

SECTION 5

Support for the cancer patient

CHAPTER 32

Supportive and palliative care

David Hui and Eduardo Bruera

Introduction to supportive and palliative care

Cancer patients often experience significant symptom burden starting before the time of diagnosis, during cancer treatments and with disease progression [1, 2]. Indeed, patients with advanced cancer report an average of eight to 12 symptoms in cross-sectional surveys [3, 4]. These symptoms may be caused by the tumour itself resulting in obstruction, compression, direct infiltration, or effusions and various complications such as inflammation, thrombosis, infections, and paraneoplastic syndromes. Treatments aimed at reducing the tumour burden can also result in significant side effects. Moreover, patients often experience significant deterioration in their bodily function, sexuality, body image, family dynamics, jobs, financial status and spirituality, resulting in psychological distress. Cancer-related symptoms, treatment side effects, and psychological stressors, coupled with pre-existing comorbidities, significantly decrease patients' quality of life and increase caregiver burden.

In addition to symptom burden, cancer patients often have informational needs regarding their disease, symptoms, prognosis, investigation findings, therapeutic options, and coping strategies. They also require assistance with complex decision-making surrounding treatment choices and advance care planning. As patients approach the end of life (i.e. six months or less of life expectancy), their care needs increase dramatically [2].

Palliative care is an interprofessional discipline that specifically addresses the symptom management, communication, and decision-making aspects of care. It aims at improving 'the quality of life of patients and families who face life-threatening illness by providing pain and symptom relief with spiritual and psychosocial support from diagnosis to the end of life and bereavement' [5]. The terms 'supportive care' and 'Hospice Care' have similar, yet distinct, meanings (Figure 32.1). 'Palliative care' focuses on caring for patients with advanced diseases and includes both hospital-based acute palliative care services and community-based hospice care programmes that are limited to patients with a life expectancy of six months or less. 'Supportive care' encompasses not only palliative and hospice care, but also care for patients with early disease and survivorship [6]. A recent survey of oncologists and mid-level providers suggested that they were more comfortable with the term 'supportive care' than 'palliative care' [7], and referred more patients after our palliative care programme adopted the name 'supportive care' [8]. Given the significant overlap between 'supportive care' and 'palliative care', we will use the term 'supportive and palliative care' for the purpose of this book chapter.

Recognizing the role of supportive and palliative care in optimizing patient care, the Institute of Medicine (IOM) [9], the National Comprehensive Cancer Network (NCCN) [10], the American College of Surgeons Commission on Cancer (CoC) [11], and the American Society of Clinical Oncology (ASCO) [12, 13] all support increased integration of palliative care into oncologic care. Oncologists caring for cancer patients should be familiar with the principles of palliative care and should be equipped with some core skills of symptom management, communication, and decision-making. They should also know when to refer cancer patients to a specialist palliative care team (see Table 32.1). The aim of this chapter is to describe the structure, processes, and outcomes of palliative care, and to discuss contemporary models of integration between oncology and palliative care.

Structure of supportive and palliative care programmes

Palliative care is, by definition, interprofessional. Palliative care programmes typically consist of nurses, physicians, mid-level providers, social workers, psychologists, counsellors, chaplains, physiotherapists, occupational therapists, and a wide number of other disciplinarians including art therapists, music therapists, and volunteers.

Acute palliative care programmes are located within acute care facilities. The four major branches of acute palliative care are (1) inpatient consultation teams, (2) acute palliative care units, (3) outpatient clinics and (4) palliative home care programmes [14]. Each has a unique function and complements the other branches.

Inpatient palliative care consultation teams represent the backbone of palliative care. In a survey of US cancer centres, 92% of National Cancer Institute designated cancer centres reported having a palliative care inpatient consultation team [15]. The consultation team provides advice in symptom management and transition of care for hospitalized patients. Because patients are often acutely ill, the time from referral to death is short (days to weeks) [16, 17].

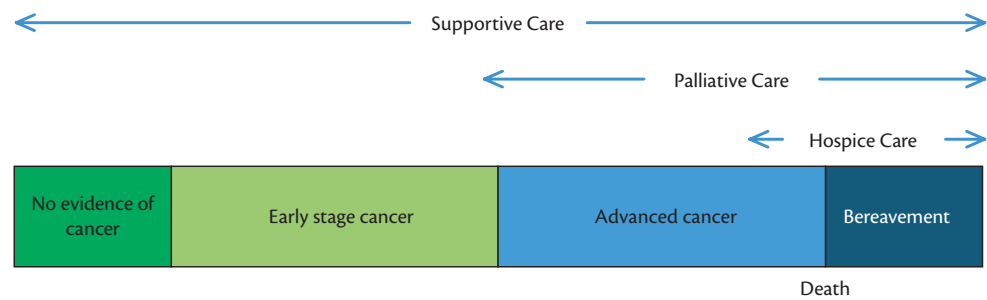
Patients in severe physical and/or emotional distress seen by the consultation team may be transferred to an acute palliative care unit, which provides intensive symptom management and psychosocial counselling with an interdisciplinary team. Through impeccable communication, education about end-of-life care, family meetings, and goals of care discussions, the palliative care team plays an important role in facilitating transitions of care and discharge planning. In a study of our palliative care unit, approximately one-third of all admissions died in the hospital and the remainder was discharged to the community, mostly with hospice care in place. The median survival from discharge to death was 21 days [18]. In addition to end-of-life care, acute


Fig. 32.1 Scope of supportive care, palliative care, and hospice care. Based on a recent systematic review, hospice care provides community-based care for patients at the end of life with a prognosis of six months or less. Palliative care provides care for patients with advanced cancer in the acute care setting through inpatient consultation teams, acute palliative care units, outpatient clinics, and home care services. Supportive care is the most expansive and addresses the need for both early-stage and advanced cancer patients. It includes survivorship care, palliative care, and hospice care programmes.

palliative care units can facilitate simultaneous care by effectively addressing cancer treatment-related adverse effects and complications [19].

Palliative care outpatient clinics aim at providing care to patients earlier in the disease trajectory, with months between referral to death [15, 20]. Outpatient clinics represent the ideal setting for integration between oncology and palliative care. Symptoms may be managed or prevented effectively before crisis occurs, and recommendations can be given to optimize patients' nutritional and functional status during concurrent cancer treatments. Multiple clinic visits also allow the palliative care team to establish a long-term relationship with patients and their families, to establish trust, to provide longitudinal counselling, and to initiate discussions regarding goals of care and advance care planning.

Table 32.1 Palliative care referral

Why should we refer?	To improve the symptom burden, satisfaction, quality of life, and potentially quantity of life of patients with advanced cancer.
Who should be referred?	Studies suggest that patients with advanced cancer should be referred within two months of diagnosis, regardless of their distress level. However, given that few palliative care programmes have the infrastructure to accommodate a large number of patients, selective referral is recommended at this time.
	The National Comprehensive Cancer Network suggested that patients with uncontrolled symptoms, moderate to severe distress, serious comorbidities, life expectancy less than or equal to 12 months, patient/family concerns about the course of disease and decision making, or self-expressed interest should be referred to interdisciplinary palliative care teams for further management [10].
Who should be providing palliative care?	Oncologists (primary palliative care) and palliative care team (secondary palliative care) should work together to deliver comprehensive cancer care.
When should patients be referred?	Earlier is better to facilitate symptom detection and treatment, longitudinal counselling and advance care planning.
How comprehensive should palliative care programmes be?	Studies suggest that interdisciplinary palliative care programmes providing comprehensive services are more effective than when only a few disciplines are involved.

Palliative home care teams deliver healthcare services to patients' homes for those who are not already enrolled onto hospice programmes. In the US, palliative home care is an extension of services from the acute care system, while hospice enrolment means that the patients receive only community-based care. By conducting home visits, the palliative care team can assess symptoms and home safety, delivery medications, address psychosocial issues, while at the same time, minimize patient travel and wait time.

Processes of supportive and palliative care programmes

Principles of symptom management

Symptom management is one of the most important aspects of palliative care. Over the past few decades, multiple principles related to symptom assessment and management have emerged based on an increased understanding of the pathogenesis and natural history of symptom development.

First, symptoms are highly prevalent. In a systematic review of symptom prevalence in patients with advanced cancer, 74% had fatigue, 71% had pain, 53% had appetite loss, and 48% had nervousness [21]. Thus, symptoms should be routinely screened and treated.

Second, symptoms often occur together. Patients with advanced cancer experience on average eight to 12 symptoms at any one time. This may be related to common pathogenesis (e.g., inflammatory cytokines could result in fatigue, anorexia, cachexia and depression) or the fact that symptoms often exacerbate each other (e.g., pain can cause insomnia and anxiety, and anxiety could, in turn, worsen pain). Identification of the cause(s) is an important part of the assessment. Validated symptom batteries are available for clinic use; for instance, the Edmonton Symptom Assessment Scale (ESAS) consists of ten symptoms assessed by numeric rating scale ranging from 0 (no symptom at all) to 10 (worst possible) [22].

Third, symptoms often have multiple etiologies. For instance, cancer-related fatigue may be due to cytokine dysregulation, electrolyte abnormalities, anaemia, deconditioning, and depression in a particular patient [23]. The implication is that multidimensional assessments and interventions are needed. In this example, successful interprofessional intervention may include use of dexamethasone and correction of hypernatremia and anaemia by the palliative care physician, exercise with physiotherapy, and counselling sessions with psychology. Importantly, recommendations should be tailored to the individual's needs.

Fourth, symptom expression can be modulated by multiple factors, such as age, sex, culture, delirium, psychological distress, and secondary gain. Figure 32.2 illustrates how the generation, perception, and expression of various symptoms are related to each other. For instance, pain expression may be 10/10 in a patient with advanced cancer with minimal nociceptive pain but severe psychological distress. Proper management in such patients would include counselling, rather than escalating the opioid dose and nerve blocks.

Fifth, symptom expression fluctuates over time and increases steadily in the last months of life. Seow et al. serially examined the symptom burden in advanced cancer patients in the ambulatory setting. In the last few weeks of life, they found a significant increase in dyspnoea, fatigue, drowsiness, anorexia, and a decrease in well-being [2]. Patients should be educated to anticipate an increased symptom burden and that effective treatment options are available for many symptoms, resulting in more resources needed at the end of life (i.e. last six months).

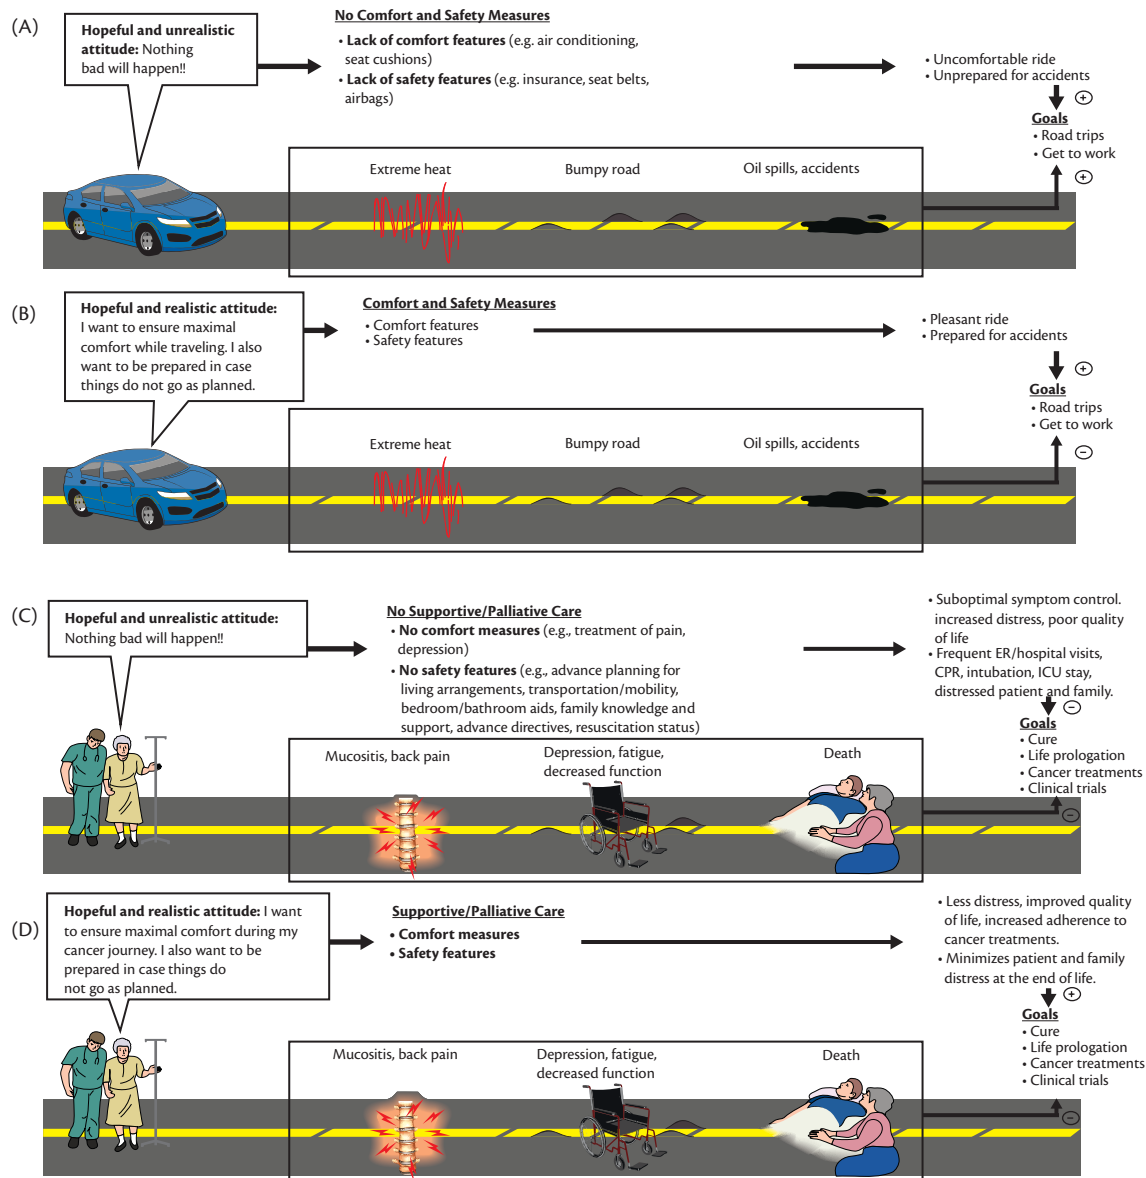
Sixth, symptom expression is subjective by definition and should be assessed with validated patient reported outcomes tools. No objective measures can replace subjective reporting. Caregivers generally overestimate the symptom burden, while health


Fig. 32.2 Goals of care discussions [71]. Palliative care referral and advance care planning are analogous to comfort features and safety features in a car. (A) A hopeful and optimistic driver going on a road trip believes that nothing bad will happen along the way, and may not worry about comfort and safety. (B) A hopeful and realistic driver is aware of challenges along the way, and would want to have maximal comfort features, as well as safety measures and car insurance to ensure he can get to his destination comfortably and safely. (C) Similarly, a hopeful and optimistic patient may only want to seek cancer treatments without addressing symptom control and advance-care planning. This lack of preparation may negatively affect the patient's ability to attain his goal. (D) In contrast, a hopeful and realistic patient understands the role of concurrent supportive care. He is more likely to attain his goal of getting more cancer therapies and life prolongation, while maximizing quality of life. He also has peace of mind because of advance care planning.

professionals often underestimate the symptom profile. Studies utilizing patient-reported outcomes found that they provide more information than healthcare professional's assessments and even correlate with survival.

Seventh, more research is needed to examine pathophysiology, assessment and interventions for various symptoms [24, 25].

Cancer pain

Pain is one of the most common symptoms reported by cancer patients, and is associated with decreased function, appetite, sleep, mood, and quality of life. Proper evaluation of pain should include characterization of its location, intensity (0–10 numeric rating scale), nature, duration, and previous therapies. It is also important to conduct a comprehensive assessment of potential causes and to identify modulating factors such as cognitive failure and psychological distress. For patients on opioids, it is also critical to monitor patients for opioid-related side effects, such as nausea, drowsiness, hallucinations, myoclonus, and vivid dreams. Furthermore, clinicians should be aware of aberrant behaviours suggestive of opioid misuse, including unusually high doses, frequent use of breakthrough doses, recurrent loss of prescriptions, as well as concurrent psychotropic medications, alcoholism, and illicit drug use.

Over time, it becomes clear that pain is much more difficult to control in some patients than others. A number of pain assessment tools have been developed to assist clinicians to identify such individuals. The Edmonton Staging System (ESS) includes seven factors (mechanism of pain, pain characteristics, previous narcotic exposure, cognitive function, psychological distress, tolerance, and past history). Patients with any one of neuropathic pain, incidental pain, psychological distress, rapidly increasing dose (>5% of initial dose per day), and positive history of alcoholism or drug addiction were considered to have a poor prognosis for pain control; those with mixed or unknown pain syndrome, >300 mg of morphine equivalent daily dose per day, and altered cognitive function have an intermediate prognosis for pain control; and the remaining patients have a good prognosis [26].

Subsequently, the Edmonton Staging System was revised (rESS) to include five factors only: pain mechanism, incidental pain, psychological distress, addiction, and cognition to facilitate daily practice [27]. This has been found to be predictive of pain control to a certain extent along with pain intensity at baseline [28].

According to the WHO pain ladder, mild pain can often be treated with non-opioids such as non-steroidal anti-inflammatory drugs (NSAIDs) and acetaminophen. Moderate and severe pain may warrant the use of opioids. Common weak opioids include hydrocodone, codeine, and tramadol. Strong opioids include morphine, hydromorphone, oxycodone, oxymorphone, fentanyl, and methadone. Importantly, adjuvant treatments should always be considered to optimize pain management and to minimize the dose of opioids. For example, tricyclic antidepressants, gabapentin, pregabalin, and venlafaxine are all reasonable choices for neuropathic pain. NSAIDs, steroid, bisphosphonates, or radiation may be considered for bone pain. Involvement of services such as palliative care, pain services, and radiation oncology may be helpful.

A working knowledge of opioids is essential for good pain management. With the exception of methadone, all strong opioids are available in extended release and immediate release formulations. Methadone has a long half-life and is fast acting, and is appropriate for both long- and short-acting purposes. All strong opioids have similar efficacy in pain relief at equianalgesic doses. Furthermore, extended-release opioids are similarly as efficacious as immediate-release opioids given around the clock, with the only advantage being fewer doses [29]. When used as a rescue dose, immediate-release opioids should be dosed at 10–20% of the total opioid daily dose, given every one to two hours on an as-needed basis. Because opioids can have serious long- and short-term side effects, it is crucial that patients are educated about their proper use and potential adverse reactions. Importantly, constipation, drowsiness, and nausea can be prevented with laxatives, methylphenidate, and metoclopramide, respectively. Opioid rotation is important for patients who have developed severe opioid toxicity, who have poor pain control despite high doses of opioids, or need to switch opioids for logistic reasons (e.g., cost or change of route of administration).

Cancer-related fatigue

Cancer-related fatigue is the most common concern among cancer patients, particularly among those on cancer treatments and at the end of life [30]. It does not typically improve with rest. Cancer-related fatigue is multifactorial in nature, related to cytokine upregulation, hypothalamic pituitary axis dysregulation, circadian rhythm disturbance, serotonin neurotransmitter alterations, vagal afferent activation, and changes in muscle metabolism [23]. Other conditions commonly found in cancer patients may also contribute to fatigue, and include immobility, electrolyte abnormalities, hypothyroidism, anaemia, and depression.

Routine screening of cancer-related fatigue will improve its detection and treatment. A simple approach is to use a numeric rating scale (0–10). It is important to assess patient function, weakness, activity level, and potential causes.

Treatment of cancer-related fatigue includes both pharmacological and non-pharmacological measures. Specifically, exercise is the most evidence-based treatment for patients both during and after cancer treatment. Aerobic exercises may offer greater benefit than resistive exercise [31]. Although the optimal duration of exercise has yet to be determined, a general recommendation is 30 minutes of moderate exercise per day most days [32].

Medications such as methylphenidate and modafenil have mixed evidence for reducing cancer-related fatigue and may be effective for selected individuals [33, 34]. Dexamethasone could modulate cytokine activity and has been shown to improve fatigue in one randomized, controlled trial [35]. Ginseng may also offer some potential benefits and is being actively investigated [36]. Finally, it is important to correct any reversible causes such as hypothyroidism or severe anaemia.

Depression

Cancer patients experience many psychological stressors throughout their cancer journey. In the first week of cancer diagnosis, the rates of suicide and death from cardiovascular events increase significantly [37]. With each appointment, investigation, or treatment, patients have to face bad news, disappointments, and uncertainties. Furthermore, cancer patients experience significant changes in regard to their body image, sexuality, bodily function, ability to work, ability to engage in their hobbies, family relationships, self-esteem, self-identity, and spirituality. Understandably, psychiatric conditions occur in approximately half of cancer patients and may include adjustment disorder, depression, and anxiety [38, 39].

Psychological distress is associated with increased symptom expression and decreased quality of life [40]. The ESAS consists of two numeric rating scales on depression and anxiety. Other screening questions, including 'Are you depressed?', for anhedonia may also be used [41]. A proper diagnosis of depression is based on the DSM-IV criteria.

Patients with mild to moderate depression would benefit from counselling such as short-term psychotherapy, expressive supportive counselling, and cognitive behavioural therapy [42–44]. Supervised exercise programmes are also useful for depressive symptoms [45]. Patients with severe depressive symptoms would require antidepressants such as selective serotonin reuptake inhibitors (SSRIs) and tricyclic antidepressants. Psychostimulants also have a role in treating depression because of their rapid onset [46]. Referral to psychiatry may be warranted.

Communication and decision-making

Studies have found that most cancer patients are interested in learning more about their disease status, therapeutic options, and prognosis [47]. This information is essential for them to make many personal and financial decisions, as well as various healthcare decisions such as stopping chemotherapy or hospice enrolment. For instance, cancer patients who were aware that they had a poor prognosis were less likely to choose chemotherapy [48]. Surprisingly, a recent study showed that a majority of patients with metastatic lung and colorectal cancer were not aware that their disease is incurable, highlighting a communication gap [49].

Communication is a key determinant of patient satisfaction [50, 51]. Specific techniques such as prompting, non-verbal cues, empathic statements, use of silence and listening may improve the quality of communication [52]. However, studies have found that physicians consistently miss empathic opportunities [53, 54], and that few of them routinely discussed prognosis [55]. This may partly be related to oncologists' concern that prognostic disclosure could negatively affect hope; however, studies have found that patients were able to maintain their level of hope after prognosis discussions [56, 57]. The relative lack of training in communication for oncologists may also contribute to the communication gap [12].

End-of-life discussions address many topics relevant to patient care in the last six months of life, including expected survival, symptom profile, functional changes, goals of care, advanced care planning (i.e. surrogate decision maker(s), advance directives, and out-of-hospital do-not-resuscitate orders). These discussions are important to facilitate end-of-life decision-making and to ensure that patients receive care consistent with their preference. Furthermore, these discussions have been shown to be associated with increased hospice enrolment, higher quality of life, and fewer aggressive measures at the end of life [58, 59]. End-of-life discussions should occur longitudinally, tailored to patients' understanding and readiness. Various communication aids such as recording of the interview, information pamphlets and educational videos may also facilitate the complex decision-making process [60, 61]. The involvement of palliative care teams can facilitate goals of care discussions and advanced care planning [62].

Figure 32.2 illustrates an approach to initiate end-of-life discussions. We use the examples of comfort features and safety features in a car to describe the need to involve palliative care and advanced care planning for cancer patients, respectively. The presence of these would help the patient to better attain the goals of getting more cancer treatments and living longer, while having peace of mind.

Outcomes of supportive and palliative care programmes

Through the provision of comprehensive holistic care, supportive and palliative care programmes have a positive impact on many outcomes, including symptom burden, quality of life, quality of care, satisfaction, and healthcare costs [63]. However, because of heterogeneous study design, inception cohort, palliative care interventions and outcome measures among existing studies, the optimal model of palliative care delivery remains a topic of active investigation.

A meta-analysis found that specialist palliative care was associated with reduced symptom burden [64]. Several randomized controlled trials further demonstrated superiority of palliative care compared to routine oncologic care for depressive symptoms and quality of life among patients with advanced cancer [65, 66].

Through end-of-life discussions, advanced care planning and documentation of care goals [58], palliative care also has a significant impact on improving the quality while reducing the cost of end-of-life care, predominantly by decreasing aggressive interventions in the last days of life, such as emergency room visits, hospital admissions, intensive care unit stays, chemotherapy use, intubations, and resuscitations. The increased use of hospice care also contributes to improved end-of-life care [67, 68].

Systemic reviews on palliative care as an intervention have shown increased patient and caregiver satisfaction [64, 69]. Furthermore, palliative care involvement is associated with improved caregiver bereavement [58].

Integration between oncology and palliative care

With an ageing population, there is an increased number of patients with a cancer diagnosis. Furthermore, patients with advanced cancer are living longer with improved cancer treatment options. Oncologists are faced with an increased demand to coordinate both cancer treatments and support measures. Because of the lack of time, routine screening, interprofessional input, and specific training in supportive and palliative care, many symptoms and patient needs are under-detected, under-diagnosed, and under-treated [70]. To improve the quality of care for cancer patients, we urgently need to integrate palliative care with oncology.

Integration may take place at three levels: primary, secondary and tertiary. At the primary level, oncologists provide front-line supportive care for patients. To ensure a good standard of care, oncologists need to include basic symptom management, communication skills, prognosis-driven patient-centred decision-making, and advance care planning discussions as part of their core training. Furthermore, they need to know when to involve secondary palliative care.

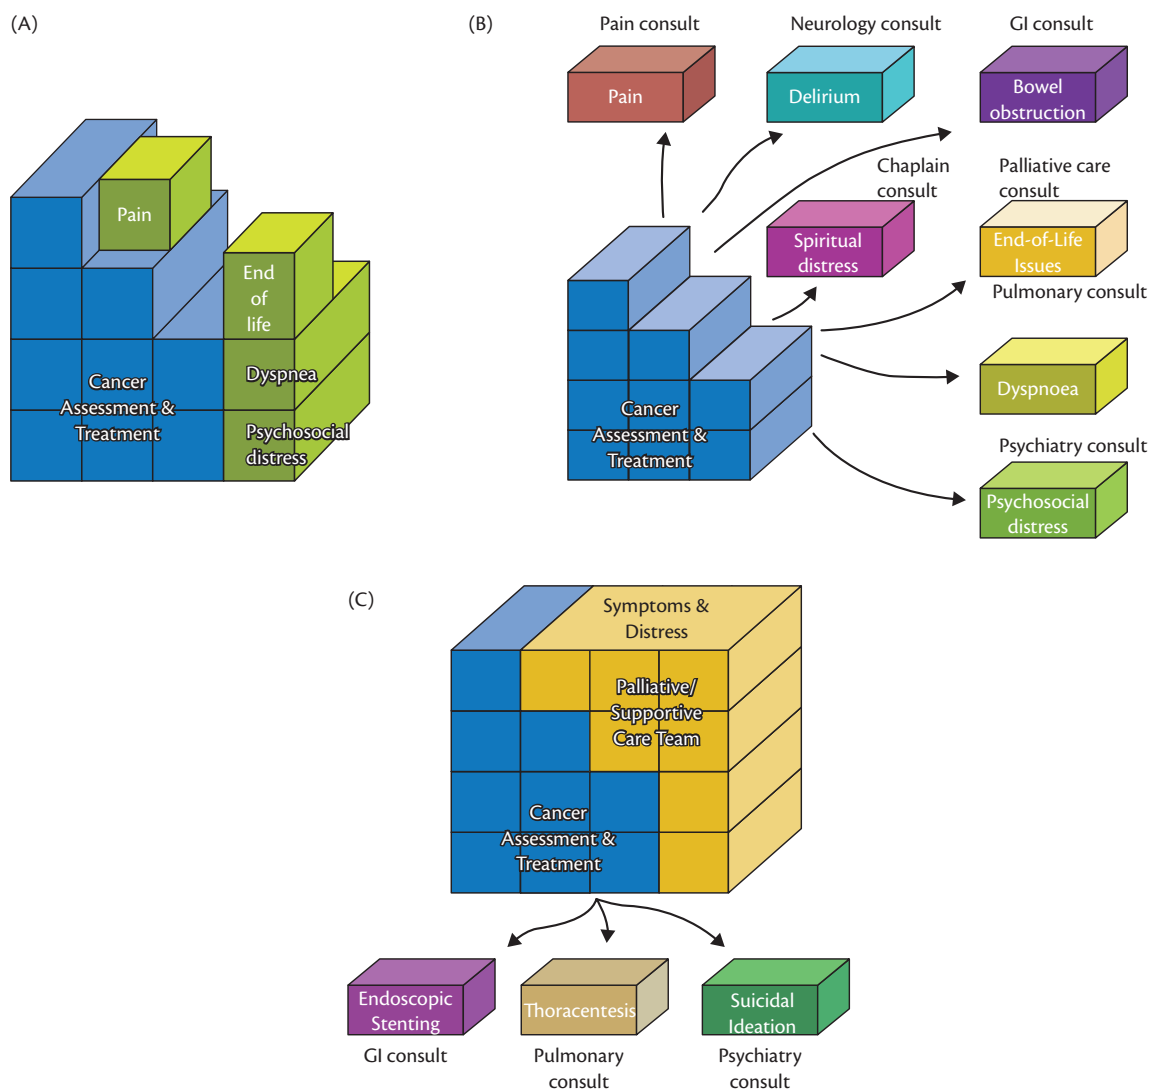
Secondary palliative care is delivered by interprofessional palliative care teams. Patients and family members in severe physical or emotional distress, or those with high care needs, are best managed by an interdisciplinary team with multidimensional interventions. Rather than referral to multiple disciplines for each symptom (e.g., pain service for pain, fatigue clinic for fatigue, physiotherapy


Fig. 32.3 The cancer care package [71]. (A) In the solo practice model, the oncologist is responsible for both cancer treatments and supportive care. The supportive care needs may not be addressed fully because of limited time, expertise, and resources. (B) In the congress model, each supportive care need is contracted out to various specialists. This can be extremely expensive and inefficient. (C) In the integrated care model, the oncologist collaborates with the palliative care team to delivery comprehensive cancer care.

for weakness), the palliative care team can address many of the patients' concerns comprehensively while minimizing overlap.

Tertiary palliative care involves research collaborations between palliative care specialists and oncologists further to advance our knowledge in symptom management, communication, and decision-making. It requires specialized centres with fully developed palliative care and oncology services.

Figure 32.3 illustrates how oncologists can provide supportive care in everyday practice [71]. In the solo approach, the oncologist is the only provider of both oncologic treatments and primary palliative care (Figure 32.3A). The comprehensiveness of cancer care is dependent on the oncologist's time, expertise, attitude, and resources, and may sometimes be limited. To compensate for this, the oncologist may choose to consult various specialists for each supportive care need under the congress approach (Figure 32.3B). Although patients may receive expert care, this approach is expensive and time consuming, and may result in

conflicting recommendations by different teams. The integrated care approach involves palliative care referral early in the disease trajectory (Figure 32.3C). The oncologist focuses on providing cancer management recommendations and may deliver as much primary palliative care as they are able, knowing that the palliative care team will address a majority of patients' supportive care needs. This model allows patients to access timely and expert supportive care through a coherent team while minimizing confusion when many other specialties are involved.

Summary

Patients with advanced cancer often experience significant physical and psychological symptoms. They also have tremendous communication and decision-making needs. Palliative care is an interdisciplinary team with expertise in addressing the care needs for patients with life-limiting illness and their families. Early involvement

of palliative care is associated with significant improvement in symptom control, patient and caregiver satisfaction, quality of life and—potentially—quantity of life. Oncologists equipped with basic palliative care skills can deliver effective front-line supportive care. Patients in distress may also benefit from early referral to specialist palliative care teams.

Quality of life

Neil K. Aaronson and Peter M. Fayers

Introduction to quality of life

In the medical context, the question: 'How are you?' represents more than a simple social ritual. It is usually the first question that is asked by the doctor in the consulting room. It represents an informal invitation to the patient to talk about his or her health. In clinical research we cannot afford to rely on such informal means of collecting information about the patients' health and well-being. In evaluating the effect of a treatment, we need to define what we consider to be the most important outcomes of interest. In clinical oncology, these have traditionally been objective outcomes, including tumour response, disease-free survival, and overall survival. In other words, the question 'How are you?' has usually been posed in purely biologic terms.

There has been a growing recognition that these traditional markers of therapeutic success are often insufficient for evaluating the effect of cancer treatment, and that it may be appropriate—and even essential—to broaden our focus to include formal and systematic assessments of the extent to which cancer and its treatment impact on the quality of life (QoL) of the patient.

What lies behind this shift of focus? In part, it reflects general trends in the distribution of disease in the modern, industrialized world from acute towards chronic health conditions. In contrast to infectious diseases, where cure is often a realistic goal of treatment, chronic diseases typically require a moderation of both patients' and physicians' expectations. While slowing of the disease process may be possible, the patient often must learn to adjust to long-term functional limitations. The primary goals of treatment become symptom relief and minimizing the impact of the disease on the patient's physical and psychosocial functioning.

Although treatment is often directed initially towards cure, it may be important to weigh any gains in survival time against the morbidity caused by the treatment. Many treatments aimed at tumour control are quite aggressive, with a range of side effects. The introduction of formal QoL evaluations in such situations helps us weigh treatment costs and benefits. A substantial percentage of patients will eventually receive treatment with palliative intent. In this context, assessing QoL as part of the evaluation of the effectiveness of palliation is perhaps even more important.

Who should assess the QoL of patients with cancer?

In most clinical studies in oncology, the clinical investigator is asked to assess the patient's performance status, using a rating scale that summarizes the patient's symptom levels and ability to perform normal, everyday activities at home and at work. However, performance status measures such as the Karnofsky,

ECOG, and WHO scales assess only a few issues related to physical health and activities of daily living, and ignore psychosocial health. Methodologically, inconsistencies have been noted in performance status ratings provided by different physicians of the same patient, and in ratings of physicians versus patients [1, 2]. Physician-based performance status ratings cannot substitute for more direct measures of patients' QoL. It is today widely accepted that the patient must be the *primary* source of information about his or her QoL.

How do we define QoL?

Although most of us have some intuitive sense of what QoL means, a precise definition remains elusive. QoL is an omnibus term summarizing a broad range of issues. As Alvan Feinstein, one of the early advocates of a patient-centred approach to clinical medicine, once put it: 'the idea has become a kind of umbrella under which are placed many different indexes dealing with whatever the user wants to focus on' [3].

One way of avoiding this problem of definition is to view QoL as a Gestalt that can best be measured at a global level. Some years ago, Ian Gough and his colleagues suggested that one need only ask a single question to evaluate the QoL of patients with cancer: 'How would you rate your QoL today?' [4]. They supported their position by demonstrating a relatively strong correlation between answers to this single question and scores derived from a more extensive battery of questionnaires. H.L. Mencken, the American author and pundit, once said: 'There is an easy solution to every human problem—neat, plausible, and wrong' [5]. What, then, is wrong with this approach?

In choosing an appropriate therapy for an individual patient, or in developing treatment guidelines for a specific diagnostic group, physicians require very specific information on which to base their decisions. For example, it is expected that results of a blood test will be reported in appropriate detail (including calcium, iron, pH, and cholesterol levels), and not as a single value representing a summary of the findings. The same holds true for evaluation of the QoL of patients. How are we to interpret a patient reporting a low overall QoL? Is the patient in pain? Is he so tired that he can no longer carry out his normal daily activities? Is he very anxious or depressed? Or, more likely, is it a combination of such factors? For this reason, QoL assessment should be approached from a multidimensional perspective. Such an approach allows us to disentangle the positive and negative effects of a given treatment.

This still leaves the question of what should be measured. An important limiting factor is that the focus be on 'health-related QoL' or 'health status assessment'. The 1948 constitution of the

World Health Organization defined health as: 'a state of complete physical, mental and social well-being, and not merely the absence of disease and infirmity' [6]. This definition offers a holistic alternative to the classic medical model in which disease and illness are defined in strictly biologic terms.

Also in 1948, Karnofsky and Burchenal [7] identified four sets of criteria necessary to establish the therapeutic value of anti-cancer treatment. The first of these was described as: 'The patient's subjective improvement … in his mood and attitude, his general feelings of well-being, his activity, appetite, and the alleviation of distressing symptoms such as pain, weakness and dyspnoea.'

Taken together, the WHO definition of health and Karnofsky and Burchenal's subjective improvement criteria provided the elements that today, some 50 years later, form the core of QoL measurement in oncology. These include: (1) common disease-related and treatment-related symptoms and (2) the patient's level of functioning, defined in physical, psychological, and social terms [8]. Beyond this core set of domains, there are many additional issues that may be of importance when studying specific groups of patients. Body image may be of particular relevance in studies of patients with breast cancer, head and neck cancer, and other forms of cancer where treatment often involves mutilating surgery. Sexual functioning may be at issue in gynaecological and genitourinary tract cancers. Cognitive functioning may be of particular concern in studies of childhood cancer or of adults with brain tumours. Ultimately, the QoL issues that should be assessed in a given study depend on the patient population, the nature of the applied treatments, and the specific research questions (e.g., whether we are interested in short-term or long-term effects).

How should QoL be measured?

QoL instruments used in clinical oncology can be placed along a continuum reflecting their intended spectrum of application: (1) generic instruments for both the general population and for a wide range of patient populations; (2) disease-specific measures for use with cancer patients in general; and (3) diagnosis-specific measures (e.g., for use with patients with breast cancer, prostate cancer, etc.).

Generic QoL instruments

Generic QoL measures allow comparison of results across studies of different patient populations and facilitate comparison of patient groups with normative data from the general population. This is particularly relevant for issues of health policy and resource allocation. While there are a number of well-known, generic QoL measures, including the Sickness Impact Profile (SIP) [9], the Nottingham Health Profile [10], and the World Health Organization QoL Questionnaire [11], the Medical Outcomes Study Short-Form Health Survey (SF-36) [12] dominates the health outcomes field.

The SF-36 has 36 items forming eight subscales assessing: physical functioning, role limitations due to physical health problems, pain, general health perceptions, vitality, social functioning, role limitations due to emotional problems, and general mental health. Two higher-order summary scores for physical and mental health can also be calculated. Extensive background information on the SF-36, as well as standard scoring algorithms and interpretation guides, are available elsewhere [13].

Cancer-specific QoL instruments

Generic instruments may be limited in their ability to detect small, yet clinically meaningful group differences in QoL, or in detecting changes in QoL over time. Sensitive, cancer-targeted QoL questionnaires include the Functional Living Index—Cancer (FLIC), the Edmonton Symptom Assessment Scale (ESAS), the Rotterdam Symptom Checklist (RSCL), the Cancer Rehabilitation Evaluation System (CARES), the European Organization for Research and Treatment of Cancer Core QoL Questionnaire (EORTC QLQ-C30), the Functional Assessment of Cancer Therapy (FACT-G). Of these, the QLQ-C30, the FACT-G and the ESAS are perhaps the most widely used, and are described in more detail below.

The European Organization for Research and Treatment of Cancer QLQ-C30

The QLQ-C30 [14] was developed by the EORTC QoL Study Group specifically for use in international clinical trials in oncology. Originally published in 1993, the current version (version 3.0; see Figure 33.1) contains 30 items organized into five functional scales (physical, role, emotional, cognitive, and social), three symptom scales (fatigue, nausea and vomiting, and pain), and an overall QoL scale. Additional single items assess other common symptoms of cancer and its treatment (e.g., dyspnoea, loss of appetite, constipation and diarrhoea, etc.). The questionnaire employs a one-week time-frame, and four-point categorical response choices. It has been translated into more than 80 languages and has been tested extensively in multinational research settings. More recently, an abbreviated version of the QLQ-C30, the QLQ-C15-PAL has been generated for use in palliative care settings [15].

The Functional Assessment of Cancer Therapy—General

The FACT-G [16], originally published by Cella and colleagues in 1993, is also designed primarily for use in clinical trials. The current version of the questionnaire (version 4; see Figure 33.2) contains 27 items grouped into four primary domains: physical well-being, social/family well-being, emotional well-being, and functional well-being. A total, summary score can also be generated. The questionnaire employs a one-week time-frame, and five-point categorical response choices. It has been translated into a wide range of languages, which facilitate its use in oncology multinational clinical trials and observational studies in many regions of the world.

The Edmonton Symptom Assessment Scale (ESAS)—palliative care

The ESAS [17] is a standard one-page screening tool of symptoms in palliative care. It contains ten items, each assessed on a numerical rating scale from 0 to 10, and takes about two to five minutes to complete. It is widely used for individual patient management, in which case the scores for each symptom are used, as well as for clinical trials and other research, where the focus may be either on individual symptoms or the total score. Richardson and Jones provide an extensive review of the reliability and validity of the ESAS [18].

Condition-specific and treatment-specific instruments

Both the EORTC and the FACT measurement systems employ a 'modular approach' to QoL assessment whereby supplemental questionnaire modules are developed to assess condition-specific or treatment-specific issues not (sufficiently) addressed by their core instruments. Information on currently available modules and on modules under development can be found via the EORTC and the FACT groups. Both groups provide news of their activities via internet sites [19, 20].

EORTC QLQ-C30 (version 3)

We are interested in some things about you and your health. Please answer all of the questions yourself by circling the number that best applies to you. There are no "right" or "wrong" answers. The information that you provide will remain strictly confidential.

Other groups are also developing condition-specific questionnaires. For example, in the area of prostate cancer, at least four instruments, in addition to those developed by the EORTC and FACT groups, have been published [21–24].

Computer-adaptive testing (CAT)

Self-administered questionnaires have traditionally been paper-based. Apart from groups of items that are skipped over as not applicable, all patients complete the same questionnaire items. Computer-adaptive testing, in contrast, enables questions to be tailored to the individual patient, offering two advantages: questionnaires can be shorter and the scale scores can be estimated more precisely for any given test length. A CAT involves the use of a large item bank of calibrated questions and a computer program that selects the most appropriate and informative items for each patient. The CAT system mimics a clinical interview in that the choice of successive questions depends on the patient's response to previous questions. Despite the apparent simplicity of a CAT, the mathematical algorithms underpinning the process can be quite complex and involve item response theory (IRT) to ensure that the results for all patients are on a common metric that enables comparisons between patients.

CAT versions are being developed for standard instruments such as the EORTC QLQ-C30 [25], while the Patient-Reported Outcome Measurement Information System (PROMIS) is an initiative funded by the US National Institutes of Health to create 'a national resource for precise and efficient measurement of

patient-reported symptoms, functioning, and health-related quality of life, appropriate for patients with a wide variety of chronic disease conditions' [26].

Application of QoL assessments in clinical oncology research and practice

The substantial investment of time, energy, and resources in developing reliable, valid, and practical tools for assessing the QoL of cancer patients can only be justified if these measures are put to good use. Have QoL studies advanced our understanding of the burden of disease and the impact of treatment on patients' lives? Have they contributed to evaluating the effectiveness of anti-cancer treatments? Can they be used in the day-to-day care of our patients? How can they contribute to establishing clinical practice guidelines?

Observational QoL studies

Langendijk and colleagues assessed the effect of radiotherapy-induced toxicity on the quality of life of patients with head and neck cancer [28]. Although xerostomia (dry mouth) was the most prevalent side effect of radiotherapy, the QoL of patients was most affected by swallowing problems. These results suggested that future radiotherapy in this patient population should employ a lower radiation dose to minimize the effects on the salivary glands, and should avoid the anatomical structures involved in swallowing.

In observational studies of mid- to long-term cancer survivors, comparisons are often made between the cancer survivors and age- and gender-matched peers from the general population. For example, Rossen et al. [28] conducted a long-term follow-up of 400 Danish testicular cancer survivors as compared to men from

the general population, and found their QOL was not significantly different. Although patients treated with chemotherapy reported higher levels of peripheral neuropathy, ototoxicity, and Raynaud-like phenomena, treatment strategies were generally unrelated to QoL.

For many patient groups, however, we still know very little about the short- and long-term effects of the disease and its treatment. Only by carrying out well-designed, descriptive studies can we identify areas where support and rehabilitation services are most needed.

It is important to look beyond average effects: the 'average' patient is a statistical convenience, not someone seen in the doctor's office. Descriptive studies should aim to identify subgroups of patients who are particularly 'at risk' for psychosocial morbidity. Conversely, there may be much to learn from those patients who do well.

Evaluative QoL studies: phase III clinical trials

An important application of QoL measures is in comparing the effects of two or more cancer treatments. QoL measures have sometimes been useful in confirming clinical impressions or expectations about the psychosocial benefits of one treatment over another. For example, many trials comparing breast-conserving therapy with mastectomy in the treatment of early-stage breast cancer confirm that saving a woman's breast helps her maintain a sense of femininity and preserves a positive body image [29].

The useful half-life of QoL studies would probably be very short if they merely confirmed clinical expectations. That the results of such studies sometimes challenge widely held beliefs explains, in part, the growing enthusiasm for their use. Drawing again on the example of operable breast cancer, it has often been suggested that breast-conserving therapy, while holding certain psychosocial advantages over mastectomy, might increase a woman's fear that the cancer will recur. Yet empirical investigations have not supported this hypothesis [30].

Assessment of QoL is essential in palliative care. In a study of metastatic non-small-cell lung cancer, patients were randomly assigned to receive either early palliative care integrated with standard oncologic care or standard oncologic care alone [31]. The primary outcome was the change in the QoL at 12 weeks. Early palliative care led to significant improvements in both QoL and mood. Compared with patients receiving standard care, patients receiving

early palliative care had less aggressive care at the end of life but, interestingly, longer survival.

A final example is a clinical trial that compared medroxyproges-terone acetate (MPA) to a placebo in increasing appetite and promoting weight gain in patients with advanced-stage cancer [32]. MPA had a significant, albeit modest, beneficial effect on both endpoints. However, these gains in appetite and weight did not translate into improvement in QoL. Rather, a decline in the mean QoL scores of *both* the MPA and placebo groups was observed over the 12-week study period. Direct indicators of treatment success do not necessarily translate into improved functioning or sense of well-being.

Interestingly, patients' ratings of their functioning, symptoms and overall well-being obtained *prior* to the start of treatment are significant, independent predictors of survival. Gotay and colleagues [33] reviewed 39 cancer clinical trials that included data relevant to assessing the prognostic value of baseline (i.e. pre-treatment) patient-reported outcomes (primarily QoL measures). QoL was a significant predictor of survival, after adjusting for other known prognostic indicators such as performance status, stage of disease, weight loss, and serum markers. Similarly, Quinten and colleagues reviewed 14 EORTC clinical trials with more than 2200 patients. Patient-reported symptoms added significantly to the prediction of survival in multivariate models that also employed clinicians' ratings of these symptoms [34]. These results should not be over-interpreted; they do not indicate that the emotional state or personality of patients can affect the course of the disease. They do suggest that our current health status is one of the best predictors of future morbidity and mortality, and that patients can be quite accurate in rating their current health [35, 36].

Incorporating QoL assessment in clinical trials

QoL assessment is only relevant to some types of clinical trial. It is rarely necessary in phase I or phase II trials, where the primary aim is to determine tumour response and toxicity. The main role for QoL instruments lies in phase III trials. There are four settings in which QoL assessment is particularly relevant:

1. Palliative studies in which improved QoL may be the principal aim of the intervention and thus QoL assessment may provide the principal endpoint.

2. Equivalence trials, in which little difference is anticipated in terms of improved survival or cure, but where there may be differences in side effects, symptomatology, or morbidity.

3. Trials in which a difference in survival or cure rate might be anticipated, but where the improvement may be small and accompanied by major toxicity or side effects.

4. Studies involving health economic cost-effectiveness.

Various guidance documents have been published on incorporating QoL assessments into clinical trials, including those of the US Food and Drug Administration [37], the European Medicines Agency [38], and the Center for Medical Technology Policy [39]. Additionally, an extension of the CONSORT (Consolidated Standards of Reporting Trials) has recently been published to improve the reporting of QoL results from randomized controlled trials [40].

Interpretation and clinical significance of QoL results

One topic that deserves particular attention is the interpretation and clinical significance of QoL data generated in clinical trials. Typical conclusions from a clinical trial might be that one treatment resulted in 'statistically significant' reduction (or increase) in a QoL scale. But what does such a statement mean? Statistical significance tests only examine whether the differences observed in a clinical trial might be due to chance fluctuations, and tell us nothing about the clinical importance of the results. A large-sized trial will be able to detect trivially small differences in QoL, and results may be (statistically) highly significant even though the differences could be regarded as clinically unimportant. How, therefore, can we decide what is clinically important?

Percentage of 'cases'

Perhaps the simplest method is to report the percentage (or proportion) of patients with particular QoL scores. Many people find it relatively easy to obtain a feeling for percentages (e.g., '30% of patients reported quite a bit of problem with tiredness'), but it is more difficult to use this approach for multi-item scales such as those that summate several items and produce a scale score between, say, 0 and 100.

Reference against normative data from healthy subjects

For many of the more widely used instruments, *normative* data are available, showing the results that may be expected in a random sample of the general population. For example, Ware et al. have provided norm-based interpretations of SF-36 scores based on percentile rankings obtained from large, representative samples from the US general population [13]. Similarly, Hjermstad et al. [41] report normative data for the QLQ-C30 in a randomly selected sample of 3000 people from the Norwegian population. These normative data may serve as a guideline when interpreting QoL in groups of cancer patients.

Contrast with reference data from patient groups

Reference values are often available for groups of patients with different cancer diagnoses. For example, the EORTC Quality of Life Study Group has produced a manual of reference data [42], based upon pooled data from many clinical trials and observational studies. The manual tabulates age- and gender-specific values for the QLQ-C30 and its scales. Investigators can contrast their results with those found in comparable groups of patients.

Measurement of minimal changes that are important to patients

Osoba and colleagues have suggested guidelines for interpreting the 'subjective significance' of change scores on the EORTC QLQ-C30, based on a comparison with direct estimates of change provided by patients retrospectively using so-called 'health transition' or 'global

rating of change' questions [43]. In their study, patients were asked to complete the QLQ-C30 on two occasions. At the time of the second administration, they were also asked about *perceived changes* in physical, emotional, and social functioning and in global QL, using a 7-point scale ranging from 'much worse' to 'no change' to 'much better'. Patients who reported 'a little' change for better or worse on a particular SSQ scale had corresponding pre-test/post-test QLQ-C30 changes of about 5 to 10 points, those reporting 'moderate' change on the SSQ had QLQ-C30 changes of about 10 to 20 points, and those reporting 'very much' change on the SSQ had QLQ-C30 changes of greater than 20 points. Other studies [44, 45] have employed related strategies for defining a palliative response or 'clinical response benefit' based, in part, on patients' self-reported changes in symptom burden.

Anchor-based interpretations

Anchor-based interpretations compare the changes seen in QoL scores ('anchored') against other clinical changes. In a study by King and colleagues [46], 'known groups' of patients who were expected to differ in terms of QoL scores were compared. For example, patients with limited disease were compared to those with advanced disease. For most scales a difference of 5 or less was a 'small' difference, but the definition of a 'large' difference varied for each scale: for example, large differences were 16 for global QoL, 27 for physical functioning, and 7 for emotional functioning. This approach has subsequently been extended for many cancer sites and for both the EORTC QLQ-C30 [47, 48] and the FACT-G [49].

Distribution-based interpretations

Distribution-based interpretations are based on the statistical distributions of results. The most commonly used statistic is the *effect size* (ES), which relates the observed change to the baseline standard deviation [50] or the *standardized response mean* (SRM), which uses the standard deviation of the change. Norman et al. [51] reviewed 38 studies that reported some 62 effect sizes and confirmed that in most cases the thresholds deemed to be clinically significant corresponded to an ES of approximately 0.5 (half a standard-deviation).

Conclusion: future directions

The many years of effort devoted to developing the science of QoL assessment are now bearing fruit. What are the important questions for future research? In the area of measurement, there are a number of methodological challenges. First, efforts should be continued to develop supplemental questionnaires for use with specific groups of patients. More specific instruments are best able to detect treatment effects in clinical studies. Second, we need to develop a much better understanding of the clinical significance of QoL scores. We can accelerate our learning curve by generating normative or reference data for groups of patients with different diagnoses, stages of disease, and treatment experiences. Third, we need to evaluate the performance of questionnaires in diverse cultural settings, including ethnic and cultural minorities within countries. Fourth, research is needed to develop QoL instruments with very high degrees of precision for use at the level of the individual patient in daily clinical

practice. The current efforts of the PROMIS group in the US and the EORTC Quality of Life Group in Europe to develop sophisticated CAT measurement systems are anticipated to usher in a new era of QoL assessment, with measures that are flexible and powerful when used in both clinical research and clinical practice settings.

In the realm of clinical trials, funding agencies and review committees should require that clinical investigators provide an explicit, well-argued rationale for *including* or *not including* QoL outcomes in their trial protocols. When QoL assessment is appropriate, sufficient funding should be made available to facilitate the additional data collection. The most expensive study is that which fails to meet its objectives because of an inadequate research infrastructure. Effective ways are required for communicating the results of QoL studies, both for presenting results so that doctors can interpret and use them in counselling their patients, and so that patients can draw on such information to make more informed choices.

Finally, allocation of healthcare resources is increasingly based on considerations of QoL and survival data, yielding quality-adjusted life years (QALYs). Such an approach arguably oversimplifies a very heterogeneous set of considerations. The process of deciding which medical treatments society is willing to pay for, and which it is not, is rather complex. Those working in the QoL field can perhaps best inform the public debate over healthcare financing by generating high-quality data on the full range of effects that our medical technologies have on patients' functioning and well-being. This will ensure that the patients' perspective is represented in healthcare policy decisions.

Cancer survivorship and rehabilitation

Rachel L. Yung and Ann H. Partridge

Introduction to cancer survivorship and rehabilitation

Cancer survivorship is a relatively new area of clinical focus and research. Although practising oncology providers have long contended with the issues that burden their patients with a history of cancer, survivorship has only recently gained recognition as an important and unique component of cancer care and research. In a pivotal editorial on the topic, Mullan described the concept of survivorship in terms of seasons in the cancer trajectory and helped to galvanize efforts to 'map the middle ground of survivorship and minimize medical and social hazards' after cancer [1]. Over the past three decades there has been a slow but steady recognition of the importance of cancer survivorship in the biomedical community, including the launching of the Office of Cancer Survivorship at the National Cancer Institute (NCI) in 1996. Today, survivorship has received international attention in cancer organizations. There are burgeoning survivorship programmes within cancer centres and an increased body of research and quality improvement initiatives focus on issues salient to cancer survivors. Nevertheless, given the heterogeneity of cancer types, treatments, latency periods for issues to arise, and funding constraints, coordinated efforts in this area have been challenging. Much of the research to date has defined the relatively short-term issues that survivors face, with more limited available evidence-based information regarding how to optimally follow cancer survivors or make interventions to improve outcomes.

When is a patient considered a survivor?

The NCI's Office of Cancer Survivorship adopted the National Coalition for Cancer Survivorship's (NCCS) definition of survivorship, defining someone as a cancer survivor from the time of diagnosis and for the balance of life [2]. Survivorship often also refers to the period in the cancer continuum after the completion of active treatment and before end of life. Although family and loved ones have sometimes been included as survivors, the focus for this chapter will be on those with a cancer diagnosis who have completed active treatment.

In the US alone, there are now approximately 12 million adult cancer survivors, a dramatic increase since 1971 when there were fewer than three million [3]. This number is anticipated to grow to 18 million by 2022 [4]. This reflects the increased life expectancy of those with cancer: in 2003, 67% of adult cancer patients lived longer than five years compared to fewer than 50% in the 1970s

[3]. The distribution of cancer survivors reflects both the incidence and survival of different cancer subtypes. Those with breast, colorectal, and prostate cancers make up over half of all survivors (Figure 34.1). Most cancer survivors are over 65 years old (60%), 35% are 40 to 64 years old, 4% are 19 to 39 years old, and 1% are less than 19 years old [3]. Mirroring population demographics, incident cancer cases in people over the age of 65 are projected to double over the next 40 years [5]. This will result in an ageing of the survivorship population. While special attention is clearly needed for younger cancer survivors who have unique concerns, such as employment and fertility, caring for older survivors who are more likely to have comorbidity makes care coordination between their oncologists and primary care doctors paramount. This highlights the need for personalized survivorship care that mirrors the direction of all of cancer care.

Worldwide, the demographics of survivorship are harder to estimate and this in fact is a significant research question. In developed countries with cancer programmes, an interest in survivorship issues has motivated better prevalence estimates. Data from the UK puts their figure at two million survivors [6]. Estimates of survivors in developing countries have been calculated given a country's unique distribution of type of cancer, average survival after treatment, and general life expectancy [7]. Therefore, much of the evidence base has grown out of initial research done in North America; however, recently the research has been global in nature. There is international agreement that survivorship is a key part of cancer treatment.

The essential components of survivorship care include: (1) surveillance, screening, and prevention of recurrence and new cancers, including adherence to clinical guidelines and risk-reducing treatments; (2) identification and management of late and long-term effects; (3) improving modifiable health behaviours; and (4) coordination of care between providers to ensure that individual patients' health needs are met [8]. While great strides have been made in each of these areas, there is much work to be done to improve our understanding of the needs of cancer survivors as well as optimizing cancer survivorship care to improve patient disease and quality of life outcomes.

Surveillance, screening, and prevention

Surveillance for recurrent cancers and screening for new primary cancers are important survivor issues. Cancer-specific recommendations exist (please see the appropriate disease-oriented chapters for cancer-specific details); however, the weight of the evidence
Fig. 34.1 Distribution of primary cancer type of survivors.

Source: data from Howlader N, Noone AM, Krapcho M, Neyman N, Aminou R, Waldron W, Altekruse SF, Kosary CL, Ruhl J, Tatalovich Z, Cho H, Mariotto A, Eisner MP, Lewis DR, Chen HS, Feuer EJ, Cronin KA, Edwards BK (Eds.), *SEER Cancer Statistics Review, 1975–2008*, National Cancer Institute, Bethesda, Maryland, USA, available from <http://seer.cancer.gov/csr/1975_2008/>. Based on November 2010 SEER data submission, posted to the SEER website, 2011.

behind them varies. We do have some data from prospective randomized studies; these results have been incorporated into guideline recommendations and should be followed. For example, surveillance for recurrence with imaging and tumour markers has been shown not to be beneficial in breast cancer [9–12] or ovarian cancer [13] where recurrence is usually incurable and early detection does not improve outcomes. In contrast, intensive surveillance for recurrence is used in colorectal cancer, lymphoma, and testicular cancer where recurrent disease is potentially treatable with curative intent. Surveillance is critical for risk-adapted treatment that limits therapy (and side effects), such as for patients with low-stage seminoma treated with surgery only [14]. Ideal surveillance strategies for many cancer types have yet to be proven in a rigorous manner, but research is ongoing. For example, a Cochrane meta-analysis reported an overall survival benefit for high-intensity versus low-intensity follow-up for colorectal cancer. However, they were unable to comment on the ideal modalities (i.e. imaging, blood tumour markers, and endoscopy) [15]. Currently, there are three large ongoing prospective, randomized controlled trials in Europe evaluating the optimal surveillance for colorectal patients [16–18]. For most diseases, however, there are only limited data to inform follow-up care and future research is necessary.

Screening for new primary malignancies is another priority for survivorship care. Screening in survivors is appropriate where evidence exists to recommend screening for the general population (e.g., breast, colon) and for those patients at higher risk secondary to environmental risks (e.g., smoking and lung cancer), genetic risk factors (e.g., frequent enteroscopy for patients with Lynch syndrome), or at increased risk secondary to previous cancer treatment (e.g., breast cancer screening for women who received mantle irradiation for Hodgkin lymphoma). However, evidence has suggested limited uptake of cancer screening among survivors, bringing to light the gaps in implementation of survivorship care [19–21].

Prevention of recurrence and second primaries is cancer type-specific, but falls into the general categories of optimization of modifiable health behaviours (discussed later in the chapter) and

adherence to chemoprevention, such as adjuvant hormone therapy for breast cancer. There is a large literature demonstrating that, despite the well-known benefit from adjuvant hormone therapy for breast cancer, there are many women who do not initiate or complete a full course of treatment [22–24].

Long-term and late effects of cancer and cancer treatment

There are myriad long-term and late effects that can result from cancer and cancer treatment. Technically, long-term effects are those which appear during treatment and persist, while late effects are those that manifest after cancer treatment has ended [25]. Long-term and late effects can be physical as well as psychosocial. Future survivorship research will also likely reveal additional concerns as well as help develop better management strategies.

Physical late and long-term effects

People with a history of cancer compared to those without a history of cancer have a two-fold higher rate of functional disability, impaired independent activities of daily living [26] and lower ratings for their health status [27]. Tables 34.1, 34.2, and 34.3, list many of the common late and long-term physical effects associated with specific cancer type and treatment. Many patients receive multimodality cancer treatment and late effects can result from combination therapy.

Fatigue

Fatigue is often multifactorial and can be associated with pain, medications, psychosocial distress, anaemia, hypothyroidism, poor nutritional status, or sleep disturbance/insomnia [28]. Although fatigue is a common side effect during active treatment, the prevalence of fatigue after active treatment is more difficult to determine. Fatigue is also common in the general population, making it difficult to determine how much is attributable to cancer and its treatment. However, a comprehensive review reported slightly higher average

Table 34.1 Potential long-term and late effect of systemic anti-cancer therapy (chemotherapy, hormonal, and targeted therapy)

Organ system	Effect	Causative agents
General	Second cancers	Steroids, alkylating agents, nitrosoureas, topoisomerase inhibitors, anthracyclines, tamoxifen
Bone and soft tissue	Osteoporosis, avascular necrosis	Steroids, aromatase inhibitors
Cardiovascular	Inflammation of the heart, congestive heart failure	Anthracyclines, high-dose cyclophosphamide, cisplatin, taxanes, trastuzumab, sunitinib
Endocrine	Diabetes	Steroids
Gastrointestinal	Motility disorders	Vinca alkaloids
Genitourinary	Haemorrhagic cystitis Erectile dysfunction	Cyclophosphamide, ifosfamide, transplant therapy GnRH agonists
Gonadal	Infertility, premature menopause, low testosterone	Cyclophosphamide, nitrosoureas, procarbazine hydrochloride, combination chemotherapy, GnRH agonists
Haematologic	Low blood counts, myelodysplastic syndrome, acute leukaemia	Alkylating agents, anthracyclines, nitrosoureas, topoisomerase inhibitors, purine analogs, any high-dose therapy with autologous transplantation
Hepatic	Abnormal liver function, cirrhosis, liver failure	Methotrexate, carmustine (BCNU)
Immune system	Impaired immune function or immune suppression	Steroids, anti-thymocyte globulin (ATG), methotrexate, rituximab, alemtuzumab, purine analogs, any high-dose therapy with autologous transplantation
Nervous	Cognitive effects Neuropathy Hearing loss	Combination chemotherapy, methotrexate, bortezomib Taxanes, vinca alkaloids, oxaliplatin, cisplatin Cisplatin
Ophthalmologic	Cataracts	Steroids, tamoxifen
Pulmonary	Pulmonary oedema Pulmonary fibrosis	Imatinib, dasatinib, Bleomycin, carmustine, methotrexate
Renal	Renal dysfunction/failure	Cisplatin, methotrexate, nitrosoureas

Table 34.2 Potential long-term and late effects of radiation

Organ system	Effect
General	Second cancers
Bone and soft tissue	Atrophy, deformation, fibrosis, and bone death
Cardiovascular	Scarring or inflammation, coronary artery disease
Dental/Oral	Caries, dry mouth
Endocrine	Hypopitutiary, hypothyroidism, infertility, premature menopause, testosterone deficiency
Gastrointestinal	Malabsorption, stricture, fistulas
Genitourinary	Bladder scarring, cystitis, fistulas, urinary incontinence
Haematologic	Low blood counts, myelodysplastic syndrome, acute leukaemia
Hepatic	Abnormal liver function, liver failure
Immune system	Impaired immune function, immune suppression
Lymphatic	Lymphoedema
Nervous	Problems with memory, thinking, learning
Ophthalmologic	Cataracts, dry eyes, visual impairment
Pulmonary	Lung scarring, decreased lung function, radiation pneumonitis
Renal	Hypertension, impaired kidney function

Adapted with permission from *From Cancer Patient to Cancer Survivor Lost in Transition*, National Academy of Sciences, Washington, DC, USA, Copyright © 2006.

showed that the rates of fatigue had diminished slightly in the survivor group [34]. Risk factors for chronic fatigue in survivors include depression, pain, multimodality cancer therapy, and other comorbidities [30, 31]. Evaluation and treatment of underlying causes of fatigue, if detected, may improve symptoms. Exercise, behavioural therapy, sleep interventions, and medications such as antidepressants and psychostimulants may help in the management of fatigue. See the National Comprehensive Cancer Network (NCCN) guidelines for additional recommendations for evaluation and treatment of cancer-related fatigue in patients post-treatment [37].

Chronic pain

Acute pain management for patients being actively treated for cancer and with advanced disease is more extensively covered in Chapter 43 on 'Supportive palliative care'. Chronic pain can be characterized as nocioceptic (visceral and somatic) neuropathic, idiopathic, psychogenic, and mixed [38]. It can be secondary to the cancer itself (i.e. compressive neuropathies), cancer treatments (e.g., radiation-induced plexopathies, chemotherapy-induced neuropathy, arthralgias from anti-hormonal agents, or post-surgical pain), or unrelated to the cancer diagnosis (e.g., low back pain). The prevalence of chronic pain in survivors varies by treatment modality. For example, post-surgical series show patients may experience pain at one year up to 50% after breast surgery, 60% after thoracotomy, and 40% after head and neck surgery [39, 40]. In populations that included both cancer and non-cancer patients, predictors of chronic post-surgical pain include chronic preoperative pain, repeat surgeries, passive coping skills, anxiety, depression, worker's compensation claims, risk of nerve damage for a given surgical approach, poorly controlled postoperative

fatigue scores in those with a history of cancer (who had completed active treatment) compared to the non-cancer population, suggesting long-lasting effects of the cancer or treatment [29]. Prevalence estimates of fatigue in the survivor population range from 17% to 56% [30–36]. Fatigue can be persistent. In a population of Hodgkin lymphoma survivors the prevalence was 24–27% at 12 years, compared to 9–12% in controls [35]; however, follow-up at 20 years

Table 34.3 Potential long-term and late effects of surgery

Procedure	Late effect
General	Pain, cosmetic defects, scaring, psychosocial
Neurosurgery	Impairment of any body function
Head and neck	Difficulties with communication, eating, breathing; cosmetic
Endocrine surgery (i.e. pituitary/thyroid)	Endocrinopathies/hypofunction: hypopituitarism, hypothyroidism, hypoparathyroidism
Lymphatic	Lymphoedema, retrograde ejaculation
Abdominal	Risk of obstruction, hernia, fistula
Splenectomy	Impaired immune function, predisposition to sepsis
Pelvic surgery	Sexual dysfunction, infertility, incontinence, hernia, bowel obstruction
Amputation	Functional changes, cosmetic, psychosocial impact, phantom limb pain, arthritis, neuropathic pain
Lung resection	Breathing difficulty, fatigue, general weakness
Prostatectomy	Urinary incontinence, sexual dysfunction
Oophorectomy	Premature menopause and Infertility
Orchiectomy	Infertility, testosterone deficiency
Ostomy	Bowel obstruction or incontinence, sexual dysfunction, poor body image

pain, radiation, or chemotherapy [40]. Rates of radiation-induced plexopathies are estimated at 1–5% for breast cancer patients, while 20% of patients with pelvic radiation complain of dysuria at one year [39]. Chronic pain management in the cancer survivor population has been mostly based on data from the non-cancer population and uses a multidisciplinary approach with pharmacological, behavioural and physical interventions. Pharmacologic interventions include traditional opiate and non-opiate analgesics as well as anti-depressants and anti-convulsants for treatment of neuropathic pain [41, 42]. Additionally, cognitive behavioural therapy, physical therapy, and rehabilitation therapy focused on functional outcomes can be effective strategies for patients with chronic pain.

Cognitive effects

Long-term cognitive effects of intrathecal or intraventricular chemotherapy and cranial irradiation for CNS malignancy are widely acknowledged. Cognitive dysfunction after systemic treatment of chemotherapy for non-CNS malignancies, sometimes referred to as 'chemobrain', has been less widely accepted, potentially because of difficulty measuring it. There are some data supporting cognitive dysfunction of patients during or shortly after systemic cytotoxic cancer treatment. Persistent or late cognitive effects of chemotherapy have been more difficult to evaluate. Cognitive dysfunction includes domains such as attention, memory, and processing speed. Early studies lacked standardized tests and cut-offs defining cognitive dysfunction [43] which is reflected in the wide variation in estimated incidence (13–70%) [44]. Therefore, recent task force recommendations call for standard testing and definition criteria

[44]. Incidence of self-reported cognitive impairment tends to be higher than that measured by neuropsychiatric testing. This might reflect recall bias, but it is also plausible that testing has not been sensitive for true changes that might be perceptible to patients. Adding to the difficulty investigating this topic are the potential confounders, including fatigue, insomnia, anxiety, depression, and stress that are common among cancer patients [43]. It is reasonable to acknowledge that this is likely a long-term side effect of cancer therapy and try to improve function with treatment of compounding conditions as well as considering referral to occupational therapy. To date, pharmacological agents have not been shown to be effective.

Cardiotoxicity

Many cancer treatments, including cytotoxic chemotherapies (e.g., anthracycline use), radiation, and newer targeted agents such as trastuzumab and sunitinib are known to cause cardiac side effects, including accelerated atherosclerotic disease as well as cardiomyopathies (Tables 34.1 and 34.2). Risk factors for developing cardiac dysfunction with anthracyclines are cumulative dose, age (both <18 and >65), pre-existing cardiac disease and concomitant administration of other cardiotoxic agents or mediastinal radiation [45, 46]. Treatment is generally similar to that of nonanthracycline-induced cardiomyopathies; however, this has not been extensively evaluated in the survivor population. Survivors who received cisplatin, for instance for testicular cancer, have accelerated atherosclerosis [47, 48]. Despite ongoing investigation, currently there is no standard for monitoring asymptomatic survivors for development of cardiac toxicity caused by these agents [49]. Strategies evaluated include imaging, such as echocardiograms or MUGA, serum testing for B-type naturetic peptide (BNP) or troponin levels, exercise testing, or more invasive testing such as endocardial biopsies or cardiac angiography.

The cardiac dysfunction seen with trastuzumab is usually not fatal and usually reversible with discontinuation and/or treatment with cardiac medications [50]. Early studies demonstrated marked increased rates of cardiac toxicity when it is given concurrently with an anthracycline, which is no longer regularly done. Other risk factors include increasing age and cardiac dysfunction after receiving anthracyclines [51, 52]. Generally, cardiac functioning is monitored with echocardiogram or MUGA during treatment and treatment is held for asymptomatic reduction in left ventricular ejection fraction [53]. Less is known about the late cardiac effects or how patients at risk should be followed. Cardiac toxicity is also seen with other targeted agents, such as the tyrosine kinase inhibitors, that can cause oedema, hypertension, and occasionally heart failure [54].

Radiation can cause damage to all of the anatomical parts of the heart resulting in pericarditis, myocarditis, valvular damage, atherosclerosis, and conduction abnormalities. This is most pronounced in patients who have undergone chest radiation, but has been documented in breast cancer as well as head and neck cancer survivors. More modern radiation techniques such as limited radiation fields, conformational techniques, image-guided therapies, and lower radiation doses have decreased the burden of cardiac side effects; however, follow-up is limited [55]. Few studies have evaluated cardiac screening in this population. The incidence of asymptomatic disease is not known, and it is also not known if treatment of asymptomatic disease would improve outcomes [49].

Pulmonary toxicity

Pulmonary toxicity can be caused by many types of chemotherapy (Table 34.1) or radiation (Table 34.2). The most studied agents include bleomycin and taxanes, which can result in acute pneumonitis. Risk factors for bleomycin-induced pneumonitis include age, smoking, renal dysfunction, mediastinal radiation, and use of oxygen [56, 57]. Additionally, an interstitial pneumonitis has been described with newer targeted therapies such as erlotinib; this occurs generally during or soon after treatment and can be responsive to steroids and discontinuation [58]. Radiation pneumonitis is not uncommon in the treatment of lung cancer, occurring in 5–15% of patients receiving external beam radiation therapy [59] but is much less common in patients with lymphoma (3–11%) [60] or breast cancer who receive radiation (<1% for breast-conserving approach) [61]. Rarely, these patients go on to develop progressive pulmonary fibrosis. Interstitial pneumonitis, due to idiopathic pneumonia syndrome or bronchiolitis obliterans, is common in survivors of bone marrow transplantation, occurring in up to 34% [62].

Endocrine effects

Primary hypothyroidism can be caused by external radiation [63] or tyrosine kinase inhibitors [64] and is well-documented in patients undergoing hematopoietic stem cell transplant [65, 66]. NCCN recommends that survivors of head and neck cancer who have a history of neck irradiation should have screening for hypothyroidism every six to 12 months after completing treatment [67]. Additionally, hypothyroidism is a treatable cause of cancer fatigue and should be evaluated in patients complaining of this symptom [37].

Bone health/osteoporosis

Osteopenia and osteoporosis are common side effects of cancer treatments such as aromatase inhibitors, androgen-deprivation, corticosteroids, radiation, and premature menopause from chemotherapy, radiation, surgery, or ovarian suppression. NCCN, the American Society of Clinical Oncology (ASCO), and the European Society of Medical Oncology (ESMO) guidelines recommend monitoring of bone mineral density (BMD) measurements with dual-energy X-ray absorptiometry (DEXA) for patients on treatment that lowers sex steroids (including premature menopause) at initiation of treatment and with periodic follow up [68–72]. NCCN further recommends the addition of risk calculators, such as FRAX™, which incorporate other clinical characteristics to help guide management [71]. Treatment for osteopenia/osteoporosis includes vitamin D and calcium supplementation, weight-bearing exercise, smoking cessation, antiresorptive agents (e.g., bisphosphonates, oestrogen, raloxifene) and newer agents such as teriparatide and denosumab. Bisphosphonates are the mainstay of medical treatment. Use of hormones and anabolic agents such as teriparatide should be used cautiously in the cancer population, as they are contraindicated in certain cancer types.

Weight gain/metabolic syndrome

Weight gain is common in cancer survivors and can be secondary to inactivity, ageing, medication side effects (i.e. corticosteroids), low androgen levels (from androgen-depleting medication, radiation, or surgery), or smoking cessation. Additionally, those who have had stem cell transplantation (especially those with a history of chronic graft versus host disease) are at higher risk of developing diabetes than their siblings [66]. Counselling and education interventions have been modestly successful, with those that address multiple components (e.g., diet, exercise, and behavioural modification) having better results than those that focus on only one aspect [73].

Lymphoedema

Lymphoedema is fluid accumulation secondary to disruption of lymphatic vessels, usually in a limb, and is a common side effect of surgery (Table 34.3), radiation (Table 34.2), or a combination of both. It is measured with circumferential or volumetric methods. Although commonly associated with breast cancer, it can occur any time lymphatic drainage is disturbed, such as in nodal evaluation for melanoma, surgery for sarcoma, or any pelvic treatment. It can result in pain, dysfunction, and a propensity to infections. Rates of lymphoedema vary based on the type of surgery, the use of adjuvant radiation, and lymph node evaluation. In breast cancer survivors, the incidence of lymphoedema is decreasing as sentinel lymph node biopsy is used more in place of a full axillary node dissection. Lymphoedema rates for patients having sentinel lymph node biopsy compared to axillary node dissection are <10% versus >10% [74].

Effective treatment includes complete decompressive physiotherapy, compression (bandages/garments/pneumatic devices), manual lymphatic drainage, and exercise. Complete decompressive physiotherapy is a regimen that combines compression and manual lymphatic drainage and is superior to compression alone [75]. Additionally, careful weight-based exercise improves outcomes [76]. Early recognition and treatment are felt to be important.

Bowel and bladder dysfunction

Patients undergoing treatment for prostate, colorectal, bladder, and gynaecological surgeries are at risk for bowel and bladder dysfunction (Table 34.3). Treatment for prostate cancer with surgery can result in urinary incontinence and erectile dysfunction, whereas treatment with radiation can result in both urinary and faecal incontinence. Newer nerve-sparing surgeries reduce the risk of erectile dysfunction for men. Similarly, improvements in the treatment of bladder cancer have been made with research underway in the use of bladder-sparing treatments and continent urinary ostomies.

Patients can have ostomies after many types of pelvic surgeries (rectal, gynaecological, bladder). There is some evidence that ostomies result in more sexual dysfunction, psychological distress, and restrictions on social functioning than sphincter-preserving surgeries [77]. In contrast, a newer Cochrane Review did not find consistent results in the published literature and concluded that quality of life might not be worse for those rectal cancer patients treated with surgery that included creation of a colostomy [78].

Sexuality

Sexuality is multifaceted and influenced by physical, hormonal, psychological, and social factors even without a cancer diagnosis. Cancer can affect each of these aspects. Local treatment such as surgery or radiation for gynaecological, urinary, or gastrointestinal cancers can result in loss or dysfunction of sexual anatomy or in bowel or bladder incontinence. Hormonal therapies can affect erectile function, libido, and vaginal plasticity and dryness. Changes in

appearance or emotional state can result in less confidence and comfort in intimate situations. Because of the complexity of issues that often underlie sexual dysfunction, a multidisciplinary team including psychiatric/psychological and medical evaluations and lifestyle and cognitive behavioural therapy techniques is recommended [79–81].

Premature menopause

Premature menopause can result at the time of treatment or years later. It results in infertility (discussed below separately), vasomotor symptoms such as hot flashes and sleep disturbance, hormonal changes resulting in dyspareunia, and other health effects such as accelerated cardiovascular disease and osteoporosis. Management of vasomotor symptoms includes treatment with hormone replacement if appropriate oncologically, antidepressants such as venlafaxine, as well as complementary treatments such as acupuncture. It is important to encourage healthy habits such as sufficient vitamin D and calcium intake combined with weight-bearing exercise for bone health in conjunction with regular interval screening for osteoporosis and appropriate treatment if found. Management of these symptoms is described in Table 34.4. All of these effects should be monitored and managed.

Infertility

Fertility is an important and often inadequately addressed issue for many younger patients facing a new cancer diagnosis. Although many survivorship issues might be best addressed at the time that the effects become evident, fertility is a survivorship issue that is most appropriately addressed prior to cancer treatment if at all possible. Chances of treatment-induced infertility depend on

Table 34.4 Management of premature menopause

Issue	Management
Hot flashes	Antidepressants
	◆ SSRIs (selective serotonin reuptake inhibitors)
	◆ (avoid strong cyp2da inhibitors with concurrent tamoxifen)
	◆ Venlafaxine
	◆ Gabapentin
	Hormone replacement therapy (if oncologically appropriate)
	Complementary treatments (e.g., acupuncture)
Sleep disturbance	Zolpidem
	Exercise
Dyspareunia	Water-based lubricants
	Hormone replacement therapy (if oncologically appropriate)
Bone Health	Sufficient vitamin D and calcium intake
	Weight bearing exercise
	Regular osteoporosis screening
	Tobacco cessation
	Recommendations for alcohol in moderation
Cardiovascular health	Age and risk-based assessment and primary prevention
	Encourage optimal health behaviours (e.g., tobacco cessation)

Table 34.5 Fertility preservation strategies for men and women undergoing cancer treatment

Status	Men	Women
Clinically available	Sperm banking Embryo cryopreservation	Embryo cryopreservation Conservative gynaecological surgery Oophoropexy
Investigational	Testicular tissue cryopreservation	Oocyte cryopreservation Ovarian tissue cryopreservation Gonadal suppression with GnRH antagonists

sex, age, prediagnosis factors, and specific treatment regimens. Standard techniques for fertility preservation include sperm and embryo cryopreservation, but many others are under investigation (Table 34.5). Conservative gynaecological surgery and oophoropexy, which is a procedure to shield the ovaries from radiation, are other methods of preserving fertility in appropriate patients [82]. Given that there are viable options available for patients it is important to be proactive in addressing fertility early in a diagnosis. Published guidelines recommend discussion of fertility as part of informed consent and stress that this should be done as early as possible [82]. Although data are limited, fertility preservation does not appear to increase cancer recurrence, even for hormonally sensitive tumours. Very little is published about adoption after a cancer diagnosis, although it does appear that there can be hurdles for those who chose this option [83]. There are several patient-centred informational websites that provide information and help with decision-making [84, 85].

Improvements in treatment over time

Recognition of these late and long-term effects has resulted in the modification of treatment regimens with the purpose of improving survivorship while maintaining similar efficacy/cure rates. Widely adopted predictive testing of the effectiveness of chemotherapy for individual women with hormone-sensitive breast cancers allows women to forgo chemotherapy in situations in which they are unlikely to benefit [86]. Furthermore, surgical approaches minimizing morbidity, such as limb-sparing [87] and larynx-sparing surgeries [88], are increasingly achieved, as is the omission of radiation for low-risk Hodgkin lymphoma [89].

Psychosocial long-term and late effects

Cancer can have a profound effect on an individual's psychosocial health (Table 34.6). Survivors can experience long-lasting psychological effects including depression, anxiety, body image concerns, and loss of social role functioning, including partnering, parenting, and working. Recently, psychosocial late effects have been better recognized and are actively being researched with increased focus on patient-centred outcomes.

Depression

Depression is not uncommon in the survivor population. Risk factors for distress (depression and/or anxiety) are younger age, more advanced disease, more physical symptoms, and shorter time since

Table 34.6 Potential Psychosocial Late Effects

Potential psychosocial late effects	Population/details	Recommendations/management*
Depression and Anxiety	At higher risk: Younger age More advanced disease Physical symptoms Shorter time since diagnosis Rates of 20–30% at five years	Treatments: Antidepressants Individual and group therapy Psycho-education Relaxation Non-pharmacological treatments appears more effective for patients with anxiety
Fear of recurrence	At higher risk: Younger age White or Hispanic (versus Black) Less education Shorter time since diagnosis Treatment with chemotherapy Depression	Recognition of the problem by physicians Identification of patients at higher risk
Personal Growth	Approximately one-half of patients report personal growth after a diagnosis of cancer. More likely in women and younger patients.	Provide positive reinforcement.
Finances	Younger survivors are at particularly high risk to not be employed. Cancer expenses are high. Many survivors forgo care secondary to expense.	Routine questioning about financial concerns and referral to appropriate resources including social workers, occupational therapists, etc. Educating patients about important survivorship follow up
Disability	Rates are higher than in the general population.	Newer treatment approaches might help prevent disability. Referral to physical and occupational therapy.
Social Role Functioning	Marriage: Interpersonal relationships, such as marriage, are stressed. Parenting: 24% of cancer survivors have children under 18 years of age.	Routine questioning and involvement of social workers and other psychotherapists. Specialized social work care targeted at parents that assists with conversations about disclosure and coping.

* Recommendations are largely based on clinical practice rather than evidence-based because of lack of supporting studies.

diagnosis [90]. Depression rates range from 3% to 17% for survivors, but are higher in those with active cancer [32, 90, 91]. Survivors more than five years out from diagnosis frequently still report symptoms of depression or anxiety (20–30%) [92]. Depression is inversely correlated with quality of life [90]. Furthermore, depression has been associated with poorer cancer outcomes [93]. Cancer survivors have also recently been shown to have increased rates of suicidality [94]. Thus, routine screening for distress in survivors is important as effective treatments are available, such as antidepressants as well as non-pharmacological treatments including individual and group therapy, cognitive behavioural therapy, psychoeducation, and relaxation [95, 96].

Anxiety

The prevalence of anxiety in cancer survivors appears close to that in the general population; however, there is likely a subgroup that experiences considerable anxiety secondary to cancer diagnosis and treatment. Risk factors for anxiety are similar to that of depression. Non-pharmacological interventions appear to be slightly more beneficial in survivors with anxiety rather than depression [96].

Fear of recurrence

Survivors and their families often experience a fear of cancer recurrence that can result in interpretation of somatic stimuli to be symptoms of recurrence, increased general anxiety or limited planning for the future [97, 98]. Most long-term survivors (>5 years from diagnosis) have some concern about recurrence, with a smaller percentage (10–31%) having high levels of fear of recurrence [99]. Factors associated with higher levels of fear of recurrence are younger age, white or Hispanic race (versus black), less education, fewer years since diagnosis, and treatment with chemotherapy. Fear of recurrence is also associated with lower quality of life, fatigue, and depression. Potential strategies to address this fear are education and psychotherapy. The goal is not to eliminate worry, but to reduce maladaptive fear of recurrence and to redirect worry into positive self-care. Patient–provider interactions are likely critical.

Personal growth

In contrast to studies suggesting worse psychological state after cancer, there is also a literature that suggests improvement, which has aptly been named post-traumatic growth [100, 101]. A survey

study of survivors reported that their cancer experience had provided new philosophy of life (59% of respondents), greater appreciation of life (47%), and emotional growth of the family (38%) [101]. This effect appears to depend on gender and age: women and younger patients report more personal growth after a cancer diagnosis, whereas men and older patients tend to minimize the impact of cancer on their lives [102].

Social role functioning

Social roles, including partnering, parenting, and working, change considerably over a person's lifetime and a cancer diagnosis can have a profound effect on these roles. Much of the literature looking at partnering and parenting is in survivors of childhood cancer. However, a diagnosis of cancer in young adulthood can also have significant effects on these roles and subsequently on quality of life [103]. Although survivors of childhood cancer have lower marriage rates, there appears no consistent difference in marital status between adult cancer survivors and the general population [104–107]. However, the effect of a cancer diagnosis on quality of life depends on both the gender and coping strategies of the survivor and their spouse in married cancer survivors [108–110]. Better studied is the effect of social support, specifically in marriage, on cancer outcomes; a large meta-analysis demonstrated better social support is associated with lower cancer mortality [111].

Although 24% of cancer survivors have children younger than 18 years of age in the US, accounting for 2.85 million children [112], relatively little has been published about either the children or the survivor parents. Most of the studies are small and qualitative, but do describe important themes of disclosure, communication, and family life [113]. Recently, quantitative scales evaluating parenting-specific distress have been developed [115]. Appropriately, NCI has designated family issues a top research priority [115].

Economics/disability

A diagnosis of cancer can have profound financial effects. Cancer survivors are more likely to be unable to work [26, 27] and to have public rather than private medical insurance [116] compared to those with no cancer history. Out-of-pocket medical expenses for cancer patients are high [117, 118]. Many survivors (up to 21%) forgo medical care secondary to cost [116, 118].

Health behaviours

Survivorship focuses on prevention of recurrent disease, new primary malignancies, and improving functionality. Central to these goals are modifiable health behaviours (Table 34.7). Encounters with the medical profession are 'teachable moments' that can be used to influence patients to choose healthy behaviours, such as tobacco cessation, diet, physical activity, and weight management [8]. Indeed there is a power of suggestion as demonstrated by a randomized controlled trial in which an oncologist's recommendation to exercise after an early diagnosis of breast cancer increased rates of exercise significantly compared to control [120]. Timing also appears critical, with early intervention (within three months of diagnosis for tobacco cessation) being more effective than later recommendations [121].

Smoking cessation

Of modifiable behaviours, tobacco cessation may be the one that physicians are best poised to affect (Table 34.7). A physician's recommendation to quit is an important motivator for many smokers. Tobacco cessation is important in prevention of second primary tumours and primary prevention of heart and lung disease. Smoking at diagnosis is related to worse cancer-specific morbidity and survival [122]. Evidence-based methods to improve abstinence among the general population should be effective in cancer survivors as well [123]. Among smokers diagnosed with cancer, several interventions have been effective including those with nurse-delivered interventions, telephone counselling, peer counselling, education, and nicotine replacement.

Smoking prevalence in cancer survivors varies by age and cancer type. Of considerable concern is the stunningly high rate in adult survivors aged 18–40 compared to the general population who smoke (38–45% compared to 26–30%) [124–126]. In this young adult population our efforts should include a focus on prevention as well as cessation [127]. Although lung cancer patients have higher smoking rates at diagnosis, there is a higher proportion that quit compared to colorectal cancer survivors [128] suggesting specific opportunities to improve care.

Physical activity, diet, and weight management

Physical activity/exercise, diet, and weight management are interconnected and are all emerging as important factors in cancer prevention. Exercise has been fairly well studied in cancer survivors and is associated with better quality of life, physical functioning [129], anthropometric measures, and social functioning, and with less sleep disturbance. Despite the myriad of improvements exercise can provide to survivors, the effect of exercise on cancer recurrence is unknown. More data is emerging showing that weight is independently associated with cancer outcomes. Given its integral part in weight management, along with diet, exercise becomes a target for cancer treatment.

To date, no specific diet has been found definitively to prevent cancer or cancer recurrence [130]. Several diet interventions have been carried out. The largest two are Women's Intervention Nutrition Study (WINS) randomizing 2437 postmenopausal breast cancer survivors to the intervention of a low-fat diet [131] and the Women's Healthy Eating and Living (WHEL) study of high vegetable and fruit intake in 3088 breast cancer survivors [133]. Encouragingly, both studies showed improvement in diet in the intervention arms, but the cancer endpoints were mixed. In the WINS trial, patients on the low-fat diet had lower breast cancer recurrence; however, there was no overall survival benefit. No difference in breast cancer recurrence or overall survival was seen in the WHEL study. Post hoc analyses suggested potential benefit for those who lost weight or those who were more physically active, underscoring the intrinsic relationship between diet, exercise, and weight management and their effects on cancer. Although more research is needed to understand these effects and to determine effective interventions, the American Cancer Society (ACS) has published general recommendations on nutrition and physical activity for survivors (Table 34.7) [130].

A diagnosis of cancer is often a life-changing event; patients can feel a loss of control and often explore ways to regain a sense of well-being. Improving lifestyle behaviours is one possible way of doing this, and this can have significant effects on their physical functioning, quality of life, and even cancer outcomes. Additionally, it is recognized that cancer survivors are also at increased risk of

Table 34.7 Modifiable health behaviours to consider in cancer survivors

	Evidence/situation	Recommendation
Tobacco cessation	Smoking is a carcinogen. Depression and alcohol/substance abuse may require more intense interventions	5As: Ask, Advise, Assess willingness to quit, Assist, Arrange follow-up Both brief and intensive interventions are effective. National quit hotline Pharmacological treatment which reliably improved abstinence rates: ◆ Buproprion SR ◆ Nicotine replacement therapy ◆ Varenicline
Alcohol use	Alcohol is a primary risk factor for head and neck, oesophageal and hepatocellular cancers. It possibly increases risk of primary breast and colorectal. Moderate alcohol intake is likely safe.	Screening questions for at risk patients Physician recommendations Referral to counselling Pharmacologic deterrents: ◆ Naltrexone ◆ Disulfiram ACS Guideline: Limit alcohol consumption to one drink/day for women and two drinks/day for men.
High-risk sexual behaviours and illicit drug abuse	HIV and HPV related cancers	Take a sexual history Counsel on risk reduction if appropriate
Diet	Mixed results on benefit of low fat/high fibre	ACS guidelines: Consume a healthy diet with emphasis on plant sources: ◆ maintain healthy weight ◆ 5+ vegetables and fruits/day ◆ choose whole grains over processed ◆ limit consumption of processed and red meats Focus on weight management
Physical activity/ exercise	Benefits include weight management, improves distress measures, and functional status.	ACS guidelines: Recommend 30+ minutes of vigorous exercise daily 5/week. Refer to physical and occupational therapy when appropriate to improve functional outcomes.
Weight management	Obesity is a risk factor for primary breast, colorectal, oesophagus, liver, gallbladder, pancreas, kidney, uterus, and advanced prostate cancer. Evidence suggests that obesity at diagnosis and weight gain may increase the risk of cancer recurrence for some types of cancer (breast, colorectal cancer).	ACS guidelines: ◆ Balance caloric intake with physical exercise ◆ Avoid weight gain over time ◆ Achieve and maintain a healthy weight if current overweight or obese.

Note: ACS guidelines are for cancer prevention (not specific to survivors).

other diseases including heart disease, diabetes, and osteoporosis, all of which benefit from improved health behaviours.

Coordination of care

One area of active research is optimal follow-up care for survivors. Some survivors' needs are unique, but not generally out of the purview of primary care providers. Randomized controlled trials of early stage breast cancer patients have demonstrated no difference in cancer outcomes regardless of whether an oncologist or a primary care doctor who is educated about patients' cancer-related concerns provides follow-up care [133]. Surveys of both Canadian and US primary care physicians consistently show that there is reasonable willingness to care for survivors, even exclusively, but that most want specific guidelines, open communication with the oncologist, and specific survivorship training [134–136]. This model of care-sharing by primary care doctors has been readily adopted for many medical subspecialties including psychiatry, cardiology, neurology, nephrology, and endocrinology. The willingness of primary care doctors, stipulated upon need for guidance, underscores the need for development of comprehensive evidenced-based survivorship guidelines. Taking this a step further,

countries with nationalized healthcare that recognize the importance of self-management in the process of recovery from cancer have begun to develop programmes in this area [137].

Survivorship care planning

One proposal to assist in coordination of care has been survivorship care plans [8]. It has been recommended that every cancer survivor receive a care plan which contains a personal treatment summary, as well as possible late/long-term effects, signs of recurrence, guidelines on follow-up care, identification of a patient's providers, lifestyle recommendations, and supportive resources [8, 138–140]. Early studies of survivorship care plans have been mixed; one randomized controlled trial evaluating the effects of care plans showed no difference in patient-reported outcomes [141]. Further, the ideal structures for provider–patient and provider–provider communications in survivorship remain unknown. Regardless, there is clearly a need for improved communications: in practice, it appears that little information is provided to patients who have completed active treatment. A population-based survey found that only 40% received written summary of treatment, and only 74% received follow-up instructions [142], suggesting significant room for improvement. There are resources available to assist providers and patients in care planning from the office of cancer survivorship at NCI [143], through the Lance Armstrong Foundation [144], and through ACS [145]. These resources are being developed internationally and country-specific resources are mounting (e.g., National Cancer Survivorship Institute in the UK [146]) [137].

Clinical practice guidelines

Guidelines for survivorship care are cancer-type specific and can be tailored for the individual's cancer subtype, stage, and treatment received. There are a myriad of different guidelines published by reputable cancer organizations, which were compiled and reviewed by Committee on Cancer Survivorship and published in *Cancer Patient to Cancer Survivor* [8]. Ideally guidelines would address all aspects of survivorship issues, namely: (1) surveillance for recurrent disease; (2) monitoring/prevention of a second primary; (3) management of late sequelae of disease; (4) management of late complications of treatment; (5) management of psychological, social, and spiritual issues; (6) management of genetic issues (reviewed in Chapter 31) and 7) locus of care [8]. However, existing guidelines tend to focus on surveillance and screening with far fewer addressing issues of physical late effects and fewer addressing psychosocial concerns. Furthermore, many recommendations rely on expert consensus/opinion rather than high-quality evidence. Recently, ASCO launched a survivorship committee that plans to develop guidelines focused on survivorship care.

Conclusion: future directions

As cancer incidence and life expectancy after a cancer diagnosis continue to increase, a higher proportion of the population will be cancer survivors. Survivors face unique challenges in terms of disability, chance of recurrence, or second primary malignancy and long-term or late effects of disease or treatment (physical and psychosocial) that are important to recognize and address. Much of the research thus far has been focused on documenting these issues.

Providing optimal survivorship care to all patients with a history of cancer requires evidence-based clinical practice guidelines and systems to implement them. At present, however, there are substantial limitations to the evidence base, available guidelines, and current care delivery systems for cancer survivors. To address these significant gaps, the NCI has delineated several priorities for survivorship research including: (1) chronic and late effects; (2) interventions; (3) healthy lifestyles and behavior; and (4) family issues [115]. Continued efforts to coordinate survivorship care, incorporating new information as it comes along, is also paramount to enhance the lives of the growing population of cancer survivors.

Epidemiology

Head and neck squamous cell carcinoma (HNSCC) is a heterogeneous disease arising from the mucosal epithelium of the oral cavity, pharynx, and larynx. The most common risk factors for HNSCC development are tobacco and alcohol use, as well as high-risk human papillomavirus (HPV) infection [1, 2]. Concomitant use of tobacco and alcohol also appear to contribute synergistically to HNSCC carcinogenesis. Human papillomavirus-associated squamous cell carcinoma typically occurs in the oropharynx and its incidence is increasing in the Western world [3]. HPV-negative and -positive HNSCC are demographically, biologically and clinically distinct entities with more favourable outcomes associated with HPV-positive tumours of the oropharynx [4–6].

Molecular biology of head and neck cancer

Molecular progression

Human papillomavirus-negative HNSCC develops predominantly in smokers, and a stepwise progression of molecular alterations in the squamous epithelium has been well-established (see Figure 35.1) [7]. It is currently believed that the molecular progression model associated with the phenotypic transformation of normal epithelium to dysplasia and invasive carcinoma constitute stepwise genetic and epigenetic alterations that include gene amplification, deletion, mutation, and methylation [7]. Although the primary events remained unknown, the early alterations associated with increased genomic instability in the squamous mucosal field comprise of frequent loss of heterozygosity, functional loss of tumour suppressors and/or a functional gain of oncogenic activity [7].

In contrast to the HPV-negative HNSCC, the molecular progression of HPV-associated cancer remains largely unknown. HPVs are small, non-enveloped DNA viruses, and their genome encodes various oncoproteins (E5, E6, and E7) and two capsid proteins (L1 and L2) for virion production [8]. The integration of the virus and the human genome entails the disruption of the early exons of the HPV leading to the activities of the E6 and E7, as the critical drivers of carcinogenesis through the degradation of p53 and pRb, respectively (see Figure 35.2) [9, 10]. Loss of p53 and pRb, two potent tumour suppressors, initiates genomic instability and leads to cell cycle deregulation [9]. Although the E6 and E7 are clearly deleterious, the simple expression of these oncoproteins is not sufficient to transform reticular epithelial crypt cells into invasive cancer. Additional genetic aberrations must be acquired. Thus, the genetic alterations required for further malignant transformation after initial HPV infection still need to be elucidated.

Loss of tumour suppressor genes

Based on the current genomic data, it is clear that the majority of HNSCC-related mutations or deletions occur within critical tumour suppressors, resulting in loss of function. Additionally, these alterations are particularly inherent to HPV-negative disease. Among the compromised tumour suppressors, *TP53* and *CDKN2A* (p16) are well established as poor prognostic biomarkers in HNSCC.

Wild type p53 is involved in a wide range of cellular processes including autophagy, DNA damage response, cell cycle regulation, senescence, apoptosis, and ATP generation by oxidative phosphorylation [11]. Mutated p53 accumulates in the nucleus as its altered tertiary structure does not allow for proper folding, ubiquitination, and degradation. Recent data indicate mutations that affect p53 DNA binding (disruptive mutations) are associated with worst clinical outcome compared to non-disruptive mutations. However, the presence of any *TP53* mutation is associated with worse outcome compared to wild-type *TP53* patients treated with surgery for curative intent [12]. Thus, further delineation of TP53 mutant functional complexity is of critical importance for the incorporation of these biomarkers into the development of novel HNSCC therapeutics [11].

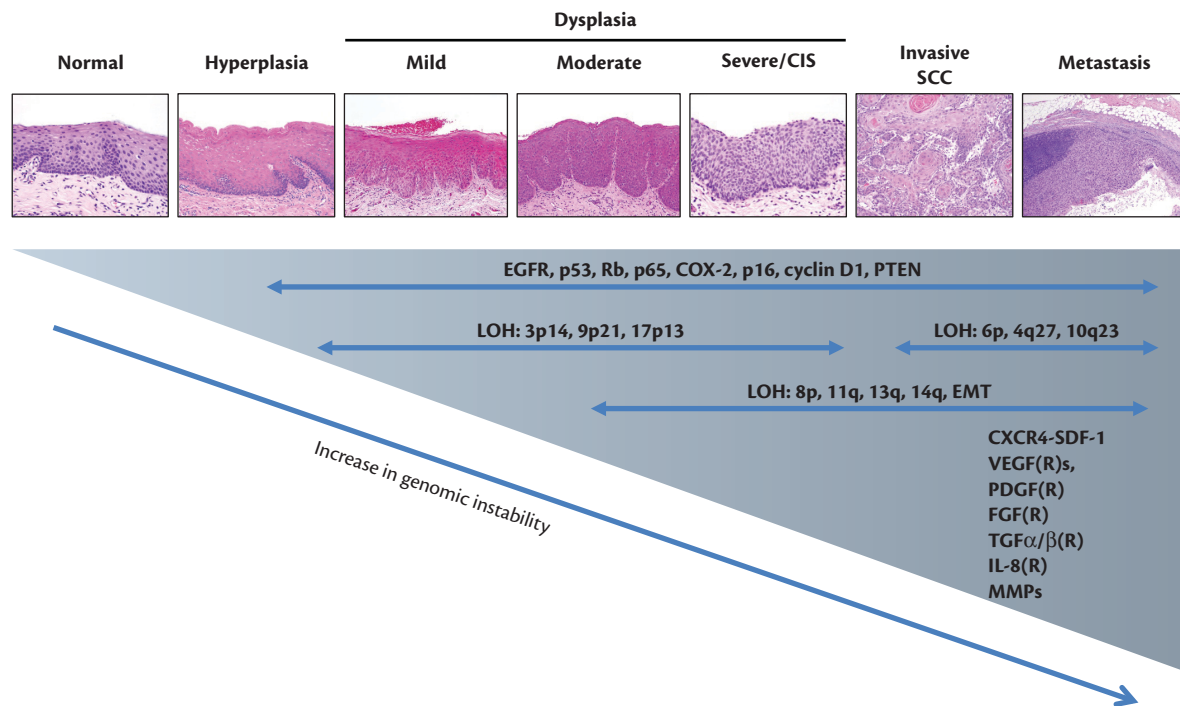
Another important tumour suppressor gene in HNSCC is *CDKN2A*, which encodes p16. *CDKN2A* is located at Chr 9p21 and inhibits the kinase activity of CDK4 and CDK6, which induces cell cycle arrest [13]. p16 protein expression is cell cycle dependent and is focally expressed in only 5–10% of normal squamous epithelium. In HNSCC, p16 function is frequently lost by either mutation,


Fig. 35.1 Molecular progression of human papillomavirus-negative head and neck squamous cell carcinoma. Each step is associated with increased genomic instability or aneuploidy involving frequent loss of heterozygosity (i.e. chromosome 3p14, 9p21, 17p13, 8p, 11q, 13q, 14q, 6p, 4q27 and 10q23), functional loss of tumour suppressors (i.e. p53, NOTCH1, p16, PTEN and pRb) and/or functional gain of oncogenes (i.e. cyclin D1, EGFR, RAS and PI3K).
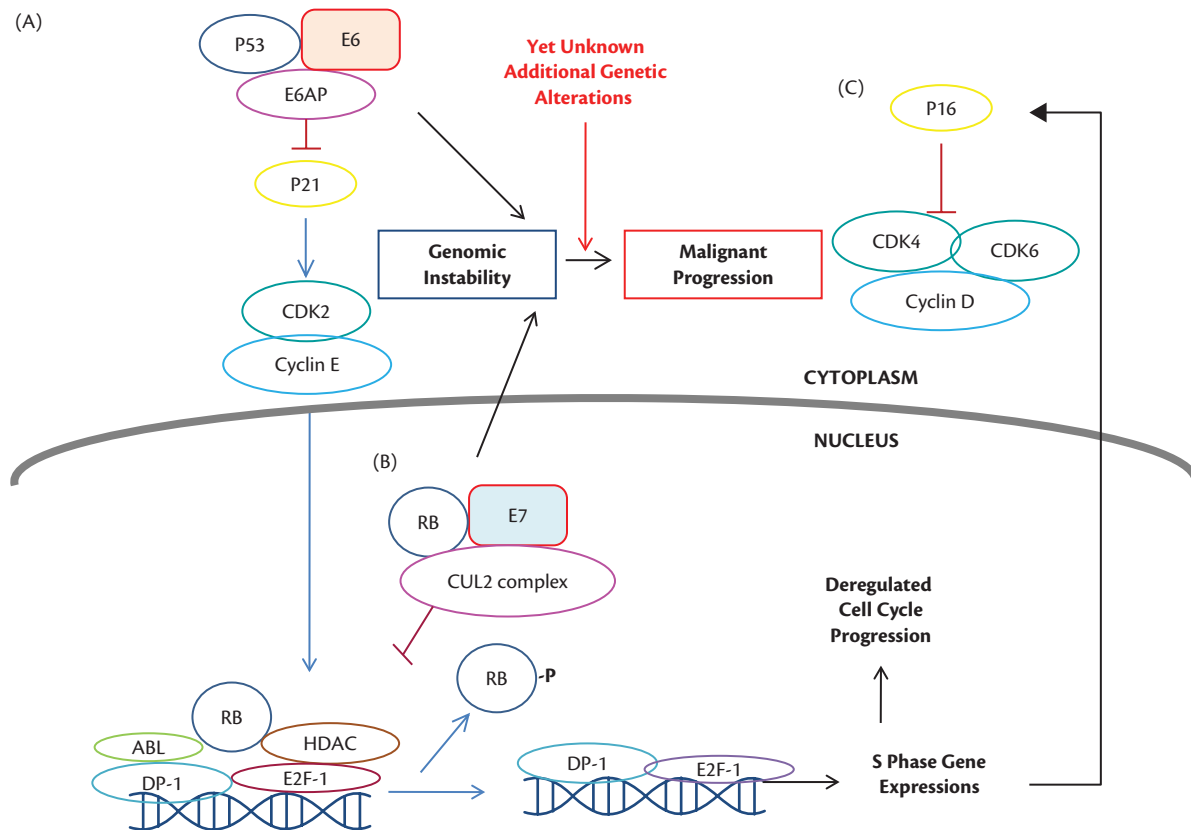

Fig. 35.2 Carcinogenesis induced by human papillomavirus. (A) E6-mediated degradation of p53; (B) E7-mediated degradation of pRb; and (C) upregulation of p16 through feedback loop induced by pRb loss and uncontrolled cell cycle progression.

gene/chromosome deletion, or promoter hyper-methylation of the *CDKN2A* gene [14]. Collectively, deregulation of p16 can occur in up to 90% of HPV-negative HNSCC, while p16 up-regulation is observed in HPV-positive tumours due to E7-related pRb loss (see Figure 35.2) [9, 15]. This results in diffuse over-expression of p16 in tumour cells and is considered a reliable surrogate biomarker for HPV positivity in oropharyngeal HNSCC.

Gain of oncogenic function

HNSCC-specific oncogene characterization is important for targeted therapies. Three common oncogenic alterations are observed in HNSCC: *CCND1* (cyclin D1), *EGFR*, and *PIK3CA*. Although these modifications are shared between HPV-positive and -negative HNSCC, differences in the frequency of their distribution are evident. In HPV-negative tumours, *CCND1, EGFR*, and *PIK3CA* mutation/amplification are seen in 32%, 15%, and 34%, respectively [16]. Meanwhile, the same alterations occur in 8%, 3%, and 56% of HPV-positive tumours [16], respectively [15]. Consequently, these data may have therapeutic implications and further clinical research targeting these alterations is required.

Genetic characterization

Recent whole exome sequencing studies of HNSCC have further validated the separation of HPV-negative and -positive HNSCC into molecularly distinct entities [5, 6]. When tumours were stratified by HPV status, HPV-positive tumours had significantly fewer mutations compared to HPV-negative tumours (4.8 versus 20.6 mutations per tumour). Commonly mutated genes included *TP53, NOTCH1, CDKN2A, HRAS, PTEN*, and *PIK3CA* [5, 6]. Of these, *TP53* is the most commonly mutated gene, disrupted in 62–78% of HPV-negative tumours while it was not detected in HPV-positive tumours to any appreciable degree [5, 6]. These mutations would functionally disrupt epithelial differentiation and cell cycle regulations and lead to an increase in cellular proliferation. Additional mutations were observed in pathways that regulate nuclear polarity, calcium sensing, and suppression of apoptosis, which would collectively arrest maturation and provide a proliferative advantage [5].

Molecular and growth factor characterization

At the expression level, Chung, et al. described four subtypes of HNSCC based on gene expression with distinct molecular characteristics: Group 1 tumours with high EGFR and ligand (TGFA) expression demonstrating significant EGFR activation; Group 2 tumours demonstrating epithelial-to-mesenchymal transition (EMT) with high expression of vimentin; Group 3 tumours with normal mucosal epithelium-like features; and Group 4 tumours with an up-regulation of xenobiotic metabolism, mostly observed in heavy smokers [17]. Subsequently, these four subtypes were validated by two independent datasets and each group was termed the Basal, Mesenchymal, Atypical, and Classical subtypes, respectively [15, 18]. The Atypical subtype included the majority of the HPV-positive HNSCC. In addition, various aspects of the HPV-negative HNSCC progression model could be associated with the subtypes defined above [18].

In addition, a recent gene expression study enriched with HPV-positive HNSCC (44% compared to 10–19% in other studies) revealed that tumours in the Atypical subtype can be further subdivided into two groups, resulting in five potential molecular subtypes of HNSCC [19]. Current evidence suggests the Atypical subtype

should be reclassified as HPV-Mesenchymal and HPV-Classical subtypes due to the gene expression these tumours share with the Mesenchymal and Classical subtypes. However, these tumours that are aetiologically distinct harbour HPV-specific gene expression. Further delineation of the molecular characteristics associated with HNSCC through functional genomics is expected greatly to advance the development of targeted therapeutics by identifying and characterizing subtype-specific prognostic and predictive biomarkers.

Summary of molecular biology of head and neck cancers

Using the current technological advancements in genomic analysis, we have gained comprehensive knowledge and insight into the molecular biology of HNSCC. In every respect, HNSCC is a heterogeneous disease which has now been molecularly characterized into five subtypes. Predominantly, these alterations are defined by tumour suppressor loss in HPV-negative disease, which is associated with poor prognosis and therapeutic challenges. In contrast, HPV-positive patients have good overall prognosis; however, a subset of these patients associated with worse outcome has been identified. The challenge facing future investigations is efficiently to translate what we have learned with these tools into clinically meaningful advancements in patient treatment. These are challenging goals and will require the concerted effort of HNSCC investigators from a variety of disciplines.

Pathology of head and neck tumours

The histopathologic neoplastic entities of the head and neck region are widely diverse and complex. The most common tumours arise from lining epithelium, salivary glands, and sinonasal sites. This section will focus on the most frequently encountered malignancies at these locations.

Squamous mucosal tumorigenesis

Carcinoma arising from the squamous and metaplastic mucosal lining of the head and neck sites can be broadly classified into conventional and viral-associated squamous carcinoma.

Conventional squamous carcinoma

Squamous tumorigenesis develops from the squamous mucosa of the larynx and sinonasal sites, of the oral cavity, larynx, and squamous metaplasia of respiratory epithelium [20]. These lesions are typically seen in relatively older individuals with history of exposure to and/or abuse of tobacco products and alcohol. Squamous carcinoma at these sites is typically preceded by premalignant lesions [21]. The incidence of progression of these lesions to invasive carcinoma varies considerably from patient to patient and it is currently believed to range from 10–45% [21, 22].

Premalignant squamous lesions

The progression of premalignant lesions to invasive squamous carcinoma is a multistep process resulting from progressive accumulation of genetic and epigenetic alterations [22–24] leading to invasive carcinoma (Figure 35.1).

Squamous carcinoma

Histopathologically, squamous carcinoma are classified into conventional and non-conventional forms. The conventional form is the most dominant, and is graded based on the level of squamous

Table 35.1 Head and neck squamous subtypes

Factor	Verrucous	Papillary	Basaloid	Sarcomatoid
Age	>50	30–50	>50	30–50
Grade	Low	Low	High	High
Sex	>Male	>Male	>Male	>Male
Gross	Exophytic	Exophytic	Endophytic	+/−polypoid
Site	Oral, larynx	Larynx, nasal cavity	Hypo-, oro-pharynx	Larynx, lip, oral cavity
Viral	No	?	Yes in oropharynx	No
Metastasis	No	Low	High	High when endophytic

manifestations and keratin differentiation into well, moderate, and poorly differentiated. The pathologic features associated with aggressive outcome include finger-like invasive pattern, perineural invasion, depth of invasion, and distance of tumour to resection margins.

There are several less frequent phenotypic variants of squamous carcinoma; some are also shared with viral associated carcinoma of the oro- and nasopharyngeal sites (see Table 35.1 and Figure 35.3).

Verrucous carcinoma (VC)
VC is a locally aggressive, well-differentiated squamous carcinoma characterized by a warty-like appearance and broad-base rete ridges with downward growth into the stroma. In its pure form this lesion does not metastasize while hybrid verrucous and conventional squamous carcinoma may retain the potential for metastasis. The differentiation of these lesions is from verrucous hyperplasia and is difficult on small biopsies or partial excisions. The distinction can be made, however, by en bloc excision of the lesion with the adjacent mucosal shoulders. Both lesions should be excised completely.

Papillary squamous carcinoma
This is a rare type of squamous carcinoma that is generally restricted to certain locations including the larynx and the nasal cavity. It is characterized by papillae lined by neoplastic cells and an exophytic appearance with and without invasion. Evidence from an association with high- and low-risk human papilloma virus (HPV) infection has been reported.

Basaloid squamous carcinoma
This is a high-grade variant that typically presents in the pyriform sinus, tonsils/oropharyngeal sites. In non-oropharyngeal sites they are negative for HPV and associated with premalignant non-invasive lesions. The significance of recognizing this variant is important in the differential diagnosis with solid adenoid cystic carcinoma, basal cell carcinoma, small-round-cell tumours, and melanoma on small biopsy materials. A selective panel of immunohistochemical markers can be used to establish the diagnosis.

Sarcomatoid squamous carcinoma
This rare form assumes sarcoma-like morphology and represents a transformation of conventional squamous carcinoma. The most common presentation is in the larynx, which may present as an
Fig. 35.3 Non-conventional squamous carcinoma subtypes in head and neck. (A) Verrucous carcinoma; (B) papillary; (C) basaloid; (D) sarcomatoid.
Fig. 35.4 Oropharyngeal (OPC) and nasopharyngeal carcinoma (NPC). (A) Light microscopic, HPV in-situ positivity in tumour cell nuclei, and p16 immunostaining note strong homogeneous (cytoplasmic and nuclear) positivity in tumour; (B) light microscopic and EBV (EBER, Epstein–Barr virus-encoded small RNA) in-situ image of typical undifferentiated squamous carcinoma highlighted also by keratin.

exophytic polypoid mass or with deeply infiltrative endophytic growth. These lesions may cause differential diagnostic challenges with sarcoma, spindle cell melanoma, and pseudosarcomatous lesions. Immunohistochemical positivity for keratin may allow for the exclusion of sarcoma and melanoma. Negative results, however, may occur and close interaction between pathologists and head and neck surgeons are critical to the diagnosis and management of these lesions.

Viral associated head and neck carcinoma

These entities are commonly seen as undifferentiated/basaloid squamous carcinoma morphologies. Both arise in neighbouring structures that are lined by respiratory or squamous epithelium that covers and overlies lymphoid rich stroma. The distinctions between these forms may often be arbitrary if the tumour presents at the boundary of the naso- and oro pharynx.

Nasopharyngeal carcinoma

The nasopharyngeal carcinoma is linked to the Epstein–Barr virus (EBV) especially in endemic locations (see Figure 35.4). Occasionally both EBV and HPV testing may be required for their differentiating. These tumours are histologically classified by WHO into keratinizing (type I) and undifferentiated subtypes (types II and III).

HPV-associated squamous cell carcinoma (oropharyngeal)

In contrast, to conventional squamous carcinoma which accounts for only a subset of tumours in this region, this form occurs in a different demographic population and frequency varies by country. The vast majority of these tumours are non-keratinizing/basaloid squamous carcinoma but keratinizing squamous carcinoma may also occur at these sites. The most common locations are at the base of the tongue and tonsils. These sites are characterized by invagination of squamous epithelium within the lymphoid stroma. Tumour, therefore, arise in the hidden crypts at these sites especially the tonsils. Conventional premalignant dysplastic lesions, therefore, are rarely identified. Not uncommonly, because of their location, a neck metastasis may precede the identification of the primary and may show cystic features. The majority of these cases are caused by occult primary at the base of the tongue or the tonsils. Tonsillectomy is therefore advised if the primary tumour cannot be identified by imaging. HPV in situ hybridization of high-risk variants of HPV and immunostaining by p16 are sufficient to confirm the diagnosis [25] (see Figure 35.4).

Pathology evaluation

Intraoperative evaluation

Frozen sections are central to the evaluation of depth of invasion and of oral and lingual lesions, and in assessing the status of margins. Margins assessment requires a close cooperation between surgeon and specialized pathologist. Margins can be submitted from the defect by the surgeon or by the pathologist from the specimen. Intraoperative assessment is considered the final evaluation of margins. It is generally acceptable that a distance of 5 mm from the edge of the tumour to closet margin is a safe margin [26]. The final pathologic evaluation of the primary tumour should include positive or negative statements of the following features: size, differentiation, pattern of invasion, depth of invasion, perineural involvement, status of margins, and distance from nearest margin. If lymph node dissection is performed, the report should include the type of dissection, the number
Fig. 35.5 Morphologically diverse sinonasal malignancies. (A) Squamous carcinoma (left) rising in an inverted Schneiderian papilloma (right); (B) non-enteric sinonasal adenocarcinoma, low-grade; (C) High-grade enteric sinonasal adenocarcinoma (intestinal/colonic type); (D) NK/T-cell lymphoma (angiocentric).

of positive and negative nodes per level, the size of the largest positive node, and whether extra-nodal extension is present or absent [27–29]. Other information that can also be included such a degree of immune response and vascular invasion. Since large numbers of squamous carcinoma undergo induction and/or adjuvant therapy prior to resection, the pathologic measurement should be adjusted to reflect the therapeutic effect on the resected tumour [30].

Pathologic reporting
Primary

The pathology report of conventional squamous carcinoma must include certain gross and microscopic features for accurate staging and clinical management. Typically the initial diagnosis is based on a core or biopsy of the index lesion. The biopsy evaluation should include the phenotype, the differentiation status, the presence or lack of submucosal invasion, and, if present, the depth.

The report of surgically excised specimens must include the following information: the histologic type, differentiation status, size of the tumour (three-dimensional), depth of invasion, perineural involvement, pattern of invasion (finger-like/pushing), distance of the closest margin (in mm), and involvement of adjacent structures cartilage/bone, and skeletal muscle.

Lymph node dissection

Close cooperation between the surgeon and the pathologist handling the case is critical to accurate orientation and proper reporting of the node status. Neck lymph nodes should either be submitted intact and then oriented on a template, or submitted as individual levels separately by the surgeon. The latter method is preferred.

Reporting should include the following information:

1. Total number of lymph nodes identified and the number of positive nodes.
2. The location/level of each positive node and the total lymph nodes in that level.

3. The size of the largest positive node.
4. The presence or absence of extracapsular spread (focal or extensive).

Sinonasal and paranasal sinuses

The spectrum of tumours arising in the sinonasal region is diverse arising from specialized Schneiderian respiratory mucosa, seromucous glands, and underlying supporting cells giving rise to some distinctly unique tumour types in this region (Figures 35.5 and 35.6). As sinonasal tumours except squamous carcinoma are rare, careful morphologic evaluation and more importantly immunophenotyping to confirm lineage is usually required [31].

NUT midline carcinoma (a genetic subtype of squamal cell carcinoma (SCC))

This molecularly defined tumour (rearrangement of the NUT gene on Chr 15) is favoured to be a subtype of SCC. Often midline, though not exclusively, this highly aggressive malignancy requires ancillary testing (immunohistochemistry or fluorescence in situ hybridization [FISH]) for definitive classification which is essential for prognostic implications [32].

Adenocarcinoma

Adenocarcinomas of the sinonasal region comprise 10–20% of sinonasal malignancies and are divided into three categories based on differentiation: enteric (intestinal type), non-enteric, and salivary. They are compared in Table 35.2. Prognosis is based on the tumour subtype, grade (if applicable), and stage at presentation.

Sinonasal undifferentiated carcinoma (SNUC)

This rare, aggressive tumour of still debated origin often presents as locally advanced disease morphologically showing high-grade features including frequent mitoses and prominent necrosis (see Figure 35.6C). The differential includes squamous carcinoma (often keratinizing), nasopharyngeal carcinoma (usually EBV+), neuroendocrine carcinoma, high-grade adenocarcinoma, as well as the
Fig. 35.6 Sinonasal 'small' round cell tumours morphologically overlap particularly on small biopsies. (A) Olfactory neuroblastoma with prominent Homer Wright 'pseudorosettes'; (B) sinonasal mucosal melanoma; (C) sinonasal undifferentiated carcinoma; (D) rhabdomyosarcoma, alveolar subtype.

'small blue cell tumours' [33]. A comparison of the clinicopathologic features of undifferentiated carcinomas is shown in Table 35.3.

Olfactory neuroblastoma (aesthesioneuroblastoma)

The most common neuroendocrine tumour in the sinonasal region is olfactory neuroblastoma (ONB) often a polypoid mass in the region of the cribriform plate [34] (Figure 35.6A). The Hyam's grading system (I–IV) utilizes histologic tumour features of differentiation to define risk (necrosis, mitoses, pleomorphism, architecture, rosettes, gland formation, matrix, and calcification). However, this system is currently undergoing revalidation to exclude the newer pathologic entity of SNUC [35]. As one of the 'small round blue cell' primitive tumours, ONB must be differentiated from rhabdomyosarcoma, Ewing's sarcoma, mucosal

melanoma, and the rare pituitary adenoma extending to this region. Clinicopathologic features of the small-round-cell tumours and the Immunohistochemical evaluation essential to confirm tumour lineage for treatment are highlighted in Table 35.4.

Non-epithelial tumours of the head and neck

Mucosal melanoma

Mucosal melanomas of the upper aerodigestive tract are histologically variable (small cells, rhabdoid, spindled, and pleomorphic), overlapping other tumour types particularly in the sinonasal region [36]. Risk factors, staging, and molecular profile are distinct for mucosal melanomas contrary to skin origin (see Table 35.4 and Figure 35.6B).

Sarcoma

Essentially any sarcoma may arise in the head and neck, larynx, sinonasal, and skull base regions including chondrosarcomas, osteosarcomas, rhabdomyosarcoma, Ewing's sarcoma, and chordomas, as well as rare subtypes including mesenchymal chondrosarcoma, which morphologically mimics a small-round-cell tumour in the sinonasal region [37]. Pathologic review by an experienced pathologist, in conjunction with the clinical history and radiographs, aids in a timely optimized diagnosis for treatment of these rare entities.

Rhabdomyosarcoma

Rhabdomyosarcoma, a primitive malignant tumour of skeletal muscle derivation, accounts for 45% of all head and neck sarcomas with the orbit and nasopharynx being most common. There are three subtypes with variability in differential age of onset, site predilection, and prognosis. The embryonal subtype (including spindled and botryoid variants) represents the majority of cases in children. The alveolar subtype is the prevalent morphology seen in the sinonasal region, often shows a molecular translocation, and may express aberrant markers leading to misdiagnosis [38, 39] (see Table 35.4 and Figure 35.6C). Pleomorphic rhabdomyosarcoma is rare in adults and mimics other high-grade tumours including carcinomas, melanomas and other sarcomas.

Lymphoma

The spectrum of lymphomas may involve the head and neck, often presenting in lymphoid-rich areas (tonsil, base of tongue, nasopharynx, neck and parotid lymph nodes). Three prominent subtypes of lymphoma occur in the sinonasal region: B-cell derived, T-cell derived (EBV-), and NK/T-cell (angiocentric) lymphoma, which is an EBV-positive tumour of the sinonasal region often presenting as a midline destructive process [40] (see Figure 35.5D). Lymphomas must be differentiated from other tumours and non-tumorous conditions (Wegener's granulomatosis and cocaine abuse), which may show similarly presenting destructive symptoms.

Salivary gland tumours

Salivary gland tumours represent approximately 10% of all head and neck neoplasms [41, 42]. Histopathologically, they comprise of widely varied subtypes with often overlapping features that may lead to differential diagnostic difficulties. The WHO classification of these neoplasms recognizes numerous benign and malignant subtypes. The primary assessment of salivary neoplasms is generally by fine needle aspiration cytology. This procedure is less sensitive in differentiating benign and malignant tumours. It is very helpful, however, in excluding reactive metastatic, infectious, and lymphoreticular malignancies. Primary benign and malignant salivary neoplasms are primarily managed by surgery. The pathological evaluation of the received mass may require intraoperative evaluation for assessment of malignancy and margins.

Pleomorphic adenoma

The most common benign tumour encountered clinically is pleomorphic adenoma. These tumours may not uncommonly recur or develop carcinoma. Careful histologic examination of the cellularity and malignant transformation is necessary. Of the 24 well-recognized salivary carcinomas, mucoepidermoid, adenoid cystic, and adenocarcinoma are the most common.

Mucoepidermoid carcinoma (MEC)

MEC is the most common salivary malignancy in both adults and children. It is formed of epidermoid, transitional, and mucinous

cells and graded into low, intermediate, and high based on the presence of cystic, cellular, and cytological features. The low grade is predominantly cystic and runs a benign course if completely excised. The intermediate and high-grade MEC are more aggressive and may recur and/or develop metastasis. Therefore, grading of these tumours is important for management.

Adenoid cystic carcinoma (ACC)

This is the second most common salivary malignancy and the most biologically relentless subtype [43–46]. Histologically, the tumour is generally composed of dual epithelial and myoepithelial cell formations to form tubular, cribriform, and solid patterns. At least two of these forms exist in a given tumour. The presence of a solid component is considered an ominous feature. ACC tumours are not graded and their dominant pattern typically reflects the clinical course. ACC invariability manifest perineural invasion.

Adenocarcinoma/salivary duct carcinoma

This is generally a high-grade malignancy with poor prognosis. They may present as de novo or as a malignant transformation of pleomorphic adenoma [41, 47, 48]. This entity is characterized by a remarkable morphologic and normal resemblance to mammary duct carcinoma. The following pathologic features are critical to the management of patients with these neoplasms: tumour type, grade if appropriate, size, perineural involvement, and encapsulation and margins status. In general, the tumour type and adverse features including perineural invasion, soft tissue extension, and margins status determine the postoperative therapy.

Imaging techniques for head and neck tumours

Ultrasound

Main applications include salivary and thyroid gland and lymph nodes. For salivary and thyroid gland lesions, ultrasound should aim to differentiate benign from malignant lesions, guide biopsy or the need for further imaging evaluation by computed tomography (CT) or magnetic resonance imaging (MRI), respectively, assessing lesion number and location, texture and/or cystic content, and providing an anatomical background for nuclear imaging [49, 50]. Usually, ultrasound-guided fine needle aspiration cytology (FNAC) or biopsy is mandatory for definitive diagnosis. Ultrasound (US) is the primary modality for nodal staging in thyroid cancer and complementary in HNC. In papillary thyroid cancer, an accuracy of 89% can be obtained in 6 mm lymph nodes (see Figure 35.7) [51]. In HNC, US has variable accuracy compared to CT and MRI; which can be increased by additional FNAC, reaching specificities of 100% and sensitivities to 73% [52, 53].

Computed tomography–magnetic resonance imaging

CT is performed after injection of an iodinated contrast agent using multidetector technology. MRI is performed with high-resolution T1- and T2-weighted sequences. T1-weighted imaging is repeated after contrast injection with Gadolinium. Recently, functional diffusion-weighted MRI (DWI) is progressively included in the imaging protocol. Technical advances enable MRI to cover the entire head and neck, similarly to CT [54]. CT and MRI balance each other's advantages and disadvantages. CT has a short examination time, and has straightforward execution. MRI shows superior contrast resolution, absent radiation exposure, and allows easy integration of functional imaging.

CT is preferred for evaluation of laryngeal, hypopharyngeal, and oropharyngeal cancer, while MRI is preferred for sinonasal, nasopharyngeal, oral, salivary gland and thyroid cancer, as well as skull base tumours and sarcomas.

Pretreatment imaging

Imaging should provide information about the anatomic subsite of the tumour, deep tumour extent over the (sub)mucosa, muscles, and skeleton, and the neurovascular bundles and nodal stage. CT better depicts subtle cortical skeletal invasion whereas MRI is stronger for detecting bone marrow infiltration [55, 56]. MRI surpasses CT to detect perineural spread for which imaging signs include obliteration of fat in or widening of the bony foramina and enlargement and contrast-enhancement of the affected nerves. Muscle invasion is best evaluated by CT or T1-weighted MRI.

In laryngeal and hypopharyngeal cancer, anatomical parameters predict local control after radiotherapy. Pretreatment tumour volume in supraglottic, glottis, and hypopharyngeal cancers identifies patients with higher likelihood of local control to radiotherapy, with tumour volume showing an inverse correlation to local control [57–60]. CT-determined cartilage abnormalities are not an independent predictor of outcome [60]. In patients with supraglottic and glottic carcinoma examined by MRI, invasion of the pre-epiglottic space, thyroid and cricoid cartilage, and hypopharynx are strong predictors of local outcome post radiotherapy [61, 62].

For detection of nodal metastases, sensitivities between 48% and 97% and specificities between 39% and 96% [63] are reached using the criterion of 10 mm for short axis diameter. Morphological criteria like necrosis and extracapsular spread improve sensitivity but are rare in subcentimetric nodal metastases. Therefore, anatomical imaging criteria lack sufficient accuracy to stage the N0-neck.
Fig. 35.7 Patient with papillary thyroid cancer. (A) ultrasound shows lymph node with heterogeneous reflective architecture (arrows) and dispersed microcalcifications (dashed arrows); (B) marked hypervascularity of the lymph node can be seen at Colour Doppler ultrasound. Diagnosis is compatible with metastatic lymph node.

Post-treatment imaging

Tumour recurrence appears as a contrast-enhancing soft tissue mass originating at the irradiated primary site or along the resection margin [64]. In contrast, mucosal necrosis is characterized by absent contrast enhancement and sometimes the occurrence of gas bubbles (see Figure 35.8). Laryngeal necrosis shows variable soft tissue swelling, fluid around the necrotic cartilage and/or cartilage fragmentation, collapse, dislocation, lysis or sclerosis [64].

Combining post-treatment baseline and three-months CT or MRI during follow-up improves detection of tumour recurrence in laryngeal and hypopharyngeal cancer. CT can detect tumour recurrence with sensitivity of 83% and specificity of 95% [64]. In contrast, for oropharyngeal cancer, CT scan six weeks post treatment does not have major incremental value to clinical evaluation. MRI six to eight weeks post treatment can predict local control with 48% sensitivity and 85% specificity [51].

For lymphadenopathies, CT eight weeks post treatment may avoid neck dissection. A decrease ratio of more than 50% measured on CT imaging tends to result in a negative hemineck, while high negative predictive value (NPV) up to 95% can be reached based on nodal diameter and absence of focal lucency. However, anatomical imaging criteria suffer from low discriminative value in enlarged lymph nodes [65, 66].

Functional CT and MRI

Functional CT and MRI provide a surrogate marker for perfusion (CT perfusion and perfusion MRI) and cellularity (DWI).

Perfusion imaging is acquired by continuous scanning during contrast injection. Main applications include prediction and early response assessment. Pretreatment CT perfusion may predict response after induction chemotherapy, chemoradiation or surgery [66]. CT perfusion after 40 and 70 Gy of radiation in patients treated with chemoradiation allows treatment monitoring [67]. Pretreatment perfusion MRI parameters are predictive for outcome in stage IV nodal disease and differentiate complete versus partial response to chemoradiation at six months follow-up [68].

DWI probes water mobility changes related to tissue cellularity, quantified by the apparent diffusion coefficient (ADC) being used for nodal staging, post-treatment imaging and response assessment [54]. DWI shows sensitivities between 83% and 98% and specificities between 97% and 87% for detecting nodal metastases [54, 69]. For detecting post-(chemo)radiotherapeutic recurrence, DWI shows sensitivities between 84% and 94% and specificities between 90% and 100% (Figures 35.8 and 35.9) [70, 71]. For response assessment during chemoradiation, absent ADC-changes (ΔADC) relative to baseline, one week, two weeks, and fours weeks during CRT were predictive for tumour recurrence during six months follow-up, respectively. At two years follow-up, significant increase of ADC was a strong predictor of clinical remission [72, 73]. Sensitivities to predict tumour relapse ranged from 86% to 100% and specificities from 83% to 96%. In a study, evaluating the ΔADC, three weeks after completion of chemoradiation, DWI showed a positive predictive value (PPV) of 89% and negative predictive value (NPV) of 100% to predict local control and PPV of 70% and NPV of 96% to predict nodal regional control [74].

^{18}F-FDG PET/CT

^{18}F-FDG is the most commonly used tracer for clinical PET imaging and has gained major advances with hybrid PET/CT, integrating metabolical and morphological information. Typically, PET/CT is initiated 60 to 90 minutes after injection of the radiotracer after scanning the CT portion. High-dose CT with intravenous contrast is recommended. A dedicated CT of the head and neck
Fig. 35.8 Patient four months after chemoradiotherapy for laryngeal cancer: (A) CT-scan shows diffuse swelling of the soft tissues, dislocation and sclerosis of the right arytenoid (arrow) and small air bubbles adjacent to the arytenoid (dashed arrow). (B) ^{18}F-FDG-PET shows marked hypermetabolism in the larynx not able to distinguish tumour recurrence from inflammation. (C) T2-weighted MRI shows diffuse laryngeal hyperintensity indicating oedema. (D) No focal abnormalities are seen at the b1000 DWI while the (E) calculated ADC-map is bright. Histopathology showed laryngeal necrosis.
Fig. 35.9 Patient five months after chemoradiotherapy for supraglottic laryngeal cancer shows (A,B) metastatic adenopathy in level 2 of the right neck at PET/CT. Inflammatory changes are seen in the tonsillar area (dashed arrow). (C) T2-weighted and (D) DWI confirm the adenopathy where the viable tumour deposits appear hyperintense at DWI (bright; arrow). In correlation to (E) contrast-enhanced MRI, (F) DWI shows a small hyperintense lesion in the left epiglottis suspect for recurrent primary tumour; confirmed at biopsy after endoscopy.

can be performed prior to whole body imaging, increasing sensitivity for detecting small lesions such as small nodal metastases [75].

Pretreatment imaging

In general, PET or PET/CT improves the detection of primary tumours reaching sensitivities and specificities of 95% and 92% compared to 68% and 69% for CT [76]. PET detects unknown primaries in 10% to 60% of patients with neck lymphadenopathy [77]. In patients with negative physical examination and MRI, PET detects up to 27% of unknown primaries. Baseline FDG-PET characteristics may hold prognostic value. Patients with high FDG uptake have significantly lower control rate (55% versus 86%) and disease-free survival (42% versus 72%) than patients with low uptake [78].

For nodal staging, PET increases sensitivity ranging between 70% to 100% and specificity between 82% and 94% for PET compared to contrast-enhanced CT showing sensitivities between 48%

and 97% and specificities between 39% and 96% [78]. PET complements anatomical imaging by detecting subcentimetre lymphadenopathy. However, the low spatial resolution of PET restricts its use in the N0 neck.

Staging of distant metastases is a core application for PET/CT (Figure 35.10). PET can detect unknown distant metastases in up to 10% of patients during screening [79]. In addition, PET/CT can detect synchronous lung or upper digestive tract tumours. In a study by Schwartz et al., FDG-PET detected distant metastases or second primary in 30% of patients [80]. In a prospective multicentre study by Lonneux et al, FDG-PET detected unknown metastases or second primary tumours in 13 of 233 patients [81].

Post-treatment imaging and response assessment

^{18}F-FDG-PET/CT more accurately detects tumour recurrence than anatomical imaging with sensitivities between 83% and 100% and
Fig. 35.10 Patient presenting with new diagnosis of (A) and (B) right-sided pyriform sinus cancer with multiple lymphadenopathies in the right neck at T1-weighted contrast enhanced MRI and T2-weighted MRI. (C) Additional ^{18}F-FDG-PET shows hypermetabolic lymph node in the right hilum of the lung (arrow) confirmed as nodal metastasis after endobronchial ultrasound guided biopsy.

specificities between 61% and 94% compared to 38% to 75% sensitivities and 44% to 100% specificities for CT or MRI [77]. It is generally considered that ^{18}F-FDG-PET two to four months post treatment allows better assessment of possible tumour recurrence than scanning at an earlier phase [77]. Four months ^{18}F-FDG-PET is a better predictor of tumour recurrence, while the specificity of ^{18}F-FDG-PET decreases significantly when performed earlier than 12 weeks post chemoradiation (see Figure 35.8) [81, 82]. For imaging surveillance post chemoradiation, ^{18}F-FDG-PET shows sensitivities between 93% and 100%, with specificities between 63% and 94% [83].

Data on ^{18}F-FDG-PET response assessment during non-surgical treatment are relatively scarce. ^{18}F-FDG-PET four weeks after start of radiotherapy shows an NPV of 100% but a low PPV of only 17% to predict local control [84]. In ^{18}F-FDG-PET before and one to three weeks after radical non-surgical treatment, high metabolic ratio post treatment is associated with 62% complete remission rate and 35% five-years' overall survival, while a low metabolic ratio is correlated to a 96% complete remission rate and a 72% overall survival [85].

Summary of imaging for head and neck tumours

Various imaging techniques are available for diagnostic evaluation of head and neck cancer patients, and the choice of imaging technique is usually based on clinical presentation and stage as well as patient tolerance and technique availability. Ultrasound, CT, and MRI remain the primary imaging modalities for HNC, providing lesion characterization, staging, and prognostication. Functional imaging improves the diagnostic yield in HNC.

Tumours of the nasal cavity and paranasal sinuses

Introduction to tumours of the nasal cavity and paranasal sinuses

Tumours of the nasal cavity and paranasal sinuses are rare and include a wide spectrum of malignancies, squamous cell carcinoma being the most frequent in the adult population and sarcoma in children. They account for 0.2–0.8 of all malignant tumours and 3% of those arising in the head and neck. Males are twice as affected as females. The peak incidence ranges between 50 to 70 years of age [86, 87]. Sinonasal tumours originate most frequently in the maxillary sinus (60%) followed by the nasal cavity (20–30%), ethmoid sinus (10–15%), and sphenoid sinus and frontal sinuses (less than 1%). Differences in histology distribution relate to the site of occurrence. Moreover, adenocarcinoma prevails in the ethmoid sinus in all the European series [88, 89], whereas the American series often report a higher prevalence of squamous cell carcinoma [90, 91].

Wood and leather workers have an increased risk of developing an ethmoid adenocarcinoma (5- to 50-fold). Tobacco smokers have a consistent association with sinonasal cancer and particularly with SCC. Exposure to formaldehyde, diisopropyl sulfate, or thorium oxide (Thorotrast), a radioactive thorium-containing contrast material used for radiographic study of the maxillary sinuses represents an additional risk factor [92]. These tumours tend to spread from one sinus to another through the foramina and fissures of the surrounding bone and show vascular, perineural, and lymphatic extension. Finally, they can involve the whole sinus complex and extend to vital structures such as the carotid artery, the cavernous sinus, the orbit skull base, and the brain.

Sinonasal tumours are usually asymptomatic in an early stage. Tumours often masquerade as a chronic inflammatory condition until they are advanced. The extension of the disease at diagnosis and the complexity of the anatomic field make the treatment of these tumours a challenging task.

Complete surgical resection followed by radiotherapy or radio-chemotherapy are widely recognized as the gold standard for these tumours. Despite refinement of surgical techniques and more sophisticated chemoradiation protocols, the prognosis of these tumours continues to be disappointing.

Diagnosis and staging

Sinonasal tumours are often diagnosed at an advanced stage. Initial symptoms are generally non-specific including nasal obstruction,

moderate epistaxsis, and hypoanosmia. Once the neoplasm increases in volume, the clinical appearance depends on structures that have been involved by tumour extension. Swelling of the cheek or palate and loose teeth may be associated with oral cavity invasion; diplopia, impaired ocular motion, and proptosis when the orbit is invaded; trismus when tumour extends to the masticatory space and pterygoid; neurologic deficit, headache or cerebrospinal leakage when tumour erodes the skull base and involves dura and brain.

Bone destruction is found in up to 80% of the cases. About 60% of ethmoidal tumours present with intracranial involvement [93] and 66–82% show orbital wall invasion [94]. Orbital invasion occurs in 60–80% of maxillary sinus malignancies and in about 45% of nasal tumours. Cervical lymph node enlargement can also be detected.

Biopsy is mandatory to define the nature of the lesion and to plan the proper clinical approach. The exact definition of the anatomical margins of the tumour has significant implication for staging, treatment selection and prognosis. Consequently computed CT and MRI of the head and neck along with investigations to demonstrate distant metastases are always required. CT scans provide important evaluation of bony cortical erosion and information about the extent of the tumour through the surrounding bone such as orbital floor, lamina papiracea, cribriform plate, hard palate, and skull base. Better distinction of the tumour from the adjacent soft tissue can be achieved with MRI. In particular, MRI gives better indication about tumour invasion of the orbital contents, carotid artery encasement, perineural invasion and perineural tumour spread, dura mater, and brain and cavernous sinus involvement. MRI and CT scan are both useful to asses posterior spread of tumour into the pterygopalatine fossa [95]. Paranasal tumours are staged according to TNM–AJCC classification (TNM, 7thed.). In 2005 Cantù and coworkers validated on a large series of patients a new classification (INT classification) for malignant ethmoid tumours based on the most commonly accepted prognostic factors. This classification does not include N status but in comparison with the TNM staging system seems to provide a better prognostic discrimination among T classification [96].

Treatment

The choice of treatment strictly depends on site and extension of the disease and histology. Surgery associated with radiation or radio-chemotherapy therapy is the gold standard in many cases.

For certain tumours with very poor prognosis such as melanoma, neuroendocrine carcinomas including undifferentiated carcinoma (SNUC) and sarcomas, the role of surgery is questionable. Usually, these malignancies are well treated with radiochemotherapy therapy and surgery is considered for palliation or sometimes for rescue after locoregional recurrences.

Surgery

Limited tumours of the maxillary sinus or nasal vestibule can usually be treated with surgery alone. Advanced tumours of the maxillary sinus are treated according to the extension and location of the neoplasm with an anterior craniofacial resection or tailored maxillectomy. The surgical management of the orbital involvement is still controversial. Any attempt should be made preoperatively to distinguish between erosion of the bony orbital wall, involvement of the periosteum, and deeper penetration involving the orbital soft tissue. The orbital contents can usually be spared when there is no invasion of orbital fat and musculature or involvement of the orbital apex [94].

The invasion of the pterygopalatine fossa and the infratemporal fossa can be dominated by an anterolateral craniofacial approach. Ethmoid tumours growing far from the lamina cribrosa can be treated by transfacial ethmoidectomy. Ketcham in 1963 described the technique of craniofacial resection for a large tumour involving the nasal cavity and the ethmoid sinus approaching or involving the skull base [97]. For many years this combined transcranial-transfacial approach remained the gold standard of anterior skull base tumours [93, 98]. In the late 1990s, these tumours were also treated by an innovative endoscopic technique with or without craniotomy [99, 100]. The comparison between the techniques in terms of outcome and complications is difficult to make. However, recent reports seem to support that endoscopic resection results in a low complication rate and acceptable disease-free survival in selected cases.

The current contraindications to classical craniofacial resection are far less stringent compared to those outlined by Ketcham in his experience. Large brain involvement, encasement/invasion of the internal carotid artery, extensive skull base erosion, and invasion of the cavernous sinus are usually considered a contraindication for surgery.

The contraindications for endoscopic surgery are extensive lacrimal pathway infiltration, involvement of the anterior wall and lateral portion of the frontal sinus, hard palate, nasal bone, and infiltration of the bony walls of the maxillary sinus, with the exception of the medial one.

Neck dissection is indicated only when positive nodes have been clinically detected.

Radiotherapy

Depending on the location and the histopathology of the tumour, treatment using radiation therapy is either in the definitive or adjuvant setting. Because multiple critical normal tissues are located within or near the skull base (e.g., frontal and temporal lobes of the brain, the optic chiasm, the cranial nerves, the orbits, the lacrimal glands, and the brainstem), radiotherapy techniques are focused on treating the tumour while minimizing toxicities and complications. Using conventional radiotherapy techniques, the lacrimal apparatus and the optic pathway structures (retina, optic nerves, chiasm) often received doses equal to the target prescription dose. Conventional radiation therapy for sinonasal cancer resulted in significant ocular toxicity [101, 102]. Local control rates of 90–70% in stages T1–T2 and below 50% in stages T3–T4 were, however, achieved with prescription doses of 56–75 Gy [103].

In this framework, the use of intensity modulated radiation therapy (IMRT) has progressively emerged as the method of choice. IMRT allows selective under-dosage of organs at risk by creating concave dose distributions around the optic pathway structures together with steep cranial, lateral, and caudal gradients outside the planning target volumes to spare the lacrimal apparatus and the central nervous system. In a series of 62 patients with sinonasal tumours (ethmoid sinus, maxillary sinus, and nasal cavity) with adenocarcinoma and squamous cell carcinoma, the four-year actuarial local control after surgery and IMRT was above 80% for patients with T1-T4aN0M0 disease [104]. Eleven patients had T4b tumours with invasion of the dura or brain through the cribriform plate. Fatal relapses occurred within a year after treatment in all of those patients. IMRT implementation was clearly not able to reverse the dismal local control rates that are known to exist in stage T4b

with cribriform plate invasion. In this series, severe dry-eye syndrome could be avoided in almost all patients if attempted. Severe optic pathway injury occurred in about 5% of patients. Such complication rates were much lower in comparison to patients previously treated in the same institution prior to the implementation of the IMRT technique.

Chemotherapy

Overall, there are very few reports on the use of chemotherapy in sinonasal carcinomas, and sinonasal squamous cell cancer is not included in the typical head and neck prospective randomized trials on chemotherapy (and/or radiotherapy). Nevertheless, the principles of chemotherapy as outlined in the section on locoregionally advanced larynx and hypopharynx cancer and the section on recurrent/metastatic squamous cell carcinoma of the head and neck are also applicable for sinonasal squamous cell carcinoma. Different schedules have been used in the locoregionally advanced disease setting, but regimens most often applied were platinum based, with a response rate ranging from 36% to 87% [105–107]. Survival figures of different treatments of advanced squamous cell carcinoma of the paranasal sinuses have not changed significantly in the last 20 years. Local recurrence at the primary site and distant metastases are the most common patterns of treatment failure. New approaches should therefore focus on these issues. The incorporation of induction chemotherapy (ICT) in the multimodality treatment of advanced cancer of the paranasal sinuses has shown some promise in this regard [106, 107]. Tumour response to ICT in such patients was suggested to be predictive of treatment outcome and prognosis, giving, moreover, a reasonable chance of organ preservation [106]. Data from the Milan Cancer Institute suggests that sinonasal adenocarcinomas are also chemosensitive, and that patients with such tumours might also be candidates for primary chemotherapy [108]. In the subgroup of patients with ethmoidal intestinal-type adenocarcinomas it was found that those patients who reached a pathologic complete response showed significantly less recurrences in follow-up than those who did not. Moreover, they found that p53 status could be a promising biomarker to predict response to chemotherapy [109, 110].

Sinonasal malignancies with neuroendocrine differentiation (with the exception of esthesioneuroblastomas (ENB) might also benefit from trimodality management, given the higher rates of systemic failure for patients with SNUC, sinonasal neuroendocrine tumours (SNEC) and those with small-cell cancers (smCC) than for those with ENB [111, 112]. In contemporary studies cisplatin is the drug of choice when given concurrently with radiation, and taxane/platinum based regimens for induction, such as TPF (docetaxel, cisplatin, 5-fluorouracil).

A different approach for adenocarcinoma (often found in patients with a woodworker's history) of the ethmoid sinus has been described by the Rotterdam group [113], using a techniques modified from that originally described by Sato et al in 1970 [113, 114]. Surgical debulking performed via an extended anterior maxillary antrostomy is followed by a combination of repeated topical chemotherapy (5-fluorouracil) and necrotomy [113]. Of the 62 patients treated, eight (13%) required additional radiotherapy for local recurrence, while one patient needed surgery for regional lymph node metastases. Results were surprisingly good. Adjusted disease-free survival at five and ten years was 87% and 74%, respectively. Periorbital swelling occurred in 40%, cerebrospinal fluid leakage in 8%, and meningitis in one patient. A similar observation has been made by another research group [115].

Prognosis

Histology, tumour stage, margin status (where applicable), and site of occurrence affect the prognosis of sinonasal malignancies.

Despite the improvement of surgical techniques and novel radiochemotherapy regimens, the prognosis of these malignancies remains poor with an overall treatment five-years' survival ranging between 30% and 50%. Esthesioneuroblastoma has the best prognosis of all paranasal sinus tumours with a five-year disease-free survival (DFS) of up to 84% to 100%. The prognosis is good for minor salivary gland tumours and low-grade sarcomas with a five-year DFS of about 70%, while patients with adenocarcinoma have a better DFS than those with squamous cell carcinoma (52% versus 43.6%). Sinonasal undifferentiated carcinoma show a five-year DFS less than 20%, while all the patients with mucosal melanoma die of disease within two years after treatment. Intracranial and orbital involvement are also significant predictors. The tumour invasion of the skull base, dura, and brain progressively decreases the five-year DFS from 55.1% to 28.4%. Orbital invasion correlates with poor prognosis with a five-year DFS of 75% in patients with no orbital involvement compared with a DFS when there is periosteum/bone involvement of 40.7%. The importance of a proper surgical approach is well demonstrated by the effect of surgical margins status on disease-specific survival. Complete removal of the tumour with clear margins results in a five-year DFS of 68% compared with less than 30% when surgical margins are positive at histology [98].

Nasopharyngeal carcinoma

Introduction and epidemiology

Nasopharyngeal carcinoma (NPC) differs in many respects from other mucosal head and neck cancers. Its complicated location juxtaposed to the central skull base, and extremely high propensity to develop lymph node metastases in surgically inaccessible sites (e.g., retropharyngeal) means that the role for surgery in initial treatment is limited. The geographic and ethnic distribution is also distinct with the overwhelming majority of patients presenting in Asia, particularly in southern China (including Hong Kong, where the incidence is 25 cases per 100,000 per year, compared to 1–3 per 100,000 in Europe and North America) [116, 117], with high rates also found in Indonesia and neighbouring countries. Unexpected and intermediate rates are also evident among Inuit peoples of North America and certain regions in North Africa and the Mediterranean littoral regions. While all ages and gender are at risk, the peak is in the 40–60-year range in high-risk regions and bimodal peaks at 15–24 and 65–79 years in low-risk regions [118]. The incidence is two-to-threefold higher in men compared to women. A multifactorial aetiology includes inherited genetic predisposition, viral infection, and exposure to dietary/environmental factors in the first decade of life.

Histopathology classification of the nasopharynx includes non-keratinizing, keratinizing, and basaloid types according to the World Health Organization (2005) system. Most patients, especially in high-risk regions, have the non-keratinizing type, which is almost invariably associated with EBV, irrespective of patient ethnicity. It is further subclassified into undifferentiated and differentiated subtypes, although this distinction confers no obvious

clinical significance. Human papillomavirus and/or smoking may contribute to cases in lower risk populations [119].

Presentation and primary disease assessment

The most common presenting symptom is a painless enlarging upper neck mass, classically in level 2, but any regional lymph node area is a candidate for involvement. Retropharyngeal nodes are very common and usually require imaging to detect them. Level 1 and parotid lymph nodes may be uncommonly involved. The primary tumour is often asymptomatic or may be associated with blood-stained postnasal secretion and nasal obstruction. Symptoms of tinnitus or impaired hearing are frequent and should prompt specific workup in an Asian patient. More advanced presentations may include aural pain or discharge, headache, facial numbness, diplopia, trismus, dysphagia, and dysarthria.

Initial assessment involves a detailed history and physical examination with special focus on cranial nerves (sixth being most common). Diagnosis is often established by nasopharyngoscopy and biopsy in the ambulatory setting. Preferred initial imaging is MRI, but if unavailable, contrast-enhanced CT is an alternative. Unfortunately, CT is less effective in evaluating perineural intracranial extension without bone erosion, cavernous sinus involvement, and in differentiating retropharyngeal nodal disease from posterolateral extension of primary disease.

Additional staging and supportive approaches

Audiometry and dental assessment are required. Additional workup should include complete blood count, serum biochemistry (including liver and renal function tests) to address disease-related issues but to also prepare for the use of chemotherapy. This should include hepatitis screening in risk patients, since polymerase inhibitors to block hepatitis B replication may be needed to address associated compromise in delivering chemotherapy. For stage III–IV, metastatic workup should include PET with CT; a CT of chest and abdomen and isotope bone scan may be used instead. Pre- and post-treatment plasma/serum load of EBV-DNA measured by copy number can prognosticate in the early phase of management, including attention to the rate of clearance of the viral load [120]. EBV copy number may also augment traditional TNM staging with evidence that it may surpass the prognostic value of some subsets of anatomic stage [121]. This test also facilitates early detection of disease recurrence, especially distant metastasis [122]. Serum EBV serology to assess the IgA response to the viral capsid antigen may be useful for screening and diagnosis, but studies suggest less value for prognostication and post-treatment surveillance [123, 124].

Radiotherapy for NPC

Definitive IMRT, generally with chemotherapy, is the primary treatment for NPC because it is radiosensitive and its anatomic location makes surgery technically difficult. This results from the need to eradicate insidious disease in the base of skull and to address the retropharyngeal nodes. Initially, institutional reports more than a decade ago showed dramatically improved tumour control with IMRT compared to historical expectation. These investigators demonstrated four-year estimates of locoregional and distant progression-free rates of 98% and 66% respectively [125] which has effectively changed the standard of care for this

disease while recognizing that distant disease remained the predominant problem. These observations were coupled with the observation of dramatic reversal of xerostomia rates, due to the salivary sparing capability of IMRT, with only very few suffering from grade 3 xerostomia after two years. The Radiation Therapy Oncology Group (RTOG) confirmed these results in a multicentre single-arm phase II trial showing two-year locoregional, and distant metastasis-free rates of 89.3%, and 84.7%, respectively. Only two patients complained of grade 3 xerostomia at one year [126].

Subsequently, randomized phase II trials were designed to demonstrate the ability of IMRT to ameliorate normal tissue-related sequelae (xerostomia and quality of life) in early disease [127, 128] but were underpowered to address efficacy. Locally advanced disease was presumably not included in these randomized studies due to the challenges in protecting adjacent critical anatomy with non-IMRT techniques. However, these results were recently corroborated in a large phase III trial involving 616 patients that also showed a survival advantage (80% versus 67%, p = 0.001) for IMRT compared to two-dimensional conformal treatment (2D-CRT) [129]. The five-year actuarial local control rate was 90.5%, 91%, and 81.5% for IMRT versus 84.7%, 80%, 62.2% for 2D-CRT for all cases, T3, and T4, respectively, with corresponding improvements in xerostomia and hearing loss favouring IMRT.

General treatment approaches

Early disease

Stage I disease should be treated by radiotherapy alone (preferably IMRT) with an excellent expectation of outcome.

In stage II, concurrent chemoradiotherapy is often recommended without induction or adjuvant chemotherapy. Supporting data are limited but evident from a single randomized trial [130]; however, concerns remain since many low-risk patients can be safely treated by radiotherapy alone.

Locally advanced disease
Concurrent chemotherapy

Stage III IVB disease is universally accepted as requiring combined modality treatment with both IMRT and chemotherapy. In the only individual patient data (IPD) meta-analysis of chemotherapy in NPC (MAC-NPC), an 18% risk reduction in overall survival, representing a five-year absolute reduction in death of 6% from 56% to 62%, was seen [131]. The main contribution was from concurrent chemotherapy (risk reduction of 40% with only modest contributions from induction and adjuvant chemotherapy). Other literature-based meta-analyses and the embodied contributing clinical trials have also supported this. There is therefore no doubt that concurrent cisplatin-based chemotherapy in addition to radiotherapy is absolutely necessary if the best chances of disease control and survival are to be achieved. However, controversies continue regarding the other aspects of treatment sequencing which are the focuses of future clinical trials.

Adjuvant chemotherapy

The need for subsequent adjuvant chemotherapy, a traditional component of management, has recently been challenged by a negative phase III multicentre randomized trial that compared concurrent chemoradiotherapy with or without adjuvant chemotherapy in locoregionally advanced disease [132]. Progress may

be realized from the design of future biomarker-guided trials that stratify patients at completion of concurrent chemoradiotherapy according to residual EBV load before randomization to address the need for and intensity of adjuvant chemotherapy in different risk groups. Multicentre trials of this kind will also require attention to collaborative efforts to harmonize such quantitative plasma EBV DNA assays [133].

Induction chemotherapy

Induction chemotherapy is attractive in very advanced disease because its pre-emptive use may eradicate micro-metastasis while also reducing the size of overt gross locoregional disease; this may permit safer delivery of high-dose radiotherapy to ensuing gross disease close to critical structures (e.g., brainstem, optic chiasm), but should not reduce the dose to the elective target regions at risk of harbouring microscopic disease [134]. However, an ongoing concern is whether full-dose induction chemotherapy could compromise the delivery of the essential concurrent phase in terms of total dose of chemotherapy, numbers of cycles, and the delivery of radiotherapy to its intended completion, and whether such compromises are meaningful from a clinical outcomes perspectives. These are the focus of ongoing randomized trials that especially address newer agents, such as taxanes that were not traditionally used for induction approaches in NPC. Promising results are suggested by a small phase II randomized trial that compared neoadjuvant docetaxel and cisplatin versus cisplatin alone [135].

Very advanced disease

Stage IVC requires individualized approaches. Radical treatment should be considered for patients with good performance status and disease confined to oligometastasis [136–138].

Management of treatment failure

Patients should be closely monitored because early detection of recurrence significantly affects the chance of survival. Aggressive salvage should be considered for patients with local/regional recurrence or oligometastasis.

Management of local and/or regional failure

Options for local failure include surgery, external beam re-irradiation (EBRT), brachytherapy, stereotactic radiosurgery, chemotherapy, and photodynamic therapy. The choice of treatment is determined by the extent and location of the tumour, the availability of local resources and expertise.

Surgery is generally considered the treatment of choice if the tumour is resectable. For small and superficial recurrence, resection via the endoscopic approach, or by transoral robotic surgery, is preferred [139]. When the tumour extends across the midline or invades the parapharyngeal space, open surgical approach is indicated; approaches include a lateral infratemporal approach, and inferior transpalatal, transmaxillary, and transcervical approaches [139–141]. For regional failure, neck dissection is indicated. When resection margins are positive or there is extracapsular disease, post-operative re-irradiation is recommended.

If salvage surgery is not feasible, re-irradiation with or without concurrent chemotherapy may be considered. Smaller than usual radiotherapy fraction sizes delivered twice daily may reduce late toxicity.

Brachytherapy has shown good results for small recurrences with a five-year control of 62% [142]. With radioactive gold implants five-year local control of 70% and overall survival of 64% are achieved [140, 143].

Stereotactic radio surgery can be delivered in one fraction or fractionated. Local control rates do not differ significantly from the results of brachytherapy, but there is a wide range [143]. In addition, severe complications including massive epistaxis, cranial nerve palsies, and temporal lobe necrosis occur. Tumours near the fossa of Rosenmuller and foramen lacerum have the highest risk of haemorrhage due to the location of the carotid artery. Complication rates for fractionated stereotactic surgery are marginally lower than stereotactic surgery, but survival rates do not differ. Long-term results are awaited to evaluate superiority.

A relative new approach is photodynamic therapy (PDT). After intravenous administration of a photosensitive drug, illumination of the tumour will result in cell death with a penetration depth of 0.5–1 cm. Although only small studies are available, preliminary results are promising [144, 145]. Pain is the worst side effect and sometimes 'sunburn' is evident if the patient is exposed to sunlight too soon. A gradual return to sun exposure over two to three weeks is necessary.

Management of distant metastasis

Distant metastasis is the main form of failure. For oligometastasis, surgery, radiation and chemotherapy can be used, and cure is possible in a small subset of patients [138]. For extensive metastasis, palliative chemotherapy with/without radiotherapy to symptomatic sites can be considered. When patients are chemo-naive, cisplatinum-based regimens give the best responses. Otherwise combinations of platinum-based chemotherapy with gemcitabine, capecitabine, or docetaxel could be used [146].

Tumours of the oral cavity

Introduction to tumours of the oral cavity

Therapy of squamous cell carcinoma of the oral cavity (OCSCC), including tumours of the anterior two-thirds of the tongue, hard palate and buccal mucosa, upper and lower alveolar process, and lips is an interdisciplinary task but mainly guided by primary surgical approaches. Radiotherapy and systemic therapies have additional character and are relevant (but not leading) parts in therapy concepts. Therefore, the main task for decision-making in therapy for OCSCC is to answer the question whether the tumour is resectable (with good functional outcome after reconstruction) or not. The following section is related to the German evidence-based clinical Guidelines [147] which are based on the current literature until 2012, analysed for evidence according to the evidence-graduation system of the Scottish Intercollegiate Guidelines Network (SIGN [148]). Furthermore, diagnostics and treatment strategies are based on the criteria of GCP (good clinical practice) which are currently emphasized and recommended in high-evidence-level clinical trials.

Role of surgery

Due to the diagnostic procedure, the role of surgery is to confirm the histological entity of the lesion. Therefore, biopsies have to be taken in the marginal sites of the lesion including panendoscopy in total anaesthesia to exclude metachronous or secondary primary carcinomas of the upper aerodigestive tract. The pathologist should be provided with sufficient information including extension and clear

localization of the lesion including clinical TNM (UICC) definition of the staging result. The pathological report must include histological analysis according to the WHO classification: grading, depth of invasion [149], lymphatic, blood vessel, and perineural microinvasion, and other locally infiltrated structures [150]. After completion of the staging procedure, the individual tumour situation should be presented and discussed at the interdisciplinary tumour board (minimum composition of the entire board: medical (or clinical) oncologist, radiation oncologist, radiologist, pathologist, and head and neck surgeon). In case the patient has an acceptable performance status and resectable disease, surgery is recommended as first-choice treatment and first-step procedure in multimodality treatment concepts in OCSCC. Criteria for reasonable resectability are: individual situation of the patient, accessibility of clear resection margins (R0 resection margin according to TNM, UICC), and predictable post-operative quality of life after surgery including functional reconstruction. According to GCP the best available tumour distance to the resection margin should measure not less than 3–5 mm at the formalin fixed resection specimen and there should be a palpable approximately 1 cm tumour border in the patient while in surgery. In the case of R+ or a less than 3 mm resection margin described in the pathology report, localized re-resection is recommended. Continuity of the mandible should be preserved if no infiltration of the bone intra-operatively and in pretherapeutic imaging has been shown. Techniques of reconstruction should be planed related to the individual oncologic situation and as an integrated part of the primary surgical procedure. The extent of reconstruction should be balanced in relation to functional and aesthetic outcomes. For reconstruction of the oral cavity microvascular free flaps have been shown to be feasible and are recommended worldwide for excellent defect closure and functional outcomes. In OCSCC, 20–40% of neck nodes present occult metastases in the neck at level I–III, less often at level IV,V. Consequently, surgical treatment of the neck is recommended according to the worldwide accepted Robbins neck dissection classification guidelines [151]. Additional to invasive definitive OCSCC, squamous intraepithelial neoplasia 3 (SIN 3) lesions also have to be surgically treated since the probability of malignant transformation is nearly 90% [152].

Role of radiation oncology

In OCSCC, the main role of radiotherapy is in the adjuvant setting since response to primary radiotherapy and concurrent chemoradiation is poor compared to the other head and neck sites. Adjuvant radiotherapy is following the degree of the resection margins (R0, R1, R2) or the extent of the primary tumour (>T3) and the N+– neck situation according to the post-surgical staging results. The more recent metanalysis, conducted on all head and neck sites, showed that there is a significant improvement of overall survival and event-free survival by adding systemic therapy to radiation, and this is true both for the curative and the post-operative setting with a five-year overall survival benefit of 6.5%. It was also shown that cisplatin alone, given concomitantly with radiation, is able to achieve the same results as a combination of antineoplastic drugs [153]. In this context, concomitant chemoradiation is considered the state-of-the-art treatment when surgery is not feasible, or post-operatively when high-risk features are present in the pathological report, such as R1 or R0 <5mm (intermediate risk) resection or the presence of nodal disease with extracapsular spread. It should be recognized that this form of treatment may be associated with severe toxicity, and for this reason its indication should be reviewed on an individual basis by an expert multidisciplinary team.

Potential role of primary systemic therapy

Only a small benefit was shown by induction chemotherapy that included cisplatin and fluorouracil (PF). Based on these encouraging results, induction chemotherapy was further studied by adding a third drug: taxotere to PF (TPF). The triple regimen was superior to PF in terms of overall survival; however, we still lack the evidence that induction chemotherapy is adding to standard locoregional treatment [154]. For this reason this is not considered a standard treatment. Induction chemotherapy has been specifically used in advanced operable oral cavity cancer where patients were treated either with induction chemotherapy followed by surgery and radiation, or surgery followed by radiation. The first randomized study included PF [155] and a more recent one TPF [156]. Both trials were negative with respect to the primary endpoint, which was overall survival, but there was an interesting signal of the potential role of response to induction chemotherapy in terms of sparing mandibulectomies and/or post-operative radiation. In both studies patients achieving a major pathological response with induction chemotherapy had the best prognosis. This observation has been done in other neoplasms treated with induction chemotherapy, such as breast cancer and osteosarcomas. It is clear that a better recognition of chemosensitive patients, for example by exploiting high-throughput techniques together with better drugs, is warranted for future treatment developments.

Tumours of the oropharynx

Introduction and clinical assessment

Oropharyngeal cancer (OPC) originates from the mucosa of the oropharynx, which includes the base of tongue and vallecula anteriorly, the posterior oropharyngeal wall, the tonsillar region and lateral oropharyngeal walls, and the soft palate and uvula superiorly. The incidence is approximately ten per 100,000 inhabitants. They are classified into two disease entities: smoking/alcohol-related and human papillomavirus-related (HPV-positive) OPC squamous cell carcinomas. The former generally have well to moderately differentiated keratinizing morphology, whereas HPV-associated lesions are typically poorly differentiated with a non-keratinizing or basaloid morphology (see also the section 'Pathology of head and neck tumours').

Frequent initial symptoms are a sensation of a foreign body in the throat or pharyngitis, followed by otalgia or odynophagia. Palpable lymph nodes in the neck are very frequent and may be the first and sole symptom. The traditional smoking/alcohol-related case often has a larger primary tumour size, less advanced nodal disease, and a correspondingly less advanced stage group. In contrast the HPV-positive case will generally have a smaller and less infiltrative primary but more extensive nodal disease (and often cystic appearance that may erroneously be considered a 'branchial cleft cyst').

The initial workup requires a comparative evaluation of the local extension with endoscopy, often under general anaesthesia, and imaging. For details on imaging, see 'Imaging techniques for head and neck tumours'.

Epidemiology and disease behaviour

The past decades have witnessed an unprecedented worldwide increase in the emergence of the HPV-positive cases. The

traditional form is generally seen in a more debilitated population with less social support and with ongoing comorbidities largely related to lifestyle and the exposure to alcohol and tobacco. The HPV-positive cancers occur in younger patients with a much better performance status, and less intense or even minimal tobacco/alcohol consumption. Males are more commonly affected in both diseases. Aetiology through the sexual transmission of the HPV 16 or 18 viruses is suggested in these lesions.

Irrespective of treatment modality, the HPV-positive variant has a better prognosis, except for distant metastases. Concern has been raised that contemporary treatments developed for the traditional form of the disease may be 'over-treating' the more favourable HPV-associated variant. As a consequence, although treatment does not differ at present, de-intensification clinical trials are in design or ongoing to address treatment options for the different risk groups of HPV-positive and HPV-negative OPC. These include studies addressing the role of radiotherapy alone, transoral surgical techniques (including laser or robotic surgery), and different forms of systemic treatment.

Contemporary standard for locally advanced disease: chemotherapy and radiation

The interaction between chemotherapy and radiation specifically in locoregionally advanced OPC has only been studied to a limited extent. There is a single phase III trial that showed a survival benefit to using induction chemotherapy prior to local treatments [157], and only two trials showed survival improvement with the use of concurrent chemoradiation (CCRT) when compared with conventional radiotherapy alone [158, 159]. Although specific data on OPC are limited, the literature is replete with trials where the oropharynx is the predominant subsite, thereby underpinning the results of the meta-analysis of chemotherapy in head and neck cancer (MACH-NC) reported by Pignon et al. [160, 153]. This meta-analysis showed a significant interaction between the timing of chemotherapy and outcome (CCRT being superior to either induction or adjuvant regimens) and provides the foundation for considering CCRT as the contemporary gold standard for management in the locally advanced (stage III/IV) OPC, irrespective of the HPV status.

An alternative strategy for improving the outcome of 'favourable' locally advanced head and neck cancer is targeting the EGFR based on the improvement in survival from cetuximab delivered concurrently with radiotherapy compared to radiotherapy alone in a randomized trial [161]. Approximately 60% of this trial's population comprised OPC, which was also the subgroup with the most benefit from concurrent cetuximab in this setting, and with a toxicity profile that seemed to be less than that expected from traditional concurrent chemotherapy. While the latter has been disputed, approaches using cetuximab have led initial attempts to reduce toxicity and de-intensify treatments for the HPV-associated cancers by potentially replacing concurrent cisplatin with cetuximab or other anti-EGFR agents in ongoing trials. Another approach is using induction chemotherapy to select patients for a reduced radiotherapy dose (e.g., the completed single arm ECOG 1308 phase II trial). The induction strategy provides an intriguing possibility for the subset of the HPV-positive population with the greatest risk of distant metastasis, now the leading cause of death for this disease. An induction chemotherapy strategy (e.g., a combination of docetaxel, cisplatin, and 5-fluorouracil (TPF)) with response assessment to minimize or omit concurrent chemotherapy seems a strategy that could be incorporated into future trials when one considers the impact of this approach on distant metastases, as shown in a more recent MACH-NC analysis, 39% of which consisted of OPC (although not HPV-specific) [154].

Risk-stratified management

Considering OPC as a single group of tumours has proved problematic. In the first publication of the RTOG 0129 trial, Ang and colleagues reported that HPV negative status, >10 pack-year tobacco exposure, T4, and N2b-N3 status were adverse predictors for overall and progression-free survival for OPC, and three risk groups could be constructed using these parameters based on risk of death in patients undergoing concurrent chemoradiotherapy [4]. Subsequently O'Sullivan and colleagues performed a similar analysis on an institutional cohort of prospectively compiled HPV-positive stage III/IV patients but addressed distant metastasis risk, rather than survival outcomes alone, in patients treated with either radiotherapy alone or CCRT [162]. Risk of distant metastases was significantly associated with T4 category disease, the degree of nodal involvement, and the same intriguing relationship with smoking history observed in RTOG 0129. Thus, heavy or light smokers with T1–T3, N0–N2a disease seemed relatively immune to the risk of distant metastases whether or not chemotherapy was used, but a smoking history of >10 pack years was important in N2b disease, and N2c and N3 disease were at risk of distant metastases irrespective of smoking history. Recognition of such characteristics has begun to guide contemporary clinical trial designs with several evolved protocols emerging that address different risk groups based on whether the patients belong to a favourable risk group with minimal risk of distant metastases, or require more intense locoregional treatment.

The only phase III randomized trial of an intensive concomitant boost altered fractionation RT alone regimen compared to CCRT with cisplatin in OPC of unknown HPV status was recently reported, and found no difference in DFS or OS [163]. In fact, tolerance was better with altered fractionation and a subset analysis suggested that the efficacy of altered fractionation appeared more pronounced in stage III disease. However, in stage IV, CCRT with cisplatin fared better and was most obvious in more extensive lymph node disease. Garden et al. recently reported a large single institution experience, also of unknown HPV status, indicating that low volume disease (e.g., T1–T2, N1–N2), has extremely favourable outcome with RT alone (exceeding 90%) despite being nominally classified as stage III or IV [164]. Thus, radiotherapy alone may provide very effective control for low-volume 'locally advanced' HPV-positive cases, but as the nodal disease stage increases, especially among heavy smokers, outcome is compromised due predominantly to the risk of distant metastases in the HPV-positive population, though the risk may be mitigated with chemotherapy [162].

Radiotherapy approaches

IMRT is usually used because of its ability to relatively spare normal tissues, most obviously salivary tissues. Pharyngeal constrictor muscles and mandibular regions can often be protected to some degree as well. Eisbruch et al. reported an RTOG multicentre single-arm phase II study of IMRT in OPC which validated one of the major reasons for using IMRT, the reliable and important

ability to protect salivary function while achieving high locore-gional control [165]. This benefit was confirmed in the PARSPORT trial, a UK multicentre randomized controlled study of IMRT versus conventional radiotherapy in pharyngeal cancer patients (85% OPC), showing reduced incidence of xerostomia with IMRT and significantly better recovery of saliva secretion with improvements in associated quality of life [166].

Contemporary radiotherapy approaches typically employ treatment intensification by the use of chemotherapy as discussed earlier, or hyperfractionation with dose intensification supported by meta-analysis data [167]. In addition, the observed benefit of moderately accelerated radiotherapy was also found to be independent of HPV status in the DAHANCA 6 and 7 trials, suggesting that this strategy should be maintained if the intensity of chemotherapy is reduced [168].

Surgery for oropharyngeal tumours

Although most oropharyngeal tumours are treated by a non-surgical approach, surgery remains important, either for initial treatment or salvage. Careful attention to the goals and needs of each case will provide the rationale, and indication for different surgical approaches for the primary site are summarized below. Elective neck surgery must also be considered if there is doubt about disease eradication, based on clinical and imaging initially or eight to 12 weeks following radiotherapy.

Transoral surgery is an attractive approach for tumours limited to the site of origin. Electrocautery was used initially followed by the laser CO_2 knife in the mid-70s, which became the most common approach. Although providing alternatives to open surgery in selected cases, these techniques remained limited due to the restricted access to the base of the tongue and the glossotonsillar sulcus. More recently, transoral robotic surgery (TORS) has been developed, providing excellent global visualization, with a magnified three-dimensional view, allowing access to difficult areas, and this has expanded the indications for using TORS [169].

There are two main approaches to open surgery: firstly, the mandibular swing approach that provides the same access to the lateral oropharynx as the traditional hemi-mandibulectomy but preserving the mandibular arch via the osteosynthesis performed after tumour resection. Submandibular approaches represent the second group. Thus resection of the posterior wall of the oropharynx may be performed via the opening of the larynx by anterior access between the hyoid bone and the base of tongue. Vallecular tumours may be resected by a supraglottic laryngectomy extended to the base of tongue.

Although limited resections do not ordinarily require reconstruction, reconstruction underpins the ability to undertake much modern head and neck surgery. Improvements in reconstructive surgery have substantially reduced the post-surgical functional and cosmetic sequelae. Local mucosal flaps (such as the FAMM, facial artery musculo-mucosal, flap) may be used in some cases. Pedicled flaps (dorsal flap, trapezius flap, or the most commonly used, the major pectoralis myo-cutaneous flap) have significantly improved volume and surface reconstruction as well as prevention of post-operative complications in the case of salvage surgery in irradiated fields. The introduction of microvascularized free flaps was an important milestone in oropharyngeal surgery. Some flaps are able to reconstruct a mucosal surface (radial forearm free flap) or tongue volume (dorsal free flap, anterolateral thigh free flap) or

the mandible (iliac crest free flap, scapular free flap, or preferably the fibula free flap) [170].

Tumours of the larynx and hypopharynx (including organ preservation)

Introduction and clinical assessment

The large majority of larynx and hypopharynx cancers are SCC. The few other cases comprise glandular carcinomas, sarcomas, melanomas, and lymphomas. The annual world incidence of head and neck cancer is estimated to be nearly 700,000 and globally, with some variations between countries, 20–25% are larynx cancers and 10% are hypopharynx cancers. The incidence of larynx cancer is decreasing in North America and in Western Europe; it is stable or slightly increasing in other countries. The incidence of hypopharynx cancer seems rather stable [171]. The incidence is much higher in males (85–90%) with a peak incidence between 50 and 60 years.

The larynx is divided in three levels: the glottis (true vocal cords), the supraglottic (epiglottis, aryepiglottic folds, false vocal cords, and the ventricles), and the subglottis (between the glottis and the trachea). The hypopharynx is divided into pyriform fossae, the post-cricoid area, and the posterior wall. These cancers are the result of tobacco consumption possibly associated with alcohol abuse for supraglottic and hypopharyngeal cancers.

The presenting symptoms are a sore throat, dysphonia, or a referred otalgia. Dysphagia and dyspnoea occur later. Metastatic lymph nodes are frequent in supraglottic and hypopharyngeal cancers. The initial workup consists of a clinical examination, an endoscopy under general anaesthesia (in 95%; and with biopsy), and imaging. CT is the most useful imaging for detecting in depth extension (cartilages, paraglottic spaces, pre-epiglottic space) and metastatic lymph nodes that are missed by the clinical examination. For details on imaging, see section 'Imaging techniques for head and neck tumours'. Staging should be carried out according to the TNM classification of malignant tumours, with stage groupings I, II, III, IVA, IVB, and IVC.

Management issues

When the initial workup is completed all cases must be discussed during a tumour board meeting (including surgeons, radiation oncologists, medical oncologists, radiologists, pathologists, etc.) in order to select the most appropriate treatment for each patient. Treatment choices depend on patient characteristics (age, occupation, comorbidities) and preferences, tumour characteristics, as well as local expertise and resources.

Early disease

For early disease, the choice is between conservative surgery or radiotherapy, which seem comparable in outcome (although never prospectively compared), while chemotherapy has no role to play.

Locoregionally advanced disease

For advanced disease, the choice is between 'mutilating' surgery (with or without post-operative irradiation) or definitive irradiation with or without chemotherapy or biotherapy (cetuximab), and with surgery in reserve as salvage therapy. There is no randomized study comparing both attitudes that could help in selecting one or the other. Clearly the choice is mainly institution-dependent and

must be considered in the light of clinical trials on larynx preservation (see below). For more advanced and unresectable disease, the choice is between irradiation alone with different fractionation schedules and chemo- or bioradiotherapy under different settings. Such approaches are frequently studied in the framework of clinical research.

Recurrent/metastatic disease

For recurrent and/or metastatic disease, for each case one should consider whether a potentially curative option (surgery or re-irradiation) is still feasible. For other options see 'Management of recurrent and/or metastatic squamous cell carcinoma of the head and neck'.

Treatment options

Surgical options

There is a large surgical armamentarium for laryngeal and hypopharyngeal cancers [172]. Transoral CO_2 laser is a widely accepted approach for early diseases pending an excellent endoscopic access and a complete view of the tumour in all directions. This type of surgery is sometimes advocated for larger tumours, particularly in Germany, but is directly linked to the surgeon's expertise. More recently, TORS has been proposed by some teams but should be considered at the moment to be experimental, requiring larger series and cost-effectiveness evaluation.

Open partial surgery ranges from very limited resections (such as cordectomy, epiglottectomy, or lateral pharyngectomy) to large resections (such as supracricoid partial laryngectomy or supracricoid hemi-laryngopharyngectomy) allowing the surgeon to cope with all local extensions.

Total laryngectomy is required for large tumours and may be associated with either partial or circumferential pharyngectomy, requiring either pedicled or free flaps for closure.

A neck dissection is systematically performed (except for tumours confined to true vocal cords).

Radiation therapy options

For early-stage tumours (T1–N0), a standard fractionation regimen delivering a therapeutic dose of 64–66 Gy and a prophylactic neck dose in the order of 50 Gy in daily fractions of 2 Gy, five times a week is recommended. For T1 glottic carcinoma, a dose of 60–64 Gy to the glottic larynx without nodal irradiation is standard. For moderately advanced tumours (T2–N0 or N1), hyperfractionation or accelerated fractionation schedules have shown to be more effective than standard radiotherapy [168]. For these tumour stages, there is no compelling evidence for the use of induction or concomitant systemic treatment (chemotherapy or biotherapy). For locally advanced disease (T3 or T4, more than N1), a therapeutic dose of 70 Gy in daily fractions of 2 Gy, five times a week, and a prophylactic dose of 50 Gy are recommended, in particular when concomitant chemotherapy or biotherapy is used [153]. In case of contraindication to systemic treatment, the use of hyperfractionation, accelerated fractionation, or simultaneous integrated boost radiation therapy is recommended.

Post-operative RT is recommended in the case of inadequate resection margins, T3 or T4 tumour, multiple positive lymph nodes, and in the case of extracapsular spread of disease [173, 174]. Typically, a dose of 60–66 Gy will be delivered with daily fractions of 2 Gy, five times a week. In case of R1 resection and/or presence of extracapsular extension, the use of CCRT has been demonstrated to be superior to radiation alone [175].

Regarding the radiation technique, as demonstrated in randomized trials, the use of IMRT should be standard to decrease the incidence of late morbidity, especially the incidence of xerostomia [167]. For T1 glottic, however, conformal radiation therapy still remains a standard. Consensus guidelines on target volume selection and delineation for a state-of-the-art delivery of IMRT have been provided [176].

However, even in the IMRT era, the use of modified fractionation regimens and the use of CCRT or bioradiotherapy (BRT) is associated with an increased incidence of acute and late toxicity compared to standard radiotherapy alone, with unexplained deaths reported in up to 10% of cases with adequate follow-up after CCRT [177]. Variables that seem to correlate with the development of late severe toxicity are older age, advanced T stage, larynx/hypopharynx site, and neck dissection after CCRT [177]. These alarming data need specific attention and are a further plea to treat head and neck cancer patients in referral centres that meet all the requirement for an optimal care for such patients.

Chemotherapy and biotherapy options

The role of chemotherapy is slowly moving towards a more prominent position within the different treatment paradigms in patients with squamous cell carcinoma of the head and neck. The use of CCRT is generally accepted as a standard therapy post-surgery in high-risk patients (see above), in patients with resectable disease, when the anticipated functional outcome and/or prognosis is so poor that multilating surgery is not justified, and in patients with unresectable disease [178]. The optimal chemotherapy regimen for that approach is cisplatin 100 mg/m^2 days on 1, 22, and 43 during RT. CCRT improves survival and locoregional control over RT alone in patients with locoregionally advanced squamous cell carcinoma of the head and neck [153, 179]. Alternative non-surgical approaches in such patients are BRT with cetuximab (the only approved anti-EGFR monoclonal antibody) and the use of induction chemotherapy (ICT) before local therapies. The addition of cetuximab to RT improved survival and locoregional control over RT alone in one single randomized phase III study [161]. The hazard ratios for survival with RT plus cetuximab versus RT alone were comparable to those reported for CCRT versus RT alone in nearly 10,000 patients included in the MACH-NC meta-analysis [153]. However, there has been no direct comparison between RT plus cetuximab and CCRT in phase III reported. Despite that, there are sufficient data available suggesting that compliance with RT plus cetuximab seems to be better than with CCRT. The MACH-NC meta-analysis indicates that the role of ICT is less than that of platinum-based CCRT. However, the optimal ICT was not part of that analysis. The optimal ICT regimen has been defined by two major phase III trials, TAX 323 and TAX 324, both showing improved survival and progression-free survival with docetaxel, cisplatin and 5-fluorouracil (TPF) compared to PF in patients with resectable and unresectable locoregionally advanced head and neck cancer [180, 181]. In addition, a more recent meta-analysis on TPF versus PF indicated significantly less distant metastases and significantly less locoregional failure with TPF [154]. However, a direct comparison of CCRT versus TPF induction followed by RT has not been performed. So far, randomized trials of sequential

therapy, i.e. ICT followed by CCRT versus CCRT alone, have not shown a clear benefit for the sequential approach and this approach should not be considered standard therapy for the moment. It is also unclear whether replacing 5-fluorouracil with cetuximab in the triple regimen might lead to better outcome. Further studies for both approaches are needed. With respect to larynx preservation procedures, platinum-based chemotherapy given during RT (CCRT), preceding RT (ICT→RT), or alternating with RT are all acceptable approaches (see below).

Larynx preservation

At the beginning of the twentieth century two major options were available: surgery (partial or total) and external beam irradiation. Up until the 1980s the surgeons tried to extend the indications of partial surgery with larger procedures and to improve rehabiliation after total laryngectomy with voice prostheses. At the same time radiation oncologists improved the efficacy of irradiation with a better delineation of the irradiated area and with modification of the fractionation. But there was no direct comparison of total laryngectomy and definitive irradiation.

In the 1980, the results of studies with ICT using the PF combination concluded that ICT was able to produce notable tumour regression and that this regression was predicting a high radiosensitivity [182]. This supported the initiation of a period of challenging clinical research on larynx preservation.

The first two adequately powered trials validating the concept of larynx preservation were the Veterans trial in the US for laryngeal cancer and the EORTC 24891 trial in Europe for hypopharyngeal cancer. Both trials compared total laryngectomy with ICT (with PF) followed by RT in good responders or by total laryngectomy in poor responders [183, 184]. Both survival and disease control were found similar in both arms of the respective studies and 56% of patients could retain their larynx in the ICT arm.

The next two trials compared ICT (with PF) to alternating chemoradiotherapy (EORTC 24954 in laryngeal and hypopharyngeal cancer), and ICT (with PF) to cisplatin-based CCRT and to RT alone (RTOG 91-11 in laryngeal cancer) [185, 186]. The first trial failed to find any difference in survival or larynx preservation between both arms. The long-term results of the RTOG 91-11 trial concluded that induction PF followed by RT and CCRT showed similar efficacy for the composite endpoint of laryngectomy-free survival. Locoregional control and larynx preservation were significantly improved with CCRT compared with the ICT arm or the RT alone arm. Overall survival did not differ significantly, although there was a trend towards a worse outcome with CCRT relative to ICT and deaths not attributed to laryngeal cancer were higher with CCRT (30.8% versus 20.8% with ICT and 16.9% with RT alone) [187].

The fifth trial compared two ICT regimens (TPF versus PF) in patients with locally advanced laryngeal and hypopharyngeal cancer as an alternative to total laryngectomy (GORTEC 2000-01). Responding patients received RT with or without additional chemotherapy. Larynx preservation was significantly higher in the TPF arm of the study (70.3% versus 57.5%), without any difference in overall survival [188].

The last trial compared CCRT and biotherapy (RT + cetuximab) in patients responding to ICT with TPF (GORTEC TREMPLIN trial). The overall toxicity was substantial, there was no signal that one arm could be superior to the other, or in favour of RT alone as found in the previous trials [189].

Evidently, the optimal approach for larynx preservation has still not been identified. Several treatment options are available, each with different levels of tolerability but little difference in outcome. CCRT with three courses of cisplatin and TPF induction followed by RT in good responders is the treatment now mostly used. Superiority of one over the other can only be assessed by a randomized trial.

Squamous cell carcinoma of unknown primary site

Introduction to squamous cell carcinoma

Cervical nodal metastasis from clinically undetectable SCC primary sites accounts for approximately 3% of all head and neck malignancies [190], and most frequently manifests in the upper jugular and mid-jugular lymph nodes. Histologically, SCC accounts for the majority of cases, particularly when masses are situated in the upper two-thirds of the neck, and generally indicates an origin from a hidden primary somewhere in the head and neck region. It constitutes a favourable-risk cancer of unknown primary (CUP) group compared to patients with less favourable histologies, such as adenocarcinomas.

Diagnostic workup

Physical examination, including comprehensive nasofibroscopy and endoscopic assessment under general anaesthesia conducted by experienced otolaryngologists or head and neck surgeons, detects primary head and neck SCC in over 50% of patients presenting with cervical lymph node metastases [191]. Locoregional imaging should ideally be performed before endoscopy as it may identify suspicious mucosal areas guiding biopsy sampling. Systematic tonsillectomy has been advocated by some authors as up to 45% of occult primary have been reported [190]. The role of FDG-PET has been extensively studied over the last few years, with detection rate of a primary tumour in up to 30% of patients, and a systematic review has recommended its routine use in patient management [192]. To optimize the yield of guided biopsies, FDG-PET/CT should be performed before the endoscopy. This examination, however, needs to be considered as an adjunct to comprehensive clinical examination, and not as a replacement. Another advantage of FDG-PET examination is that it gives the metastatic workup a higher accuracy than CT or MRI [192].

For pathological confirmation of the disease in the neck, fine needle aspirate is the preferred modality. In case of repetitive negative examination, a surgical procedure removing the entire node, possibly followed by a neck node dissection, is recommended. For pathological examination, in case of poorly differentiated or undifferentiated carcinoma, EBV testing should be routinely performed to exclude the presence of an undifferentiated carcinoma, which has a different prognosis and requires a different treatment approach. HPV testing could also be performed, although no study has so far demonstrated that HPV-positive SCC should be differently managed than HPV-negative SCC. More advanced molecular techniques performed on the lymph node and the random mucosal biopsies have been described, but so far none of these studies has profoundly altered the clinical management of patients with CUP [193].

The staging of CUP follows the staging of the neck for head and neck primaries. It should, however, be emphasized that the 'T'-site

should be classified as 'T0' and not as 'Tx', the latter depicting a primary tumour staging that has not been performed, rather than a staging which did not identify any primary tumour.

Therapeutic strategies

In the past, treatment of CUP commonly consisted of lymph node dissection and elective irradiation of the putative mucosal sites and bilateral neck plus supraclavicular nodes. Recently, however, primary concomitant chemoradiotherapy, followed by a selective neck node dissection only in case of residual node disease, has been introduced. In addition, the dogma that radiotherapy for CUP should always include irradiation of both sides of the neck and the oropharyngeal, hypopharyngeal, and laryngeal mucosa has been challenged.

Neck node dissection with or without post-operative radiotherapy

In non-CUP series, for limited disease in the neck (i.e. pN1), neck node dissection procedures (typically selective neck node dissection or modified radical neck node dissection) without post-operative radiotherapy in the absence of extracapsular extension has shown control above the clavicles in the order of 95% plus (see review in [194]). Applied to selected CUP patients, such policy has shown high neck control, but with a significantly higher rate of emergence of primary tumours in the untreated mucosa compared to patients who benefited from post-op or primary radiotherapy [195]. In this series from Denmark, however, there was no difference in disease-specific survival among patient groups. It will always remain impossible to differentiate between the emergence of the putative primary and a subsequent head and neck primary, which typically occurs with a frequency of 1–2% per year.

For patients treated by surgery for a known primary tumour and who presented with multiple nodes and/or capsular rupture, post-operative radiotherapy or chemoradiotherapy (in case of capsular rupture) has been recognized as evidence-based practice [196]. There is thus no reason not to apply such policy to patients with CUP. The question of prophylactic treatment on both sides of the neck and the oropharyngeal, hypopharyngeal, and laryngeal mucosa however still remains unanswered.

Primary radiotherapy

In non-CUP series, it is recognized that radiotherapy alone yields a high rate of regional control above the clavicle around 90–95% for patients with N1 disease (see review in [194]). For patients with advanced neck disease, it has also been reported that altered fractionation radiotherapy or concomitant chemoradiotherapy followed by selective neck node dissection for residual disease yielded neck control rate in the same order of magnitude than after primary neck node dissection. Along this line, there has been a progressive change in the management of patients with CUP towards more use of primary radiotherapy or concomitant chemoradiotherapy. In a large retrospective review of 1726 patients with CUP treated either by surgery and post-operative radiotherapy or chemoradiotherapy (based on extracapsular extension) or by primary chemoradiotherapy, no statistically significant difference in five-year overall survival was observed between the two groups [197]. In this latter series, as reported in non-CUP series, the extent of the nodal disease and the presence of extracapsular extension were strong independent prognostic factors.

Indications for post-radiotherapy neck node dissection

The use of radiotherapy or concomitant chemoradiotherapy as primary treatment modality raises the question of the role of node dissection following radiotherapy for patients with N2–N3 disease at initial diagnosis. Residual neck mass may be present in up to 30–60% of patients after completion of chemoradiotherapy. For those patients, irrespective of the neck stage, there seems to be a consensus in the literature favouring an immediate neck node dissection because of the low probability of achieving a neck control with salvage surgery when recurrence develops [198]. For patients with complete neck response after radiotherapy or chemoradiotherapy, there are currently many arguments supporting the position that systematic planned neck dissection is no longer justified, and many institutions have switched to neck dissection for residual disease in the neck only [199]. Improvement in assessing the neck status with imaging has contributed enormously to this change in paradigm. Very high negative predictive values of CT, MRI, and more recently FDG-PET have indeed been reported for assessing the neck after radiotherapy or concomitant chemoradiotherapy [200, 201]. All the data mentioned above are from series of patients with a known primary tumour; there is however no reason not to extrapolate them to the situation of the CUP patients.

Target volumes in radiotherapy

As already alluded, the choice of the appropriate target volumes for radiotherapy of CUP remains controversial. First, the potential gain with comprehensive radiotherapy in controlling the putative primary carcinoma should be weighed, even in the new IMRT area, against its effect on quality of life resulting from increased acute and persistent morbidity such as xerostomia. Second, as already mentioned, it is possible that a head and neck carcinoma detected later in this patient subset is actually a second primary tumour instead of the putative cancer. Last, the possibility of conservative surgical approaches and the feasibility of re-irradiating the head and neck region (especially in the non-treated areas) are being recognized should a cancer emerge after ipsilateral radiotherapy. In the series from Denmark, although the rate of subsequent mucosal primary was higher in patients who did not receive comprehensive radiotherapy on both side of the neck and on the mucosa, no difference in disease-specific survival could be observed [195]. When all data from small retrospective series are put together totalling up to 1000 patients, no difference in the rate of subsequent head and neck primaries could be detected between patients who got surgery alone, unilateral radiotherapy, or bilateral radiotherapy including the head and neck mucosa (personal data).

Conclusion

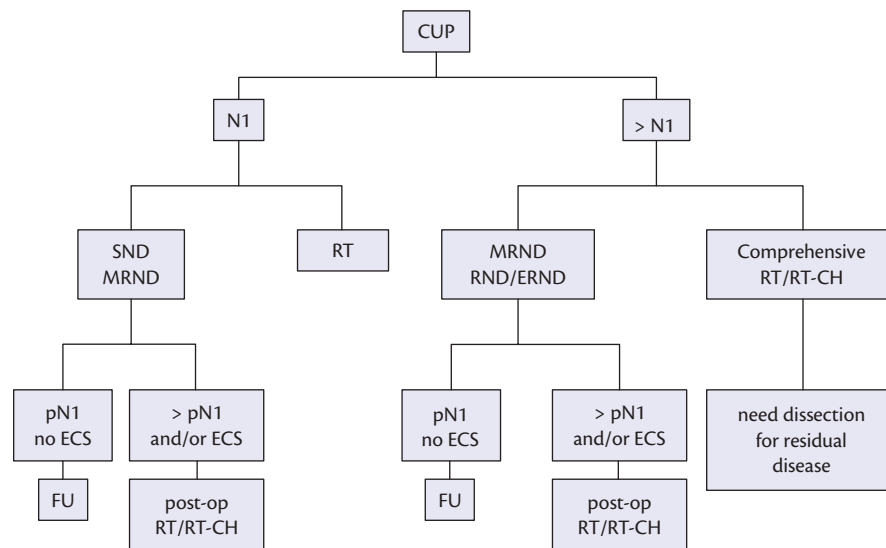
The diagnosis of CUP is made after exclusion of the presence of a mucosal primary. There are two mains options for the primary treatment of CUP: either a neck node dissection followed by post-operative radiotherapy or chemoradiotherapy, or a primary radiotherapy or chemoradiotherapy depending on the nodal stage, followed in case of residual neck disease by a selective neck dissection (see Figure 35.11). There is no data to suggest the superiority of one over the other. For radiotherapy, unilateral neck or bilateral neck, including the oropharyngeal, hypopharyngeal, and laryngeal mucosa are possible options. There is no definite data to demonstrate the superiority of one over the other, but owing to the reduced toxicity of unilateral irradiation, and the possibility of salvage treatment in


Fig. 35.11 Treatment algorithm of carcinoma of unknown primary (CUP).
Abbreviations: ECS, extracapsular spread; ERND, extended radical neck dissection; FU, follow-up; MRND, modified radical neck dissection; RND, radical neck dissection; RT, radiotherapy; RT-CH, concomitant chemoradiotherapy; SND, selective neck dissection.

case of emergence of a mucosal primary and/or a contralateral neck node development, the former is becoming the preferred option.

Recurrent and/or metastatic squamous cell carcinoma of the head and neck

Extent of the problem

Squamous cell carcinoma of the head and neck (SCCHN) is in great majority a locoregional complex disease, with evidence of dissemination in 10% or less at first presentation. Therefore, achieving adequate locoregional disease control of this primary disease, whether by surgery, radiation (with or without the additional use of systemic treatment), or a combination of these, is of central importance when managing patients with SCCHN. Failing to do so will lead to persistant disease (disease left behind after completion of primary treatment), recurrent disease (to be differentiated from second primary tumours (SPTs) in time and location [202]) and/or distant metastases. Moreover, past and current lifestyle choices in many cases increase the risk for new primary cancers even when the initial tumour has been cured. According to the MACH-NC data from 50 CCRT trials and 30 ICT trials, the rates of local and/or regional recurrences (LRRs) at five years were 50.8% and 47.5% in the experimental arms, respectively, and 60.1% and 46.5% in the control (RT alone) arms of the trials, respectively [203]. The corresponding rates of distant metastases (DM) were below 20%. Factors to be considered when choosing treatment in these circumstances include the extent of the recurrence, the type of initial curative treatment and the time interval between that treatment and the recurrence, the patient's performance status comorbidities and preferences after being well informed. Curative intent strategies in case of local and/or regional recurrences will be possible only in 50% or less [204].

Retreatment strategies

Surgery

Salvage surgery is the treatment of choice for all patients with resectable LRRs or second primary tumours and sufficient good health,

and therefore should be considered first at all times. Goodwin reported that based on a meta-analysis of 32 studies a survival rate of 39% could be expected at five years with salvage surgery [205]. However, the best chances of cure were in those patients with early-stage recurrent tumours and in those with recurrent cancer of the larynx, whereby the treated site seemed to be of less importance than the recurrence stage [205]. Unfortunately, those with limited tumour bulk (after adequate staging with PET or PET/CT) who are also medically fit comprise only 20% or less of the LRRs. Consultation with a radiologist and a careful examination under general anaesthesia is needed. Not only the extent of the recurrence is of importance but also the original extent of the tumour, since it is generally considered mandatory to excise the original extent of the tumour with a generous margin to obtain microscopic radicality. Major salvage surgery nearly always requires flap reconstruction for adequate wound healing and to permit the best post-operative function and quality of life. After (chemo-) radiotherapy, microvascular surgery is often possible and probably still the favoured method, especially for oral and oropharyngeal cancers because pedicled flaps may result in less optimal wound healing and yield inferior functional results. Tonsillar defects can often be reconstructed well with a relatively thin fasciocutaneous flap, whereas base-of-tongue reconstruction often requires an intermediate thickness flap. Laryngectomy defects require a free or pedicled flap as reinforcement of the suture line or as a patch. As to surgery for isolated residual or recurrent disease in the neck, there is a tendency to perform (super)selective neck dissections that remove only the level(s) that contain disease. This does not seem to compromise control of disease, obviates the need for flap surgery, and limits complication rates. Most authors reserve salvage neck surgery for those patients that have evidence of regional recurrence, and refrain from planned neck dissections even for the higher N stages. Salvage laryngectomy for laryngeal cancer recurrence offers survival in the range of 35–66%, albeit with a substantial risk of complications [206–208]. Good function outcome can be expected; the vast majority of patients are able to produce speech

using a voice prosthesis, and have a 'normal' or 'soft' diet. Major salvage surgery for other sites yields results that are less favourable (27–40% survival) and likewise carry a fairly high complication rate [205]. Positive surgical margins are the main negative prognostic factor in multivariate analysis, pointing to the great importance of appropriate selection of patients. Regional control after salvage neck dissection can be achieved at five years in the order of 80% [209].

Re-irradiation

Proper selection of patients for re-irradiation is also of major importance. Only those with no or insignificant organ dysfunction and comorbities should be considered candidates for re-irradiation [210]. If possible, the functional status of the patient should be assessed by using standardized measures, such as the Charlson comobidity index or ACE-27 grading [204]. Favourable prognostic factors are the possibility of removing the recurrence beforehand, having a long interval between the recurrence and the initial treatment, and being able to give an adequate radiation dose, while prior CCRT is an unfavourable condition [211].

Patients with resectable recurrences or new primary cancers in a previously irradiated area who undergo salvage surgery should be considered for re-irradiation plus concurrent systemic treatment (whether cytotoxic or non-cytotoxic) when histopathology is showing high-risk features such as positive margins or extracapsular extension. This will lead to a better locoregional control rate, but at the expense of a higher toxicity (grade 3–4 late toxicity in >1/3 of patients and up to 8% treatment-related deaths) and no clear survival advantage compared to no post-operative reirradiation [205, 212, 213]. Expected OS rates at two years are in the order of 40–50% [205].

Patients with unresectable disease, as expected, do less well. Reviews have suggested that one-quarter to one-third of the patients will be free of locoregional disease at two years and two-year OS will be in the order of 10–30%. Grade 3–4 late toxicity in these cases will occur in up to 40%, and nearly 10% of patients will have treatment-related deaths. In general, a radiation dose in the range of ≥60 Gy is recommended, delivered by using conventional fractionation (1.8–2 Gy/fx), hyperfractionation or hypofractionation (in case of stereotactic RT). General advice is to irradiate the gross tumour volume with a sufficient margin (around 5 mm) and no elective treatment of adjacent regions.

Alternative local therapies

Photodynamic therapy involves the use of a light-sensitive drug or photosensitizer (given systemically or topically), in combination with light of a visible wavelength, to destroy the target cells. Patients with early recurrences in the oral cavity, nasopharynx, and larynx might be candidates for such treatment when conventional treatments are not available or not appropriate [214, 215]. In addition electrochemotherapy (ECT) can be seen as an alternative. ECT is the local application of pulses of electric current to tumour tissue to render the cell membranes permeable to otherwise non-permeant or poorly permeant anticancer drugs, thereby facilitating a potential localized cytotoxic effect [216, 217]. However, experience with ECT is still rather limited and the optimal indication is rather uncertain. Both approaches suffer from lack of comparative data versus adequate salvage surgery or re-irradiation.

Systemic treatment

Unfortunately, most patients with recurrent/metastatic (R/M) SCCHN are only eligible for palliative treatment. Treatment options in these patients include supportive care only or supportive care plus single-agent chemotherapy, combination chemotherapy, or targeted therapies, either alone or in combination with cytotoxic agents. Negative prognostic factors for survival are a poor performance status, severe weight loss, tumours originating in the oral cavity or hypopharynx, well/moderately differentiated disease, and prior radiotherapy [218]. Response to cytotoxic chemotherapy also proves to be a favourable characteristic and is of prognostic significance. SCCHN is a chemosensitive disease, as is evident from responses observed with various drugs of different classes of cytotoxic agents [219]. The four most extensively studied single cytotoxic agents are bleomycin (which is hardly used anymore), methotrexate, 5-fluorouracil, and cisplatin. Newer agents from the same or other classes of cytotoxic agents also sometimes showed promising results, but when tested in randomized trials never surpassed the efficacy of methotrexate or cisplatin alone. Taxanes (when combined with platinum compounds) seem more favourable than 5-fluorouracil in the R/Ms disease setting, because they induce less mucositis, a troublesome side effect in particular in patients that have been previously treated with radiation. Table 35.5 summarizes the development of systemic therapy in R/M SCCHN and shows that 30 years after the first use of cisplatin in this disease, survival advantage was observed for the first time when platinum-based cytotoxic chemotherapy was combined with cetuximab, a chimeric IgG1 monoclonal antibody (MoAb) targeting the EGFR [220]. The safety profile of this PFE (platinum/5-FU/Erbitux®) regimen was quite acceptable, with no negative effect on quality of life and an improved response that coincided with a better symptom control [221].

Recent taxane/platinum/cetuximab combinations suggest that further response and survival improvement might be possible, but a phase III trial is necessary to prove this [222]. Unfortunately, phase III trials with other EGFR targeting agents, whether MoAbs (zalutumumab, panitumumab, nimotuzumab) or reversible selective

Table 35.5 Development of chemotherapy in R/M SCCHN. 1977: cisplatin shows efficacy in first-line SCCHN

Research group	N	Regimen	ORR (%)	Median OS (months)	Significant OS benefit

EGFR tyrosine kinase inhibitors (TKIs, such as erlotinib and gefitinib), failed to show significant survival benefit [223]. Therefore, cetuximab is the only targeted agent approved for use in R/M SCCHN in first-line in combination with platinum/5-FU, and in some countries also in platinum-refractory disease in second-line cases. Response rate with cetuximab is rather low, while EGFR expression generally is high. Identification of biomarkers predicting response to cetuximab and other anti-EGFR therapeutics is pressing, as well as unravelling of the underlying mechanisms of resistance [224]. In line with this are studies with a new generation of irreversible small molecule pan-EGFR inhibitors as well as dual targeting MoAbs and a mixture of MoAbs targeting non-overlapping epitopes on the EGFR with the hope of overcoming resistance and to further improve outcome [223]. In addition, other targeted agents, such as c-Met inhibitors, IGF-1R inhibitors, antiangiogenic agents, drugs that block the PI3K/Akt/mTOR pathway, drugs that block the STAT pathway, and drugs that target nuclear and regulatory mechanisms, such as proteasome inhibitors, HDAC inhibitors, and heat shock protein inhibitors are all being studied. It is clear that combinations or sequential targeted therapies needs to be further studied and that identification of predictive markers should get high priority.

Salivary gland cancer and paragangliomas

Salivary gland cancer

Epithelial malignancies of the paired major (parotid, submandibular, and sublingual) and minor salivary glands (MiSG) are most complicated, due to their low incidence. The incidence in the US is ten patients per 10^6 per year. In Europe, Belgium, the Netherlands, the UK, and Finland have approximately six to seven new cases per 10^6 per year. Up to 70% arise in the parotid, 10–25% in the MiSG; the rest are submandibular carcinomas, with sublingual carcinomas being very rare [225].

Clinical presentation—imaging—pretreatment tissue diagnosis

Most parotid tumours present as an asymptomatic peri-auricular lump. Malignancy is suspected by rapid volume increase, pain, enlarged cervical lymph nodes, fixation to deep structures or facial skin, or facial nerve (VIIN) dysfunction. Surgery with or without adjuvant therapy being the treatment of choice, the workup evaluates the likelihood of malignancy and the extent and location of a tumour. Imaging is needed when tumour mobility is impaired, the tumour is >4 cm, and there is any sign of malignancy. MRI outperforms CT for the retromandibular parotid, the stylomastoid foramen area, and for identifying perineural extension. PET with or without CT is performed to exclude distant metastases. The resulting information, summarized in the TNM classification, combined with other clinical, histopathological, patient, and tumour characteristics, determines treatment options [226].

A submandibular gland cancer patient mostly presents with a slow-growing, painless mass under the jaw, occasionally with distortion of the floor of the mouth. Pain (30%) suggests local tissue extension. Cervical lymphadenopathy is present in 25% of patients. Radiological evaluation of submandibular salivary gland cancer (SGC) does not differ from the parotid subsite as mentioned above.

MiSG carcinomas (MiSGCs) are found throughout the entire upper aerodigestive tract and symptoms depend upon the anatomical site involved. Most frequently the oral cavity and oropharynx are affected, with the classical presentation of a painless submucosal swelling, sometimes altering denture positioning. In the nose and pharynx, MiSGC mostly causes obstructive symptoms. Pain is reported in one in four, regional metastasis in one in six patients [227]. To estimate the anatomical involvement, imaging (CT +/– MRI) is mandatory. For MiSGC an incisional biopsy provides the histological information needed to plan further treatment. As for major SGC, the TNM-components and stage grouping are the strongest prognosticators [225].

Before embarking on treatment, for major SGC, FNAC reasonably differentiates between malignant and benign lesions (accuracy 79%). Even if FNAC suggests benign disease, removal of the tumour for further histopathology remains mandatory. In MiSGC, the submucosal tumour is accessible for incisional biopsy, providing a more representative specimen for histopathologic subclassification. The caveat to interpreting these biopsies is that many of the 24 SGC types (Table 35.6) have overlapping histological features. Increasingly, molecular biological studies are performed, on the incisional biopsy material as well [225, 228].

Table 35.6 The WHO 2005 histologic classification of malignant salivary gland tumours

Type WHO	Abbreviation
1. Acinic cell carcinoma	AcCC
2. Mucoepidermoid carcinoma	MEC

Treatment: surgery yields post-operative histopathological information

For parotid cancer the best chance of cure follows primary excision, the extent of which depends on the tumour size, the relationship to the VIIN, and extraparotid tissue invasion. For the majority of cancers with a normal functioning VIIN that are located in the superficial parotid lobe (80%), a standard superficial parotidectomy is adequate. Tumours >4 cm, located in the parapharyngeal or deep lobe, or with VIIN involvement should have a total or radical parotidectomy, considering that in high-stage, high-grade parotid cancer, the intraparotid lymph nodes may harbour metastatic disease. Alternatively, one may choose to rely on post-operative radiotherapy to control these possible microscopic deep lobe lymph node deposits [229]. In the same way, it is accepted that microscopical disease left behind on a non-involved spared VIIth branch can be controlled by post-operative radiotherapy. Regional metastasis is seen in one in three patients with parotid cancer, involves mostly levels II, III, and IV, and requires a (modified) radical neck dissection, removing levels I to V; radicality towards the non-lymphatic structures (nerve XI, jugular vein, sternocleidomastoid muscle) depends on proximity of the lymph node metastasis. In pN+ patients, radiotherapy improves locoregional control and survival [230, 231]. In patients with a cN0 neck at presentation, elective treatment (elective neck dissection or radiotherapy) depends on risk factors for occult neck disease (tumour size >4 cm, histology with clinical high-grade behaviour, age >54, perilymphatic and extraparotid extension) [8]. In our practice, we fine-tune the surgical approach to the N0 neck using preoperative USgFNAC and perioperative frozen section of the level II lymph nodes; if the latter reveal macrometastases, a modified neck dissection follows [226]. The MD Anderson approach is elective radiotherapy to the cN0 neck in high-risk patients, relying on definitive histopathology of the resected primary, because the indications for elective neck treatment concur with the indications for post-operative radiotherapy to the primary, and because pre- and perioperative typing of SGC is difficult (accuracy 51–62%) [232].

For submandibular gland cancer, treatment has shifted in the last decades from aggressive surgery, including the submandibular gland in a radical neck dissection, often with en bloc excision of the floor of mouth and lower rim of the mandible as monotherapy [233], to more limited surgery, supplemented by post-operative radiotherapy (level I–II–III dissection comprising the submandibular gland, only to be extended if disease extension dictates so) [234, 235].

For MiSGC, the treatment of choice is resection of the primary with free margins, resection margin status being the most important prognosticator, correlating strongly with anatomical extent and histological type [225]. The neck in MiSGC should be only addressed surgically for cN+ disease, for a cN0 neck when the risk of subclinical disease exceeds 20%, or when the neck is surgically entered as an approach to the primary [227]. Except in high-grade MEC, the occult metastasis rate is too low to justify elective treatment. For patients with pN+ disease, post-operative radiotherapy improves locoregional control and survival [231].

Following resection, the pathologist types the tumour using the 2005 WHO classification (Table 35.6) and identifies grade and negative prognostic factors such as perineural, vascular, and perilymphatic growth, and involved margins. Increasingly, molecular markers including chromosomal translocations with their protein products, improve accurate histological diagnosis. Some tumours express androgen receptors (AR) that could be also therapeutically exploited. There is no clear relationship between histotypes and biological behaviour, as commented by Leivo [236]. In population-based studies, the majority of major SGC are acinic cell carcinoma (AcCC) (15–17%), adenoid cystic carcinoma (AdCC) (16–27%), and MEC (14.5–19.2%). For MiSGC, AdCC (32–71%) and MEC (15–38%) outnumber adenocarcinoma not otherwise specified (ACNOS), AcCC, polymorphous low-grade adenocarcinoma (PLGA), epithelial myoepithelial carcinoma, and carcinoma ex-pleomorphic adenoma [225, 226].

Post-operative radiotherapy for parotid and submandibular carcinomas

Indicated in stage III and IV disease, and in case of adverse histopathological factors (perineural and vascular invasion, close or positive margins, high-grade pathology), IMRT is now the 'standard of care' that minimizes complications. Typically a dose of 60 Gy in 30 fractions of 2 Gy in six weeks will be delivered on the parotid bed and the neck node levels (when pathologically invaded). In case of AdCC infiltrating the facial nerve, a comprehensive coverage of the nerve up to the base of the skull is recommended. The Dutch Head and Neck Oncology Cooperative Group found a 9.7-fold reduction of local recurrence in patients receiving combined surgery and radiotherapy as compared to surgery-only patients. Post-operative radiotherapy can only be omitted for stage I–II lesions in AcCC and low-grade MEC if complete resection does not reveal adverse pathological factors [226]. For high-risk major SGC, two reports recently suggested the benefit of a post-operative platinum-based concomitant chemoradiation scheme [237, 238].

Post-operative radiotherapy for MiSGC

For MiSGC, post-operative radiotherapy to the primary site is recommended for most patients, only to be omitted in 'clear margin' stage I and II disease without lymphovascular or perineural invasion [225, 227, 231].

Radiotherapy and chemotherapy in unresectable disease

For patients who are inoperable, who refuse surgery, or who have an unresectable tumour, primary photon-based radiotherapy (dose of 66 to 70 Gy) results in 17–57% locoregional control at ten years. In a randomized trial conducted 30 years ago, neutron radiotherapy reached up to 75% five-year local control, especially for AdCC, but remains unattractive because of no survival benefit and severe late side effects [239]. More recently, encouraging results have been reported with the use of heavy ion therapy (carbon ion), which combines both the biological advantage of neutrons and an exquisite dose distribution [240].

In SGC chemotherapy remains of palliative use only, resulting in a temporary benefit in about 20% of treated patients. The most active drugs are cisplatin and doxorubicin [241–243]. Taxanes are not active in AdCC. In this latter histotype it is worthwhile suggesting a watchful approach in indolent diseases. Table 35.7 lists the targeted therapies that have been explored clinically. Unfortunately, none has significantly improved results.

AR expressing tumours might be treated with androgen deprivation.

Treatment results according to site

The treatment results for parotid carcinoma in major treatment centres, listed in Table 35.8, have to be appreciated in their specific

Table 35.7 Molecular targets and corresponding therapies studied in salivary gland carcinoma

Molecular target	Salivary gland carcinoma type	Molecular therapy
c-KIT	AdCC	imatinib
ErbB−1	All types	cetuximab gefinitib
ErbB−2	All types	trastuzumab lapatinib
VEGF −family	AcCC	axinitib
NFκB − proteasomes degrading its inhibitor (I-κB)-α	AdCC	bortezomib

context of stage, percentage high-grade, treatment period and corresponding treatment regimens, patient inclusion criteria, and adequacy of follow-up. Many univariate and multivariate statistical analyses have focused on prognostic factors in SGC to fine-tune the individual patient's prognostic estimate [226].

Treatment results for submandibular gland cancer have increased recently as compared to the earlier series where post-operative radiotherapy was not yet customary. The five-year disease-free survival (DSS) of 61% and the ten-year DSS of 51% in Amsterdam [234] are similar to the findings in Toronto with a five-year DSS of 60% and a ten-year DSS of 48% [244].

For MiSGC, five-year survival ranges from 66% to 80% and ten-year survival from 56% to 70%, whereas initial tumour control is expected to be 56–62%. MSGCs overall do not imply a poorer prognosis than their submandibular and parotid counterparts, although specific subsites (e.g., the skull base) imply a worse outcome [225].

Summary

Every step in the management of SGC is complicated: the clinical and radiological evaluation, the pathology, the ablative and reconstructive surgery, the radiotherapy and eventual chemotherapy, and the management of complications. The best care can undoubtedly be provided when these patients are centralized in specialized tertiary referral centres.

Cervical paragangliomas

Cervical paragangliomas (PG) are highly vascular soft tissue tumours, originating from the paraganglia receptors in the vascular adventitia. They follow the course of cranial nerve X in the skull base and the parapharyngeal space lower down. With decreasing frequency they arise from the carotid body, jugular, tympanic, and vagal locations. The incidence of these rare head and neck tumours remains unclear, since most are benign tumours, not registered by cancer registries. About 6–19% are reportedly malignant, evidenced only by imaging studies showing local invasion, regional or distant metastasis, since the histological appearance of malignant PG is identical to that of benign tumours [245].

Genetics

About nine in ten PGs are sporadic; in one in ten patients a mutation in the succinate dehydrogenase (SDH) subunits (SDHD, SDHB, SDHC) genes typically causes development of multifocal PG at age <40, and in combination with pheochromocytomas [246].

Clinical presentation—workup

Most patients with carotid PG present with an asymptomatic pulsatile neck mass which patients report to vary in volume. At other sites, symptoms of PG reflect the cranial nerves they interfere with, ranging from vague pain through hearing loss, pulsatile tinnitus (n VIII), velopharyngeal insufficiency (n IX), chronic cough, dysphagia, dysphonia, aspiration (n X) and shoulder weakness (n XI). Up to 3% of PGs secrete catecholamines, detected by urinalysis. CT+/− MRI+/−MR angiography of the head and neck are so typical (salt and pepper appearance, flow voids, splaying of the carotid bifurcation for carotid body tumours, anterior displacement of both internal and external carotid artery in vagal paraganglioma) that they are sufficient for diagnosis, obviating a (hazardous) biopsy. Imaging studies reveal location, extent, relation to the great vessels, and eventual coexistent PG at other sites. For the latter, a somatostatin receptor scanning (octreotide scan) is also useful.

Treatment and outcome

There are three valid options to choose from. The slow growth rate, with half of the tumours not showing volume increase during long-term follow-up, supports an initial wait-and-scan policy for many patients [247, 248]. Alternatively, in volume-increasing lesions, both surgery and radiotherapy (IMRT: moderate-dose RT of 44–50 Gy over 22–25 fractions or in selected very small skull base lesions, stereotactic radiosurgery) are valid options [245, 249]. Given the potential complications, surgery is usually reserved

for limited PG where minimal morbidity is expected. Typically, these are the 70% of carotid body tumours that are Shamblin class I (small and easily dissected from the vessels) and class II (glomus tumour partially surrounds the vessels). For all other tumours (class III carotid body tumours and vagal—jugular –tympanic PG), new post-operative cranial deficits are hard to avoid. A recent review looking at 'all surgically treated carotid PG' observed 22% new cranial nerve deficits, 3% stroke, and 1% peroperative deaths [250]. The same authors reviewed the literature on vagal and jugular PG and concluded that on average 1 extra post-operative cranial nerve deficit is observed per patient operated, as opposed to eight post-treatment cranial nerve deficits per 100 patients treated with RT, at a comparable local control rate of 80–90% for both modalities. Ten-year local control rates using RT of 94% and higher are reported [251, 252]. It can be concluded that RT has comparable tumour control and significantly less morbidity than surgery. A choice for surgery should put in the balance the patient's age, tumour size, predicted tumour growth, and cranial nerve function in order maximally to safeguard quality of life.
