It is unusual for patients to have melanoma bone metastases without metastatic disease at other sites, and the main role of surgery is to prevent or relieve symptoms. This may involve bone resection, enucleation of the tumour (then filling the resulting cavity with bone cement), joint replacement, operative bone fixation, or the use of external braces or a cast. Many bone metastases can be treated effectively with radiotherapy, and radiation is often given as adjuvant therapy following a surgical procedure for a bone metastasis. Metastases involving the spinal vertebrae have potentially serious implications, because pathological fractures or tumour expansion may cause spinal cord compression. When this occurs, urgent decompressive laminectomy may be required with adjuvant postoperative radiotherapy. If there is judged to be no imminent risk of spinal cord compression, most vertebral metastases can be treated effectively with external beam radiotherapy.

Systemic therapy for Stage IV disease

Targeted drugs

BRAF inhibitors

The MAPK pathway is strongly activated in 90% of melanomas. In approximately 50% of cases this is caused by activating mutations in BRAF; the most common of these is substitution of glutamic acid for valine at amino acid position 600 (V600E), which locks the kinase in activated conformation. Other activating mutations also occur, including V600K, V600D, and V600R. Vemurafenib

and dabrafenib are potent and selective inhibitors of mutant BRAF. They induce tumour regression in the majority of patients who have V600-mutant BRAF melanoma, with overall response rates of 50–60%. Responses occur in all sites, including brain. In a Phase 3 trial of vemurafenib in treatment-naive patients there was a statistically significant improvement in overall survival from 9.6 months with the standard comparator, dacarbazine (DTIC), to 13.2 months with vemurafenib. The true benefit of vemurafenib was underestimated in this trial, however, because 50 dacarbazine-treated patients crossed over to receive vemurafenib 12 months after trial commencement when the clear benefits of the test drug became obvious at interim data monitoring. Vemurafenib and dabrafenib have both been approved by the FDA for treatment of V600-mutant BRAF melanoma.

Median progression-free survival with vemurafenib and dabrafenib is 5–6 months, and this has prompted vigorous examination of mechanisms of emergent resistance to therapy with BRAF inhibitors [6]. Most clinically relevant mechanisms involve reactivation of the MAPK pathway by upstream activation, including NRAS mutation and RTK over-expression, amplification of mutant BRAF, and emergence of active splice variants of BRAF which are unaffected by BRAF inhibitors. Approaches to overcome resistance to BRAF inhibitors include combining BRAF and MEK inhibitors (see below), adaptive trial design using other combinations of targeted drugs, and the use of pulsed therapy, which has shown remarkable efficacy in an animal model.

BRAF inhibitors are well tolerated. The most common side effects are skin rashes, including Grover's disease, papillomas and verrucas, and other keratopathies. Vemurafenib, but not dabrafenib, is severely photosensitizing, an effect unrelated to BRAF inhibition. Paradoxical activation of the MAPK pathway may occur in keratinocytes carrying upstream activators like RAS mutations. In the presence of BRAF inhibition this results in heterodimer formation between RAF family members and downstream MAPK stimulation. In 10–20% of treated patients this may result in the formation of keratoacanthomas or squamous cell carcinomas. These are readily treated by surgical excision, but regular skin surveillance is essential for patients on BRAF inhibitors. This paradoxical oncogenesis has also been associated with an increased incidence of second primary melanomas and induction of acute leukaemia.

MEK inhibitors

MEK inhibitors are active in patients with mutant BRAF melanoma, presumably because of the high level of stimulation of the pathway downstream of BRAF in these tumours. A number of drugs in this class are undergoing clinical development. Trametinib confers benefits in both progression-free and overall survival compared to standard chemotherapy, with an overall response rate of 22%. Some MEK inhibitors such as MEK162 show some evidence of activity in mutant NRAS melanoma, for which there are currently no other established targeted systemic treatment options, and clinical trials are proceeding with these drugs.

The dominant toxicities of MEK inhibitors are acneiform rashes, diarrhoea, nausea, oedema, and fatigue. Central serous retinopathy and retinal vein occlusion are rare side effects which mandate careful ophthalmological monitoring of all patients treated with these agents.

Combined BRAF and MEK inhibition

The demonstration that MAPK reactivation was responsible for most cases of emergent resistance to BRAF inhibition, together with in vitro demonstrations of synergy and reduced toxicity, led to clinical trials of combined BRAF and MEK inhibition. In a randomized Phase 2 study the combination of dabrafenib plus trametinib in patients naïve to BRAF inhibitors showed an overall response rate of 63% in the maximally dosed cohort, with a median progression-free survival of 9.4 months compared with 5.8 months in the single-agent dabrafenib arm and 12-month progression-free survival of 41% vs 9%. The combination also rescued some patients refractory to BRAF inhibitors, with an overall response rate of 19% and median progression-free survival of 3.6 months. Phase 3 trials have commenced comparing the doublet with single-agent dabrafenib or vemurafenib, but these early results suggest that dual MAPK blockade with BRAF and MEK inhibitors is likely to become standard therapy for BRAF-mutant melanoma. The impressive activity of this combination has led to the dabrafenib/trametinib doublet being tested in the adjuvant setting in the 'Combi-AD' trial.

Some of the more notable toxicities of the MAPK inhibitors cancel each other out when used in combination. The presence of a MEK inhibitor appears to block paradoxical MAPK activation in keratinocytes, reducing SCC incidence to near-background levels, and BRAF inhibition appears to block the acneiform rash of MEK inhibitors. Drug-induced fever occurs, however, in more than 50% of patients on the dabrafenib/trametinib combination.

Other BRAF/MEK inhibitor combinations being assessed in early clinical trials include LGX818/MEK162 and vemurafenib/cobimetinib.

KIT inhibition

A small subset of mucosal, acral, and chronic sun-damaged skin melanomas carry activating mutations in the KIT oncogene. Some, but not all, of these mutations are sensitive to inhibition with imatinib, sunitinib, or nilotinib. The likelihood of response correlates with the ratio of mutated:wild-type KIT alleles in the melanoma cell. Response duration is generally measured in months.

Other molecular targets

Approximately 20% of cutaneous melanomas carry NRAS mutations. These are nearly always reciprocal to BRAF mutations, unless the tumour has been previously exposed to the selective environment of BRAF inhibition. NRAS is a difficult target for designing small molecule inhibitors, and preclinical and early clinical focus is on downstream effectors including MEK and PI3K.

There is evidence for activation of the AKT/PI3K pathway in many melanomas, and in a subset of tumours resistant to BRAF inhibitors. Multiple PI3K inhibitors are being assessed in clinical trials both as single agents and in combination with MAPK inhibitors.

The high frequency of CDKN2A/p16 alterations in melanoma and amplification of cyclin D1 both point to the importance of this for regulation of the melanoma cell cycle, and drugs targeting this axis are in early clinical development.

Immunotherapy

Vaccines

Despite the presence of detectable immune responses in 30–60% of patients, tumour regression occurs in only a minority of vaccine-treated

metastatic melanoma patients. Vaccine therapy remains under intense investigation in the adjuvant setting, and may have a role in combination with other immunotherapies in metastatic disease.

Adoptive immunotherapy

In carefully selected patients, high rates of disease control are reported with adoptive immunotherapy programs. These involve harvesting, then ex vivo expansion and sometimes genetic manipulation, of tumour infiltrating lymphocytes (TIL). Typically, patients are conditioned with lymphodepleting cytotoxic chemotherapy, with or without cytokines and whole body radiotherapy, before reinfusion of expanded TIL. The best series response rates were 50–70%, with small numbers of patients remaining disease-free at over four years. Inpatient support is required following immunoconditioning and toxicity includes febrile neutropaenia in 12–16% of patients. Several centres internationally are developing simplified and less toxic protocols of adoptive immunotherapy, including the use of genetically-engineered T cells expressing chimeric antigen receptors (CAR-T cells).

Interleukin-2 and interferon-alpha

Interleukin-2 (IL-2) is FDA-approved for treating metastatic melanoma based on a retrospective series showing sustained disease control in a small subset of treated patients. Although the overall response rate was just 16%, one quarter of responding patients had sustained disease control, most beyond five years. Gene expression profiles may assist in identifying those who may benefit from IL-2. The toxicity of IL-2 therapy is high and includes hypotension in 64% of patients and treatment-related mortality in 2.2%.

Single agent interferon-alpha has a response rate of approximately 20% in metastatic melanoma in Phase 2 trials but response duration is brief and use is restricted by the high incidence of influenza-like toxicity including fatigue and fever. Routine use is not recommended by most international guidelines except in the adjuvant setting and in clinical trials.

Immune check-point regulators

Activation of the immune response is kept in check at both induction and effector phases by complex molecular interactions inducing feedback inhibition of T cell proliferation and cytokine release to dampen down the immune response and prevent autoimmunity. Melanoma cells subvert this system to induce immunological tolerance. Molecules which target check-point regulation induce potent immune responses against melanoma cells and are active in the treatment of metastatic disease.

CTLA4 inhibitors

Ipilimumab is a monoclonal antibody which binds to CTLA4 on regulatory T cells, inhibiting its interaction with B7 on antigen-expressing cells, and removing a regulatory brake on T cell activation. In a phase 3 clinical trial of metastatic melanoma patients refractory to prior systemic therapy, ipilimumab (3 mg/kg) with or without a gp100 vaccine proved superior to vaccine control in overall survival. In first-line therapy of metastatic melanoma, the combination of ipilimumab (10 mg/kg) with the cytotoxic drug dacarbazine proved superior in overall survival to dacarbazine/placebo control. Notable in this trial was a 10% improvement in landmark absolute overall survival benefit at two years (28.5% vs 17.9%) and three years (20.8% vs 12.2%).

Tumour response rates to ipilimumab are low (~10%), and grade 3–4 autoimmune toxicity occurs in more than one half of all treated patients. Dermatitis and colitis are the most common toxicities, but are readily reversible with corticosteroids. Biopredictors of the subgroup of metastatic melanoma patients who respond to CTLA4 inhibition are eagerly sought, as they are for all forms of immunotherapy of this disease. Ipilimumab is FDA approved for the treatment of metastatic melanoma.

A second anti-CTLA4 monoclonal antibody, tremelimumab, showed similar promise to ipilimumab in Phase 2 clinical trials, but failed to show superiority over chemotherapy as first-line therapy. The reasons for the failure of tremelimumab to replicate the benefits of ipilimumab are not clear but may relate to dosage schedules or pharmacokinetic and pharmacodynamic factors.

Drugs targeting PD-1 and PD-1 ligand

Pro-death receptor-1 ligand 1 (PD-L1) is expressed on many melanoma cells. PD-1 is an immune check-point regulator expressed on cytotoxic T lymphocytes which dampens the immune response and induces immune tolerance. Phase I trials of the monoclonal antibodies nivolumab and lambrolizumab, which target the interaction between PD-1 and its ligand, show promising activity with remissions in around 20–50% of patients. Autoimmune toxicity seems much lower than that seen with ipilimumab. Expression of PD-L1 on tumour and stromal tissue is being investigated as a possible biomarker predicting response to anti-PD-1 therapy. Monoclonal antibodies against PD-L1 also have activity against metastatic melanoma and are in clinical trials.

Combined use of nivolumab with ipilimumab provides synergistic benefit in patients with metastatic melanoma, with tumour remissions that are frequent, rapid and durable, with median two-yearly survival close to 80% and with manageable toxicity [7].

Chemotherapy

Melanoma has formidable defences against the induction of apoptosis and this probably accounts for its relative resistance to cytotoxic chemotherapy. Single-agent dacarbazine (DTIC), temozolamide, and fotemustine are used as systemic therapy of metastatic melanoma because of their relatively low toxicity and simplicity of administration, and because of the failure of more toxic combination therapies to show superiority in terms of survival outcomes. However, response rates to dacarbazine and temozolamide in recent randomized trials have been less than 10%, the median duration of response is brief, and the median overall survival nine months. The small group of patients who benefit cannot be reliably predicted by tumour biomarkers. Chemotherapy response is more likely in subcutaneous, lymph node, and pulmonary metastases than in other visceral sites, and in those with better performance status. A Phase III Trial of three-agent chemotherapy versus the same drugs plus interferon-alpha and interleukin-2 ('biochemotherapy') produced a slightly higher response rate and progression-free survival for biochemotherapy, but this was not associated with either improved quality of response or better overall survival. NAB-paclitaxel shows improved progression-free survival over dacarbazine and the combination of paclitaxel and carboplatin also produces slightly higher response rates (18%). However, these small gains are not matched by overall survival benefits and are only achieved at the cost of higher haematological and neural toxicities.

The role of radiotherapy for Stage IIIC and Stage IV melanoma

Sixty years ago it was suggested that melanoma was a tumour type that was particularly resistant to radiation therapy. However, this perception was based on the results of radiotherapy techniques that have long since been superseded.

Today radiation therapy is widely used to treat metastatic melanoma at distant sites. It is usually given with palliative intent, and in some patients prolonged disease control is achieved. A detailed consideration of the clinical radiobiology of melanoma is beyond the scope of this chapter, but is discussed in detail elsewhere.

Cutaneous and subcutaneous metastases

When surgical excision of troublesome cutaneous or subcutaneous metastases at distant sites is not possible, radiotherapy may be an effective treatment option.

Lymph node metastases

Extensive metastatic lymph node disease that is not amenable to surgical treatment and has failed to respond to systemic therapy can often be effectively palliated with radiotherapy. A commonly used treatment schedule involves the administration of 20 Gy in five daily fractions. A bolus dose may be required for nodal masses that have fungated.

Cerebral metastases

Cerebral metastases frequently cause significant morbidity and without treatment the prognosis of patients who develop cerebral metastases is bleak; their median survival is only three to four months, and up to 95% of them die as a direct result of their brain metastases. Although it is difficult to separate out the effects of case selection, there is persuasive evidence that treatment involving surgery and/or radiotherapy can extend survival times considerably. There is also evidence that stereotactic radiosurgery (SRS) is as effective as surgical excision of single brain metastases, but several metastases may be readily treated by SRS, whereas surgery is rarely considered feasible under these circumstances. Control rates reported after SRS for the treatment of melanoma metastases in the brain are high, with individual treatment centres reporting local control rates of 80–90%.

The role of WBRT after surgical resection of cerebral metastases or following their treatment with SRS remains controversial. The main deterrent to the use of WBRT has been the perception that there is a treatment-related decline in neurocognitive function following its use. A large prospective, multicentre randomized trial assessing the value of WBRT following treatment of melanoma cerebral metastases by surgery or SRS is currently in progress.

Spinal cord compression due to melanoma metastases

This problem usually arises as a result of extra-dural compression from an expanding vertebral metastasis. Occasionally, however, the compression arises from a metastasis within the spinal cord itself or as a result of diffuse meningeal involvement. The classical clinical picture is of progressively severe back pain in a patient known to have disseminated melanoma. This is followed by the typical clinical signs and symptoms of spinal cord compression, with loss of bladder and bowel control, loss of strength in the lower limbs, with paresthesiae or numbness, and ultimately paraplegia. Malignant spinal cord compression constitutes an oncological emergency. The definitive investigation is an MRI scan of the spine, and high-dose corticosteroids should be commenced immediately if the condition is suspected. Treatment options are surgical decompression or urgent radiotherapy. A decision about which treatment to offer the patient depends on numerous factors, not only the location and extent of the metastasis that is causing the problem, but also the patient's general condition, the presence of systemic metastases at other sites, and the extent of spinal involvement. There is general consensus that patients with isolated vertebral lesions causing spinal cord compression who are considered to have a reasonable life expectancy should be offered decompressive surgery followed by post-operative radiotherapy. In patients who are not considered to require urgent surgery, radiotherapy should be offered. Steroid therapy is continued throughout the treatment course and then slowly tapered when it is complete. If neurological deterioration is observed during the course of palliative radiotherapy to the spine, urgent surgical decompression must be considered to avoid paraplegia. However, relief of symptoms after palliative radiotherapy for threatened spinal cord compression has been reported in two-thirds of patients.

Bone metastases

Metastases involving bone (other than the vertebral column) are a common problem in patients with disseminated melanoma. Patients with bone metastases typically present with pain, with progression to pathological fracture of the involved bone in many cases if the lesion is not treated. Bone metastases frequently extend into the surrounding tissues, a situation that may be apparent on CT or MRI scans. Bone metastases are often well managed by palliative radiotherapy, which provides relief of pain in over 65% of cases. Threatened or actual pathological fractures require internal fixation, followed by post-operative radiotherapy.

Other sites that may be treated with radiotherapy

Other indications for the treatment of metastatic melanoma with radiotherapy include metastases in soft tissues that are causing pain as a result of local invasion, lesions that are causing blood loss, e.g., in the bronchial tree, and lesions that are causing obstructive symptoms, e.g., metastatic nodes in the mediastinum or metastatic deposits in the oropharynx, pharynx, trachea, or the bronchial tree. Another situation where radiotherapy is sometimes useful is when there is metastatic disease in the orbit, causing proptosis, diplopia, and impaired visual acuity.

Metastatic melanoma from an unknown primary site

In approximately 10% of patients in whom metastatic melanoma is diagnosed in lymph nodes, there is neither evidence of nor any prior history of a primary melanoma. This phenomenon is attributed either to complete regression of a previously existing unrecognized primary melanoma, or to de novo development of melanoma in naevus cells within a lymph node (which are commonly observed). Whatever the aetiology of the condition, the prognosis for the patient is somewhat better than for a patient with equivalent nodal disease from a known primary site. Much less frequently, systemic metastases are diagnosed when there is no known primary melanoma site. In both situations, treatment should be the same as for metastatic disease from a known primary site.

Non-cutaneous melanoma

Although the majority of melanomas arise in the skin, melanomas can also develop at mucosal sites. Ocular melanomas are considered in Chapter 57, Tumours of the eye and orbit. Mucosal melanomas are rare. Sites at which they can develop include the oropharynx, oesophagus, lung, stomach, gall bladder, small bowel, large bowel, rectum, anus, urethra, vagina, and cervix. The principles of treatment for primary melanomas arising in all of these sites are similar, i.e., by complete surgical excision whenever possible. There may be a role for radiotherapy as definitive therapy in the management of mucosal melanoma.

Guidelines for the management of melanoma and the importance of multidisciplinary care

Over the past twenty years, the surgical management of primary cutaneous melanoma has changed substantially. Whereas elective dissection of regional lymph node fields was routine in many melanoma treatment centres until the early 1990s, the introduction of SLNB has meant that the great majority of patients have been spared the morbidity of that approach, and only those found to have metastatic disease in a SLN (around 20% of those with melanoma >1mm in thickness) are subjected to CLND. The recommended width of excision for a primary cutaneous melanoma has reduced progressively, after clinical trials indicated that 1–2cm margins were adequate for most patients, with very low rates of local recurrence and no adverse effect on melanoma-specific survival compared with wider excision margins. More recently, the introduction of several forms of effective systemic therapy has changed management strategies for patients with Stage IV disease; these may be quite complex, depending on drug availability and eligibility for clinical trials. What this proliferation of treatment options means for patients with Stage III and Stage IV disease is that he or she is best served if a management plan is discussed by a multidisciplinary team. This approach will ensure that all treatment options are canvassed, and an appropriate management strategy devised for each patient. It is also important for patients to be offered participation in clinical trials whenever possible, so that new options for adjuvant therapy (in patients with surgically resected Stage III and Stage IV disease) and for definitive therapy (in patients with unresectable Stage IV disease) can be properly assessed and outcomes further improved. A particular multidisciplinary challenge is posed by brain metastases. Targeted drugs and immunotherapy have activity in brain metastases, so careful clinical planning is required, involving neurosurgeons, radiation oncologists, and medical oncologists. For patients with straightforward Stage I and Stage II disease, management according to nationally-agreed guidelines will ensure that optimal treatment outcomes are achieved.

Skin cancer: non-melanoma

Diona L. Damian, Richard A. Scolyer, Graham Stevens, Alexander M. Menzies, and John F. Thompson

Non-melanoma skin cancer and the oncologist

Non-melanoma skin cancer (NMSC) is the most common malignancy in fair-skinned populations. In areas with high solar ultraviolet (UV) irradiance such as Australia, NMSC is more than four times as common as all other cancers combined. In Australia, the annual incidence of NMSC is ~1000 per 100 000 person-years, which is ten times that in the United Kingdom, a country with lower solar exposure. The vast majority of NMSC are basal cell carcinomas (BCCs), which rarely metastasize, or squamous cell carcinomas (SCCs), which do have metastatic potential, especially in immune-suppressed individuals. Because of their high frequency in the general population, particularly in older people, NMSCs are likely to occur in many general oncology patients. Skin cancer risk can be additionally increased in oncology patients as a result of disease-induced immune suppression (e.g., non-Hodgkin lymphoma) or by a range of cancer treatments including iatrogenic immune suppression, radiation therapy, arsenic, and BRAF inhibitors. Chronic stress suppresses skin immune responses and increases susceptibility to UV-induced SCC in murine models.

Aetiology

UV radiation reaching the earth's surface at sea level comprises UVB (wavelength 290–320 nm), which causes sunburn, and longer-wave UVA (320–400 nm). UV exposure is estimated to cause 95% of NMSC. Even at very low exposure doses, well below the sunburn threshold, both UVB and UVA can cause genetic damage in the skin and can profoundly suppress the skin's anti-tumour immune defences.

Skin tumours are generally more antigenic than internal malignancies, and hence immune suppression is a potent enhancer of skin cancer development. Chronically immune-suppressed organ transplant recipients have rates of SCC 80-fold higher than immune competent controls, whilst rates of BCC are ~fivefold higher in transplant recipients. The incidence of Merkel cell carcinoma has also been reported as increased 70-fold in this population. Tumours developing in immune-suppressed individuals tend to be more aggressive as well as more plentiful, with skin cancer the main cause of death in cardiac transplant recipients at ten years post-grafting in Australia.

Other causes of immune suppression are also linked with increased skin cancer risk, including HIV infection and chronic haematological malignancies such as chronic lymphocytic leukaemia (CLL). Patients with CLL have greatly elevated risks of developing both primary NMSC (including a 16-fold increase in Merkel cell carcinoma and increases in adnexal carcinomas and atypical fibroxanthomas as well as BCC and SCC) and also metastatic SCC. Tumours in these patients tend to exhibit peritumoral infiltrates of immune suppressive leukaemic B cells, and extend histologically further beyond their clinically apparent edge than comparable tumours in immune competent individuals. The mortality rate from cutaneous SCC in CLL patients with these lesions is more than 10%, whereas SCC-related deaths in the immune competent population are rare.

Ionizing radiation exposure can cause a two- to three-fold increase in risk of BCC and smaller increases in cutaneous SCC, with a latency of many years to decades after radiation exposure. The use of ionizing radiation in the past as a treatment for acne in young patients has been especially associated with increases in BCC incidence. Exposure to more than 350 treatments with psoralens and UVA (PUVA) for the treatment of psoriasis is associated with a sixfold increase in cutaneous SCC, but with only modest increases in BCC. Chronic inflammation within burns scars or other chronic wounds can also give rise to highly aggressive SCCs with greatly elevated metastatic risk ('Marjolin's ulcer').

Arsenic acts as a co-carcinogen with UV radiation, causing arsenical keratoses and NMSC. Arsenic contamination of drinking water from tube wells causes high rates of NMSC in populations in West Bengal and Bangladesh, whilst arsenical cancers are still observed in elderly patients given Fowler's solution (arsenic trioxide) as a treatment in the 1950s for conditions such as psoriasis and asthma. Arsenic trioxide is in current use for acute promyelocytic leukaemia, and probably increases skin cancer risk in this setting also.

A variety of rare genetic syndromes are associated with increased NMSC risk. Gorlin's syndrome (basal cell naevus syndrome; autosomal dominant) results from a mutation in the PTCH1 gene at 9q22-31 and is associated with multiple BCCs, developing from childhood or early adolescence. Other features of Gorlin's syndrome include macrocephaly, falx calcification, bifid ribs, palmo-plantar pits, odontogenic keratocysts, medulloblastoma, cardiac and ovarian fibromas, foetal rhabdomyoma, and ovarian fibrosarcoma. These patients must not be treated with ionizing radiation, as this results in even greater numbers of BCCs.

Xeroderma pigmentosum (XP) is an autosomal recessive disorder of nucleotide excision repair. These patients can display extreme sensitivity to sunburn and UV-induced immune suppression, neurodegeneration, central nervous system tumours, and

genomic instability, as well as a 10 000-fold increase in the risk of skin cancers, which often develop in patients younger than 20 years old if rigorous sun protection is not practised. The average age of onset of NMSC in XP patients is less than ten years, compared to ~22 years for onset of melanoma, highlighting the importance of DNA repair in protection from NMSC.

Epidermolysis bullosa (EB) comprises a heterogeneous group of genodermatoses characterized by skin fragility and blisters, reflecting mutations in ten different basement membrane genes. More than 90% of patients with recessive dystrophic EB (mutation in type VII collagen) develop cutaneous SCC by 55 years of age at sites of chronic skin erosion, with a greater than 85% risk of death by age 45 due to metastatic SCC. Risk of metastasis does not correlate with tumour grade, and even apparently well-differentiated SCCs can prove fatal. There is also an increased SCC risk, although with later age of onset, in patients with junctional EB (mutations in laminin 5 or type XVII collagen).

Basal cell carcinoma

Basal cell carcinoma (BCC) is the most common malignancy in Caucasian populations, and in immune-competent individuals BCC is three to four times as common as SCC. Dysregulation of the hedgehog pathway (for example by deletion of PTCH1 or overactivation of Smoothened) is central in the pathogenesis of BCCs, which are currently thought to derive mainly from hair follicle bulge stem cells, but which might also originate from other epidermal locations under conditions such as wounding. BCC is associated with patterns of intermittent, recreational sun exposure; the use of artificial UV tanning devices has also been associated with an increased risk (odds ratio 1:5) for this tumour. BCCs tend to be slowly growing (over months to years), and whilst locally invasive, they rarely metastasize.

BCCs occur in a range of subtypes, which determine treatment options and predict tumour behaviour (Figure 50.1). Superficial and nodular BCCs are the most common subtypes. Superficial BCCs (sBCCs) are erythematous, slighty pearly patches or plaques, which may be multifocal. Nodular BCCs (nBCCs) are clinically thicker and present clinically as papules, nodules, or plaques, are generally pearly and often display surface telangiectases. Nodular BCCs may be flesh-coloured or pigmented and are characterized histologically by round lobules of tumour cells with peripheral palisading (Figure 50.2). Micronodular BCCs, which have small tumour islands less than 0.15mm in diameter, tend to have higher rates of recurrence and greater subclinical extension, leading to higher recurrence rates. Tumour cell aggregates in infiltrating BCCs extend irregularly and widely through the dermis, making clinical detection of these subtle lesions difficult and preventing accurate clinical distinction of tumour margins. Morphoeic BCCs, which have a dense fibrotic stromal reaction compressing the tumour islands into narrow strands, are also very difficult to delineate clinically and have higher rates of recurrence than superficial or nodular BCCs. Micronodular, morphoeic, and infiltrating BCCs often exhibit substantial subclinical tumour extension (Figure 50.1).
Fig. 50.1 (A) A large superficial basal cell carcinoma (BCC) is seen on the thigh of this 60-year-old woman. (B) Nodular BCCs are characterized by an often rolled, pearly edge and surface telangiectases. (C) Infiltrating BCCs are often clinically subtle, in this case presenting as scar-like changes and central erosion. These tumours can exhibit wide subclinical extension, as revealed during microscopically controlled excision. (D) This patient had substantial perineural involvement.
Figures 50.1 (c,d) reproduced courtesy of Dr Andrew Satchell.
Fig. 50.2 Basal cell carcinoma (BCC) histological subtypes: (A) superficial BCC; (B) nodular BCC; (C) infiltrating BCC with perineural involvement; (D) metastatic BCC involving bone.

BCCs may also exhibit atypical squamous differentiation; when it is moderate or severe this can predict higher rates of recurrence and occasionally metastatic spread ('basosquamous' or 'metatypical' BCC'). Many BCCs do however contain multiple growth patterns.

Prognosis

The risk of BCC recurrence is influenced not only by tumour subtype, but also by tumour size, with larger diameter tumours more prone to recurrence. Tumour site is also a determinant, with lesions located in the 'H' zone of the face (ears, periocular) and those at embryonal fusion planes being more likely to recur. The presence of perineural invasion on histopathology indicates a greater risk of tumour recurrence, as does host immune suppression.

Management of basal cell carcinoma

Although most BCCs can be diagnosed clinically, tissue pathology diagnosis is desirable whenever possible. This can be achieved by punch or shave biopsy as well as by complete lesion excision. Such procedures will provide confirmation that the lesion is indeed BCC (and exclude clinical differential diagnoses such as amelanotic melanoma) and will also provide information on BCC subtype. This is important because many treatment options suitable for superficial BCC will be relatively ineffective for other BCC subtypes.

Surgery

Standard excision with 3 mm clinical margins enables histological clearance in ~85% of primary BCCs, whilst use of 4 mm margins

extends histological clearance rates to 98%. Cure rates for all modalities are lower for recurrent tumours. For difficult primary BCCs, such as infiltrating or morphoeic subtypes with ill-defined borders, and for nodular BCCs at cosmetically challenging sites where large arbitrary margins will compromise cosmetic outcomes (such as the nasal tip) and for recurrent BCCs, microscopically-controlled excision (Mohs' surgery) enables both the highest possibility of cure and also maximal conservation of normal tissue. This technique involves histological examination of excised tissue margin en face as frozen sections, so that the entire excision margin, both laterally and at depth, can be examined for residual tumour. Cure rates of 99% and 96% have been reported with Mohs' surgery for primary and recurrent BCCs, respectively.

Cryotherapy, curettage, and cautery

Cryotherapy with liquid nitrogen (30 second double freeze-thaw cycle) can also be used for some primary superficial BCCs, with long-term cure rates of ~90%. Some superficial BCCs may be suited to shave, curettage, and cautery, which can provide both diagnosis and treatment in a single procedure, with cure rates of ~80–90% depending on tumour site and diameter.

Radiotherapy

Radiotherapy is a valuable non-surgical option for BCCs in people with multiple medical comorbidities and for tumours at surgically difficult or cosmetically sensitive sites particularly in elderly patients. BCCs, with a 5–10 mm margin, can be effectively treated with fractionated courses of superficial X-rays or electron beams,

with careful attention to ensure adequate dose at the depth of the tumour. BCCs can be effectively treated with superficial X-rays or electron beams, with a 5–10 mm margin. Long-term BCC cure rates with radiotherapy are >90%. Adjunctive radiotherapy also has a valuable role in reducing the risk of recurrence in high-risk BCCs, such as lesions demonstrating significant perineural invasion or lesions with positive margins after surgery. Radiation therapy also has a role in the palliation of inoperable tumours.

Imiquimod

Imiquimod is a topical immune response modifier and toll-like receptor 7 agonist. It is applied to the BCC with a 5 mm margin of surrounding normal skin five to seven nights per week for six weeks. An inflammatory reaction is generated at the treatment site, which may develop crusting or ulceration if inflammation is severe. Patients treating larger surface areas with imiquimod may report flu-like symptoms of myalgia, fatigue, and malaise, reflecting imiquimod-induced production of α-interferon (intralesional injection of α-interferon was previously used for treatment of nodular BCC). Five-year clearance rates with imiquimod are approximately 80% for superficial BCC and 40–75% for primary nodular BCC. Imiquimod is less effective against recurrent tumours and is not suitable for micronodular, infiltrating, morphoeic, or metatypical BCCs.

Topical photodynamic therapy

In topical photodynamic therapy (PDT), haeme precursors such as aminolaevulinic acid (ALA) and its esters are applied to skin lesions under occlusion for three to six hours. During this time, the haeme precursors are preferentially taken up by tumour cells and converted to the photosensitizer protoporphyrin IX, which accumulates in dysplastic and neoplastic tissue with an absorption peak at 633 nm (red light used to irradiate the photosensitizer-treated tumour). As well as causing direct necrosis and apoptosis of tumour cells mediated via reactive oxygen species generation and mitochondrial damage, PDT can also cause vascular shutdown around tumours. Topical PDT is especially useful for tumours involving cosmetically sensitive sites and is a relatively non-invasive treatment for frail or elderly patients, for tumours at sites prone to poor healing such as the lower legs, and for patients with huge numbers of NMSC where surgery is not feasible. PDT is best suited to primary superficial BCCs where it offers cure rates of ~80%. Cure rates for PDT in nodular BCC are ~70–75%. PDT is not a suitable treatment for recurrent BCC, or for infiltrating, morphoeic, or micronodular BCC.

Metastatic and unresectable BCC

Metastatic BCC is rare. When it does occur, metastasis is mainly to regional lymph nodes, with pulmonary, bony, and distant skin the next most frequent sites, respectively. The rate of metastasis is estimated to be ~0.03 to 0.1%, with 85% of metastatic cases originating from primary head and neck BCCs. The median age of these patients is 45 years. Risk factors for metastasis include multi-recurrent lesions, large primary size, male gender, and immunosuppression. Five-year survival in patients with metastatic BCC is ~10%, with a median survival of 13.6 years for nodal metastases and eight months in patients with distant disease.

Regional nodal metastases are managed by surgical dissection if operable, either alone or followed by adjuvant radiation therapy, depending on the pathological findings. The true benefit of chemotherapy for metastatic BCC has not been proven with clinical trials, but review of case reports in the literature has suggested response rates of up to 83%, including 37% complete response rates, in metastatic BCC treated with cisplatin-containing regimens. This agent has been used alone and also in combination with doxorubicin, bleomycin, 5-fluorouracil, methotrexate, and paclitaxel. Almost 40% of BCCs show strong expression of epidermal growth factor receptor (EGFR), and there have been isolated case reports of the effectiveness of the anti-EGFR antibody cetuximab for metastatic BCC patients.

Abnormal signalling in the hedgehog/glioma-associated oncogene pathway is a central feature of BCC pathogenesis; all sporadic BCCs have upregulated hedgehog signalling, often associated with mutations in the tumour suppressor gene PTCH1. This results in disinhibition of Smoothened, which then activates glioma-associated oncogene proteins. The Smoothened inhibitor vismodegib has been used orally in a Phase II clinical trial setting in 33 patients with metastatic BCC, with a response rate of 30% and median response duration of 7.6 months. A further 63 patients with locally advanced, unresectable BCC demonstrated a response rate of 43% and similar response duration. Adverse events were reported in 30% of patients, including weight loss, fatigue, muscle spasms, and taste disturbance. This agent and sonidegib, another inhibitor of the hedgehog signalling pathway, are now FDA-approved.

Follow-up

Patients with BCC should have regular follow-up after treatment, especially after non-surgical treatments, both to check for recurrence and for new primary skin cancers. The risk of subsequent NMSC is proportional to the number of previously diagnosed skin cancers; in a US study, the 5-year risk of developing another skin cancer was estimated at >60% for individuals with two previous BCCs and at >90% for individuals with four or five previous BCCs; a third of this group developed new skin cancers within 12 months.

Squamous cell carcinoma

Cutaneous SCCs are ~four times less common than BCCs in immune-competent individuals, with SCC risk tending to reflect recent, chronic sun exposure rather than intermittent, recreational exposure. There is also a 50% increase in cutaneous SCC incidence in smokers, which is not seen for BCC. UV-induced mutations of the gene for Tp53, which is centrally involved in cellular apoptosis, proliferation, and DNA repair are present in a high proportion of SCCs, but also in premalignant actinic keratoses (AKs) and normal skin. Activating RAS mutations are also found in 10–30% of cutaneous SCCs, whilst RAS overactivation has been observed in the majority of both SCCs and AKs. RAS mutations are frequent in SCCs in melanoma patients receiving treatment with the BRAF inhibitors vemurafenib and dabrafenib. In this setting, SCCs tend to have higher rates of RAS mutation than sporadic SCCs, and can develop—often from verrucal keratosis—within weeks of commencing treatment with BRAF inhibitors. Human papilloma virus is also believed to be contributory to cutaneous SCC development, especially in immune-compromised individuals.

Fig. 50.3 (A) The spectrum of squamous lesions includes premalignant actinic keratoses (AKs), which in this elderly man are accompanied by a preauricular invasive squamous cell carcinoma (SCC). (B) SCC in situ (Bowen's disease), presents as a scaling plaque which may be clinically difficult to differentiate from superficial basal cell carcinoma. (C) This lesion was one of dozens of SCCs developing in a patient receiving the BRAF inhibitor vemurafenib for metastatic melanoma.

Actinic keratoses (Figure 50.3) are scaling, erythematous lesions which occur mainly on chronically sun-exposed skin, and which affect more than 60% of the >40 years of age population in Australia. AKs may progress to SCC, at an estimated rate of ~1 in 1000 to one in 10 000 lesions, with progression often heralded by an increase in tenderness of the lesion. AKs may also remain stable, and often spontaneously regress. This presumably immune-mediated regression is observed particularly during the winter months, when reductions in AK counts of up to 25% have been reported. Histologically, AKs are characterized by basal rather than full-thickness epidermal keratinocyte atypia.

Squamous lesions composed of dysplastic squamous cells filling the entire epidermal thickness are referred to as SCC in situ (Bowen's disease; Figures 50.3 and 50.4). Bowen's disease can present as indolent, scaling erythematous plaques which may remain essentially static for many years. These lesions can sometimes be clinically indistinguishable from superficial BCC. Approximately 3–5% of Bowen's disease lesions are thought to progress to invasive SCC. Keratoacanthomas (KAs) are considered a well-differentiated SCC variant, which demonstrate spontaneous regression usually starting six to eight weeks after first appearance. Mature keratoacanthomas have a characteristic central keratin-filled crater. In many instances, confident histological distinction between keratoacanthoma and SCC is not possible. Keratoacanthomas are generally treated in the same way as invasive SCCs.

Invasive SCC (Figure 50.3) usually presents as a rapidly growing nodular lesion, which may develop within weeks to months. There are a range of SCC subtypes and grades of differentiation which strongly influence tumour treatment and outcome (Figure 50.4). SCC can be both locally invasive and metastatic. More than 80% of SCC metastases occur in draining lymph nodes, with subcutaneous metastases the next most common site. Pulmonary and bone metastases are also seen.

Management of squamous cancers and precancers

Actinic keratoses

AKs can be reduced by 30–40% by daily use of a broad-spectrum, high sun protection factor (SPF) sunscreen, often within a few months of commencing sunscreen use. Hence, sunscreen should be considered an active treatment for patients with multiple AKs, and not only a preventive measure. Patients with only a limited number of AKs may have lesions treated successfully with cryotherapy. More extensive lesions are better treated with field therapies such as topical 5-fluorouracil (5-FU), which is applied by patients twice daily, usually for two to three weeks, until a brisk level of inflammation in the AKs is observed (Figure 50.5). AKs on the hands and arms can also be treated with 5-FU, but a longer treatment duration (usually four to eight weeks) is required for these sites. For facial AKs, 5-FU can clear >90% of lesions, with most patients not needing further 5-FU for many years. Sun-damaged patients receiving systemic 5-FU for internal malignancies may also experience dramatic inflammation within their AKs.
Fig. 50.4 (A) Bowen's disease is characterized pathologically by full-thickness epidermal dysplasia with no invasion of the underlying dermis. (B) In contrast, this well-differentiated invasive SCC has squamous cells irregularly infiltrating the dermis associated with a reactive fibroinflammatory response, with well-formed intercellular bridges and keratin formation (hallmarks of squamous differentiation). (C) This poorly-differentiated SCC shows a much greater degree of cellular atypia, and metastasized to bone within a few months of diagnosis.

Other treatment options for multiple AKs include topical imiquimod (usually three times per week for two to four weeks) with reported clearance rates of 50–60%, and topical diclofenac, which requires three months of twice daily treatment and can reduce AKs by ~60%. Topical photodynamic therapy has also been used for AKs, but can be exceptionally painful for patients with sun-damaged skin and multiple AKs.

SCC in situ (Bowen's disease)

In very elderly or frail patients, observation may be the only appropriate management option. Active therapies for Bowen's disease include excision, curettage and cautery, or cryotherapy. These lesions may also be effectively treated with topical imiquimod, which produces clearance rates of ~75% for Bowen's disease, topical 5-FU, or topical PDT, which produces long-term clearance in ~66–80% of lesions.

Keratoacanthoma and invasive SCC

Keratoacanthomas are usually excised, but can sometimes be treated with intralesional agents such as bleomycin, methotrexate, or 5-FU. Invasive SCC is best treated surgically whenever possible. Mohs surgery is sometimes helpful for clinically more subtle
Fig. 50.5 Multiple actinic keratoses can be effectively treated with topical 5-fluorouracil, which causes inflammation within areas of dysplastic skin, whilst normal skin is unaffected. (A) Most patients achieve a suitable level of inflammation about two weeks into treatment. (B) 5-fluorouracil is then ceased, with both inflammation and AKs resolving over the next one to three weeks.

lesions, and especially for infiltrating SCC, at cosmetically sensitive sites. The role of sentinel node biopsy in SCC is still unclear, but may be indicated for very high-risk head and neck lesions, such as those with poor differentiation, large tumour diameter and thickness, host immune suppression, and where there is perineural and/or lymphovascular invasion. Post-operative radiotherapy to the tumour bed may be indicated for SCC at high risk of recurrence, including tumours with lymphovascular or perineural invasion and close (or positive) margins. Radiation doses to 60 Gy are required to reduce risk of recurrence. For perineural infiltration of large nerves, particularly cranial nerves or their major branches, the radiation fields should include the entire course of the nerve.

Radiation treatment planning is complex, requiring CT and/or MRI image acquisition. In common with BCCs, definitive radiation therapy (RT) may be preferred to treat SCCs in the elderly in sites requiring difficult reconstruction, particularly around the nose and eyes. Short courses of hypofractionated superficial or electron RT with custom lead cutouts result in high local control rates.

Prognosis in SCC

Factors influencing the risk of SCC recurrence and metastasis include tumour size, differentiation, infiltration, perineural invasion, and lymphovascular invasion. Host immune suppression is a critical determinant of SCC outcome, with metastatic risk dramatically elevated in chronically immune-suppressed individuals. Head and neck SCCs, especially at vascular sites such as lip and ear, have higher rates of metastasis than tumours on the trunk and limbs; overall, the risk of metastasis from cutaneous SCC is ~2–2.5%, with reported rates of metastasis from lesions >2cm in diameter rising to almost 6%. Almost 95% of SCC metastases occur within five years of the primary tumour diagnosis, with an average interval to metastasis of ~two years.

Unresectable and metastatic squamous cell carcinoma

Unresectable SCC, or primary tumours where only partial surgical clearance is possible, may be suitable for radiation therapy. Tumours with perineural or local bony invasion should also be considered for postoperative adjuvant radiotherapy [1], as should nodal basins harbouring multiple involved lymph nodes and/or extranodal disease. Radiotherapy is also valuable for palliative treatment of locally-advanced SCC.

A range of systemic therapies has been used for unresectable primary SCC, including oral retinoids such as isotretinoin and etretinate, sometimes in combination with interferon, the EGFR inhibitor cetuximab and the oral 5-FU prodrug capecitabine. Occasionally, patients with extreme numbers of high-risk primary lesions may need systemic therapy. Capecitabine was used in three organ transplant recipients with multiple primary SCCs, with reduction in numbers of new tumours from a baseline of 35 cancers in the six months prior to capecitabine, compared to one cancer in six months after commencing treatment [2].

Intravenous agents such as platinum compounds, sometimes in combination with doxorubicin, 5-FU, or paclitaxel, have also achieved some rapid responses in unresectable disease, maintained for up to three years. Bleomycin, vincristine, cyclophosphamide, methotrexate, and 5-FU have also been used intravenously for inoperable primary SCC. For multirecurrent or inoperable primary SCC on a distal limb, isolated limb perfusion or isolated limb infusion with agents such as melphalan, bleomycin, vincristine, and actinomycin have been effective.

Suspected nodal disease may be initially investigated with fine needle biopsy, ideally under ultrasound guidance so that nodal morphology can be assessed and the most abnormal area(s) targeted for biopsy. Staging of patients with known metastatic disease can be done using computed tomography; fluorodeoxyglucose positron emission tomography (PET) may also be useful in metastatic SCC, whilst magnetic resonance imaging (MRI) can provide the best definition of perineural invasion.

Systemic therapies for metastatic SCC have most commonly included cisplatin, often in combination with doxorubicin. Other reported agents include 5-FU, methotrexate, bleomycin, and vindesine. Complete response rates of ~30%, and overall response rates of more than 80%, have been reported in this setting [3].

Follow-up after cutaneous squamous cell carcinoma

Frequency and duration of follow-up after treatment of squamous lesions is determined by the nature of the primary lesion, the type of treatment given and host immune status. Non-invasive lesions such as Bowen's disease, treated non-surgically with agents such as PDT, imiquimod, or 5-FU, should be reviewed ~three months after therapy and then twice-yearly follow-up considered for two to three years [3]. Following diagnosis of an invasive SCC, the three-year cumulative risk of subsequent primary SCC has been estimated at 18%, providing additional reason to maintain close surveillance [3]. Immune-suppressed patients with large numbers of aggressive SCCs, such as organ transplant recipients, may need follow-up every two to three months indefinitely.

Merkel cell carcinoma

Merkel cell carcinoma (MCC) is a rare aggressive cutaneous neuroendocrine tumour, with an estimated incidence of 0.44 per 100 000 people, although this rate is increasing. It usually develops at chronically sun-exposed sites (predominantly the head and neck) in elderly individuals; mean age at diagnosis is 69 years and 95% of patients are fair-skinned [4]. Merkel cell carcinoma is more common in men [4]. Clonally-integrated Merkel cell polyomavirus is found in the genomes of ~80% of MCCs suggesting that it is aetiologically implicated in MCC pathogenesis, and a greatly increased incidence of MCC is observed in the setting of chronic immune suppression.

Clinically, MCC may present as a rapidly growing violaceous or erythematous nodule; erosion is frequent and tumours can double in size within a week, although spontaneous regression is occasionally observed [4]. Histologically, MCC is characterized by monomorphous sheets of cells with neuroendocrine nuclear characteristics (granular chromatin, inconspicuous nucleoli) and minimal cytoplasm. The cells stain positive for various cytokeratins (CK) including CK20 in 95% of cases, and for one or more neuroendocrine markers (such as chromogranin, synaptophysin, neuron specific enolase, and CD57; Figure 50.6). Primary tumour thickness and lymphovascular invasion are predictors of recurrence and survival in clinically localized MCC patients. Lymphatic
Fig. 50.6 Merkel cell carcinoma. Cohesive clusters of mitotically active tumour cells with granular chromatin, inconspicuous nucleoli and minimal cytoplasm are infiltrating between dermal collagen bundles.

invasion tends to occur early, with a local recurrence rate of ~30%; nodal involvement is present in 30% of patients at the time of presentation, ultimately affecting 50% of all patients [4]. Hence, staging investigations, such as PET-CT, should be considered at the time of initial diagnosis.

Primary MCC is usually treated with wide excision, usually with 2–3 cm margins if surgically feasible. MCCs are, however, highly radiosensitive and radiation therapy alone, generally at doses of 50–55 Gy in 20–25 fractions, may also achieve local control, with in-field control rates of 75% reported. Adjuvant irradiation of regional node fields has been reported to reduce the risk of nodal recurrence, although without impact on overall survival. If radiation therapy is considered appropriate, it should be delivered as promptly as possible, as higher rates of disease progression are seen in patients whose radiation therapy is delayed by more than 24 days. Alternatively, sentinel node biopsy may be offered in MCC at the time of local wide excision, although a greater SNB false negative rate has been reported for MCC compared to melanoma and surgical patients may experience greater delays in receiving radiotherapy.

Distant metastasis to sites such as bone, lung, skin, brain, and liver, is associated with a median survival of nine months. MCC is often initially (although not durably) chemosensitive, and systemic agents such as cisplatin, carboplatin, and etoposide have been used in an adjuvant setting as well as for treatment of known metastatic disease [4]. The use of systemic agents may also enhance the efficacy of concurrent radiation.

Atypical fibroxanthoma

Atypical fibroxanthoma (AFX) is an uncommon cutaneous tumour that appears malignant histologically but paradoxically is associated with benign clinical behaviour. It usually presents as a rapidly-growing nodule in chronically sun-damaged skin of elderly men (male:female ratio of 7:1), with a predilection for head and neck sites (75%) compared to trunk and limbs. AFX is now generally regarded as a superficial counterpart of an undifferentiated pleomorphic sarcoma (so-called malignant fibrous histiocytoma; MFH). Its excellent prognosis is a consequence of its smaller size,

superficial location, and amenability to complete excision. Because a histologically identical tumour would be diagnosed as MFH if it extended into the subcutis or exhibited lymphovascular invasion, necrosis or diameter >2cm, a definitive diagnosis of AFX cannot be made on the basis of an incomplete biopsy. AFX has been reported in younger patients with XP. AFX are comprised of atypical spindle cells, often with frequent mitoses, within a fibrous stroma. Other malignant tumours, including sarcomatoid (spindle cell) SCC and spindle cell melanoma, can be histologically indistinguishable from AFX on haematoxylin-eosin stained sections. Therefore, a diagnosis of AFX requires exclusion of such possibilities and immunochemical stains are mandatory in the pathological work up. There are no currently known specific immunochemical markers diagnostic of AFX, which remains a diagnosis of exclusion. Hence S100, HMB45, and MelanA should be used to exclude melanoma as well as high molecular weight keratin stains (such as CK5/6, 34BE12, and MNF116) to rule out SCC.

AFX is regarded as a tumour with little metastatic potential, particularly if strict diagnostic criteria are applied. Treatment is by surgical excision with clear margins. Recurrence is reported to occur in approximately 5% of cases, but in most instances this is due to incomplete removal. Mohs' micrographic surgery may yield a higher cure rate than standard excision, but all patients should have close follow-up, at least six monthly, for recurrence as well as for other NMSC, which are very common in AFX patients. The risk of metastatic spread, almost always to regional nodes, is ~1%. Risk factors for metastasis include immune suppression, subcutaneous tumour extension, and tumours arising in previously irradiated skin.

Skin cancer prevention

Sun minimization and use of appropriate clothing, hats, and sunglasses are essential to reduce NMSC risk, especially in high-risk individuals. Sunscreens can reduce both the DNA-damaging and also the immune suppressive effects of UV exposure. Daily use of broad-spectrum sunscreens, which reduce exposure to both UVB and UVA, can reduce numbers of premalignant AKs by up to 40% within a few months and have been shown to reduce SCC incidence by a similar proportion within two years of follow-up. There is some evidence suggesting that reductions in BCC risk (and in melanoma) may occur with follow-up extending beyond eight years.

Individuals with large numbers of NMSC may benefit from systemic chemoprevention. Retinoids such as acitretin can modulate keratinocyte growth, differentiation, and apoptosis and have been found to reduce numbers of SCCs and sometimes BCCs in both immune-competent and immune-suppressed patients, and in patients with XP. Skin cancer incidence in patients taking retinoids does tend to return to baseline levels upon drug discontinuation. Side effects of oral retinoids include cheilitis, dry eyes, skin fragility, hair loss, liver function abnormalities, increased serum lipids, and teratogenicity, whilst very long-term use can cause osteoporosis.

The enzyme cyclo-oxygenase 2 plays a key role in skin carcinogenesis, and population-based case-control studies have found that use of nonsteroidal anti-inflammatory drugs (NSAIDs) is associated with a reduced risk of SCC but not BCC. The COX2 inhibitor celecoxib reduced numbers of new NMSCs, but not AKs, within 11 months compared to placebo in 240 patients presenting with actinic keratoses (RR 0.43). NSAIDs do, however, carry risks of

gastric bleeding and irritation, renal impairment, and hypertension, and may not be suitable for long-term use in many patients.

Nicotinamide (vitamin B3) is a precursor of NAD+, and replenishes cellular energy levels, which are depleted after UV exposure. Nicotinamide prevents UV-induced immunosuppression and carcinogenesis in mice, and prevents UV immunosuppression in humans. This agent has an established safety profile, without the vasodilatory effects of nicotinic acid. In Phase 2 studies, nicotinamide reduced AKs by 30% compared to placebo and also reduced incidence of new NMSCs in heavily sun-damaged Australian patients. Nicotinamide may provide an inexpensive, non-toxic approach to systemic skin cancer chemoprevention and Phase 3 studies of this agent are currently underway.

CHAPTER 51

Acute leukaemias

Adele K. Fielding, Charles G. Mullighan, Dieter Hoelzer,
Eytan M. Stein, Ghada Zakout, Martin S. Tallman,
Yishai Ofran, Jacob M. Rowe, and Ross L. Levine

Prognostic factors in acute myeloid leukaemia

Although the majority of patients with acute myeloid leukaemia (AML) achieve complete remission with induction chemotherapy, relapse after achievement of clinical remission remains the most critical clinical challenge facing AML patients and clinicians today. Although consolidation with high-dose cytarabine or stem cell transplantation reduces relapse rates and offers the possibility of cure to a subset of AML patients, the majority of AML patients suffer relapsed disease. Notably, outcomes in AML remain highly heterogeneous, such that some patients achieve cure with existing therapies and other patients relapse, despite presenting with similar clinical, pathologic, and flow cytometric characteristics. There is therefore a pressing need to improve prognostication in AML.

Current standard of care for molecular prognostication in acute myeloid leukaemia

In the current clinical setting, chromosomal translocations—specifically CBF translocations and *PML-RARA*—predict for favourable outcome and, in the case of *PML-RARA*-positive APL, confer sensitivity to all-trans retinoic acid (ATRA) and arsenic trioxide. However, the field of prognostication in AML, and the utility of molecular markers to inform prognosis and outcome in AML, changed with a seminal study by Schlenck et al. [1]. They performed targeted mutational analysis of more than 800 patients with cytogenetically normal AML. In their study, normal karyotype-AML patients with *CEBPa* mutations, or with NPM1 mutations without co-occurring *FLT3-ITD* mutations, had an improved outcome. By contrast, patients with *FLT3-ITD*, or who were negative for mutations in *NPM1, FLT3*, and *CEBPa*, had a significantly worse outcome. These data demonstrated, for the first time, that mutational profiling could be used to inform prognostication in AML, particularly in patients with cytogenetically-defined, intermediate-risk disease.

However, this study had a second, equally important, observation. Given that patients in the trial cohort were assigned to receive consolidation alone or to receive allogeneic stem cell transplantation (ASCT) based on donor availability, the authors were able to determine if different genetically-defined subsets of AML patients derived benefit from allograft. Specifically, this allowed them to demonstrate that allogeneic transplantation improved

outcomes in patients with *FLT3-ITD* mutations and in patients without mutations in *NPM1, FLT3*, and *CEBPa*, but not in normal karyotype-AML patients with *CEBPa* mutations, or with NPM1 mutations without co-occurring *FLT3-ITD* mutations.

This study represented the first demonstration of how mutational profiling can inform AML biology and prognosis, and led to the incorporation of testing for *CEBPa, NPM1*, and *FLT3-ITD* into the routine clinical care for AML patients who are less than 60–65 years of age. However, there are several important caveats to this study, particularly with regard to its relevance to the clinical setting. First, the data have not been robustly validated in an independent cohort. Second, although the findings relating to outcome and response to allogeneic transplantation were statistically and clinically significant, the numbers of patients in specific subgroups (e.g., patients with *CEBPa* mutations) were quite small, such that one might well base important therapeutic decisions in the clinical setting on a single study cohort with less than 20 patients. Third, and most importantly, since this study a series of novel disease alleles have been identified in AML patients, such that an updated molecular prognostic schema is needed to further refine our ability to predict outcome in AML. Nonetheless, this study established the need for real-time genotyping of AML patients for specific somatic mutations and paved the way for subsequent studies investigating prognosis in AML (Figure 51.1).

Role of novel acute myeloid leukaemia disease alleles in predicting outcome

Our understanding of the molecular pathogenesis of AML has been markedly improved by a series of recent discoveries of novel, recurrent, prognostically significant disease alleles in AML patient samples. The first study to use whole-genome sequencing to elucidate the somatic mutational spectrum in AML, or in any malignancy, was reported by Ley and colleagues [2] who performed whole-genome sequencing of a patient who presented with normal karyotype AML. Whole-genome sequencing and detailed bioinformatics analysis identified somatic mutations in *NPM1* and the *FLT3-ITD* allele as well as a small set (eight in total) of novel mutations which were not observed in other patients in detailed recurrence testing. Although this first study did not identify novel recurrent disease alleles of biologic or clinical relevance, it opened the way to a series of studies using whole-genome and whole-exome sequencing to identify mutations in IDH1 [3], *DNMT3a* [4, 5], and mutations

Revised Risk Stratification

Cytogenetic Classification		Mutations	Overall Risk Profile
Favourable		Any	Favourable
Normal karyo-type or inter-mediate-risk ctyogenetic lesions	FLT3-ITD-negative	Mutant NPM1 and IDH1 or IDH2	
	FLT3-ITD-negative	Wild-type ASXL1, MLL-PTD, PHF6, and TET2	Intermediate
	FLT3-ITD-negative or positive	Mutant CEBPA	
	FLT3-ITD-positive	Wild-type MLL-PTD, TET2, and DNMT3A and trisomy 8–negative	
	FLT3-ITD-negative	Mutant TET2, MLL-PTD, ASXL1, or PHF6	Unfavourable
	FLT3-ITD-positive	Mutant TET2, MLL-PTD, DNMT3A, or trisomy 8, without mutant CEBPA	
Unfavourable		Any	

Test Cohort
Effect of Mutational Profiling

in the cohesin complex [6]. Moreover, copy number analyses and candidate gene studies have identified additional recurrent somatic mutations in AML patients including in *TET2* [7, 8], *ASXL1* [9, 10], *IDH2* [11, 12], and *PHF6* [13]. The critical question, though, is how these seminal discoveries improve prognostication in AML and whether mutational profiling can be used to inform outcome and therapy in AML.

IDH1, IDH2, and *TET2* mutations in acute myeloid leukaemia

IDH1 mutations were first identified in exome sequencing studies of malignant glioma [14, 15]. The first study identified *IDH1* mutations in patients with glioblastoma multiforme (GBM), and subsequently mutations in *IDH1* and in *IDH2* were found to occur

most commonly in patients with lower-grade astrocytic neoplasms that subsequently progress to GBM. Ley and colleagues used whole-genome sequencing to identify recurrent *IDH1* mutations in AML [16]. Subsequent studies identified recurrent *IDH2* mutations in AML [11, 12], including mutations at residue R140, which are seen in leukaemias but not in epithelial malignancies.

In 2009, microdeletions and copy neutral loss of heterozygosity on chromosome 4q24 were used to identify recurrent somatic mutations in *TET2* in patients with myelodysplastic syndromes (MDS) and with myeloproliferative neoplasms (MPN) [7, 17]. *TET2* mutations occur in 10% of AML patients [8]. *TET2* is a member of the TET family of proteins that catalyze conversion of 5-methylcytosine (5-mC) to 5-hydroxymethylcytosine (5-hmC) [18]. 5-hmC placement leads to subsequent DNA demethylation; TET2-mutant AML patients are characterized by loss of 5-hmC and by and increased promoter methylation [19]. Of note, murine conditional targeting studies indicate loss of TET2 results in increased self-renewal and in myeloid transformation in vivo [20–23].

IDH1 and IDH2 are enzymes critical in the Krebs cycle that normally convert isocitrate to alpha-ketoglutarate in an NADP$^+$ dependent manner. Biochemical studies have shown that mutant IDH proteins have neomorphic enzymatic activity and convert alpha-ketoglutarate to 2-hydroxyglutarate (2-HG) [24]. Notably, 2-HG can be detected in vast excess in the serum of AML patients with *IDH1/2* mutations [12, 25], suggesting 2-HG may serve as an effective biomarker for minimal residual disease and as a method to prospectively track leukaemic disease burden. Notably, the observation that mutations in *IDH1/2* and *TET2* do not co-occur in the same patients suggested functional convergence by these disease alleles. Indeed, IDH-mutant mediated 2-HG production inhibits TET2 function and promotes hypermethylation [19].

ASXL1

Targeted genomic studies aimed at identifying mutations in epigenetic modifiers led to the discovery of mutations in *ASXL1* in MDS and AML patients [9]. *ASXL1* mutations occur in MPN, MDS, AML and chronic myelomonocytic leukaemia (CMML) and are associated with a poor outcome in all myeloid malignancies studied to date [9, 26]. *ASXL1* mutations are uncommon in younger patients with AML (3–5%) [27], but increase in prevalence with increasing age [28]. Given that the majority of *ASXL1* mutations are somatic nonsense or frameshift mutations, *ASXL1* mutations likely result in loss of ASXL1 function. Recent work suggests ASXL1 loss results in loss of histone H3 lysine 27 methylation, a histone mark associated with transcriptional repression, and with diminished recruitment of the polycomb repressive complex 2 (PRC2) to specific target loci [29].

DNMT3A

Next-generation sequencing of a set of genes involved in haematopoietic development led to the discovery of mutations at the highly conserved R882 residue in *DNMT3A* [30]. Subsequent genome/exome sequencing identified *DNMT3A* mutations at a high frequency in AML [5, 31]. *DNMT3A* mutations occur in more than 20% of de novo AML patients. *DNMT3A* functions as a de novo methyltransferase; however, the specific role of *DNMT3A* mutations in altering epigenetic patterning and in AML pathogenesis has not been conclusively delineated. Importantly, approximately

50% of AML patients present with mutations at codon R882 while retaining the second, wild-type *DNMT3A* allele consistent either with a novel oncogenic or dominant negative function.

Recently identified acute myeloid leukaemia disease alleles

More recent studies have identified additional disease alleles in AML patients. Welch and colleagues performed whole genome sequencing of 24 patients with AML [6]. In addition to previously described disease alleles, they identified mutations in members of the cohesin complex in AML, including in *SMC1A* and *SMC3*. Majeti and colleagues performed exome sequencing of purified leukaemia stem cells to profile the complement of somatic mutations in leukaemia initiating cells and identified mutations in the cohesin complex in AML [32]. More recently, mutations in the splicesome complex [33–35], and in the BCOR/BCORL1 complex [36, 37], have been identified in patients with myeloid malignancies, including AML. The prognostic and therapeutic relevance of these recently-identified disease alleles remains unknown, but we would predict that these disease alleles would allow us to better discriminate outcome and therapeutic response in AML.

Prognostic relevance of newly identified genes

We now have an ever-increasing set of mutations and over-expressed genes with prognostic relevance in AML. However, few of these biomarkers have been adopted into clinical practice. The relative paucity of clinically-utilized biomarkers is due to several factors. Many biomarker studies focus on a specific genetic lesion and its prognostic relevance, without assessing whether specific mutations independently predict outcome in AML in multivariate analysis compared to all known clinical/molecular biomarkers. In addition, most correlative studies are performed in small, retrospective single-institution cohorts such that the effects of treatment on outcome cannot be controlled and investigated. Finally and most importantly, most studies have not validated their prognostic schema in independent sample sets, which is needed to demonstrate robustness of the clinical predictor and to conclusively demonstrate a specific biomarker or molecular classifier is sufficiently valid for use in the clinical setting.

In an effort to determine if a larger set of mutant disease alleles can inform outcome in AML, we recently performed mutational profiling of all known AML disease alleles from a large set of patients enrolled in a single phase III trial cohort of AML patients younger than 60 years of age [38]. This seminal clinical trial evaluated the use of anthracycline dose intensification during induction therapy. At enrollment, patients were randomized to receive standard induction with 45 mg/m^2 of daunorubicin plus cytarabine or to receive dose-intensive induction with 90 mg/m^2 of daunorubicin plus cytarabine. This allowed us to perform extensive mutational profiling from diagnostic samples and to correlate molecular data with outcome including disease-free and overall survival and response to induction therapy.

Given the established importance of the three broad cytogenetic risk categories in AML, it is therefore important to determine if

mutational status for specific mutations or for combinations of mutations have an impact on the outcome in different cytogenetic risk categories. As discussed previously, mutational analysis of *CEBPA, NPM1*, and *FLT3*-ITD can risk-stratify intermediate-risk AML patients [1]. By contrast, more detailed mutational analysis better discriminates intermediate-risk AML patients into distinct risk groups. In the subset of patients with *FLT3*-ITD-negative intermediate-risk AML, *FLT3*-ITD-negative, *NPM1/IDH* mutant patients had a more favourable outcome than patients with inv(16) or t(8;21)-positive AML. *FLT3*-ITD-negative *NPM1*-mutant patients without concurrent *IDH* mutations had a much less favourable outcome. In addition, mutations in *ASXL1, PHF6*, and/ or *MLL*-PTD conferred adverse overall survival for *FLT3*-ITD wild-type, intermediate-risk patients. Patients with *FLT3*-ITD mutations and co-occurring mutations in *TET2, DNMT3A, MLL*-PTD, or trisomy(8) also had very poor outcome.

These data suggest that mutational profiling can be used to improve prognostication in AML, such that intermediate-risk patients can be reclassified as having favourable, intermediate, or poor risk based on the mutational status of nine genes. Most importantly, patients with mutationally-defined adverse-risk AML have an outcome similar to patients with adverse karyotypic risk, such that standard therapies are not sufficient to offer a chance of cure to patients with these poor-risk molecular lesions. We believe clinical trials should aim to identify genetically-defined high-risk patients and to offer these patients novel therapies early in their disease course, in an effort to reduce relapse and increase cure.

Although studies suggest mutational profiling offers significant added value to prognostication in AML, validation of these findings in other large, homogeneously treated patient cohorts should remain the highest priority. As such, subsequent biomarker efforts should determine if different mutational genotypes predict outcome in large cohorts of younger and older adults treated with different AML therapies. Moreover, we need to incorporate additional, recently defined molecular lesions, including *BCOR/BCORL1* mutations, cohesin mutations, spliceosome mutations, and epigenetic/microRNA alterations, into our biomarker studies and into our integrative analyses, to determine which molecular lesions are independently predictive of favourable/unfavourable outcomes in large AML patient cohorts.

Anthracycline dose intensification for induction therapy in acute myeloid leukaemia

The ECOG E1900 trial evaluated the use of anthracycline dose intensification during induction therapy by comparing the efficacy of induction with 45 mg/m^2 of daunorubicin or a higher dose of 90 mg/m^2. The higher dose cohort was associated with a significant, albeit modest, improvement in overall survival. Post hoc analysis revealed that high-dose daunorubicin markedly improved outcomes for patients with *DNMT3A* mutations [27], *MLL* fusions or with *NPM1* mutations, but not in patients wild-type for these genes (Figure 51.2). Although these findings need to be further validated in a prospective clinical trial, these data suggest specific molecularly defined subsets of AML patients benefit from dose-intense induction chemotherapy, and demonstrate how genomic studies can inform prognosis and therapeutic decisions.

Translating novel genetic findings to the clinic

With the discovery of novel genes associated with AML pathogenesis, the challenge is to integrate this knowledge into the clinical context. Although whole-genome and whole-exome sequencing have been critical technologies in cancer discovery efforts, their applicability to the clinic today presents several challenges in the wider clinical setting. Welch et al. [39] used whole-genome sequencing to identify a cryptic *PML-RARA* translocation in a patient with M3-AML who had negative FISH analysis for PML-RARA. Whole-genome sequencing may become part of the standard diagnostic evaluation within the next few years; however, the cost, turnaround time, and bioinformatics challenges limit the use of genome and exome sequencing in the current clinical context. We would contend that targeted next-generation sequencing may represent the best option for clinical utilization of molecular genetic information in the near-term. Newer sequencing technologies will allow for rapid, higher throughput, mutational studies in the clinical setting such that this data can used to inform induction and post-remission therapies in AML.

However, there remains a second, equally important challenge: the lack of robust data for novel disease alleles on clinically annotated, homogeneously treated patient cohorts. We would predict that the continued development and implementation of cost-effective genomic profiling platforms will empower collaborative efforts to evaluate novel biomarkers for clinical utility in AML. This will require use of large patient datasets with high quality material and clinical annotation and validation studies to determine which molecular lesions are most useful in the near-term clinical setting. While functional studies of novel disease alleles will lead to a greater understanding of AML pathogenesis, we believe the incorporation of novel biomarkers into the clinical setting is the most important short-term goal facing AML patients and clinicians today.

Basic biology of acute myeloid leukaemia

AML is a clonal haematopoietic malignancy characterized by differentiation block and proliferation of immature myeloid cells (myeloblasts) that leads to peripheral blood cytopenias, and eventual bone marrow (BM) failure. Without treatment and in the face of treatment resistance, patients succumb to the complications of anaemia, thrombocytopenia, and neutropenia and/or the effects of hyperleukocytosis. In this section, we discuss the basic epidemiology, aetiology, clinical presentation, and diagnosis of AML.

Epidemiology

20,830 people are estimated to be diagnosed with AML in 2015 in the US [40]. Of these, 12,730 are estimated to be men and 8100 are estimated to be women, resulting in 10,460 deaths. Although AML is diagnosed in patients of all age groups (including children) it is primarily a disease of older adults with a median age at diagnosis of 72 years [41]. Unfortunately, the outcomes of older adults diagnosed with AML have remained stagnant since the 1970s, both in Europe and the US. Burnett and colleagues collected outcome data from patients over the age of 60 treated on European clinical trials between 1970 and 2009 [42]. According to these data, five-year

Mutant *DNMT3A* or *NPM1*, or *MLL* Translocation
No. at Risk

Standard dose	83	24	14	3
High dose	88	45	26	9

Wild-type *DNMT3A* and *NPM1* and *MLL* Translocation
No. at Risk

Standard dose	107	51	23	3
High dose	108	51	25	6

Outcomes with High-Dose vs. Low-Dose Induction

	Mutant *DNMT3A* or *NPM1*, or *MLL* Translocation	All Other Genotypes
High Dose	3-yr OS: 44%	3-yr OS: 35%
Standard Dose	3-yr OS: 25%	3-yr OS: 39%

Fig. 51.2 Molecular determinants of response to high-dose daunorubicin induction chemotherapy. Shows benefit of high-dose vs standard-dose daunorubicin in patients with *NPM1/DNMT3A* mutations or with MLL translocations vs those wild-type for all three AML disease alleles.

survival rates in older adults remained below 10% between 1970 and 2004 (Figure 51.3). While the data from Burnett shows a slight increase in survival for older patients with AML on clinical trials between 2005 and 2009, this is not supported by the 'real world' population-based outcomes collected in the Surveillance, Epidemiology, and End Results (SEER) dataset. This may be attributable to the adoption of reduced-intensity conditioning allogeneic transplantation in patients who were historically considered too old to endure the rigours of BM transplantation [40]. The poor outcome of older adults has multiple explanations. Patients older than 60 often present with poor-risk disease at baseline that is relatively resistant to induction chemotherapy. These poor-risk subtypes include AML with a complex karyotype and AML that evolves from an antecedent haematologic disorder [43–46]. In addition, new drugs that are more effective for AML have not yet emerged to supplant primary induction therapy, which is an anthracycline in combination with cytarabine, developed in the early 1970s. Finally, traditional induction chemotherapy is poorly tolerated—and often not able to be offered at all—among patients older than 60 given the presence of medical comorbidities such as cardiac dysfunction (ischaemic heart disease or heart failure), renal insufficiency, and liver abnormalities. For the small number of elderly patients able to tolerate induction chemotherapy and who achieve a complete remission (CR), strategies for consolidation are limited. Patients older than 60 do not tolerate high-dose cytarabine, and the

morbidity and mortality from even a reduced intensity allogeneic transplant is significant.

In contrast, the outcomes for patients younger than 60 have steadily improved since 1970 both in the US and Europe, with approximately 50% of patients surviving five years from the time of diagnosis [42]. Like older adults, this improved survival is unrelated to new drugs to treat AML, but rather due to modifications of dosing of older drugs, such as intensified dose daunorubicin, and procedures like allogeneic transplantation and better antimicrobials [47]. The exception is acute promyelocytic leukaemia (APL), a subtype of AML that is remarkably responsive to the differentiating agent all-trans retinoic acid (ATRA) and arsenic trioxide (ATO). These two agents, in combination with an anthracycline, have increased the cure rates of APL to well above 80% [48–50].

Clinical presentation

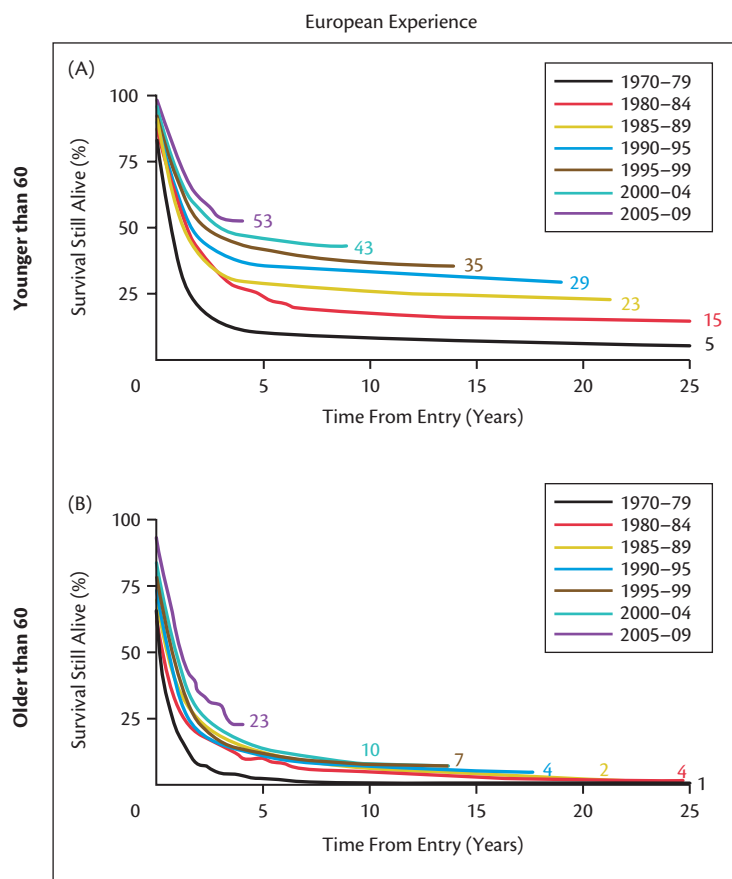
The clinical presentation of AML is often related to anaemia, thrombocytopenia, and/or neutropenia. Patients may present to their physicians with fatigue, dyspnoea on exertion, pallor, petechiae, purpura, gastrointestinal bleeding, or frequent infections. It is not uncommon, however, for the initial presentation of AML to be in an asymptomatic patient who is noted on routine blood counts to have a mild cytopenia. This inevitably leads to a diagnostic evaluation that includes a bone marrow (BM) aspiration and biopsy that confirms the diagnosis of AML. Patients with APL


Fig. 51.3 Survival rates for younger (A) and older (B) adults with AML enrolled on European clinical trials.

commonly present with bleeding, usually subcutaneous, in the central nervous system, or in the gastrointestinal tract, which can be life-threatening and may be catastrophic.

Diagnosis

The diagnostic criteria for AML require the demonstration of a block in myeloid differentiation and proliferation of immature myeloblasts. The presence of 20% or greater myeloblasts in the peripheral blood or BM is sufficient to establish a diagnosis of AML. Patients with an elevated myeloblast percentage that is less than 20% are said to have a myelodysplastic syndrome. Of course, progression from MDS to AML is a continuum, and whether patients with 19% myeloblasts behave clinically in a way that is different than those with 21% myeloblasts is doubtful. An exception to the '20% rule' is made for AML with recurrent cytogenetic abnormalities such as t(15;17) and the so-called core binding factor leukaemias [inv(16), t(8;21)], where the presence of characteristic cytogenetic abnormalities is sufficient to make a diagnosis of AML, even in the absence of the threshold 20% blast percentage.

Initially, a BM aspirate and biopsy is performed and the clinician will estimate a percentage of blasts from the aspirate smear. Wherever possible, a trephine biopsy should be obtained with the aspirate both to confirm the percentage of blasts seen in the aspirate, to assess the overall architecture of the BM, and to perform immunohistochemical testing to establish blast lineage. The initial designation of blast lineage—whether myeloid or lymphoid—is crucial, as patients with elevated lymphoblasts have acute lymphoblastic rather than acute myeloid leukaemia, leading to significant changes in the diagnostic evaluation, treatment, and prognosis. Myeloblasts can be distinguished from lymphoblasts morphologically by the presence of prominent nucleoli, relatively open nuclear chromatin, and cytoplasmic granulation. In some cases, cytoplasmic granules coalesce to rod-like structures called Auer Rods in AML (Figure 51.4). Although immunohistochemical stains can help confirm the blast lineage, in all cases the BM aspirate should be sent for immunophenotyping by flow cytometry to confirm the myeloid lineage. Myeloblasts typically express CD33, CD34, CD117 and myeloperoxidase, although aberrant expression of a lymphoid marker is not uncommon. However, the percentage of blasts should not be routinely based on flow cytometric findings (e.g., percentage of CD34$^+$ cells) as some myeloblasts do not express CD34 and
Fig. 51.4 Myeloblasts with auer rods.

haemodilution during processing can produce falsely low estimates of the myeloblast percentage. The diagnosis of highly undifferentiated AML (M0 in the French American British classification system) can only be established by immunophenotyping.

In some cases, the blast lineage is ambiguous, with two separate populations of cells, one expressing myeloid markers and one expressing lymphoid markers or the co-expression of myeloid and lymphoid markers on the same cell. The World Health Organization (WHO) classifies this subtype of leukaemia as acute leukaemia of ambiguous lineage. This diagnosis should be confirmed at a centre with experienced haematopathologists. Whether to treat acute leukaemia of ambiguous lineage with regimens for AML or acute lymphoblastic leukaemia (ALL) should be made in consultation with an experienced leukaemia physician at a tertiary referral centre.

Once the blast lineage has been established, AML is grouped into specific subtypes. Historically, the French, American, and British (FAB) classification was used and based on morphology and cytochemical stains alone. Currently, the most accepted classification system is that devised by the WHO and is based on morphology, cytochemistry, immunophenotype, cytogenetics, and molecular genetics of the abnormal myeloblasts. Practically, these classifications allow better prognostication of expected responses to therapy and the determination of whether patients should proceed to consolidation with an allogeneic transplant or high-dose chemotherapy once they have reached a complete remission after induction chemotherapy. The exception to this rule is APL, which has a specific morphologic appearance (differentiation block at the promyelocyte stage) and a recurrent reciprocal balanced translocation involving chromosomes 15 and 17. As mentioned earlier, APL is treated differently from other forms of AML and incorporates the use of the differentiating agent ATRA.

Pathophysiology

The development of AML is surmised to result from a genetic event in a putative leukaemic stem cell. This cell, relatively resistant to the effects of chemotherapy, gives birth to the abnormal clone of myeloblasts that cannot differentiate, but can proliferate. A model proposed by Gilliland and colleagues suggests a two-hit model of AML pathogenesis: the first hit is a mutational event in a gene related to differentiation and the second hit is a mutational event in a gene related to proliferation [51]. In recent years, it has become apparent that this model should be expanded, as many mutations have been discovered in genes that encode epigenetic modifications that activate or suppress gene transcription. These epigenetic genes include *IDH 1* and *IDH2, ASXL1* and *DNMT3A*, among others [52–55].

Much has been written about the leukaemic stem cell, a cell that acquires the genetic or epigenetic aberrations that leads to the development of AML and is relatively resistant to the effects of chemotherapy [56].While the leukaemic stem cell may initiate the disease and its progression, the cytopaenias and BM failure that are characteristic of AML may not be related to 'crowding out' of the marrow by proliferating myeloblasts. This is evident in routine clinical evaluations, as the percentage of myeloblasts does not always correlate with the degree of cytopenia. It is likely that changes in the BM environment induced by the abnormal myeloblasts, rather than proliferation, is the cause of the cytopenias seen in the disease.

Aetiology

Aside from a few well-known environmental factors and genetic syndromes, the causes of the genetic and epigenetic changes that lead to AML in most patients are poorly understood. Of the few known genetic and environmental risk factors for AML, syndromes such as Down syndrome and Fanconi anaemia, exposure to ionizing radiation, prior cytotoxic chemotherapy, and benzene exposure all increase the risk of developing AML [57–59].

Benzene exposure

It is well known that benzene is a potent carcinogen that can lead to the development of AML. Less appreciated is that exposure to even low levels of benzene, either by accidental environmental exposure or through the inhalation of byproducts of cigarette smoke, can also lead to the development of AML [60–63].

Cytotoxic chemotherapy

It is well established that cytotoxic chemotherapy itself, given for other malignancies, can induce changes in DNA that promote leukaemogenesis [64–66]. The most common agents implicated in the development of therapy-related AML are alkylating agents like cyclophosphamide, topoisomerase II inhibitors such as etoposide, and anthracyclines. These agents produce characteristic patterns of AML with alkylating agents most often inducing changes in chromosomes 5 and 7 approximately five years after administration and topoisomerase II inhibitors causing abnormalities of chromosome 11 at position 11q23. Therapy-related AML developing after exposure to alkylating agents typically has a relatively long latency and often an antecedent myelodysplastic syndrome phase. In contrast, those arising after exposure to the epipodophyllotoxins and anthracyclines usually have a shorter latency period, no period of myelodysplasia, and monocytic morphology.

Ionizing radiation

The survivors of the atomic bombings at Hiroshima and Nagasaki, as well as individuals exposed to large doses of radiation after the Chernobyl nuclear accident, have increased risks of developing AML. The effect of exposure to low levels of radiation over a lifetime, from medical radiological imaging, radon, and frequent travel in airplanes, is unknown [67, 68].

Management of acute myeloid leukaemia

Evaluation and general consideration

Acute myeloid leukaemia (AML) is the most common acute leukaemia in adults. Survival of AML patients is continuously improving, especially among younger patients [69]. Nevertheless, only 35–40% of newly diagnosed AML patient younger than 60 years are cured of their disease (Figure 51.5) [70, 71, 151, 152]. Treating an AML patient with curative intent requires inducing the most durable remission and prescribing some form of post-remission therapy. During evaluation and therapy initiation, infectious complications, tumour lysis syndrome (TLS), hyperleukocytosis, and disseminated intravascular coagulation (DIC) are common and require special attention and treatment [72]. Active infection and occult bleeding should be ruled out and chest radiography, complete blood count, blood chemistry studies and coagulation panel, including fibrinogen, are indicated.

Adequate hydration to maintain high urinary flow and rapid response to any signs or symptoms of infection are mandatory.

Daily biochemistry studies are recommended and, in some rapidly proliferative conditions, pseudohypoxaemia or pseudohyperkalaemia may be observed [73]. A 25% rise from baseline of two or more of LDH, uric acid, potassium, creatinine, BUN, and phosphorus, or a decrease in calcium level, is suggestive of tumour lysis syndrome [74]. Hyperuricaemia is common, and allopurinol—or in patients presenting with severe renal failure, at least a single dose of recombinant urate oxidase (rasburicase)—should be prescribed [75]. Dyspnoea and stupor, ischaemic symptoms of heart, kidneys, distal extremities, or priapism, in the absence of alternative aetiology, may suggest hyperleukocytosis and leukopheresis should be considered [76]. Fundoscopy is indicated whenever the white blood cell count is >100 000 cells/μl.

Extramedullary leukaemic infiltration may exist but no routine evaluation or imaging is required. Brain imaging and lumbar puncture are indicated only when clinical symptoms are suspicious for central nervous system involvement [77]. It may also be justified in patients presenting with very high counts, but should be delayed until blasts are eradicated from peripheral blood. Blood products should be used punctiliously. Prophylactic transfusion are indicated when the platelet count is lower than 10 000/μl. There is no numerical cut-off for obligatory red cell transfusion. Irradiated and leukodepleted blood products are recommended to prevent transfusion-related graft-versus-host-disease (GVHD) and allo-immunization, especially in patients who may be candidates for allogeneic stem cell transplantation (allo-SCT). Of all cancers, acute leukaemias are particularly recognized for a very rapid progression from diagnosis to initiation of therapy.

Induction

Achievement of complete remission (CR) is the sine qua non for cure of AML. Of long-term AML survivors, 91% attain CR [78]. In recent years, multiple ways of intensifying the traditional protocol of three daily doses of anthracycline and a week-long continuous infusion of cytarabine (3 + 7) have been tested. Doubling daunorubicin doses from 45 to 90 mg/m^2 yielded a significantly higher CR rate (70.6% vs 57.3%) with no increase in adverse event rate [79]. However, intensifying induction by administering 50 mg/m^2 of daunorubicin for five days failed to improve patient outcome [80]. It may well be that achievement of high peak plasma levels is more important than the total daunorubicin administrated dose. The ongoing Medical Research Council (MRC) AML17 trial is prospectively comparing daunorubicin doses of 60 and 90mg/m^2; doses of 45 mg/m^2 should no longer be considered appropriate [81]. Escalated doses of cytarabine (1 g/m^2 every 12 hours for five days) in combination of idarubicin failed to improve CR rate [82]. The addition of cladribine 5 mg/m^2, administered in a three-hour infusion on days one to five, to a standard 3 + 7 protocol improved CR and overall survival (OS) rates in a prospective phase III randomized trial [83].

Induction intensification by prescribing an additional intensive chemotherapy cycle between days 20–22 of therapy to all patients, regardless of the results of the first induction course, is known as a double induction approach. Several double induction protocols exist but only few have been compared to a regular 3 + 7 protocol. The Acute Leukemia French Association (ALFA) conducted a three-arm prospective randomized trial comparing 3 + 7 with daunorubicin 80 mg/m^2 and cytarabine 200 mg/m^2 to a double induction with identical 3 + 7 followed by mitoxantrone and cytarabine
Fig. 51.5 Overall survival from diagnosis of patients younger than 60 years with acute myeloid leukaemia. Virtually identical survival curves from major co-operative groups, despite varying treatment regimens, population size, and countries.

on day 20 or to a timed-sequential protocol [84]. The CR rate, duration, and adverse event rate were identical for all three arms. In the MRC AML15 study [85], 1113 patients younger than 60 were randomized to either receive or not receive a CD33-targeted therapy, gemtuzumab ozogamicin (GO, Mylotarg®), in addition to induction. Surprisingly, the survival benefit of GO was not associated with the expression of CD33 on myeloid blasts with favourable cytogenetics. For patients presenting with intermediate-risk cytogenetics, a multivariable model was in favour of GO administration with the exception of those with a low-performance status and older age. Similar results were observed in a French randomized, open-label, phase III study (ALFA 0701) [86]. Currently GO is not commercially available, but since the effect of GO was not CD33-related and daunorubicin doses used in those trials were 50 and 60 mg/m^2, it might resemble the effect of other induction intensification. Similarly, with high daunorubicin doses the median

survival of patients with favourable or intermediate cytogenetic profile has been significantly improved (from 20.7 to 34.3 months) but not in patients with unfavourable cytogenetics [79], although the number of patients (n = 5a) in this cohort was relatively small (Figure 51.6).

Considering the dismal prognosis of patients who experience induction failure, early identification of resistant disease is warranted. In typical US cooperative group prospective studies, the presence of >10% blasts in a non-hypoplastic BM at day 12–14 of induction calls for re-induction. Data from 1980 patients who participated in six different Eastern Cooperative Oncology Group (ECOG) protocols demonstrated that the long-term outcome of patients who attained CR following re-induction at day 14 is identical to those who entered CR following a single induction [87]. Such data were derived, as the post-remission therapy in these studies was not altered by the number of cycles needed to achieve
Fig. 51.6 Effect of induction with intensified daunorubicin dose on overall survival. Intensifying induction by doubling daunorubicin dose improves OS in patients with favourable and intermediate cytogenetics (A). Such a difference could not be demonstrated, in smaller numbers, among patients with unfavourable cytogenetics (B). CR. Unfortunately, the positive and negative predictive value of BM examinations on either day 14 or 21 are low [88].

Discriminating patients who are likely to achieve CR with current protocols from those who are in need of novel therapies is a challenge. High doses of anthracyclines are safe and, although less beneficial for those with adverse cytogenetics, the 3 + 7 regimen remains the gold standard for all patients with AML.

Induction in older patients

Age is a prominent independent prognostic factor in AML, with adverse genetic profiles more prevalent in the elderly. Yet, in patients older than 60 who present with a favourable cytogenetic or genotype, CR rate has been reported to be as high as 80% following intensive induction [89]. Unfortunately, partly due to the inability to deliver maximal post-remission therapy, relapse rates are higher in older patients and only a small portion of patients can be cured.

The decision regarding a patient's fitness for intensive induction depends very much on the doctor's clinical impression and the patient's preference. The following data should guide physicians in their judgement and must be carefully explained to patients. Mortality rate during the first month following intensive induction protocol is 10% in patients over 60 years, compared to 5% in younger patients. However, early deaths are mainly attributed to leukaemia and not to therapy. This is intuitively understandable when death is due to hyperleukocytosis or tumour lysis syndrome, but is also true in cases of fatal infections or bleeding which have similar prevalence among patients treated with palliative care only [90]. Comorbidities and performance status—but not age alone—are predictive parameters for early death [90]. In older adults, intensifying induction with high daunorubicin dose of 90 mg/m^2 is safe, induces more remissions, and may also provide a survival advantage for some patients over 60 [91]. Moreover, the addition of gemtuzumab ozogamicin 3mg/m^2 to induction with daunorubicin 50 mg/m^2 plus either cytarabine or clofarabine reduced relapse rate and improved OS [92]. However, there is no reason to believe that the same results could not have been achieved using a higher anthracycline dose. Thus, attenuating standard induction for older adults should be discouraged. Low-intensity induction protocols may have fewer side effects but are much less effective in inducing complete remission [93]. Data from Swedish and Swiss registries suggest that older patients, even those with poorer performance status, do better with intensive induction than with best supportive care only [90] (Table 51.1).

Table 51.1 Outcome with different first line approaches in older AML patients

A summary of outcome results of prospective studies of different first line approaches designed for older patients with AML. The cited CR rate is the rate achieved by a single induction cycle not including patients who went into remission following a second induction or salvage protocols. Early death is the mortality rate from all causes within the first 30 days of therapy. OS is for two or three years depending on the period reported in each study.

* Studies that used 7 + 3 regimen with daunorubicin at a dose of 60 mg/m^2 or lower.

Studies that used 7 + 3 regimen with daunorubicin doses higher than 60 mg/m^2

CR, complete remission; OS, overall survival.

Alternative induction regimens for older patients have been suggested. Phase II studies of intravenous clofarabine at 30 mg/m^2/day for five days as monotherapy reported a CR rate of 32–38% in high-risk patients [94]. The addition of daily 20 mg/m^2 cytarabine subcutaneously for 14 days to clofarabine improved remission rate to 63%, but with a price of increased induction mortality [95]. Overall survival following clofarabine induction and consolidation was 10–12 months in all reported studies. However, a phase III ECOG study in older adults (E2906), comparing induction with clofarabine 40 mg/m^2/day for five days to a standard 3 + 7 regimen (with 60 mg/m^2 of daunorubicin) was suspended in early 2015 due to differences in survival rates favouring standard induction and consolidation compared to clofarabine induction and consolidation.

The role of low-dose cytarabine and hypomethylating agents

Cytarabine has been used in AML therapy for nearly 40 years. In 1990, Tilly et al. randomized 87 patients older than 65 to receive either low-dose cytarabine or intensive induction and reported a lower number of early deaths but also lower CR with the low-dose cytarabine arm [96]. OS was similar in both arms. Currently, low-dose cytarabine (s.c. 10 mg/m^2 bid for 10–14 days) is reserved for patients considered unfit for intensive induction. A randomized study conducted by the MRC established the superiority of low-dose cytarabine over hydroxyurea in this palliative setting [97].

Azacitidine and decitabine are cytidine nucleoside analogs which are incorporated into DNA, inhibit DNA methyltransferase, and thus induce DNA damage and hypomethylation. Azacitidine activity in AML was shown in a sublet analysis of a phase III study. In this study, patients with myelodysplastic syndrome (MDS) were randomized to azacitidine or to one of three alternative predetermined physician-chosen therapies (intensive chemotherapy, low-dose cytarabine, and best supportive care). Analyzing outcome of 113 MDS patients who presented with >20% blasts, and therefore regarded as AML, demonstrated a superior two-year OS (50% vs 16%, p = 0.001) with azacitidine [98]. However, great caution is indicated in interpreting these data. Only 63 (56%) patients were randomized to best supportive care and the number of patients randomized to low-dose cytarabine and intensive chemotherapy was also small. Decitabine was prospectively compared in AML patients older than 65 years of age in a study of a similar design [99]. For patients randomized to not receive decitabine, low-dose cytarabine was offered to 88% and only 12% of patients were assigned to supportive care. No clinically significant effect was demonstrated with decitabine. Several studies of AML patients treated with azacitidine and decitabine [98–100] have reported low CR and early mortality rates (13–24% and 7–12%, respectively) that are similar to results with low-dose cytarabine but inferior to reported rates in fit patients treated with intensive chemotherapy. Therefore, azacitidine or decitabine, though they may prolong survival of some patients, should not be a substitute for intensive chemotherapy in patients who can tolerate it (Table 51.1). The OS advantage with azacitidine that was demonstrated in patients with low blast count [98] suggested that benefit of hypomethylating agents is most pronounced in low-proliferative diseases.

Post-remission therapy

The importance of post-remission therapy in AML is well recognized. A three-arm study that compared intensive consolidation, low-dose protracted maintenance, or no further therapy for AML patients in first complete response was interrupted following interim monitoring. The non-treatment control arm was terminated due to a significantly shorter remissions and higher relapse rates [101]. Eventually, all patients who received no post-remission therapy relapsed. This study also demonstrated that a single intensive consolidation cycle of IV cytarabine 3 g/m^2 over one hour every 12 hours for 12 doses followed by amsacrine 100 mg/m^2/d for three days is superior to maintenance with oral thioguanine and subcutaneous cytarabine for two years [102]. Retrospective analysis of 1414 patients from six different ECOG protocols demonstrated a survival benefit with escalation of post-remission intensity [103]. In a landmark study by the Cancer and Leukemia Group B (CALGB), consolidation with four cycles of twice daily cytarabine 3 g/m^2 in a three-hour infusion on days one, three, and five, significantly prolonged OS compared to lower cytarabine doses when followed by four cycles of maintenance therapy—a point largely ignored by the community at large [104]. In this study, a four-year disease-free survival (DFS) of 44% and an OS of 52% were reported; thus this consolidation protocol was adopted by many centres, even though no evidence is provided that four cycles of high-dose cytarabine are needed [105].

There were several attempts to further improve long-term results using different consolidation protocols. Intensifying cytarabine dose, up to 3 g/m^2 twice daily for six consecutive days in combination with mitoxantrone failed to improve outcome; five-year DFS and OS rates of 33% and 38%, respectively, were reported [106]. When prospectively compared, three cycles of sequential multiagent chemotherapy were equal to three cycles of high-doses cytarabine (HIDAC) [107]. In larger studies that also included patients with intermediate-risk cytogenetics, DFS and OS following three or four HIDAC courses did not improve outcome even with the addition of up to eight consolidation courses or with concurrent administration of multiple chemotherapy agents [108–110].

Post-remission therapy in older patients

Unlike in younger adults, there is no unequivocal evidence that any form of post-remission therapy changes the long-term outcome in older patients [105]. Nevertheless, virtually every major study in older adults includes some form of post-remission therapy.

The question of the optimal number of consolidation cycles in older patients was addressed by the MRC11 trial [111]. The reported results of comparable long-term outcome with either one or three consolidation cycles following double induction should be carefully interpreted. While some young adults in first complete response (CR1) can be cured by repetitive consolidations, for older patients in CR1, the lifelong relapse rate following identical regimen can reach 80%. In addition, the toxicity and mortality with each consolidation cycle is age-dependent. Mortality, mostly due to infection, after a single consolidation cycle, was reported to be 1–2% in younger but 5–10% in older patients. Thus, the cumulative mortality risk related to the administration of three to four cycles can reach 5% in younger and 30% in older adults.

Thus, for patients in CR1 in a non-transplant setting, data support the administration of at least one course of intensive consolidation. However, only in young adults do the benefits of repetitive consolidations outweigh toxicity. There is no agreement regarding the number, drug combination, or doses of consolidation cycles. The common practice of administrating multiple courses is based on retrospective data and, except for patients with favourable cytogenetics, a considerable relapse risk should be expected [112]. For most AML patients, if cure is desired, alternative post-remission modalities should be considered.

The role of autologous stem cell transplantation in first complete response

Autologous stem cell transplantation (auto-SCT) augments the anti-leukaemic activity of chemotherapy by significant dose intensification. Indeed, in multiple studies, auto-SCT during CR1 was followed by a lower relapse rate. Results of auto-SCT reported decades ago were characterized by a relatively high treatment-associated mortality rate. With improvement of supportive care, mortality has decreased and is now predicted as low as 0–4% [113, 114]. As a result, the 2010 LeukemiaNet expert panel recommended that, in patients with favourable- and intermediate-risk cytogenetics, auto-SCT is at least as good as repetitive chemotherapy cycles [77]. Recently, younger adults in CR1 were prospectively randomized in a phase III study between auto-SCT and intensive chemotherapy. Auto-SCT was found to be associated with a lower relapse rate (58% vs 70%, p = .02). However, five-year OS was similar (44% vs 41%) because patients relapsing on the chemotherapy arm had more salvage opportunities [115]. Promising results with auto-SCT were also reported by a similarly large ECOG trial [114].

Allogeneic stem cell therapy in first complete response and patients' assignment for transplantation

Of all post-remission strategies, the most prominent anti-leukaemic effect leading to the lowest relapse rates is provided by allogeneic stem cell transplantation (allo-SCT) [116–118]. Some retrospective studies suggest that if allo-SCT is performed shortly after completion of induction, the single high-dose consolidation course that is usually advised can be spared [119, 120]. With the introduction of high-resolution tissue typing and the availability of large international donor repositories, allo-SCT should be considered for a significant portion of AML patients [121]. Nevertheless, since allo-SCT is associated with considerable non-relapse mortality and morbidity, doctors and patients alike often hesitate to elect an allo-SCT while in CR1. A prospective trial and meta-analysis of three additional studies, demonstrated an OS benefit of 12% for allo-SCT over repetitive consolidations for all AML patients except those with favourable cytogenetics [116]. Allo-SCT is therefore a reasonable option for most AML patients in CR1 [112]. However, more definitive indications for all SCT are required. Improvement in conditioning protocols and in supportive care to reduce transplant-related toxicity will hopefully crystallize the indications of an allo-SCT. In addition, with novel genetic prognostication, a more accurate prediction of relapse risk will enable a more personalized allo-SCT indication.

The European LeukemiaNet AML Working Party has recently published a consensus statement on the usage of allo-SCT in CR1 [122]. In this statement, an integrated risk-adapted approach is suggested. The benefit from allo-SCT, calculated as the actual reduction in relapse risk, is predicted for each individual patient weighed against the predicted transplant-related mortality risk. Allo-SCT in CR1 is only indicated when transplant is predicted to more likely prevent a leukaemic relapse than the likelihood of an adverse transplant-related outcome. In general, the relative reduction in relapse risk following an allo-SCT is around 50% across most AML risk categories [116, 123]. For patients presenting with a 'favourable' genetic characterization, a relative reduction of 50% from the projected relapse risk of 35% with repetitive chemotherapy courses, will translate into 20% actual risk reduction. Non-relapse mortality (NRM) rate following allo-SCT is higher than 20%, even in young patients with no other co-morbidities who are being transplanted from a fully matched donor in optimal conditions. Thus, although allo-SCT in 'favourable' risk AML can prevent a relapse in one out of five patients, the transplant-related risk outweighs its benefit; until the NRM is reduced it should not be recommended. At the other end of the spectrum, data from allo-SCT in patients with monosomal karyotype suggest that, in this very poor risk group, allo-SCT prevents much less than 50% of relapses [124–126]. However, for patients presenting with a monosomal karyotype who enter CR1, the unsatisfying results with allo-SCT are still the best available compared to the ultimate risk of relapse with any other modality. Thus, allo-SCT is currently indicated in patients with very poor risk AML.

The vast majority of AML patients present within a wide intermediate-risk zone. Cytogenetics was traditionally the sole molecular parameter that served as an indication for allo-SCT in AML patients in CR1 [127]. With the growing number of

mutations identified with additive prognostic value to cytogenetics, the traditional discrimination between 'favourable' or 'unfavourable' cytogenetics is now being replaced by more complex genetic profiles [128, 129]. Progress in genetic risk classification allows a more accurate prediction of relapse risk [130, 131] significantly decreasing the number of patients in CR1 in whom the predicted relapse rate is moderated within a wide range.

Transplant-related mortality risk is also individualized. Three general transplant-related risk score systems were suggested based on retrospective data from the European Group for Blood and Marrow Transplantation (EBMT) [132], the Dana Farber Cancer Institute (DFCI) [133], and the University of Washington [134]. When discussing allo-SCT as a therapeutic option for an AML patient in CR1, the risk of disease relapse and the safety of allo-SCT should be weighed. The more likely the risk of relapse and the safer the transplant, the stronger the indication for allo-SCT. Table 51.2 summarizes the allo-SCT recommendation along the integration of both AML relapse risk and mortality risk.

Patients with high-risk acute myeloid leukaemia or high transplant-related risk

The most challenging clinical situations are patients in CR1, in whom the probability of relapse is high but there is also risk from allo-SCT. Such clinical scenarios are common, especially in older patients where unfavourable genetics are frequent and the probabilities for transplant-related complications are high. Two main paths of therapy exist in such conditions but it must be recognized that they are directed at different goals. The first, aiming for cure, requires allo-SCT. For a patient considered unfit for full myeloablative allo-SCT, a reduced-intensity condition (RIC-allo-SCT)

is an option. The effectiveness of RIC-allo-SCT in AML has been reported in retrospective studies to be comparable to traditional full myeloablative allo-SCT. RIC-allo-SCT was associated with a lower early death rate but with a higher risk of leukaemic relapses, with OS similar to that anticipated with a full myeloablative conditioning. To better address this issue, a German intergroup study prospectively randomized AML patients in CR1 between full- and reduced-intensity conditioning protocols. The study was stopped due to slow accrual but results from randomization of 195 patients were recently published [135]. With a median follow-up of 27 months, no difference was detected in non-relapse mortality, relapse rate, and OS. Thus, RIC-allo-SCT is an option for elderly patients and cure may be achieved, but morbidity and mortality remain high.

Alternative strategies for high-risk patients not considered candidates for any kind of allo-SCT is administration of at least one high-dose consolidation cycle followed by either observation or some maintenance therapy. Since ultimate relapse is predicted, the main goal of such therapy is prolonging life with the best quality. A French study suggested that in older patients, prolonged less intensive consolidation protocol is associated with higher two-year OS rates [136].

Maintenance therapy in acute myeloid leukaemia

In the well-cited CALGB study that confirmed the value of high-dose cytarabine as post-remission therapy, both arms received four cycles of maintenance therapy but its value has never been reassessed [104]. A large Japanese study demonstrated that for patients receiving three intensive consolidation courses, the addition of maintenance improved outcome no better than a shorter

Table 51.2 Risk-adapted approach recommendation for allo-SCT in CR1

AML risk group	AML risk assessment*	Risk of relapse following consolidation approach (%)		Allo-SCT is indicated only if	
		Chemotherapy or Auto SCT	Allo-SCT	Predicted NRM is less than (%)	Risk score is
Good	t(8;21) with WBC ≤20 Inv(16)/t(16;16) Mutated *CEBPA* (double allelic) Mutated NPM1 (no *FLT*3–ITD mutation) Early first complete remission and no MRD	35–40	15–20	15	None
Intermediate	t(8;21) with WBC >20 Cytogenetically normal (or with loss of X and Y chromosomes), WBC count ≤100 and early first complete remission (after first cycle of chemotherapy)	50–55	20–25	25	EBMT score ≤2 HCT-CI score ≤2
Poor	Otherwise good or intermediate, but no complete remission after first cycle of chemotherapy Cytogenetically normal and WBC >100 Cytogenetically abnormal	70–80	30–40	30	EBMT score ≤3 HCT-CI score ≤3
Very poor	Monosomal karyotype Abn3q26 Enhanced Evi-1 expression	>90	40–50	40	EBMT score ≤5 HCT-CI score ≤5

The European LeukemiaNet AML Working Party consensus statement suggested that allogeneic-HSCT should be indicated only if the disease-free survival benefit of transplant exceeds 10% for an individual patient compared with consolidation by a nonallogeneic-HSCT approach.

*Includes response to first induction. Categorization requires one of the parameters indicated.

Abbreviations: AML, acute myeloid leukaemia; EBMT, European Group For Blood and Marrow Transplantation; Evi-1, Ecotropic viral integration site 1, HCT–CI, haematopoietic cell transplantation comorbidity index; HSCT, haematopoietic stem cell transplantation; *CEBPA*, gene encoding CCAAT enhancer-binding protein α; *FLT3*, gene encoding fms-like tyrosine kinase receptor-3; ITD, internal tandem duplication; NA, not advocated; *NMP1*, gene encoding nuclear matrix protein; MRD, minimal residual disease; WBC, white blood cell count; NRM, non-relapse mortality.

protocol with four high-dose courses [137]. Reducing relapse risk and prolonging survival were demonstrated with maintenance of histamine dihydrochloride and interleukin-2 [138] and with azacitidine post-allo-SCT for patients with early signs predicting for relapse [139]. Thus, maintenance protocols that carry a low risk may be justified during CR1 in patients with a high risk of imminent relapse who are not candidates for allo-SCT. It seems that this modality has not been adequately studied in large prospective trials, including maintenance for young adults after intensive chemotherapy, autologous transplant, or even allogeneic transplant.

Incorporating minimal residual disease monitoring into clinical decisions

The role of minimal residual disease (MRD) monitoring in ALL is well established. It has been suggested that in the future quantifying of MRD may guide post-remission therapy in AML. Support for such approach was demonstrated in a paediatric population using multi-parameter flow-cytometry [140].

Immunophenotyping has been traditionally accepted as the backbone of MRD measurement and efforts have been made towards standardization of measurement techniques [141]. In addition, some molecular aberrations can serve as sensitive markers for imminent relapse [142]. It should be emphasized that large-scale observational studies are required for assessing a specific laboratory component as sufficient for a change in treatment plan, especially if allo-SCT is considered.

The role of targeted and adoptive therapy

Currently there is no 'imatinib-like' magic bullet in AML. FLT3 inhibitors are in clinical trials; quizartinib and sorafenib are the most promising. Acquired point mutations in FLT3 gene are common and contribute to resistance to the targeted agent [143]. Excluding donor lymphocyte infusion post-allo-SCT, adoptive therapy is still an experimental therapy in AML. Recently, a Chinese group demonstrated that infusion of HLA-mismatched peripheral blood stem cells concurrent with induction improved long-term outcome [144]. These investigators have further shown that repetitive infusions of G-CSF mobilized HLA-mismatched cells following each of three consolidation cycles yielded a promising six-year leukaemia-free survival [145]. A measurable anti-leukaemic T-cell response was demonstrated, with no signs or symptoms of GVHD.

Treatment of relapsed/refractory disease

In relapsed/refractory AML, allo-SCT is the only curative modality. Retrospective observations of different large cohorts identified early relapse (<one year), poor cytogenetics, and FLT3-ITD (FLT3-internal tandem duplication) as poor prognostic factors in relapsed disease [146]. Multiple novel agents have been studied with various promising results, however, these agents can only serve as a bridge to transplantation. If allo-SCT is not an option, therapy should focus on prolongation of the patient's life with the best possible quality. Intensive chemotherapy aiming at second remission is appropriate in patients with late relapse and no adverse factors. For patients with poor prognosis for relapse, however, the chance of entering second remission with intensive chemotherapy is as low as 20% [147] and mortality rate from induction therapy is as high as 20% [148]. Therefore, in these patients, intensive chemotherapy targeting second remission may be considered futile. If a donor is

available, such patients may be candidates for cytoreductive chemotherapy followed by RIC-allo-SCT and prophylactic transfusion of donor lymphocytes [149]. The role of azacitidine or lenalinomide in relapsed AML has yet to be determined. Preliminary data suggest that given with first signs of molecular relapse, they may delay relapse and may serve as a bridge to allo-SCT [139, 150].

Prognostic factors in acute lymphoblastic leukaemia

The survival rate for ALL in the 1970s was only about 10%, and a variety of single prognostic factors had been found to have an influence on treatment outcome. However, such factors became relevant only with uniform treatment strategies and larger patient numbers from prospective multicentre trials. The first described prognostic factors for remission duration and OS were age, white blood cell count, and time to achieve complete remission [154].These prognostic factors, still used in most studies, were later extended to immunophenotypes, cytogenetic and genetic alterations [155, 156]. The aim of evaluating prognostic factors in acute lymphoblastic leukaemia is to stratify patients into good- and poor-risk groups and to adapt different treatment strategies accordingly. There are principally two phases where prognostic factors are evaluated; the first is the patient characteristics at diagnosis and the second is the response to treatment.

Pretherapeutic prognostic factors

The most important prognostic factors evaluated at diagnosis are given in Table 51.3.

Age

Increasing age is associated with poorer outcome. The age cut-point at 35 years was the best separation in the survival curve, and was considered the age-limit for allo-SCT [154]. This age-limit is still of relevance since recently-applied paediatric-inspired protocols for adolescents and young adults (AYA) were applicable up to an age of 35–40 years. Patients above this age-limit have a poorer outcome [155, 156] and an increasing incidence of adverse risk factors.

White blood cell count

An increased WBC, reflecting a large leukaemic tumour mass, has been shown to be an adverse influence in nearly all studies. In most

Table 51.3 Major adverse prognostic factors in adult ALL

Factor	
Age	Worse outcome with advancing age
White blood cell count	B-lineage: >30 x 10^9/L T-lineage: >100 x 10^9/L
Immunological subtype	Pro-B ALL vs Pre/Common B-ALL Early T-ALL/Mature T-ALL vs Thymic T-ALL
Cytogenetic markers	t(9;22)/BCR-ABL t(4;11)/MLL-AF4 t(8;14) t(1;19) Complex karyotype
Molecular markers	ERG/BALLC expression NOTCH1 mutations IKAROS deletions/sequence mutations CRLF2 over-expression CEBPalpha FLIT3

studies, a $>30 \times 10^9$/L for B-cell lineage ALL and $>100 \times 10^9$/L for T-cell ALL is considered a poor prognostic factor [154–156].

Immunophenotype

The earlier observed adverse prognostic impact of T-lineage ALL compared to B-lineage ALL has disappeared. There are, however, differences within the immunophenotypically-defined ALL subgroups.

- In *B-lineage ALL* patients, those with a pro-B ALL, defined as CD10-negative—mostly associated with the cytogenetic aberration t(4;11)—have an inferior outcome compared to pre-B and common ALL, but benefit from an allo-SCT in CR1 [157].

- In *T-lineage ALL* there is a strong correlation of outcome to the subtypes cortical/thymic T-ALL vs early T-ALL or mature T-ALL. Thymic T-ALL is CD1a-positive and constitutes about half of adult T-ALL patients; their survival at five years is >50–60% [158]. The subtypes, early-T-ALL and mature T-ALL, have a lower rate of CR and a poorer survival; both subtypes profit from an allo-SCT in CR1. Early T precursor (ETP), a recently genetically defined subgroup, confirms this poor prognosis. Recently, the prognostic impact of genetically defined T-ALL subgroups was retrospectively analysed [159, 160] but implications for prospective risk classification in trials are limited.

- *Antigen-expression as a prognostic marker*. With emerging targeted monoclonal therapies directed against surface antigens, e.g., CD20, CD19, CD22 [161–164], the question arises whether antigen expression itself is a prognostic marker. CD20 expression, observed in ~40% of adult pre-B/common B ALL, seems to have an adverse impact, but the data are controversial [161], and was recently shown not to have an adverse impact in childhood ALL. Also, the improved outcome of CD20+ B-lineage ALL receiving anti-CD20 monoclonal antibody (rituximab) has already abolished the potential adverse influence [162, 163].

- *Cytogenetics*. The most frequent cytogenetic abnormality in adults is the Philadelphia chromosome, which accounts for 25% of all adult B-lineage ALLs. There is a strong age-related incidence on Ph-positivity, increasing from <3% in children up to 40-50% in adults aged >50–60. Ph+ ALL is the poorest ALL subtype with a CR rate of ~70%, a survival at five years of <10% with chemotherapy, and <30% with allo-SCT. Targeted therapy with tyrosine kinase inhibitors (TKIs) directed against the BCR-ABL fusion transcript has changed prognosis completely; CR rates are now >90% and survival >50%. Several other cytogenetic abnormalities (Table 51.3) are also associated with a poor outcome [155, 156]. In addition, there are a large number of other chromosomal aberrations in ALL, but with a low frequency and with undetermined prognostic impact [155, 156].

- *Molecular genetics*. There is an increasing number of well-defined genetic alterations in ALL (Table 51.3). Their prognostic impact often remains uncertain and they are not always included in prospective trials. However, they have the great therapeutic potential for new targeted therapies, e.g., inhibitors of BCR-ABL, NOTCH1, or FLT3.

Response measures

Response measures after induction therapy are most predictive for outcome of a patient with an ALL, such as time to achieve a CR within three to four weeks [154–156]. The rate of CR is prognostically less relevant, since >95% of children and >90% of adults achieve a CR. Although CR rates are high, 40–50% of adult patients eventually relapse. One reason is the limited sensitivity to measure the cell reduction by cytomorphology, with potentially 1–5% leukaemic cells in the bone marrow. There are more sensitive methods that detect leukaemic cells on a molecular level to identify minimal residual disease (MRD); standardized methods for MRD are well defined [165, 166].

Stratification into risk groups

Pretherapeutic prognostic factors and response parameters, now preferably MRD, are used to define risk groups. Standard-risk (SR) patients are defined as those without any of the previously described risk factors, whereas high-risk (HR) patients have one or more risk factors. Several large adult ALL study groups have similarly-defined risk groups [155, 156]. The aim of these prognostic models is to identify a SR group with a good outcome, e.g., with an expected >50% survival probability at five years in adults, and the HR patient group with a less favourable outcome. HR patients are generally candidates for an immediate SCT in CR1, whereas SR patients in most studies continue with consolidation cycles ± reduction and maintenance therapy.

Will minimal residual disease evaluation replace pretherapeutic risk factors?

Questions arise as to whether the evaluation of MRD overcomes all the pretherapeutic risk factors, whether it should be combined with the pretherapeutic risk factors, or whether it should remain as the only stratification criterion [167, 168].

The following risk model (Figure 51.7) used in the risk stratification of the GMALL studies (German Multicenter Study Group for Adult Acute Lymphoblastic Leukemia) is a practical approach to bring the conventional prognostic factors and MRD into a decision algorithm. At diagnosis, patients are stratified into SR or HR patients. Since HR patients are candidates for a SCT in CR1 after induction and consolidation therapy, the optimal time point for the donor search is immediately after diagnosis. By this, a suitable HLA-matched, mostly unrelated, donor will be found within the period of ~three months to guarantee a SCT rate of 79–80%. Initial diagnosis also identifies the patients who are candidates for a targeted therapy; e.g., Ph/bcrabl-positive patients for tyrosine kinase inhibitors or those with specific surface antigens for a treatment with monoclonal antibodies, e.g., CD20 + B-lineage patients for anti-CD20 rituximab.

Minimal residual disease response after induction therapy and impact on outcome

Achievement of molecular remission after induction therapy is the most relevant independent prognostic factor associated with better outcome in several recent trials [167, 169]. The molecular CR rate in relation to cytologic CR rate is given in Table 51.4. Albeit MRD is the most relevant independent prognostic factor, other high-risk features such as age or WBC still has prognostic impact in some, but not in other, studies. If there is no opportunity to evaluate MRD, patients should be stratified according to their conventional risk factors.

Patients with molecular failure after induction therapy have the worst outcome of all ALL subgroups and are candidates for a SCT. In a Northern Italy Leukemia Group study [170] the probability for DFS at four years in patients with SCT was 0.33 vs 0 for those with chemotherapy. In a GMALL study [169], there was also a substantial benefit for SR patients with molecular failure receiving SCT, with a probability
Fig. 51.7 Subclassification of childhood ALL. Blue wedges refer to B-progenitor ALL, yellow to recently identified subtypes of B-ALL, and red wedges to T-lineage ALL.

Table 51.4 Cytologic and molecular response rates after induction (day 71) in correlation to prognostic factors

	Cytologic CR rate N = 1648		Molecular CR rate N = 580

Standard risk	92%	.0001	77%	<.0001
High risk	85%		51%	

The data are from the largest prospective trial (GMALL07/2003) with MRD evaluation and demonstrate the relation of Cytologic CR rate and Molecular CR rate; with an implication on outcome. SR patients with a molCR at week 16 had an five-year OS of 81% ± 3% compared to 43% ± 6% for SR patients with molecular failure (p <0.0001).

of complete cytogenetic response (CCR) after five years of 66% vs 12% for non-SCT patients (p < 0.001). MRD evaluation may also become relevant for autologous SCT. A retrospective analysis showed a significant survival benefit for auto-SCT in patients who were MRD-negative at time of transplant [171], with no residual disease in the patients or in the stem cell harvests. With an increasing fraction of patients achieving MRD-negative status, partly due to the addition of targeted therapy, prospective trials are ongoing to prove this concept.

MRD is also an efficacy parameter for other targeted therapies. In several studies with antibody therapy, e.g., directed against CD20, CD22, or CD19, within the patients achieving a CR the rate of molecular remission was high [161].

Prognostic impact of targeted therapies on minimal residual disease

When the tyrosine kinase inhibitor (TKI) imatinib (IM) became available, most multicentre adult ALL trials added IM to intensive induction chemotherapy in Ph + ALL. The molecular CR rate (bcr-abl negativity) increased from ~5% to 50–80%, translating to substantially better outcome. Maintenance with IM after SCT can substantially reduce the negative impact of MRD positivity before or after SCT [172].

Minimal residual disease conversion as a new study endpoint for clinical trials

Patients with a molecular relapse have a poor outcome since it precedes clinical relapse by several months. Conversion of MRD positivity to MRD negativity is therefore a reasonable clinical endpoint. Thus, in a study of B-lineage adult ALL patients who were MRD refractory or relapsed received the bispecific (CD3/CD19) antibody, with a conversion rate to MRD negativity of 80% and promising survival, with or without SCT [173]. The question arises as to whether patients with a molecular relapse profit from earlier therapy compared to patients treated later at relapse. Although there is no randomized study to compare these approaches, there is some evidence that earlier intervention is of benefit.

Pitfalls of minimal residual disease prediction

Unfortunately, 20–30% of adult ALL patients with MRD negativity after induction therapy will experience relapse. There are several

potential reasons for failure to predict relapse by MRD. The first is sensitivity: MRD negativity is consensus-defined as $<1 \times 10^{-4}$ leukaemic cells. However, the biologically relevant MRD level may vary for different ALL subtypes, e.g., in bcr-abl positive ALL a positive signal at the level of 10^{-5} is highly predictive for relapse. Second, for various genetic aberrations, the molecular CR rate is different [165], but it is noteworthy that in larger multicentre trials MRD is measured by flow cytometry or PCR for Ig/TCR and not for the specific genetic aberration. Third, clonal evolution of leukaemic subclones is a further reason for failure to predict relapse by MRD, since it detects the major clone but the number of potentially emerging subclones is much larger than expected [174]. Next generation sequencing (NGS), based on high-throughput sequencing that universally amplifies antigen-receptor gene segments and identifies all clonal gene rearrangements at diagnosis, may be a new technical tool to increase sensitivity and to explore different relevant MRD levels for ALL subtypes [175].

Conclusion

MRD evaluation has emerged as the most important prognostic marker in childhood and adult ALL for treatment decisions and is now an integral part of most prospective trials. Other pretherapeutic markers and patient characteristics at diagnosis are, however, still relevant. Patients with molecular failure after induction reflect refractoriness to chemotherapy ± targeted therapy and are now the most poor prognosis ALL subgroup, and are thus candidates for an experimental treatment approach or immediate SCT. MRD conversion from positive to negative status will most likely be a new endpoint accepted for clinical studies in the near future, with the advantage of being better quantified and allowing a shorter follow-up. The future goal is to identify within the MRD negative group the 20–30% patients relapsing despite a MRD 'remission'; with new methods, their residual leukaemic cells will hopefully be detected.

Basic biology of acute lymphoblastic leukaemia

ALL is a neoplasm of immature lymphoid cells, termed leukaemic blasts, that infiltrate the bone marrow, blood, and extramedullary sites, notably the central nervous system. ALL may be of either B-progenitor or less commonly, T-cell lineage. ALL is the most common childhood malignancy, with an incidence of approximately three to four cases per 100 000 per year, and a peak incidence at 2–5 years of age. Progressive refinements in combination chemotherapy and central nervous system prophylaxis have witnessed increases in long-term disease-free survival rates to over 80% in developed countries. However, relapse occurs in approximately 20% of patients with ALL, and is associated with low cure rates. As discussed in the section on chromosomal aberrations, ALL comprises a number of subtypes characterized by constellations of gross and submicroscopic structural DNA alterations and sequence mutations; specific subtypes are associated with relapse risk [176, 177]. However, relapse occurs across the spectrum of ALL subtypes, and there is consequently great interest in defining the genetic basis of ALL and identifying genetic alterations that may serve as new diagnostic and therapeutic targets. While ALL is less frequent in adults, the outcome is inferior to that in children. Chromosomal alterations associated with favourable outcome in childhood ALL (e.g., *ETV6-RUNX1* rearrangement and high hyperdiploidy) are less common, and unfavourable alterations (e.g., *BCR-ABL1* and *MLL* rearrangement) are more common, but these do not fully explain the poor outcome of adult ALL.

ALL is one of the most comprehensively studied neoplasms at the genetic level. The first chromosomal rearrangement identified in cancer—the 'Philadelphia' chromosome—was first identified in chronic myeloid leukaemia (CML) and subsequently in ALL, and was subsequently shown to be a reciprocal chromosomal translocation between chromosomes 9 and 22 t(9;22)(q34;q11) [178]. Over 10 years later, it was shown that this rearrangement led to the fusion of the *BCR* gene at 22q11 to the *ABL1* gene at 9q34. This results in a chimeric *BCR-ABL1* fusion gene that induces CML in experimental models and is a founding lesion of *BCR-ABL1* positive ALL [179–183]. Subsequently, multiple recurring chromosomal alterations have been identified in ALL, including aneuploidy (high hyperdiploidy and hypodiploidy) and additional rearrangements, shown to be the initiating lesions in leukaemogenesis.

Chromosomal translocations are the result of an exchange of genetic material between two chromosomes, and resulting in either the juxtaposition of an oncogene to the vicinity of strong promoter elements from the immunoglobulin heavy genes (*IGH*) or the T-cell receptor genes (*TCR*). This leads to aberrant expression of the oncogene or, more commonly, the disruption of two genes and subsequent re-joining of coding sequences from the two genes and creation of a chimeric fusion gene. Typically, the genes rearranged by the latter mechanism encode transcription factors that are important regulators of normal haematopoiesis. By dysregulating or encoding chimeric fusion genes, the chromosomal rearrangements in ALL commonly deregulate the function of the rearranged transcription factor, resulting in excessive activity or acquisition of functions not otherwise observed in normal haematopoiesis [184].

Several observations indicate that additional genetic changes are required for the development of clinically manifest leukaemia. Commonly, expression of the chimeric fusion genes encoded by the chromosomal rearrangements fails to induce leukaemia alone in experimental models. Several chromosomal rearrangements, such as *ETV6-RUNX1*, arise in utero but leukaemia does not manifest for several years [185, 186]. Together, these observations suggest that additional genetic changes not evident on conventional cytogenetic analysis, including submicroscopic deletions and gains (amplification) of DNA and sequence mutations or epigenetic changes are also required for leukaemogenesis. In support of this, low-resolution genomic profiling studies and sequencing of individual genes have identified recurring genetic changes in genes encoding tumour suppressors and cell cycle regulators (e.g., *TP53* [p53] and *CDKN2A/CDKN2B* [INK4A/ARF]) and Ras signalling genes (*NRAS* and *KRAS*).

Our understanding of the genetic basis of ALL has been transformed in the last decade by the advent of high-resolution genome-wide approaches to identify alterations in the genome, transcriptome, and epigenome. These findings have been extended in the last few years by the availability of high-throughput NGS, including whole-exome and whole-genome sequencing and sequencing of the expressed genome (transcriptome sequencing, or RNA-seq) [187]. Although the individual targets of mutation vary between ALL subtypes, several pathways are frequently mutated, including loss-of-function mutations targeting transcriptional regulation

of lymphoid development; activating mutations driving cytokine receptor, tyrosine kinase, and Ras signalling; mutations disrupting tumour suppressors; and regulators of cell cycle; and epigenetic modifiers [188, 189]. It is likely that the majority of ALL cases require alterations perturbing several or all of these pathways. In addition, there is growing evidence of clonal heterogeneity in ALL, and the nature of genetic alterations that drive resistance to therapy and disease relapse. While much effort has focused on cataloguing somatic (tumour-acquired) genetic alterations, inherited or germline genetic variations are also important determinants of population-based risk of ALL, and also in promoting the development of familial ALL. Genome-wide studies of epigenetic alterations are less mature than studies profiling structural genetic alterations, but emerging data are identifying subtype-specific epigenetic alterations, and also illustrating the complex but important interrelationship between structural genetic alterations, epigenetic alterations, and the leukaemic transcriptome.

Chromosomal aberrations in paediatric B-cell precursor (BCP)-acute lymphoblastic leukaemia

Gross chromosomal alterations including aneuploidy and chromosomal translocations are present in the leukaemic cells of approximately three-quarters of childhood ALL cases, and are important for diagnosis and risk stratification (Table 51.5, Figure 51.8). The key genetic and biologic features of some important subtypes are reviewed in the following section; more detailed features are included in the tables and figures.

High hyperdiploid acute lymphoblastic leukemia

High hyperdiploid ALL (51-67 chromosomes) is identified in about 25–30% of BCP-ALL cases and is characterized by recurring, non-random gain of at least five chromosomes, most commonly X, 4, 6, 8, 10, 14, 17, 18, and 21. High hyperdiploidy is associated with a favourable prognosis with an overall survival of about 90%; however, 15–20% of cases relapse [190, 191]. High hyperdiploidy is strongly associated with BCP-ALL and is less common in adult ALL and rare in T-cell leukaemia. There is a pronounced age peak at 2–4 years of age with a median age of 3.7 years. Attempts have been made to identify cytogenetic subtypes among high hyperdiploid ALL that correlate with outcome, suggesting that gain of chromosomes 4, 10, 17, and 18 are associated with a favourable prognosis [190, 192]. About 50% of cases contain a structural variation in addition to the high hyperdiploidy; most commonly, the structural variants are unbalanced changes and include partial gains if 1q, deletions of 6q, and isochromosome 7q or 17q. Balanced translocations are rarely seen [193].

The mechanisms leading to the generation of hyperdiploidy, and its contribution to leukaemogenesis, are poorly understood. The highly stereotyped patterns of chromosomal gain and copy-neutral loss-of-heterozygosity of non-triplicated chromosomes suggests an early catastrophic chromosomal loss and reduplication event leading to hyperdiploidy, rather than the ongoing chromosomal aberrations characteristic of aneuploid solid tumours. The molecular evidence behind the formation of high hyperdiploidy points

towards two major routes, with the most common (70%) being a simultaneous gain in one single abnormal cell division and less common (30%) initial tetraploidy with subsequent loss of chromosomes [193]. It has been suggested that overexpression of genes on the gained chromosomes is important. Microarray gene expression profiling has shown that the majority of genes on the triplicated chromosomes exhibit increased expression, with a minority showing no increase or absent expression. This suggests alternate mechanisms of regulation of gene expression, such as epigenetic changes deregulating gene expression [194, 195]. Consistent with this notion, genome-wide studies of cytosine methylation in ALL have shown that a substantial proportion of genes on triploid chromosomes that do not show increased expression are subject to methylation-induced silencing [196].

Co-operating mutations in high hyperdiploid ALL include activating mutations in the receptor tyrosine kinase/Ras pathway in approximately one-third of cases: *FLT3* in 10–25%, *KRAS/NRAS* in 15–30%, and *PTPN11* in 10–15% [197]. These mutations appear to be mutually exclusive suggesting that activation of the RAS pathway or kinase signalling is an important co-operating event in this ALL subtype. Mutations of *CREBBP*, encoding in the *CREB*-binding protein (also known as CBP) are present in two-thirds of relapsed high hyperdiploid ALL cases [198]. *CREBBP* mutations are also common in other BCP and T-lineage ALL cases that relapse [199]. CREBBP acetylates both histone and non-histone targets, and has a role in regulating the transcriptional response to glucocorticoid therapy. Glucocorticoids such as prednisolone and dexamethasone are key agents in ALL therapy, and poor responsiveness to initial steroid treatment predicts a high risk of relapse. These findings suggest that *CREBBP* alterations confer resistance to glucocorticoids and promote the emergence of steroid resistance subclones.

Hypodiploid acute lymphoblastic leukemia

Hypodiploid ALL with less than 46 chromosomes comprises 5% of BCP-ALL, with the majority having 45 chromosomes [200, 201]. Hypodiploid ALL can be divided into three genetic subtypes: near-haploid (24-31 chromosomes), low hypodiploidy (32-39 chromosomes), and high hypodiploidy (40-45 chromosomes) [200, 202]. Near-haploid cases tend to be younger with a median age of 7 years [200, 203–205]. The prognosis is poor with a three-year event-free survival of 29%. Low hypodiploid (33-39 chromosomes) patients tend to be older than the near-haploid cases, with most being ten years or older and a median age of 15, and also have poor outcome [200, 205, 206].

High hypodiploidy (42-45 chromosomes), accounts for the majority of hypodiploid cases with a modal number of 45 being by far the most common. Common alterations in cases with a modal number of 45 are loss of a sex chromosome and the presence of dicentric or isochromosomes, most commonly involving chromosomes 7, 9, 12, and 20 [200, 202].

Until recently, little was known regarding the additional, submicroscopic genetic alterations and mutations underlying the pathogenesis and poor prognosis of hypodiploid ALL with less than 44 chromosomes. Genomic hypodiploid ALL cases, using single nucleotide polymorphism (SNP) and gene expression

Table 51.5 Key cytogenetic subtypes of ALL

Subtype	Frequency (%)	Comment
B cell precursor		
Hyperdiploidy with more than 50 chromosomes	20–30	Excellent prognosis with antimetabolite-based therapy
Hypodiploidy <44 chromosomes	1–2	Poor prognosis, high frequency of Ras pathway and IKAROS gene family mutations
t(12;21)(p13;q22) *ETV6-RUNX1*	15–25	Expression of myeloid antigens, excellent outcome
t(1;19)(q23;p13) *TCF3-PBX1*	2–6	Increased incidence in blacks, generally excellent prognosis, association with CNS relapse
t(9;22)(q34;q11.2) *BCR-ABL1*	2–4	Historically dismal outcome, improved with addition of imatinib to intensive chemotherapy
PAX5 rearrangement	~2%	Multiple partners, commonly from dic(7;9), dic/t(9;12) and dic(9;20), outcome unknown
ABL1, PDGFRB, JAK2 rearrangements	2–5	Multiple rearrangements encoding chimeric proteins fusing 5' partners with 3' kinase domains. Associated with *IKZF1* alteration and very high leukocyte count, potentially amenable to tyrosine kinase inhibitor therapy
t(4;11)(q21;q23) *MLL-AF4*	1–2	Common in infant ALL (especially <6 months of age), poor prognosis
t(8;14)(q24;q32), t(2;8)(q12;q24), t(2;8)(q12;q24); *MYC* rearrangement	2	Favourable prognosis with short term high-dose chemotherapy
CRLF2 rearrangement (*IGH-CRLF2*; PAR1 deletion and *P2RY8-CRLF2*)	5–7	Extremely common in Down syndrome ALL (55%); association with *IKZF1* deletion/mutation and *JAK1/2* mutation and poor prognosis in non-Down syndrome ALL
ERG deletion	7	Defines a novel subtype of B-ALL with distinct gene expression profile; favourable outcome
T-lineage ALL		
t(1;7)(p32;q35), t(1;14)(p32;q11) and interstitial 1p32 deletion *TAL1* dysregulation	15–18	Generally favourable outcome
t(11;14)(p15;q11) and 5' *LMO2* deletion; LMO2 dysregulation	10	Generally favourable outcome
t(10;14)(q24;q11) and t(7;10)(q35;q24); *TLX1 [HOX11]* dysregulation	7	Good prognosis
t(5;14)(q35;q32); *TLX3*	20	Commonly fused to *BCL11B*, also a target of deletion/mutation in T-ALL. Poor prognosis
t(10;11)(p13;q14); *PICALM-MLLT10 [CALM-AF10]*	10	May have poor outcome
MLL-MLLT1 [MLL-ENL]	2–3	Superior prognosis to other *MLL*-rearranged leukaemias
NUP214-ABL1	6	Potentially amenable to tyrosine kinase inhibitors, also identified in high-risk B-ALL; other kinase fusions identified in T-ALL include *EML1-ABL1, ETV6-JAK2, ETV6-AL1*
t(7;9)(q34;q34)	<1%	Rearrangement of *NOTCH1*, mutated in >50% T-ALL
Early T-cell precursor	12	Immature immunophenotype, expression of myeloid and/or stem cell markers, very poor outcome. Underlying genetic alterations unknown; *MEF2C* dysregulation.

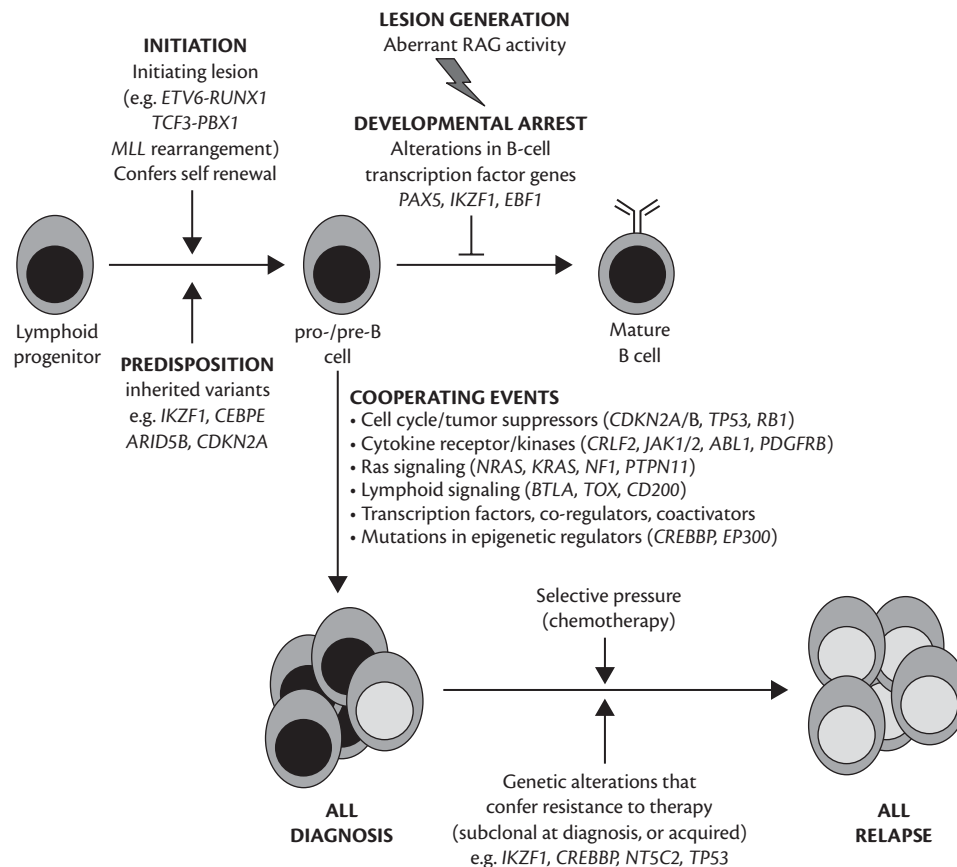
microarray analysis and second-generation sequencing (whole genome, exome, and transcriptome sequencing) demonstrated that near haploid and low hypodiploid ALL have distinct transcriptomic signatures and submicroscopic DNA copy number alterations and sequence mutations differ from other B-ALL subtypes [207]. Hypodiploid cells from both near-haploid and low hypodiploid cases exhibit activation of Ras-Raf-MEK-ERK and phosphatidylinositol-3-OH kinase (PI3K) signalling that is sensitive to PI3K and PI3K/mTOR inhibitors, suggesting that PI3K inhibition represents a therapeutic approach. An unexpected finding was that the *TP53* sequence mutations identified in low hypodiploid ALL are commonly present in matched non-tumour cells, suggesting germline inheritance. This has been confirmed in a limited number of kindreds, indicating that low hypodiploid ALL is a manifestation of Li-Fraumeni syndrome [207, 208]. Additional deleterious germline mutations were identified in other hypodiploid ALL cases, including activating mutations of *NRAS* and *PTPN11*.


Fig. 51.8 Schema for the nature and timing of acquisitions of genetic alterations in the pathogenesis of B-ALL. Chromosomal rearrangements are acquired early in leukaemogenesis, and drive transcriptional and epigenetic dysregulation and aberrant self-renewal. These lesions and/or secondary genetic alterations disrupt lymphoid development and result in an arrest in maturation. Additional genetic alterations target cellular pathways including cell cycle regulation, tumour suppression, cytokine receptor and kinase signalling, and chromatin modification. Diagnosis ALL samples are commonly clonally heterogeneous, and genetic alterations in minor clones may confer resistance to therapy and promote relapse. A similar schema can be proposed for T-ALL, where lesions targeting lymphoid development, self-renewal, and kinase signalling are also observed; and in which there are multiple targets of mutation of unknown role in leukemogenesis (e.g., PHF6, WT1).

t(12;21)(p13;q22) *ETV6-RUNX1* acute lymphoblastic leukemia

The t(12;21)(p13;q22) rearrangement is identified in about 25–30% of childhood BCP-ALL cases [209–211], but is uncommon in adults with ALL (1–4%) [212–215]. The t(12;21) is usually cryptic on cytogenetic analysis and may be identified by fluorescence in situ hybridization (FISH) or molecular assays [216]. This translocation fuses the *ETV6* gene (encoding ETS variant 6, or TEL) at 12p13 to the runt-related transcription factor 1 (*RUNX1*, formerly *AML1*) gene at 21q22, resulting in expression of the *ETV6-RUNX1* chimeric fusion [217, 218]. *ETV6-RUNX1* positive childhood ALL has a favourable outcome, with overall survival of approximately 88% [209, 210, 225, 226]. Recent data indicates that relapse is rare with contemporary risk-directed therapy [226]. The rearrangement commonly arises in utero [227–229], but the prolonged latency to overt leukaemia [219–224] together with twin studies [229] suggest that additional genetic events are needed for the development of overt leukaemia. In addition, screening of normal cord blood has shown that the *ETV6-RUNX1* fusion gene is present at up to a 100-fold higher incidence than the corresponding risk of the leukaemia [230], although the exact frequency of this fusion in neonatal studies has varied among studies [231]. Taken together, these data suggest that additional secondary genetic events are required for the development of leukaemia [232–246].

t(1;19)(p13;q22) [*TCF3-PBX1*]

The t(1;19)(p13;q22) results in the *TCF3-PBX1* fusion gene that is present in about 5% of childhood and about 3–6% of adult ALL cases, with a higher incidence in younger adults and African-American ancestry [247–249]. *TCF3-PBX1* ALL was originally considered a high-risk leukaemia that often presented with central nervous system involvement and an increased risk of relapse [250–254]. With intensified protocols, the presence of a *TCF3-PBX1* fusion gene stratifies the patient to a standard-risk protocol, but the presence of the *TCF3/PBX1* fusion gene is still an independent risk factor for CNS relapse [255, 256].

11q23/*MLL* gene rearrangements

Rearrangements of the mixed lineage leukaemia (or myeloid lymphoid leukaemia; *MLL*) gene at chromosome band 11q23 are common in acute leukaemia, in particular among infants where >70% carry a rearrangement of the *MLL* gene [257–259]. *MLL* rearrangements are seen in all ages and in both lymphoid and myeloid leukaemias and are present in 1–3% of childhood ALL [260–262], 15–20% of childhood AML cases [263–265], and in 4–9% of adult leukaemia cases [266–269]. In addition, *MLL* rearrangements are associated with secondary leukaemias in patients previously treated with topoisomerase inhibitors [270–272]. The prognosis of *MLL*-rearranged infant leukaemia is poor with an

event-free survival of only 22–48% [273–276]. Among older children with ALL, the event-free survival is 42–65%, with the t(4;11) and t(9;11) being associated with a worse prognosis [273, 277–284]. Over 121 fusion partners of *MLL* have been reported [285], however five account for around 80% of the *MLL* leukaemias, including t(4;11)(q21;q23) (*MLL-AFF1* (*MLL-AF4*)), t(9;11)(p22;q23) (*MLL-MLLT3* (*MLL-AF9*)), t(11;19)(q23;p13.3) (*MLL-MLLT1* (*MLL-ENL*)), t(10;11)(p12;q23) (*MLL-MLLT10* (*MLL-AF10*)), and t(6;11)(q27;q23) (*MLL-MLLT4* (*MLL-AF6*)). For accurate diagnosis of *MLL*-rearrangements, a combination of genetic and molecular genetic analyses is needed and includes cytogenetic analysis, FISH, Southern blot, and/or RT-PCR for specific fusion genes.

MLL-rearranged childhood leukaemias are characterized by early acquisition of *MLL* rearrangement (in utero for most childhood cases), lymphoid and myeloid features, and poor outcome. *MLL*-rearranged leukaemias are also exceptional in the spectrum of childhood ALL cases for the paucity of additional DNA copy number alterations and sequence mutations, with the exception of Ras mutations [188, 286–319]. New and targeted therapies for *MLL*-rearranged leukaemias are being actively pursued due to the aggressiveness of this form of leukaemia. One promising target is the methyltransferase DOT1L which interacts directly or indirectly with several of the *MLL* fusion partners [320–324]. Selective killing of *MLL*-rearranged leukaemic cells on exposure to a potent DOT1L inhibitor was recently shown [325]. DOT1L is required for successful transformation and maintenance of *MLL-MLLT3* (*AF9*) leukaemia in vivo [326]. In addition, inhibitors towards the protein-protein interaction between MLL fusion proteins and menin show promising result with reversal of the oncogenic activity of *MLL*-rearranged leukaemias [327].

t(9;22)(q34;q11.1) [*BCR-ABL1*] acute lymphoblastic leukemia

The t(9;22)(q34;q11.1) rearrangement results in the formation of the Philadelphia chromosome and is seen in most cases of CML, in 25% of adult ALL and in 3–5% of paediatric ALL [213, 328–331]. The Philadelphia (Ph) chromosome was first identified by Nowell and Hungerford in 1960, and was subsequently shown by Janet Rowley in 1973 to be the product of a reciprocal chromosomal translocation between chromosome 9 and 22 [178]. This rearrangement results in fusion of the human homolog of the Abelson murine leukaemia virus, *ABL1*, at 9q34 to a 5.8kb region of the Breakpoint Cluster Region (*BCR*) gene at 22q11 [332–334]. The *BCR* gene encodes a serine/threonine kinase and *ABL1* encodes a protein structurally similar to the Src family of kinases. The leukemogenic properties of BCR-ABL1 are dependent upon the constitutive activity of ABL1. Multiple signalling pathways have been shown to become activated upon transformation by BCR-ABL1 including RAS/MAPK, STAT, PI3K, JNK/SAPK, and NF-κB [335]. In addition, BCR-ABL1 results in deregulation of apoptosis, differentiation, and cell adhesion.

The majority of Ph+ALL cases have additional secondary aberrations present at diagnosis including gain of a second copy of the Ph chromosome, a hyperdiploid karyotype, or −7/7q- [336]. Thus, in cases with a hyperdiploid karyotype it is important to identify the Ph chromosome so the patient receives appropriate treatment with tyrosine kinase inhibitors. The *BCR-ABL1* fusion gene is present in 3–5% of paediatric ALL and is associated with and older age (median age of about eight years), a high incidence of CNS involvement at diagnosis, a high leukocyte count, a pseudodiploid karyotype, resistance to therapy, and adverse outcome [328, 329]. Prior to the advent of tyrosine kinase inhibitor therapy, the outcome of *BCR-ABL1*-positive leukaemia was poor with a three-year event-free survival of about 25–30% [328–330, 337–342]. However, the introduction of imatinib mesylate [343] has transformed the prognosis of this leukaemia. The combination of intensive chemotherapy and imatinib resulted in improved event-free survival of 80% [344]. More potent second generation kinase inhibitors such as dasatinib and nilotinib may potentially further improve outcomes [345, 346].

CRLF2 rearrangements and Janus kinase mutations in acute lymphoblastic leukaemia

The cytokine receptor gene *CRLF2* is rearranged or mutated in approximately 7% of childhood B-ALL (Figure 51.8), and 50% of cases are associated with Down's syndrome (DS-ALL) [347–350]. *CRLF2* is located in the pseudoautosomal region (PAR1) at Xp22.3/Yp11.3 and encodes cytokine receptor-like factor 2 (also known as thymic stromal lymphopoietin receptor, TSLPR). With the interleukin-7 receptor alpha peptide, CRLF2 forms a heterodimeric receptor for TSLP (thymic stromal lymphopoietin). CRLF2 is rearranged by translocation into the immunoglobulin heavy chain locus (*IGH-CRLF2*), or by a focal deletion upstream of *CRLF2* that result in expression of *P2RY8-CRLF2* that encodes full-length CRLF2. Both rearrangements result in aberrant over-expression of CRLF2 on the cell surface of leukaemic lymphoblasts that may be detected by immunophenotyping [349].

Approximately half of *CRLF2*-rearranged ALL cases harbour activating mutations of the Janus kinase genes *JAK1* or *JAK2* [348, 349, 351], which with the exception of T-lineage ALL are otherwise uncommon in ALL [352, 353]. The JAK mutations are most commonly missense mutations at or near p.Arg683 in the pseudokinase domain of JAK2. *CRLF2*-rearranged leukemic cells exhibit activation of JAK-STAT and PI3K/mTOR pathways, and are sensitive to JAK and mTOR inhibitors in vitro and in vivo [354–360]. The activity of the JAK inhibitor ruxolitinib in childhood B-ALL cases with JAK-STAT activating lesions, including *CRLF2*-rearrangements, is being evaluated in clinical trials.

In non-DS ALL, *CRLF2* alterations and JAK mutations are associated with *IKZF1* deletion/mutation and poor outcome, particularly in cohorts of high-risk B-ALL [361–364]. *CRLF2* and *IKZF1* alterations are associated with inferior outcome in multiple cohorts, and elevated *CRLF2* expression in the absence of rearrangement is also an adverse prognostic feature [365].

'BCR-ABL1-like' or 'Ph-like' acute lymphoblastic leukaemia

Recently, a new subtype of B-ALL has been described in which leukemic cells lack expression of BCR-ABL1, but exhibits a leukaemic cell gene expression profile similar to Ph-positive ALL and like Ph-positive ALL commonly harbours deletion or mutation of *IKZF1* [366, 367]. BCR-ABL1-like, or Ph-like ALL comprises up to 10–15% of childhood B-ALL, and up to one-third of B-ALL in adolescents and young adults, and is associated with poor outcome [368, 369]. Approximately half of BCR-ABL1-like ALL cases harbour *CRLF2* rearrangements and concomitant JAK1/2 mutations. Transcriptome and whole genome sequencing has shown that non-*CRLF2*-rearranged Ph-like ALL cases harbour a diverse range of genomic alterations that activate cytokine receptors and tyrosine kinases including *ABL1*, *ABL2*, *CSF1R*, *EPOR*, *JAK2* and *PDGFRB* [370]. These alterations are most commonly chromosomal rearrangements resulting in chimeric fusion

genes deregulating tyrosine kinases (e.g. *NUP214-ABL1*, *ETV6-ABL1*, *RANBP2-ABL1*, *RCSD1-ABL1*, *BCR-JAK2*, *PAX5-JAK2*, *STRN3-JAK2* and *EBF1-PDGFRB*) and cytokine receptors (*IGH-EPOR*). Up to 20% of BCR-ABL1-like cases lack a chimeric fusion, and additional alterations activating kinase signalling, including activating mutations of *FLT3* and *IL7R*, and focal deletions of *SH2B3*, or LNK, which constrains JAK signalling [371], have been identified in fusion-negative cases. These diverse genetic alterations activate a limited number of signalling pathways, notably *ABL1* and *PDGFRB* and JAK-STAT signalling, and it is predicted that the majority of BCR-ABL-like ALL cases will be amenable to therapy with a limited number of tyrosine kinase inhibitors: imatinib-class TKIs for *ABL1, ABL2, CSF1R*, and *PDGFRB* rearrangements, and JAK inhibitors such as ruxolitinib for alterations activating JAK-STAT signalling (*EPOR, IL7R, JAK2*, and *SH2B3*). These rearrangements have been shown to activate signalling pathways in model cell lines and in primary leukaemic cells [360, 370], and xenografts of BCR-ABL1-like ALL are highly sensitive to TKIs in vivo. There are also multiple anecdotal reports of responsiveness of refractory BCR-ABL1-like ALL to appropriate TKI therapy, for example *EBF1-PDGFRB* ALL to imatinib [372, 373].

B-progenitor ALL with intrachromosomal amplification of chromosome 21 (iAMP21)

iAMP21 is characterized by gain of at least three copies of a (usually large) region of 21 that always includes *RUNX1* [374–376]. The presence of iAMP21 is generally associated with unfavourable outcome, although this is mitigated with intensive chemotherapy [377].

ERG-altered acute lymphoblastic leukaemia

While many of the recurrent focal deletions observed in ALL are observed in multiple ALL subtypes, a notable exception is alteration of the ETS-family transcription factor *ERG* (ETS-related gene), which occurs exclusively in cases lacking known chromosomal rearrangements and is a hallmark of a novel subtype of B-ALL with a distinct gene expression profile [378]. Such cases frequently express a truncated form of ERG. Notably, despite the presence of *IKZF1* alterations in a proportion of *ERG*-deregulated cases, the outcome of this subtype of ALL is favourable [362, 379, 380].

Submicroscopic genetic alterations in B-lineage acute lymphoblastic leukaemia

Microarray-based profiling of DNA copy number alterations permits the identification of DNA copy number alterations (deletions and gains) at sub-kilobase resolution. Widely-used platforms include single-nucleotide polymorphism microarrays that also permit interrogation of copy-neutral loss-of-heterozygosity (LOH, also known as acquired somatic uniparental disomy), and array-based comparative genomic hybridization (array-CGH) [381]. From 2007, microarray profiling studies, and subsequently, genome sequencing studies have shown that while ALL genomes typically harbour fewer structural alterations than many solid tumours, over 50 recurring deletions or amplifications have been identified many of which involve a single gene or few genes (details are included in Table 51.6 and Figure 51.8) [188, 382–384].

Many of the focal deletions in ALL genomes arise from aberrant activity of the recombinase activating gene (RAG) enzymes. The RAG enzymes normally mediate productive rearrangement of the lymphoid antigen receptors, and recognize conserved motifs (heptamers, spacers, and nonamers) in order to juxtapose members of the antigen receptor variable, diversity and joining (V, D, and J) gene families [385, 386]. The terminal deoxynucleotidyl transferase (TdT) enzyme adds additional nucleotides between the antigen receptor segments to further increase diversity. Sequencing of the genomic breakpoints of recurring deletions in ALL (e.g., *PAX5, BTG1, IKZF1*, and *NF1*) has demonstrated partly- or fully-conserved heptamer recognition sequences immediately within the deletion breakpoints, and additional non-template nucleotides between the flanking genomic regions [188, 207, 337, 387, 388]. Moreover, many of the targets of deletion in ALL are expressed during B lymphoid ontogeny. These observations, and high level of RAG gene expression in several subtypes of BCR-ALL, such as *ETV6-RUNX1* ALL, suggest that aberrant RAG-mediated deletion of developmentally regulated genes in B cell precursors confers a selective advantage to preleukaemic clones harboring founding translocations (such as *ETV6-RUNX1*, or *BCR-ABL1*) and are co-operating lesions in leukaemogenesis. Consistent with this notion, experimental BCP-ALL generated in *Rag* null mice exhibit a dearth of secondary focal genomic alterations [389]. This hypothesis provides a potential explanation for the observation that focal deletions are uncommon in subtypes of leukaemia that exhibit low RAG activity, such as *MLL*-rearranged leukaemia [286, 287, 390] and AML [391–393].

The nature and frequency of genetic lesions are subtype-dependent. *MLL*-rearranged leukaemias harbour very few additional structural or sequence alterations [188, 287, 390]. In contrast, the majority of non-*MLL* ALL cases harbour recurring submicroscopic deletions, for example at least six to eight per case in *ETV6-RUNX1* and *BCR-ABL1* ALL [188, 236, 337].

Alteration of transcription factor genes in B-lineage acute lymphoblastic leukaemia

Deletion, sequence mutation, or rearrangement of genes encoding transcriptional regulators of lymphoid development is a hallmark of B-ALL. Alteration of *PAX5* (~35%), *IKZF1* (~15%), and *EBF1* (~5%) are the most common alterations, with at least two-thirds of B-ALL cases harbouring one or more lesions in this pathway [188, 394]. These alterations are usually loss of function or dominant negative lesions that result in arrested lymphoid maturation, which is characteristic of leukaemic cells. Notably, while *PAX5* alterations are the most common genetic alteration in B-ALL, they are not associated with outcome [394, 395]. In contrast, alteration of *IKZF1* (IKAROS) is a hallmark of high-risk ALL, particularly BCR-ABL1-positive ALL [337, 338, 396], and BCR-ABL1-like (Ph-like) ALL [366, 367, 370]. *IKZF1* encodes IKAROS, the founding member of a family of zinc finger transcription factors that is required for the development of all lymphoid lineages [397]. The *IKZF1* alterations include focal or broad deletions that result in loss of expression of IKZF1, and deletions of coding exons 4–7 that remove the N-terminal DNA-binding zinc fingers, leading to expression of a dominant negative isoform, IK6. *IKZF1* alterations are present in over 70% of *BCR-ABL1* lymphoid leukaemia, including de novo ALL and CML at progression to lymphoid blast crisis [337], and are associated with poor outcome in both BCR-ABL1-positive ALL and BCR-ABL1-negative B-ALL [361, 365, 366, 396, 398–407]. Experimental data support a role of alterations of these B-lineage transcriptional factor alterations in leukaemogenesis. Deletion of *Pax5* and *Ikzf1* accelerates the onset of leukaemia in retroviral BM transplant and transgenic models of

Table 51.6 Key submicroscopic genetic alterations in ALL

Gene	Alteration	Frequency	Pathway and consequences of alteration	Clinical relevance	References
PAX5	Focal deletions, translocations, sequence mutations	31.7% of B-ALL	Transcription factor required for B-lymphoid development. Mutations impair DNA binding and transcriptional activation		[188, 337, 383]
IKZF1	Focal deletions or sequence mutations	15% of all paediatric B-ALL cases.	Transcription factor required for development of HSC to lymphoid precursor. Deletions and mutations result in loss of function or dominant negative isoforms		[188]
IKZF1		Over 80% BCR-ABL1 ALL and 66% CML in lymphoid blast crisis		Associated with poor outcome	[337, 338, 396]
IKZF1		One-third of high-risk BCR-ABL1 negative ALL		Tripling in CIR	[367, 394, 399]
IKZF1	Inherited variants			Increased risk of ALL	[539, 540]
JAK1/2	Pseudokinase and kinase domain mutations	18–35% DS-ALL and 10.7% High-risk BCR-ABL1-ALL	Constitutive JAK-STAT activation. Transforms mouse Ba/F3-EpoR lymphoid haematopoietic cell line.		[356–358]
CRLF2	Rearrangement as IGH-CRLF2 or P2RY8-CRLF2 resulting in over-expression	5–16% paediatric and adult B-ALL, and >50% DS-ALL 50% of BCR-ABL1-like ALL	Associated with mutant JAK in up to 50% of cases. CRLF2 mutations and JAK mutations cotransforming in Ba/F3 cells and results in constitutive STAT activation.		[348, 349, 351]
CRLF2		14% paediatric high-risk ALL	Associated with IKZF1 alteration and JAK mutations	Associated with poor outcome	[361, 363]
Kinase and signalling alterations	Rearrangements of ABL1, ABL2, CSF1R, EPOR, JAK2, PDGFRB; sequence mutations of IL7R and FLT3, deletions of SH2B3	10% childhood B-ALL, up to 30% ALL in adult ALL. Associated with BCR-ABL1-like gene expression profile.	Activate kinase signalling pathways and amenable to tyrosine kinase inhibitor therapy	Associated with high risk features and increased risk of relapse. Anecdotal reports of response to TKI therapy	[366, 368, 370, 372, 373]
CREBBP	Focal deletion and sequence mutations	19% of relapsed ALL. Also mutated in non-Hodgkin lymphoma	Mutations result in impaired histone acetylation and transcriptional regulation.	Mutations selected for at relapse, and associated with glucocorticoid resistance.	[199]
NT5C2	Focal mutations	Up to 20% relapsed mutation	Mutations confer resistance to nucleoside analogies	Mutations selected at relapse	[531, 532]
TP53	Deletions and focal mutations	Hallmark of low hypodiploid ALL at diagnosis; 50% of which are inherited. Otherwise uncommon in major clone at diagnosis. Associated with disease relapse			[522, 524, 525]

BCR-ABL1 ALL, and in chemical and retroviral models of leukaemia [408, 409].

Chromosomal rearrangements in T-lineage acute lymphoblastic leukaemia

T-ALL is characterized by an older age of onset than B-ALL, male sex preponderance, and inferior outcome in comparison to B-ALL [410]. Chromosomal abnormalities and rearrangements are evident on cytogenetic analysis in up to 70% of T-ALL cases, and commonly involve one of the T-cell antigen receptor loci, including TRA and TRD at 14q11, TRB at 7q34 and TRG at 7p14. These rearrangements occur in approximately one-third of T-ALL cases, but may be cryptic on cytogenetic analysis. These rearrangements may arise from aberrant antigen receptor gene recombination mistakes in the normal recombination process involved in the generation of functional antigen receptors [411]. The rearrangements in T-ALL commonly dysregulate transcription factor genes [412], including members of the bHLH family (MYC, TAL1, TAL2, LYL1, and BHLHB1) [413–419], genes encoding the LIM-only domain proteins (LMO1 and LMO2) [420–422], and homeodomain genes (HOX11, also known as

TLX1, and *HOX11L2*, also known as *TLX3*) [422–425]. Similar to BCP-ALL, T-ALL is also characterized by the presence of sub-microscopic deletions and sequence mutations, including activating mutations of *NOTCH1* [426], deletion/mutation of *PTEN* [427], *WT1* [428], *FBXW7* [429], and amplification of *MYB* [188, 430, 431].

TAL1 rearranged T-lineage acute lymphoblastic leukaemia

Alteration of *TAL1* (*SCL, TCL5*) at 1p32 is the most frequent transcription factor rearrangement in childhood T-ALL. This arises from either a t(1;14)(p32;q11) that occurs in 3% of cases and juxtaposes *TAL1* into the *TRA/TRD* locus [432–439], or the more frequent cryptic interstitial deletion at 1p32 that is present in approximately 15% of cases, and results in a chimeric *SIL-TAL1* fusion transcript [435, 439, 440]. Additional cases without these rearrangements express high *TAL1* mRNA levels [439, 441]. Less commonly, the *TAL2* gene is juxtaposed to the *TRB* locus as a result of a t(7;9)(q34;q32) rearrangement [417]. TAL1 and LYL1, over-expressed in T-cell leukaemias carrying the t(7;19), are members of the class II family of bHLH proteins and heterodimerize with class I bHLH proteins, such as TCF3 (E2A) [442, 443]. TAL1:TCF3 complexes have been detected in erythroid cells and T-cell leukaemias and bind DNA in a site-specific manner. Additional studies have shown that *Tal1* is required not only for erythropoiesis [444, 445], but also for the earliest steps in the lineage commitment of pluripotent embryonic haematopoietic stem cells [446, 447]. TAL1:TCF3 heterodimers are transcriptionally inactive [448, 449] and the observations that loss of TCF3 function induces T-cell leukaemia in mice [450, 451] and that the DNA-binding domain of TAL1 is dispensable for transformation support the notion that TAL1 mediates leukemogenesis through a dominant negative mechanism [452–460].

The homeobox family of transcription factors comprises two classes of genes. Class I HOX genes are in four clusters (*HOXA, HOXB, HOXC*, and *HOXD*), and class II genes are distributed throughout the genome. The HOX genes exert key roles in anteroposterior patterning, differentiation, and also regulation of haematopoiesis and leukaemogenesis [461–464]. Two HOX genes, *HOX11* and *HOX11L2*, are rearranged in T-ALL. Approximately 7% of childhood T-ALL cases have ectopic expression of *HOX11* arising from t(10;14)(q24;q11) and the variant t(7;10)(q35;q24) translocations that juxtaposes *HOX11* to the *TRA* or *TRB* loci [423, 424, 465, 466]. Approximately 20% of childhood T-ALL cases exhibit over-expression of *HOX11L2* [474–476], most commonly from a cryptic t(5;14)(q35;q32) rearrangement that juxtaposes *HOX11L2* to *BCL11B* (274), a zinc finger protein expressed during T-cell ontogeny, and recently identified as a target of deletion and somatic sequence mutation in T-ALL [467–473, 477–481]. *MLL* is rearranged in 4–8% of T-ALL cases, most commonly to *MLLT1* (*ENL*) [482]. This rearrangement is commonly observed in adolescents and has a superior prognosis to other *MLL*-rearranged leukaemias [483]. Other *MLL* fusions are occasionally seen. *MLL*-rearranged T-ALL represents a distinct biologic entity with a transcriptional profile that differs from other *MLL*-rearranged cases [441, 484].

The t(10;11)(p13;q14) rearrangement is observed in up to 10% of T-ALL cases, may be cytogenetically cryptic, and results in expression of the *PICALM-MLLT10* (*CALM-AF10*) fusion [485, 486]. Notably, both partner genes are infrequently fused to *MLL*, and like *MLL*-rearranged ALL, *PICALM-MLLT10* cases exhibit upregulation of *HOX* genes and *MEIS1*, suggesting common oncogenic pathways. This rearrangement is typically seen in γδT-ALL cases, either in immature or mature cells, and is associated with poor outcome [486–488]. Expression of the fusion in haematopoietic cells, either by retroviral transduction or as a transgene, results in the development of leukaemia, which is often myeloid in phenotype [489–491].

A substantial proportion of T-ALL lacks a known genetic alteration, and the genetic basis of these cases is poorly understood.

Early T-cell precursor acute lymphoblastic leukaemia

Early T-cell precursor (ETP) ALL is an aggressive subtype of immature leukaemia that is associated with very poor outcome [492–494]. Various laboratory criteria have been proposed to identify these immature cases, but the original definition utilized immunophenotypic criteria: the expression of T-lineage markers (e.g., cytoplasmic CD3) but lack of expression of markers otherwise characteristic of T-ALL, such as CD1a and CD8, weak or negative CD5 expression, and aberrant expression of myeloid and/or stem cell markers [492]. This pattern is reminiscent of the murine early T-cell precursor [495], the earliest stage of thymic T-cell maturation that retains lineage plasticity.

Whole genome sequencing (WGS) of tumour and matched non-tumour DNA of 12 ETP ALL cases, and mutation recurrence testing of selected genes in 94 additional ETP and non-ETP T-ALL cases, identified marked diversity in the frequency and nature of genetic alterations [353]. These included inactivating mutations targeting genes regulating hematopoietic and lymphoid development (e.g. *RUNX1*, *GATA3*), mutations activating cytokine receptor and kinase signaling (e.g. *IL7R*, *JAK1*, and *JAK3*), and loss of function mutations targeting epigenetic mutations, particularly genes encoding the polycomb repressor complex 2 (PRC2; *EZH2*, *SUZ12*, *EED*), that mediates histone 3 lysine 27 trimethylation [496–512].

Although similarly comprehensive studies of 'typical' T-ALL are awaited, recent studies have performed exome sequencing of T-ALL that have identified additional targets of mutation including *CNOT3*, a member of transcriptional regulatory complex, and ribosomal proteins [513]. To gain further insight into the male sex preponderance of T-ALL, Ferrando and colleagues performing targeted capture and sequencing of X chromosome genes, and identified sequence mutations and deletions of PHF6 in 16% and 38% of childhood and adult T-ALL, respectively [514]. The *PHF6* alterations result in loss of *PHF6* expression and are associated with *TLX1/3* and *TAL1* rearranged ALL [514, 515]. The role of PHF6 in leukaemogenesis is poorly understood, but has been shown to be a RNA-interacting protein and component of the nucleosome remodeling and deacetylation (NuRD) complex [516, 517]. Thus, PHF6 may have complex and multifactorial roles as a tumour suppressor.

Relapsed acute lymphoblastic leukaemia

Several chromosomal alterations such as *BCR-ABL1* and *MLL*-rearrangement are associated with a high risk of treatment failure; however, relapse occurs across the spectrum of ALL subtypes. It has also long been recognized that ALL genomes are not static but exhibit acquisition of chromosomal abnormalities over time [518]. There is thus great interest in genomic profiling of matched diagnosis and relapse samples to dissect the genetic basis of clonal heterogeneity in ALL, and the relationship of such heterogeneity to risk of relapse. SNP microarray profiling has demonstrated that the majority of ALL cases show changes in the patterns of structural genomic alterations from diagnosis to relapse [518–520], and that many relapse-acquired lesions, including *IKZF1* and *CDKN2A/B,* are present at low levels at diagnosis [519, 521].

Apart from low hypodiploid ALL, *TP53* mutations are uncommon in major clones at ALL diagnosis, but are associated with treatment failure and emerge in major clones at relapse [522–526]. Sequencing of 300 genes in matched diagnosis-relapse samples identified mutations in the transcriptional coactivator and histone and non-histone acetyl transferase CREBBP (CREB-binding protein, or CBP) as a relapse-acquired lesion in up to 20% of relapsed ALL samples [199, 527, 528]. CREBBP has an important role in mediating the transcriptional response to glucocorticoids [529, 530], and histone deacetylase inhibitors were active in steroid-resistant ALL cell lines [199]. Recently, two groups independently identified relapse-acquired mutations in the 5' nucleotidase gene *NT5C2* that confer increased resistance to purine analogues [531, 532]. Thus, mutations that confer resistance to drugs commonly used to treat ALL represent a key mechanism of treatment failure and resistance.

Germline genetic variation and acute lymphoblastic leukaemia risk

Inherited genetic variants are associated with the ALL, clinical features and outcome. These include common inherited polymorphisms that influence ALL risk. In addition [533, 534], several inherited germline mutations associated with segregation of ALL in kindreds have recently been reported [207, 535]. The risk to siblings of developing ALL is modest, and while the development of ALL in monozygotic twin pairs is well described, this may be explained by transmission of pre-leukaemic clones between twins rather than inherited predisposition [536]. A notable setting of increased risk of ALL is Down syndrome, which is associated with a markedly elevated risk of both ALL (~40-fold at age 0–4 years) and AML [537]. The reasons for this elevated risk are poorly understood, although somatic rearrangement of *CRLF2* is a hallmark of Down syndrome-associated ALL [349].

Multiple studies have used a case-control approach to associations between common inherited polymorphisms and ALL risk, initially with a candidate gene approach [538], and more recently with genome-wide association studies (GWAS) [534]. GWAS examine associations between hundreds of thousands to millions of inherited variants and a phenotype. Such studies typically examine hundreds to thousands of patients and ethnically-matched, require stringent p value thresholds to account for the large number of comparisons made, and verify findings by examining associated SNPs in one or more independent cohorts [539–546]. The associations between inherited single nucleotide variants and disease risk typically have modest effect sizes (odds rations of 1.5 or less), and it is likely that multiple variants together influence the risk of developing leukaemia. The most reproducible associations have been in four genes (*IKZF1, ARID5B, CEBPE,* and *CDKN2A*), three of which are involved by somatic genetic alterations in ALL (*IKZF1* by deletions and sequence mutations, *CEBPE* by rearrangement, and *CDKN2A/B* by deletion). IKZF1 and CEBPE are transcriptional regulators, and *CDKN2A/B* encodes the INK4/ARF family of tumour suppressors and cell cycle regulators, suggesting that the associated variants may influence gene expression and leukaemogenesis. In addition, specific variants are associated with ALL risk and outcome in specific ethnic groups (*ARID5B*) and with specific subtypes of ALL (*GATA3* and Ph-like ALL). Thus, it is likely that inherited genetic variants and somatic genetic alterations together drive leukaemogenesis.

Deleterious germline mutations are also implicated in both sporadic and familial ALL. Whole genome sequencing of hypodiploid ALL identified germline *TP53* mutations in approximately half of low hypodiploid ALL cases, as well as germline variants were identified in the Ras pathway genes *NRAS* and *PTPN11*. A number of additional novel variants were identified that were predicted to be deleterious and that involved key cellular pathways, particularly DNA damage and repair.

Familial ALL is uncommon, but such kindreds may be exceptionally informative in enabling the discovery of germline variations or mutations that influence the risk of developing ALL. A recent example is the identification of a novel *PAX5* sequence mutations, p.Gly183Ser in three unrelated kindreds with autosomal dominant ALL [535, 547]. Somatic *PAX5* sequence mutations are common in B-ALL, and typically involve the DNA-binding paired domain (and interfere with binding of PAX5 to its DNA targets) or the C-terminal transactivating domain. The Ser183 mutation is otherwise rare in ALL and involves the octapeptide domain. This mutation results in partial loss of transcriptional activation, and may act by impeding interaction between PAX5 and cofactors that enhance PAX5 activity. All patients with this mutation exhibited loss of the *PAX5* wild-type gene by deletion of chromosome 9p, indicating that transmission of this mutation is tolerable in the heterozygous state, but severe attenuation of PAX5 activity is required for leukemogenesis. Germline mutations in a second transcription factor gene, *ETV6*, have also been identified in several kindreds with familial ALL.

Management of acute lymphoblastic leukaemia, including transplantation

The outcome of therapy for ALL has improved over the past two decades, particularly in the paediatric population [548–556]. With the exception of those over 60 years, the reported survival rates from US registry data significantly improved over a twenty-year period [556]. The improvement in survival can be attributed to multiple factors: more precise risk stratification leading to risk-adapted therapeutic approaches, improved techniques for monitoring residual disease, better understanding of leukaemic and host cell

pharmacokinetics and -genetics, improved supportive care, and the advent of some novel targeted treatment strategies. As a result, the current overall CR rate is about 95%, the estimated five-year OS rate is over 85% and the cure rate approaching 90% in paediatric ALL [548–558]. However, treating adults remains challenging with a greater frequency of higher-risk cytogenetic profiles, larger proportion of drug-resistant disease, and poorer tolerance of therapy.

Concepts of treatment

Leukaemic cell expansion adopts a Gompertzian growth curve with near exponential growth [559]. The primary aim of induction therapy is to induce cytological remission thereby allowing normal haematopoiesis with the least adverse events. The second aim is to offer adequate prophylactic therapy to sanctuary sites such as the central nervous system (CNS). Although specific treatment regimens, drug and dosing schedules, and treatment duration across different age groups and ALL subtypes differ, the basic principles are similar. The standard therapeutic approach for de novo ALL consists of an intensive chemotherapy framework starting with remission induction, followed by consolidation/

intensification, then maintenance. The majority of these treatment regimens are modifications of those originally developed by the Berlin-Frankfurt-Munster (BFM) Group for paediatric patients, later adopted in adults [559]. Although CR rates are similar, retrospective studies have consistently shown that event-free survival rates (EFS) among the adolescents and young adults (AYA) treated on paediatric protocols were substantially higher than those of the same age group treated according to adult protocols [560–568]. Comparative retrospective studies attributed this to earlier and more intensive CNS prophylaxis and/or higher cumulative doses of non-myelosuppressive agents in paediatric-inspired protocols [560, 562, 564] (Table 51.7). These findings partly explain the greatest statistically significant improvement in survival [553, 556] noted among such groups particularly the 15–19 years age bracket [556]. Hence, AYA ALL patients should be treated, at least initially, with intensive 'paediatric-inspired' regimens. The feasibility of the 'paediatric' approach in the 'older' adults remains to be determined. Poor tolerance and significant toxicities [562] result in both treatment delays and treatment-related deaths, both being major reasons for poor outcome in this age group [569]. In regimens designed specifically for older patients, the average CR rate

Table 51.7 Comparison of selected retrospective analytic studies involving AYA ALL patients

Study Group	N	Age (median)	Ph+ (%)	T-cell (%)	CR (%)	OS	EFS	Relapse rate (%)

is 71% (43–90%) and survival rate is 33% (16–71%) [570–575]. Table 51.8 summarizes selected prospective trials for Philadelphia chromosome-negative (Ph⁻) older ALL patients.

Remission induction chemotherapy

The initial phase of therapy involves the administration of a multi-drug regimen typically based on a backbone of a steroid, vincristine, and an anthracycline, with or without asparaginase and/ or cyclophosphamide [563, 576–579]. Whilst prednisolone was the 'traditional' steroid used, several randomized studies comparing it with dexamethasone as part of induction therapy, in paediatric ALL patients dexamethasone significantly decreased CNS relapse rate, improved EFS outcomes [580–582], significantly reduced risk of events (death from any cause, refractory or relapsed leukaemia, or second malignancy) [583], and improved overall outcome [584]. This is attributed, in part, to better CNS penetration of dexamethasone [585]. Anthracyclines have been an integral part of remission induction chemotherapy with CR rates and median remission duration superior in those receiving compared to those who did not [586, 587]. Whilst the most frequently used is daunorubicin, there is no difference in anthracycline dosing or schedule [587–589]. Attempts at dose escalation in adults were not associated with improved outcome [590] although in paediatric setting dose reduction was associated with improved outcome [591]. Another fundamental component of ALL induction and consolidation therapy is L-asparaginase (L-Asp), currently available in several formulations with different pharmacologic and immunogenic properties [592]. Increased dose intensity of L-Asp as opposed is associated with significant improvement in EFS and reduced risk of haematologic and CNS relapses in paediatric patients [593, 594]. Currently there is growing evidence supporting its potential for improved survival in adult patients [595, 596]. The pegylated form of Escherichia coli L-Asp (PEG-Asp) has widely replaced the native formulation due to its convenient administration route, less frequent dosing, and less immunogenicity [592, 597]; the latter may or may not (referred to as silent hypersensitivity and subsequent silent inactivation [598]) result in hypersensitivity reactions [592]. Cross-reactivity between anti-asparaginase neutralizing antibodies against the two E coli forms has been reported [597]. These can be clinically significant as they result not only in decreased asparaginase activity

[599] but also in higher dexamethasone clearance, which in turn was reported to be associated with higher risk of any relapse [600]. To overcome this, Erwinia L-Asp can be used as there is no cross-reactivity between antibodies [601] and its use did not negatively impact EFS outcome [602]. The most notable L-asp-related toxicities include hepatotoxicity, pancreatitis, and coagulopathy, particularly associated with a high rate of thrombosis. Adverse events can be severe (i.e., grade 3–4) [603], are more frequent in older patients [604, 605], and results in difficult decisions regarding the continuation of the drug. Management of thrombosis is difficult, but continuation of L-asp therapy with anticoagulation and antithrombin replacement is a reasonable strategy [606].

Consolidation/intensification chemotherapy

Consolidation/intensification, is aimed at eliminating any potential residual leukaemic cells. This, too, involves a combination of drugs fundamentally similar to those used during the induction phase, with one or two re-induction blocks but with the addition other agents including methotrexate, cytarabine, mercaptopurine, and high-dose L-asp given for an extended period. There is no consensus on the optimum regimen or duration. A number of therapeutic strategies however have been noted to impact either outcome measures or pharmacodynamic profiles. For example, altering the dose of dexamethasone during delayed intensification appeared to reduce the incidence of osteonecrosis in paediatric patients [607]. Paediatric patients with B cell ALL who received L-asp intensification had significantly higher EFS than those who did not (71% vs 31% at a median follow-up of 9.4 years) [608]. Higher doses of methotrexate appear to improve outcome of patient with T-cell ALL [609] and patients with TCF3-PBX1 fusion [610] as blast cells in these subtypes accumulate lower levels of methotrexate polyglutamates than B-cell ALL and those without the genetic abnormality, respectively [610].

Maintenance chemotherapy

The majority of maintenance regimens include a core of daily mercaptopurine and weekly low-dose methotrexate with periodic addition of steroids and vincristine for a total duration of two to three years. This phase is crucial—attempts at omitting or shortening

it were associated with inferior outcome in B-ALL but it may be less significant in T-cell precursor ALL [611]. Dose adjustment to the limits of haematologic tolerance has been associated with improved outcome [612]. Polymorphisms in function and expression of drug metabolizing genes are well described and have influenced treatment responses [613]. One of the most widely studied is thiopurine methyltransferase (TPMT) gene polymorphism. TPMT is the enzyme that catalyzes S-methylation of thiopurines to its inactive forms. Patients with TPMT deficiency are at risk of thiopurine-induced haematologic toxicity and lately noted to be at higher risk of developing second malignant neoplasms [614]. Guidance on dose adjustments based on enzyme phenotype/genotype has been recently published aiming at reducing haematologic toxicity without compromising efficacy of ALL therapy [615].

Central nervous system-directed prophylaxis

CNS-directed prophylaxis has long been recognized as an integral aspect of ALL therapy to clear leukaemic cells at sites inaccessible by systemic chemotherapy to prevent CNS disease/relapse [589]. The five-year cumulative incidence of CNS relapse was 3–5% in paediatric [616, 617] and 2–6% in adult patients [618–621] who received intrathecal and/or intensive systemic chemotherapy for CNS prophylaxis. Most commonly used treatments include intrathecal chemotherapy, cranial irradiation, and high-dose blood-brain-barrier penetrating chemotherapy [563, 577, 585]. With the current combination of effective systemic and intrathecal chemotherapies and the devastating late-onset sequel of cranial radiotherapy [622, 623] (particularly in long-term survivors of paediatric ALL cranial irradiation) it is often omitted. Several studies in paediatric [554, 557, 623, 624] and adult [624, 625] age groups have shown omission is not associated with inferior outcomes or increased risk of CNS relapse. The optimum prophylactic intrathecal therapy has yet to be defined. Triple intrathecal therapy (methotrexate, cytarabine, and hydrocortisone) was associated with significantly lower incidence of CNS relapse than intrathecal methotrexate but with significantly more haematologic and testicular relapse resulting in significantly inferior survival [626]. However, a meta-analysis showed that intravenous methotrexate improved outcome when added to triple intrathecal therapy but had no significant benefit in those treated with intrathecal methotrexate [627].

Role of minimal residual disease monitoring in acute lymphoblastic leukaemia therapy

One of the major developments over the past two decades that defined ALL management is MRD evaluation. Its detection and quantification is now considered the most powerful independent predictor of EFS and OS for paediatric [628–635] and adult ALL patients [636–643]. Hence, it has become an integral part of treatment protocols employing its quantitative assays at specific protocol-defined informative time-points to risk-stratify and monitor therapy. A prospective study by the German Multicenter Study Group for Adult ALL (GMALL) has identified a subset of standard-risk ALL patients with molecular relapse who became MRD positive after an initial post-therapy documented negative result [643]. The median duration from molecular to clinical relapse was 9.5 months. This further underscores the highly predictive power of MRD monitoring, although what interventions would be appropriate in this situation remain unclear.

Several studies in paediatric and adult ALL patients observed that a difference may exist in leukaemic cell eradication kinetics between the two groups. By the end of initial induction therapy 60–75% of paediatric patients [628, 630, 631, 637] achieved MRD negativity versus only 30–50% of adults [640, 642]. The slower rate of leukaemic cell clearance in adults is at least in part related to differences in ALL pathobiology and therapeutic regimens.

Transplantation in acute lymphoblastic leukaemia

The role of allogeneic haematopoietic stem cell transplantation (allo-HSCT) for ALL patients in first CR (CR1) remains to be determined as non-transplant therapies evolve. The role of auto-HSCT was evaluated in a number of trials which revealed inferiority [644] or at best no difference in terms of outcome when compared to conventional consolidation/maintenance chemotherapy [645, 646]. Firm evidence of the donor T-cell-medicated graft-versus-leukaemia (GvL) effect [644, 647] in addition to the potential benefits of higher dose chemotherapy with total body irradiation have made allo-HSCT the 'ultimate' post-remission therapy. However, the high treatment-related mortality (TRM), particularly in adults, and morbidity from graft-versus-host disease (GvHD) in long-term survivors mandate prudence in patient selection.

Several trials [648–650], including a meta-analysis [646,] have confirmed the survival advantage in having a sibling donor. The largest, UKALLXII/US Eastern Cooperative Oncology Group (ECOG) 2993 [644] where the five-year OS of Ph- ALL patients with standard-risk disease who had such a donor was significantly better than those who did not (53% vs 45%; p = 0.01), associated with lower relapse rate risk [644] noted across all adult age groups. However, there was no advantage to having a donor in the high-risk group, attributed to the high non-relapse mortality (36% at two years vs 14%, respectively) of older patients in the high-risk category. PETHEMA ALL-93 [651] trials did not show inferior outcomes in those without a donor in this group. In standard-risk ALL, the evidence is less conclusive and is controversial. Similar results were reported by the HOVON co-operative group whereby the donor arm had a significantly higher five-year DFS rate and lower five-year cumulative incidence of relapse when compared to the no-donor arm (60% vs 42%, p < 0.01; 24% vs 55%, p < 0.001, respectively) [652]. The feasibility of using unrelated and alternative donors has been explored. Retrospective analysis of outcome data from the Center for International Blood and Marrow Transplant Research (CIBMTR) in unrelated donor transplants in Ph- ALL in CR1, the five-year TRM, relapse, and OS were 42%, 20%, and 39%, respectively [653]. Several retrospective studies have addressed the issue of donor type in ALL in CR1 using myeloablative conditioning and these showed no difference in TRM, relapse rate, or OS between related and unrelated donor transplants [654–656]. However, the TRM was higher with HLA-mismatched donors; with TRM the major cause of treatment failure, selecting closely HLA-matched unrelated donors should improve results [653]. With more resolute HLA-matching [657] and improved supportive care [658] this has mitigated the differences in outcome between the two groups [659–661]. Alternative donor transplantation has

recently become a viable option for those lacking suitable donors with current experience showing reasonable OS rates [662–665] but with the disadvantage of significantly higher TRM, GvHD, and graft failure.

Reduced-intensity conditioned (RIC) allo-HSCT, using the principle of a conditioning regimen that promotes GvL effect and mitigates the acute associated transplant-related toxicities, is increasingly used in ALL. Current evidence on efficacy of RIC transplantation is based on retrospective data that includes small cohort of patients that are therefore subject to considerable bias, but encouraging results have been reported [666–668]. In a retrospective comparative study of patients receiving RIC or myeloablative conditioning, multivariate analysis showed that conditioning intensity did not affect TRM or relapse risk [669]. Data from the European Blood and Marrow Transplantation (EBMT) registry from 97 patients showed a two-year OS and leukaemia-free survival of 52% and 42% with RIC transplants in CR1, respectively, and non-relapse mortality of 18% [670]. The MRD status pre-transplant impacts the outcome of RIC transplants. A report from the Fred Hutchinson Cancer Research Center revealed that three-year OS rate in high-risk ALL patients using low-dose TBI approach was 62% in those with evidence of MRD vs 73% who did not [667]. The use of T-cell depletion (TCD) to lower risk of GvHD has been used with encouraging results though with the disadvantage of increased relapse risk. In a report from the British Society of Blood and Marrow Transplantation Registry (BSBMT), 96% of 48 adults with high-risk Ph- ALL reported a five-year OS, DFS, and relapse mortality of 61%, 59%, and 13% using in vivo TCD using alemtuzumab [671]. The incidences of acute grade II-IV GvHD and extensive chronic GvHD were 27% and 22%, respectively [671]. The encouraging results have made RIC transplantation in the 'older' ALL patient a more plausible option—this is currently subject to a prospective trial in the UK, UKALL14.

In summary, allo-HSCT is currently recommended for patients with high-risk disease in CR1 who have a reasonable performance status and a 'suitable' donor [644, 646, 672]. Patients with molecular failure defined as persistence of MRD at a protocol appropriate time point are also considered a high-risk group, relapsing after a median of 7.6 months with a five-year continuous CR and OS rate of 12% and 33%, respectively [673] if they do not receive HSCT in CR1. Table 51.9 summarizes the other high-risk criteria in Ph- ALL patients as defined by selected large international trials in whom allo-HSCT have been considered. With better understanding of disease pathobiology through high-resolution genome-wide analyses most of the patient demographic criteria are no longer as relevant as disease risk factors.

Treatment of Philadelphia chromosome-positive (Ph+) acute lymphoblastic leukaemia

Ph+ ALL, where BCR-ABL1 oncogenic protein is expressed as result of t(9;22), carries one of the worst prognosis amongst ALL subsets with a median survival of eight months [687]. With the advent of targeted therapy in the form of BCR-ABL specific tyrosine kinase inhibitors (TKIs) there has been a significant improvement in initial responses resulting in higher CR rates reaching to almost 95% [688–693] without additional toxicities. The most widely used TKI is imatinib. Table 51.10 summarizes the outcome of selected studies in de novo Ph+ ALL.

Given the significant TKI-attributed improvement in CR rates, the plausibility of reducing or omitting chemotherapy from initial induction therapy was contemplated. However, despite several studies reporting an almost 100% CR rate with single-agent TKI or in combination with minimal chemotherapy [703, 705, 708] the long-term outcome of a chemotherapy-free/minimal chemotherapy approaches is not clear. Dasatinib, a second generation TKI that inhibits BCR-ABL and SRC family kinases, has a 325-fold greater potency in inhibiting in vitro growth of wild-type BCR-ABL cells than imatinib [709] and may theoretically hold more promise of long-term benefit than imatinib. Phase II and III dose comparison studies showed it to induce rapid haematologic and cytogenetic responses in imatinib-resistant or -intolerant adult patients [710–712]. Initial data of combinations with dasatinib with steroid or chemotherapy confers promising results with better OS rates in adults [702, 705, 708]. Unlike imatinib, which penetrates poorly the blood-brain-barrier with concentration around two logs lower in the cerebrospinal fluid (CSF) [713], dasatinib appears to exhibit activity against CNS leukaemia [714]. Nevertheless, results from studies to date (which include small numbers, relatively short follow-up duration, and lack of randomized controlled head-to-head comparisons with imatinib) cannot explicitly justify adding dasatinib to chemotherapy combinations for de novo Ph+ ALL therapy. Safety profile and tolerability of dasatinib are not as favourable as imatinib, with bleeding and pleural effusions being a concern [702].

Despite high CR rates, such response is short-lived and relapses are common [697, 715]. With virtually no alternative therapeutic modality to date that offers long-term survival, benefit allo-HSCT remains the mainstay of treatment for eligible patients although associated with significant toxicities. Outcome data from the UKALLXII/ECOG collaboration [706] showed the addition of imatinib to chemotherapy in the absence of allo-HSCT did not confer survival benefit even on excluding patients in remission who did not survive to allo-HSCT. A similar conclusion was reported by GMALL group [716]. Prospective data from the UKALLXII/ECOG 2993 trial showed the relevant three-year OS was 59% with combination of imatinib-based chemotherapy and myeloablative allo-HSCT despite the TRM [717]. Reported three-year OS by the GMALL group was 72% with myeloablative allo-HSCT when an imatinib-based induction was used [716]. The Japanese Adult Leukemia Study Group reported a three-year OS of 65% using the same approach [718]. In a recent retrospective analysis of long-term follow-up data from the American Society for Blood and Marrow Transplantation, TKI use pre- or post-HSCT did not significantly impact transplant outcomes [719]. Based on this evidence allo-HSCT is considered the standard of care for adult Ph+ ALL, but its role in paediatric patients is less clear, particularly in the TKI era. A retrospective study in paediatric Ph+ ALL who underwent allo-HSCT (aged 1–16 years) the addition of imatinib pre-and/or post-HSCT did not significantly improve outcomes (three-year DFS rate 62% vs 53% and three-year relapse rate 15% vs 26% for those who did not receive imatinib) [720]. A study from the Spanish Cooperative Group of outcomes of children up to the age of 15 years treated with imatinib-based chemotherapy followed by allo-HSCT showed significantly higher three-year EFS rate when compared to historical controls who did not receive imatinib (79% vs 30%)

Table 51.9 High-risk criteria in Ph⁻ ALL patients as defined by selected large international trials in whom allo-HSCT have been considered

Risk stratification criterion that defined HR	Risk subset	Study group(s)/data source	Outcome
At diagnosis			
Age	Advancing age	MRC UKALLXII/ECOG 2993 [717], CALGB [589], GMALL [674]	Worse outcome—no clear age cut-off in adults
Presenting WBC count	> 30x 10⁹/l (B-cell ALL) >100 x 10⁹/l (T-cell ALL)	MRC UKALLXII/ECOG 2993 [718], GMALL [674]	Inferior outcome measures—CR rates, OR, EFS, DFS
Immunophenotype	T-cell ALL vs B-cell ALL Blast expression of CD20	MRC UKALLXII/ECOG 2993 [718], GMALL [674]	In adults, T-ALL can have a better outcome than B-ALL Increased CD20 expression—inferior CR rates and OS
Cytogenetics	Poor: t(4;11)(q21;q23), t(8;14) (q24.1;q32), complex (>5 abnormalities), low hypodiploidy, near triploidy	MRC UKALL XII/ECOG 2993 [675], SWOG 9400 [676]	Inferior rates of DFS and OS when compared with other patients
Specific molecular abnormalities	CRLF2 +/- JAK1/2 sequence mutation 'BCR-ABL-like' gene with IZKF1 'BCR-ABL-like' gene lacking CRLF2 dysregulation IKZF1 deletions TP53	COG [677] Mulligan et al. [678] Den Boer et al. [679] MRC UKALLXII/ECOG 2993 [680], GRAALL [681] Hof et al. [682]	Poor outcome High relapse risk irrespective of age, WBC count, cytogenetics or MRD status post induction Inferior outcome Poor outcome
Response to Therapy			
Steroid responsiveness	Response to steroids has clear relationship with outcome in childhood ALL. Less well defined and tested in adult ALL	Schrappe et al. [683]	Poor OS
Speed of initial response	Rapid initial response	PALG [684]	CR within 4 weeks predicts better outcome. Not uniformly demonstrated
MRD	Clear relationship between MRD at protocol-specific time points and outcome irrespective of risk stratification at diagnosis [91, 94, 95]	◆ MRC UKALLXII/ECOG 2993 [685] ◆ GMALL [642, 673] ◆ PETHEMA [686] ◆ NILSG [636]	MRD −ve vs +ve: ◆ 5-year DFS 74% vs 30% ◆ SR: 5-year OS 67% vs 38% ◆ HR: 5-year OS 66% vs 42% ◆ 4-year DFS 54% vs 2-year DFS 31% ◆ 5-year DFS 72% vs 14%

[695]. A study by the Children's Oncology Group (COG) in Ph⁺ ALL patients up to the age of 21 years treated with imatinib-based intensive chemotherapy showed an improved three-year EFS rate of 80% +/- 11% among those who received continuous imatinib, more than twice historical controls with no appreciable increase in toxicity [694]. Three-year EFS rate was similar for patients treated with chemotherapy plus imatinib (88% +/−11%) or sibling donor HSCT (57% +/- 22%) [694]. Whilst such studies question the role of allo-HSCT in paediatric Ph⁺ ALL, these were not powered to address the dispensability of allo-HSCT; long-term follow-up data may answer this. Older patients unfit for myeloablative allo-HSCT, RIC-HSCT would be an alternative given its acceptable TRM. No optimal conditioning regimen has been described. Whether TKI

is needed post allo-HSCT is not clear. An ongoing German study randomizing patients to either starting imatinib three months post allo-HSCT versus only on BCR-ABL positivity has noted its poor tolerability [700].

BCR-ABL monitoring by real-time quantitative polymerase chain reaction (RQ-PCR) has been increasingly employed to assess MRD in Ph⁺ ALL. However, optimal practice, methodology standardization, and interpretation of results are unclear in addition to conflicting reports on its association with long-term outcome. In the pre-imatinib era good correlation between BCR-ABL transcript levels and outcome have been reported [721, 722]. Based on clinical trials that included TKIs, BCR-ABL transcript levels correlated with response [707] though there is no consensus on what constitutes

Table 51.10 Outcome of selected studies in de novo Ph+ ALL where TKI was added concomitantly to induction therapy at various intensities, following induction or intermittently between cycles of chemotherapy across different age groups

an optimal response. A recent study by Lee et al. [723] has shown a significant correlation between MRD kinetics and long-term HSCT outcome in adult Ph+ ALL treated with imatinib-based chemotherapy before allo-HSCT. Intermediate and poor molecular responders had worse relapse and DFS rates in comparison to early molecular responders [723].

An emerging significant issue in Ph+ ALL is resistance [696] to one or more TKIs developing during therapy [700] or resistance prior to therapy [712, 721, 724, 725] and carries a particularly poor prognosis. Unlike CML, these are less well studied and do not necessarily arise from the dominant tumour clone(s), the latter perhaps arising in response to TKI-driven selective pressure [724]. This explains why an initial reduction in BCR-ABL transcript level does not correlate with good long-term outcome [693, 704, 722, 726]. ABL-kinase domain point mutations [724, 726, 727] are one of the common causes of imatinib resistance and involve the following regions: ATP binding pocket (P-loop), catalytic domain (most often at the 'gate-keeper' residue threonine 315), and activation

loop (A-loop) [724]. Less commonly are those involving alternative signalling pathways mediated by SRC family kinase (SH2 or SH3 contact) [727]. BCR-ABL mutations associated with relapse with imatinib are predominantly in the P-loop and T315I, whilst dasatinib is most frequently associated with T315I mutations. In patients receiving imatinib who are in complete haematologic remission an increase in BCR-ABL level should suggest mutational analysis.

Management of relapse/refractory disease

Despite the major advances in ALL therapy and high remission rates, 20% of paediatric [728, 729] and 50–60% [589, 618, 619, 730–733] of adult patients relapse following initial CR to first-line chemotherapy. The estimated incidence of primary refractory ALL is almost 2% in children and around 10% in adults. Management of relapsed/refractory ALL poses an extremely challenging problem with post relapse strategies rarely resulting in long-term survival [734–737]. Only 30% of paediatric ALL patients go on to achieve long-term

remission with salvage therapy [738, 739]. Data from COG studies has shown that EFS and OS outcomes of relapsed paediatric ALL depended on timing and site of relapse with early (defined as within 18 months from diagnosis), with isolated bone marrow relapse having the worst prognosis [729, 740] where the five-year survival was only 11.5% [729]. Similarly, data from two of the largest series of adults with relapsed ALL have shown a median OS after relapse of 4.5–6 months and five-year OS rate of 7–10% [737, 741]. Less than 30% of patients achieve a second CR with salvage therapy [741]. CNS involvement and relapse within two years of diagnosis were the worst prognostic factors on multivariate analysis and initial therapy does not affect the outcome after relapse [737]. A recent report from the GMALL group identified relapse site, response to salvage, performance of allo-HSCT and age as prognostic factors for survival [742]. With currently available induction chemotherapy largely aimed at preventing relapse, and hence survival benefit, once relapse occurs subsequent cure becomes unlikely [737]. Furthermore, only a small proportion of patients who received chemotherapy alone are eligible for allo-HSCT and go on to achieve second CR. Much attention has now been directed towards novel, targeted therapeutic agents commonly delivered within prospective clinical trials. Clofarabine, a nucleoside analog, given as a single agent or in combination was noted to be active in relapsed/refractory ALL in paediatric [743, 744] and adult [745] patients. Reported CR rates are variable and reach 50% with OS of 18 months [743]. Nelarabine, another nucleoside analog with T-cell specific action recently approved for treatment of relapsed/refractory T-cell ALL achieved responses in 48% of adult [746] and 55% of paediatric patients following first relapse and 27% in second relapse [747]. Remissions were not durable with the only chance of cure being allo-HSCT. Blinatumomab, a T-cell engaging anti-CD3/CD19-bispecific monoclonal antibody has shown early promising results with 67% of patients with relapsed/refractory B-precursor ALL achieving CR [748]. Other targeted investigational agents developed following recent insights from genome-wide analyses include phosphorylase inhibitors; anti-CD22 monoclonal antibody/-drug conjugates; inhibitors of NOTCH1, histone deacetylase, proteosome, and DNA methyltransferase; and kinase-dependent signalling pathways [749].

Management of extramedullary disease

CNS involvement at diagnosis is uncommon, but over 50% of patients would eventually develop it if CNS-directed therapy were not given [563, 577]. Its presence at diagnosis in paediatric patients is associated with significantly decreased EFS rates [591, 617]. In adults, although the five-year DFS rates were no different when compared to those with no involvement at diagnosis, it was associated higher risk of CNS relapse [750, 751] and inferior OS [750]. CNS-directed therapy includes similar therapeutic options as the prophylactic approach. With more effective intrathecal and high-dose systemic chemotherapy regimens, the role of cranial irradiation is diminishing particularly given its association with neuro-cognitive dysfunctions and secondary malignancies [577, 585, 752]. Intrathecal chemotherapy needs to continue bi-weekly until resolution of CNS disease evidenced by clearance of blasts from the CSF. In T-cell ALL upregulation of the CCR7 gene via NOTCH signalling appears to be essential in directing ALL cells into the CNS, a finding that could be targeted with novel therapeutic approaches [753].

Testicular involvement, more commonly seen in T-cell ALL patients, should be treated with testicular irradiation if not fully resolved by the end of induction chemotherapy.

Late effects of therapy

With significant improvements in survival rates in the context of a disease most prevalent in paediatric age group more patients experience late adverse events [754]. Their occurrence depends on type, intensity, and age at which patients were exposed to therapy. For example, children under six years of age have the highest risk of neurocognitive impairment following cranial irradiation and intrathecal chemotherapy [622, 623]. High-dose cranial irradiation in children and adolescents also increases the risk of stroke, auditory-vestibular-visual deficits, seizures, coordination defects [623, 755], and reduced fertility [756]. Osteonecrosis is a well-recognized problem with steroids, most often affecting weight-bearing joints. Adolescents, rather than children or adults, appear to have the highest incidence of such complications [757–759]. Other than age, a lower albumin, high lipids, and dexamethasone exposure are associated with an increased risk of osteonecrosis [760]. Anthracycline-related cardiotoxicity [761] has become an infrequent late complication with current regimens that use these agents at lower doses. Second neoplasms, the most common being haematologic and brain malignancies [762, 763], are serious late effects in successfully treated ALL patients [764]. In one series, the overall cumulative risk of second neoplasms was 2.1% at five years, 4.9% at ten years and 9.4% at 15 years [765].

Therefore, given the risk of such late effects it is prudent that all survivors of ALL continue to be followed-up following completion of chemotherapy.

CHAPTER 52

Chronic leukaemias

Hemant Malhotra, Lalit Kumar, Pankaj Malhotra, Devendra Hiwase, and Ravi Bhatia

Introduction to chronic leukaemia

The chronic leukaemias are a group of monoclonal haematological malignancies characterized by proliferation and accumulation of cells of one or more haematopoietic lineage. Even without treatment, survival is possible for several months, and sometimes several years. These are usually adult diseases with age of onset in the fifth or sixth decade in the majority of patients. Chronic lymphocytic leukaemia (CLL) is the most common haematological cancer seen in Africa and the Western hemisphere. However, in Asia chronic myeloid leukaemia (CML) is the most common adult leukaemia. Why CML is more common in Asia is not clear, but the aetio-pathogenesis is more likely to be due to genetic rather than environmental factors.

These two common chronic leukaemias (CML and CLL) and some other less common leukaemias will be discussed in this chapter.

Chronic myelogenous leukaemia

Epidemiology

CML is a clonal disorder of a leukaemic pluripotent stem cell that affects several lineages, primarily the myeloid lineage. The molecular hallmark of CML is the presence of the Philadelphia chromosome (reciprocal translocations of genetic material between chromosomes 9 and 22) which brings the BCR gene into proximity to the ABL gene, forming a new fusion chimeric gene—BCR–ABL—which has oncogenic potential and is responsible for the pathogenesis of the disease. The BCR–ABL gene is expressed in nearly all patients of CML and this fact has been utilized in the developments of specific tyrosine kinase inhibitor (TKI) therapies targeting the gene. Since the development and availability of these agents, there has been a paradigm shift in the treatment of CML with the majority of patients now experiencing multi-decade survival. These drugs have affected a change in the natural disease of the disease and form the model for targeted treatment of several other solid and haematological cancers.

The age-adjusted annual incidence of CML in the US from 2004–2008 was 1.6 cases/100 000 population, with an estimated 4 870 new cases expected in 2010 [1]. CML accounts for approximately 11% of all leukaemias. With the prolonged survival achieved with TKIs, CML prevalence in the US in the coming decades is expected to increase substantially. Mortality associated with CML decreased by 7.2% from 2003–2007. Overall five-year survival for US patients diagnosed with CML from 2001–2007 was 57.2%.

The exact incidence in Asian countries in not known, but CML is the most common adult leukaemia in this region and is much more common than CLL. The disease onset is reported to be about a decade earlier in Asian countries compared to the West, with more patients presenting in higher stages at diagnosis.

Staging and diagnostics

More than 80% of patients of CML are diagnosed in the chronic phase of the disease. The disease usually takes a triphasic clinical course—chronic phase (CP), accelerated phase (AP), and blastic phase (BP). Sometimes, the patient can progress directly from the CP to the BP without an intervening AP. In CP, the patient is usually asymptomatic or minimally symptomatic, and historically had a median survival of four to five years [2]. Approximately 10% of patients are diagnosed incidentally during workup for some other medical illness or on routine testing. Without adequate therapy, all patients will eventually go to an end-stage BP with a median survival of only three to six months. The BP is usually of myeloblastic type (50%) but could be of lymphoblastic type (20–30%) or of undifferentiated phenotype (25%) [3].

Different criteria have been used in the literature to define CP, AP, and BP; Table 52.1 presents some of the most frequently used criteria. The University of Texas MD Anderson Cancer Center (MDACC) classification [4] has been used in all studies with TKIs and most of the interferon studies and, therefore, is supported by the most data with modern therapy. Other criteria have been proposed, but some of these, such as the World Health Organization (WHO) proposal [5] have not been clinically validated. The expected survival in all stages has changed with the use of TKIs [6]. An analysis of 3 548 patients with CML referred to the MDACC from 1965–2010 indicated that the overall survival (OS) of patients has significantly improved in all CML phases [7].

For the patient in the CP of the disease, the prognosis can be further defined by the Sokal score [8], which uses clinical and laboratory parameters (age, spleen size, platelet count, and percentage of blasts in the peripheral blood) to define a risk score that is associated with long-term outcome. The three Sokal prognostic groups are identified with hazard ratios of <0.8, 0.8–1.2, and >1.2, with historical median survivals of 2.5, 3.5, and 4.5 years, respectively [8]. Although the score was designed long before the era of TKIs, it is still applicable today and the probability of response to these agents is greatly influenced by the Sokal risk score. Other prognostic scores such as the Hasford score, [9] and the EUTOS score [10] are less frequently used but may have similar prognostic implications.

Table 52.1 Criteria for diagnosis of accelerated and blast phase of common chronic leukaemia (CML)

Chronic phase: None of the criteria for accelerated phase or blast phase			
Accelerated phase			
	MDACC	IBMTR	WHO
Blasts, %	15–30	10–30	10–19
Blasts + promyelocytes, %	≥30	≥20	NA
Basophils, %	≥20	≥20*	≥20
Platelets	<100	Unresponsive increase or persistent decrease	<100 × 10^9/L, or >1000 × 10^9/L unresponsive to treatment
Cytogenetics	CE	CE	CE not at the time of diagnosis
WBC	NA	Difficult to control, or doubling in <5 days	NA
Anaemia	NA	Unresponsive	NA
Splenomegaly	NA	Increasing	NA
Other	NA	Chloromas, myelofibrosis	Megakaryocyte proliferation, fibrosis
Blast phase			
Blasts, %	≥30	≥30	≥20
Other	ED	ED	ED

*Basophils + eosinophils.

CE, clonal evolution; ED, extramedullary disease with localized immature blasts; MDACC, MD Anderson Cancer Center; IBMTR, International Bone Marrow Transplant Registry; WHO, World Health Organisation; NA, not applicable; WBC, white blood cell count.

Molecular biology

CML develops from transformation of a haematopoietic stem cell (HSC) by the BCR–ABL gene, which results from a chromosomal translocation that leads to juxtaposition of the 5' portion of the BCR gene on chromosome 22 and the 3' portion of the ABL gene on chromosome on chromosome 22 [11, 12]. The derivative shortened chromosome 22 is also referred to as the Philadelphia chromosome (Ph). The resulting messenger RNA usually contains an e13a2 (formerly b2a2) or e14a2 (or b3a2) BCR–ABL junction. Both BCR–ABL mRNA molecules translate into a 210-kd fusion protein (p210BCR–ABL) [13]. Other variant fusions can rarely give rise to oncogenic BCR–ABL proteins. The translocation is found in cells of multiple lineages, consistent with a HSC origin of the disease. CML patients may have a karyotype of normal appearance but have a cytogenetically occult BCR–ABL gene. It has been suggested that CML may have multistep pathogenesis, with clonal haematopoiesis preceding acquisition of the t(9;22) translocation [14]. However, expression of a BCR–ABL fusion gene in HSCs appears to be sufficient to initiate CML in various mouse models [15].

The mechanisms of BCR–ABL-mediated cellular transformation have been extensively studied [16]. The tyrosine kinase activity of the ABL protein is constitutively activated by addition of N-terminal BCR sequences, which promote protein dimerization, leading to phosphorylation of tyrosine residues in the kinase-activation loops and constitutive activation of kinase activity. The fusion of BCR sequences to ABL also adds new regulatory motifs to ABL. The uncontrolled kinase activity of BCR–ABL and enhanced interaction with a variety of effector proteins leads to deregulation of cell-signalling mechanisms that regulate proliferation. The BCR–ABL protein and associated biochemical pathways have been extensively studied. The ABL tyrosine kinase is crucial for oncogenic transformation, further substantiated by the success of kinase inhibitor therapy for CML. Other domains in BCR–ABL play important roles in regulating ABL kinase activity or connect to downstream signalling pathways. For example the amino-terminal coiled-coil oligomerization domain of BCR is an important activator of ABL kinase activity; phosphorylation of BCR at tyrosine 177 generates a GRB2-binding site, which is important for RAS activation; and mutations in the ABL SH2 domain reduces BCR–ABL induced myeloproliferation in mice. Many signalling proteins interact with BCR–ABL through various functional domains and are phosphorylated, leading to activation of signalling, through RAS, PI3K, AKT, JNK, and SRC family kinases, protein phosphatase, STATs, nuclear factor-B, and MYC. BCR–ABL also induces expression of cytokines such as interleukin-3, granulocyte colony-stimulating factor (G-CSF), and granulocyte–macrophage colony-stimulating factor (GM-CSF), potentially contributing to expansion of leukaemic cells.

Progression to AP and BC is associated with increase in immature blast cells. It is likely that a variety of molecular mechanisms contributes to maturation arrest, enhanced proliferation, survival, and increased tissue invasiveness in BC CML [17]. Increased BCR–ABL expression appears to be a key factor in the development of BC. Additional cytogenetic and molecular changes are frequently seen during progression. Genetic instability may be related to increased oxidative stress, reduced DNA repair, or reduced DNA

damage response. Genetic changes observed in leukaemic cells from BP CML patients include non-random cytogenetic changes and point mutations in TP53, RB, and CDKN2A. The block in myeloid differentiation in BC may involve defects in haematopoietic transcriptional factors. The granulocyte/macrophage progenitor (GMP) pool is expanded in patients with BP CML, which may be related to increased WNT signalling and increased self-renewal capacity [18, 19].

Pathology

Patients usually present with leucocytosis, thrombocytosis, and anaemia. The total leukocyte count is usually over 25×10^9/L, and rises progressively without treatment. Granulocytes at all stages of differentiation are seen on differential counts. Granulocytes are usually normal in appearance. Circulating blasts between 0.5% and 10% are seen. Low or absent neutrophil alkaline phosphatase activity is seen in 90% of patients. The absolute basophil count is consistently increased. Basophils are usually less than 15% in CML CP. The absolute eosinophil count is usually increased, although the eosinophils percentage is usually not increased. The absolute lymphocyte count may be increased related to increased T cells. The platelet count is often elevated at diagnosis. Platelet function abnormalities with reduced second wave of aggregation to epinephrine may be seen. Most patients have reduced haematocrit at diagnosis. Small numbers of nucleated red blood cells and mild reticulocytosis may be seen. Clinical chemistry may reveal hyperuricaemia and hyperuricosuria, elevated serum LDH, increased serum vitamin B12-binding capacity related to release of transcobalamin I and II from mature neutrophils, and an average of tenfold increased serum B12 levels. Release of potassium from WBC during clotting may cause pseudohyperkalaemia. Consumption of glucose and oxygen by neutrophils after a sample is drawn may result in spurious hypoglycaemia or hypoxaemia.

Bone marrow (BM) examination usually shows marrow hypercellularity up to 75–90%. There is increased granulocytic/erythroid ratio. Eosinophils and basophils are often increased. Blasts usually represent less than 5% of cells in CP CML. Presence of more than 10% blasts indicate transformation to AP. Megakaryocytes are typically smaller and may be hypolobated. About 40–50% of patients show increased megakaryocyte proliferation. Collagen type III staining is typically increased. Increased reticulin fibrosis is seen in 50% of patients often associated with increased marrow megakaryocytes. The spleen shows infiltration of red pulp cords with granulocytes at various stages of maturation. Granulocytic cell infiltration may be seen in the portal areas and hepatic sinusoids of the liver.

On cytogenetic examination, the t(9;22)(q34;q11) is seen in more than 90% of patients. Additional chromosomal abnormalities, including -Y and +8, are seen in 20% of patients at diagnosis. 5% of patients show variant Ph chromosomes, with complex rearrangements. Cryptic or complex translocations can be detected by fluorescence in situ hybridization (FISH) or polymerase chain reaction (PCR) assays in a small proportion of patients where the t(9;22) may not be detected. Real-time quantitative polymerase chain reaction (RQ-PCR) provides an accurate measure of the total leukaemia cell mass. Circulating BCR–ABL transcript numbers and marrow cytogenetics should be studied in every new patient with CML before initiation of treatment.

Cytogenetics allows identification of unusual translocations or additional cytogenetic abnormalities. BCR–ABL RQ-PCR identifies whether the commonly observed transcripts, or a less common fusion transcript not amplified in the standard assay, are present. FISH on blood specimens using dual probes for the BCR and ABL genes is also useful for confirming the diagnosis, and may also detect deletions in the derivative 9q, which have prognostic significance [20].

Medical management

Chemotherapy

CML chemotherapy with busulfan (BU), introduced in the 1950s, is associated with serious adverse effects, including prolonged aplasia and pulmonary fibrosis. Treatment with hydroxyurea, started as an alternative to BU, is less toxic than BU, with the major adverse effect being reversible marrow suppression. Neither drug significantly suppresses the leukaemic clone. The main aim of treatment with these agents is to control disease and symptoms with initiation of treatment with imatinib (IM) or other disease-specific therapies.

Interferon

Interferon-α (IFN) was recognized to have efficacy in the treatment of CML in the 1980s. The activity of IFN in CML may be related to inhibition of proliferation, correction of altered microenvironmental interactions, or stimulation of immune response. Treatment of CP CML patients results in complete and partial cytogenetic remissions rates from 0% to 38% [21]. Remissions are more common in younger patients, less advanced stage disease, favourable prognostic stage, and those treated soon after diagnosis. Haematologic remissions usually occur within one to three months, and complete cytogenetic remissions 9 to 18 months, after starting IFN. Durable responses may be seen in patients who achieve a complete cytogenetic remission. Virtually all patients receiving IFN experience constitutional adverse effects. Acute adverse effects include flu-like symptoms such as fever, chills, and malaise. Additional more severe acute reactions and chronic complications can occur. These are usually dose- and duration-dependent, and may require discontinuation of treatment. Randomized studies show an improvement in survival rates with IFN treatment compared with BU or hydroxyurea [22–24]. Meta-analysis shows a five-year survival rate of 57% (50–59%) for IFN and 42% (29–44%) for chemotherapy [25]. IFN increases life expectancy by a median of approximately 20 months compared with chemotherapy. However, IFN may not enhance survival for patients in the late CP or with more than 10–30% blasts in peripheral blood. Adding cytosine arabinoside to IFN appears to enhance survival benefit but at the cost of increased toxicity [26]. Therefore, although IFN clearly is beneficial in patients with CML patients, benefit is limited by low levels of cytogenetic response and considerable toxicity. Its use in the modern treatment of CML patients has been replaced by use of IM and other TKIs, although there has been revived interest recently in combination treatment.

Tyrosine kinase inhibitors (TKIs)

The introduction of TKIs into clinical practice has dramatically changed CML treatment. TKI therapy induces remissions in most patients with CP CML, leading to excellent survival, and is now the mainstay of treatment. However in AP and BC CML, TKI resistance can occur, usually as a result of tyrosine kinase domain point mutations. Resistance to the first-generation TKI IM can often be treated by 'second generation' TKIs, such as dasatinib, nilotinib,

bosutinib, or ponatinib. These drugs may be even more effective than IM for front line treatment of CML and the first two (dasatinib and nilotinib) have been approved in that indication.

IM mesylate (STI571; Gleevec®) is a small molecule kinase inhibitor of ABL-containing proteins, the platelet-derived growth factor receptor, and the c-KIT receptor [27]. IM competitively binds the ATP-binding site in the kinase domain of ABL, and blocks the ability of BCR–ABL to phosphorylate its substrates. Initial phase 1 and phase 2 trials established that IM induced haematologic and cytogenetic responses in most CP CML patients who had failed other treatments and was well tolerated [28]. The International Randomized Interferon and STI571 (IRIS) study compared IM (400 mg daily) with IFN-α plus cytosine arabinoside in 1106 newly-diagnosed CP CML patients. In the initial analysis, the estimated complete cytogenetic response (CCR) rate was 76.2% (95% CI, 72.5–79.9) in the IM group and was superior to 14.5% (95% CI, 10.5–18.5) in the IFN plus cytosine arabinoside group (p <0.001) at 18 months [29]. The estimated freedom from progression to AP or BC at 18 months was 96.7% in the IM group and 91.5% in the IFN group (p <0.001). IM was better tolerated than IFN therapy. A 60-month follow-up report for this study found an estimated cumulative incidence rate of complete haematological response (CHR), major cytogenetic response (MCR), and CCR of 98%, 92%, and 87% at 60 months for patients on first-line IM. The estimated event-free survival (EFS) at six years was 83%, and the estimated OS was 88% [30].

IM 400 mg daily is currently the standard dose for initiating therapy in newly-diagnosed CP CML patients. Higher dose IM (800 mg) provide faster responses CCR rates at six months (57% vs 45%, respectively), but there are no significant differences at 12 months (70% vs 66%, respectively) or 24 months (76% in both groups), with no difference in EFS, progression-free survival (PFS), or OS. However, a subset of patients that can tolerate higher doses of IM, may have a better response [31]. The results of IM therapy in the community setting may be somewhat less favourable. A report from the Hammersmith Hospital calculated that the five-year EFS on IM treatment was only 63% [32]. Pretreatment risk factors can predict the likelihood of achieving and maintaining response to IM. The risk of disease progression was higher for patients with a higher pretreatment Sokal score. The achievement of certain milestones of response can also predict prognosis as discussed in the next section. Lack of adherence to medication is a major underlying reason for failure of treatment [33, 34].

Results of IM therapy are poorer in AP patients, with haematologic response in 82% of patients, CHR in 34% of patients, MCR in 24% of patients, with 17% complete responses [35]. Estimated 12-month PFS rates were 59%. Myeloid BC patients treated with IM showed an overall response rate (ORR) of 52%, with 31% of patients having haematologic responses lasting at least four weeks [36]. The median survival was seven months. These results compare favourably with historical results showing three-month median survival for patients treated with chemotherapy. Although 60% of Ph-positive acute lymphoblastic leukemia, also known as acute lymphocytic leukaemia or acute lymphoid leukemia (ALL), patients responded to IM, the duration of response was relatively short, with a median estimated time-to-disease progression of only two months.

IM treatment may result in myelosuppression, which is more common in patients with advanced disease. Grade 3 and 4 neutropaenia is frequent, particularly in advanced phases. Central

nervous system and gastrointestinal haemorrhages occur most frequently in patients in BC. For otherwise healthy patients in CP, the goal is to avoid potentially dangerous neutropaenia and platelet transfusion dependence. For patients with BC or AP disease, the approach is to balance risks and benefits, and support patients with critically low platelet count. For absolute neutrophil count <500/mm^3, IM is continued if the marrow is hypercellular or if there are >30% blasts. Where the marrow is hypocellular and the absolute neutrophil count (ANC) is <500/mm^3, IM may be held, the dose reduced or myeloid growth factors used [37]. Common IM-related non-haematologic adverse events include nausea, muscle cramps, fluid retention, diarrhoea, musculoskeletal pain, fatigue, and skin rashes. Grade 3 or 4 toxicity is uncommon, and the rate of discontinuance of therapy because of toxicity is 2–5%. Most adverse effects can be managed successfully with supportive measures.

Both de novo and acquired resistance may occur in IM-treated CML patients. The most common mechanism associated with resistance is point mutations in the BCR–ABL gene that prevent IM from inhibiting kinase activity, although BCR–ABL-independent mechanisms may also contribute to IM resistance in some patients. Over 90 different amino acid substitutions are reported to result in IM resistance, with varying frequency and degrees of IM resistance [38]. Cells with pre-existing BCR–ABL mutations that confer IM resistance may have a selective clonal growth advantage during IM treatment. A mutation resulting in substitution of isoleucine for threonine in the T315 position (T315I) affects residues that directly contact IM. ABL kinase P-loop mutations prevent conformational changes required for IM binding. Mutations in the activation loop result in the kinase being fixed in the active conformation and unable to acquire the inactive conformation required for IM binding. Resistance to the second-generation TKIs, dasatinib and nilotinib, is related to a much narrower spectrum of mutations. These mutations are non-overlapping, with the exception of the T315I mutation. Knowledge of BCR–ABL mutation status is being integrated into therapeutic decision-making algorithms for patients. Mutation analysis is recommended in IM-resistant patients planned to receive an alternative TKI [38].

BMS-354825 (dasatinib, Sprycel®) is a dual SRC–ABL kinase inhibitor exhibiting 300-fold higher potency against native BCR–ABL [39]. Dasatinib effectively inhibits most clinically-detected BCR–ABL kinase domain mutants at low nanomolar concentrations, except for T315I. Another compound, AMN107 (nilotinib, Tasigna®) was synthesized by modification of IM to enhance BCR–ABL kinase-binding activity [40]. Nilotinib binds ABL with increased avidity and can overcome resistance of most kinase domain mutants, with the exception of T315I. These agents have significant activity in IM-resistant CML, yielding CCR in approximately 50% of CP CML cases, and leading to stable responses [41, 42]. Both of these drugs have been evaluated as first-line therapy in newly diagnosed CP CML. The Dasatinib Versus Imatinib Study In Treatment-naive CML (DASISION) study tested 100 mg dasatinib daily versus 400 mg IM daily [43]. The Evaluating Nilotinib Efficacy and Safety in Clinical Trials Newly Diagnosed Patients (ENESTnd) study compared two nilotinib doses (400 mg twice daily and 300 mg twice daily) with IM 400 mg daily [44]. These studies found that dasatinib and nilotinib were superior to IM in achieving the primary endpoints (dasatinib: CCR by 12 months; nilotinib: major molecular response (MMR) at 12 months). Patients treated with nilotinib had a significantly reduced risk of progression. Based on these results, nilotinib and dasatinib have been approved for first-line therapy of

newly-diagnosed CP CML patients. However, the choice of TKI in newly-diagnosed patients remains open to debate. Although dasatinib and nilotinib are associated with faster and deeper reduction in leukaemia burden, no differences in OS have yet been observed, and long-term data from the randomized clinical studies are needed to confirm the initial findings. IM is less expensive and there is longer experience with its use. A direct comparison between nilotinib and dasatinib has not been performed. Since their overall efficacy appears to be similar, the selection may be based primarily on side effect profile and convenience. Dasatinib treatment is associated with higher rates of myelosuppression and with pericardial and pleural effusion. In contrast, nilotinib can induce an increase in pancreatic enzymes, hyperglycaemia, and hyperbilirubinaemia. The fact that the T315I mutant is not responsive to either dasatinib or nilotinib underscores the need for drugs with T315I inhibitory activity [45]. The multi-target kinase inhibitor ponatinib (Iclusig®) is active against all BCR–ABL mutants, including T315I, and has shown promising activity in initial trials [45, 46].

An increasing proportion of TKI-treated patients appear to enter a molecular remission over time. However, even patients with negative PCR (so-called complete molecular response [CMR]) may retain significant numbers of residual malignant cells. Several groups have identified BCR–ABL-expressing leukaemia stem cells in patients with sustained undetectable molecular residual remission [47]. The STIM (Stop IMatinib) trial evaluated IM discontinuation in patients with sustained undetectable minimal residual disease (MRD) for >2 years. Approximately 40% of patients did not develop molecular recurrence after one year [48]. Patients with undetectable MRD after IM therapy continued to have BCR–ABL rearrangement detectable at the genomic level indicating persistence of residual leukaemic cells not detected by reverse transcription polymerase chain reaction (RT-PCR). These data suggest that IM may not eradicate the leukaemic clone and patients at present are recommended to continue medication indefinitely.

Allogeneic haematopoietic cell transplantation

HLA-matched sibling donor haematopoietic cell transplants (HCTs) were initially performed as therapy for CML patients in the 1980s and became the first curative treatments for CML. Data reported to the International Bone Marrow Transplant Registry (IBMTR) showed a probability of survival of 69% ± 2% for patients transplanted within the first year from diagnosis, and 57% ± 3% for patients transplanted more than one year from diagnosis. Several single institution studies demonstrate excellent outcomes with HCT, related to advances in preparative regimens, supportive care, and HLA typing for unrelated donors. For example, the Seattle group has reported a three-year post-transplant survival of 86% using a preparative regimen of targeted BU plus cyclophosphamide (CY) in consecutive CP CML patients [49]. The outcome of allogeneic HCT (alloHCT) in CML is influenced by the phase of disease, type of donor used (related or unrelated), the source of the stem cell product (marrow or peripheral blood), and the age of the patient. Outcomes are superior for HCT in CP compared to advanced phases of disease. Transplantation for patients in BC is associated with poor prognosis, related to a high rate of relapse and transplant-related mortality. Only a third of patients have HLA-matched family member donors. Advances in donor selection, graft-versus-host disease (GVHD) prophylaxis, and supportive care have resulted in continued improvements in outcome for matched unrelated donor transplants, which in many institutions are almost equivalent to those seen with matched sibling transplants. Registry data reports 65% survival at five years among younger patients transplanted within a year of diagnosis. Although marrow was initially used as the stem cell source, large randomized trials have shown that use of G-CSF mobilized peripheral blood haematopoietic cells leads to more rapid myeloid and platelet recovery when compared to marrow, without significant differences in GVHD and OS, although relapse rates may be lower in the peripheral blood group. For patients transplanted in CP, increased interval from diagnosis to transplant is associated with a worse outcome. The effect of delay could be related to the disease evolution over time and cumulative toxicity of prior therapy. Prevention of GHVD by removing T cells is associated with high rates of graft failure and relapse, leading to poorer DFS. These findings illustrated the critical role of the graft-vs-leukaemia (GVL) effect in eradicating CML following allogeneic transplantation. There has been interest in preventing GVHD without loss of GVL by combining T-cell depletion with delayed reinfusion of viable donor lymphocytes.

There is considerable evidence in support of GVL-effect in CML, including high rates of relapse following syngeneic and T-cell-depleted transplants, close association between acute and chronic GVHD and freedom from relapse, and the high response rate of post-transplant relapse to donor lymphocyte infusions. Reduced-intensity conditioning (RIC) approaches may potentially avoid the toxicities of conventional high-dose conditioning regimens while maintaining GVL effects. Reduced-intensity transplantation may be safe and effective for CP CML, but not be sufficient for advanced phase patients [50]. Donor lymphocyte (or leukocyte) infusion (DLI) can induce complete cytogenetic responses in 50–100% of patients with relapsed CP CML. The major complications of DLI are transient marrow failure and the development of GVHD. The overall incidence of GVHD following DLI can be reduced with fractionated administration of T cells and escalating dosage as required. Complications of recurrence of GVHD and granulocytopaenia were seen. More recently, IM has been shown to be active as post-transplant therapy.

Prior IM treatment does not appear to adversely affect transplant outcomes, with no difference in regimen-related mortality, survival, or relapse compared to historical controls, and similar cumulative incidence of acute and chronic GVHD. Conventional prognostic indicators continue to be the major predictors of transplant outcomes [51]. With the establishment of TKI as first-line therapy for CML, the number of patients undergoing allogeneic transplantation has dramatically declined. Currently, allogeneic transplantation is recommended for patients who have failed a second-generation TKI, with TKI-resistant mutations such as T315I, and in AP or blast phase. Allogeneic transplantation is an effective option for treatment for T315I-mutated leukaemias [52] and an effective salvage treatment for TKI-resistant patients [53]. Since patients with advanced disease have worse outcomes after transplantation, this procedure should be considered early for patients responding poorly to a second-generation TKI.

Disease monitoring

Monitoring response is critical even in the era of effective TKI therapies

TKIs are extremely effective in CML CP patients; however, 45% [54, 30] of IM-treated, 25–30% of dasatinib- [55, 56] and

nilotinib- [44, 57, 58] treated patients discontinue first-line of therapy. The majority of these patients can be salvaged with second- and third-generation TKI therapy [59–61]. All current therapies are more effective in CP than advanced phase; hence, the aim of monitoring the response is to identify patients earlier who can benefit by switching to other effective therapies and preventing transformation to advanced phase disease. Multiple studies show that an early response can predict a long-term outcome. Clinicians have to be more vigilant during the initial two to three years of therapy, as the majority of events occurred within the first three years (5.2% per year, averaging out to 0.9% per year for the subsequent three years [30, 62]).

Tools for response monitoring and response definition

Integral parts of the initial assessment and monitoring include physical examination, complete blood count (CBC) examination, BM morphology, cytogenetic analysis, and molecular monitoring (Table 52.2). In a newly-diagnosed CML patient, TKI therapy progressively reduces the disease burden. Therefore, as the number of leukaemia cells decrease, the sensitivity of the techniques used to monitor the disease effectively must increase accordingly.

All patients treated with TKI therapy should have a CBC every two weeks until complete haematologic response (CHR) (see Table 52.2) is achieved, followed by further testing every three months, unless patients develop unexplained cytopaenias [63]. Cytopaenia in the first three to six months is not unexpected, but if it evolves at a later stage, the possibility of underlying marrow abnormalities should be considered.

Cytogenetic analysis

Bone marrow (BM) morphology and cytogenetic analysis are essential at diagnosis to confirm the diagnosis of CP CML and to establish a baseline regarding the presence of any additional cytogenetic abnormalities (ACA). European Leukemia Net (ELN) guidelines recommend cytogenetic analysis at three and six months after starting TKI therapy, and then every six months until complete cytogenetic response (CCR) is achieved and confirmed. Once CCR is achieved, BM cytogenetic analysis can be repeated once a year, if regular molecular monitoring cannot be assured [63]. BM cytogenetic testing is also recommended in patients with unexplained cytopaenia or loss of response. Typically, cytogenetic responses are divided into several categories (Table 52.2), which are usually determined by metaphase chromosome analysis (using at least 20 metaphases) of the BM.

Conventional cytogenetic testing can also detect additional chromosomal abnormalities in Ph+ chromosomes (ACA) and Ph- metaphase cells (other chromosomal abnormality, OCA). Approximately 5–12% of newly diagnosed CML CP patients and 30–80% of patients with AP and BC have ACA [64–67]. WHO recognizes ACA in Ph+ chromosomes evolving during therapy as a sign of disease progression to the AP; however, ACA at diagnosis is not recognized as a sign of advanced phase disease. ACA includes variant translocation, lack of Y chromosomes (-Y) and major and minor route ACA. Major route ACA includes trisomy 8, a second Ph+ chromosome, isochromosome (17)(q10), and trisomy 19. While minor route ACA includes t(3; 12), t(4;6), t(2;16), and t(1;21) (rarely observed in CML AP or BC) [65]. Five-year OS and PFS was significantly poorer in patients harbouring major route ACA (53% and 50%, respectively) compared with patients with minor route ACA (96% and 96%, respectively), -Y (87% and 88%, respectively), t(v;22) (87% and 81%, respectively), and t(9;22) (92% and 90%, respectively) [64]. Similarly the GIMEMA study also showed an inferior outcome in patients with ACA [68]. Variant Philadelphia chromosome translocations have been reported in 5–10% of patients and have no impact on cytogenetic or molecular responses or on outcome [69, 70]. Deletions of the derivative chromosome 9 [der(9)] are not associated with poor prognosis in patients treated

Table 52.2 Definition of response and frequency of monitoring newly diagnosed common chronic leukaemia chronic phase (CML CP) patients treated with first-line TKI therapy

Test	Frequency of monitoring	Definition of response
Complete blood count	◆ Baseline then ◆ Every 15 days until CHR, then ◆ Every three monthly unless otherwise required	◆ Complete haematological response: ◆ Platelets ≤ 450 × 10⁹/L ◆ WBC count ≤10 × 10⁹/L ◆ Differential without immature granulocytes and with ≤5% basophils and ◆ Non-palpable spleen
Cytogenetic (cytogenetic should be performed by chromosome banding analysis of bone marrow metaphase cells)	◆ Baseline then ◆ At 3 and 6 months then ◆ Every six months until confirmed CCyR, then ◆ Every 12 months if reliable molecular testing is not available	◆ Complete (CCgR): No Ph+ chromosome ◆ Partial (PCgR): 1% to 35% Ph+ metaphase ◆ Minor (mCgR): 36% to 65% Ph+ metaphase ◆ Minimal (minCgR): 66% to 95% Ph+ metaphase ◆ None (noCgR): >95% metaphase
BCR–ABL RQ-PCR BCR–ABL/control gene ratio on international scale	◆ Baseline ◆ Three monthly until stable MMR ◆ Then 3 to 6 monthly	◆ MMR: ≤0.1% BCR–ABL/housekeeping genes ratio on IS ◆ CMolR: Undetectable BCR–ABL1 mRNA transcripts by RQ-PCR and/or nested PCR in two consecutive blood samples of adequate quality (sensitivity >10⁴)
Mutation analysis	◆ Suboptimal response or failure ◆ Always required before changing to other TKI therapies	

with IM [71, 72]; hence, recent ELN guidelines do not consider it as a warning sign [63] unlike previous guidelines [73].

OCA has been reported in Ph⁻ cells of about 5% of patients who achieved CCR with IM [74–76]. The most common abnormality is trisomy 8 (50%), but deletion of chromosome 7 alone or with other abnormalities is observed in about 15% of cases [75]. In some cases, OCA has been associated with the development of a myelodysplastic syndrome or acute myeloid leukaemia, mainly in patients with a deletion of chromosome 7 and/or other complex abnormalities, but also in some patients with isolated trisomy 8 [76]. However, some patients remain in CCR and haematological remission after the detection of OCAs and, in some cases, OCAs may be transient. The presence of OCAs without dysplastic features in the blood is probably not an indication for a change in therapy based on our current understanding.

The limitations of BM conventional cytogenetic include a 10–25% failure rate or inadequate metaphase for analysis. FISH (see below) might be useful at this stage to determine if patients have achieved CCR. FISH is used in some countries for monitoring patient response.

Fluorescence in situ hybridization (FISH)

FISH studies use peripheral blood samples and analyse approximately 200 interphase cells. The sensitivity of dual-colour FISH ranges from 0.1–1%. FISH studies cannot be used interchangeably with metaphase cytogenetic analysis, as the long-term outcome data from prospective studies is based on conventional cytogenetic analysis but not on FISH. However, for 82% of patients there is correlation between CCR by FISH and conventional cytogenetic testing; 18% of patients in CCR by standard cytogenetic testing had 1% to >5% FISH-positive cells [77]. Whether patients in CCR (i.e., 0% Ph-positive by cytogenetic analysis) but FISH positive would have a similar or worse prognosis to FISH-negative patients is unknown. Clinicians should also be cautious in establishing response failure to treatment based on low levels of positivity by FISH. False-positive rates of 1–10% can also hinder interpretation of the findings. Another significant limitation of FISH technology is its inability to detect clonal chromosome abnormalities in Ph⁺ or Ph⁻ cells. With the availability of molecular monitoring, the value of FISH analysis in current clinical practice is limited.

Real-time quantitative polymerase chain reaction (RT-PCR)

Patients with leukaemia at presentation or relapse usually have a total burden of 10^{11} to 10^{12} malignant cells; cytogenetics and conventional FISH have a maximum sensitivity of 1%. Thus, a patient with negative results using these assays may harbour as many as 10^9 to 10^{10} residual leukaemic cells. Real-time quantitative PCR (RT-PCR) is a sensitive assay to detect minimal residual disease (MRD) and is commonly used for monitoring patients after achieving CCR. The level of BCR–ABL transcripts is calculated by normalizing the absolute value of BCR–ABL to that of a housekeeping gene. The three genes that have been studied extensively and appear most suitable for BCR–ABL quantitation are BCR, ABL, and b-glucuronidase (GUSB) [78]. Efforts are ongoing to standardize molecular responses derived in different laboratories using an International Scale. Expressing quantitative RT-PCR values on the International Scale using an individual conversion factor unique to each laboratory may facilitate comparisons of molecular response data [79].

We perform BCR–ABL1 PCR at baseline in all newly-diagnosed CML-CP patients to confirm the transcript type; uncommon rearrangements (e.g., e19a2, e14a3, and e13a3) may not be detectable by the standard PCR probes. Not having a baseline PCR on a patient with such abnormality could create confusion when subsequent evaluation comes with undetectable BCR–ABL transcripts, which could be interpreted wrongly as complete molecular response (CMR). Baseline absolute BCR–ABL1 transcript value does not influence the long-term outcome; however, transcript type may influence the outcome. Although CCR [80], MMR and MR4.5 were achieved earlier in patients with e14a2 transcript type, there was no difference in OS and PFS [81].

Correlation between cytogenetic response and molecular response

By assessing simultaneous blood real-time quantitative polymerase chain reaction (RQ-PCR) and BM cytogenetics, Ross et al. reported that 98% of patients who achieved 1–2 log (BCR–ABL1 1 to ≤10% IS) reduction from standardized baseline were in MCR, and 95% of patients who had achieved 2–3 log (1 to 0.1% IS) reductions were in CCR. The correlation between CCR and BCR–ABL1 transcript is better at 12 months of IM therapy, as compared with earlier time points [82].In the DASISION study, 96% and 83% of dasatinib and IM-treated patients achieving at least PCR had BCR–ABL1 transcript ≤10%, while only 68% and 26% of dasatinib and IM-treated patients achieving CCR had BCR–ABL1 ≤1% [83].

Target response during tyrosine kinase inhibitor therapy

There is substantial evidence that early molecular and cytogenetic responses predict long-term survival. Hence, the expert panel for the European Leukemia Net (ELN) provides guidelines for monitoring and milestone responses at different time points during TKI therapy [63] (see Baccarani et al. 2013 [73]). Optimal response means there is no indication that changing therapy may improve survival, while suboptimal response means that the patient may still have a substantial long-term benefit from continuing a specific treatment, but the chances of optimal outcome are reduced, so suboptimal responders may be eligible for alternative approaches. Failure means continuing the same therapy is unlikely to result in a favourable outcome and a change in therapy is recommended when possible [63]. These guidelines were developed and revised when only IM was available as first-line therapy; with the availability of second generation TKI as first-line therapy and the availability of more data, these guidelines are under revision. The current ELN recommendation and recent data demonstrating the impact of early molecular response on the long-term outcome are summarized below.

Target response at three months after starting tyrosine kinase inhibitor therapy

According to ELN criteria, achieving CHR at three months (96–100% of IM treated patients) and minor CR (80–82% of IM treated patients) is considered as an optimal response [63]. However, long-term OS and PFS are significantly lower in patients failing to achieve at least partial cytogenetic response (PCR) PCyR and/or BCR–ABL1 transcript ≤10% at three months (Table 52.3) [83–87]. Moreover, cumulative incidence of CCR and major molecular response (MMR, MR)4.5 at three years were significantly lower in patients failing to achieve BCR–ABL1 transcript ≤10% at three months [83, 86, 87]. 25–35% of IM [83, 86, 87], 9%

Table 52.3 Comparison of overall survival (OS) and progression-free survival (PFS) according to cytogenetic and molecular response at three months

Study	PCyR vs No PCyR		BCR–ABL1 ≤10% vs .>10%	
	OS	PFS	OS	PFS
German CML study (n = 460 patients) Five years follow-up	95% vs 87%; p = 0.03	94% vs 87%; p = 0.016	96% vs 87%; p <0.002	95.2% vs 87%; p <0.001
DASISION study (Three years follow-up)				
Dasatinib (n = 259)	96.4% vs 84.2%; p = 0.01	93.9% vs 71.3%; p = 0.21	95.9% vs 85.9%; p = 0.03	93.1% vs 68.2%; p = 0.0003
Imatinib (n = 260)	93.9% vs 93.1%; p = 0.36	93.7% vs 77.3%; p <0.002	96% vs 88%; p = 0.003	95.9% vs 75.3%; p< 0.0001
ENESTnd study (Three years follow-up)				
Nilotinib (n = 258)	NA	NA	95.6% vs 82.9%; p = 0.002	96.9% vs 86.7%; p = 0.003

of nilotinib-treated [86], and 16–19% [83, 85] of dasatinib-treated patients fail to achieve PCR and/or BCR–ABL1 transcript ≤10% at three months and are considered as a high-risk group. These patients would need a different approach. In the ongoing Australian TIDEL II study, IM (600 mg starting dose) treated patients failing to achieve ≤10%, 1%, and 0.1% BCR–ABL1 transcript at three, six, and 12 months, respectively, were changed to either high-dose IM (cohort I) or nilotinib (cohort II) therapy [88]. IM intolerant patients were switched to nilotinib in both cohorts. Although this strategy has achieved a higher rate of MMR at 12 months of 69% compared to 47% in TIDEL-I study (IM dose intensification), the improvement in molecular response is mostly attributable to improved responses in patients intolerant to IM. Deeper responses were uncommon (only 13% achieved MMR after changing over to nilotinib) in patients failed their early molecular targets response [88]. This suggests that patients failing to achieve early milestone response on IM therapy may not be effectively rescued with second generation TKI therapy. Patients treated with second generation TKI therapy and failing to achieve ≤10% and/or PCR at three months (10–15%) would also need an alternative approach. However, there is no good alternative therapy today that can match an expected survival greater than 98%. Further randomized clinical trials over the next few years should focus on addressing this issue.

Target response at six months after starting tyrosine kinase inhibitor therapy

According to ELN guidelines, achieving at least PCR (~89% of IM-treated patients) by six months of IM therapy is considered as an optimal response, while less than PCR (7% of IM-treated patients) and a lack of cytogenetic response (3% of IM-treated patients) is considered as a suboptimal response and failure, respectively [63]. Although ELN recommends changing therapy for IM failure patients, guidelines are vague for suboptimal responder patients. However, five-year OS (81.8% vs 91.7% vs 97.9%; p = 0.02) and PFS (73.4% vs 61.5% vs 92%; p = 0.002) was significantly lower in both IM failure and suboptimal responders compared to optimal responders [89]. Hence, patients failing to achieve at least PCyR at six months on IM therapy may benefit by changing to more potent second-generation TKI therapy. 67–73% of patients treated with dasatinib or nilotinib achieve CCR at six months [55, 44] and patients failing to achieve CCR at six months had poor EFS; these patients will also need alternative approach.

The landmark analysis of the IRIS study showed inferior EFS (56% at 84 months) in patients with BCR–ABL1 (IS) >10% at six months compared with patients with BCR–ABL1 0.1 to ≤1% and those with >1 to ≤10%, all of whom had EFS rates of 85% at 84 months (see Figure 52.1A and 52.1B) [90]. In the ENESTnd study, 97% and 84% of patients treated with nilotinib and IM achieved BCR–ABL1 ≤10% at six months [86]. In both treatment groups patients achieving BCR–ABL1 ≤10% at six months had significantly superior OS and PFS as compared to patients with >10% at six months. In both treatment arms, there was no significant survival difference in patients achieving BCR–ABL1 ≤1% and >1–10% [86]. While other groups reported inferior OS, PFS, and EFS in patients failing to achieve CCR or BCR–ABL1 transcript ≤1.67% by six months [84, 91, 92].

These data suggest that failing to achieve BCR–ABL1≤10% and/ or PCR (suboptimal responders) at six months predict an inferior outcome and warrant changing therapy. Other groups have proposed more aggressive approaches and recommend changing therapy in patients failing to achieve CCR and/or ≤1% BCR–ABL1 transcript at six months [84, 91].

Target response at 12 months after starting tyrosine kinase inhibitor therapy

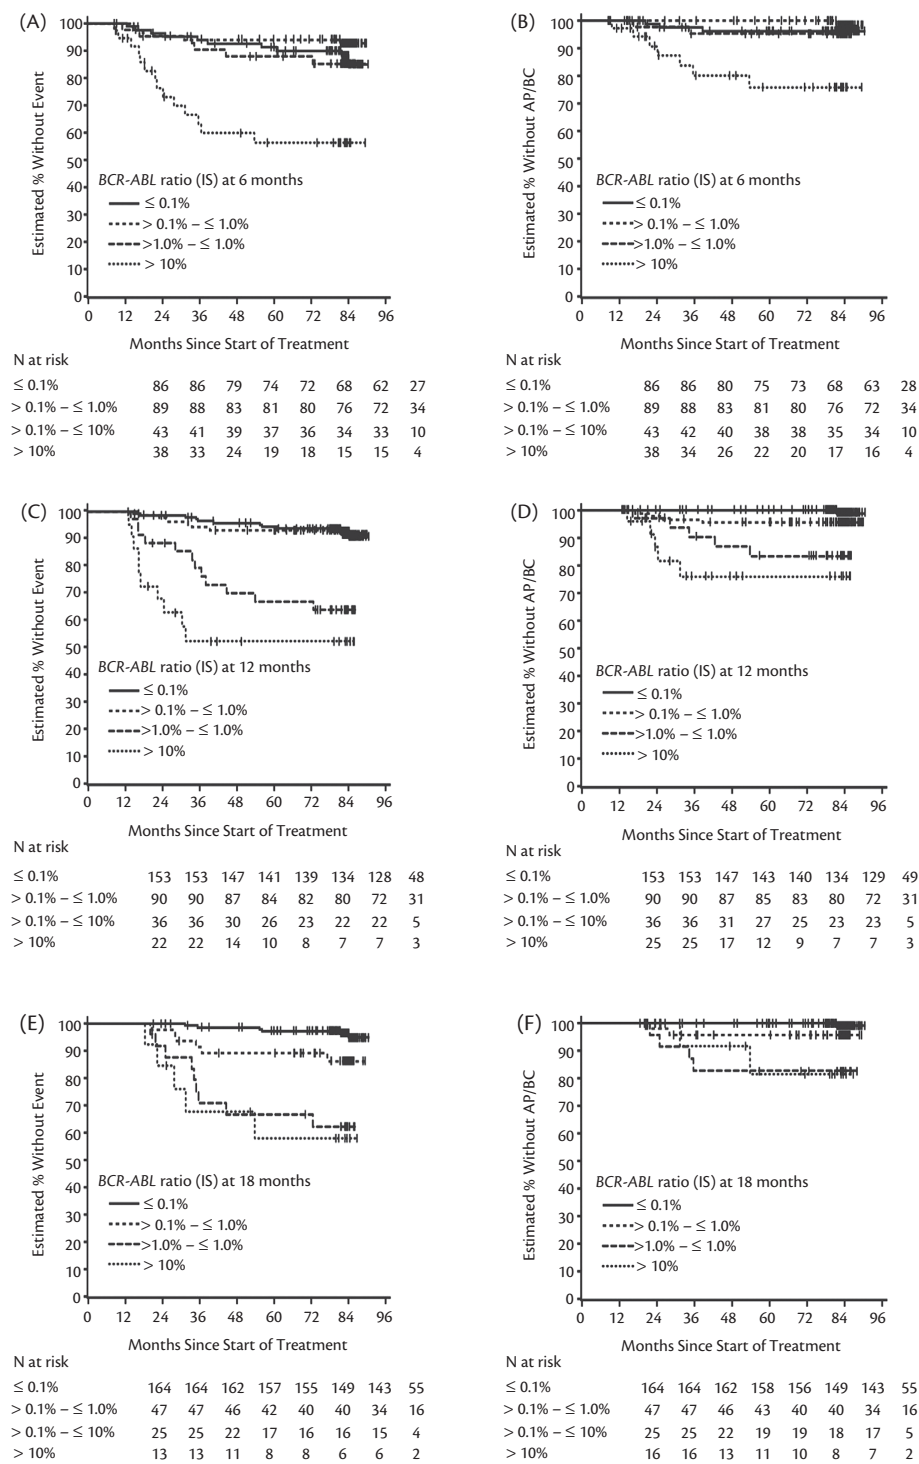
ELN guidelines consider less than PCR at 12 months as IM treatment failure while achieving CCR and PCR at 12 months as an optimal response and suboptimal response, respectively [63]. However, the five-year OS (85.4% vs 98.4%), PFS (73.4% vs 96.1%),


Fig. 52.1 Seven-year event-free survival and time to AP/BC according to molecular response at 6, 12 and 18 months of imatinib treatment.
Reproduced from Hughes TP et al., Long-term prognostic significance of early molecular response to imatinib in newly diagnosed chronic myeloid leukemia: an analysis from the International Randomized Study of Interferon and STI571 (IRIS), *Blood*, Volume 116, Issue 19, pp. 3758–3765, Copyright © 2010 American Society of Hematology.

and probability of achieving CCR (77.8% vs 100%) are significantly lower in suboptimal responders than patients achieving an optimal response at 12 months [89]. This is further substantiated by the three-year follow-up results of the DASISION study. Patients who had failed to achieve CCR at 12 months had significantly inferior PFS and OS in both IM- and dasatinib-treated patients [83].

Similarly, long-term follow-up of the IRIS study suggest that seven-year-EFS (91% vs 64%), OS (93% vs 85%), and PFS (96% vs 83%) was higher in IM-treated patients achieving BCR–ABL1 ≤1% compared with patients with >1% at 12 months (see Figure 52.1C and 52.1D) [90]. Patients with MMR (≤0.1%) and those with BCR–ABL1 (IS) level >0.1 to ≤1% had similar 84 months EFS rate [90]. In the DASISION study, in both dasatinib and IM-treated patients, there was also no difference in three-year PFS and OS in patients achieving CCR and MMR compared with patients with CCR but no MMR at 12 months [83].

These data suggests that failing to achieve CCR and/or ≤1% BCR–ABL1 on IM (28% of patients) [54, 89, 90], dasatinib (17% of patients), [83] or nilotinib (20% of patients) [93] warrants changing therapy; further clinical trial are required to address this issue.

Target response at 18 months after starting tyrosine kinase inhibitor therapy

The lack of CCR by 18 months of IM therapy is considered as IM failure and ELN guidelines suggest changing therapy [63]. However, the long-term outcome was superior in patients achieving MMR at 18 months compared with all other response categories with an EFS of 95% compared to 86%, 62%, and 58% for patients in the >0.1 to 1%, >1% to ≤10% and>10% categories, respectively (see Figure 52.1E and 52.1F) [90]. Moreover, 97% of patients with MMR at 18 months remained in CCR at 84 months compared with only 74% of the patients with molecular response >0.1 to ≤1.0% remaining in CCR (p <0.001) [90].

Target response beyond 18 months of first-line TKI therapy: the Holy Grail for most physicians treating CML is eradicating leukaemic stem cells, which is less likely in the majority of patients treated with TKI therapy. However 'operation cure' is possible which means patients can maintain CMR without TKI therapy. The term CMR does not always indicate eradication of leukaemia. Rather, it is used to describe the sustained undetectable BCR–ABL transcript with sensitive RQ-PCR assay (sensitivity with 4.5 to 5 logs). Up to 10^7 leukaemic cells could still be present in the absence of measurable BCR–ABL. Hence to avoid confusion, more recently MR^4 (≤0.01% IS), $MR^{4.5}$ (detectable transcript ≤0.0032% or undetectable BCR–ABL1 with sample sensitivity of ≥4.5) and MR^5 (≤0.001% IS) is commonly used to denote the log reduction below the standardized baseline [94].

Significantly more numbers of patients treated with dasatinib (22%), and nilotinib (32%) achieve $MR^{4.5}$ compared to IM-treated patients (12–15%) [83, 86, 87, 90]. Patients achieving CMR have the most favourable relapse-free survival rates: only one out of 28 patients in CMR lost CCR while 11 out of 48 patients in MMR lost CCR [95]. Another important benefit of achieving CMR is the possibility of maintaining a molecular response off TKI therapy. In the French Stop Imatinib (STIM) study, IM treatment was discontinued in patients with CML (n = 100) who were in CMR (>5-log reduction in BCR–ABL and ABL levels and undetectable transcripts on quantitative RT-PCR and who have received IM >2 years). Within six months of stopping IM therapy, 61% patients developed molecular relapse while 39% patients remained in CMR off TKI therapy [48]. Similarly, in an Australian study, 40% patients remained in CMR off TKI therapy [96]. All patients developing molecular relapse re-responded to IM therapy. These studies suggest that about half of the patients who achieve and maintain CMR for two years on IM therapy remain in CMR after stopping IM. Many of these patients have remained in CMR off TKI therapy for three to four years. Currently, however, this approach should only be considered in the clinical trial setting; it cannot be recommended outside clinical trial scenarios.

Mutation screening

Mutations in the BCR–ABL kinase domain can cause or contribute to resistance to TKI therapy. This section will address the practical issues faced in clinical practice, such as when to screen for mutation? Which methods should be used? How to use mutation results for managing patients treated with TKI therapy?

Baseline BCR–ABL kinase domain mutations analysis is not recommended in newly-diagnosed CML CP. It can be performed in rare patients presenting in the AP or in BC. Due to the very low frequency of BCR–ABL kinase domain mutation in responding patients, screening at regular intervals is not recommended in all CML CP patients on therapy. Mutation analysis is recommended only in the case of failure, suboptimal response to IM therapy, and in patients with a rise in BCR–ABL transcript associated with a loss of MMR [63]. It has been estimated that, overall 29–43% of IM failure CML CP patients harbour BCR–ABL kinase domain mutations [97, 98]. Although differences exist in mutation incidence across different categories of 'failure', mutations are more frequent in patients with secondary resistance rather than patients who failed to achieve milestone response [63, 89, 99]. None of the patients who failed to achieve CHR or minor cytogenetic response by three and six months, respectively, had BCR–ABL1 kinase domain mutations [100]. On the other hand, the mutation detection rate was higher in patients who failed to achieve late ENL milestone responses: 24% and 22% patients who did not achieve MCR and CCR by 12 and 18 months, respectively, had BCR–ABL1 kinase domain mutations [89, 100]. Similarly, mutation rates were also higher in patients transforming to AP or BC (21%), and patients losing CHR (41%), CCR (13%), or MMR (13%) [98]. The mutation rate is lower in patients with a suboptimal response: 4%, 10%, and 0% of patients who did not achieve MCR, CCR, and MMR at 6, 12, and 18 months, respectively, had BCR–ABL1 kinase domain mutations [100].

Several groups reported that a rise in BCR–ABL1 transcript should be viewed as a trigger for BCR–ABL1 kinase domain mutation analysis; however, there is no agreement regarding the level of BCR–ABL1 transcript rise. Earlier studies suggested that patients with >2 to 2.6-fold rise BCR–ABL1 transcript have a high probability of detecting BCR–ABL1 kinase domain mutations [101, 102], while other groups reported a >5.5-fold rise [103] and NCCN guidelines suggest a >10 fold rise in BCR–ABL1 transcript is significant. Emerging consensus is that BCR–ABL kinase domain mutation should be checked in patients with a consistent rise in BCR–ABL1 transcript on two independent samples and associated with a loss of MMR. Patient compliance should be checked before requesting BCR–ABL1 kinase domain mutation studies [38].

BCR–ABL1 kinase domain mutations can be detected by direct sequencing with sensitivity to detect 10–20% of the mutant clone

[38]. Denaturing high-performance liquid chromatography followed by direct sequencing is another assay with increased sensitivity which can detect the mutant clone at levels down to 1–5%. Other methods used for mutation detection include sequencing after subcloning of PCR products, allele-specific oligonucleotide PCR, restriction-fragment-length polymorphism-based assays, and pyrosequencing. Although these are more sensitive methods for mutation detection, they may not be suitable for routine screening. Moreover, the clinical utility of very small mutant clones detected by these sensitive methods remains the source of conjecture. Hence, the ELN expert panel recommend direct sequencing for BCR–ABL kinase domain mutation screening [38].

In IM-treated patients, >90 BCR–ABL kinase domain mutations have been identified in association with resistance and they are located throughout the kinase domain. However, 15 common mutations account for >90% of all mutations detected during IM therapy. These common mutations include T315I, Y253F/H, E255D/K/R/V, M351T, G250A/E, F359C/L/V, and H396P/R [104, 105]. Although in the ENESTnd study mutation rate was lower in the nilotinib (3.9% vs 7%) group compared with IM-treated patients, most of the nilotinib-treated patients developed nilotinib-resistant (T315I, n = 3) or less sensitive mutations (E255K/V, F359C/V, Y253H; n = 6) [58, 93]. In the DASISION study, mutation rates were similar in dasatinib and IM-treated patients (3.8% vs 3.8%), but dasatinib-resistant mutations such as T315I (n = 7), F317L (n = 2), and V299L (n = 1) were commonly detected in the dasatinib group, while in IM-treated patients, there were ten different mutations and none of the patients developed the T315I mutation during three years of follow-up [55, 56].

Detection of some specific mutations can influence the choice of the second- or subsequent-line TKI. For patients with V299L, T315A, or F317L/V/I/C mutations, nilotinib is more effective, while for patients with Y253H, E255K/V, or E359V/C/I mutations dasatinib is probably more effective than nilotinib [38]. In the case of all other mutations except T315I, dasatinib and nilotinib are likely to be similarly effective. Moreover, patients with multiple mutations detected by multiplexed mass spectrometry assay is associated with lower rates of CCR (50% vs 21%; p = 0.003), MMR (31% vs 6%; p = 0.005), and higher rates of new resistant mutations (25% vs 56%; p = 0.009) [106].

A T315I mutation is refractory to dasatinib, bosutinib, and nilotinib. Phase II studies of ponatinib demonstrated efficacy in patients with T315I mutation. CCR and MMR were achieved in 66% and 50% of patients, respectively, in this scenario [107].

Management of the relapse/refractory patient

The role of high-dose imatinib in patients with imatinib resistance

Some patients who have suboptimal responses on standard-dose IM may benefit from higher dosing [108]. In one study, almost 50% of CP CML patients with disease resistance achieved MCR after having their dose escalated to 300–400 mg bid [109]. However, the response to high-dose IM appears to be transient and the therapy was poorly tolerated: 82% of patients discontinued high-dose IM (compared to 28% in the dasatinib arm, p < 0.0001). Most discontinuations (61%) in the high-dose IM group were due to a lack of response or disease progression [110, 111]. As the toxicity of high-dose IM is greater than standard-dose IM, it may not be a

viable option for many patients, particularly those who could not tolerate standard-dose IM.

The role of dasatinib in imatinib-resistant patients

Promising results of phase I and phase II studies were further substantiated by the phase III randomized study, demonstrating superior efficacy of dasatinib over high-dose IM in patients failing standard-dose IM therapy. Significantly higher CHR (93% vs 82%), CCR (40% vs 16%), and MMR (16% vs 4%) rates were achieved in the dasatinib arm as compared with high-dose IM [110, 111].

The six-year follow-up of another phase III, dasatinib dose optimization study in IM-resistant/intolerant CP CML patients (n = 670), demonstrated that dasatinib 100 mg/daily is as effective as 50 mg/bd, 140 mg/day and 70 mg/bd, with a significantly more favourable toxicity profile [112]. Comparable six-year OS (70–77%), PFS (40–51%), MMR (67–71%) rates were achieved in all four groups [112]. Although there was no difference in response rates between patients who had a baseline mutation and those who did not, a significant difference in response rates emerged when results were analysed according to the specific mutation developed. MCR (61% vs 46%), CCR (53% vs 32%), and MMR (38% vs 23%) were higher in patients harbouring mutations with low IC50 (≤3 nM; G250E, Y253F/H, M315T, E355G, F359V, V379I, L387M, H396P, H396R, M244V) compared with patients with intermediate sensitivity (IC50 >3 ≤60 nM; Q252H, E255K/V, V299L, and F317L/V) [113]. The responses were particularly poor in patients harbouring F317L (7%) and V299L (0%) and T315I (0%) mutations. Other studies also demonstrated lower response rates with dasatinib in patients with F317L [114, 115]. These data indicate that dasatinib is effective in the majority of patients with IM resistance except for patients with T315I, F317L, and V299L mutations.

Role of nilotinib in imatinib-resistant/intolerant patients

The phase II nilotinib registration study, demonstrated the efficacy of nilotinib in IM-resistant and -intolerant patients [104]. Of the 321 patients initially enrolled in the study, 98 (31%) were treated for at least four years; 224 (69.8%) patients discontinued therapy, primarily due to disease progression (30%) or adverse events (21%). The estimated OS and PFS at 48 months were 78% and 57%, respectively. MCR and CCR rates were 59% and 45%, respectively [59]. Baseline mutations (those detectable at the time of IM resistance) were present in 55% of IM-resistant patients [104]. After 12 months of therapy, MCR (49% vs 60%; p = 0.1), CCR (32% vs 40%; p = 0.2), and MMR (22% vs 29%; p = 0.3) were not significantly different in patients with or without baseline mutations [104]. However, when responses were analysed according to individual mutations, patients harbouring T315I, Y253H, E255V/K, and F359V/C had less favourable responses. None of the patients with resistant mutations achieved CCR by 12 months in contrast to 43% of patients with other mutations. Similarly, patients who failed nilotinib therapy displayed frequent mutations at 253, 255, 359, and 311 residues [104]. Thus for most IM-resistant patients, nilotinib is effective except for patients with T315I, Y253H, E255V/K, and F359V/C mutations [104].

Bosutinib in imatinib-resistant/intolerant CP CML patients

Bosutinib (SKI-606; Bosulif®) is an orally bioavailable dual Src/Abl inhibitor, 100- to 200-fold more potent (in vitro) than IM. In a phase I/II study of IM-resistant or -intolerant CP CML patients, 86%, 53%, and 41% of patients achieved CHR, MCR, and

CCR, respectively. At two-years OS and PFS were 92% and 79%, respectively [116].

Ponatinib in imatinib-resistant/intolerant CML CP patients

Ponatinib (AP24534; Iclusig®), an orally available TKI, is a potent pan-BCR–ABL inhibitor with activity against T315I. With median follow-up at 10 months, 66% and 50% patients with T315I mutation achieved CCR and MMR, respectively [107]. The response rate was dependent on the number of patients with prior TKI therapy; the CCR rate in patients who failed IM, two and three prior TKI therapies was 80%, 74%, and 48%, respectively. In the majority of patients the response rate was stable [107].

Allogeneic stem cell transplantation in imatinib-resistant patients

In the era of TKI therapy, alloSTC is restricted to patients with advanced phase disease (AP and BC) and CML CP patients failing at least two or three lines of TKI therapy and/or harbouring T315I mutations.

Monitoring of patients on second-generation tyrosine kinase inhibitor

Monitoring of IM-failure patients treated with second-line, second-generation TKI therapy (2GTKI) is guided by the phase of disease and the reason for starting 2GTKI (IM intolerance or resistance). IM-intolerant or slow-responding CP CML patients (patients who have demonstrated a progressive drop in Ph+ chromosomes and/or BCR–ABL1 transcript but failed to achieve target response) who are switched to 2GTKI can be monitored with CBE every two weeks; RQ-PCR for BCR–ABL1 every three months; and BM cytogenetic analysis at six months, 12 months, and then annually. Patients who lose a previously achieved response (but maintain CP) and/or have a rapidly rising BCR–ABL1 level or Ph+ metaphases should be monitored very closely with RQ-PCR for BCR–ABL1 monthly until a progressive fall in BCR–ABL1 is demonstrated and then be monitored three-monthly. These patients may need BM aspiration and cytogenetic analysis at three, six, and 12 months. The frequency of mutation analysis will depend on the baseline mutation status. Patients with baseline mutations probably need mutation analysis every three months as well as at the time of confirmed rise in BCR–ABL1 transcripts or Ph+ chromosomes. Patients without baseline mutations may not require regular mutation analysis unless the BCR–ABL1 value at three months is >10%.

The long-term response to second-line therapy depends on the disease phase at the time of starting therapy and response to prior IM therapy [59, 117]. Patients with haematologic resistance and ACA have poor outcome with second-line TKI therapy and are considered as a warning sign in ELN provisional guidelines [63]. Early response to 2GTKI can also predict the longer-term outcome. Current ELN guidelines do not provide definition of optimal response to second-line TKI therapy. However, suboptimal response to second-line therapy is defined as minor CR, PCR, and lack of MMR at three, six, and 12 month of second-line TKI therapy, respectively. Failure is defined as the development of new mutations and/or lack of cytogenetic response; minimal CR; and less than PCR at three, six, and 12 months, respectively [63]. Recent data suggest that PFS (63.5% vs 25.9%; p < 0.0001) and OS (85% vs 59.7%; p < 0.001) were significantly higher in dasatinib-treated patients achieving BCR–ABL1 transcript ≤10% at three months compared with patients with BCR–ABL1 transcript >10% [112].

Similarly, in IM-resistant/intolerant CML CP patients treated with nilotinib, BCR–ABL1 transcript levels at three and six months predicted four-year PFS and OS. The estimated PFS (85% vs 67% vs 42%; p <0.002) and OS (95% vs 81% and 71%; p = 0.03) at four years were significantly higher in patients achieving BCR–ABL1 transcript ≤1% at three months compared with patients with >1% to 10% and >10% at three months. At 24 months, MMR rates were significantly higher in patients with three-month BCR–ABL1 ≤1% compared with patients with 1–10% and >10% (86% vs 34% vs 9%; p <0.01) [59]. Similarly the BCR–ABL1 transcript level at six months also predicts long-term survival. The estimated PFS (86% vs 58% vs 39%; p <0.001) and OS (95% vs 82% vs 73%; p = 0.009) at 48 months were significantly higher in patients achieving BCR–ABL1 transcript ≤1% compared to patients > 1 to 10% and >10% at six months, respectively [59]. Patients with CCR at 12 months had a higher PFS compared with patients without CCR at 12 months (89% vs 56%; p <0.0001) [59].

Future directions in treatment for CML

With the remarkable progress in first-line treatment for CML, one of the major remaining problems related to CML treatment include the small subset of CML patients that do not achieve sustained adequate and sustained response to TKI treatment and continue to have a poor prognosis. Although BCR–ABL kinase domain mutations are a well-characterized mechanism of resistance, resistance is clearly a more complex phenomenon, and it is likely that additional mechanisms, including BCR–ABL-independent mechanisms, appear to contribute to resistance. Other than the T315I mutant, in vitro sensitivity does not correlate well with in vivo response. With the availability of pan-TKI inhibitors with anti-T315I activity, these BCR–ABL independent mechanisms may become the dominant resistance mechanisms. Patients with primary resistance to TKI usually do not have BCR–ABL kinase domain mutations. Patients showing poor initial PCR response to IM usually do not respond well to second-line inhibitors. These observations suggest that inter-patient biological heterogeneity may determine resistance. Improved understanding of such resistance mechanisms is critical for strategies to target the small population of CML patients that does not respond well to TKIs.

Another important issue in the future will be whether patients can actually be cured with TKI treatment. An increasing proportion of CML patients treated with TKI have undetectable BCR–ABL levels on RQ-PCR. These patients may still have significant numbers of residual malignant cells. Some patients can maintain a BCR–ABL-negative status for >1 year following discontinuation of IM treatment [118]. Although the long-term durability and frequency of such responses are not known, it may be argued that at least some of these patients are functionally 'cured'. The definition of a 'cure' for these patients remains unresolved. It has been argued that patients may be considered 'cured' if there is no clinical recurrence after stopping treatment. Such a situation may be similar to what is seen in some CML patients post allogeneic transplantation or in AML associated with the t(8;21). On the other hand, late relapses can be observed in some leukaemia patients in prolonged remission, suggesting that definition of cure is still uncertain. Additional factors related to the leukaemogenic potential of residual cells, and immune or microenvironmental factors may determine risk of relapse. In the future, a better understanding of these factors may allow improved prediction of patients

in whom treatment can be stopped without recurrence, and support development of improved strategies to enhance the number of CML patients in whom TKI treatment can be stopped and who are effectively 'cured'. Several preclinical and clinical studies addressing these questions are already underway.

Chronic lymphocytic leukaemia

Epidemiology

CLL is a heterogeneous disease characterized by the progressive accumulation of functionally incompetent mature B lymphocytes. The clinical course is variable with an indolent, minimally symptomatic course in many patients for many years. CLL accounts for about 20–30% of leukaemia cases in the West and is the most common form of leukaemia among adults. The median age is 64 years and male to female ratio 1.2:1. The incidence of CLL is low in Japan, China, India, and other Asian countries. Based on hospital-based data, CLL accounts for <10% of leukaemia cases in these countries. CLL occurs at relatively younger age in Asia, at 55–58 years, and male to female ratio is 2.8:1; <20% of cases are diagnosed at an asymptomatic stage compared to 60–70% in the West [119–120].

Staging and diagnostics

Almost 20–60% of patients are diagnosed while asymptomatic on routine blood counts or during investigation for an unrelated illness. The remainder present with various symptoms including constitutional symptoms, such as fatigue, weight loss, and fever. Common signs include lymph node enlargement or lump in abdomen (splenomegaly). Sometimes, enlarged lymph nodes, with the development of an infection is the initial manifestation of disease. Bacterial infections, such as pneumonia, are more common in patients who present with advanced stage disease. Infections secondary to opportunistic organisms, particularly Herpes zoster, may occur. However, B symptoms (fever, night sweats, weight loss) are relatively uncommon in patients with CLL. In contrast to lymphoma, fever in the absence of infection is rare in CLL. An exaggerated skin reaction to bee stings or insect bites is frequent (Well's syndrome). Skin involvement occurs in fewer than 5% of cases. Leptomeningeal leukaemia is rare and, if present, is usually seen in patients with refractory disease. Physical findings include localized or generalized lymphadenopathy, splenomegaly (30–40% of cases), hepatomegaly (20% of cases), petechiae, and pallor.

Investigations

A list of investigations to be performed in a case of CLL is given below (Box 52.1). Haemogram (CBC) reveals lymphocytosis with an absolute lymphocyte count of 5000/μL or higher. CLL cells typically resemble small mature lymphocytes, have clumped chromatin, scanty cytoplasm, and lack nucleoli. Peripheral blood film usually shows the presence of 'smudge', 'smear', or basket cells, which are artefacts due to damaged lymphocytes during the slide preparation. For diagnosis of CLL, absolute lymphocyte count must be 5000/μL or above. The pathologic features of the lymph node are those of a small lymphocytic lymphoma. BM involvement could be interstitial, nodular or diffuse.

Immunophenotype

Flow cytometry of peripheral blood is the most common method for confirming the diagnosis of CLL. The monoclonal population of B cells in CLL expresses CD19, CD5, and CD23 and has reduced

level of membrane IgM, IgD, and CD79b, a phenotype of mature, activated B lymphocytes. Other conditions which can mimic with are mantle cell lymphoma, indolent lymphoma, splenic villous lymphoma, hairy cell leukaemia (HCL), and pro-lymphocytic leukaemia. The latter has a typical phenotype that is positive for CD19, CD20, and surface membrane immunoglobulin and negative for CD5. Immuno-phenotyping is key in differentiating CLL from these disorders (Table 52.4).

CLL with >55% prolymphocytes is considered B-cell prolymphocytic leukaemia (PLL), whereas typical CLL is associated with 10–55% prolymphocytes and are traditionally classified as CLL/PLL. In such cases, on flow cytometry, transformed prolymphocytes (CLL/PLL) often retain CD5 expression. In contrast, de novo PLL are CD5 negative. Other laboratory abnormalities include elevated serum B2 microglobulin, but LDH is rarely elevated.

Diagnosis

Diagnostic criteria were proposed in 1989 by the International Workshop on CLL (IWCLL) and these have been revised by the National Cancer Institute-sponsored CLL Working Group (NCIWG) in 1996 [121]. For diagnosis, an absolute lymphocyte

Table 52.5 Binet staging of common chronic leukaemia (CLL)

Binet stage	Lymphocytosis	Lymph node areas	Hb (<11G %)	Platelets <100,000/cmm	Survival (years)
A	N/A	<3	No	No	12
B		3 or more	No	No	5
C		+/−	+/−	Yes or low Hb	2

Stage A includes Rai stage 0, 2/3rd of stage I and 1/3rd of stage II.

Reproduced with from Binet et al., A new prognostic classification of chronic lymphocytic leukemia derived from a multivariate survival analysis, *Cancer*, Volume 48, Issue 1, pp. 198–206, Copyright © 1981 American Cancer Society, with permission from John Wiley and Sons Ltd.

count of ≥5000/μL with lymphocytes co-expressing CD5 and a B-cell marker (CD19, CD20, and CD23) and BM lymphocytes of ≥30%. NCIWG criteria do not require a BM aspiration/biopsy for diagnosis. These criteria correlate well with modified Rai and Binet staging.

Staging

Two staging systems are popular: Rai staging in US [122] and Binet in Europe [123] (the Binet staging is given in Table 52.5). Based on the presence of lymph node, liver and spleen enlargement, Hb (G/dl), and platelet counts, CLL can be staged from stage 0 to IV (Rai Stage). There is good correlation between Rai staging and median OS. Binet staging divides CLL into stage A, B, and C, depending upon lymph node areas involved and haematological parameters. Almost 50–60% of patients have Rai stage 0 and I or Binet stage A at presentation.

Molecular biology and pathology

CLL is a clonal B-cell lymphoid leukaemia and is thought to originate from 'activated' B cells. Expression of the CD5 antigen is the hallmark of CLL cells; CD19, CD20, and CD23 are other B-cell markers expressed on CLL cells. Surface immunoglobulin, FMC7, CD22, CD11c, and CD79b are either weakly expressed or negative in CLL. Molecular changes leading to the pathogenesis of the disease are still poorly understood. Approximately 50–70% of CLL cases have somatic hypermutation of immunoglobulin variable gene (IgVH, a marker of B-cell maturation in the follicular germinal centre) and thus appear to arise from post-germinal B cells [124]. Remaining cases appear to arise from naive B cells; these have inferior outcome.

Cytogenetic abnormalities have been detected on conventional cytogenetics in 40–50% of patients. However, a low proliferative rate is a limitation for conventional cytogenetics. In the past decade, FISH using DNA probes has greatly enhanced the ability to detect molecular abnormalities in almost 80% of cases of CLL. 13q deletion is the most common genetic aberration present in CLL (55%) followed by 11q deletion (18%), 12q trisomy (16%), and 17p deletion (7%) [125, 126].These abnormalities have been correlated with outcome. Patients with 17p or 11q deletion generally have more advanced disease with frequent splenomegaly, mediastinal, and abdominal lymphadenopathy and more extensive peripheral lymphadenopathy. Presence of 17p deletion correlates with low incidence of IgVH mutation and also resistance to fludarabine

therapy. In contrast, patients with leukaemic cells that have mutant IgVH genes usually present in an early clinical stage, frequently have 13q14 chromosomal deletions do not have alterations of p53, do not require therapy, and have a long survival [127, 128].

Zeta-associated protein (ZAP-70), a member of the Syk–ZAP-70 protein tyrosine kinase family, is normally expressed in T cells and natural killer cells, and has a critical role in the initiation of T-cell signalling. Expression of ZAP-70 has been shown to correlate inversely with IgVH gene mutation [126]. ZAP-70 is commonly measured by flow cytometry. A reliable flow cytometry strategy is needed to separate ZAP-70 expression on malignant CLL cells from that of back ground T- and NK-cell populations. More recently, a whole-genome sequencing study by a Spanish Group have identified four recurrent mutations in CLL; these are notch 1 (NOTCH1), exportin 1 (XPO1), myeloid differentiation primary response gene 88 (MYD88), and kelch-like 6 (KLHL6). Mutations in MYD88 and KLHL6 are predominant in cases of CLL with mutated immunoglobulin genes, whereas NOTCH1 and XPO1 mutations are mainly detected in patients with an unmutated IgVH gene. Based on the patterns of somatic mutation, supported by functional and clinical analyses, it appears that recurrent NOTCH1, MYD88, and XPO1 mutations are oncogenic changes that contribute to the clinical evolution of the disease [129].

Medical management of chronic lymphocytic leukaemia

All patients of CLL must initially be kept under observation before starting cytotoxic chemotherapy unless there is clear indication. The blood lymphocyte count must be charted at diagnosis and at each follow-up to determine the doubling time.

Indications for treatment

- Increasing BM failure (anaemia, thrombocytopaenia) [121]
- Auto-immune haemolytic anaemia
- Auto-immune thrombocytopaenia, poorly responsive to corticosteroid
- B symptoms (fever and night sweats without evidence of infection, weight loss >10% of normal body weight)
- Extreme fatigue. Rule out other causes of fatigue, e.g., cardiovascular disease, sleep apnoea, depression, hypothyroidism, or secondary malignancy
- Massive or progressive lymphadenopathy, massive splenomegaly
- Disease-related recurrent bacterial infections
- Short lymphocyte doubling time (>50% over two to three months); or if total number of lymphocytes is $>150–300 \times 10^9$/L
- Leukostasis and hyperviscosity-related complications may requires leukapheresis

Many patients may have a slow course (smouldering CLL) and may not require treatment for a long period of time. Early treatment should not be considered for young patients with smouldering CLL until some evidence of progression occurs. Smouldering CLL is suggested by (i) Binet stage A disease, (ii) non-diffuse BM involvement, (iii) absolute lymphocyte count of $<30 \times 10^9$/L, (iv) Hb >13g%, and (v) lymphocyte doubling time >12 months. Risk of progression for such patients is 14–17% at five years, with a clinical outcome similar to age-matched control population [128, 130].

General guidelines for stage-wise management
Early-stage disease (Binet stage A)

◆ Low-risk disease (smouldering CLL). Only follow-up initially; treatment only if progression.

◆ High-risk disease (includes one-third of stage IA). This is defined as (i) elevated β2 microglobulin or elevated thymidine kinase, (ii) lymphocyte doubling time <12 months, (iii) non-nodular BM infiltration. Treatment options are: (i) chlorambucil, (ii) fludarabine, (iii) fludarabine + cyclophosphamide, or (iv) observation.

Symptomatic Binet stage B and all patients of Binet stage C

In recent years, there are several options available for first-line therapy in CLL and also for patients who relapse. Selecting the best treatment for an individual patient is sometimes difficult and challenging. The various old and new drugs available and recommended for the treatment of CLL include fludarabine, chlorambucil, bendamustine, lenalidomide, and monoclonal antibodies (immunotherapy) such as rituximab and alemtuzumab, and multiple combinations of these agents.

Younger patients with unfavourable biological risk factors should be considered for high-dose chemotherapy and autologous or reduced-intensity alloSTC as part of a clinical trial. Patients either relapsing rapidly or not responding to first-line chlorambucil should be considered for fludarabine-containing regimens. Patients relapsing soon after or progressing while on fludarabine-based chemotherapy may be considered for treatment with alemtuzumab, possibly followed by autologous or alloSTC in the context of a clinical trial.

The majority of patients treated with these agents and combinations have a partial response. However, newer agents and combinations do produce more complete responses. Response criteria have been well defined (Table 52.6).

Commonly-used drugs and combinations
Alkylating agents, corticosteroids, and combinations

Before the availability of purine analogues, chlorambucil with/without prednisolone was the only available and commonly-used treatment of CLL, producing a response rate of between 35–75%

Table 52.6 Response criteria in common chronic leukaemia (CLL)

Complete response	◆ Resolution of constitutional symptoms
	◆ Resolution of lymphadenopathy and organomegaly
	◆ PB lymphocyte count <4000/cmm
	◆ ANC >1500/cmm, platelets >100,000/cmm
	◆ BM aspiration/biopsy—normal or nodular or focal infiltrate
Partial response	◆ Change from Binet stage C to A, B, or from stage B to A
	◆ More than 50% decrease in PB lymphocyte count
	◆ More than 50% decrease in size of Lymph nodes, spleen and liver size
	◆ Hb >11g%, ANC >1500/cmm, Platelets >100,000/cmm or an improvement of 50% in these values from baseline

but few complete remissions. The CHOP regimen (cyclophosphamide, doxorubicin, vincristine, and prednisolone) and other related regimens like CVP (cyclophosphamide, vincristine, and prednisolone) have not been shown to be more effective than chlorambucil [131–133]). Chlorambucil is still indicated for use in the low-risk patient and elderly patients who have a poor performance status. Alkylating agents like cyclophosphamide are still used in several regimens like FCR (fludarabine, cyclophosphamide, rituximab).

Bendamustine, another alkylating agent also having purine analogue properties, has been recently approved as front line therapy for CLL based on the results of a phase III trial [134]. This agent, although new to the US, has been in use in Eastern Europe for several years. Bendamustine in combination with rituximab is also recommended for previously untreated CLL based on data from another phase III study, as well as for patients relapsing after a purine analogue [135, 136].

Prednisolone or dexamethasone have activity in CLL and have been used in combination with chlorambucil. These agents are also a part of several effective CLL regimens, with or without rituximab. Infections remain a concern with prolonged corticosteroid use [137].

Purine analogues and combinations

Purine analogues (fludarabine, cladrabine, and pentostatin) form one of the most effective groups of drugs, which are part of most CLL regimens of treatment. When compared with chlorambucil and alkylating agent combinations (CHOP, CAP), fludarabine and fludarabine-containing combinations has been shown to produce more responses, more complete remissions, and a survival advantage in some studies [138–141].

Infections and myelosuppression are the major toxicities of purine analogues. The drug also suppresses both T and B lymphocytes with resultant increase in bacterial, viral and opportunistic infections [142, 143].

Combinations with purine analogues

Even though purine analogues have significant single-agent activity in CLL, they are most commonly used in combination with cyclophosphamide and/or rituximab.

◆ Fludarabine plus cyclophosphamide (FC). The combination of fludarabine and cyclophosphamide has shown a synergism which has been utilized in the treatment of patients of CLL [144]. Three randomized trials have shown the superiority of this combination over fludarabine alone. The FC regimen has been demonstrated to have higher overall response rates, higher complete response rates, and longer PFS over single-agent fludarabine [138, 145, 146]. Benefit with regards to OS is less clear. Even though the combination produces more myelosuppression, infection rates and mortality due infection have not been found to be increased. The FC regimen remains an important treatment option for the patient with good performance status who is unable to tolerate rituximab. The monoclonal antibody directed against CD20 (ofatumumab; Arzerra®) can be combined with the FC regimen to yield high complete response rates (30–50%) [147].

◆ Fludarabine plus rituximab. Fludarabine can be combined with the anti-CD20 monoclonal antibody, rituximab (Rituxan®), with preclinical and clinical synergy [148]. The FR combination regimen has been shown to be better than the two drugs used in a sequential fashion [149]. This regimen is a viable option for

patients of CLL in the first-line setting [150]. When combined with the alkylating agent, cyclophosphamide, the FCR regimen can achieve a high complete remission rate.

◆ Fludarabine, cyclophosphamide, rituximab (FCR). The FCR regimen, combining the three most effective agents, is now one of the standard first-line treatments for CLL, with about 25–72% patients achieving a CR. However, grade 3 and 4 neutropaenia have been reported in 51% patients [151, 152]. There is presently no prospective head-to-head comparison between FCR vs FR, and therefore, neither can be labelled as superior. A trial designed to answer this question is presently ongoing. FCR has been compared with FC in two prospective, multicentre phase III clinical trials. Both have demonstrated the superiority of the former over the latter in terms to response rates, CR, PFS, and OS. Grade 3/4 neutropaenia was significantly more common in the three-drug regimen [153, 154]. Along with FR, FCR is currently the treatment of choice for first-line CLL and both regimens are acceptable for first-line treatment. The superiority of the three-drug regimen remains to be established.

Monoclonal antibodies and immunotherapy

◆ Rituximab. Rituximab, a chimeric monoclonal antibody which targets the CD20 receptor, is an effective drug in CLL and forms an integral part in most regiments. Single-agent responses are of short duration [155]. Combination of rituximab with purine analogues and/or alkylating agents significantly adds to activity and potency [152, 154, 156]. Several combination regimens are now standard of care first-line therapies. A combination of rituximab with an anti-CD52 monoclonal antibody (alemtuzumab) has also shown synergy and is a useful combination in patients, especially those who have bulky lymphadenopathy [157, 158]. Rituximab administration can be associated with significant infusion toxicities including rigors, anaphylactic reactions, and hypotension. As a rule, premedication with steroids and antihistaminics should be given to all patients and the infusion should be initiated slowly under careful monitoring of vital parameters.

◆ Alemtuzumab. Alemtuzumab (Lemtrada®) is a fully humanized monoclonal antibody targeting CD52, which is expressed in most patients with CLL. The initial approval of the drug was for patients who were refractory to fludarabine [159] but recently it has been approved for first-line use also. The drug is most effective on peripheral blood, BM, and spleen but has relatively less activity on bulky lymph nodes [160, 161]. There are some reports suggesting that alemtuzumab may have significantly more activity than standard treatment in high-risk patients who have 17p and 11q deletions [160, 162]. The drug has shown encouraging activity when combined with fludarabine [163, 164] and chlorambucil [162]. Anaphylactic and other infusion-related toxicities are troublesome. Subcutaneous administration of the drug is effective and is being tested in clinical trials [165, 166]. Because of activity on normal B and T lymphocytes, the major toxicities of alemtuzumab are cytopaenias and immune suppression with consequent increase in opportunistic infections especially *Pneumocystis jiroveci* pneumonias, and cytomegalovirus (CMV) (re)activation and infection. All patients receiving the drug should receive pneumocystis prophylaxis and be closely monitored for CMV infection [162, 167].

Prognostic factors

Clinical stage remains the most important prognostic factor in CLL. Other prognostic factors are listed below (Table 52.7) A number of biological markers, particularly serum markers, cytogenetic abnormalities, IgVH mutations, CD38, and ZAP-70 expression in leukaemic cells offer important, independent prognostic information.

Management of the relapse/refractory chronic lymphocytic leukaemia patient

The most important consideration in the choice of therapy for the patient who relapses is the initial treatment and the duration of response to the same. For example, for the patient who has been treated with the FCR regimen and has relapsed after more than 12 months, another trial of the same regimen is appropriate. For the patient with early relapse, a change of regimen is indicated. Bendamustine with rituximab (the BR regimen) is a useful combination in patients who relapse after a purine analogue-containing regimen (FR or FCR) with expected response rates of approximately 59% [168].

The anti-CD52 monoclonal antibody, alemtuzumab, is important as second-line treatment. The drug is indicated either alone or in combination with fludarabine or rituximab. In a phase II study of patients with relapsed CLL, the combination of fludarabine, alemtuzumab, and cyclophosphamide produced an overall RR of 67% with a CR rate of 30% [169].

Table 52.7 Prognostic factors in chronic lymphocytic leukaemia (CLL)

Factor	Outcome
Clinical stage	Rai stage 0 & 1: good, stage II intermediate, III–IV poor Binet stage A >B >C
Degree of BM infiltration	Nodular good, Diffuse poor
Absolute lymphocyte count	<30,000/cmm better than higher
Lymphocyte doubling time	>12 months better than <12 months
Serum levels of β- 2 microglobulin	Normal better than elevated
Serum levels of thymidine kinase	Normal better than elevated
CD38 expression	Negative good, high poor
Cytogenetic abnormality	13q del: good, 11q del: intermediate, del 17p: poor **Median OS:** 13q- =133m, 11q del (+) = 79 mon, 17 p del (+) = 72 mon
Mutation of IgVH gene	Unmutated poor (median OS 84 months, and PFS 68 months); mutated good (median OS not reached, 70% 12 year survival, PFS 141 months)*

Lumiliximab, an anti-CD23 monoclonal antibody, when used in combination with the FCR regimen can produce response rates of 65% (CR in 52%) in relapsed CLL patients and can be considered in this setting in clinical trials [170].

Ofatumumab (Arzerra®) is a new anti-CD20 humanized monoclonal antibody that binds to a distinct epitope from rituximab. Use of this agent in patients who are refractory to both fludarabine and alemtuzumab in early trials is impressive, with a reported RR of 58% [171]. Obinutuzumab, a glyco-engineered monoclonal antibody targeting the CD20 (also known as GA101), in combination with chlorambucil, has shown impressive activity, especially in patients with significant co-morbidities as compared to chlorambucil alone [172].

Another new concept in treating relapse/refractory CLL is the use of cyclin-dependent kinase pathway inhibitor alvocidib (also known as flavopiridol). In a phase II study, encouraging response rates of 48% have been reported in 117 relapsed CLL patients [173].

A recent major advance in the understanding and treatment of CLL has been the discovery and targeting of the Bruton's tyrosine kinase (BTK) pathway. BTK is an essential component of B-cell-receptor signalling, mediates interactions with the tumour microenvironment, and promotes the survival and proliferation of CLL cells. Ibrutinib (Imbruvica®), a first-in-class BTK inhibitor has shown very good results in a recent phase I/II multicentre study with overall RR of 71% and PFS rate of 75%; OS was 83% after more than two-years of follow-up [174].

There has been a reawakening of the use of immune-therapy in lymphoid malignancies, including CLL. In a recently published phase 1 clinical trial, autologous chimeric antigen receptor-modified T cells (CART) were infused in one heavily pretreated patient with relapsed refractory B-cell CLL. The patient achieved CR and continues to be in remission three months at the time of the report of the trial [175].

Future directions in chronic lymphocytic leukaemia

After a gap of several years, in recent times several new agents and strategies have emerged on the therapeutic front for the treatment of CLL. The most promising of these are the BTK inhibitors like ibrutinib, the immune-modulatory agent lenalidomide, and the use of modified autologous T-cells against the disease.

Lenalidomide (Revlimid®) is presently approved for use in multiple myeloma and in patients of myelodysplastic syndrome with 5q deletion. Several clinical trials have demonstrated significant activity of the drug in CLL in the relapse setting, either alone or in combination with rituximab. Lenalidomide has also been found useful in consolidation therapy after induction with FCR-like regimens [176–178].

Dasatinib (Sprycel®), used primarily in CML, has some activity as a single agent in relapsed or refractory CLL [179].

Other new agents include CAL-101, a phosphatidylinositol 3-kinase (PI3K) delta inhibitor [180]; TRU-016, a novel B-cell selective agent which targets CD 37 [181]; the new BTK inhibitor bafetinib; and the proteasome inhibitor carfilzomib [182].

Other less common chronic leukaemias

Hairy cell leukaemia

HCL is considered as one of the curable chronic B-cell lymphoproliferative neoplasms. The usual presentation is in a middle-aged man with splenomegaly and pancytopaenia. The diagnosis is made on finding hairy cells on peripheral blood film or on BM examination and immunophenotyping. Asymptomatic patients require observation and follow-up. Purine analogues are considered to be the first-line therapies of choice. Rituximab in combination with purine analogues is being tested in relapsed patients.

HCL has fascinated haematologists and oncologists ever since its first description more than fifty years ago [183]. Ewald first described it as leukaemic reticuloendotheliosis in 1923. But it was after Bouroncle's classic paper in 1958 and Schrek and Donnelly's observations of hair-like projections under phase contrast microscopy in 1966 that it came to be referred as HCL. Approximately 500–800 new patients are diagnosed every year [184]. Recent discovery of BRAF mutations in most patients with HCL and development of targeted therapy has renewed the interest of the researchers in this field [184–186].

Molecular biology and pathology of hairy cell leukaemia

HCL is a B-cell lymphoproliferative neoplasm. The cell of origin in HCL is the same as is proposed in CLL, i.e., antigen-experienced memory/marginal zone B cell. This was suggested with the demonstration of rearrangement of the B-cell receptor (BCR) Ig genes and heavy chains in hairy cells. Such is the similarity with CLL that HCL may also be differentiated into two types depending on mutation status of the immunoglobulin heavy chain (IGH) as mutated and unmutated HCL, with the same connotation as in CLL. However, the exact cell of origin remains debatable, as in CLL. HCL has a unique tumour mass distribution. Infiltration in the spleen occurs exclusively in the red pulp with sparing of the white pulp, liver involvement is restricted to sinusoids, and lymph node infiltration is rare [187]. This has been attributed to the interaction of the tumour necrosis factor alpha (TNFα) released by hairy cells and integrins α4β1 and its ligand VCAM-1 expressed on endothelial cells [188]. The fibrosis seen in the involved tissues is thought to be due to the secretion of fibronectin by the hairy cells, which is an extracellular matrix ligand for a4b.

Staging and diagnostics of hairy cell leukaemia

The usual presentation of HCL is a middle-aged man with splenomegaly, pancytopaenia, and circulating hairy cells. The median age onset in HCL is 50 years and the male to female ratio is 4:1 [189]. About a quarter of patients present either with easy fatigability, infections, incidental splenomegaly, or abnormal blood counts. Splenomegaly is present in 90% and one-third have hepatomegaly. Though peripheral lymphadenopathy is uncommon (10%), abdominal lymphadenopathy at presentation is found in 17% and in 75% at autopsy.

Infection rates in HCL have varied from 32% in recent series to 68% in older series. Mortality due to infections has varied from 7% in older series [189] to 0.8% in recent series [190]. The commonest infections remain gram-positive and gram-negative bacteria. However, certain unusual organisms like atypical mycobacteria, *Pneumocystis jirovecii*, Legionella, Listeria, and fungi occur more frequently than in other lymphoproliferative disorders. The reason for higher infection rates in HCL is thought to be due to neutropaenia, monocytopaenia, T-cell, and NK-cell dysfunction [191].

Various autoimmune conditions like polyarteritis nodosa, scleroderma, and polymyositis have been shown to be associated with HCL. Presentation is often non-specific with symptoms of fever, malaise, weight loss, arthralgias, and palpable purpura. Skin biopsy

Fig. 52.2 Skin vasculitis in a patient with hairy cell leukaemia (HCL).

Fig. 52.4 HCL trephine: bone marrow trephine biopsy section showing interstitial excess of atypical lymphoid cells with conspicuous perinuclear halo giving the cells a 'fried egg' appearance (H&E stain, magnification 40×).

may reveal leucocytoclastic vasculitis (see Figure 52.2). The reason for this association is hypothesized to be antigenic cross reaction between hairy cell antigens and epitopes on endothelial cells as well as defective immune complex clearance by the functionally impaired immune mechanisms [192].

Laboratory investigations

A complete blood count with a peripheral blood film (PBF) examination offers the first clue to the diagnosis of HCL. Most patients have variable degree of cytopaenias and more than half have pancytopaenia [189]. Monocytopaenia is common in HCL. Romanovsky-stained PBF may reveal hairy cells in a few on light microscopy. These hairy cells are so-called because of their circumferential fine hairy-like cytoplasmic projections. These cells can be demonstrated to be TRAP (tartrate-resistant acid phosphatase) positive and is a useful test in centres without flow cytometry facilities. TRAP is not specific for HCL and can be seen in other conditions as well. BM aspiration may yield a dry tap due to the reticulin fibrosis. The cellularity of the aspirate may vary from hypercellular to hypocellular (see Figure 52.3). Trephine is therefore almost always informative (see Figure 52.4). BM infiltration is focal, diffuse, or interstitial. The mononuclear cells are

Fig. 52.3 HCL BM: bone marrow aspirate smear showing atypical lymphoid cells, slightly larger than mature lymphocytes, rounded nuclei, homogeneous chromatin, absent nucleoli, moderate amount of cytoplasm with fuzzy borders (May Grunwald Geimsa stain; magnification 100×).

10–25µ in size, with a perinuclear zone of abundant pale region giving it a fried egg appearance, which is attributable to cytoplasmic retraction accentuated by reticulin fibrosis. Nuclei vary in size and shape and may be indented to bilobed. Other haematopoietic elements may or may not be adequately represented in the biopsy specimens. Reticulin fibrosis is increased. Immunohistochemistry on trephine is often not done in the era of immunophenotyping. Flow cytometry immunophenotyping is helpful in the classification of chronic lymphoproliferative disorders and often can differentiate HCL from others [193]. HCL is classified as a CD5 and CD23 negative CLPD. HCL is typically positive for B-cell markers CD19, CD20, CD22, CD79a, CD79b, and FMC7, and CD11c, CD25, CD71, CD103, CD123, which are specifically expressed in HCL [194]. One needs to be aware of the immunophenotypic variations that can be seen in up to 35% of the cases. It is vital to differentiate hairy cell variants on the basis of leucocytosis, lack of monocytopaenia and absent CD25 expression, as they respond poorly to standard treatment. Flow cytometry can be used to monitor residual disease after treatment [195].

Medical management of hairy cell leukaemia

The indication for treatment of HCL is similar to other chronic lymphoproliferative disorders. Only symptomatic disease needs intervention. Symptomatic cytopaenias, organomegaly, constitutional symptoms interfering in the activities of daily living of the patient are common indications for treatment. Even in the current era, there is a role for watchful-waiting. It is important to intervene if there is a rapid worsening of blood counts, as treatment itself entails a further risk of worsening the cytopaenias [196].

Splenectomy, which had been the treatment of choice for HCL for the last three decades, is no longer offered to patients due to its poor complete remission rates and durability. The mechanism of action of splenectomy has remained an enigma. It was thought to be due to sequestration. Response rates reported with splenectomy are in the range of 40–70%; however, durability is only 20 months [197]. An intriguing fact is that a minority of patients remain in complete remission for periods of 15–25 years. There have been studies showing a survival benefit as well as those refuting it. Despite this, the long-term results of splenectomy as a debulking procedure in HCL are not clear.

Since its first use in 1984 for HCL, interferon-alpha (IFNα) has lost the battle to newer generation of drugs. IFN has an immunomodulatory effect by affecting other cytokines and promoting apoptosis. The dose of IFN used in HCL is two million IU/m2 subcutaneously three times a week for 12–18 months. Response rates range from 75–90%; though better than splenectomy, complete responses are only occasional. The median time-to-failure of response is 31.3 months. The toxicity profile of IFN has limited its current use.

The discovery of purine analogues came from the observation of adenosine deaminase (ADA) deficient severe combined immunodeficiency (SCID) in paediatric patients. These children had accumulation of deoxyadenosine triphosphates which led to DNA damage and defective repair, thereby leading to lymphocyte apoptosis. This principle was applied in developing purine analogues which irreversibly bind and inhibit ADA enzyme 2'-deoxycoformycin (pentostatin, [Nipent®]) or are resistant to the action of ADA 2-chlorodeoxyadenosine (cladribine; Leustatin®) [198,199]. The results with these two new agents were so remarkable that the response criteria were redefined. Complete response (CR) is defined as disappearance of hairy cells from the blood and BM, normalization of blood counts (haemoglobin>12 g/dL, platelet >100,000/μL, and absolute neutrophil count>1000/μL) and resolution of splenomegaly. Partial remission (PR) requires more than 50% reduction in hairy cells and splenomegaly with normalization of blood counts.

Following their discovery, many case series were published using pentostatin and cladribine. However, there is no clinical difference in outcomes when used as either first- or second-line therapy. The overall CR rate is 81% and DFS is 16 years. Achieving a CR is the only factor associated with relapse- free survival. Patients in CR at five years have a relapse risk of only 25% by 15 years [200]. Pentostatin is given as 4 mg/m2 intravenously every two-weekly until remission. Cladribine is traditionally given as a single cycle of 0.1 mg/kg/day continuous infusion for seven days. To overcome the inconvenience of seven-day continuous infusion, alternative dosing schedules were designed: daily intravenous pulse of 0.14 mg/kg for five days, weekly intravenous pulse of 0.15 mg/kg for six weeks, and daily subcutaneous injection of 3.4 mg/m2 for seven days. All these regimens were found to have equivalent efficacy, toxicity, and outcomes [201]. In the absence of randomized control trials, the choice between cladribine and pentostatin rests with the physician and the patient. Although some authors prefer to use pentostatin as it permits titration of dose and schedule with fewer episodes of febrile neutropaenia, cladribine is overall accepted as the first-line treatment of choice, with pentostatin reserved for relapses. The major concern with the use of these purine analogues is the immunosuppression that occurs after their use, increasing the predisposition to infections. CD4 lymphocyte count may take years to recover [202]. For patients presenting with severe cytopaenias and life-threatening infections, IFN or rituximab can be considered as a bridge to therapy with purine analogues. Currently, there are no established criteria or optimal methods for minimal residual disease (MRD) detection. In the absence of data supporting improved survival by MRD eradication, no recommendation can be made to treat MRD [203].

Late relapses (more than one year of purine nucleoside therapy) can be retreated with either the same or the other purine nucleoside with similar responses as those achieved after first line.

Early relapses (within one year) can be enrolled in clinical trials with novel agents, offered splenectomy, or may be treated with monoclonal antibodies like rituximab [204, 205]. Immunotoxin conjugates LMB-2 and BL22 have been used in relapsed patients with encouraging results. The most recent agent, HA22, has shown CR and PR of 34.6% and 38.5% in relapsed patients, respectively [206].

With current options, patients with HCL have survival approaching the normal population. The leading cause of death in HCL is infections and secondary malignancies [207]. The etiology for second malignancies has been variably attributed to therapy and HCL itself. This debate will continue, however, till more robust data are forthcoming.

Major long-term studies have not shown a plateau in relapse-free survival curves even with current therapies, suggesting disease control but not cure [208]. Recently, the association of BRAF V600E mutation with HCL was identified [185]. BRAF mutations have already been targets for treatment in melanoma and in pilot studies with HCL [186].

Prolymphocytic leukaemia

Prolymphocytic leukaemias (PLL) are rare lymphoproliferative disorders. Though they are labelled as chronic, their clinical behaviour is aggressive. They are of B and T cell type and both show poor response to chemotherapy or immunotherapy. Allogenic HSC transplantation is curative; however, because of old age of presentation, it is carried out only in a minority of patients.

Molecular biology and pathology

PLL are rare, constituting 2% of mature chronic lymphoproliferative disorders. The prolymphocyte cell is twice the size of a CLL lymphocyte (the term prolymphocyte is a misnomer) with prominent nucleus and nucleolus and faintly basophilic cytoplasm. First recognized in 1973 and 1974 as a variant of CLL, PLL is now considered a distinct clinical and pathological entity with further subdivision into T- and B-cell type depending upon their cell of origin. 80% belong to the B-cell phenotype (B-PLL) and 20% belong to the T-cell phenotype (T-PLL) [209].These leukaemias are generally aggressive in their clinical behaviour and exhibit poor response to chemotherapy.

B-cell phenotype

B-cell phenotype (B-PLL) is diagnosed when the number of prolymphocytes in the peripheral blood is more than 55% (see Figure 52.5). Generally the patients are elderly and present with rapidly rising white cell count, progressive anaemia, thrombocytopaenia, and splenomegaly. Systemic B symptoms (fevers, weight loss, night sweats) are generally present. Significant lymphadenopathy is uncommon. Patients have hypergammaglobulinaemia and a small monoclonal band in their serum. The diagnosis is made on the morphology of the cells seen on the peripheral blood film (PBF) and on BM (see Figure 52.5). Immunophenotyping of these cells reveal B cells expressing surface IgM+/− IgD, CD19, CD20, CD22, CD79a, CD79b, FMC7, and bright kappa or lambda light-chain. CD5 and CD23 (hallmarks of CLL) are present in only 20% of cases. Cytogenetic profile shows del(17p) mutations in more than 50% of cases and presence of these mutations are generally responsible for chemoresistance. The differential diagnosis of B-PLL consists of leukaemic phase of mantle cell lymphoma (differentiated by cyclin D1 positivity and t(11;14)(q13;q32) translocations) and HCL
Fig. 52.5 Peripheral blood film showing a prolymphocyte, two times the size of mature lymphocyte, with opened up chromatin, prominent nucleoli, moderate amount of basophilic cytoplasm (May Grunwald Giemsa stain, magnification 100×).

Fig. 52.6 Skin infiltration in a case of T-cell phenotype (T-PLL).

variants (differentiated by hairy cytoplasmic projections, CD11c, and CD103+).

Medical management of B-cell phenotype

Because of the rarity of this leukaemia, treatment guidelines are not available. The median age of the patients is 69 years and hence many of the patients are not candidates for aggressive therapies because of co-morbidities present at this age. Even with aggressive treatment approaches, the median survival rarely goes beyond three years. Before the availability of purine analogues, CHOP (cyclophosphamide, doxorubicin, vincristine [Oncovin®], prednisolone) was used to induce remission in symptomatic patients. Later, single-agent purine analogues were used in the treatment, with response rates approaching 50%. Combinations of purine analogues with cyclophosphamide increased the median survival of patients compared to that achieved by purine analogues alone. Because of strong CD20 expression, combinations of purine analogues with cyclophosphamide and antiCD20 antibody rituximab is an attractive treatment option [210]. Various chemotherapy drugs like mitoxantrone, bendamustine, and epirubicin have been used in combinations with each other to increase response rates. Presence of TP53 abnormalities confers primary resistance to purine analogues; in these patients alemtuzumab has been used successfully to treat this condition [211]. Eligible patients should undergo alloSTC to take the benefit of GVL effect in curing this disorder, though only a small percentage of patients undergo this procedure because of advanced age and co-morbidities. Most transplant physicians prefer reduced-intensity conditioning because of these reasons. Splenectomy has been used successfully as palliative therapy in very frail patients and in patients with poor performance status [212].

T-cell phenotype

The T-cell phenotype (T-PLL) is generally more aggressive in clinical behaviour and shows poorer response to chemotherapy than B-PLL [213]. The median age of presentation is between 65–70 years (similar to B-PLL). Patients with the genetic condition ataxia-telangiectasia have the ATM (ataxia-telangiectasia mutant) gene and tend to develop T-PLL at a younger age. The clinical features of T-PLL are similar to those seen in B-PLL with additional clinical findings in the skin (20% of cases) in the form of nodules, maculopapular rash, and erythroderma (see Figure 52.6); serous effusions in 12% of patients; and generalized lymphadenopathy in 46% of patients.

Molecular biology and pathology of the T-cell phenotype

Three morphological variants of T-PLL are described; typical (75%), small cell (20%), and cerebriform (5%). The immunophenotype of PLL cells is characteristically post-thymic phenotype (CD1a and TdT negative), pan T-cell positive (CD2, CD3, and CD7), and strongly positive CD52. In 60% of patients, the CD4+/CD8- phenotype is seen, while 15% of cells co-express CD4+/CD8+ and the same proportion co-express CD4-/CD8+. Clonal rearrangement of TCR is seen in almost all patients as well as genetic abnormalities involving chromosome 14 (most common), 11, and 8. Inversion and tandem translocation of chromosome 14 leads to activation and expression of proto-oncogene TCL1 that can also be used to detect residual disease post-chemotherapy either by immunohistochemistry or flow cytometry on BM samples. A host of other chromosomal abnormalities have been described, e.g., [t(X;14)(q28;q11)], idic(8p11), t(8;8), trisomy 8q, 11q23, loss at 22q, 13q, 6q, 9p, 12p, 17p and gains at 22q and 6p. T-PLL needs to be differentiated from other T-cell leukaemias mainly adult T-cell leukaemia lymphoma (ATLL), T-cell large granular lymphocytic leukaemia (T-LGL), and Sézary syndrome (SS). The differentiation from these disorders sometimes becomes difficult and morphology, immunophenotypic features, cytogenetics, and progression of the disease help in making this differentiation. A few investigations are very helpful, e.g., presence of human T-lymphotropic virus type 1 serology and hypercalcaemia in ATLL, granular lymphocyte with CD8, CD57, CD16+/- in T-LGL, and distinct morphology and skin findings in SS [214].

Medical management of T-cell phenotype

Similar to CLL, treatment is indicated only in symptomatic patients with progressive disease. Asymptomatic patients require closer clinical and laboratory monitoring than asymptomatic CLL

patients. In the past, purine analogues were used to treat this condition with RR of 45% and CR of 9%. T-PLL cells strongly express CD52 antigen stimulating interest in the monoclonal antibody against CD52, alemtuzumab, which is the current treatment of choice [215].Though the earliest use of this antibody was reported in 1989, it was only in 1997 that its effectiveness in achieving complete remission rates of 60% was reported in patients refractory to purine analogues. The mechanism of action of alemtuzumab in causing cell lysis is postulated to be due to antibody-dependent cellular cytotoxicity, complement activation, and direct apoptosis. When used as first-line agent, complete remission rates up to 81% have been achieved. However, most responses are transient and these patients require additional consolidative therapy in the form of HSC transplantation [216]. Eligible patients should undergo alloSCT, while other patients can be consolidated with autologous SCT to increase their DFS. Alemtuzumab is highly immunosuppressant agent and these patients should receive anti-infective prophylaxis with co-trimoxazole for *Pneumocycstis jerovicii* and acyclovir or valcyclovir for herpes. CMV activation occurs in substantial number of patients, mandating weekly monitoring of CMV viremia. Anti-infective prophylaxis is generally continued for three months post-completion of treatment as CD4+ cells remain suppressed for a long period of time. Relapsed T-PLL cases have a poor prognosis and a combination of purine analogues with cytotoxic chemotherapy such as mitoxantrone and cyclophosphamide can be used. Eligible patients should be transplanted if possible [217]. Repeat treatment with alemtuzumab may work in a few patients in whom the CD52 expression is still present. As always, patients should be enrolled in well-designed clinical trials.

Large granular lymphocyte leukaemia and hairy cell leukaemia-variant

Large granular lymphocytic leukaemia (LGL) and HCL variant (HCL-v) are rare types of chronic lymphoproliferative disorders. LGL can be of T-cell and NK-cell origin, depending upon the phenotype. LGL is generally seen in patients with rheumatological or autoimmune disorders. HCL-v is now considered as separate disorder from classic HCL. HCL-v is generally more aggressive and shows poor response to chemotherapy or immunotherapy.

Large granular lymphocyte leukaemia

LGLs are distinct subset of lymphocytes 15–18 μm in size containing abundant azurophilic granules and constitute 10–15% of peripheral blood mononuclear cells. Loughran et al. in 1985 observed three patients who had increase in LGLs along with splenomegaly, chronic neutropaenia, and multiple auto-antibodies and named it as LGL leukaemia [218]. The WHO 2008 classification of tumours of haematopoietic and lymphoid tissues classify this leukaemia into T-cell large granular lymphocytic leukaemia and chronic lymphoproliferative disorders of NK cells, based on the immunophenotyping of the cells. These disorders are still controversial, as many believe that the T cell represents reactive proliferation and not malignant proliferation. Recently, the presence of STAT3 mutations has been documented in large number of patients, correlating with malignant potential of these disorders [219].

T-cell large granular lymphocytic leukaemia

T-cell large granular lymphocytic leukaemia (T-LGL) is diagnosed when the peripheral blood T lymphocytes (immunophenotypically CD3+, CD57+, CD56-) shows persistence of these cells numbering between $2–20 \times 10^9$/L for more than six months without any identifiable cause. This leukaemia represents 2–3% of mature lymphocytic leukaemia and 85% of LGL leukaemias. The majority of the cases occur between 45–75 years of age without any sex predilection. In 40–60% of cases, associated rheumatic (most common rheumatoid arthritis) or other autoimmune disorders are seen. Based on these associations, an immune aetiology has been proposed for this disorder [220]. Clinical presentation is mostly indolent with splenic enlargement. Haemogram shows either normal or low haemoglobin with severe neutropaenia and lymphocytosis and normal platelet count. Recurrent infections occur in 20–40% of cases because of neutropaenia. Asymptomatic patients require only observation and treatment of the underlying autoimmune or rheumatological disorder [221]. Symptomatic patients (fatigue, recurrent infections) are treated with low-dose methotrexate, corticosteroids, cyclophosphamide, or cyclosporine. Patients with severe neutropaenia but who are otherwise asymptomatic can be treated with intermittent granulocyte colony stimulating factors.

Chronic lymphoproliferative disorder of NK cells

These are rare disorders and constitute only 15% of LGL leukaemias [222]. These are diagnosed when NK cells numbering $\geq 2 \times 10^9$/L persist in the peripheral blood for more than six months without a clearly identifiable cause. The immunophenotype of the cells is CD3-, CD56+, and CD16+. The WHO 2008 classification has defined this as a provisional entity. The presentation is similar to T-LGL. The median age of onset is 60 years. There are a few differences with T-LGL in the form of slight male preponderance in the ratio of 3:2, absence of splenomegaly and lymphadenopathy, and less severe neutropaenia [223]. The treatment, however, is similar with asymptomatic patients require observation and symptomatic patients are treated with methotrexate, cyclophosphamide, corticosteroids, and cyclosporine [221].

Hairy cell leukaemia-variant (HCL-v)

Initially described as a variant of HCL, this disorder has now gained entry into the WHO classification of haematopoietic disorders as an independent provisional entity. The cells of HCL-v exhibit phenotypic features that overlap between classic HCL and B-PLL, hence the synonym prolymphocytic variant of HCL. It is a relatively uncommon condition and constitutes 10% of HCL cases and 0.4% of chronic lymphoproliferative disorders [224]. The median age of presentation is 71 years. Most patients have splenomegaly, high white blood cell count without monocytopaenia or neutropaenia, and thrombocytopaenia. The BM can easily be aspirated and is hypercellular. HCL-v cells are smaller than the HCL cells and show high nuclear cytoplasmic ratio and no ribosome-lamella complexes. The cells resemble prolymphocytes in the form of prominent nucleoli and basophilic cytoplasm. The immunephenotype consists of CD19, CD20, CD22+ve (B cell phenotype), CD11c+, CD10-, CD23-, CD25-, CD5-, and variable expression of CD103 and bright monotypic surface immunoglobulin [225]. The treatment consists of observation in asymptomatic patients. Symptomatic patients generally do not respond very well to purine analogues and IFN. Most patients are still treated with splenectomy. Weekly administration of monoclonal antibody against CD20 (rituximab) has shown promising results. Other therapies that have been used successfully are anti-CD22 and anti-CD25 immunotoxins, alemtuzumab, and HSC transplantation. The prognosis is less favourable than classic HCL patients [226].

CHAPTER 53

Myeloma

Charlotte Pawlyn, Faith Davies, and Gareth Morgan

Introduction to myeloma

Multiple myeloma (myeloma or MM) is the second most common haematological malignancy in the UK and is characterized by the proliferation of clonal plasma cells in the bone marrow. It was first described in the mid-nineteenth century when a patient in London was noted to have a large amount of protein in his urine. His physicians, Dr William MacIntyre and Dr Thomas Watson, sent a sample of urine to Dr Henry Bence Jones, a well-recognized physician and chemical pathologist at St George's Hospital. Dr Jones described characteristic changes on heating and cooling the urine and quantified the protein and recognizing its diagnostic importance. After the patient's death, Dr John Dalrymple described cells—consistent with plasma cells—taken from the lumbar vertebrae and a rib, and in 1850 Dr McIntyre published a description of the case with characteristic clinical, urine protein, and bone marrow features [1, 2].

Myeloma is divided into a number of distinct clinical phases. The first, a premalignant stage termed MGUS (monoclonal gammopathy of undetermined significance) in asymptomatic patients, in which there is a population of clonal plasma cells that produce a monoclonal protein or 'paraprotein'. This syndrome is present in 3% of adults over the age of 60 [3] with a risk of progressing to myeloma of 1% per year [4]. The next stage, asymptomatic myeloma, has a higher percentage of plasma cells in the bone marrow but without end-organ damage. Myeloma requiring treatment is defined as disease causing detectable damage to the bones or kidneys and/or suppression of normal bone marrow function or disease defined by 'biomarkers of malignancy'. Plasma cell leukaemia is the most aggressive stage of disease and is characterized by the ability of plasma cells to survive outside of the protective bone marrow microenvironment.

Epidemiology

Myeloma is predominantly a disease of those aged over 60 and as such the incidence is increasing as the population ages. There are currently approximately 20 000 new cases diagnosed each year in the US and 4500 in the UK [5, 6]. Epidemiological studies have established increasing age, male gender, familial background, and a past history of MGUS as risk factors for MM [7, 8]. It has been suggested that myeloma is always preceded by MGUS as the abnormal plasma cells in both conditions share many of the same genetic abnormalities. Two long-term cohort studies support this view, which is now generally accepted [9–11], The risk of developing clinical myeloma is either related to the development of MGUS or to the transition from MGUS to MM, either of which can be contributed to by inherited genetic variation.

The male:female split observed is 60:40, both in clinical trial data and population statistics, with differences seen in the underlying cytogenetic abnormalities seen between sexes [8]. There is also a difference in incidence dependent on racial background, with a higher prevalence in African-Americans compared to those with a European background [10, 12, 13]. MGUS has a similar profile suggesting the higher prevalence in African-Americans is due to differences in the primary genetic event causing MGUS rather than the risk of progression from MGUS to MM. The rates in American Chinese, Japanese, and Mexican populations are lower than the general population [14, 15].

Myeloma risk has also been linked to a number of lifestyle and environmental factors including obesity [16], autoimmune disease [17], exposure to agricultural or chemical toxins [18], and radiation. The evidence for a familial basis for the development of multiple myeloma is not clear. Over 37 families with two or more affected members have been reported, but case control studies have not always yielded evidence as to whether or not family members of patients with multiple myeloma are at a significantly increased risk of developing the disease [19]. The first-degree relatives of patients with MGUS or MM have been shown to have a consistently increased risk of myeloma in epidemiological and case control studies [19–22]. The largest study to date, involving 11 752 MM patients diagnosed in Sweden between 1958 and 2002, showed that the risk of MM was increased fourfold in first-degree relatives (95% CI 1.81–8.41) [20]. Several other studies have also supported this data [23–28] and shown a possible increased risk of MM in family members of those with other cancers such as prostate cancer, melanoma, non-Hodgkin lymphoma, and chronic lymphocytic leukaemia [19, 20, 29, 30]. Collectively, these data are consistent with a two- to fourfold inherited genetic susceptibility to MM.

The possible cause for this inherited genetic risk has been identified in large genome-wide association studies [31–33]. These identified single nuclear polymorphisms (SNPs) at 2p23.3, 3p22.1, 3q26.2, 6p21.33, 7p15.3, 17p11.2, and 22q13.1, which were associated with increased risk of myeloma. These are associated with different genes (Table 53.1). These genes have not been previously investigated in the context of myeloma and further work is required to assess their functional role.

Molecular biology and pathology

Normal plasma cell development

The primary function of a plasma cell is to secrete antibody or immunoglobulin, molecules of which comprise two larger, heavy

Table 53.1 Single nuclear polymorphisms (SNP) identified in genome-wide association studies associated with an increased risk of myeloma and possible candidate genes associated with each SNP

SNP	Possible candidate genes	Function
2p23.3	DNMT3A	DNA methyltransferase
	DTNB	β-dystrobrevin, a component of the dystrophin-associated protein complex
3p22.1	CTNNB1	β catenin gene which activates transcription factors including MYC
	ULK4	Regulator of mTOR mediated autophagy
	TRAK1	Endocytic trafficking of the GABA(A) receptors
3q26.2	TERC	Involved in maintenance of telomere length
6p21.33	PSORS1C1	Psoriasis susceptibility gene
7p15.3	CDCA7L	Cell cycle regulation, directly interacts with MYC
	DNAH11	Dynein heavy-chain microtubule-dependent ATPase motor involved in respiratory cilia movement
22q13.1	CBX7	Encodes a polycomb group protein

chains and two smaller, light chains. In order to generate antibody diversity, a complex sequential system of rearrangements within the germline DNA of immunoglobulin genes has evolved. Heavy (H)-chain rearrangement precedes that of light (L)-chains and kappa (k)-light chain precedes lambda (l) during productive immunoglobulin gene rearrangement. One of a number of variable (V), diversity (D), and joining (J) sequences are brought together to form a functional IgH heavy-chain gene. Diversity results from the ability to use combinations of these different families and from the random insertion of nucleotides by the enzyme terminal deoxyribonucleotidyl transferase at the junctional regions. The same process is undertaken at the immunoglobulin light-chain locus. A functional immunoglobulin molecule is produced by fusion of a variable region with a constant region. The variable regions provide antibody specificity and the constant regions provide specific functions such as complement fixation and activation of other effector functions. The immunoglobulin gene product is present on the surface of a virgin B cell as a receptor. This is composed of the gene product, which provides the specificity, with CD79a and b, the B-cell receptor accessory molecule, and b2-microglobulin.

If virgin B cells encounter an antigen recognized by their surface receptor, they are stimulated to divide. A proportion of the cells produce low-affinity IgM antibodies and the remainder migrate to a germinal centre. Within the germinal centre, affinity maturation utilizes the process of somatic hypermutation (SHM) to introduce DNA mutation into the immunoglobulin (Ig) genes to produce highly specific and avid antibodies [34]. The functionality of these antibodies is potentiated by the ability to use different classes of heavy-chain, a process termed class switch recombination (CSR) as a result of which the class of immunoglobulin produced is changed from IgM or IgD to IgG, IgA, or IgE.

CSR and SHM are essential for the generation of effective antibodies and confer a major survival advantage. Both of these processes require the expression of activation-induced deaminase, which results in double strand breaks (DSBs) in the Ig loci. DSBs are necessary to carry out CSR and SHM and are usually successfully repaired. However, mis-joining of DSBs to others formed elsewhere in the genome is inevitable at a low rate and can result in mutations and chromosomal rearrangements, which can potentially lead to malignancy.

On leaving the germinal centre the plasma cell differentiates from a centroblast to a mature antibody-secreting cell. The main function of a plasma cell is to secrete immunoglobulin, so surface immunoglobulin is no longer expressed but is present in the cytoplasm. Similarly, the B-cell receptor accessory molecules, CD79a and b, are no longer expressed on the cell surface. There are a number of other changes in antigen expression, including downregulation of CD19 and upregulation of CD38 and CD138 (syndecan 1). This process of plasma cell development requires the coordination of several intracellular processes including cell cycle arrest, the compaction of chromatin, the downregulation of proteins not required to produce antibodies, and the upregulation of the protein-producing machinery of the cell. This series of events requires the coordinated expression of transcription factors. These molecules include IRF4, which results in the downregulation of BCL6, whilst BLIMP1 and XBP1 are upregulated. The final stages of plasma cell development depend critically on the expression of XBP1, which mediates the unfolded protein response (UPR). IRE1a senses intracellular stress and the accumulation of unfolded protein and results in the splicing of XBP1 to XBP1s which upregulates proteins providing key mechanisms to effectively manage the accumulation of proteins and promote cell growth and survival (Figure 53.1).

Once in the bone marrow, the normal plasma cell either dies as a result of resolution of the immune response or becomes a long-lived memory plasma cell and survives by interacting with the bone marrow microenvironment.

Myeloma initiation and progression

Myeloma development was previously thought to be the result of the sequential acquisition of aberrant lesions resulting in the transition from normal plasma cell to MGUS and then to MM. It is becoming increasingly clear that the molecular events acquired during this process are not acquired in a linear fashion and rather that branching non-linear pathways, as suggested by Darwin to explain the 'evolution of species', is a crucial feature of disease progression (Figure 53.2) [35]. The events that occur at the roots of the developing disease are either chromosomal translocations, thought to occur as a result of aberrant resolution of double strand breaks, or the acquisition of hyperdiploidy. These events are usually found in close to 100% of clonal cells and are therefore thought to be aetiologic events.

Aetiologic translocations result in oncogenes being placed under the control of strong immunoglobulin gene enhancers on chromosome 14 as shown in Table 53.2. These translocations have prognostic implications for cases in which they are detected, with t(4;14), t(14;16), and t(14;20) associated with poor-risk disease whilst t(11;14) is associated with standard risk. (Risk stratification of myeloma is discussed further below.) The deregulation of the G1/S transition in the cell cycle is recognized as a critical early event in myeloma pathogenesis. It is mediated via the upregulation
Fig. 53.1 The B-cell immune response. Encouraging antigen drives a virgin B cell to generate a low-affinity plasma cell or stimulates its migration to a germinal centre. In the germinal centre, affinity maturation occurs and is mediated through two processes: somatic hypermutation and antigen selection. Subsequently, class switch recombination (CSR) occurs, leading to the development of immunoglobulin (Ig) isotypes. Once this process is complete, the plasmablast leaves the germinal centre and migrates to the bone marrow where it becomes a long-lived plasma cell that produces antibody. The machinery that is necessary to generate these physiological DNA rearrangements can malfunction, leading to mutations in crucial oncogenes and tumour suppressor genes, and malignant change. Key challenges for a plasma cell include switching off cellular characteristics that are no longer required, such as cell cycling, activating programmes that are essential for antibody production, and undergoing apoptosis if they do not find a receptive niche in the bone marrow. Failure to complete these programmes correctly could potentially leave active cellular processes, which may result in the features of myeloma. The key transcription factors underlying this coordinated differentiation process are also showed.
BCL-6, B-cell lymphoma 6; BLIMP1, B-lymphocyte-induced maturation protein 1; CIIITA, MHC class II transactivator; ID3, DNA-binding protein inhibitor ID3; PAX5, paired-box gene 5; XBP1, X box-binding protein 1.

of cyclin-D as a result of the t(6;14) and t(11;14) translocations but also via non-translocation based upregulation of CCND2, including downstream of MAF and MMSET/FGFR3 activation. Loss of negative regulators of the cell cycle including RB1 and CDKN2C are also important in this transition and the mechanism causing their loss is discussed further below.

Secondary events

There are numerous further genetic events and intracellular pathways that are affected later in the disease process and collaborate with the aetiologic/initiating lesions previously described. These are summarized in the following sections:

Copy number abnormalities/chromosomal gains/losses

Loss or gain of whole or portions of chromosomes resulting in copy number alterations are common in myeloma. Interstitial losses of copy number cause deletion of tumour suppressor genes. Mostly, tumour suppressor genes need both allele copies to be deleted to produce an oncogenic phenotype and driver genes have been identified through analysing mutations along with copy number status. Genes known to be deleted with each chromosomal deletion are 1p: CDKN2C, FAF1, and FAM46C; 11q: BIRC2 and BIRC3; 13: RB1 and DIS3; 14q: TRAF3; 16q: CYLD and WWOX; and 17p: TP53. The latter (del17p) results in the deletion of a gene involved in mediating the apoptotic response to chemotherapy which may be the cause of the poor prognosis in these patients [36].

In contrast, copy number gains lead to the over-expression of oncogenes, for example 1q: CKS1B, ANP32E, BCL-9, and PDZK1.

Translocations

In addition to the translocations previously described, further translocations also occur later in the disease process and are not driven by CSR. These include t(8;14) which causes upregulation of *MYC*. In addition, less well-characterized translocations can occur not involving the immunoglobulin heavy-chain region.

Mutations

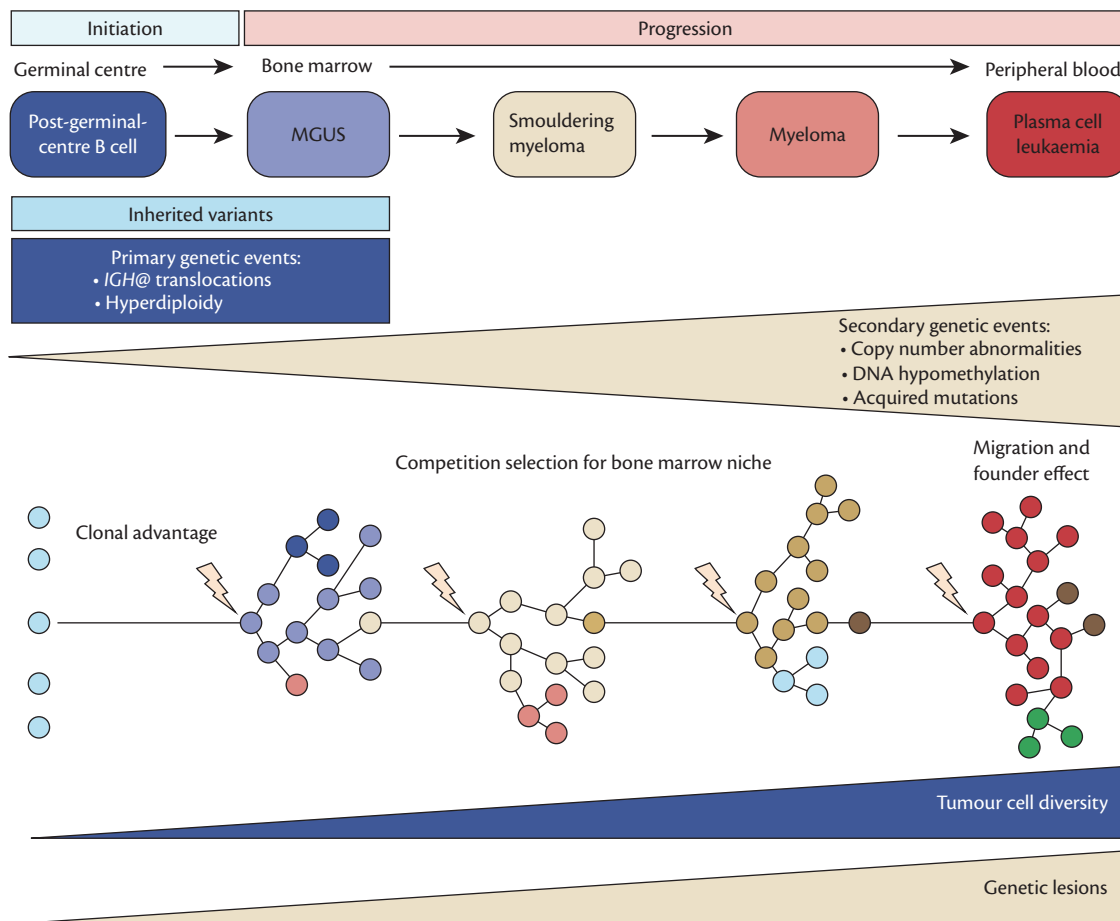
The incidence of non-synonymous mutations in myeloma is approximately 35 per case [37]. This number lies between the genetically simpler acute leukaemias and those present in highly complex epithelial tumours such as lung cancer. The few recurrently mutated genes are mostly known oncogenes but some novel genes have also been identified including FAM46C in 13% of cases and DIS3 in 11% of cases. There is a stark contrast to other haematological malignancies such as hairy cell leukaemia which is unified by mutations in the *BRAF* gene. The fact that this is not the case in myeloma supports the theory that it is deregulation of intracellular pathways that is critically important in the pathogenesis of myeloma. Particularly implicated are the RAS/MAPK pathway, constituents of which are mutated in approximately 50% of cases, implying that myeloma is a disease of aberrant RAS signalling.


Fig. 53.2 Initiation and progression of myeloma. Monoclonal gammopathy of undetermined significance (MGUS) is an indolent, asymptomatic condition that transforms to myeloma at a rate of 1% per annum. Smouldering myeloma lacks clinical features; by contrast, symptomatic myeloma has various clinical features that are collectively referred to as calcium, renal, anaemia, and bone abnormalities (CRAB), which provide an indication that treatment is required. Later in the disease progression, the myeloma plasma cells are no longer restrained to growth within the bone marrow and can be found at extramedullary sites and as circulating leukaemic cells. It is thought that transition through these different states requires the acquisition of genetic abnormalities that lead to the development of the biological hallmarks of myeloma. The initial deregulated cell belongs to the MGUS clone; however, subsequent to the development of sufficient genetic abnormalities, it acquires a clonal advantage, expands and evolves. This clonal evolution is through the branching pathways that are typically associated with Darwin's explanation of the origin of species. During the evolution of MGUS to myeloma these processes lead to the development of numerous ecosystems, which correspond to the clinically recognized phases of disease. At the end of this evolutionary process, at the stage of plasma cell leukaemia (PCL), the clone is proliferative and no longer confined to the bone marrow; the clone expands rapidly and leads to patient death. Cells at this stage are substantially altered genetically, and the precursor subclones will be present at low levels because of competition for access to the stromal niches in the bone marrow: these clones may be eradicated by more aggressive clones. In evolutionary terms, this phase of disease could be considered to be initiated by a migration and founder effect whereby a cell that is able to survive and grow in the peripheral blood is faced with no competition, thus limiting its clonal expansion.

Abbreviation: IGH@, immunoglobulin heavy-chain locus.

Epigenetic aberrations

Epigenetic modifications regulate the process of normal B-cell development and plasma cell differentiation. Several specific epigenetic aberrations have been identified in myeloma pathogenesis. MMSET (WHSC1/NSD2) is a histone lysine methyltransferase of H3K36 that is over-expressed frequently in multiple myeloma as a result of the aetiologic translocation t(4;14) and is associated with a poor prognosis [38]. Other methyltransferases and histone demethylases are also implicated in myeloma pathogenesis including EZH2 (H3K27 methyltransferase) and UTX/KDM6A (H3K27 demethylase), which is mutated in 10% of cases [37].

DNA methylation changes have also been clearly demonstrated to be associated with disease progression [39]. At the transition from MGUS to myeloma, global hypomethylation with gene specific hypermethylation is seen, whilst at the transition from myeloma to plasma cell leukaemia there was re-methylation across the genome [39, 40]. There is also a distinct signature in different cytogenetic subgroups with the most distinct being the t(4;14) subgroup which over-expresses the histone methyltransferase MMSET.

Interaction with the bone marrow microenvironment

MM plasma cells rely on the protective bone marrow microenvironment in order to survive and this is particularly crucial for the myeloma progenitor cell. The interactions between the bone marrow niche and plasma cells have been well studied. The importance of several cytokine and adhesion molecule networks including interleukin 6 (IL-6), tumour necrosis factor α (TNFα), B-cell

Table 53.2 Frequency of translocations associated with the immunoglobulin heavy-chain gene enhancer

Translocation	Frequency	Gene
t(4;14)	11%	MMSET/FGFR3
t(6;14)	<1%	CCND3
t(11;14)	14%	CCND1
t(14;16)	3%	MAF
t(14;20)	1.5%	MAFB

activating factor (BAFF), and hepatocyte growth factor (HGF) has been established [41].

MYC dysregulation

MYC dysregulation is associated with poor prognosis and aggressive disease features. It is present in 15–20% of patients at diagnosis [42, 43]. It can be the result of the (8;14) translocation described previously but *MYC* translocations do not always involve the *IGH* gene, with 40% of translocations involving different partner genes. Moreover, when the *IGH* locus is involved, the breakpoint does not usually occur within switch regions or V(D)J sequences, and the translocation is often complex with more than two chromosomes involved or with associated segmental amplification or inversion [44]. In addition, *MYC* may be upregulated through mutations or other mechanisms [45].

Dysregulation of intracellular pathways

Ras/Raf/MEK/ERK. This pathway is involved in regulation of cell proliferation, differentiation and survival. There is a high frequency of mutations in the ERK pathway shown by whole-genome sequencing (*NRAS* 24%, *KRAS* 27%, and *BRAF* 4%) [37]. This suggests that the ERK pathway is crucial to myeloma cell development.

PI3K/Akt/mTOR. Upregulation of PI3K enhances cell survival by reducing apoptosis. Whilst there are no mutations seen in the PI3K pathway it is known to be deregulated with phosphorylated AKT, indicative of PI3K activity, in 50% of cases. IL-6, IGF-1, and HGF all induce Akt phosphorylation, which in turn activates several downstream targets including mammalian target of rapamycin (mTOR), GSK-3B, and forkhead transcription factor (FKHR). Akt activation has been linked to resistance to dexamethasone-induced apoptosis, mediated through inactivation of capsase-9 [46]. In addition, DEP domain-containing mTOR-interacting protein (DEPTOR) is upregulated, often as a result of MAF translocations [47, 48].

NF-kB. The NF-kB pathway is upregulated in myeloma cells and causes disruption of cell cycle and apoptotic pathways. It also has a role in bone marrow stromal cells where it triggers cytokines such as Il-6 and BAFF [49–54]. 11q, 16q, and 14q deletions, some interstitial copy number gains, and some mutations affect genes involved in the Nf-kB pathway further indicating that upregulation of this pathway is important in myeloma.

JAK/STAT. This pathway has been shown to be upregulated in 50% of myeloma samples [55].

Clinical presentation

Myeloma causes clinical disease though the accumulation of malignant plasma cells in the bone marrow which secrete a monoclonal immunoglobulin called a 'paraprotein'. Presenting symptoms include anaemia in 50–75% of patients, hypercalcaemia (15%),

Table 53.3 Myeloma defining events. Clonal bone marrow plasma cells >=10% or biopsy proven bony or extramedullary plasmacytoma and either evidence of end organ damage (1) or a biomarker of malignancy (2)

(1) Evidence of end organ damage that can be attributed to the underlying plasma cell proliferative disorder specifically:	
Hypercalcaemia	Serum calcium >0.25mmol/L (>1mg/dL) higher than the upper limit of normal or >2.75 mmol/L (>11 mg/dL)
Renal insufficiency	Creatinine clearance <40ml /min or serum creatinine >177umol/L (>2 mg/dL)
Anaemia	Haemoglobin value of >20 g/L below the lower limit of normal , or a haemoglobin value <100g/L
Bone lesions	One or more osteolytic lesions on skeletal radiography, CT or PET-CT.
(2) Any one or more of the following biomarkers of malignancy:	
Clonal bone marrow plasma cell percentage >= 60%	
Involved:uninvolved serum free light chain ratio >=100	
>1 focal lesions on MRI studies

renal impairment (20%), and bone disease (70–80%) [56–58]. These clinical features are part of the diagnostic criteria for initiating treatment in myeloma (Table 53.3) [58, 59].

Lytic bone lesions

The cellular proliferation of myeloma cells in the axial skeleton produces the bone pain and destruction that dominates the clinical picture of myeloma. Malignant plasma cells uncouple the process of normal bone formation by osteoblasts and bone resorption by osteoclasts. The result is osteolytic lesions, which are present in 60–70% of patients at diagnosis [60]. Lytic lesions increase the risk of skeletal-related events defined as pathological fractures, spinal cord compression, the requirement for radiotherapy or surgery, and hypercalcaemia. Although bone pain may be gradual in onset, pathological fractures are frequent and are usually indicated by the sudden onset of local tenderness and pain. Fracture may be caused by minor trauma. Loss of height due to collapse of vertebrae and kyphosis are common.

Hypercalcaemia

Bone destruction releases calcium into the blood resulting in hypercalcaemia. Approximately one-fifth of patients will be hypercalcaemic at presentation and about half of these will have symptoms on close questioning. Many more patients will become hypercalcaemic during the course of their illness. Symptoms include nausea, vomiting, polyuria, polydipsia, constipation, or confusion. Characteristically, despite hypercalcaemia and radiological bone destruction, the serum alkaline phosphatase is not greatly raised because of the lack of osteoblastic bone regeneration.

Immunoparesis

Myeloma patients are immunosuppressed and susceptible to bacterial infections, particularly with gram positive bacteria. The causes

of this immunodeficiency are complex but mainly involve abnormalities of immunoglobulin production. Patients may be hypogammaglobulinaemic and demonstrate an impairment of the primary immune response, while the secondary immune response and cellular immunity remain relatively preserved in untreated patients. The risk of infection is particularly important in early phases of anti-myeloma therapy. In cases of hypogammaglobulinaemia and recurrent infection intravenous immunoglobulin supplementation may be helpful. Patients with MGUS may also be immunosuppressed with an increased risk of developing bacterial and viral infections at twice the rate of controls [61, 62].

Renal failure

20–30% of patients have renal impairment at diagnosis and up to 10% may require dialysis [63]. The most direct mechanism of renal failure is a result of the precipitation of immunoglobulin free light-chains in the lumen of the distal tubule causing intratubular obstruction resulting in interstitial inflammation and fibrosis and classical cast nephropathy. Light-chains may also cause damage in the glomerulus, such as that seen in amyloid light-chain amyloidosis (AL) and light-chain deposition disease, or in the proximal tubule which characteristically presents with acquired Fanconi syndrome or progressive renal fibrosis [64]. Renal failure can also be caused by hypercalcaemia leading to dehydration, infection, contrast media, non-steroidal anti-inflammatory drugs, and (rarely) as a result of renal vein thrombosis. These factors may also precipitate cast nephropathy. The presence of a high urine albumin should raise the suspicion of amyloid deposition or light-chain deposition disease [65]. The advent of tests to monitor light-chains in the blood has enabled early intervention prior to renal failure to reduce serum free light-chains.

Cytopenias

Bone marrow occupancy by plasma cells reduces the ability of normal bone marrow precursors from developing, leading to anaemia, thrombocytopenia, and neutropenia. Anaemia is often compounded by low erythropoietin levels due to renal failure.

Hyperviscosity

Symptoms of hyperviscosity may be seen with very high concentrations of monoclonal protein (typically IgA >40g/L or IgG >60g/L) which may lead to hypervolaemia. The clinical hyperviscosity/hypervolaemia syndrome includes a predisposition to bleeding, particularly from mucosal surfaces, and dilatation and segmentation of retinal and conjunctival veins. A range of central nervous system disturbances are seen, characterized by headache, drowsiness, weakness, and confusion that may progress to epileptic fits, paralysis, and coma. Symptomatic hyperviscosity should be treated as a medical emergency.

Soft tissue plasmacytomas

Extramedullary plasmacytomas may be present at diagnosis and involvement of almost every organ has been described. Extradural deposits may occur with resultant cord compression.

Cryoglobulins

Some 5% of myeloma paraproteins can precipitate in the cold [66] but this usually does not result in clinical problems. Occasionally, cryoglobulinaemia in myeloma can produce vascular problems, leg ulcers, and Raynaud's phenomenon as well as renal, central nervous system, and gastrointestinal disorders. Biopsies will usually show a vasculitis. In severe cases, peripheral gangrene, renal failure, severe purpura, or gastrointestinal perforation can result, so that vigorous treatment of the underlying myeloma and avoidance of cold exposure is indicated.

Other biochemical findings

Hyponatraemia and a low anion gap

Cationic proteins can lead to an artefactual hyponatraemia associated with retention of chloride and bicarbonate, leading to a low anion gap, usually not requiring treatment.

Hyperlipidaemia

The finding of high- and low-density lipoproteins to paraprotein has been described, which can lead to the clinical syndrome of xanthomatosis and marked serum lipidaemia.

Hyperuricaemia

Hyperuricaemia results from an increased cell turnover and decreased renal excretion of urate; theoretically, this could be a factor in the development of renal failure in myeloma. Prophylactic allopurinol is widely recommended at the time of initiating treatment.

Diagnostic investigations

Patients with a detected paraprotein or clinically suspected myeloma should be investigated as outlined in Figure 53.3. Specific clinical scenarios prompting investigation include:

- Unexplained anaemia, hypercalcaemia, or hyperviscosity
- Identified serum or urine paraprotein/abnormal serum free light-chain ratio
- Lytic lesions detected on radiological imaging
- Cast nephropathy, amyloid or light-chain deposition on biopsy (renal or other)
- Immunoparesis
- Plasma cells seen on blood film

Tables 53.3 and 53.4 summarize the International Myeloma Working Group (IMWG) diagnostic criteria for myeloma, asymptomatic myeloma, and MGUS updated in 2014.

The investigations essential to make the diagnosis of myeloma and stage the disease are described in the following section.

Detection and quantification of the monoclonal protein

This is done by serum and urine electrophoresis (SPEP/UPEP) where the abnormal accumulation of a large amount of protein of exactly the same size causes a 'spike' that can be quantified. This detects the whole immunoglobulin molecule that is overproduced. The presence of a spike of any level is always abnormal though may be due to a number of different underlying causes and is not always indicative of a neoplastic process. The type of paraprotein present is identified by immunofixation, which uses antisera specific to the different potential immunoglobulin types to identify them.

More recently, assays have been developed to identify the production of light-chains, which are usually produced in excess of heavy-chains during the antibody development process and so are likely to be detectable at high levels when immunoglobulin

(A)

Blood tests	Bone marrow	Imaging studies	Protein studies
Full blood count and Erythrocyte Sedimentation Rate (ESR)	Aspirate for morphology, flow cytometry iFISH and cytogenetics	As per local protocols to look for evidence of myeloma related bone disease.	Serum protein electrophoresis, immunofixation and M-protein quantification
Serum Urea and electrolytes (U+Es) and live function (LFTs)	Trephine	MRI in case of suspected cord compression	Serum immunoglobulins
Serum albumin, calcium and uric acid	See part (B), (C) and (D)	See part (E), (F), (G), (H)	Serum Free light chain levels and ratio
B_2 microglobulin			Urine electrophoresis and immunofixation
C-reactive protein (CRP)			24 hour urine for creatinine clearance and urinary protein or urinary protein: creatinine ratio
Lactate dehydrogenase (LDH)			
Vitamin B12 and folate			
Coagulation screen			
Blood film			
Fig. 53.3 (A) Basic diagnostic work up for myeloma/suspected plasma cell dyscrasia. In patients with MGUS, bone marrow and imaging studies are not considered essential provided there is no evidence of end-organ damage and the disease is classified as low risk for progression, i.e., IgG paraprotein <15g/L with normal SFLC ratio and no symptoms or other clinical features of concern. (B) Haematoxylin and eosin stain (× 60) of bone marrow trephine demonstrating asynchronous plasma cells in a patient with relapsing myeloma. (C) CD138 immunohistochemical staining (× 10) of bone marrow trephine highlights plasma cell infiltrate and enables quantification. (D) Bone marrow aspirate (× 60) demonstrating abnormal plasma cells including binucleate forms in a newly-diagnosed patient. (E) Whole-body diffusion weighted MRI demonstrating multi-focal bone disease throughout the axial skeleton. (F) 18F-FDG PET-CT of a 67-year-old myeloma patient with widespread FDG avid sites of disease infiltration seen in the skeletal system. (G) Sagittal T1 weighted MRI, and (H) axial T2 weighted MRI. Images show classical malignant collapse: bulging posterior cortex, involvement of pedicles, and soft tissue component causing compromise to the spinal canal.
Fig. 53.3 Continued

production is in overdrive. They may be overproduced along with a detectable paraprotein and are called serum free light-chains (SFLC). The use of free light-chain assays, however, has also enabled the detection of measurable protein in patients who would have been previously classified as non-secretory (i.e., without a detectable paraprotein or urine protein by SPEP or UPEP but with an infiltrate of plasma cells on bone marrow) [34]. Rare true non-secretory disease is, therefore, now classified as the absence of paraprotein by SPEP, immunofixation and UPEP, and normal SFLC analysis. In a cohort of 2709 MRC myeloma trial patients in the UK, 85% secreted a whole paraprotein (56% IgG, 27% IgA and 2% IgD). In those who produced a whole paraprotein there were sufficient FLC secreted to exceed the renal threshold and become detectable in urine in 70%; in over 90% the SFLC ratio was abnormal. In 13% of the total cohort only SFLC were secreted and just 2% were oligo/non-secretory [67].

Assessment of plasma cell infiltration by bone marrow aspirate and trephine

The proportion of plasma cells in normal bone marrow is usually less than 4% of nucleated cells, although a working level of 5% is often taken as normal. In reactive plasmacytoses, the proportion of plasma cells may exceed 30%, emphasizing how difficult it is to define a normal level for plasma cells. The morphology and distribution of plasma cells can help in distinguishing reactive from malignant proliferations. The morphological features that differentiate malignant plasma cells from their normal counterparts include a considerable variation in size, shape, basophilia, nuclear maturity, and the number of nuclei present within the plasma cells [68, 69]. The trephine biopsy is most useful in distinguishing reactive plasmacytoses from myelomatous infiltration. Normal plasma cells usually occur singly and in close proximity to the bone marrow microvasculature. In myeloma, this distribution is altered and plasma cells are situated between fat cells away from the vasculature. Within the bone marrow the plasma-cell infiltration is uneven, so that the percentage infiltration in a single trephine biopsy might not be representative of the level of infiltration in the marrow as a whole. When infiltration is heavier, in addition to focal deposits it can become diffuse.

A sample of the bone marrow aspirate should also be sent for flow cytometry assessment. Flow cytometry allows the determination of neoplastic vs normal plasma cells. This is done by using antibodies,

Table 53.4 International Myeloma Working Group criteria for diagnosis of other plasma cell dyscrasias

	MGUS	Light-chain MGUS	Smouldering myeloma
Clonal plasma cells present in bone marrow	<10%	<10%	≥10% but <60%
Monoclonal protein	Serum: <30 g/L Urine: <500mg/24hrs	Serum: None but abnormal serum free light chain ratio (<0.26 or >1.65) with elevated level of involved light chain. Urine: <500mg/24hrs	Serum: ≥30 g/L Urine: >=500mg/24 hr
End organ damage attributable to underlying plasma cell proliferation	No	No	No
Other features	Non-IgM in most cases precedes progression to myeloma or solitary plasmacytoma. IgM – more likely to progress to Waldenström's macroglobulinaemia

labelled with fluorescent moieties, against cell surface markers known to be present in different patterns on normal or malignant cells. Myeloma plasma cells show abnormal patterns of expression of cell surface proteins with under-expression of CD19, CD 27, and CD45, over-expression of CD38, CD138, and CD56, and asynchronous expression of CD20. They express only one type of light-chain, kappa or lambda, consistent with monotypic features. Several other cell surface glycoproteins, present on normal cells but over-expressed on myeloma plasma cells, have been identified and are also targets for therapy. These include CS1 (CD319/SLAMF7) a cell surface receptor that belongs to the signalling lymphocytic activation molecule (SLAM) family and HM1.24 (CD317), a transmembrane glycoprotein.

Cytogenetics

Previously the only way to analyse cytogenetics in myeloma was by G-banded chromosome profiling of chromosomes in metaphase. The problems with this technology are the time and cost involved, and that metaphases are often not achievable and reciprocal translocations can be missed. Interphase fluorescence in situ hybridization (FISH) is now commonly used, with fluorescently-labelled probes which hybridize to the regions of DNA of interest. This remains an expensive technique, however, and for this diagnostic information to be more widely available and at a lower cost, new modalities—particularly to look for translocations associated with adverse outcomes—are being developed, such as polymerase chain reaction (PCR) techniques [70].

Bone imaging

Skeletal survey has been the gold standard for the detection of myeloma-associated lytic lesions, which appear as radiolucent areas on plain film skeletal survey of at least the skull, ribs, pelvis, entire spine, and both humeri and femora. The procedure is time-consuming, interpreter-dependent, and not very sensitive; in addition, it is necessary to lose >30% of trabecular bone to detect a lytic lesion on a plain film. There is also difficulty in detecting bone healing and a new vertebral collapse, for example, may not necessarily represent new disease.

There is increasing evidence for the use other imaging modalities, including low-dose CT, whole-body diffusion-weighted MRI, PET-CT, and standard MRI. Low-dose CT can image all bones and more accurately assess the extent of bone destruction, identifying lesions that would not appear on a skeletal survey. It does not, however, give any further information about activity or viability of tumour cells. By contrast, MRI and PET-CT give a more functional image as they can provide a surrogate for tumour activity. Using MRI scanning, signal changes can indicate when the marrow is infiltrated by tumour cells. In addition, MRI is the best way to image the spine. It can detect lesions in areas difficult to interpret on plain films, determine the presence and extent of spinal cord or nerve root compression and identify soft tissue masses. A spinal MRI should be performed in all patients otherwise classified as smouldering myeloma to rule out lesions that would prompt treatment. PET-CT is able to identify metabolically active lesions by the uptake of fluorodeoxyglucose (FDG) in cells with high glucose demand but is not as sensitive as MRI at detecting lesions in the spine.

Each modality, therefore, has advantages and disadvantages and should be considered based on the clinical history and availability until clinical trial data is available to further inform choice. The radiation dose of each approach should also be considered in an era where patients are surviving beyond ten years. These more sensitive imaging techniques can upgrade disease in a number of cases, which may have an impact on response and progression data from clinical trials. It is important to note that isotope bone scans are not useful in myeloma because the lesions are lytic and do not take up the scan isotope which recognizes sclerotic lesions only.

Disease risk assessments

Monoclonal gammopathy of undetermined significance (MGUS) risk stratification

The risk of progression from MGUS to myeloma has been linked to the size of the paraprotein (>15g/L), type of paraprotein (non-IgG), and the concurrent presence of an abnormal free light-chain (SFLC)

ratio [71]. The absolute risk is 5% at 20 years for patients with no risk factors with this increasing to 21% with one risk factor, 37% with two and 58% with three. Flow cytometry can also provide useful information regarding risk of progression with the percentage of clonal plasma cells correlating with risk along with the trajectory of increase in the paraprotein. These risk factors should be considered when approaching the workup of a patient with apparent MGUS. However, the consensus opinion is that a bone marrow aspirate and imaging investigations may not be indicated in cases where the paraprotein is an IgG <15g/L and the SFLC ratio is normal, provided there are no other clinical features of MM.

Smouldering risk stratification

The risk of progression from smouldering myeloma (SMM) to multiple myeloma has been shown to be increased with the coexistence of paraprotein level >30g/L and >10% plasma cells in the bone marrow [71]. In another study, the presence of aberrant plasma cells by immunophenotyping and the presence of immunoparesis predicted for shorter time to progression [72]. It is becoming increasingly clear that there are two populations of SMM: one with a poor prognosis and rapid transition to myeloma and the other behaving more like MGUS. Separating these subtypes of disease accurately is difficult using flow cytometry alone, although gene expression profiling may help.

Myeloma risk stratification

Diagnostic investigations can be used to assess disease risk. The international staging system (ISS) scoring system has now replaced the previously used Durie-Salmon criteria. The ISS risk stratification combines β_2 microglobulin (β_2M) and albumin at diagnosis and correlates with disease outcome, even in the era of novel therapies. For stage I, serum β2 microglobulin is <3.5 mg/L and albumin ≥35 g/L; stage II does not meet the criteria for stage I or III, and stage III serum β2 microglobulin is ≥5.5 mg/L [73].This essentially combines an assessment of the burden of disease and renal function (β_2M) with an assessment of overall patient condition (albumin). Using this model, patients are classified in three groups with very different median overall survival: 62 months for stage I, 44 months for stage II, and 29 months for stage III. However, MM is a heterogeneous disease at the cellular level and an increased knowledge of the impact of genetic events combined with the ISS can give improved prognostic accuracy. The most important genetic predictors of an adverse outcome are the t(4;14), del17p, and 1q+ abnormalities. The IMWG has therefore divided patients into iFISH-ISS groups with group I comprising those patients with ISS stage I or II with no adverse cytogenetic lesions, group 2 ISS 3 with no adverse lesions or ISS stage I with an adverse lesion, and group 3 ISS stage II or III with an adverse cytogenetic lesion. The four-year progression-free survival (PFS) and overall survival (OS) estimates are 44%, 23%, and 12% for PFS and 76%, 52%, and 33% for OS, respectively (p <0.0001 in each case), showing that the criteria were clearly prognostic. Accuracy was confirmed on subgroup analysis according to age, treatment strategy, etc. [74]. In addition, it has been shown that accumulating more than one adverse genetic lesion predicts for a worse survival [75].

A number of different gene expression signatures using microarrays technology have been reported. Although the technology used is now well understood and validated there is very little overlap in signatures defined by different groups [76, 77]. This lack of concordance may signify different aspects of myeloma biology and attempts are being made to unify gene expression profiling prognostic signatures using prognostic modelling [78].

Other predictors for a poor response to therapy and shorter OS include the presence of blastic morphology and renal failure at diagnosis. The purpose of using these risk stratification approaches should be to move away from treating all myelomas alike to tailoring treatment towards a particular risk group. Several groups have developed models for this but none has yet been universally adopted [79].

Response assessment

Disease response can be monitored by repeat measurement of the serum paraprotein and serum free light-chains. It is important to remember, however, that the half-lives of these vary from two to four hours for SFLC to 25 days for IgG, which should be considered when interpreting results. Repeat bone marrow aspirates are performed to look for evidence of plasma cells by morphology both on the aspirate and trephine. More recently, multiparameter flow cytometry, clonal specific PCR techniques and next-generation sequencing approaches have become available to look for a low level of plasma cells remaining that would not be visible using other techniques and in the absence of an abnormal paraprotein or SFLC analysis. This is termed minimal residual disease (MRD). PCR techniques are time-consuming, whilst flow cytometry is more widely available. Using standardized, eight-colour flow panels, the presence of one malignant cell in 1×10^6 cells can be detected.

The response of disease to treatment has been standardized and the IMWG criteria are shown in Table 53.5 [80]. The inclusion of the stringent complete response (sCR) criteria, including the absence of MRD by flow cytometry and a normal SFLC ratio, reflects the correlation between MRD negativity and improved survival [81, 82]. The clinical benefit rate (CBR) for a drug is defined as the proportion of patients achieving at least a minimal response (MR) to a treatment. This is used for responses to agents given in the relapsed disease setting when the depth of response is less critical but disease control is a more central focus.

Management at diagnosis

Patients with myeloma-defining events (criteria in Table 53.3) require immediate treatment as without treatment OS is only ten months. Increasingly, agents have become available that modify the natural history of disease and can prevent end-organ damage. These have improved outcomes with significant numbers of survivors at ten years, leading some investigators to talk of a cure for myeloma [83]. In addition, these agents are being increasingly evaluated earlier in the natural history of the disease such as in high-risk smouldering myeloma, especially for younger patients.

Monoclonal gammopathy of undetermined significance/smouldering myeloma

There is no evidence that any intervention currently available is able to delay the progression of MGUS to myeloma. Therefore, at this stage there is no indication that population screening would be of benefit. Once identified, MGUS patients should be followed depending on their risk of transformation to multiple myeloma. The risk of progression remains fairly constant throughout the lifetime of an individual and so follow-up should be lifelong. Several conditions have been linked to MGUS indirectly associated with

Table 53.5 International Myeloma Working Group response criteria

sCR (stringent complete response)	As CR (below) plus normal SFLC ratio and absence of clonal plasma cells by immunohistochemistry or flow cytometry
CR (complete response)	Negative immunofixation of serum and urine Disappearance of any soft tissue plasmacytomas and <5% plasma cells in bone marrow (In the case of SFLC only myeloma CR also requires normalization of SFLC ratio)
VGPR (very good partial response)	Serum and urine M-protein detectable by immunofixation but not on electrophoresis or >= 90% reduction in serum M-protein plus urine M-protein level <100 mg/24hrs (In the case of SFLC only myeloma then reduction in the difference between involved and uninvolved SFLC by >= 90%)
PR (partial response)	>= 50% reduction of serum M-protein and reduction in 24 hours urinary M-protein by >= 90% or to <200 mg/24 hrs If the serum and urine M-protein are unmeasurable, a >= 50% decrease in the difference between involved and uninvolved SFLC is required In non-secretory myeloma a >= 50% reduction in bone marrow plasma cells (provided baseline was >= 30%) If soft tissue plasmacytoma present the >= 50% reduction in size
SD (stable disease)	Not meeting criteria for sCR, CR, VGPR, PR, or PD
PD (progressive disease)	Increase of >= 25% from lowest response value in one or more of: Serum M-protein (absolute increased must be >= 5g/L) Urine M-protein (absolute increased must be >= 200 mg/24hrs) If serum and urine M-protein are unmeasurable, the difference between involved and uninvolved SFLC (absolute increase must be >100 mg/L) Bone marrow plasma cell percentage (absolute percentage must be >10%) Bone lesion or soft tissue plasmacytoma (or the development of new lesions) Or Development of hypercalcaemia that can be attributed solely to the plasma cell proliferative disorder
Only used in the setting of response assessment for novel agents used in relapsed refractory patients:	
MR (minimal response)	>= 25% (but <= 49%) reduction of serum M-protein and reduction in 24 hr urine M-protein by 50–90% plus 25–50% reduction in size of plasmacytomas if present and no increase in number of bone lesions
CBR (clinically beneficial response)	MR, PR, VGPR, CR, and sCR combined

the paraprotein and these should be monitored during follow-up. These include an increased risk of infections as a result of immunodeficiency from a reduced level of uninvolved immunoglobulins [14], osteoporosis [84, 85], venous thromboembolism [86] and malignancy [87]. Patients with osteoporosis should be managed with bisphosphonates and calcium/vitamin D supplements. Related to their paraprotein, patients may develop cryoglobulinaemia, neuropathy, and renal impairment. If patients develop severe symptoms directly attributed to the MGUS clone, then treatment to eradicate the clone should be initiated.

Patients with high-risk MGUS (defined as paraprotein >15g/L, non IgG paraprotein, or the presence of an abnormal SFLC ratio) and those meeting the criteria for asymptomatic myeloma should be followed-up in a specialist haematology clinic. Trials of treatment of high-risk smouldering myeloma show that early intervention may be beneficial, with some studies already reporting an increased OS for early treatment [88]. It is recommended that patients with high-risk smouldering myeloma should receive bisphosphonate therapy [89].

Serious conditions, discussed in the following section, manifested by a small paraprotein that should be actively managed include POEMS syndrome and amyloid (discussed below).

Myeloma treatment

Strategy

The ultimate aim of myeloma treatment is to completely eradicate the clonal plasma cells to achieve a cure. In many cases this is not achieved and the goal shifts to maintaining a low level of disease for as long as possible, postponing relapse and the point at which patients require further treatment. The depth of response to treatment predicts for time-to-progression, so that achieving maximal response, where no clonal cells are detectable by any currently available technologies, is the target of initial therapy (Figure 53.4).

Current strategies of treatment utilize blocks of therapy, termed induction and consolidation, to exert as much pressure as possible on the clonal cells, using different modalities of treatment in each, so that subclones resistant to the first type of chemotherapy given may also succumb. Consolidation therapy can be in the form of
Fig. 53.4 The graph shows the hypothesized tumour bulk on the y axis with the number of clonal cells present. At present our diagnostic criteria (CR, VGPR, etc.) define a small range of reduction in tumour cells. Trial data suggests that the greater the reduction in tumour bulk for example achieving an sCR rather than PR following ASCT is associated with a longer overall survival. Reducing the tumour burden still further by the use of consolidation chemotherapy may improve outcomes further. Improved methods of detection of residual clonal cells to lower levels may help us make more informed decisions about further treatment requirements enabling the reduction of tumour bulk still further and ultimately curing patients of disease.

an autologous transplant and/or further blocks of chemotherapy, given after or without autologous transplant. Maintenance chemotherapy involves continuing treatment to kill remaining myeloma stem cells as they come into cell cycle and to control any residual cells. The aim of maintenance is to modify the disease biology and prolong survival; it is of crucial importance for a maintenance regimen to maintain quality of life.

The mainstay of induction treatment over the past ten years has been the so-called 'novel' drugs bortezomib, a proteasome inhibitor, and thalidomide and lenalidomide, immunomodulatory agents. In the UK, five-year survival rates increased from 26% between 1996–2000 to 37% between 2005–2009. Median OS for younger, fitter patients eligible for autologous stem cell transplant is now greater than six years, with a recent study in the US showing median OS not reached at 5.9 years of follow-up for those <65 years and 5.0 years for those aged >65 years. These improvements in OS were particularly notable in the older population [83]. The majority (62%) of patients included in this analysis received a lenalidomide-containing regimen with >90% receiving at least one novel agent. PFS also continues to improve; in patients treated with bortezomib-containing regimens PFS was 35.9 months for those eligible for autologous stem cell transplant (ASCT) in a recent meta-analysis [90]. This compares to 20.3 months for those receiving a thalidomide-containing regimen in a meta-analysis of transplant-ineligible patient trials [91]. As treatment continues to improve, it takes longer for survival data to mature so that surrogate markers of benefit, e.g., response rates, are increasingly important.

The improvements seen in survival rates have mainly been for patients with low-risk disease as defined by cytogenetics. Patients at higher risk are generally either poorly responsive or resistant to first-line treatment or have a good response but relapse quickly. It is thought that their outcomes could be improved by using more intensive chemotherapy regimens followed by continuous therapy in order to achieve and maintain remission.

Novel agents are commonly given in combination with steroids (dexamethasone or prednisolone) and with the oral alkylating agents melphalan or cyclophosphamide. The use of anthracyclines, such as doxorubicin, has declined since the arrival of novel agents but are still used in certain situations. Benefit from combining two novel agents has also been demonstrated. The modes of action and side effects of commonly used drugs are summarized in Box 53.1.

When deciding on a treatment schedule for myeloma patients it is important to consider both the age and comorbidities of the patient. Younger, fitter patients generally have their response to induction chemotherapy consolidated with an autologous stem cell transplant whilst older or less fit patients likely will not tolerate the intensive chemotherapy given during this procedure.

Younger/fitter patients
Induction

The novel agents thalidomide, bortezomib, and lenalidomide have significantly improved patient outcomes. They are used as induction therapy for myeloma in two, three, or four drug combinations, which are capable of inducing rapid disease response and lasting remissions. Which drugs are combined in the first-line setting should be determined by patient factors such as pre-existing neuropathy (for lenalidomide and thalidomide) or the presence of renal failure, which may require the avoidance of certain therapies, and tumour factors. For example, there is evidence that bortezomib can overcome the poor prognosis associated with the t(4;14) cytogenetic lesion and also is the most effective agent for patients presenting with renal failure. The availability of certain drugs in specific clinical settings or limitations by funding bodies or regulatory approvals in different countries also need to be taken into account.

Benefit has been demonstrated from the combination of novel agents with dexamethasone and a third agent (often the alkylating agent cyclophosphamide). Clinical trials have demonstrated benefit from the use of three drugs over two [104, 105]. Four drug

Box 53.1 Drugs used in myeloma

Bortezomib (Velcade®) is a proteasome inhibitor, which works by multiple mechanisms including targeting the unfolded protein response (UPR), inducing endoplasmic reticulum (ER) stress, inhibiting NFkB and suppressing several anti-apoptotic proteins [92]. It is usually given as a 21-day cycle of treatment with subcutaneous injections twice weekly for two weeks followed by a week off. Common side effects include thrombocytopenia, peripheral neuropathy, autonomic neuropathy, gastrointestinal toxicity, and fatigue. The use of the subcutaneous administration route and weekly dosing has reduced the incidence of neuropathy compared to intravenous use [93]. There are standard dose reduction protocols shown in the summary of product characteristics to be followed in the event of these side effects occurring during treatment. Bortezomib is commonly given in combination with the steroid dexamethasone and the alkylating agent cyclophosphamide. It may also be combined with immunomodulatory drugs with evidence that this improves response rates. Bortezomib is safe to give even at low GFR and due to this and its rapid reduction in tumour bulk is considered standard first-line treatment in patients presenting with renal function. There is some evidence that it can overcome the adverse risk associated with t(4;14) myeloma.

Thalidomide was the first in the family of immunomodulatory drugs (IMiD) to be used in the treatment of myeloma. It has been shown to block several pathways important for disease progression in myeloma. It was initially investigated due to its known anti-angiogenic properties but also inhibits IL-6, activates apoptosis and augments natural killer cell function and number thereby enhancing the anti-myeloma immune response [94–96]. More recently, it has been shown that many of these effects occur as a result of IMiDs binding to the intracellular protein cereblon and it is reported that low cereblon expression is correlated with drug resistance and poor survival but measuring cereblon levels is difficult and we need antibodies that can measure the protein and studies to address the impact of reduction in its expression level [97, 98].

Thalidomide is usually given continuously as a 21-day cycle. Common side effects include peripheral neuropathy, constipation, fatigue, bradycardia, skin rashes, thyroid dysfunction and, rarely, cytopenias. When given in combination regimens it is associated with an increased risk of thromboembolism and so thromboprophylaxis is given whilst patients are on therapy. The teratogenic effects of thalidomide should be carefully considered and patients counselled to avoid pregnancy; both in females of childbearing potential and in the partner of male patients. Schemes for pregnancy counselling and regimens for testing are followed strictly prior to prescribing. It is commonly given with dexamethasone and cyclophosphamide. It may also be combined with proteasome inhibitors or older agents such as bendamustine.

Lenalidomide (Revlimid®) is a newer, more efficacious, oral IMiD with a similar mechanism of action to thalidomide but with a slightly different side effect profile with a higher incidence of cytopenias but lower risk of peripheral neuropathy. It is usually given as a 28-day cycle with three weeks of daily treatment followed by a week break due to the higher incidence of cytopenias. The risk of teratogenicity persists. Combination treatment

with dexamethasone is usual. Lenalidomide is renally excreted and so needs to be dose reduced in renal failure with close monitoring of haematologic toxicities in case it accumulates.

Bendamustine is an anti-tumour agent with mechanisms of action similar to both alkylating agents and purine analogues. It can induce both single and double strand breaks in DNA, which are more durable than those seen with other agents, and result in impaired DNA synthesis and repair [99, 100]. It is administered intravenously and commonly given on days one and eight of a 28-day cycle or one and two of a 28-day cycle. Studies have demonstrated efficacy in relapsed myeloma in combination with steroids and novel chemotherapy agents. Due to its similarity to purine analogues it is recommended that patients who receive bendamustine should have irradiated blood products to prevent the risk of transfusion associated graft-vs-host disease [101].

Melphalan is an alkylating agent and can be given intravenously, for example as the high dose chemotherapy prior to ASCT or as oral tablets for older, less fit patients often in combination regimens.

Cyclophosphamide is an alkylating agent, which has substantially less mutagenic toxicity than melphalan [102]. It is administered orally in combination with either IMiDs or proteasome inhibitors as part of induction or relapse regimens. It is also used as a mobilization agent for stem cell harvesting.

Doxorubicin (Adriamycin®) is an anthracycline which was previously commonly used as induction treatment for myeloma. Its use has been superseded following the introduction of novel agents, however, it is still used in certain contexts, for example in the treatment of highly aggressive or proliferative disease. It has well-recognized side effects of cardiotoxicity with cumulative dosing and can also cause hair loss, cytopenias, and will discolour urine for 24–48 hours after administration.

Corticosteroids usually dexamethasone or prednisolone, have activity against myeloma as single agents but also show additive and synergistic activity with other chemotherapeutic agents and are included in almost all combination regimens.

Pomalidomide is a new generation IMiD which has a high potency in vitro and a similar side effect profile to lenaliomide. It has anti-angiogenic, anti-proliferative (NFkB inhibition), pro-apoptotic, and immunomodulatory properties including downregulation of inflammatory cytokines and stimulation of cytotoxic T-cells. It is structurally similar to lenalidomide and thalidomide but differs functionally and in its side effect profile, the most common side effects being myelosuppression and venous thromboembolism. It is an oral drug, recently licenced, and is administered on day 21 of a 28-day cycle in combination with low-dose dexamethasone. Pomalidomide plus low-dose dexamethasone prolonged PFS to 4 months vs 1.9 months for patients treated with high-dose dexamethasone alone in a recent phase III clinical trial [103].

Carfilzomib is a new generation epoxyketone proteasome inhibitor which irreversibly binds and inhibits the 20S subunit of the proteasome. This leads to more sustained inhibition. It is more potent that bortezomib in vitro and demonstrates less cross reactivity with off-target enzymes with lower rates of peripheral neuropathy in early stage clinical trials. A phase III trial directly comparing bortezomib and dexamethasone to carfilzomib and dexamethasone in the relapse setting is ongoing. Its use earlier

in the disease course is also being investigated in three or four drug combinations both in young patients and the elderly. Other proteasome inhibitors in development include NPI-0052 (marizomib) which inhibits all three catalytic subunits of the 20S proteasome and MLN9708 (ixazomib) which is administered orally.

combinations published to date show no further benefit over three, largely due to increased toxicity [106], however the availability of new agents with better side effect profiles are enabling this to be studied further in current trials. Regimens commonly used with good response rates include:

- Bortezomib (Velcade®) and dexamethasone—VD [107]
- Cyclophosphamide, bortezomib, and dexamethasone—CVD [108, 109]
- Cyclophosphamide, thalidomide (Thalomid®), and dexamethasone—CTD [104]
- Lenalidomide (Revlimid®) and dexamethasone—RD [110]
- Bortezomib, thalidomide, and dexamethasone—VTD [111]
- Bortezomib, lenalidomide, and dexamethasone—VRD

These regimens have not been evaluated in head-to-head clinical trials, but examples of their response rates following induction chemotherapy from different trials are shown in Figure 53.5.

Two approaches to induction treatment are either to give a fixed number of cycles or to continue treatment to maximum response prior to stem cell transplant. There are no data comparing these approaches directly; however, trial data suggests that reaching a complete response to induction treatment is associated with prolonged PFS and OS [104, 112, 113].

Autologous stem cell transplant

Consolidation of response to induction therapy with an autologous stem cell transplant (auto-ASCT) following high-dose melphalan is the current standard of care in fit patients, supported by several large phase III studies [114, 115]. Induction treatment aims to maximize response whilst preserving bone marrow stem cell function and enabling stem cell harvesting. Patient stem cells are mobilized using growth factor granulocyte colony stimulating factor (GCSF) and/or cyclophosphamide chemotherapy and collected from peripheral blood by apheresis. There is little evidence generated from comparison of mobilization regimens; pragmatically, harvesting is better at maximum response with only low levels of residual disease and seems to be associated with less myeloma cell contamination of the stem cell product. In patients who fail to mobilize with these regimens, it may be due to continued infiltration of the bone marrow in which case further treatment may be appropriate. The aim at the time of harvesting is to collect enough stem cells for more than one possible autologous stem cell transplant and to store cells for patients in case they are needed for a repeat transplant in the future.

The standard dose of melphalan administered prior to stem cell return is 200 mg/m², with a lower dose used in renal failure. Carefully selected patients can increasingly be maintained at home after this procedure until they become neutropenic, at which point they should be reverse-barrier nursed in hospital. Studies have evaluated the use of tandem autografts, a second autograft shortly after the first, with results suggesting late benefit in patients who do not respond to the first [116, 117] and trials are ongoing to address the value of this approach. While the necessity of auto-ASCT in the era of novel therapies is being questioned, currently available evidence suggests that it remains the standard of care for younger, fitter patients.

Allogeneic transplant

Allogeneic transplant (allo-ASCT) has previously been described as the only way of achieving a 'cure' in myeloma. This is mediated via a graft-vs-myeloma effect, whereby the donor lymphocytes recognize the myeloma cells as 'foreign' and destroy them. This effect is demonstrated by achieving a complete response of disease with repeat donor lymphocyte infusions [118]. However, the graft-vs-myeloma effect is not very strong and so it is essential that patients are in very good and stable remissions prior to allograft and it cannot be relied upon to eradicate aggressive end-stage disease. This had led to the use of an allo-ASCT prior to mini-allograft as an effective strategy.

Allografting has significant transplant-related mortality and risk of graft-vs-host disease with associated morbidity, especially in the elderly. Trials to assess allografts in the context of molecularly defined high-risk disease at presentation are currently underway to further inform the place of allografting in myeloma.

Consolidation

Achieving a complete response following induction and ASCT predicts for longer survival [119]. However, improving the response to the level of the relatively recently defined sCR—where minimal residual disease is no longer detectable—is even better [81, 120]. Strategies to achieve sCR include the use of consolidation chemotherapy after ASCT. This can improve response rates, a benefit that has been demonstrated with the use of single-agent bortezomib [121] and bortezomib combined with thalidomide/dexamethasone [122] showing benefit over thalidomide/dexamethasone alone. The triplet combination also improved PFS. Lenalidomide has also been used in this setting with improved response rates when given after a single ASCT [123]. Further trials are ongoing with lenalidomide in combination with bortezomib and also comparisons of consolidation with a second ASCT or bortezomib, lenalidomide, and dexamethasone, or no consolidation.

Maintenance

Maintenance therapy has been used historically in myeloma with alkylating agents, steroids, interferon and, most recently, thalidomide. Steroids and interferon have shown improved PFS, and interferon was associated with a statistically significantly improved OS in a large meta-analysis [124], but use was often accompanied by side effects limiting prolonged treatment [125–127]. Thalidomide as a maintenance treatment is associated with improved PFS but with less clear impact on OS [128–130]. The MRC Myeloma IX study showed a prolonged PFS, though not OS, for thalidomide in patients with favourable cytogenetics, and no prolonged PFS and a worse OS for patients with unfavourable cytogenetics [131]. This result is supported by one previous study [128] though the results are different in other studies [132]. Meta-analyses showed an OS benefit [133–135] but there are limitations to the use of thalidomide maintenance; for example, early cessation of treatment is evident with the median duration of therapy on the MRC Myeloma IX study only nine months for younger, fitter patients.
Fig. 53.5 An example of response rates (VGPR or CR) with different regimens for transplant eligible (younger, fitter) patients. It should be noted that these data are taken from different trials with varying populations and some are based on small single-centre experiences that have yet to mature with survival data. It demonstrates, however, an overview of the differences between older agents such as VAD or CVAD, the use of doublets such at TD or VD and the improved responses seen with triplet or quadruplet regimens.

VGPR, very good partial response; CR, complete response; VAD, vincristine, adriamycin, dexamethasone; CVAD, cyclophosphamide, vincristine, adriamycin, dexamethasone; TD, thalidomide, dexamethasone; VD, bortezomib, dexamethasone; PAD, bortezomib, adriamycin, dexamethasone; CTD, cyclophosphamide, thalidomide, dexamethasone; vtD, bortezomib, thalidomide, dexamethasone (reduced doses of bortezomib and thalidomide); VTD, bortezomib, thalidomide, dexamethasone (standard doses); VRD, bortezomib, lenalidomide, dexamethasone; CVRD, cyclophosphamide, bortezomib, lenalidomide, dexamethasone.

The newer and more tolerable IMiD (structural and functional analogues of thalidomide) lenalidomide has more recently been used in trials of maintenance therapy with promising results and demonstration of prolonged OS in one of three studies [123, 136, 137]. There have been some reports of an increase in second primary malignancies with the use of lenalidomide [138] but the absolute risk is very low, likely to be outweighed by the benefit of maintenance treatment. Taken together with data post-ASCT and at relapse long-term exposure to this agent is beneficial.

The impact of maintenance with bortezomib is difficult to determine as it has been used following different induction regimens in clinical trials. It has been shown to be safe and tolerable, however, either as a single agent or in combination with thalidomide [130, 139] and its use is being further investigated.

Older, fit patients

There is no consensus of the age at which ASCT is contraindicated. Decisions regarding whether to use this treatment should be based on individual patients' biological status and an informed decision following discussion between doctor and patient. Pragmatically, in our experience, it is rarely appropriate to use full-dose ASCT in those much over 70 years. Until recently, for those not thought to be fit for ASCT, melphalan and prednisolone (MP) had been the standard of care. The addition of novel agents to this regimen has improved outcomes, although with slightly higher rates of side effects for the combinations of melphalan, thalidomide, and prednisolone (MPT); cyclophosphamide, thalidomide, and dexamethasone (CTDa); and melphalan, bortezomib, and prednisolone (VMP) [91, 113, 140, 141]. The use of lenalidomide and low-dose dexamethasone for this group of patients is also becoming increasingly attractive due to its excellent tolerability with good safety and efficacy data for this group of patients in the relapsed setting [142]. A first line phase 3 study comparing MPT to lenalidomide plus low-dose dexamethasone for 18 cycles or lenalidomide plus low-dose dexamethasone to disease progression shows an OS and PFS benefit for the latter treatment [143].

Frail, older patients

Human aging is associated with deterioration in physiological reserve including organ function and haematopoietic reserve. As 37% of myeloma patients are over the age of 75 at the time of diagnosis, a significant number will fall into the category of frail and elderly and will not be able to tolerate full drug doses [144]. They are more likely to have co-morbid conditions and so will be more susceptible to side effects and drug interactions. Their OS is shorter than younger or fitter patients. For example, in a recent trial comparing MPR to MP, despite younger patients having good responses and improved PFS, those age >75 years did not have any benefit with 20% of patients discontinuing treatment due to toxicities [145].

It is important to screen for frailty and vulnerability in order to identify this group by using validated indices and also to carefully evaluate cardiac, respiratory, renal, hepatic, and neurological function. Comorbidities, disability, and frailty should be taken into account. Alkylating agents may be inappropriate in the presence of impaired haematopoietic reserve and dose reductions of other agents, especially steroids, should be considered. Specific clinical trials are needed in this group to better define optimum treatments.

Bisphosphonates

Myeloma bone disease is a central feature of MM and is actively managed by bisphosphonates. There is evidence for many bisphosphonates, including clodronate, zolendronic acid, and pamidronate, in reducing skeletal-related events (SREs) and pain [146]. Zolendronic acid has also been shown to reduce SREs following diagnosis, even in patients with no bone disease at baseline and with improved overall survival in a large phase III study [60, 147, 148], suggesting that it may exert a direct anti-myeloma effect. There was continued benefit from the use of bisphosphonates beyond two years in patients who were not in a CR; for these patients administration continues indefinitely [89]. The IMWG consensus recommendations include the use of bisphosphonates for all MM patients receiving first-line therapy, regardless of the presence of osteolytic bones lesions on conventional radiography. This recommendation was made even though as yet it is unknown whether bisphosphonates offer any advantage to patients with no bone disease as determined by MRI or PET-CT.

The side effects of bisphosphonates include renal impairment and osteonecrosis of the jaw. The latter is slightly higher with the use of zoledronic acid compared with other bisphosphonates and a dental assessment is indicated prior to commencing treatment. Renal function should be monitored and dose adjustments made as necessary. Calcium and vitamin D deficiency can be prevented by using supplements.

Myeloma emergencies and complications

Discussion of the management of patients with myeloma tends to focus upon specific measures to reduce the tumour bulk. However, it is also of immediate clinical concern to first treat medical emergencies arising as a result of myeloma.

Spinal cord compression

Cord compression in myeloma can be caused by a spinal plasmacytoma invading into the spinal canal causing compression of the cord in association with a paraspinal mass or as a result of vertebral collapse. Extramedullary deposits of myeloma near the dura may also impact on the spinal canal, but myeloma within the substance of the spinal cord is rare. Patients present with pain in the spine as well as neurological symptoms including numbness, limb weakness, difficulty walking, and loss of bowel or bladder function. Patients should be educated to be aware of the emergence of these signs and symptoms.

As myeloma is a chemo- and radio-sensitive malignancy, optimal management may differ from other cancers. Pain relief should be commenced and urgent MRI imaging of the whole spine is performed to elucidate the exact location, cause, and extent of cord compromise. If the compression is related to bone, surgical intervention may be required. More commonly, it is the result of soft tissue or plasmacytoma encroachment into the spinal canal in a patient with a known diagnosis of myeloma, immediate high-dose steroids and definitive treatment with anti-myeloma therapy is initiated as soon as possible. Radiotherapy to affected spine may also be appropriate. If the diagnosis is unknown and patients present for the first time with spinal cord compression, a neurosurgical procedure to obtain tissue may be required. Patients with spinal cord compression are at high risk of venous thromboembolism due to their immobility and underlying disease.

Vertebral collapse

In patients presenting with acute back pain, vertebral compression fractures should be considered. Balloon kyphoplasty or vertebroplasty may relieve symptoms and improve function and quality of life [89, 149]. This may alter the forces exerted on adjacent vertebrae with risk of further compression, so the whole spine should be carefully imaged prior to intervention. These procedures should not delay the commencement of systemic therapy at diagnosis; sometimes, it may be more appropriate to wait until induction chemotherapy has been completed.

Hypercalcaemia

Treatment of hypercalcaemia must begin with correction of salt and water depletion and high fluid throughput of three to four litres of normal saline per day with careful monitoring of fluid balance and serum electrolytes. The use of loop diuretics will help to maintain fluid output in the rehydrated patient and increase calcium loss in the urine by depressing renal calcium reabsorption.

Amino-bisphosphonates are the drugs of choice for the treatment of hypercalcaemia. When given intravenously, they will rapidly inhibit bone resorption and lower serum calcium levels. Zoledronic acid is more potent at controlling hypercalcaemia than pamidronate and is the bisphosphonate of choice in this setting. Bisphosphonates are remarkably free from acute side effects and normocalcaemia may be sustained for three to four weeks after a single treatment. Doses need to be adjusted in the presence of renal failure.

Hyperviscosity

Symptoms of hyperviscosity include blurred vision, headaches, mucosal bleeding, and heart failure. Symptoms rarely occur until an IgM level of at least 30 g/L, an IgA level of 40 g/L, or an IgG level of 60 g/L are reached [150]. It is possible to measure plasma viscosity; however, the results are often not immediately available. Therapy with plasmapheresis and saline and albumin replacement is, therefore, commenced based upon the presence of symptoms alone. This should also be combined with a strategy to reduce the level of paraprotein directly with systemic therapy.

Renal failure

As previously described, the causes of renal failure in myeloma are multifactorial. Even in patients with apparently normal renal function, the maintenance of a fluid intake of at least three litres per day is important [151]. Precipitating factors of renal failure (such as hypercalcaemia, dehydration, infection, and hyperuricaemia) should be treated, as should the underlying myeloma. Other precipitating factors, such as the use of non-steroidal anti-inflammatory drugs and aminoglycoside antibiotics should be avoided. If the underlying myeloma responds to chemotherapy, renal function should improve and may normalize in many patients. The best responses in renal recovery are associated with a rapid normalization of serum free light-chain levels; the speed of reduction is more important than the agent used. Some agents, such as lenalidomide and cyclophosphamide, need to be dose adjusted whereas bortezomib can be used safely at the usual dose. The use of plasmapheresis to remove light-chains directly from the blood has not been successful [152] but the use of high-cut-off haemodialysis membranes is now being investigated in clinical trials. Patients requiring long-term dialysis for renal failure may still be safely given high-dose therapy and ASCT with a reduced melphalan dose [153].

Pain control

Bone pain is challenging because of its severity and the relationship of pain to movement. Patients may be pain-free at rest but severely limited on any movement ('incident pain') and their analgesic requirements are therefore closely related to mobility. A clinical assessment will often reveal clinical evidence of nerve entrapment or pathological fractures which can be amenable to local measures. However, opiate analgesics remain the mainstay of pain control and specialist pain management teams are often valuable. Non-steroidal anti-inflammatory drugs should be avoided due to the additive risk of renal impairment. Although a sudden exacerbation of pain may indicate a pathological fracture, this can occur in myeloma without radiological evidence of fracture or progression of the underlying disease. In this circumstance, these episodes may be self-limiting, presumably resulting from fractures not visible on radiographs or from subperiosteal haemorrhages. Low-dose radiotherapy (up to 30 Gy) can be beneficial for bone pain and to prevent impending fracture.

Neuropathic pain is a well-recognized side effect of both the proteasome inhibitor bortezomib and the immunomodulatory drugs. It is best managed with dose reductions but calcium channel blockers (such as gabapentin) or serotonin noradrenaline reuptake inhibitors (such as amitriptyline) may also be beneficial.

Fractures

Fractures can occur in any weight-bearing bone or in ribs. Internal fixation of long bones is desirable to minimize pain, speed mobilization, and avoid non-union. Bones at risk of pathological fracture identified on imaging should have pre-emptive internal fixation. Rib fractures are usually managed with analgesia and maintenance of mobility.

Anaemia

The aetiology of anaemia in myeloma is multifactorial, resulting from the combined effects of bone marrow infiltration, renal failure, the blunting of the erythropoietin response by cytokines and the effects of chemotherapy. Adequate specific therapy will usually correct the anaemia in patients responding to treatment and transfusions will maintain adequate control in others. Anaemia may be an indication of active myeloma requiring specific treatment. Recombinant human erythropoietin can be considered [154] although its benefit-risk ratio should be carefully considered, particularly in the context of IMiD treatment which can increase the risk of venous thromboembolism [155].

Prevention of infection

Recurrent bacterial infections are a major cause of morbidity and mortality in patients with myeloma. The risk of infection is highest in the first few months after diagnosis and decreases with response to therapy [156] but still remains the major contributor to early deaths [57]. The most commonly identified pathogens are *Streptococcus pneumonia, Haemophilus influenza*, and *Escherichia coli* [148–159]. Febrile patients with neutropenia or severe systemic infections are hospitalized and given broad-spectrum antibiotics and G-CSF (granulocyte-colony stimulating factor) where appropriate. Aminoglycosides are avoided because of the likely additive impact on renal function. Routine prophylactic antibiotics are not currently recommended. Patients are offered vaccination against seasonal influenza, *Streptococcus pneumonia*, and *Haemophilus influenza*, but the vaccination may not produce an effective response due to defective immune systems. Patients with proven hypogammaglobulinaemia may benefit from prophylactic intravenous immunoglobulin replacement.

Antiviral, antifungal, and *Pneumocystis jirovecci* prophylaxis should be given during and following an ASCT and with other immunosuppressive agents.

Prevention of venous thromboembolism

Myeloma increases the risk of venous thromboembolism (VTE), which occurs in up to 10% of patients, usually within four months of diagnosis. This risk is increased by the use of IMiD drugs; this is negligible when they are used as a single agent but higher when combined with steroids [160] or anthracyclines [161, 162]. When patients are prescribed immunomodulatory drugs in combination regimens they should begin thromboprophylaxis. The type of prophylaxis is determined by individual patient risk, with those at low risk receiving aspirin and those at higher risk either prophylactic low molecular weight heparin or warfarin [163]. Factors in the high-risk category include patient-related factors (e.g., previous VTE, co-morbidities), disease-related factors (e.g., new diagnosis of myeloma, high disease burden, hyperviscosity), and treatment-related factors (e.g., combination with high-dose steroids).

Patient information and psychological support

Patients should be given information about their disease and advised of the steps to take in the event of disease- or treatment-related adverse events, such as neutropenic sepsis, drug reactions, or new symptoms of disease. A multidisciplinary approach to the whole patient and appropriate referrals to psychological and palliative care support are important.

Relapse

Despite improvements in myeloma therapy with the advent of novel agents, disease relapse inevitably occurs in most patients. With progressive relapses, the disease becomes more difficult to treat and progression-free periods between treatments shorten [164].

Monitoring during treatment

Myeloma patients are generally monitored regularly in a specialist haematology clinic, at two- to three-monthly intervals after disease remission. This enables the close monitoring of patient symptoms, blood parameters, and paraprotein/SFLC quantification to enable early detection of relapsing disease. Traditionally, treatment is initiated when there are disease-related symptoms, organ, or tissue impairment (rising calcium, renal failure, cytopenias, new bone lesions) or if there is a steep rise in the paraprotein or SFLC. In the latter case, treatment should be started in the absence of symptoms to prevent rapid clinical deterioration. More recently, with the advent of new drugs which modify the disease natural history, there has been a tendency to start treatment earlier as soon as clinical relapse can be predicted. The IMWG have defined relapse criteria [165].

Investigations at relapse

Relapse should be confirmed by repeating the bone marrow biopsy and imaging. Assessment of risk status should also be repeated. A short PFS, often defined as <one year, following first-line therapy predicts for poor OS Cytogenetic risk factors at relapse are

comparable to those at diagnosis, although there is no clear indication of whether relapsed patients with different risk status should be treated differently. As treatments become available to target specific genetic lesions this will be of even greater importance.

The molecular events acquired as myeloma progresses are not acquired in a linear fashion but in branching non-linear pathways resulting in different clonal populations with different molecular characteristics, a concept termed intraclonal heterogeneity. These clones compete for dominance and at each relapse the dominant clone may have different features. This suggests that the sequence in which treatments with different mechanisms of action are used may affect clonal selection and, therefore, clinical outcomes. It also has an impact on the development of targeted treatments, as a treatment targeting a lesion found in only a minor subclone will not successfully eradicate the whole population. Instead, combination treatments or targeted therapies targeting a 'founder' lesion (i.e., present in a high percentage of clonal cells) should be used.

Assessment of relapse

The age and performance status of the patient at the time of relapse will help determine what type of agents may be tolerable. Side effects often accumulate with therapy and should be carefully assessed, including the presence of neuropathy, risk factors for venous thromboembolism, and the remaining bone marrow reserve. The stage of disease and number of relapses should also be considered; these have been defined by the IMWG to improve consistency in reporting of clinical trials at every stage of disease [165].

Primary refractory disease

Patients are defined as primary refractory if they have never achieved at least a minimal response (MR) to any therapy. This includes patients who have stable disease on all therapies and those who have progressive disease having never responded.

Relapse

Relapse is defined as patients who have had a period of time (at least 60 days) off therapy and have disease progression requiring treatment.

Relapsed and refractory

Patients are described as 'relapsed and refractory' if they have achieved at least MR to prior therapy but have not achieved MR on salvage therapy or relapse within 60 of salvage therapy.

The assessment of disease response to relapse treatment should also be considered differently from induction treatment. Especially in later stages of disease, it becomes more important to maintain a stable disease state rather than aim for complete response. In this setting, the clinical benefit rate (defined as response ≥MR) of an agent should be considered.

Relapsed disease management

Generally, patients who have been treated first-line with a proteasome inhibitor will be commenced on an IMiD-containing regimen or vice versa. If a thalidomide-based treatment has been used first-line then bortezomib is generally preferred at relapse, with lenalidomide reserved for subsequent relapse. If the patient had a good response to previous bortezomib treatment (usually considered as a response of ≥PR lasting >six months) then retreatment with the same agent might be considered [166]. If not, then a new agent should be initiated. Treatment with bortezomib is unaffected by prior lenalidomide [167, 168] and vice versa [169].

For patients who have previously had an ASCT with a disease-free period of 18–24 months, a repeat ASCT is feasible with good response rates with a median PFS of 17 months [170]. Importantly, even if response duration has been short in a relapsed patient with no other therapeutic options, high dose melphalan supported by stem cells may be acceptable.

For patients on maintenance treatment, for example with the IMiD lenalidomide, in addition to increasing the dose to its full therapeutic level it is possible to add another agent to their regimen (e.g., steroids +/− cyclophosphamide) at the first sign of relapse to control their disease without the need to change the chemotherapy regimen completely [171].

Relapsed and refractory disease management

Patients relapsing after prior exposure to both IMiDs and bortezomib have a poor prognosis with a median OS of six months [172]. This is a setting in which novel drugs have been evaluated with accelerated approval in the US. For example, the new generation IMiD pomalidomide has recently been licensed in the US and Europe for patients with MM relapsed and refractory to both bortezomib and lenalidomide [103]. Other options include combinations of novel agents, such as lenalidomide and bortezomib [173], the new proteasome inhibitor carfilzomib (which has efficacy even in patients with bortezomib-refractory disease) [174], or older agents such as bendamustine (see Box 53.1). There have been particularly promising results for antibody-targeted therapies (e.g., anti-CD38, anti-CD138 and anti-CS1). In addition, trials are ongoing for oral proteasome inhibitors, epigenetic therapies including histone deacetylase inhibitors, and molecularly-targeted treatment strategies.

Other plasma cell dyscrasias

Plasma cell leukaemia

Plasma cell leukaemia (PCL) is termed primary if it presents *de novo* or secondary if it presents as the end-stage of multiply-relapsed myeloma. Primary PCL is the most aggressive form of plasma cell dyscrasia and is traditionally characterized by the presence of more than 20% plasma cells in the peripheral blood and an absolute plasma cell count greater than 2×10^9/l [175] although this may underestimate the true incidence [176]. Prospective studies are required to investigate whether a lower cut-off would be more valid as even a few circulating plasma cells may indicate a highly proliferative and aggressive process.

PCL represents a stage of disease where plasma cells are no longer dependent on the bone marrow microenvironment. Patients often present with a high tumour burden and aggressive, rapidly developing clinical symptoms including anaemia, bleeding due to thrombocytopenia, and hypercalcaemia. Markers of disease activity including B_2microglobulin and LDH may be elevated and morphology often reveals anaplastic or plasmablastic plasma cells with a high proliferative index. Loss of interaction with the bone marrow microenvironment is demonstrated by the loss of CD56 on immunophenotyping. Extramedullary disease is common and should be investigated with whole-body imaging techniques. Bone lytic lesions are, however, less common than in myeloma [177]. Prognosis is poor with median OS less than one year in most

studies [177–179] and the improvement in survival for myeloma patients over the last decade has not been seen in PCL.

The goals of treatment are to rapidly control disease to minimize the risk of early death and to achieve complete responses if possible. The high tumour burden places patients with PCL at higher risk of tumour lysis syndrome when chemotherapy is commenced so that strategies to prevent this should be considered. Intensive chemotherapy regimens combining novel drugs, including bortezomib with different classes of chemotherapy and steroids, are often used. Examples include VDT-PACE (bortezomib, dexamethasone, thalidomide, doxorubicin, cisplatin, cyclophosphamide, and etoposide) given prior to ASCT [176]. Bortezomib is thought to improve disease outcome and is used in varying combinations if high-dose regimens would not be tolerated [180–182]. In younger patients, myeloablative or reduced intensity allografts and tandem autografts have also been used if they are in deep stable responses.

POEMS

POEMS is a paraneoplastic syndrome associated with plasma cell dyscrasias. It is characterized by the presence of Polyneuropathy, Organomegaly, Endocrinopathy, Monoclonal plasma cell disorder, and Skin changes. It may also include other features including papilloedema, fluid overload, sclerotic bone lesions, and elevated red blood cells or platelets [183, 184]. In contrast to other plasma cells dyscrasias, the levels of the cytokine vascular endothelial growth factor (VEGF) correlate with disease activity and it is more commonly associated with a lambda light-chain producing plasma cell clones. It should be considered in cases of myeloma where the symptoms are not typical, for example when neuropathy, endocrine abnormalities and volume overload predominate over bone pain.

Certain features of POEMS are associated with a worse overall survival including extravascular fluid overload, respiratory symptoms [185], reduced lung diffusing capacity [186], and fingernail clubbing [187]. There is also a relationship between VEGF levels and response to treatment, with lower levels predicting for better response [188].

POEMS is isolated to a solitary site, like solitary plasmacytoma of bone (SPB) as described, extramedullary plasmacytoma, or isolated to a few lesions of bone with no evidence of bone marrow involvement, then treatment should be with localized radiotherapy with an improvement in symptoms in half of patients [186], although this may take months to occur. The largest retrospective analysis of these patients showed a four-year PFS of 52% and OS of 97%. If there is evidence of a clonal plasma cell population on bone marrow biopsy or other evidence of disseminated disease then radiotherapy is not expected to be curative and treatment with systemic chemotherapy should be initiated even if the plasma cell percentage is very small. The treatment approach follows the same principles as for myeloma, although the low tumour burden often enables the avoidance of induction chemotherapy with its associated side effects, instead proceeding directly to ASCT. ASCT in POEMS is associated with relatively high peri-transplant complications but good long-term outcomes. Patients may have a poor pulmonary reserve as a result of neuromuscular impairment and a reduction in lung diffusion capacity. There is also a relatively high incidence of engraftment syndrome [189]; treatment-related morbidity and mortality can be reduced by actively monitoring and treatment with corticosteroids.

Post-transplant, the observed OS is 94% and PFS 75% at five years [190], with a median survival of 13 years [187].

Symptomatic improvement is often slow but continues over time and has been seen up to three years following treatment. VEGF levels and lesions on PET scanning can be monitored and specific organ response criteria have been suggested. VEGF levels correlate better with disease activity than paraprotein quantification or PET-CT lesions.

Amyloidosis

Amyloidosis is a condition characterized by the deposition of insoluble, fibrillar protein in the extracellular space leading to organ dysfunction. AL amyloid is the term used to describe this protein resulting from the deposition of light-chains produced by clonal plasma cells. These can cause systemic proteotoxicity. AL amyloid can result from myeloma or from a small clone of plasma cells in MGUS. Protein deposition can occur in virtually all organs but predominantly symptoms result from cardiac (70%), renal (70%), liver (17%), neurological (15%), or gastrointestinal (10%) involvement [191]. Amyloidosis may also be associated with coagulopathy due to factor X deficiency, as a result of vitamin K-dependent clotting factors binding to amyloid deposits [192]. Demonstration of amyloid deposition in the tissue is performed by Congo red staining, but further characterization of the amyloid type is also necessary to guide the correct treatment and requires the use of mass spectrometry proteomics. Typing of the amyloid protein is particularly important in MGUS as it is possible for patients with MGUS to have co-incidental AA (a complication of a number of inflammatory diseases and infections) or other types of amyloid protein, the management of which would be very different to that of AL amyloid. Following diagnosis, each organ system should be fully evaluated and investigations to look for clonal plasma cells, if their presence is not already known, should be undertaken. A SAP (serum amyloid P) scan is performed to look for the distribution and amount of amyloid. Cardiac function should also be carefully assessed, which is best done with cardiac MRI scanning.

Prognosis in amyloid is most closely associated with cardiac status. The Mayo clinic staging system divides patients into three groups based on cardiac troponin and NT-BNP (N-terminal pro-brain natriuretic peptide) results with prognosis 3.5 months (stage III, both levels high), 10.5 months (stage II, one level high), and 26.4 months (stage I, both levels normal) [193]. It has been suggested that patients with MGUS and an abnormal SFLC ratio should be screened with regular NT-BNP measurement to prompt investigations to detect amyloid early and to start chemotherapy before cardiac symptoms become apparent [191].

Treatment for amyloid is aimed at rapidly reducing the abnormal light-chain production by targeting the plasma cell clone. In addition to their prognostic role, cardiac biomarkers are also important in determining appropriate therapy. Patients with cardiac disease (high NT-BNP or clinical symptoms) are in a high-risk group for treatment in which aggressive chemotherapies or ASCT would not be tolerated without a high incidence of complications. The presence of cardiac disease should, therefore, be thoroughly investigated and assessed prior to transplant to determine an individual's risk. Patients at high risk need gentler, but rapidly acting regimens; bortezomib is often used. For patients at lower risk, more aggressive chemotherapy and/or ASCT regimens are preferred [191]. If patients do not have overt myeloma, have a low burden of disease,

and have low cardiac risk they can proceed directly to ASCT but may also benefit from consolidation chemotherapy with bortezomib or thalidomide after the ASCT, which has been shown to increase CR rates [194, 195]. Intermediate-risk patients are commonly given melphalan and dexamethasone, which induces good responses [196] although newer agents are being investigated. Where stem cell preservation is important and where improvement in organ function may enable ASCT, melphalan should be avoided and regimens of cyclophosphamide, thalidomide, and dexamethasone or cyclophosphamide, bortezomib, and dexamethasone are used [197]. The aim of treatment is a CR or at least a very good partial remission (VGPR). Haematologic and cardiac response is assessed frequently to enable therapy to be switched to a different agent and prevent progression of target organ damage if there is not a good response.

Solitary plasmacytoma of bone (SPB)

Less than 5% of patients with plasma cell malignancies present with a single bone lesion, a condition known as solitary plasmacytoma of bone (SPB). SPB occurs mainly in the axial skeleton. To meet diagnostic criteria there must be <10% plasma cells on bone marrow biopsy, a single area of disease, and no related organ or tissue impairment. There may be a small paraprotein or abnormal free light-chain ratio. The key to successful treatment is to accurately rule out the presence of disease elsewhere as truly isolated lesions can be treated with radiotherapy alone with the expectation of cure.

Extramedullary plasmacytoma (EMP)

EMP is defined as localized plasma cell neoplasms that arise in tissues other than bone. They occur most commonly in the upper air passages and oral cavity. As with SPB, there must be <10% plasma cells on bone marrow biopsy, a single area of disease, and no related organ or tissue impairment. These cases are often marginal zone lymphomas with plasma-cell differentiation and can be cured with surgical resection (although this is often technically impossible due to the location of disease) or radiotherapy. For patients with EMP that do not respond or relapse, treatment with lymphoma chemotherapy regimens should be considered, as it is more closely related to marginal zone lymphoma than myeloma.

CHAPTER 54

Malignant lymphomas

Frank Kroschinsky, Friedrich Stölzel, Stefano A. Pileri, Björn Chapuy, Rainer Ordemann, Christian Gisselbrecht, Tim Illidge, David C. Hodgson, Mary K. Gospodarowicz, Christina Schütze, and Gerald G. Wulf

Epidemiology

The incidence of lymphomas in the Western world until recently was quoted to be 10–15/100 000 inhabitants per year with rising incidence with age. However, a Surveillance, Epidemiology, and End Results (SEER) study reporting registry data of lymphoma patients by WHO subtype between 1975 and 2001 in the US showed a rising incidence of lymphomas, with a plateau since the mid-1990s with an age-standardized incidence rate of 33.4/100 000 per year [1]. The European HAEMACARE project showed an age-standardized incidence rate of lymphomas according to the WHO subtypes in Europe of 24.5/100 000, which is considerably lower as compared to the earlier reported US data [2]. The distribution of different lymphoma subtypes (excluding plasma cell neoplasms) of the HAEMACARE project are depicted as crude incidence rates per 100 000 in Figure 54.1.

   Both of these studies suggest increasing lymphoma incidences with age and lower incidence rates for lymphoma in women than in men. Improved diagnostic practice and the emergence of infections with the human immunodeficiency virus (HIV) and subsequent acquired immunodeficiency syndrome (AIDS) may partly explain this increase. Interestingly, the US SEER data demonstrated varying incidence patterns for Asian Americans, whites, and blacks with, for example, lower rates of chronic lymphatic leukaemia (CLL) and small lymphocytic lymphoma (SLL) in Asian Americans, which has also been reported in general for Asians. Both hairy cell leukaemia and follicular lymphoma (FL) were found to have higher incidences in white Americans, while plasma cell neoplasias and T/NK-cell lymphomas were found to be more frequent in black Americans. With FL being one of the most frequent non-Hodgkin lymphomas (NHLs) in the US and in Europe, it is rarely observed in developing countries—interestingly, an association of smoking and FL seems to exist [3]. Regardless of race, the SEER data demonstrated a male predominance for Burkitt lymphoma and hairy cell leukaemia. Interestingly, diffuse large B-cell lymphoma (DLBCL) was the most frequent lymphoma in whites and Asian Americans, whereas in African Americans DLBCL was second. These varying incidence rates amongst different ethnic groups, genders, and age groups (with increasing incidence for almost all lymphomas with age) may reflect a major role for host susceptibility in lymphoid malignancies. Hence, national registry data from Germany demonstrate

an increased proportion of NHL and a decreased proportion of Hodgkin lymphoma (HL), consistent with an ageing society, which might be applicable also for other developed countries and societies [4]. Geographical differences were reported in the HAEMACARE project in Europe but speculated to be confounders, due to differences in diagnostic procedures and under-reporting. However, besides diagnostic and regulatory issues, incidence and diagnosis across the world are highly variable since there exist infectious predispositions which are known initiators and mediators of NHL (and HL) such as viral infections with, for example, Epstein–Barr virus (EBV) in endemic Burkitt lymphoma (together with malaria) in the lymphoma belt of Africa [5], HIV-associated EBV-positive Burkitt lymphoma [6], and *HTLV1/2* in T-NHL in southern Japan [7]. Other infection-associated predispositions which are not specifically geographically associated but result in higher incidence of NHL include *Helicobacter pylori* and *Helicobacter heilmani* in mucosa-associated lymphatic tissue-lymphoma (MALT lymphoma), *Chlamydophilia* (formerly Chlamydia) *psittaci* in ocular adnexal marginal zone lymphoma (MZL), *Borrelia afzelii* in cutaneous B-cell lymphoma (also known as borrelial lymphocytoma), and *Hepatitis C virus* (HCV) in MZLs. Furthermore, increased incidence occur in patients who are immunocompromised due to previous cytotoxic therapies such as chemotherapy and/or ionizing radiation therapy, immunosuppressive agents for autoimmune diseases, constitutional immunosuppression in inherited immunodeficiency syndromes, or acquired immunosuppression due to HIV infection. Individuals with AIDS have a 1000-fold increased risk of suffering from NHL, and NHL constitutes one of the AIDS-defined malignancies [8]. Although antiviral therapies effectively prolong the lives of patients with HIV, the risk of developing NHL for HIV-positive patients is higher in those receiving highly active antiretroviral therapy (HAART), whereas NHL is less frequently observed in patients without adequate HIV treatment (which is likely explained by their shorter overall survival). Typically, HIV-positive patients most often present with aggressive B-NHL, advanced stage disease, and often extranodal disease [9]. Another aspect affecting treatment results and survival, which has been demonstrated for other malignancies and which was studied in DLBCL, was that patients with a low socio-economic status (SES) have greater than a one-third higher mortality rate from lymphoma
Fig. 54.1 Crude incidence rates (IR) of lymphoid malignancies per 100 000 in Europe according to the Data of the HAEMACARE project.
CLL, chronic lymphocytic leukaemia; SLL, small lymphocytic lymphoma; PLL, prolymphocytic leukaemia; HCL, hairy cell leukaemia; DLBCL, diffuse large B-cell lymphoma; HL, Hodgkin lymphoma; FCL, follicular cell lymphoma; other BCL (including WMG), other B-cell lymphomas (including Waldenström's macroglobulinaemia); TCL, T-cell lymphoma; CTCL, cutaneous T-cell lymphoma; MCL, mantle cell lymphoma; MZL, marginal zone lymphoma; NLPHL, nodular lymphocyte predominant Hodgkin lymphoma.
Source: data from HAEMACARE.

and from all other non-lymphoma related causes as compared to patients with a higher SES. Additionally, this increased mortality rate was even higher in those patients who were under the age of 65 years or unmarried [10].

Genome-wide association studies (GWAS) using next-generation sequencing (NGS) technologies will help to unravel the geographical differences, differing ethnic incidence ratios, and uneven gender distributions of lymphoma. The roles of certain single-nucleotide polymorphisms (SNPs) as factors for increasing or reducing individual risk for certain NHL subtypes are currently being discovered and interpreted [11–14]. Whether, or how, individual genetic variability needs to be considered in future treatment plans has not yet been properly addressed. International collaborative efforts such as the InterLymph Consortium are currently running advanced molecular epidemiological studies, which will hopefully shed more light on the genetic backgrounds, predispositions, susceptibilities, and their clinical implications for lymphomas.

History

A comprehensive overview of the description, hypotheses, and classifications of lymphomas which have influenced the medical community over the decades is depicted in Figure 54.2. However, as outlined at the end of the previous section, there are currently a multitude of collaborative efforts combining epidemiologic, genetic, and medical data to not only illuminate the mechanistic backgrounds which occur in the heterogeneous group of lymphomas but also to demonstrate how these findings might be translated from bench to bedside to improved patient outcomes. A comprehensive 4th WHO classification of lymphomas was published in 2008 by the International Agency for Research on Cancer (IARC) [15]. The WHO Classification on Lymphoid tumours (see pp. 812–813) depicts the mature B-cell, T-cell, and NK-cell neoplasms as well as HL and post-transplant lymphoproliferative disorders (PTLD). Although many genetic alterations were acknowledged in the 2008 WHO classification, data from microarray studies, GWAS, or mutational profiling were not been taken into account since they were regarded to be premature for inclusion. However, future

classifications will most likely include more genetic characteristics to improve diagnosis, classification, risk-prognostication, and treatment modalities for malignant lymphomas.

Clinical entities

In the daily clinical setting, NHLs are dichotomized as either low-grade or high-grade NHL, with a comparable separation into indolent and aggressive NHL. However, although these distinctions are commonly used, they are poorly defined. In general, aggressive NHL such as DLBCL or Burkitt lymphoma will result in short- or very short-term progressive disease and lead to death when not treated immediately. This depends on the NHL-bulk burden, stage, and accompanying complications. But, when treated appropriately, aggressive NHL now has a high rate of complete remission and long-term survival. On the other hand, low-grade or indolent NHL, such as FL or CLL, might be clinically either asymptomatic or oligosymptomatic, not progressive, and not necessitate the early initiation of therapy. Depending on symptoms, age, and patient preferences, as well as predicted treatment success, patients might be monitored to determine the time when therapy should be initiated. Some patients will never require treatment. However, separating NHL into these two clinical entities also means that some NHLs, such as mantle cell lymphoma (MCL), which are traditionally thought to be indolent may also have courses which are more like aggressive NHL, with fast-progressing and highly-symptomatic disease such that a delay of treatment cannot be advised.

HL is a B-cell-derived malignancy of the lymphatic system. Two groups of histological types are defined: nodular lymphocyte predominant (LP) and the classic HL (CHL), the latter accounting for 95% of all HL cases. This includes four subtypes: nodular sclerosis, mixed cellularity, lymphocyte-rich, and lymphocyte-depleted HL. The annual incidence is about three cases per 100 000. Patients with HL present with indolent lymphadenopathy, most commonly located in the neck, in supraclavicular areas, and mediastinal nodes. About 40% of patients show B-symptoms such as fever, weight loss, and night sweats.

1828 *Carswell*-possibly 1st descroption of HL

1898 and 1902 *Sternberg* and *Reed* – morphologic characterisation of HL

1941 and 1942 *Gall* and *Mallory*- Follicular lymphoma

1958 *Burkitt* – BL in African children

1956/66 *Rappaport* – 1st NHL classification

1974 *Lennert* – Kiel classification

1979 McMichael – 1st monoclonal antibody

1982 *Dalla-Favera* and *Taub* – cloning of *MYC* gene and translocation of *MYC/IGHα* in t(8;14)

1994 *Harris* – REAL classification

2008 *Swerdlow* – WHO classification of Tumours of Hematopoietic and Lymphoid tissues, 4th edition

1882 *Hodgkin* – "On some morbid experiences of the absorbent glands and spleen."

1925 and 1927 *Brill* and *Symmers* – description of "follicular lymphadenopathy"

1947 *Jackson* and *Parker* – 1st HL classification proposal

1964 *Epstein* – EBV in BL

1966 *Lukes* and *Butler* – modern, pathology-based classification of HL

1970s and 80s – recurrent cytogenetic abnormalities in NHL – *Klein* t(8;14) in BL – *Fukuhara* t(14;18) in FL – *Yunis* FL/BL/CLL

Early 1980s *Stein* and *Poppema* – 1st immunohistochemical characterization on frozen and FFPE sections

1994 *Küppers* – IgH gene rearrangements in Reed-Sternberg cells in HL

2000 *Alizadeh* – gene expression profiling in B-NHL

2002 Rosenwald – *gene expression profiling in DLBCL predicts survival after chemotherapy*

2007 *Juweid* – international consensus on 18F-FDG-PET for response assessment in lymphoma

Fig. 54.2 Historical overview of lymphoma from discovery and first description to recent classification systems and genetic studies which might be incorporated in future considerations regarding classifications, aetiology, and pathogenesis.

Other clinically-used terms include the distinction of nodal versus extranodal disease, which are usually included in the Ann Arbor classification or International Prognostic Index (IPI) but do not have any prognostic or therapeutic implications alone, except when affecting adjacent organ function such as pericardial effusion or infiltration into the cerebrospinal fluid (discussed in the next section).

Medical management

Since the type of lymphoma and the areas of involvement vary, clinical symptoms and complications are very heterogeneous. Clinically, aggressive and indolent lymphomas differ with patients suffering from aggressive lymphomas presenting with a short history of lymphadenopathy, organomegaly (especially splenomegaly and hepatomegaly), and B-symptoms (defined by weight loss >10% within six months, night sweats defined by the need to change pyjamas, and fever defined as increased temperatures above 38 °C). Elevated serum markers, reflecting a high cell-cycle turnover of malignant cells, such as serum lactate dehydrogenase (LDH), uric acid, β_2-microglobulin (β_2M), or soluble interleukin-2 receptor (sIL-2R) may be measured. These are most prominent in patients diagnosed with DLBCL, Burkitt lymphoma, T-cell lymphomas, MCL, or B- and T-lymphoblastic lymphoma/leukaemia. In contrast, indolent lymphomas have usually slow-progressing lymphadenopathy or organomegaly and only modest serum marker elevations. The most frequent lymphomas in this category are FL, CLL/SLL, and MZL.

Possible oncologic emergencies amongst malignant lymphomas which might be present at initial diagnosis but can also occur or progress during treatment or relapse include:

- tumour lysis syndrome (TLS)—typically in lymphomas with high tumour burden

- hyperleukocytosis (or even leukostasis)—typically in B- and T-lymphoblastic lymphoma/leukaemia
- hyperviscosity syndrome—typically in lymphoplasmacytic lymphoma due to high IgM serum levels
- pericardial or pleural effusion due to extranodal infiltration leading to cardiopulmonary insufficiency
- spinal cord/intracerebral CNS compression or neoplastic meningitis
- superior or inferior vena cava obstruction
- acute airway obstruction due to mediastinal lymphoma leading to tracheal or bronchial obstruction
- bowel or ureteral obstruction
- venous thromboembolism

The approach to a patient with suspected lymphoma includes a meticulous patient history and physical examination, focusing on lymph node sites, extranodal sites such as skin, testis, salivary glands amongst others, pleural or pericardial effusion, vena cava syndrome, and neurologic abnormalities indicative of CNS involvement. Furthermore, it must be emphasized that, whenever possible and desired, fertility preservation by obtaining a germline specimen and subsequent cryopreservation in women and men in their reproductive life time should be planned after definite diagnosis. Laboratory workup should include a complete blood count to assess cytopaenias or hyperleukocytosis, serum-calcium level (albumin-bound calcium and ionized calcium) to assess hypercalcaemia, serum-uric acid level to assess hyperuricaemia, serum-LDH level to assess the tumour burden, prognosis (in aggressive lymphomas), and lymphoma growth and shrinkage during treatment. The latter clinical setting can also be ascertained by

measuring serum-β_2M or sIL-2R. Other routine laboratory studies should include immunoglobulin analysis, HIV and Hepatitis B and C serology, and other standard laboratory analyses for kidney, liver, endocrine function tests as well as coagulation analysis. In B- or T-lymphoblastic lymphoma/leukaemia or MCL, leukaemic dissemination allows for fluorescence-activated cell sorting (FACS) analysis or cytogenetic analysis by conventional G-banding or fluorescent in situ hybridization (FISH) from peripheral blood samples. In case of suspected CNS disease lumbar puncture needs to be performed; CSF should be examined for absolute cell count, cytomorphologic assessment, FACS, and histologic workup including histochemical staining procedures. Gene-expression profiling using microarray technologies is able to distinguish GCB-type from ABC-type DLCBL (GCB refers to germinal centre B-like DLBCL and ABC refers to activated B-like DLBCL). This aids in diagnostic workup and prognostication since GCB-type DLCBL has a better prognosis compared to ABC-type DLBCL [16]. A biopsy of an enlarged lymph node is mandatory for definite diagnosis and classification. Although fine needle aspiration (FNA) is widely used in clinical practice, it should be performed only by trained clinicians and analysed only by specialty-trained cytomorphologists and flow cytometrists [17]. However, FNA might only serve as a screening procedure and might have—especially in the non-well trained setting—a high false-negative rate of diagnosis leading to unnecessary delay and misguided treatment [18]. Therefore, a tissue biopsy of an intact lymph node for complete and accurate histopathology (including histologic, immunologic, molecular, and cytogenetic analysis) is recommended in all cases where a lymph node is accessible for excision. Generally, lymph nodes with a diameter of 1.5 to 2 cm have the highest diagnostic yield [19, 20]. In case lymph nodes are not accessible for excision, computed tomography (CT)-guided biopsies might be performed to obtain tissue for a diagnostic workup. Since approximately one-third of lymphomas present at initial diagnosis with bone marrow (BM) involvement, BM examination by trephine biopsy with at least 2 cm length should be performed in all lymphoma patients at least once at initial diagnosis. Low-grade lymphomas have a higher tendency to be present in the BM while the more aggressive lymphoma subtypes occur more often in the lymph nodes [21].

Routine imaging studies which need to be performed at initial diagnosis include contrast-enhanced CT of the neck, chest, abdomen, and pelvis to accurately stage a patient according to the Ann Arbor staging classification [22]. Positron emission tomography (PET) scanning using ^{18}F-Fluoro-deoxyglucose (^{18}F-FDG), either alone or in combination with CT (^{18}F-FDG-PET-CT), is not only feasible in detecting neoplastic infiltrated/transformed lymph nodes and extranodal sites in high-grade and aggressive lymphomas but is also superior to CT-based staging alone [23, 24]. Although there exist concerns about the reproducibility of ^{18}F-FDG-PET scan interpretation, its definite role for evaluating treatment response in various settings and its unknown prognostic role on the IPI (see Risk prognostication, below), an international consensus set the following recommendations in 2007 [25]:

◆ visual assessment alone is adequate when interpreting ^{18}F-FDG-PET findings as positive or negative, when evaluating response to treatment after completion of therapy

◆ ^{18}F-FDG-PET scanning after chemotherapy or chemoimmunotherapy should be performed at least three weeks—but preferably six to eight weeks after—completion of therapy and eight to twelve weeks after radiation or radiochemotherapy

◆ mediastinal blood pool activity is recommended as the reference background activity to define ^{18}F-FDG-PET positivity of a residual mass ≥2 cm in greatest transverse diameter, regardless of its location

◆ a smaller residual mass or lymph node should be considered positive if its activity is above that of the surrounding background

◆ attenuation-corrected ^{18}F-FDG-PET is recommended

◆ outside of clinical trials or prospective registries, there is currently no routine role for ^{18}F-FDG-PET during the course of therapy

As a result of the 12th international conference on malignant lymphoma in Lugano in June 2013, recommendations were made for initial evaluation, staging, and response assessment of Hodgkin and non-Hodgkin lymphoma [26]. The Lugano workshop led to the following revised criteria (in addition to the above mentioned) for staging and response assessment in patients with lymphoma:

◆ FDG-PET was formally incorporated into standard staging for FDG-avid lymphomas

◆ a modified Ann Arbor staging system is recommended for primary nodal lymphomas

◆ if a PET-CT is performed, a bone marrow biopsy is no longer indicated in patients with HL

◆ a bone marrow biopsy is only recommended in patients with DLBCL if the PET is negative and identifying a discordant histology is important for patient management

◆ FDG-PET should be performed for response assessment in FDG-avid lymphoma , using the 5-point scale, while CT is preferred for low or variable FDG-avid lymphoma

Furthermore, the International Conference on Malignant Lymphomas Imaging Working Group has published a recent summary of recommendations for interpretation of PET-CT scans and the roles of PET-CT for staging, interim PET, and at the end of treatment [27]. These imaging procedures, which partly determine the stage of the underlying lymphoma according to the Ann Arbor classification, however, do not solely prognosticate a patient's individual risk. Over the course of time, individual prognostic scoring systems have been developed for several NHL entities which might be applied for individual risk-prognostication, decision for treatment strategies, and trial designs, discussed in the following section.

Risk prognostication

In 1993, an international consortium published collaborative data on a prognostic model for aggressive NHL [28]. Based on previously reported factors, which might influence patient outcome, the consortium used retrospective patient data to report what has been widely applied since, the International Prognostic Index and the age-adjusted IPI (aaIPI). In the meantime, prognostic indices for other NHL entities have been established for survival prognostication. Interestingly, the IPI and the aaIPI also keep their prognostic value in the rituximab era, with improved outcome within each IPI group but maintaining the order of IPI groups [29]. Nowadays, not

only the original publications but also internet-based calculators or mobile applications based on the original literature can easily be used to calculate these indices.

Pathology of malignant lymphomas

The 4th edition of the WHO Classification

In 2008, the WHO released a new edition of the Classification of Tumours of Haematopoietic and Lymphoid Tissues [30], as the 2001 version had become outdated very soon after its publication (Box 54.1). In line with the concepts of the Revised European-American (REAL) Classification [31], it consisted of a

Box 54.1   2008 WHO Classification: Lymphoid tumours

Precursor B- and T-cell neoplasms

Precursor B lymphoblastic leukaemia/lymphoma

  B lymphoblastic leukaemia/lymphoma, NOS
  B lymphoblastic leukaemia/lymphoma with recurrent genetic
    abnormalities
  B lymphoblastic leukaemia/lymphoma with t(9;22)(q34;q11.2;
    BCR-ABL1
  B lymphoblastic leukaemia/lymphoma with t(v;11Q23); MLL
    rearranged
  B lymphoblastic leukaemia/lymphoma with t(12;21)(p13;22);
    TEL_AML1,(ETV 6-RUNX1)
  B lymphoblastic leukaemia/lymphoma with hyperdiploidy
  B lymphoblastic leukaemia/lymphoma with hypodiploidy
    (hypodiploid ALL)
  B lymphoblastic leukaemia/lymphoma with t(5;14)(q31;q32);
    IL3-IGH
  B lymphoblastic leukaemia/lymphoma with t(1;19)q23;p13.3);
    E2A-PBX1 (TCF3-PBX1)

Precursor T lymphoblastic leukaemia/lymphoma

Mature B-cell neoplasms

Chronic lymphocytic leukaemia/ small lymphocytic lymphoma

B-prolymphocytic leukaemia

Splenic marginal zone lymphoma

Hairy cell leukaemia

Splenic B-cell lymphoma/leukaemia, unclassifiable

  Splenic diffuse red pulp small B-cell lymphoma

  Hairy cell leukaemia

Lymphoplasmacytic lymphoma/ Waldenström macroglobulinaemia

Heavy-chain disease

  Alpha heavy-chain disease

  Gamma heavy-chain disease

  Mu heavy-chain disease

Plasma cell myeloma

Solitary plasmacytoma of bone

Extraosseous plasmacytoma

Extranodal marginal zone lymphoma (MALT lymphoma)

Nodal marginal zone lymphoma

  Paediatric nodal marginal zone lymphoma

Follicular lymphoma

  Paediatric follicular lymphoma

Mantle cell lymphoma

Diffuse large B-cell lymphoma (DLBCL), NOS

  T-cell/histiocyte rich large B-cell lymphoma

  Primary DLBCL of CNS

  Primary cutaneous DLBCL, leg type

DLBCL associated with chronic inflammation

Lymphomatoid granulomatosis

Mediastinal (thymic) large B-cell lymphoma

Intravascular large B-cell lymphoma

ALK positive large B-cell lymphoma

Plasmablastic lymphoma

Large B-cell lymphoma arising in HHV8-associated multicentric
  Castleman disease

Primary effusion lymphoma

Burkitt lymphoma

B-cell lymphoma, unclassifiable, with features intermediate
  between diffuse and

  Large B-cell lymphoma and Burkitt lymphoma

B-cell lymphoma, unclassifiable, with features intermediate
  between diffuse and

  Large B-cell lymphoma and classical Hodgkin lymphoma

Mature T-cell and NK-cell neoplasms

T-cell prolymphocytic leukaemia

T-cell large granular lymphocytic leukaemia

Chronic lymphoproliferative disorder of NK-cells

  Aggressive NK-cell leukaemia

  Systemic EBV positive T-cell lymphoproliferative disease of
    childhood

  Hydroa vacciniforme-like lymphoma

  Adult T-cell leukaemia/lymphoma

  Extranodal NK/T-cell lymphoma nasal-type

  Enteropathy-type T-cell lymphoma

  Hepatosplenic T–cell lymphoma

  Subcutaneous panniculitis-like T-cell lymphoma

Mycosis fungoides

Sézary syndrome

Primary cutaneous CD30-positive T-cell lymphoproliferative
  disorders

  Primary cutaneous anaplastic T-cell lymphoma (ALCL)
  Lymphomatoid papulosis

Primary cutaneous gamma-delta T-cell lymphoma

Primary cutaneous CD8 positive aggressive epidermotropic cytotoxic T-cell Lymphoma

Primary cutaneous CD4 positive aggressive small-medium T-cell lymphoma

Peripheral T-cell lymphoma, NOS

Angioimmunoblastic T-cell lymphoma

Anaplastic large-cell lymphoma, ALK positive

Anaplastic large-cell lymphoma, ALK negative

Hodgkin lymphoma

Nodular Lymphocyte predominant Hodgkin lymphoma

Classical Hodgkin lymphoma

Nodular sclerosis classical Hodgkin lymphoma

Mixed cellularity classical Hodgkin lymphoma

Lymphocyte-rich classical Hodgkin lymphoma

Lymphocyte-depleted classical Hodgkin lymphoma

Post-transplant lymphoproliferative disorders (PTLD)

Early lesions

Plasmacytic hyperplasia

Infectious mononucleosis-like PTLD

Polymorphic PTLD

Monomorphic PTLD (B- and T/NK-cell types)

Classical Hodgkin lymphoma type PTLD.

list of clinicopathologic entities, each defined by the amalgamation of morphology, phenotype, cytogenetics, molecular features, and clinical data along with the recognition of a normal counterpart. The entities were subdivided into accepted and provisional, depending on their unanimous acknowledgment or the need for further validation before definitive acceptance. In particular, by comparison with the previous edition, several well-known lymphoma entities were revised and new entities were included. Thus, among peripheral B-cell lymphomas (BCL), international consensus guidelines were adopted for CLL, lymphoplasmacytic lymphoma (LPL), Waldenström macroglobulinaemia (WM), and plasma cell myeloma (PCM). In the field of CLL, the concept of monoclonal B-cell lymphocytosis (MBL) was incorporated, representing an important practical issue [32]. In addition, the EORTC consensus classification of cutaneous lymphomas was included [33]. The grading of FL was simplified by combining grades 1 and 2 and maintaining grades 3A and 3B. The latter was a matter of debate, since it might be related to DLBCL of the GCB type more than to the remaining FLs. Finally, it was decided to maintain the term FL only for cases with a pure follicular growth pattern. Furthermore, the borders of FL were broadened by

quoting the paediatric, intestinal, other extranodal, and in situ variants. In the section on MCL, in situ and indolent variants were reported as the possible result of multi-step lymphomagenesis. The spectrum of DLBCL was significantly enlarged by establishing the basic distinction between a not otherwise specified form on the one hand and subtypes and special types on the other. Notably, some provisional entities were set up: splenic B-cell lymphoma/leukaemia, unclassifiable (including diffuse red pulp small B-cell lymphoma and hairy cell leukaemia variants), paediatric nodal MZL (to be distinguished from atypical MZ hyperplasia with monotypic Ig expression), EBV-positive DLBCL of the elderly, and borderline lesions between DLBCL and BL or CHL. In particular, the term BCL was considered unclassifiable, with features intermediate between DLBCL and BL. This was applied to cases resembling BL but presented with evident pleomorphism or to typical BL carrying aberrant phenotype and/or genetic features. These cases have a *MYC*-complex karyotype and require treatment as BL [34]. BCL-unclassifiable, with features intermediate between DLBCL and CHL, more often presents in males aged between 30–40 years with a bulky mediastinal mass [35]. Morphologically and phenotypically, it shows features between CHL and DLBCL, especially primary mediastinal large B-cell lymphoma (PMBL) [35]. The behaviour is more aggressive than the one of CHL or PMBL [35]. At the time being, the optimal treatment remains matter of debate.

Peripheral T-cell lymphomas (PTCL) were also extensively revised. The chapters on PTCL-not otherwise specified (NOS) and angioimmunoblastic T-cell lymphoma (AITL) were expanded. The former included the follicular variant; similar to AITL, it is related to follicular T-helper (FTH) lymphocytes [36]. There is increasing evidence that the FTH signature is not restricted to AITL—as originally thought [37]—but does also occur in a group of PTCLs that do not fulfil the diagnostic criteria for AITL [38]. In the 4th edition of the WHO Classification, anaplastic large-cell lymphoma (ALCL) was subdivided into two categories: ALK+ and ALK−, characterized by the occurrence or absence of genetic alterations involving *ALK*. In particular, the former carries the t(2;5) translocation and variants, causing ALK gene and protein over-expression. On immunohistochemistry, the latter is aberrantly detected in the nucleus and/or cytoplasm based on the translocation at work [30]. At the present time, ALK+ ALCL is regarded as a distinct entity, most frequently occurring in children/adolescents and with a good response to therapy if the IPI is below 3 [30]. The genetic aberration that leads to ALK over-expression drives lymphomagenesis and can represent the target for tailored therapies and vaccination. ALK− ALCL is morphologically and phenotypically indistinguishable from the ALK+ form, showing the same 'hallmark' cells, cohesive growth pattern, diffusion through sinuses, CD30 expression (that represents the target of brentuximab vedotin [38]), positivity for cytotoxic markers, possible lack of CD45, frequent EMA expression, variable staining for T-cell markers, general negativity for CD15, PAX5/BSAP, and EBV, and frequent clonal *TCR@* rearrangement [30]. The ALK− ALCL category was debated at the time of the classification writing, since it was argued that it should be combined with PTCL-NOS. Finally, the decision was taken to maintain it distinct from both ALK+ ALCL and PTCL-NOS. This decision has later found validation in studies, which showed that, although more aggressive than the ALK+ form, ALK− ALCL has a response to therapy superior to PTCL-NOS [39]. Also, the gene signature

of ALK⁻ ALCL is distinct from that of PTCL-NOS, revealing instead deregulation of several pathways in common with ALK⁺ ALCL [40]. More recently, massive parallel genome sequencing has allowed the identification of a t(6;7)(p25.3;q32.3) translocation in about 30% of ALK⁻ ALCLs, causing down-regulation of *DUSP22* and up-regulation of *MIR29* micro-RNAs [41]. In the 2008 WHO Classification, the category of enteropathy-associated T-cell lymphoma (EATL) was introduced, which is much more restrictive than the enteropathy-type of the 3rd edition by indicating evidence of coeliac disease (CD). However, a variant of EATL (termed type II) was described that can also occur in the absence of risk factors or clinical signs of CD. This is characterized by monomorphic small-to-medium sized elements, expressing CD8 and CD56, and carrying *MYC* amplifications; it likely represents an entity distinct from EATL. The term 'subcutaneous panniculitis-like T-cell lymphoma' was restricted to neoplasms of peripheral α/β T-lymphocytes, characterized by a five-year OS of about 80% with conservative therapies [42]. Tumours with similar morphology, but γ/δ phenotype, were assigned to a new category termed primary cutaneous γ/δ T-cell lymphoma, with a 15-month OS [42]. Novel entities were the EBV⁺ lymphoproliferative disorders of childhood, related to a cytotoxic defect of the host response to the virus and commonly affecting children in Mexico, Taiwan and Japan [43]. Two variants of the condition are known: systemic EBV⁺ lymphoproliferative disease of children [43] and Hydroa vacciniforme-like lymphoma [44]. The former usually develops within the context of chronic active EBV infection and is rapidly fatal due to the onset of a haemophagocytic syndrome and/or multi-organ failure [43]. The latter, which is associated with insect bites and sun exposure, is limited to the skin and lasts 10–15 years before systemic progression [44]. Finally, the 4th edition of the WHO Classification ruled out the so-called NK/T-cell lymphoma, blastic type that originates from plasmacytoid dendritic cells, and listed some further provisional NK/T-cell entities. These include chronic lymphoproliferative disorders of NK-cells, clinically similar to LGL but lacking both clonality and malignancy [45], primary cutaneous CD8⁺ aggressive epidermotropic cytotoxic T-cell lymphoma, and primary cutaneous CD4⁺ small/medium T-cell lymphoma that is a very indolent condition, simply requiring complete excision when presenting in a solitary form [46].

Present challenges and pathobiology

The frequency of monoclonal B-cell lymphocytosis (MBL) tends to increase with age [31]. The elements sustaining it are clonal and carry the same phenotype as CLL [31]. However, only about 1% of cases progress to overt CLL [31]. Elements carrying the t(14;18) can be frequently detected in the peripheral blood of healthy individuals [41], their incidence becoming even higher in HCV⁺ subjects [47]. Epidemiological studies, however, indicate that this finding does not predict FL development [41]. The same holds true for t(11;14), although its detection is much rarer than that of t(14;18) [48]. Notably, both of these conditions have potential counterparts at the tissue level commonly denoted as FL and MCL in situ [49, 50], although the term 'intrafollicular' would be more appropriate. The former corresponds to the presence of some germinal centres (GCs) consisting of BCL2⁺/t(14;18)⁺ monotonous elements, within the context of an otherwise normal lymph node [49]. The latter is characterized by the accumulation of cyclin D1⁺/t(11;14)⁺ cells in the inner layer of the mantle zone of some

follicles in a preserved lymph node structure [50]. Notably, both conditions undergo progression to an overt lymphoma in only a few patients [49, 50].

Another challenging issue is the occurrence of indolent variants of usually progressive or aggressive diseases. This is the case of 'indolent MCL', clinically characterized by splenomegaly, BM involvement, leukaemic spread, and lack of lymphadenopathy. Immunohistochemistry is negative for SOX11, a finding recently questioned by some authors [51]. Molecular biology indicates a post-GC derivation with a high load of somatic mutations. Notably, SNP arrays reveal one or two genetic lesions instead of the complex karyotype of usual MCL. Examples of FL are analogously encountered in children and adults that turn BCL2⁻/t(14;18)⁻. These are monoclonal at PCR, graded 3A or 3B, and display a very high proliferation rate. Interestingly, they lack *TP53* and/or *MYC* abnormalities in contrast to aggressive FLs that are also BCL2⁻/t(14;18)⁻ [52]. Thus, the distinction of such cases from follicular hyperplasia on the one hand and highly aggressive FL on the other is of pivotal importance. In fact, stage I patients are cured by the excision of the affected node. Similar findings have been reported in the setting of the so-called paediatric-type MZL that—when observed in adults—is cured by surgery [53].

In the 2008 WHO Classification, the diagnosis of some lymphomas still represents an exclusion process. Thus, nodal and extranodal MZLs are reported to be CD5, CD10, BCL6, CD23, and cyclin D1-negative, findings which excludes CLL/SLL, FL and MCL [30]. Very recently, however, a monoclonal antibody against a formalin-resistant epitope, the IRTA1 molecule, has been developed [54]. This reacts with most nodal and extranodal MZLs, but not the splenic variant. Interestingly, its application to more than 2100 cases showed that no other lymphoid tumours are stained with the exception of some DLBCLs with para-sinusoidal distribution (which might also have MZ origin) or of FLs with MZ differentiation. In addition, in conjunction with FISH studies, it showed that the colonization of pre-existing follicles by neoplastic cells is associated with loss of IRTA1 and re-exposure of BCL6 in the absence of CD10, an observation questioning the criteria previously used for the 'exclusion' diagnosis.

As previously mentioned, the opportunity to maintain type II EATL within the same box as type I is matter of debate. In fact, it has recently been reported that most if not all 'type II' EATLs stem from γδ T-lymphocytes, type I being an αβ T-cell tumour [55]. Thus, 'type II' might represent a different entity and thus deserve a different name.

Recently developed high-throughput technologies have allowed in-depth exploration of the mechanisms sustaining the development, progression, and chemoresistance of malignant lymphomas. Relevant information is coming from next generation sequencing (NGS) that can lead to the discovery of mutations driving their pathogenesis. Besides the t(6;7) detected in about one third of ALK⁻ ALCLs, many recurrent genetic aberrations have been discovered in the setting of malignant lymphomas. Thus, all hairy cell leukaemia cases carry a heterozygous mutation in *BRAF* resulting in the BRAF V600E variant protein provided with oncogenic properties [56]. Importantly, this mutation does not occur in other B-cell lymphomas and can represent the rationale for the usage of specific inhibitors of active BRAF [56]. In CLL, NGS has shown that the recurrent *NOTCH1, MYD88*, and *XPO1* mutations are oncogenic and contribute to disease evolution [57]. In particular, Fabbri et al.

[58] reported *NOTCH1* mutations in 8.3% of patients at diagnosis, with prevalence rising up to 31% and 20.8% in patients with Richter transformation and chemorefractory disease, respectively. In conjunction with the fact that they are detected in only 3.2% of MBLs, these findings suggest that *NOTCH1* mutations represent an acquired lesion strictly related to disease progression. The application of NGS to FL and DLBCL has shown that they harbour frequent structural alterations inactivating *CREBBP* and, more rarely, *EP300*, two highly-related histone and non-histone acetyl-transferases (HATs) acting as transcriptional co-activators in multiple signalling pathways [59]. Overall, about 39% of DLBCLs and 41% of FLs display genomic deletions and/or somatic mutations that remove or inactivate the HAT coding domain of these genes. Such lesions are usually mutually exclusive and affect one allele, suggesting that reduction in HAT dosage is important for lymphomagenesis by mediating inactivation of *BCL6* and activation of *TP53*, and drugs targeting acetylation/de-acetylation mechanisms might be effective in this setting. The mutation of *MYD88* has been reported in different lymphoma categories [60]. MYD88 transduces signals from Toll-like, IL1, and IL18 receptors to the NF-κB transcription factors that, in turn, regulate the production of cytokines and anti-apoptotic molecules. It can be the target of specific inhibitors. Whole-transcriptome paired-end sequencing has revealed that *CIITA* (*MHC2TA*) breaks are highly recurrent in PMBL (38%) and CHL (15%) [61]. Functional consequences of *CIITA* fusions are down-regulation of surface HLA class II expression and over-expression of CD274/PD-L1 and PDCD1LG2/PD-L2, respectively, causing reduced tumour cell immunogenicity and antitumour immune responses. Last, but not least, *IDH2* and *TET2* mutations have been reported in PTCLs, the former being associated with AITL [62].

The goal of these technologies is to identify novel targets for tailored therapies. Interesting data have been obtained in PTCL-NOS, which has a poor response to conventional drugs including anthracyclines, with a five-year OS of 20% [63]. Recent gene expression profiling (GEP) studies have provided hints for the usage of tyrosine kinase (TKI), histone deacetylase and proteasome inhibitors [64]. In particular, aberrant activation of tyrosine kinases seems to commonly occur in PTCLs and TKIs have been found effective in ex vivo models [64].

Molecular genetics

Over the last decade, advances in technology and decreasing costs for NSG experiments have greatly increased our molecular understanding of lymphomas to the extent that not only have new categories of lymphomas been defined, but these technologies are becoming increasingly instrumental for the prediction of outcome and for identifying rationally-designed targeted treatments. While the initial landscape of frequent genetic alterations in almost all lymphoma subtypes has been reported, current efforts will shed light on the less frequent genetic alterations and the clonality of genetic events within a tumour sample. Emerging data suggest that single tumour samples harbour multiple genetic drivers and current and future efforts need to fully unveil their complex functional interplay. Therefore, we will now show in certain aggressive B-cell lymphomas how technology has been used to deepen our understanding of the molecular genetics, to predict outcome, and to identify rationally-defined targeted treatments.

Diffuse large B-cell lymphoma

Germinal centre origin

DLBCLs largely originate from germinal centres (GC), where high-affinity antibodies during humoral immune responses are formed by somatic hypermutation (SHM) and where the heavy-chain of the antibody changes from IgM and IgD to IgG, IgA, or IgE by class switch recombination (CSR) [65]. Both processes, SHM and CSR, are associated with DNA strand breaks, single nucleotide changes, small deletions, and duplications in somatic cells [65]. Consequently, these processes and the high proliferation rate in the GC predispose normal GC B-cells to malignant transformation. As a result, DLBCLs exhibit multiple low-frequency genetic alterations including chromosomal translocations, somatic mutations, and copy number alterations (CNAs) [65].

Transcriptional heterogeneity

Given the intrinsic clinical heterogeneity and numbers and types of genetic alterations in DLBCL, investigators have sought additional comprehensive classification systems to identify groups of tumours with similar molecular traits in various settings. By profiling samples at diagnosis and samples from patients who relapse after cyclophosphamide, doxorubicin, vincristine, and prednisone (CHOP), gene expression profiling has been used to identify signatures of resistance in patients [66]. This led to the identification of the protein kinase PKCß as a rational therapeutic target, prompting subsequent preclinical work and resulting in clinical testing of enzastaurin, a PKCß inhibitor, in DLBCL [67].

Transcriptional profiling has also been used to define DLBCL subsets that share certain features with normal B-cell subtypes, leading to the widely used cell-of-origin (COO) classification [68]. COO-defined DLBCLs distinguish tumours that share transcriptional signatures with GC-derived B-cells (GCB-type) and other tumours that share signatures with in vitro activated GC-B-cells (ABC-type), suggesting that each subtype originates from different stages of B-cell differentiation by acquisition of distinct oncogenic events during lymphomagenesis [68]. Therefore, each subtype is characterized by certain biological features, most notably increased NF-κB activity and less favourable outcome in ABC-type DLBCLs (see [68] for details).

An alternative transcriptional-profiling classification, termed comprehensive consensus clustering (CCC classification), identifies DLBCL subtypes solely on the basis of distinctions within primary tumours and includes three groups: B-cell receptor (BCR-type), oxidative phosphorylation (OxPhos-type), and host-response (HR-type) [69]. Within this classification, OxPhos DLBCLs have increased expression of genes regulating oxidative phosphorylation, mitochondrial function, and electron transport, resulting in different fuel utilization and metabolism of the DLBCL cell, a putatively targetable feature [69, 70]. The HR-type DLBCLs have certain genetic features with the pathological defined subtype 'T-cell histiocyte rich B-cell lymphoma'. The BCR DLBCLs rely on tonic B-cell receptor signalling owing to increased expression and activation of members of the BCR-signalling cascade [69, 71]. Hence, these tumours are susceptible to various inhibitors of the BCR-signalling cascade in vitro and in vivo [71, 72]. This led to the clinical development of various BCR-signalling inhibitors, from which SYK and BTK inhibitors are the most clinically advanced and tested in clinical trials [73]. Recently, ABC DLBCLs have been reported to be sensitive to upstream modulation of BCR signalling,

underscoring the importance of targeting this critical survival pathway in DLBCLs [74, 75].

Structural basis of underlying biological heterogeneity

Somatic mutations

The initial landscape of somatic mutations in primary DLBCL was reported by several independent groups which were limited by sample size [76–79]. As a consequence, only ten reported mutations show a high concordance between the four different cohorts using different deep-sequencing approaches (RNA Seq and whole-exome sequencing) suggesting the potential relevance of these identified recurrent mutations. However, this also underscores that to capture the full spectrum of genetic driver events (so-called 'long tail') larger, more comprehensive studies need to be performed.

One of the most frequent events reported in these studies were inactivating somatic mutations in *TP53,* found in only about 20% of patients. This is remarkable, since inactivating mutations of *TP53* in certain solid neoplasms occur in up to 100% of patients [77–80] and suggests that in DLBCL additional means of inactivating *TP53* exists (see Copy number alterations, below). In addition, infrequent mutations in cyclin D3 (*CCND3*) have been reported [78, 81]. While for some of the identified mutations the associated biology has been addressed, for the majority of mutations a functional evaluation is pending. Of note, several gain of function mutations have been linked to be the structural basis of ABC-type DLBCLs, such as activating mutations in *CD79B, MYD88*, and *CARD11* [68, 82, 83]. In addition, mutations in *FBXO11*, which encodes an F-box protein, are important to diminish the post-transcriptional degradation and thereby stabilizing BCL6, a master regulator of DLBCL biology [84–86]. Furthermore, epigenetic modifiers are frequently altered in DLBCL, such as *EZH2, MLL2,* and *MEF2B,* as well as *CREBBP* [74, 76–78, 84] (see also above).

Copy number alterations

Initial work focused on the identification of individual CNAs in smaller cohorts, which resulted in the discovery of deletions in the tumour suppressor genes *CDKN2A, RB1*, and *TP53* [78, 88–90]. With the advent of whole-genome approaches, larger cohorts were analyzed more comprehensively and several CNAs were captured concordantly, especially with respect to their differential distribution across the COO-defined subtypes of DLBCLs [91, 92]. These studies used array Comparative Genomic Hybridization (aCGH) to identify CNAs and tried to link certain CNAs to putative target genes. They reported deletion of 9p24/*CDKN2A*, trisomy 3, and amplification of chromosome 19 to be enriched in ABC-type DLBCLs. Additionally, *REL* amplification on chromosome 2 and deletion of the *PTEN* tumour suppressor are enriched in GCB-type DLBCLs [91, 92].

Recently, higher resolution technologies, such as HD-SNP arrays, allowed a more fine-grained analysis of the precise boundaries of CNAs, the associated candidate 'driver genes', and implicated pathways [93]. By integrating high-density copy number data with transcriptional profiles and performing pathway analysis in 180 primary DLBCLs, a recent study identified a comprehensive set of CNAs within the *CDKN2A-TP53-RB-E2F* axis that decreased p53 activity, perturbed cell-cycle regulation, and provided a structural basis for increased proliferation in DLBCL [93]. Since DLBCLs have infrequent inactivating somatic mutations of *TP53* and *RB1*, these data define an alternative copy number-dependent mechanism of deregulating p53 and *E2F1*-mediated cell cycle progression [93]. Of note, two-thirds of primary DLBCLs had multiple complementary CNA of p53 and cell-cycle components and were named 'complex DLBCLs', while the remaining third largely lacked these lesions ('clean DLBCLs'). Patients treated with rituximab-CHOP (R-CHOP) and with complex CNA patterns had a five-year OS of only 62%, whereas those with clean CNA signatures were all cured [93]. The association between CN complexity and outcome added prognostic value to the IPI and/or transcriptional COO categories [93]. Most interestingly, this genetic signature not only predicts outcome, but is amenable to targeted treatment with pan cyclin-dependent kinase inhibition or BET-bromodomain inhibition in vitro and in vivo [93, 94].

Translocations

Several groups reported independently on the unfavourable prognostic value of aggressive lymphomas that contain chromosomal translocations of both *MYC* and *BCL2*, commonly referred to as 'double hit DLBCL'. Initial reports used this term for DLBCLs with a chromosomal rearrangement, but as the prognosis of patients with positive immunohistochemistry for both oncogenes is also poor, this definition now also includes these cases. These 'double hit lymphomas' occur in both GCB-type and ABC-type DLBCL and their clinical management is a major challenge to active clinical investigation [95–97].

Primary mediastinal large B-cell lymphoma

Gene expression profiling (GEP) has also been used to distinguish a large B-cell lymphoma with evident different clinical features and defined a new entity of lymphoma, primary mediastinal large B-cell lymphomas (PMBL) [98, 99]. In the new WHO classification, PMBL has been fully recognized as its own entity [100]. Patients presenting with PMBL are predominantly women, with a median age of ~35 years old and an inferior outcome with standard treatment [101]. GEP revealed that PMBLs share features of CHL, such as constitutive activation of the NF-κB survival pathway [98–101]. Interestingly, an additional similarity between CHL and PMBL is the amplification of 9p24, resulting in the increased expression of several oncogenes, including *JAK2, JMJD2C*, and the two PD-1 ligands, PD-L1 (*CD274*) and PD-L2 (*PDCD1LG2*) [102, 103]. Thereby, *JAK2* co-operates with the demethylase *JMJD2C* in promoting an open chromatin structure allowing the expression of several survival genes, including *MYC* [102]. Besides promoting proliferation itself, *JAK2* also amplifies the expression of the PD-1 ligands [103, 104]. Both the PD-1 ligands, PD-L1 and PD-L2, are also targets of chromosomal translocation from transcription factor *CIITA* in cHL and PMBL [105]. The multiple genetic bases of deregulated PD-1 expression reflect an effective immune evasion strategy of the CHL tumour cells against infiltrating T-cells [103, 104]. Neutralizing antibodies against PD-1 and PD-L1 were tested in phase III trials with great success, even in diseases without a genetic basis of PD-L1/L2 deregulation [106, 107]. Most notably, this genetic basis of deregulated PD-1 ligand expression prompted the clinical evaluation of PD-1 blockade in CHL. The clinical trial evaluating the PD-1 antibody nivolumumab in multiple pretreated CHL has recently been published, reporting an overall response rate of 87% [108]. This data resulted in breakthrough status assignment by the FDA and is an example of a rationally-defined target by whole genome technologies.

Burkitt lymphoma

Transcriptional profiling was further used to define boundaries between DLBCLs and Burkitt lymphoma (BL) [109, 110]. This distinction is clinically relevant, since BL, also a GCB-derived disease with lower prevalence, resembles DLBCL in some cases morphologically and cytogenetically [100]. However, BL benefits from a more aggressive treatment than DLBCLs upfront. To that end, two independent groups demonstrated that transcriptional profiles derived from classical DLBCL and BL define both entities, but also highlighted an additional molecular BL (mBL). mBL is not morphologically distinguishable from DLBCL, but shares molecular features of BL and has inferior outcome when treated with DLBCL protocols [109, 110].

Multi-step-model-pathogenesis of Burkitt lymphoma

A hallmark event of BL is the translocation of the MYC proto-oncogene into the Ig locus, resulting in deregulated expression of *MYC* in virtual all cases of BL [100]. Transgenic expression of *MYC* leads to increased proliferation, metabolic reprogramming, and increased genomic instability of the transformed cell, and also to increased apoptosis. To overcome apoptosis, additional alterations have been postulated, but besides inactivation of *TP53* no other co-operating transforming event has been implicated in the lymphomagenesis of BL [111]. Recently, two studies have implicated additional activating events, augmenting the BCR signalling through the PI3K pathway as a major second event in the pathogenesis of BL in humans and mice [81, 112]. Human RNA-Seq data were combined with functional and structural data to implicate activating mutations in the transcription factor, *TCF3*, and inactivating mutation in its negative regulator, *ID3*, resulting in augmentation of tonic BCR signalling, and thereby providing the survival signal to overcome the pro-apoptotic part of the transgenic expression of *MYC* [81]. Consistently, mice engineered to express *MYC* and a constitutive active form of PI3K ectopically in GCB cells, resulted in the development of lymphomas after a longer latency, representing a faithful BL mice model [81, 112]. Both studies revealed mutations in cyclin D3 (*CCND3*) as tertiary events in human and mice, resulting in prolonged stability of *CCND3* [81, 112]. Thus, BL requires a multi-step lymphomagenesis, potentially targetable with compounds inhibiting the PI3K pathway and cyclin D-dependent kinases [81, 112].

Chemotherapy

Chemotherapy is the backbone of lymphoma treatment. In 1976 McKelvey et al. [113] established the combination of CHOP (cyclophosphamide, doxorubicin, vincristine, and prednisone) which became the gold standard of treatment in many malignant lymphomas. Depending on the stage of the disease and risk factors, about 30–50% of patients with aggressive lymphomas were cured with CHOP or CHOP-like regimens in the pre-rituximab era. Due to lower proliferative activity, chemotherapy has only palliative effects in indolent lymphomas. Chemotherapy is used in combination with CD20-antibody rituximab in all BCLs today. The majority of chemotherapy trials in the 1980s and 1990s included patients with BCLs as well as those with diseases of T-cell phenotype. However, in patients with (non-cutaneous and non-leukaemic) peripheral T-cell lymphomas, both response and survival after chemotherapy are worse compared to the diseases of B-cell origin [114].

Aggressive B-cell lymphomas

Aggressive B-cell lymphomas represent a clinically-defined group of entities with similar biology and prognosis. In terms of treatment, the category includes the numerous variants and subtypes of DLBCL and grade 3 FLs. MCL is also regarded as an aggressive B-cell lymphoma for which different treatment algorithms are increasingly being identified. The treatment of lymphoblastic, Burkitt and Burkitt-like lymphomas follow the complex chemotherapy concepts of acute leukaemia due to their even more aggressive behaviour.

In the 1980s, several modifications of the CHOP protocol (MACOP-B, m-BACOD, ProMACE-CytaBOM) showed superior response rates (RR) and survival in advanced NHL in phase 2 trials (overview in [115]). However, the results of these complex regimens with up to eight cytotoxic drugs could not be reproduced in a large multicentre trial in the US [116]. In patients with limited disease, combinations of a reduced number of chemotherapy cycles followed by radiotherapy of involved sites has been regarded an effective approach. Longer follow-up of a Southwest Oncology Group (SWOG) trial comparing three cycles of CHOP followed by involved-field radiation (IFRT) vs eight cycles of chemotherapy did not confirm initial promising results in terms of survival advantage for combined modality [117, 118]. Therefore, full-course CHOP-based chemotherapy remains the standard of care for patients with aggressive B-cell lymphomas.

In the 1990s, the German High-Grade Non-Hodgkin Lymphoma Study Group (DSHNHL) evaluated the effects of adding etoposide, which had been shown high single-agent activity in lymphomas, to standard CHOP protocol (CHOEP). Etoposide was given at a dose of 100 mg/m^2 on three consecutive days. In an initial phase 2 study [119], 60 previously untreated patients with aggressive lymphomas (67% with stage III/IV) received six cycles of CHOEP and IFRT. Forty-nine patients (82%) achieved a complete remission, most of them (n = 45, 75%) after the fourth chemotherapy cycle and before radiotherapy was started. Toxicity was manageable. The rate of overall response was 93%; OS depended on stage and lymphoma subtype and was about 50%. The results were reproduced in a phase 3 trial comparing CHOEP with an approach of alternating dose-intensified CHOP and IVEP (ifosfamide, vindesine, etoposide, prednisone), showing no superior benefit for alternating regimens, concluding that both are effective treatment protocols for aggressive histologic-type malignant lymphomas [120].

The second approach of the DSHNHL to improve outcome in aggressive lymphomas was to increase dose intensity by shortening the intervals between treatment cycles. A faster sequence of cytotoxic effects should cause more intense cell death and impairment of tumour regrowth. This concept is based not only on the known strong dose-response relationship in chemosensitive diseases, but also on kinetic models of tumour cell growth and development of chemoresistance [121]. In addition, interval reduction was facilitated by the availability of haematopoietic growth factors, which made the haematological toxicity manageable.

Both methods of intensification (addition of etoposide, interval reduction) were investigated in the large German multicentre NHL-B trial. Between 1993 and 2000 almost 1700 patients with aggressive NHL (B- as well as T-cell lymphomas) were randomized to receive standard CHOP or CHOEP every three weeks (CHOP-21, CHOEP-21) or every two weeks (CHOP-14, CHOEP-14). The

feasibility of the presumably most effective, but also most toxic treatment, with two-weekly CHOEP had been tested in a phase 2 trial [122]. In this pilot study, 30 patients with aggressive lymphomas received a total of 159 cycles of CHOEP-14 chemotherapy. G-CSF was given between day four and 13, and blood counts recovered completely in all cycles. Non-haematological toxicity was tolerable.

The NHL-B trial included ≤60-year-old patients with low-risk (LDH within normal range) aggressive lymphoma (NHL-B1) and all patients aged between 61 and 75 years (NHL-B2). Data of an interim analysis in 959 patients demonstrated that administration of standard-dosed and intensified chemotherapy cycles was safe and practicable in all age and risk groups [123]. For young patients with normal LDH level, CHOEP-21 was identified as the optimal regimen based on outcome and toxicity results. Complete remission (87.6% vs 79.4%, p = 0.003) and five-year-event-free survival (EFS) (69.2% vs 57.6%, p = 0.004) rates were superior to standard CHOP [124]. In contrast, two-weekly CHOP was defined to be the new standard in older patients (CR rate 76.1% vs 60.1% and five-year EFS 43.8% vs 32.5% compared to CHOP-21) [125]. The different results were interpreted to be attributable to the inclusion of patients with highly proliferative tumours in the NHL-B2 trial, whereas in the NHL-B1 study (for the younger population) elevation of LDH was an exclusion criterion. In patients >60, CHOEP-14 was associated with increased toxicities and treatment delay.

The substitution of doxorubicin by idarubicin within the CHOEP-protocol (CIVEP) was investigated in a phase 2 trial. Idarubicin had demonstrated greater cytotoxicity than daunorubicin or doxorubicin in various cell line models and showed reduced cardiac toxicity in clinical studies. However, the use within the CIVEP protocol was accompanied with increased haematotoxicity without improvement in efficacy [126, 127].

The further investigations regarding chemotherapy of lymphoma focused on three items. First, are there six or eight cycles of chemotherapy necessary to cure patients? Second, what are the best chemotherapy concepts for patients with different risk profiles? Third, are there results for treatment intensification reproducible if chemotherapy is combined with rituximab?

Eight vs six cycles of chemotherapy

Treatment of aggressive lymphomas with eight cycles of chemotherapy was established empirically based on the concept of remission 'induction' and 'consolidation' and became the standard of care, which was also used in large multicentre trials [116, 117]. Patients treated in the French GELA LNH98-5 trial, which established R-CHOP combination in first-line treatment of DLBCL, also received eight cycles of immunochemotherapy [128]. The addition of rituximab significantly improved CR-rates (76% vs 63%, p = 0.005) and survival (two-year-EFS, 57% vs 38%, p <0.001; two-year-OS, 70% vs 57%, p = 0.007). Furthermore, risk of early progression and death also were reduced significantly. The results were confirmed with longer follow-up [129].

A randomized comparison of six vs eight cycles of chemotherapy, with or without rituximab, was performed in the RICOVER-60 trial of the DSHNHL [130]. More than 1200 patients between 61 and 80 years with DLBCL were included. The study confirmed the superiority of R-CHOP over CHOP alone. In addition, no further improvement was observed with more than six cycles of CHOP or R-CHOP. Therefore, six cycles of R-CHOP-14 were recommended as the preferred regimen in elderly patients with DLBCL.

Chemotherapy in the rituximab era

The implementation of rituximab in the treatment of aggressive B-cell lymphoma improves patient outcome markedly. Furthermore, the question arose as to whether there are benefits from different strategies of dose intensification.

The role of etoposide-supplemented CHOP was redefined by the MInT-Trial [131]. This international study primarily compared CHOP-like chemotherapy with and without CD20-antibody in young patients (18–60 years) with good-prognosis DLBCL. Different chemotherapy protocols could have been used (CHOP-21, CHOEP-21, MACOP-B, PMitCEBO). While there was a significant improvement of EFS at three years with CHOEP-21 alone compared to CHOP-21 alone, no benefit with CHOEP was demonstrated if chemotherapy was combined with rituximab. Therefore, six cycles of CHOP-21 plus rituximab was defined as a standard of care in the young good-risk DLBCL population.

The optimal number and interval of chemotherapy cycles was addressed again by two large European multicentre studies. First, the French trial (LNH03-6B) included patients between 60–80 years with newly-diagnosed DLBCL and at least one risk factor according to aaIPI [132]. Compared to the German RICOVER-60 study, the LNH03-6B population was slightly older and the risk profile was higher. Patients were randomized to receive eight cycles of R-CHOP-14 or eight cycles of R-CHOP-21. The two-weekly regimen did not improve outcome, but, apart from a higher number of red cell transfusions, did also not increase toxicity. A major finding was that relative dose intensities for cyclophosphamide and doxorubicin were significantly lower in the dose-dense R-CHOP-14 arm after two, four, and eight cycles. This might be attributed also to an inconsistent use of granulocyte colony stimulating factor (GCSF), which was administered in (only) about 90% of cycles in the two-weekly regimen arm.

The second trial was undertaken by the UK Clinical Research Network and compared six cycles of R-CHOP-14 and eight cycles of R-CHOP-21 in adult DLBCL patients [133]. GCSF was given in all patients with R-CHOP-14. The median relative dose intensities of the individual cytotoxic drugs achieved almost 100% of planned doses in both arms. However, superiority of two-weekly chemotherapy could not be demonstrated in any subgroups (e.g., age, risk profile, ABC/GCB phenotype). Therefore, the conclusion was that R-CHOP-21 remains the standard of care in first-line treatment of DLBCL.

Chemotherapy of younger patients in different risk groups

Ongoing efforts target on the identification of different risk groups among lymphoma patients and on the identification of treatment strategies with the best efficacy at minimal toxicity.

Previous trials mainly addressed age or risk-adapted concepts. Algorithms for first-line treatment commonly assign young patients <60 years into a good-risk and a poor-risk group based on the IPI criteria. For poor-risk patients (IPI category high-intermediate and high-risk) more intensive chemotherapy regimen, with or without autologous transplantation, was evaluated in numerous studies. None of them could conclusively demonstrate an improvement in long-term outcome. Treatment with eight cycles of biweekly R-CHOEP showed encouraging efficacy in a randomized comparison with repetitive autografting within the German MegaCHOEP

trial (3-year EFS, 69.5% vs 61.4%; PFS, 73.7% vs 69.8%; OS, 84.6% vs 77.0 %) [134].

A major finding of the MInT trial was that young good-risk patients can be divided in two different prognostic subgroups: favourable (IPI = 0, no bulk) or less favourable (IPI = 1 and/or bulk) [131]. This study also evaluated the question of which size of bulky disease has an impact on outcome. Although the cut-off point remains arbitrary, a diameter of 10 cm was recommended as a suitable margin [135] to define populations with significantly different survival after R-CHOP. Ongoing German multicentre studies are investigating, for the young good-risk patients with less favourable profile, outcomes after six cycles of R-CHOP-14 (vs six cycles of R-CHOP-21) and the effect of a reduced number of chemotherapy cycles (from six to four) in those with favourable prognosis.

The French GELA group studied a more complex approach consisting of induction treatment and consolidation in young good-risk patients (LNH03-2B) [136]. Four cycles of ACVBP chemotherapy (see Table 54.1) combined with rituximab and intrathecal MTX administration once per cycle were administered, followed by sequential consolidation courses including methotrexate,

Table 54.1 Commonly-used chemotherapy regimen in aggressive non-Hodgkin lymphoma

(R)-CHO(E)P [113, 124, 128]	Dose		Route	Schedule
Rituximab	375	mg/m²	iv infusion	day 0 (or 1)

ifosfamide, and cytarabine. This concept was randomly compared to eight cycles of R-CHOP-21; radiotherapy was not permitted. Overall response was not different between the arms. In contrast, OS was significantly better in the R-ACVBP patients (92% vs 84% at three years, p = 0.0071). Toxicity was higher with the intensive regimen but was judged to be manageable. Five deaths unrelated to lymphoma occurred after R-ACVBP, but only three deaths in the CHOP group.

At present, new diagnostic tools and therapeutic approaches are under investigation. Tumour response by interim-PET after two, three, or four treatment cycles has been shown to be predictive for relapse rates and survival in small studies. Whether decision on therapy intensification (or de-escalation) can be made on this information is controversial. Furthermore, the use of new antibodies or signal inhibitors as adjuncts to chemotherapy could be an option in poor-prognosis patients.

Mantle cell lymphoma

Treatment of MCL has been changed over the last decade. The addition of rituximab to chemotherapy, the use of cytarabine, and the implementation of autologous transplant have improved patient outcome markedly [137].

The Houston group demonstrated promising results in patients with aggressive mantle cell lymphomas using a regimen of HyperCVAD alternating with high-dose methotrexate/cytarabine, both in combination with rituximab [138]. After ten years of follow-up, median OS was not reached and the median time-to-treatment failure (TTF) was 4.6 years for the entire study population and 5.9 years for patients ≤65 years. Similar concepts were evaluated by two European trials. Alternating courses of dose-intensified (Maxi-)CHOP and high-dose cytarabine (patients ≤60 years, 4 × 3 g/m^2; patients >60 years, 4x2 g/m^2) followed by BCNU, etoposide, cytarabine, and melphalan or cyclophosphamide (BEAM or BEAC) and stem cell rescue were given to 160 untreated patients in the Nordic MCL2 trial. In long-term follow-up, median OS and response duration were more than ten years [139].

The European MCL Network compared, in a randomized study, six courses of standard R-CHOP with alternating cycles of R-CHOP (× 3) and R-DHAP (× 3) in <65-year-old patients with stage II–IV disease [140]. Responding patients received autologous stem cell transplantation (ASCT) after TBI-containing conditioning. Response rates were high after autografting in both arms (97% vs 98%). TTF was significantly improved after CHOP/dexamethasone/high-dose ara-C/cisplatin (DHAP)/ASCT in all risk groups and there was a better OS for intermediate and high-risk patients. Furthermore, molecular remission was found to be a prognostic factor independent of the mantle cell lymphoma international prognostic index (MIPI), and the number of patients without minimal residual disease (MRD) was significantly higher in the DHAP arm [141].

For elderly patients or patients who are not suitable for intensive chemotherapy, immunochemotherapy remains the standard of care. Rituximab in combination with six to eight cycles of CHOP or six courses of bendamustine (90 mg/m^2 day 1 and 2, q4w) have been shown to be safe and effective regimens [142, 143]. Maintenance therapy with rituximab (375 mg/m^2 q2m) compared to interferon-alpha significantly reduced the risk of progression or death in a randomized trial [142]. Therefore, rituximab maintenance should be given to elderly patients responding to induction

treatment. While rituximab maintenance has also been shown to prolong response duration in relapsed or refractory patients responding to salvage chemotherapy [144], the role is not yet clear in patients after first-line ASCT.

During the last years, treatment options in mantle cell lymphomas were expanded by the development and introduction of new drugs. Temsirolimus, an inhibitor of the mammalian target of rapamycin (mTOR), has demonstrated to be effective in relapsed or refractory MCL. Twenty-two per cent of patients who received temsirolimus 175 mg intravenously weekly followed by 75 mg weekly showed a complete (2%) or partial (20%) response. Median progression-free survival (PFS) was significantly improved (4.8 vs 1.9 months, p = 0.0009) compared to other cytotoxic or antibody regimens [145]. Grade 3 or 4 adverse events were observed in about 90% of patients with temsirolimus, mainly cytopaenias and asthaenia.

A more promising approach is represented by the inhibition of Bruton's tyrosine kinase (BTK). The BTK-inhibitor ibrutinib was investigated in a phase 2 trial for patients with advanced, extensively pretreated, relapsed, or refractory disease. Ibrutinib was given at doses of 560 mg orally per day until progression or toxicity. Sixty-eight percent of patients responded completely (21%) or partially (47%). Median duration of response was 17.5 months. Side effects were mild or moderate, primarily with gastrointestinal symptoms. Grade 3 or 4 haematotoxicity occurred only in about 15% of cases [146].

Nowadays, proteasome inhibitors represent an established treatment option in multiple myeloma. This approach was also tested in patients with MCL. The use of bortezomib as a salvage regimen showed RRs in non-randomized trials in about 30–50% and promising PFS of up to 12 months [147].

Indolent B-cell lymphomas

In contrast to aggressive NHL, in which in almost all cases treatment is indicated after definitive diagnosis, disease management and treatment decisions are more complex in the indolent lymphomas. Although modern immunochemotherapy is able to reduce tumour burden substantially and complete remission can be documented in conventional and PET imaging, these treatment options have no curative potential due to the different biology of these entities.

An algorithm for decision-making in indolent nodal B-cell lymphomas is presented in Figure 54.3. Histological diagnosis should be followed by common staging procedures including CT (or MRI) scans and BM examination. Radiotherapy should be offered to patients in early-stage (Ann Arbor stage I or II, i.e., follicular) lymphoma, because there is a chance for long-lasting disease control, or even cure (dose, technique and results are discussed in chapter 'Role of radiotherapy').

This approach is supported by results from a recent retrospective SEER database study on effectiveness of first-line strategies in stage I FL [148]. Patients who underwent complete ('rigorous') staging had significantly better PFS than those who did not. Patients after systemic treatment (rituximab ± chemotherapy ± radiation) showed significantly improved PFS than patients after radiotherapy alone, but differences in OS were not observed.

A change of strategy has also been observed in patients with advanced, but asymptomatic, indolent lymphomas, with consensus for watchful waiting due to the lack of curative treatment options.

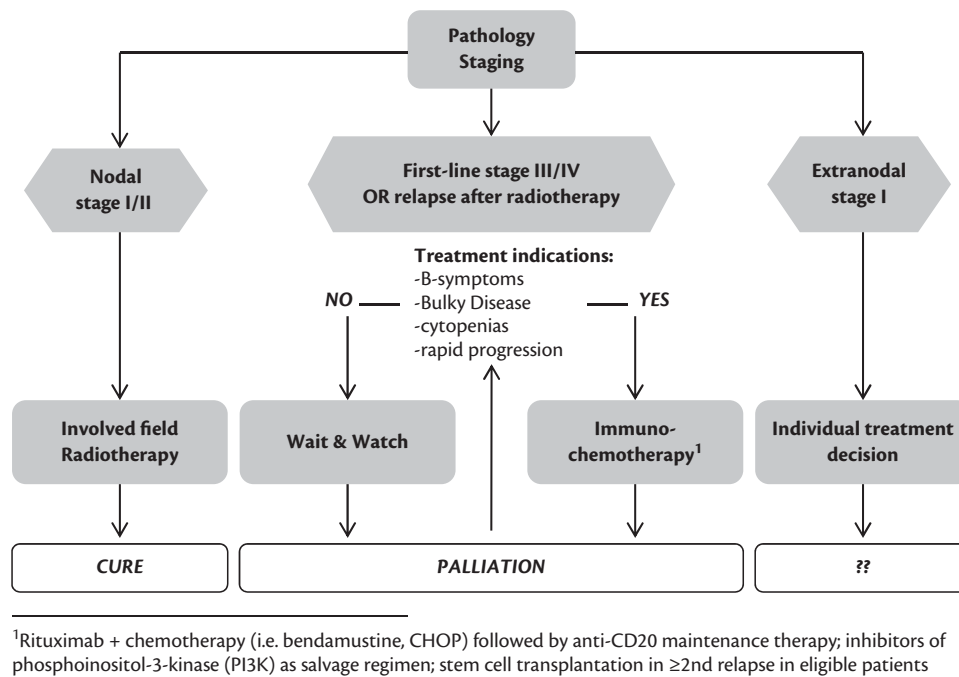
¹Rituximab + chemotherapy (i.e. bendamustine, CHOP) followed by anti-CD20 maintenance therapy; inhibitors of phosphoinositol-3-kinase (PI3K) as salvage regimen; stem cell transplantation in ≥2nd relapse in eligible patients


Fig. 54.3 Algorithm for treatment of decision making in indolent lymphomas (follicular, marginal zone, and lymphoplasmacytic).

A large British trial demonstrated a clinical benefit for patients with advanced stage, but non-bulky and asymptomatic FL, by treatment with rituximab monotherapy [148]. There was a significant longer PFS and time-to-next-therapy in patients who had received rituximab induction (375 mg/m² weekly, × 4) or rituximab induction followed by maintenance treatment (375 mg/m² q2mo × 12) compared to patients with observation only. Toxicity of antibody therapy was limited and also quality of life was not impaired; therefore, rituximab monotherapy should be considered for these patients.

The initiation of systemic treatment is clearly indicated in patients with symptomatic disease. Standard of care is a combination of chemotherapy and rituximab. Induction treatment includes six (to eight) cycles of immunochemotherapy followed by maintenance therapy with rituximab alone. Results with different commonly-used chemotherapy regimen are summarized in Table 54.2. Rituximab significantly improves treatment results, but there are different contributions with several chemotherapy regimens. The Italian FOLL05 [149] trial showed superiority of anthracycline-containing combinations CHOP and fludarabine/mitoxantrone (FM) over cyclophosphamide, vincristine, and prednisone (CVP) in RR and TTF. Data for OS in the different arms are not available because the study was not powered for this analysis. The German GLSG demonstrated in a randomized study higher RRs and reduced haematotoxicity after CHOP compared to MCP (mitoxantrone, chlorambucil, prednisolone) in patients with FL and MCLs [150]. However, there was no impact on survival.

The use of monochemotherapy with bendamustine instead of a combination regimen was investigated by the German STiL group. Bendamustine is an alkylating agent which was synthesized in the 1960s in Germany. The chemical structure is similar to classic alkylating drugs but also to purine analogues. This is hypothesized to be the background for high activity also in alkylator-resistant lymphomas [151]. Superior clinical efficacy was demonstrated

in a randomized trial comparing bendamustine to CHOP, both in combination with rituximab, in patients with indolent and MCLs [143]. More than 50% of patients in both arms had FLs, and less than 20% had MCL. Median PFS was significantly longer after R-bendamustine than after R-CHOP (69.5 vs 31.2 months, p <0.0001) for the entire group. The improvement was also found in MCL (35.4 vs 22.1 months, p = 0.0044) and Waldenström macroglubulinaemia (69.5 vs 28.1 months, p = 0.0033), but not in patients with mantle zone lymphoma (57.2 vs 47.2 months, p = 0.3249). Furthermore, the safety profile of bendamustine was much better: less haematotoxicity and infections, less peripheral neuropathy and stomatitis, and no alopecia. Therefore, R-bendamustine has been established as one of the preferred regimen in these entities.

Hodgkin lymphomas

Staging in HL is based on the Ann Arbor classification [152]. Regarding this classification and depending on precisely-defined risk factors, patients are classified into three risk groups (limited, intermediate, or advanced stages) defined by co-operative research groups (EORTC, GELA, GHSG, NCCN). The intensity of treatment depends on this stratification [153–155].

Treating patients with multi-agent chemotherapy and radiotherapy has led to significantly improved prognosis over the last decades, with five-year survival rates over 90%. The first modern combination chemotherapy, MOPP (mechlorethamine, vincristine, procarbazine, prednisone), was established by DeVita and colleagues [156]. A number of modifications were made to the original MOPP regimen by others intending to reduce toxicity. Bonadonna and colleagues established an alternative protocol, ABVD (doxorubicin, bleomycin, vinblastine, and dacarbazine), which was effective in the treatment of patients who had failed MOPP [157]. In advanced HL, the regimen was as effective as MOPP and in combination superior to MOPP alone [158, 159]. Other alternative

Table 54.2 Commonly-used chemotherapy regimen in indolent non-Hodgkin lymphoma

R-CVP [203]	Dose		Route	Schedule
Rituximab	375	mg/m²	iv infusion	d 0 (or 1)
Cyclophosphamide	750	mg/m²	iv infusion	day 1
Vincristine	1.4*	mg/m²	iv bolus	day 1
Prednisone	40	mg/m²	iv bolus or orally	days 1 to 5
repeat on day22				
R-MCP [205]				
Rituximab	375	mg/m²	iv infusion	day 0 (or 1)
Mitoxantrone	8	mg/m²	iv infusion	days 1 and 2
Chlorambucil	3 x 3	mg/m²	po	days 1 to 5
Prednisolone	25	mg/m²	po	days 1 to 5

chemotherapy regimens have been developed for the treatment of HL [160, 161].

For patients in the favourable risk group, combined modality treatment of two to three cycles chemotherapy and radiotherapy is the standard treatment of care demonstrated by the GHSG HD7 trial and the EORTC-GELA H8-F trial [162, 163]. The randomized HD10 trial of the German Hodgkin Study Group (GHSG) showed that two cycles of ABVD followed by 20 Gy of radiotherapy is sufficient and less toxic. Therefore, this approach is now the standard of care within the GHSG and an increasing number of centres worldwide [164].

For intermediate stage patients, four cycles of chemotherapy (ABVD) followed by 30 Gy IFRT is the standard of care [165]. However, the ideal chemotherapy and radiation regimens are not yet clearly defined. Therefore, several randomized trials from the GHSG and the EORTC have investigated different regimes to improve tumour control combined with reduced toxicity. According to the GHSG two cycles of BEACOPP$_{escalated}$ plus two cycles of ABVD followed by radiotherapy with 30 Gy is recommended based on the final evaluation of the HD14 trial [166]. It is still a matter of debate if radiotherapy can be suspended in selected patients. The HD17 trial and the EORTC/GELA H10U trial are evaluating interim PET results to determine whether radiotherapy can possibly be omitted in patients after chemotherapy.

Because of response rates and toxicity, the intensity of combination chemotherapy for patients with advanced-stage HL is controversial. Three treatment regimens are widely used: six to eight cycles of escalated BEACOPP, ABVD, or the Stanford V protocol [167–169]. Additional localized radiotherapy needs to be considered in case of residual lymphoma. Ongoing studies take into account early interim PET to reduce toxicity without losing efficacy of treatment. In Germany six cycles of BEACOPP$_{escalated}$ represents the standard of care for patients with advanced-stage HL demonstrated by the HD15 trial [170]. In case of PET-positive residual mass ≥2.5 cm after chemotherapy consolidation radiotherapy should be performed. Because of toxicity, patients older than 60 years should be treated with six to eight cycles of ABVD [171].

In relapsed disease, conventional salvage chemotherapy and high-dose chemotherapy with autologous haematopoietic cell transplantation (HCT) is considered the treatment of choice. For reducing tumour burden and mobilization of stem cells, several salvage regimens are used such as DHAP or ICE (ifosfamide/carboplatin/etoposide) [172, 173]. Allogeneic stem cell transplantation (alloSCT) can be considered in case of repeated relapse. However, this approach is not standard and should be conducted only within clinical trials [174–176].

Patients with progressive, resistant disease in a palliative situation can benefit by gemcitabine-based chemotherapy and/or regional radiotherapy. Brentuximab vedotin (Adcetris®) is approved by the US and European authorities for the treatment of relapsed or refractory HL in patients with progressive disease after ASCT, or after two chemotherapy regimens in patients ineligible for transplantation [177].

In recent years, new less toxic, targeted drugs are emerging such as the monoclonal antibody brentuximab targeting CD30, bi-specific antibodies, immunomodulatory drugs, HDAC, and mTOR inhibitors [178]. Recent data of PD-1 immune checkpoint blockade in HL are very promising [179]. All of these are being evaluated in clinical trials.

Concerning nodular lymphocyte pre-dominant HL, stage IA patients are usually treated with radiotherapy alone. All other LP patients are treated as cHL patients [180]. LP HL express CD20, so that anti-CD20 monoclonal antibodies have been shown to be effective [181].

Chemotherapy for relapsed or refractory disease

Treatment decisions in relapsed or refractory disease must address lymphoma histology as well as patient age and comorbidities.

In elderly and frail patients, palliative conventional chemotherapy can reduce symptom burden and improve survival. The

choice of regimen depends on previous therapies and individual reserves of haematopoietic and organ functions. The majority of patients with relapsed aggressive lymphomas are pretreated with CHOP-like regimens; salvage treatment with an anthracycline-based combination has to respect the previous cumulative dose of these drugs because of their potential cardiotoxic effects. The aza-anthracenedione derivate pixantrone should have less cardiotoxicity and was investigated in heavily pretreated patients with relapsed and refractory aggressive NHL. Pixantrone given at a dose of 85 mg/m^2 (intravenously, days 1, 8, 15, repeated day 28, up to six infusions) showed superior complete response (CR) or unconfirmed CR (CRu) rate (20% vs 7%, p = 0.021) in a randomized multicentre study compared to other single-agent chemotherapy including vinorelbine, oxaliplatin, ifosfamide, etoposide, mitoxantrone, or gemcitabine [182].

ASCT offers a chance for cure to younger and eligible patients. The sensitivity of relapsed disease to chemotherapy is one of the major prognostic factors for outcome after transplantation. There are two groups of chemotherapy regimen which are used to treat relapsed (or refractory) patients who have a transplant option; in B-cell lymphomas all combinations are given together with rituximab today.

First, platinum-based regimens, including DHAP, was established as an effective treatment in the late 1980 [183]. Later, the ICE protocol was developed [184, 185]. RRs range from 50–70% with CRs in 25–40% of patients. A recent randomized study comparing R-DHAP and R-ICE in salvage treatment of DLBCL patients showed no significant differences in response and event-free survival between the two regimens [186]. There were more grade 3 to 4 haematological toxicities and a higher number of severe renal adverse events after R-DHAP.

Second, modifications of the BEAM-conditioning regimen, such as miniBEAM [187, 188] or DexaBEAM [189–191], were evaluated in several studies in HL as well as NHL, where limited efficacy was seen. A retrospective study in patients with peripheral T-cell lymphomas showed superior RRs after DexaBEAM than after ICE (overall response 69% vs 20%, p = 0.01) prior to autologous transplantation [192]. However, there is no randomized prospective trial comparing DexaBEAM or platin-regimens in salvage treatment of lymphoma.

Role of immunotherapy

Tumour immunotherapy consists of both and 'active' and 'passive' approaches. The principle of active immunotherapy is to generate a host immune response, as in tumour vaccination strategies. In contrast, passive immunotherapy most commonly involves administering monoclonal antibodies (mAb) leading to antibody effector mechanisms including the recruitment of host immune cells to generate antibody-dependent cellular cytotoxicity (ADCC). Although considerable progress has been made in developing active immunotherapy with vaccinations, cellular therapy, and immunoregulatory mAb, all of which are now emerging as potentially important therapeutic approaches, it is the delivery of passive immunotherapy with mAb that has led to improvements in outcome for patients in a wide range of lymphomas.

More than 20 years elapsed after the advent of mAb technology in 1976 [194], before mAb began to fulfil their early promise as effective anticancer therapeutics in the routine care of lymphomas.

Numerous B- and T-cell antigens have been assessed as potential targets for mAb therapy, including the B-cell antigens CD19, CD22, CD37, HLA DR and the B-cell receptor (BCR) in B-cell malignancies as well as CD4, CD8, CD52 and, more recently, CD30 in T-cell and HL [195, 196]. CD20 was found to have favourable characteristics being expressed specifically within the B-cell lineage from pre-B-cells to mature B-cells in normal and malignant B-cells, resulting in lymphoid progenitors not being depleted after anti-CD20 mAb therapy due to the absence of CD20 on their surface, allowing them to replenish the B-cell population after anti-CD20 mAb therapy [197]. Anti-CD20 mAbs have subsequently dominated clinical development in B-cell malignancies, as unconjugated mAb and in radioimmunotherapy (RIT).

Rituximab is a chimeric mAb that targets the B-cell specific antigen CD20 and was the first mAb approved for the treatment of cancer by the US Food and Drug Administration (FDA) in 1997. The overall response rates (ORR) in patients with relapsed FL was around 50%, although single-agent complete RRs were modest at around 6% [198]. However, when rituximab was combined with chemotherapy, greatly enhanced RRs and improvements in PFS and OS in a wide range of B-cell malignancies were observed, with no or modest increases in toxicity compared to chemotherapy alone [199–207]. The initial data emerged from older patients (60–80 years) with untreated DLBCL [199]. This important finding was subsequently confirmed in young patients with good-prognosis DLBCL in the MINT (MAbthera International Study) trial. Here the addition of rituximab increased the three-year EFS compared with those assigned chemotherapy alone by 20% (79% vs 59%) and increased three-year OS by 9% (93% vs 84%) [200].

There have been numerous large international studies confirming the improved RRs, PFS, and OS for the addition of rituximab to combination chemotherapy in the initial treatment of advanced stage FL and other indolent lymphomas for patients requiring treatment (see Table 54.3) and confirmed in a meta-analysis [207]. However, the optimal combination of chemotherapy to deliver with rituximab as induction or initial treatment for patients that require therapy remains controversial. Whilst the use of anthracyclines as used in R-CHOP regimens led to higher ORR and CR rates, it is at the price of increased acute and late toxicity. The use of maintenance rituximab in patients who have achieved at least a partial response after induction chemotherapy was explored by the European Organisation for Research and Treatment of Cancer phase III trial EORTC 20981 in relapsed/resistant FL [209]. Rituximab maintenance significantly improved PFS compared with observation (median of 3.7 years vs 1.3 years). With longer-term follow-up, the superior PFS has been maintained but improvement of OS did not reach statistical significance, possibly because of the unbalanced use of rituximab in post-protocol salvage treatment. Rituximab maintenance was associated with a significant increase in grades 3 to 4 infections (9.7% vs 2.4%) [209]. More recently, in a large international randomized study the potential benefits of the addition of maintenance rituximab given two-monthly over two years was investigated. The PFS was 74.9% in the rituximab maintenance group and 57.6% in the observation group but OS did not differ significantly between the groups [208].

Over the last decade, many new insights have been discovered regarding the mechanism of action of anti-CD20 mAbs, which eliminate their targets by engaging in a range of antibody effector

pathways. These include mAb Fc-FcγR interactions [210, 211] including ADCC and phagocytosis, complement-dependent cytotoxicity (CDC), and the direct induction of programmed cell death (PCD) (reviewed in [199]). Several mechanisms of resistance to rituximab have been postulated including increased mAb metabolism, reduced tumour penetration, impaired mAb binding, 'shaving' loss/ or modulation of CD20, resistance of tumour cells to mAb-effector mechanisms, and impaired immune effector cell recruitment or function [212]. The contribution of these mechanisms to resistance to rituximab seen in the clinic currently remains unclear.

Currently, there are several new-generation anti-CD20 mAbs undergoing clinical investigation, engineered to provide theoretical advantages over rituximab. These anti-CD20 mAb include obinutuzumab [GA101], ofatumumab, PRO13192, AME133V, and multiple biosimilars [212–216]. Newer generation anti-CD20 mAb have been designed to deliver improved effector functions including enhanced FcγR binding, CDC, or PCD. Ofatumumab is at the most advanced stage of clinical development and binds a unique epitope on CD20, resulting in an unusually high ability to activate CDC. Ofatumumab has received FDA approval for use in fludarabine and alemtuzumab-refractory CLL, yet its clinical superiority over rituximab has yet to been determined [213]. Obinutuzumab (GA101) is another anti-CD20 which is at an advanced stage of clinical development. GA101 has a glyco-engineered Fc fragment with non-fucosylated oligosaccharides to enhance the interaction with FcγR, particularly FcγRIIIa, therefore enhancing ADCC and inducing direct cell death [216]. The efficacy of these next-generation mAbs compared to rituximab as initial therapy in combination with chemotherapy are being determined in large ongoing randomized clinical trials as well as efficacy in rituximab-refractory disease. Many of these ongoing clinical trials are using increased dose of anti-CD20 mAb used in comparison to the standard 375 mg/m^2 rituximab dose, making comparison of therapeutic efficacy more difficult.

Radioimmunotherapy

The radiosensitivity of malignant lymphomas makes the systemic delivery of targeted radiation in the form of radioimmunotherapy (RIT) a logical approach. RIT involves the administration of mAb or mAb-derived constructs which are chemically conjugated to therapeutic radioisotopes targeted to tumour. A wide variety of different mAb, delivery schedules, radioisotopes, and doses of radioactivity have been tested in RIT, resulting in impressive responses in the treatment of follicular NHL [217]. Various isotopes have been studied, but the commonest isotopes used in routine clinical practice are iodine-131 (^{131}I) and yttrium-90 (^{90}Y), due to their favourable emission characteristics which are shown in Table 54.4.

The ^{131}I-tositumomab regimen (Bexxar®) is completed within one to two weeks and consists of a tracer dose of the radioimmunoconjugate followed by the therapeutic dose 7 to 14 days later. Whole-body gamma camera imaging is performed three times over the week following the trace-labelled infusion to calculate

Table 54.4 Comparing the characteristics of Iodine-131 and Yttrium-90

	Iodine-131 (^{131}I)	Yttrium-90 (^{90}Y)
Emission	B and γ	β only
B-particle energy	0.6 MeV	2.3 MeV
B-particle path length	0.8 mm	5.3 mm
Physical half-life	8.1 days	2.6 days
Conjugation to mAb	Direct	Via chelator, tiuxetan
Radiation protection measures	4 to 6 day inpatient stay in shielded room	Outpatient

the whole-body half-time and the dose required for the therapeutic infusion to deliver a 65 to 75 cGy whole body dose (WBD) depending on the baseline platelet count. ^{90}Y-ibritumomab tiuxetan consists of an IgG1 anti-CD20 mAb, the murine parent immunoglobulin of rituximab, covalently attached to a metal chelator molecule tiuxetan [217].

In a pivotal study of 60 extensively pretreated patients, a single administration of ^{131}I-tositumomab was administered and disease responses compared to their previous responses to chemotherapy for follicular or transformed FL. ^{131}I-tositumomab therapy was shown to provide greatly superior relapse-free survival compared to the last qualifying chemotherapy [218]. A RR of 68%, CR rate of 30%, and a median duration of response of 14.7 months were reported in a heavily-pretreated 'rituximab refractory' patient population to rituximab treated with ^{131}I-tositumomab in [219]. For ^{90}Y-ibritumomab tiuxetan, the phase II trial in heavily pretreated rituximab-refractory disease also showed an ORR of 74% and a CR rate of 15%, with a time-to-progression of 6.8 months in all patients and 8.7 months in responders [220].

Over the last ten years, both licensed RIT reagents, namely ^{131}I tositumomab and ^{90}Y-ibritumomab tiuxetan, have demonstrated high clinical efficacy in follicular and transformed disease leading to durable remissions. RIT delivers durable remissions for some patients and an analysis of the long-term follow-up of patients treated with ^{131}I-tositumomab demonstrated an RR of 47% to 68%, with CR rates between 20% and 38% [221]. At a median follow-up of 5.3 years, five-year PFS was 17%, and 32% of the 250 patients studied had a time-to-progression of ≥ 1 year. For these patients, the median duration of response of 45.8 months and had not been reached for those who achieved a CR [221]. Higher RRs and durable responses were also observed with ^{90}Y-ibritumomab tiuxetan with the observed median duration of remission approaching two years [222, 223].

RIT consolidation therapy after first-line cytoreduction with chemotherapy or immunochemotherapy has also been extensively investigated, initially with several phase II trials involving ^{90}Y ibritumomab and ^{131}I tositumomab. The largest phase II trial in 90 patients used ^{131}I tositumomab as consolidation therapy after six cycles of CHOP without rituximab. The ORR was 91%, including a 69% CR rate. After a median follow-up of 5.1 years, the estimated five-year OS rate was 87%, and the PFS rate was encouraging at 67% [224]. This regimen was subsequently compared in a randomized study to six cycles of R-CHOP and no statistically significant differences in PFS, OS, or serious toxicities are yet demonstrable with either regimen. However, the median times to progression not yet reached for either treatment [225].

A phase III study investigated ^{90}Y ibritumomab tiuxetan given as consolidation therapy versus observation in previously untreated stage III/IV FL, following induction with a wide range of different chemotherapy regimens. Although the median PFS in the ^{90}Y-ibritumomab group was highly significantly improved from 14 months in the control group to 49 months in those that received RIT, no OS advantage has yet been seen [226]. The marked improvement in CR rates and PFS in this study along with excellent PR to CR/CRu conversion rates and a favourable tolerability profile led to the approval of ^{90}Y ibritumomab tiuxetan in April 2008 by the European Medicines Agency (EMEA) as consolidation therapy after remission induction in previously untreated patients with FL. However, around 86% of the patients in this study were not treated with the current established standard of care with rituximab-containing chemotherapy. This lack of a current standard of care in the initial treatment has led to a poor uptake of this consolidation approach in modern management of FL, as uncertainty remains as to whether the similar benefits would be seen after rituximab-chemotherapy combinations.

RIT has been tested as a single-treatment approach in untreated FL. Seventy-six patients with stage III or IV FL received, as an initial therapy, a single-course of treatment with 131I-tositumomab therapy. The ORR was 95% and 75% achieved a CR. After a median follow-up of 5.1 years, the five-year PFS was 59%, with a median PFS of 6.1 years [227]. The mature results of phase II studies with ^{90}Y ibritumomab tiuxetan in newly diagnosed patients with FL are yet to be published.

Both licensed RIT approaches are well-tolerated during treatment and non-haematologic toxicities following treatment are relatively uncommon and generally minor. The most common, clinically significant, non-haematologic toxicities are similar to ^{90}Y ibritumomab and include fever, chills, asthaenia, and nausea. Myelosuppression is the primary toxicity with neutropaenia and thrombocytopaenia occurring several weeks after treatment and recovering to pretreatment levels after two to three months. The risk of myelodysplastic syndrome (MDS) occurring after lower BM doses of radioactivity delivered by RIT, however, appears to be modest at around (1–4%) [221, 222]. The introduction of RIT into clinical practice has been slow, given the activity of the RIT drugs, and uncertainty remains as to when and how best to integrate RIT into the treatment of FL. The treatment is well-tolerated by older patients and is an effective approach for relapsed FL, but further randomized studies demonstrating efficacy compared with current standards of care with rituximab/chemotherapy combination regimens will be required before these drugs are used more frequently.

Antibody drug conjugates

Antibody drug conjugates (ADCs) offer the potential to target the tumour specifically with mAb and deliver potent drug therapies with minimal or less systemic toxicity. Although initial early phase clinical trial results were disappointing, much was learnt about the chelate chemistry and the nature of conjugated cytotoxic agents. Recently highly-promising results have been achieved with this class of drugs using brentuximab vedotin (SGN-35) which combines an anti-CD30 monoclonal antibody and the antitubulin agent monomethyl auristatin E. The CD30 antigen was first identified in the Reed Sternberg malignant cell of HL and emerged as a promising potential target for antibody treatment. Although the first-generation monoclonal anti-CD30 antibodies proved disappointing with little clinical efficacy, the delivery of ADC against CD30 proved the validity of targeting CD30 with high RRs in the phase I study [228]. In the pivotal phase II study, performed in a treatment-refractory population who had relapsed post-ASCT, an RR of 75% and a CR of 34% was observed. The median duration of response was 6.7 months, and 20.5 months in those who achieved CR [229].

Brentuximab vedotin has also demonstrated high efficacy in patients with systemic ALCL recurrent disease with 86% achieving an objective response, 57% a CR, and 29% a partial remission. The median duration of overall response and CR was 12.6 and 13.2 months, respectively. Treatment-emergent adverse events included peripheral sensory neuropathy, fatigue, nausea, and

neutropaenia; however, the majority of these were mild to moderate [230]. Grade 3/4 toxicity was primarily haematologic, with just over 5% of subjects experiencing at least one episode of neutropaenia, peripheral neuropathy, thrombocytopaenia, or anaemia. These results led to the accelerated approval of brentuximab vedotin (Adcetris®) by the US FDA in 2011 for the treatment of the treatment of relapsed or refractory HL in patients with progressive disease after ASCT, or after two chemotherapy regimens in patients ineligible for transplantation. Brentuximab vedotin was also approved for patients with ALCL who failed at least one prior treatment. Brentuximab vedotin is the first new therapy approved for the treatment of HL in over 30 years.

There are numerous ongoing studies in combination with chemotherapy in CD30-positive malignancies that will help define the role of this antibody–drug conjugate (ADC) in lymphoma management. The high durable RR of brentuximab vedotin has increased the interest in the use of ADC in treatment of lymphoma and there many drugs in this class in development. One such drug, inotuzumab ozogamicin (CMC-544), is in advanced clinical development having completed promising early phase clinical trials; phase III clinical trials are underway [231].

Role of stem cell transplantation

The introduction of high-dose therapy (HDT) followed by ASCT or alloSCT has led to substantial progress in the treatment of patients with NHLs. Haematopoietic reconstitution with peripheral blood progenitor cells (PBPC), improvement in supportive care, as well as the availability of matched unrelated donors has led to the widespread use of transplantation in the treatment of patients with lymphomas. However, the integration of the anti CD20 antibody, rituximab, has dramatically improved the prognosis of patients with B-cell lymphoma. The role of SCT for patients with B-cell lymphoma needs to be re-evaluated and will be discussed along with other lymphoma entities.

Because HDT and SCT are procedures with high acute and long-term toxicities, most studies have limited the use of this procedure to patients under the age of 65 who have good performance status and organ function. The clinical indications for HDT include several categories of patients, such as those who are refractory to initial treatment or with a poor prognosis, resistant relapse, or sensitive relapse. However, only patients sensitive to chemotherapy are eligible for this procedure. While the vast majority of patients who undergo ASCT have DLBCL, ASCT has also been used to treat patients with other types of low-grade lymphomas who have failed conventional treatment or with T-cell lymphomas. Until recently, the use of alloSCT was limited, but its application is expanding with the progress in donor selection and the use of reduced-intensity conditioning regimens (RIC) prior to alloSCT [232].

Principles of conditioning regimens

The principle underlying the use of SCT in haematological malignancies is that a more intensive cytoreductive therapy may result in an increase in the rate of CR. However, 'dose-response' is a concept that can be interpreted in many ways, including an increase in the peak dose level with a single very high dose of chemotherapy, the area under the curve or the dose intensity expressed by mg/m2/ week [233]. In the setting of ASCT, pulsed multidrug high-dose regimens are generally given together after a period of standard- or high-dose induction chemotherapy. Nevertheless, drug sensitivity is required so that the procedure can participate in disease eradication. Until the last decade, it was thought that the mechanism of curing a malignancy was entirely due to conditioning therapy and that the transplant was a supportive measure that allowed for supralethal treatment.

However, this mechanism does not apply to all antineoplastic agents; in particular, myelosuppression is not the dose-limiting toxicity for agents such as cisplatin, and is not fully limiting for etoposide or cyclophosphamide. However, most other agents used in preparative regimens are highly toxic to stem cells and require obligate stem-cell support to rescue the patient from potentially lethal aplasia. In practice, there are two main advantages for using stem-cell support during treatment. First, the duration of acute myelosuppression is dramatically reduced, and second, a broader array of non–cross-resistant agents is available.

Because ASCT relies on the principle of dose escalation (usually less than tenfold) before toxicity in non-haematopoietic organs occurs, only a few drugs can be used. Alkylating agents are particularly suitable for ASCT because their doses can be easily intensified as their main toxicity is haematologic. In addition, they possess significant antitumour activity against lymphomas and their drug-resistance mechanism is not attributable to the multidrug resistance gene. Furthermore, a five-fold increased dose can be safely administered, thereby attaining a concentration that should be able to overcome drug resistance [234].

Preparative regimens

Combination of drugs without total-body irradiation

This type of conditioning regimen is preferred for several major reasons: several centres lack access to adequate radiation facilities, long-term side effects have been more frequently described with total-body irradiation (TBI) than with combination chemotherapy [235], and some lymphoma patients have already received the maximum tolerated dose (MTD) of radiation to critical organs.

The choice of drugs was initially classified into regimens that combined BEAM or cyclophosphamide, BCNU, etoposide (CBV), which are the most popular regimens used for lymphoma patients [236–238]. More intensive therapy adds high-dose mitoxantrone to CBV or escalates the dose of cytarabine or etoposide in the BEAM regimen [239, 240].

Some conditioning regimens have been developed for treating cerebral lymphoma. These use drugs that cross the blood-brain barrier, such as thiotepa, carmustine, etoposide, thiotepa, busulfan, and cyclophosphamide [241, 242].

Dose escalation studies conducted with the major regimens used to treat lymphoma patients have demonstrated non-haematologic toxicities, mainly pulmonary or hepatic, for agents such as carmustine or busulfan.

Tandem transplant

Promising results have been reported for treating multiple myeloma with a total therapy that consists of two ASCTs performed at three-month intervals. Recent trials have suggested that ASCT may offer a measurable advantage and that a second transplant is feasible [243].

Sequential high-dose chemotherapy with peripheral blood progenitor cells support

New schedules for the escalation of chemotherapy can take advantage of the use of both growth factors and stem-cell support to modify the established MTD and to maximize the dose intensity. The use of such a strategy as a first-line therapy rather than as consolidation therapy may offer the potential benefits of the most active drugs to more lymphoma patients with poor prognoses [244]. In this setting, the pulsed multidrug doses are generally lower per cycle than those used in myeloablative conditioning regimens. However, after four to six cycles with repeated PBPC support, the total dose may remain the same. A German study group performed a randomized study to compare standard chemotherapy to repetitive HDT supported by the reinfusion of progenitor cells [245], but they did not observe a benefit for this approach in DLBCL patients with poor prognoses. Nevertheless, despite the generally reversible haematotoxicity of a chosen drug, the blood concentrations of the drugs did not reach the same peaks levels that were necessary to overcome drug-resistance mechanisms.

Combination of drugs with total-body irradiation

Early preparative regimens utilized cyclophosphamide with TBI [246], and subsequent studies evaluated the use of alternative cytotoxic drugs, such as cytarabine, etoposide, and melphalan [247]. TBI dose-escalation studies have shown that the MTD was 10 Gy when given in a single dose and 16 Gy when given in 2 Gy fractions twice a day [248]. The dose-limiting toxicities were stomatitis, veno-occlusive disease, and skin lesions. Additionally, preparative regimens combining more than one cytotoxic drug with TBI have been studied. The rationale was that combinations of drugs have been shown to be superior to single agents and that dose escalation should be possible without the marked overlapping of toxicities. The results of phase II studies have led to the establishment of the ranges of doses that can be given safely to the majority of patients. An alternative could be to replace TBI with radioimmunoconjugates as part of the preparative regimen to selectively irradiate residual tumour cells [249]. Unfortunately, a randomized study comparing rituximab-BEAM to ^{131}I tositumomab-BEAM in patients with a relapsed DLBCL did not demonstrate any benefit for this new conditioning regimen [250].

Over the last decade, a new concept involving RIC prior to alloSCT was developed [251]. This technique emphasized the importance of immune cells that were transferred along with the graft for eradicating the tumour. As such, a myeloablative conditioning regimen was no longer a crucial prerequisite for successful alloSCT. This concept was also adopted because it decreased transplant-related mortality (TRM) to the point that this procedure can now be offered to virtually any elderly patient without serious co-morbidity. Encouraging results for this regimen have also been observed in patients with a DLBCL [252].

Stem cell source

The best source of progenitor cells for reconstitution following HDT in lymphoma is still a matter of debate. The use of a sibling or a matched unrelated donor as a source of stem cells that are not contaminated with lymphoma cells, that have not been exposed to cytotoxic agents, and that may induce a graft-vs-lymphoma effect is attractive. However, complications resulting from graft-vs-host disease and increased immunosuppression are associated with an increase in mortality compared to the use of stem cells from an autologous source. Until now, in most of the patients with lymphoma long-term survival is similar or inferior to that resulting from autoSCT, despite a decrease in the relapse rate post-alloSCT [253].

The use of PBPCs has become increasingly common, and it is the main source of stem cells for ASCT and, increasingly, for alloSCT. In addition, the current use of PBPC has shortened the duration of severe hypoplasia to a median time of 12 days [254]. The procedure is also easier to perform than BM collection in an operating room. The collection of stem cells can be performed as an outpatient procedure and involves apheresis to reach a minimal of $>2 \times 10^6$ CD34 + cells/kg cells. The mobilization of stem cells is performed with chemotherapy and haematopoietic growth factors or with growth factors alone and has a success rate of 90% in relapsed lymphoma patients [255]. In cases of collection failure, the use of plerixafor in combination with growth factors can rescue half of the cases [256].

The use of purging for ASCT is also a controversial issue. However, the debate has been partially resolved through the use of rituximab for therapy, which also reduces the stem cell contamination in B-cell lymphoma. In fact, in a randomized study in FL, the PFS and OS curves of patients receiving rituximab and those who did not receive rituximab prior to the collection of stem cells and transplantation were similar [257].

Evaluation of the toxicity of the conditioning regimens

Overall toxicity

TRM and mortality following transplantation have often been considered as a necessary compromise for achieving long-term survival. Earlier studies in ASCT reported that the percentage of TRM was above 10%, and this rate remains at 7% in the European Bone Marrow Transplantation (EBMT) registry [258]. However, several major advances over the past ten years have dramatically changed the toxicities associated with treatment. The observed mortality rate has been lowered to 3.5% [258].

More generally, the choice of the conditioning regimen depends on the severity of the disease.

Conventional alloSCT showed disappointing results in the treatment of patients with relapsed DLBCL and was associated with a devastatingly high TRM of up to 50%. RIC alloSCT is also associated with a variable TRM, but this averaged 20% in most reports [252, 259] thus accounting for the increased use of alloSCT in the treatment of lymphoma.

Role of radiotherapy

Radiation therapy (RT) has been used in the management of malignant lymphoid malignancies for over 80 years. Most lymphoid malignancies are very radiosensitive and moderate doses of radiotherapy result in a durable local control. However, most lymphomas even when localized at presentation are associated with occult systemic disease and recurrence after local radiotherapy is common. Therefore, with the development of effective chemotherapy a systemic treatment approach is now the mainstay of the management for most lymphomas.

In general, radiotherapy is used as primary curative therapy in stage I and II FL and MZL and as part of combined modality approach in DLBCL, primary mediastinal lymphomas, and NK-T cell lymphomas. The technical aspects of treatment planning for lymphomas are highly dependent on the location and extent of the

target volume. In general, RT planning involves the use of immobilization devices, CT-assisted tumour localization and planning, and computerized calculation of dose distributions. The goal of these steps is to achieve dose uniformity in the target volume while minimizing RT dose to normal tissues.

Radiation volumes are defined using the information on planning CT that allows accurate delineation of target and normal tissue in a 3D perspective. The planning of radiation includes a determination of gross tumour volume (GTV), clinical target volume (CTV), and planning target volume (PTV). GTV is important in patients treated with RT alone and those with residual disease after chemotherapy. CTV includes the pretreatment tumour and what is considered to be the relevant tissues that contain microscopic disease. PTV includes an appropriate margin to the CTV to account for movement and set up variation during treatment delivery.

The toxicity of RT depends on three main factors: radiation dose, volume of tissue irradiated, and the area of the body exposed to radiation. While the acute toxicity of radiotherapy is mild to moderate, the main concern is that of late radiation toxicity that may become clinically significant decades later. In the last decade, there have been significant technologic advances that facilitate the delivery of therapeutic radiation dose to tumour while effectively protecting normal tissues.

Early-stage follicular lymphoma

Several studies have described ten-year PFS rates of approximately 50% and OS rates of 60–70% following RT alone for early-stage FL [260–263]. The large majority of relapses are in untreated sites, with long-term local relapse rates typically <10%. With follow-up longer than 15 years, there appears to be plateau in the risk of relapse, suggesting that some patients with localized disease can be cured with RT [263]. Further, a majority of patients treated with initial RT will not require chemotherapy 15 years after initial diagnosis. The contrast between the high local control rate and the suboptimal disease-free survival (DFS) illustrates in part the limitation of conventional staging investigations in identifying which patients have truly localized disease.

Radiotherapy dose

A phase III randomized study compared 24 Gy versus 40–45Gy among patients receiving RT for indolent lymphomas [264]. With 289 patients (361 sites) randomized, there was no significant difference between the dose levels in terms of in-field progression, PFS, or OS. Among 248 patients receiving RT as first-line therapy, there was no difference in PFS, with 64% in the 24 Gy arm and 54% in the high-dose arm without recurrence at last follow-up. These findings are consistent with single-arm studies demonstrating excellent local control with doses ≈30 Gy, indicating that higher doses are rarely warranted. RT target volumes should encompass enlarged nodes seen on CT-imaging and other sites consistent with lymphomatous involvement on MRI or FDG-PET, as needed. It is acceptable also to cover adjacent uninvolved nodal regions, but extended-field RT is not useful, as it does not appear to enhance disease control compared to smaller fields, though it does substantially increase the normal tissue dose [265].

Palliative radiation therapy for indolent lymphoma

Indolent lymphoma is a highly radiosensitive disease, and the use of low-dose short fractionation RT (i.e., two fractions of 2 Gy each) can provide excellent palliation of local symptoms among patients with recurrent disease. The largest study of low-dose RT included 109 patients (304 sites) with recurrent indolent lymphoma treated with 4 Gy in one or two fractions. The ORR was 92% with a median duration time until local relapse of 25 months [266]. Other single-institution studies have also demonstrated similar results, with median local control duration typically of one to two years. This is a highly effective treatment option for patients with relapsed disease with symptoms caused by local bulk [266–268].

Mucosa-associated lymphatic tissue lymphoma

Moderate dose (i.e., 25–30Gy) RT can produce long-term cure for localized extranodal MALT lymphomas. A study of 144 patients treated with RT alone reported ten-year OS and relapse-free rates (RFR) of 89% and 74%, respectively. The ten-year RFRs for thyroid and gastric lymphoma were 95% and 92%. However, for salivary gland and orbital lymphoma, RFRs were 68% and 67%, respectively, due to recurrence in paired organs for lymphomas arising in these sites [269, 270].

A full description of the principles of RT-planning for low-grade MALT lymphomas is beyond the scope of this chapter. In general, the CTV should encompass the entire organ, not only the area where abnormalities are seen on imaging or direct visualization. For example, for gastric MALT the entire stomach is generally treated, and the entire orbit is encompassed in retro-orbital cases. Prophylactic coverage of the regional lymph nodes is not necessary for indolent histologies, although for high-grade extranodal lymphomas it is often done [271]. The expected target organ motion, the spatial variation in daily set-up, and the radiosensitivity of adjacent normal tissues requires individualization of treatment with respect to the design of an appropriate RT pan.

Diffuse large B-cell lymphoma

The role of RT in the treatment of DLBCL has been the subject of randomized trials, but applying the results of these trials in the context of modern practice is challenging. This is due to several factors: the systemic therapy regimens employed have become outdated (for example, due to the absence of rituximab), studies were underpowered to detect clinically important differences in outcome, FDG-PET imaging was not available, and also results among seemingly similar trials differed with respect to the benefit of RT. A SWOG study compared eight cycles of CHOP chemotherapy with three cycles of CHOP plus IFRT (40–55 Gy) [272]. The study included 442 patients with stage I (bulky) or II non-bulky disease. Patients receiving combined modality therapy had superior PFS (77% vs 64% with chemotherapy alone) and OS (82% vs 72%, respectively (p = 0.02). In a follow-up analysis nine years following randomization, the advantage of combined modality therapy was no long statistically significant [273]. An Eastern Cooperative Oncology Group (ECOG) study, randomized 215 patients with stage I–II diffuse aggressive NHL, including bulky stage II disease who had achieved a complete response to eight cycles of CHOP chemotherapy to 30 Gy IFRT or no further therapy. Six-year FFS was 70% with the addition of RT, compared to 53% among patients receiving chemotherapy alone (p = 0.05) and six-year OS was also 12% better, though this difference was not statistically significant [274]. Although these results indicated a significant benefit with the use of combined modality therapy, other randomized trials have

found no benefit when more intensive chemotherapy regimens are used, or when only elderly patients are enrolled [275, 276].

An obvious limitation of these trials is the absence of rituximab as part of the therapy. The landmark trials demonstrating the benefit of rituximab in addition to CHOP chemotherapy employed RT to sites of bulk (variably defined between >5cm to >10cm) and extranodal involvement. Approximately 50% of patients on these trials received RT based on these criteria. A prospective non-randomized study compared patients treated on the RICOVER-60 trial with six cycles of R-CHOP-14 + two cycles of R with 36Gy to bulky sites >7.5cm with 164 patients treated with the same systemic therapy without RT. After adjusting for other prognostic factors, the omission of RT was associated with a significantly inferior results (HR = 2.7 for EFS, p = 0.011; HR = 4.3 for OS, p = 0.02) [277]. Similarly, a study of 292 patients with skeletal involvement treated on German High-grade Non-Hodgkin Lymphoma Study Group trials, including those treated with rituximab, reported that the use of RT among patients with skeletal involvement was associated with significantly superior EFS (p = 0.001) and better OS (p = 0.11) than treatment with systemic therapy alone [278]. The subsequent German High Grade Lymphoma Group study, UNFOLDER, includes patients aged <60 years with aaIPI of 0–1, and initially included a 2 × 2 randomization of R-CHOP on a 14-day vs 21-day schedule, and a randomization of RT vs no RT for patients with initial disease bulk >7.5 cm who were in CR after chemotherapy. In July 2012, the RT randomization was discontinued after an interim analysis revealed poorer outcome among patients treated with systemic therapy only, indicating that combined modality therapy remains the standard of care among patients with bulk disease.

Single-arm studies also support the use of abbreviated chemotherapy (i.e., three cycles of R-CHOP) with 30–36 Gy IFRT for patients with 0–1 IPI factor. This treatment can yield 3–8 year PFS of >80% with minimal acute toxicity and limited exposure to anthracyclines [279].

For patients with a complete response to RT, 30–36 Gy are typically considered adequate. For patients with a PR, there are very limited dose-response data, but in these cases 36–45 Gy may be warranted, particularly in circumstances in which both anatomic and functional imaging are abnormal [280, 281].

Primary mediastinal B-cell lymphoma

Primary mediastinal DLBCL is a distinct clinicopathologic entity typically presenting as a large mediastinal mass in a young patients. Because of the young age of affected patients and the recognized delayed toxicity of mediastinal RT, its role has been controversial [282]. Non-randomized retrospective studies have demonstrated superior PFS and OS among patients receiving combined modality therapy compared to chemotherapy alone. Todeschini et al., for example, reported that among 138 patients with PMBL five-year OS was 90% among those receiving RT compared to 78% without (p = 0.04) [283]. More recently, Xu et al. evaluated 79 patients with PMBL who received CHOP chemotherapy with (n = 39) or without rituximab (n = 40), and 60 patients received additional radiotherapy, and found OS and PFS rates for early-stage patients were 73.6% and 69.9% for chemotherapy and radiotherapy, and 50.8% (p = 0.076) and 36.9% (p = 0.008) for chemotherapy alone, respectively [284]. There is great interest in the use of dose-intensive regimens as a means of reducing the need for RT. Recognizing the need to evaluate RT in a randomized setting, the International Extranodal

Lymphoma Study Group (IELSG) has initiated a randomized trial comparing systemic therapy alone (including rituximab) with or without RT. Very promising results were reported from a prospective phase 2 study in 51 PMBL patients using an intensive, toxicity-adjusted, infusional regimen (DA-EPOCH plus rituximab). None of the patients received radiotherapy. After a median follow-up of five years EFS and OS were 93% and 97%, respectively; late morbidities or cardiac toxicities were not observed.

Sinonasal NK/T lymphoma

Due to the relatively chemotherapy-resistant nature of NK lymphoma, initial therapy with combined chemoradiation remains the standard of care for stage I/II disease. Several retrospective studies have demonstrated superior PFS with the use of combined-modality therapy compared to systemic therapy alone [285, 286]. Aviles et al. randomized 427 patients with stage I/II NK/T lymphoma to RT alone, chemotherapy alone, or combined modality therapy, and reported superior PFS with combined modality therapy (9% vs 78% with chemotherapy alone and 40% with RT alone, and better five-year survival (86% vs 95% CI 81–90%) for CT; 64% (95% CI 59–70%) for RT; and 45% (95% CI 39–51%) for C (p < 0.001) [287]. Initial treatment with CHOP-21 is associated with progression prior to completion of six cycles in a substantial proportion of patients and, more recently, the early introduction of RT with dose-intensive chemotherapy regimens has been advocated [288].

The RT dose required to control localized NK/T lymphoma is 45–50 Gy. Intensity-modulated RT can be used to reduce the dose to the anterior chamber of the eye and the parotid glands, thereby reducing the late toxicity of RT compared to conventional lateral parallel-opposed beams that would have been used historically (Figure 54.4).

Hodgkin lymphomas

In the modern era of HL management, RT is still an important component of treatment for many patients. Since modern therapy options have significantly improved cure rates, the vast majority of patients will survive HL and thus will face potential late effects of therapy such as secondary cancers or late cardiovascular effects. Consequently, for favourable and intermediate-risk patients, efforts have been focused on retaining high cure rates while reducing the risk of adverse late effects. Currently, the intensity of chemotherapy and the selection of patients to receive RT depend on the disease stage, the presence of risk factors, and potentially early response to treatment. Reduction of therapy-related toxicity has been achieved by the replacement of alkylator-intensive chemotherapy regimens for early-stage disease with less toxic and more effective regimens, through the judicious selection of appropriate patients to receive RT and the minimization of normal tissue dose among those receiving it. The goal of modern smaller field RT (i.e., IFRT or involved-node RT (INRT)) is to reduce both treatment volume and treatment dose while maintaining efficacy and minimizing acute and late sequelae [289–291].

The principal objective of RT in HL is to treat involved lymph nodes (as INRT or involved-site RT) with or without contiguous adjacent nodes (in the case of IFRT) to a dose associated with a high likelihood of tumour eradication [292].

It is strongly recommended that all HL patients should be treated within a multidisciplinary clinical setting to facilitate the thoughtful balance of treatment intensity and toxicity.
Fig. 54.4 RT dose distribution for sinonasal NK-T cell lymphoma. The use of intensity-modulated RT (IMRT) allows reduction of dose to optic structures and salivary glands, minimizing the risk of visual complications or xerostomia.

3D simulation and treatment planning

Recent recommendations for radiotherapy field and dose guidelines of the International Lymphoma Radiation Oncology Group (ILROG) can be found by Specht et al. [293] or the German evidence-based guidelines for HL by Eich et al. [294] or by Participants of the Lymphoma Radiotherapy Group by Hoskin et al. [295].

Planning requires modern 3D-CT-based simulation and planning capabilities. The capacity to fuse other additional imaging such as [18F] FDG-PET and MRI to planning CT datasets often enhances treatment planning.

The optimal irradiation technique includes pretreatment simulation and requires the use of 3D (i.e., CT-based) treatment planning, well-collimated megavoltage photon beams (dual-energy linear accelerator), nodal volumes, and normal tissues individually contoured to the patient´s anatomy and tumour configuration, an adequate dose, fractionated treatment, and accurate verification of patient positioning during therapy. As normal tissue dose is now well recognized as an important clinical consideration, contouring of normal tissues (i.e., 'organs at risk' such as breast, heart, and thyroid) should be viewed as an important part of treatment planning for HL. Newer treatment techniques, including intensity-modulated radiation therapy (IMRT), breath-hold, image-guided RT, and 4D

imaging, should be implemented when their use is expected to decrease significantly the risk for normal tissue damage while still achieving the primary goal of local tumour control.

Radiotherapy target definition

The International Commission on Radiation Units and Measurements (ICRU) Report 83 [296] concepts of volume determination are used for RT planning. A GTV may be defined as all individual nodes or extranodal sites of disease that are enlarged on CT, or avid on [18F] FDG-PET. The post-chemotherapy residual GTV should be outlined on the simulation study. The CTV would be defined as the original (before any intervention) GTV and includes the initial (pre-chemotherapy) location and extent of nodal disease (GTV plus the entire involved lymph node region(s)), excluding uninvolved organs.

When the target is moving, most commonly in the chest and upper abdomen with respiratory movements, an internal target volume (ITV) is defined [297] as the CTV plus a margin taking into account uncertainties in size, shape, and position of the CTV within the patient. The optimal way is to use 4D CT simulation to obtain the ITV margins. In sites (e.g., the neck) that are unlikely to change shape or position during or between treatments, outlining the ITV is not required. The PTV would include the CTV (or ITV

if created) plus a margin for set-up uncertainties in patient positioning, typically 0.5–1.5 cm. In the setting, if there is a large mediastinal mass, the post-chemotherapy treatment fields can usually conform to the width of the residual disease (unless there was pulmonary parenchymal extension), although the superior and inferior field margins should encompass the initial extent of disease.

Irradiation dose recommendations for combined modality therapy

The determinants of dose prescription for HL include the histologic subtype, clinical risk factors, and patient age.

Classical Hodgkin lymphoma

Early stage (favourable prognosis) CS IA–IIB (no risk factors)

Combined-modality treatment is the standard treatment for patients with clinical stage I/II HL. In early-stage CHL, RT is often part of the treatment program after adequate systemic chemotherapy in all age groups. Although chemotherapy alone can produce excellent disease control for selected early-stage patients, RT improves freedom from treatment failure even in patients with negative PET scans [298, 299] and allows treatment with fewer chemotherapy cycles [289]. In a recent systematic review, combined-modality treatment was found to improve tumour control and OS in patients with early-stage HL [300].

For patients with early-stage CHL in CR after chemotherapy, the dose to the CTV is determined on the basis of the results of the German Hodgkin Studies HD 10 and 11 [289, 301]. For patients with favourable characteristics according to the German criteria, the dose is 20 Gy, whereas for patients with unfavourable characteristics it is 30 Gy.

In most circumstances, the current standard treatment for these patients is combined-modality therapy consisting of ABVD × 2 (–4) cycles followed by IFRT or involved-site radiation with 20 Gy [302–307].

An alternative treatment regimen consists of Stanford V × 8 weeks followed by IFRT.

Intermediate stage (unfavourable prognosis) CS IA/B to IIA/B (risk factors, bulky/non-bulky disease)

In most circumstances, the current standard treatment for these patients is combined-modality therapy consisting of poly-chemotherapy such as escalated BEACOPP × 2 plus ABVD × 2 followed by an IFRT with 30 Gy [290, 301, 307, 308]. In North America the standard poly-chemotherapy regimen for unfavourable bulky disease would be ABVD × 4–6 or Stanford V × 12 weeks. PET/CT is applied for restaging. Based on the DEAUVILLE PET criteria [309], further treatment decisions (ABVD × 4 +/- IFRT 30 Gy) are made. The results of the preplanned interim analysis of the randomized EORTC/LYSA/FIL Intergroup H10 trial [310] evaluated whether INRT could be omitted without compromising PFS in patients attaining a negative early PET scan after ABVD × 2 as compared with standard combined-modality treatment. The combined-modality treatment resulted in fewer early progressions in clinical stage I/II HL, although early outcome was excellent in both arms.

Advanced stage (unfavourable prognosis) CS IIB, III, IV

The role of additive RT is controversial and the appropriate use of RT in advanced-stage disease is certainly challenging to define. In advanced disease, many centres treat patients with intensive poly-chemotherapy alone (especially in the absence of bulky disease). Only if a CR is not achieved will localized additive RT be used for residual lymphoma after full chemotherapy [311, 312]. The target in this situation is the residual mass after chemotherapy [313].

In advanced-stage HL two PET-based ABVD escalation or BEACOPP de-escalation trials aimed at determining the feasibility of omitting radiotherapy in interim PET-negative patients. Patients with a [18F] FDG-PET positive residual tumour after the end of chemotherapy (escalated BEACOPP or ABVD × 6 or Stanford V) should receive local radiotherapy with 30 Gy [314–316].

Nodular lymphocyte-predominant Hodgkin lymphoma early-stage IA

Nodular lymphocyte-predominant Hodgkin lymphoma (NLPHL) (stage IA) is treated with IFRT alone. The guidelines of the German Hodgkin Study Group (GHSG) for NLPHL recommend a dose of 30 Gy as sufficient [317, 318]. All fields are treated with fractions of 1.8 to 2.0 Gy, depending on the field size and patient tolerance. No advantage has been shown for doses over 30 to 35 Gy, which is the recommended dose to the CTV [319].

Nodular lymphocyte-predominant Hodgkin lymphoma >stage IA

NLPHL (>stage IA) is treated according to (the same stage) CHL with combined-modality therapy (chemotherapy followed by IFRT) [320, 321].

Ongoing clinical trials will help to clarify the role of systemic chemotherapy or antibody-based approaches in the treatment of these patients.

Paediatric Hodgkin lymphoma

A full review of RT for paediatric HL is beyond the scope of this chapter. However, paediatric protocols in both North America and Europe have typically prescribed ≈20 Gy to most patients, with only few selected patients with partial response receiving and a RT dose of 30 Gy. The marginal benefit of an additional boost dose is unclear. In contrast, adult protocols typically prescribe 30 Gy, with very favourable-risk patients receiving 20 Gy.

Peripheral T-cell lymphomas

According to the WHO classification 2008 mature T-cell and NK-cell neoplasms can be divided into cutaneous, extranodal, nodal, and leukaemic subtypes, all occurring at incidences below 1 in 100 000 people per year [322, 323]. The clinically aggressive extranodal and nodal types of T-cell lymphoma are considered as PTCL based on their descendency from peripheral (mature) T cells. Within PTCL, further histologic subtypes can be distinguished at variable prevalence depending on patient age and geography (see above). In Western countries the most common entities encompass PTCL-NOS (30%), ALCL (20%), AITL (15%), and the NK/T-cell lymphomas (15%) [323, 324]. Further subtypes of PTCL are the EATLs, of which the classical EATL mostly incurs in the small bowel and is associated with coeliac disease in patients from Northern Europe, while the monomorphic variant (type II EATL) appears to have a broader geographic distribution. The hepatosplenic T-cell lymphoma, mostly of γδ T-cell receptor type, occurs in male adolescents and young adults, 20% of which are associated with chronic immunosuppression [325, 326]. As for extranodal PTCL involving the skin, the cutaneous γδ T-cell lymphomas represent a rapidly progressive disease demanding intensive systemic

treatment, compared to the mostly indolent course of the αβ T-cell receptor-positive subcutaneous panniculitis-like T-cell lymphoma, in part occurring in association with systemic lupus erythematosus in some patients [327, 328].

Detailed immunohistopathological evaluation and molecular studies, in many cases involving reference pathology, are essential for diagnostic accuracy [323]. In cases of ALCL the expression of CD30 on the tumour cells as well as the mutational status for the ALK, constitutively activated mostly by fusion to the nucleophosmin gene (NPM) through t(2;5) or alternative partners is important for therapeutic stratification. In paediatric patients, elevated levels of antibody titers against the NPM/ALK fusion protein were found to be prognostic for favourable outcome [329]. Besides the serological screen for antiviral titres applicable to any lymphoma patient, initial workup of PTCL patients should also include T-lymphotropic virus-1 (HTLV-1) serology in order to identify HTLV-1 positive adult T-cell lymphoma/leukaemia. EBV serology is necessary to identify patients at risk for EBV-reactivation associated with lymphoma-mediated or treatment-associated immunosuppression [330]. PCR for plasma levels of EBV genome copy numbers allows monitoring of EBV-reactivation, and may serve to follow disease in some entities, particularly NK/T cell lymphoma, nasal type [331]. Further immunological and molecular markers for outcome prediction are currently under investigation, yet without current impact on the treatment stratification [332].

Staging of patients with PTCL follows standard studies, with 18-fluoro-2-deoxyglucose FDG-PET as a helpful measure to detect and follow extranodal manifestations [333]. The IPI is well suited for outcome prognosis with current treatment regimens [334], though a revised international index integrating BM involvement (PIT) has been proposed [335].

So far, evidence for treatment recommendation in PTCL patients has been derived from retrospectives analyses and phase II clinical trials only; results of current phase III protocols specifically designed to optimize the treatment of patients with PTCL are expected.

Extranodal NK/T-cell lymphoma, nasal type

Due to its prevalence in Asian and Native Americans of Mexico, Central America, and South America, knowledge about treatment strategies of extranodal NK/T-cell lymphoma, nasal type mainly stems from Asian register analyses and studies. In limited stages I and II, IFRT should be applied with curative intent. Sequential or concurrent chemotherapy further improves treatment results, leading to OS rates of 78–86% by combinations of radiotherapy with platinum-based chemotherapy [336]. The optimal protocol of either concurrent, e.g., the 2/3 DeVIC-protocol, or sequential regimens is currently accruing [336–338]. In advanced stages, systemic chemotherapy is mandatory. Results with CHOP-based regimens had been unsatisfactory with one-year OS rates of only 20%, due to the low susceptibility of the NK/T-lymphoma cells towards anthracyclines. Treatment protocols integrating ifosfamide, asparaginase, methotrexate and etoposide, e.g., the SMILE protocol, or platinum-based combinations have demonstrated improved efficacy in the salvage setting [337, 339], and should therefore be offered as first-line treatment. Consolidation of remission by high-dose chemotherapy followed by either ASCT or alloSCT is an option in first-line treatment, and should clearly be evaluated in the salvage setting.

Anaplastic large-cell lymphoma

ALCL predominantly occurs in paediatric patients and young adults, and usually responds well to current paediatric or adult chemotherapy protocols [340]. For adult patients with ALK-positive ALCL, six courses of CHOEP in trials of the German High Grade Lymphoma Group (DSHNHL) or ACVBP-been based protocols in studies of the GELA (Groupe d'etudes lymphomes adultes) lead to five-year OS rates of 90% [334, 341]. For adult patients with ALK-negative ALCL, the outcome under CHOP or CHOEP as a primary therapy is worse, so that consolidation of remission by high-dose therapy and ASCT represents an option to achieve a five-year OS rate of 70% [342]. Due to the high expression of CD30 on the ALCL lymphoma cell surface, brentuximab vedotin, a conjugate of a monoclonal anti-CD30 antibody and the microtubulin inhibitor monomethyl-Auristatin E, has significant cytostatic activity against ALCL lymphoma cells and has been available for patients since 2012. The RR as a single agent is as high as 86% in the situation of relapsed disease [343], opening a window towards definitive therapy with high-dose therapy for some patients. Whether brentuximab vedotin has a role as part of first-line treatment regimens for patients with ALCL is currently under investigation in a prospective phase III trial.

Peripheral T-cell lymphomas (angioimmunoblastic T-cell lymphoma, peripheral T-cell lymphomas not otherwise specified)

The majority of patients with PTCL, i.e., those with NOS and AITL and those with rare subtypes, are treated with six to eight courses of CHOP-based regimens, resulting in five-year OS rates of 20–50%, depending on clinical risk factors summoned in the IPI [344, 323]. The addition of etoposide to the CHOP-backbone (CHOEP) increases the RR, particularly in the ALK-negative ALCL patients [334, 342], albeit at cost of increased toxicity in elder patients; thus, CHOEP may be offered to select patients age <60 years. Novel agents to be added to, or to substitute parts of, the CHOP or CHOEP-backbone of are currently under investigation. Eligible patients are candidates for consolidating high-dose therapy with ASCT, which in several phase II studies showed five-year OS rates of 50% [342, 345, 346]. However, despite early-dose intensification, approximately 25% of patients experience primary progression or early relapse of lymphoma.

In the relapse situation, intensified multiagent platinum-based cytostatic drug combinations like ICE, DHAP, or gemcitabine-based combinations have shown significant efficacy against PTCL and thus offer a bridge for eligible patients towards definitive high-dose therapy followed by ASCT or alloSCT [335, 345, 347, 349]. For patients not eligible for multiagent chemotherapy, several agents have shown single-agent cytostatic activity and acceptable toxicity, namely the methotrexate analogue pralatrexate, the HDAC inhibitor romidepsin, as well as gemcitabine, bendamustine and the IMID lenalidomide [349–352]. Based on the results of phase II trials, both romidepsin and pralatrexate have gained FDA approval as single agents for patients with relapsed PTCL. Despite transient antitumour efficacy, both intensified cytostatic drug combinations and novel agents are not sufficient to secure long-term disease control [353]. In cohorts of patients eligible for high-dose therapy and HLA-compatible donors, alloSCT have provided DFS at rates of 40–50% [354–357], offering alloSCT as a therapeutic option with curative intent.

CHAPTER 55

Sarcomas of soft tissues and bone

Alessandro Gronchi, Angelo P. Dei Tos,
and Paolo G. Casali

Introduction to soft tissue sarcomas

Soft tissue sarcomas (STSs) represent a heterogeneous group of rare mesenchymal malignancies, with an annual incidence of approximately 5/100 000 [1]. Bone sarcomas are even rarer, with an incidence of around 0.3/100 000/year [1].

The median age of incidence of soft tissue sarcomas (STSs) is about 60 years, but varies according to histology (e.g., rhabdomyosarcoma and Ewing sarcoma occur in children and young adults, whereas pleomorphic sarcomas affect adults and the elderly). The main sites of occurrence also depend on histology, but generally the most frequently affected sites are the lower limbs, followed by upper limbs, trunk, and head and neck region. Some sites are related to specific histologies, such as the retroperitoneum for well-differentiated/dedifferentiated liposarcoma and leiomyosarcoma. Visceral primary locations are quite rare, with the exception of uterine leiomyosarcomas, with an incidence of 0.5/100,000/year, but STSs are possible in any visceral site [2, 3].

The age incidence of bone sarcomas is bimodal, with osteosarcoma and Ewing sarcoma prevailing in the second decade and chondrosarcoma in the sixth. The most frequent site of occurrence is the lower limbs, followed by the pelvis.

Surgery is the mainstay of local treatment of all sarcomas. Adjuvant radiation therapy (RT) is often used in high-grade STSs and Ewing sarcoma, while adjuvant/neoadjuvant chemotherapy can be offered in selected STSs and is part of the standard treatment of osteosarcoma and Ewing sarcoma. Of course, histology, not age, determines clinical decisions, so that osteosarcoma, Ewing sarcoma, or rhabdomyosarcoma in an adult are treated in the same way as in children. The role of medical therapy is limited in chondrosarcoma, while molecularly-targeted therapies are expected to find a role in chordoma.

Sarcomas show some peculiarities in their natural history, which have therapeutic implications. A considerable number of sarcomas typically metastasize to the lungs before spreading to other organs, and typically they lack lymph node regional extension, although exceptions exist with regard to selected histological types. Thus, surgery of isolated lung metastases is performed, especially when prognostic factors are favourable, that is, when the number of lesions is limited and the disease-free interval is reasonably long. If and how to combine surgery of isolated lung metastases with chemotherapy is uncertain, although unfavourable prognostic factors encourage the inclusion of medical therapy in the treatment program. Likewise, in most histologies, lymph nodes are generally not routinely a target of surgical exploration, unless they are clinically involved.

Staging and diagnosis

To better define the extent of extremity and truncal STSs, including depth of invasion and relationship with neurovascular structures, a contrast-enhanced MRI of the affected site is the preferred imaging study. To establish the diagnosis, a percutaneous core needle biopsy is the preferred method. Fine needle aspiration biopsy can be an alternative only in centres with a specific expertise in cytological diagnosis of sarcoma. If percutaneous core needle biopsy fails, an open biopsy is indicated. Histological diagnosis should always be obtained before making any treatment decision. Further staging studies for patients with extremity STS should include abdominal and chest contrast-enhanced CT. A bone scan is not routinely recommended if the chest and the abdomen are clear, unless clinical signs of bone involvement are apparent. Patients with abdominal visceral, pelvic, and retroperitoneal sarcomas should undergo contrast-enhanced CT imaging of the abdomen, pelvis, and chest. Patients with breast STS should undergo contrast-enhanced MRI imaging to define depth of extension; mammography is not routinely useful. Positron emission tomography (PET) is rarely indicated in routine sarcoma care. PET scans should only be ordered selectively, when attempting to resolve an ambiguous finding on other imaging or gauging treatment responses under specific circumstances.

In bone sarcomas, a plain radiograph of the affected site is the primary study. Subsequent imaging should include contrast-enhanced CT to study bone involvement and MRI to study soft tissue extension. To establish the diagnosis, a percutaneous trocar biopsy is the preferred method. If percutaneous trocar biopsy fails, an open biopsy is indicated. Histological diagnosis should always be obtained before making any treatment decision. Further staging studies include contrast-enhanced abdominal and chest CT, bone scan and/or PET scan to identify possible skip lesions in the affected bone. In Ewing sarcoma (also named primitive Peripheral Neuro-Ectodermic Tumor [pPNET]) a bone marrow aspiration biopsy is part of the staging workup, although some concerns about its value have been recently raised.

Pathology

Sarcomas are pathologically classified on the basis of a combination of clinical, morphologic, and genetic features. The radiological appearance may be relevant for the pathologic diagnosis of bone sarcomas. In general, bone and STSs are regarded as major diagnostic challenges. This is certainly due their rarity, but also to their inherent morphologic features. For example, some of the common

diagnostic criteria of malignancy used in common cancers (i.e., increased mitotic activity, cytologic atypia, and hypercellularity) do not always apply to sarcomas, requiring highly specific diagnostic expertise.

An accurate recognition of the many histologic subtypes currently represents a major requirement for proper therapeutic planning. In the past, diagnostic accuracy was less crucial when treatment options were limited. By contrast, recent therapeutic advances have made proper sarcoma classification mandatory, especially in regard to proper subtyping. This makes case referral to specialized centres strongly advised with regard to pathologic diagnosis.

During the last decade, the classification of soft tissue and bone sarcomas has significantly evolved. A major step forward was the publication of the 2002 WHO classification of bone and soft tissue tumours [2], which for the first time established a strong integration between morphology and genetics. The main conceptual advances can be summarized as follows:

1. Integration of morphologic, immunophenotypic, and genetic findings, whereas classification was previously based on pure morphology.

2. Clear definition of the category of borderline (intermediate grade) mesenchymal neoplasms:

   a. Identification of locally aggressive, non-metastasizing tumours (i.e., desmoid fibromatosis).

   b. Identification of neoplasms which rarely metastasize (<2% of cases) (i.e., plexiform fibrohistiocytic tumour).

3. Definition of atypical lipomatous tumour as a synonym (based on morphology and genetics) for well-differentiated liposarcoma (WDLPS) occurring at surgically amenable anatomic sites. This important terminological shift acknowledged the fact that WDPLSs never metastasize and, when superficially located, are cured by complete surgery.

4. Reappraisal of obsolete diagnostic labels such as malignant fibrous histiocytoma (MFH), haemangiopericytoma (HPC), and fibrosarcoma.

5. Recognition of newly-described tumour entities.

The 2002 WHO classification was updated very recently and the current classification scheme for bone and STSs is reported in Boxes 55.1 and 55.2 [3]. Labels such as MFH and HPC do not exist anymore. The main practical advantage of the current classification is to identify morphologically/genetically/clinically homogenous subgroups, setting the stage for the development of more effective therapeutic strategies. The use of the WHO classification is strongly endorsed by several clinical practice guidelines to promote the adoption of a homogeneous nomenclature [4]

Morphologic characterization of sarcomas

As highlighted by Box 55.1 and 55.2, the classification of sarcomas is pragmatically conceived according to histogenetic criteria, that is, it refers to the morphologic similarity to a hypothetic normal tissue of 'origin'. This approach is practical, but does not reflect biologic reality. Any tumour, in fact, does not originate from normal tissue, but most likely from immature mesenchymal progenitor cells, which can undergo variable differentiation steps and thus generate distinct morphologies [5].

Box 55.1 Updated WHO classification of malignant and intermediate malignancy soft tissue neoplasms

Adipocytic tumours
- Atypical lipomatous tumours/well-differentiated liposarcoma (lipoma-like, sclerosing, and inflammatory variants)
- Spindle cell liposarcoma
- Myxoid/round cell liposarcoma
- Pleomorphic liposarcoma

Fibroblastic/myofibroblastic tumours
- Desmoid fibromatosis
- Dermatofibrosarcoma protuberans (DFSP)
- Fibrosarcomatous DFSP
- Atypical fibroxanthoma
- Solitary fibrous tumour
- Inflammatory myofibroblastic tumour
- Low-grade myofibroblastic sarcoma
- Infantile fibrosarcoma
- Myxofibrosarcoma
- Myxoinflammatory fibroblastic sarcoma
- Low-grade fibromyxoid sarcoma
- Sclerosing epithelioid fibrosarcoma

So-called fibrohistiocytic tumours
- Plexiform fibrohistiocytic tumour
- Giant cell tumour of soft tissue

Smooth muscle tumours
- Leiomyosarcoma

Pericytic (perivascular) tumours muscle tumours
- Malignant glomus tumour

Skeletal muscle tumours
- Embryonal rhabdomyosarcoma
- Alveolar rhabdomyosarcoma
- Pleomorphic rhabdomyosarcoma
- Spindle cell/sclerosing rhabdomyosarcoma

Vascular tumours
- Kaposiform haemangioendothelioma
- Retiform haemangioendothelioma
- Papillary intralymphatic angioendothelioma
- Composite haemangioendothelioma
- Kaposi sarcoma
- Pseudomyogenic 'epithelioid sarcoma-like' haemangioendothelioma

- Epithelioid haemangioendothelioma
- Angiosarcoma of soft tissue

Chondro-osseous tumours

- Extraskeletal osteosarcoma

Gastrointestinal stromal tumour

Nerve sheath tumours

- Malignant peripheral nerve sheath tumours
- Malignant granular cell tumour

Tumours of uncertain differentiation

- Angiomatous fibrous histiocytoma
- Hyalinizing angiectatic tumour of soft parts
- Ossifying fibromyxoid tumour
- Myoepithelioma
- Phosphaturic mesenchymal tumour
- Synovial sarcoma
- Epithelioid sarcoma
- Alveolar soft part sarcoma
- Clear cell sarcoma
- Extraskeletal myxoid chondrosarcoma
- Mesenchymal chondrosarcoma
- Desmoplastic small round cell tumour
- Extrarenal rhabdoid tumour
- PEComa
- Intimal sarcoma

Box 55.2 Updated WHO classification of malignant and intermediate malignancy bone neoplasms.

Cartilage tumours

- Chondrosarcoma
- Dedifferentiated chondrosarcoma
- Mesenchymal chondrosarcoma
- Clear cell chondrosarcoma

Osteogenic tumours

- Low-grade central osteosarcoma
- Conventional osteosarcoma
- Teleangiectatic osteosarcoma
- Small cell osteosarcoma
- Paraosteal osteosarcoma
- Periosteal osteosarcoma
- High-grade surface osteosarcoma

Fibrogenic tumours

- Desmoplastic fibroma of bone
- Undifferentiated high-grade pleomorphic sarcoma

Ewing sarcoma

Notochordal tumours

- Chordoma

Vascular tumours

- Epithelioid haemangioendothelioma
- Angiosarcoma

Smooth muscle tumours

- Leiomyosarcoma

Adipocytic tumours

- Liposarcoma

Epithelial tumours

- Adamantinoma

The diagnostic process toward a correct diagnosis of a sarcoma can be summarized as follows:

1. Recognition of the key morphologic features (i.e., cell shape, pattern of growth, and background).

2. Integration of a panel of immunophenotypic markers.

3. Integration of genetic features when deemed necessary.

Of course, the precise knowledge of the clinical picture (age, sex, anatomic site, clinical presentation, imaging) is mandatory, underlining the crucial importance of a multidisciplinary management of sarcomas, even in the diagnostic workup. Radiological imaging plays a role in the diagnosis of bone sarcomas, wherein it can undoubtedly guide the evaluation of surgical biopsies.

Morphologic evaluation of soft tissue tumours takes into consideration the following microscopic features:

1. cell shape: spindled, rounded, epithelioid, or pleomorphic (Figure 55.1).

2. pattern of growth: fascicular, storiform, alveolar, or solid (Figure 55.2).

3. background: fibrillary, myxoid, or desmoplastic.

4. vascularization.

The combination of these morphologic features allows the identification of a restricted number of diagnostic options. A conclusive assignment to a specific diagnostic label is then generally achieved by the integration of immunophenotypic data and, when necessary, molecular assessments. It should be always
Fig. 55.1 Cell shape represents an important clue to sarcoma classification. (A) Round cell morphology, (B) spindle cell morphology, (C) epithelioid cell morphology, (D) pleomorphic cell morphology.

emphasized that sarcoma diagnosis is extremely complex and that, even in expert hands, approximately 10% of lesions cannot be classified by using current classification criteria. Instead of arbitrarily forcing the inclusion of these cases into a specific label, it is preferable to adopt a descriptive approach highlighting the morphologic characteristics that may help predict their clinical behaviour.

As already noted, the diagnostic approach to bone sarcomas includes a broad use of both clinical findings and radiological imaging. Morphologically, the identification of malignant cartilaginous and osteoid matrix is an important clue to the diagnosis of chondrosarcoma and osteosarcoma, respectively. Among primary bone tumours, immunohistochemistry (IHC) plays its greatest role in the differential diagnosis of Ewing sarcoma and chordoma,
Fig. 55.2 Cell shape needs to be evaluated in the context of the pattern of growth. (A) Herringbone pattern of growth, (B) storiform pattern of growth, (C) fascicular pattern of growth, (D) alveolar pattern of growth.

whereas molecular genetics is a key tool in the differential diagnosis of Ewing sarcoma.

Immunophenotypic characterization of sarcomas

Immunohistochemistry is extremely useful in allowing an accurate classification of sarcomas [3]. As already mentioned, IHC appears to be more useful in the diagnosis of soft tissue than bone sarcomas, wherein the number of differentiation markers is much fewer. Table 55.1 summarizes the most commonly used

Table 55.1 Selected immunophenotypic markers utilized in bone and soft sarcoma diagnosis

Antibody	Histotype	Specificity
ALK	Inflammatory myofibroblastic tumour	++--

immunohistochemical markers as well as their potential diagnostic value. It should be stressed that, with extremely rare exceptions, no immunophenotypic marker possesses absolute specificity. The immediate consequence is that the evaluation of any panel of immunoreagents should be conducted rigorously and integrated with morphology. The use of single markers should be avoided.

Histologic grading of sarcomas

The histological type does not represent the unique feature on which therapeutic decision-making is based. Analogous to other fields of oncologic pathology, several morphologic grading systems have been developed to predict prognosis. It is a broadly shared opinion that the grading system generated by the Federation Nationale des Centres de Lutte Contre le Cancer (FNCLCC) in France represents a suitable option. This grading system is based on the integration of three microscopic parameters [6–8] (Box 55.3):

1. Differentiation.

2. Mitotic index, expressed as the number of mitoses in ten high power fields (HPF).

3. Necrosis.

To avoid misunderstandings, a few important caveats should be underscored.

1. Grading systems only complement, and do not replace, histologic diagnosis. In fact, grading is performed once the histologic label is properly assigned.

2. Grading systems only apply to surgical specimens. As the use of core biopsies is rapidly expanding, one should integrate

Box 55.3 Grading system for sarcoma developed by FNCLCC

Differentiation

Score 1: Sarcomas exhibiting morphology clearly related to a normal adult mesenchymal tissue (i.e., well-differentiated liposarcoma)

Score 2: Sarcomas of certain histotype (i.e., myxoid liposarcoma)

Score 3: Undifferentiated or embryonal sarcomas, sarcoma with uncertain differentiation

Mitotic index

Score 1: 0–9 mitoses/10HPF*

Score 2: 10–19 mitoses/10HPF

Score 3: > 19 mitoses/10HPF

   *HPF (high power field) = 0.1734 mm^2

Amount of necrosis

Score 0: no necrosis

Score 1: tumour necrosis <50%

Score 2: tumour necrosis >50%

Grade

Grade 1: score from 1 to 3

Grade 2: score from 4 to 5

Grade 3 score from 6 to 8

morphology with radiological imaging. Obviously, clinicians need to be aware of the limitation of this approach.

3. Histologic grading does not apply to all histological types, since some of them are related to a selective biologic potential, whatever the grading morphological assignment.

Grading systems are far from being prognostically optimal. In particular, they often fail to discriminate prognosis within the Grade 2 ('intermediate') category. It is possible that in the future a molecularly-based approach such as The Complexity Index in Sarcoma (CINSARC, see below) may replace microscopic grading systems, provided that current technical limitations are standardized [9].

Molecular characterization of sarcomas

Sarcomas, like tumours of the haemato-lymphoid organs, are frequently associated with relatively specific genetic alterations, such as chromosome translocations, amplification of proto-oncogenes, and loss of tumour suppressor genes. A significant number of sarcomas—in particular, pleomorphic sarcomas and leiomyosarcoma—actually exhibit more complex genetic aberrations that still need to be further elucidated. Table 55.2

summarizes the most common genetic aberrations observed in soft tissue and bone sarcomas. This represents an incomplete list, as new aberrations are continuously reported as a consequence of broader applications of genetic analysis [10]. It is also possible that in the future some histological types will be defined on the basis of their molecular characteristics rather than on morphology, as anticipated in small subsets of undifferentiated round cell sarcomas of bone [11].

Chromosome translocations not only shed light on the mechanism of sarcomagenesis, but also represent a powerful diagnostic tool (Figure 55.3). As with IHC, molecular genetic findings need to be interpreted in the context of morphology. In fact, contrary to general belief, they lack absolute specificity (Table 55.3). An example is the rearrangement of the ALK gene that can occur in subsets of non-Hodgkin lymphoma, lung cancer, and inflammatory myofibroblastic tumour [12].

The most common diagnostic applications of genetic testing in sarcoma are the following:

1. Challenging differential diagnoses (i.e., poorly differentiated round cell synovial sarcoma vs Ewing sarcoma; dedifferentiated liposarcoma vs retroperitoneal leiomyosarcoma).

2. Atypical anatomical sites (i.e., visceral locations).

3. Discrepancies between morphological and immunophenotypic findings.

Chromosome translocations do not represent the only diagnostically relevant genetic alterations. Detection of MDM2 amplification (or over-expression of the protein thereof) represents a key tool in

Fig. 55.3 EWSR1 rearrangement detected by fluorescence in situ hybridization (FISH).

the recognition of well-differentiated as well as of dedifferentiated liposarcoma [13, 14]. An important example of diagnostic application of molecular genetics is the detection of mutations of the β-catenin gene in desmoid fibromatosis [15].

During the last decade, several attempts have been made to determine the prognostic value of molecular genetic findings. Most analyses have focused on Ewing sarcoma, alveolar rhabdomyosarcoma, and synovial sarcoma. Results have been conflicting; as of today no meaningful molecular prognostic stratification can be foreseen [16–20]. A notable exception is the recently published molecular signature called CINSARC (The Complexity Index in Sarcoma) that may allow better separation of intermediate-grade sarcomas [9]. Nonetheless, this attempt is based on the use of a relatively complex technique (CGH-array) and requires availability of fresh material. Both factors may unfortunately hamper the application of CINSARC on a large-scale basis.

The indisputable efficacy of KIT/PDGFRA inhibition in GIST has certainly boosted interest in targeted therapy in solid cancers, including rare ones. There exists a need for biomarkers capable of predicting response to novel treatments and identifying a preclinical rationale for their potential use. The opportunity to target ALK in inflammatory myofibroblastic tumour, PDGFβ in DFSP, mTOR in malignant PEComas and lymphangioleiomyomatosis, MDM2 in dedifferentiated liposarcoma, and KDR in angiosarcoma, are all examples of potential clinical applications [21–25] New molecular techniques such as next-generation sequencing associated with functional genomics approaches will clarify which of the many detected genetic aberrations actually represent true drivers of oncogenesis [26].

The challenge of achieving diagnostic accuracy in sarcomas

Diagnostic accuracy, both in morphology and molecular biology, is a key factor for optimal therapeutic planning. However, as sarcomas are rare diseases, it is a challenging goal [27]. As mentioned, inherent diagnostic difficulties and the low number of cases entail the risk of erroneous disease recognition. For these reasons, pathologic second opinions at reference centres or within health networks are strongly advised. In addition, as molecular testing is increasingly utilized in the diagnostic workup of sarcomas, and the quality of molecular diagnostics also tends to be extremely variable

and dependent on local expertise, it seems important that ad hoc external quality assurance programs are implemented [28].

Surgical management of soft tissue and bone sarcomas

Basic principles

Sarcomas usually present as solid masses. The periphery of the lesion is the most vital part of the mass. It is generally surrounded by a pseudocapsule of variable thickness consisting of compressed tumour cells embedded in a fibrovascular tissue, rarely associated with an inflammatory component, and in continuity with the surrounding normal tissues. This is the reason why a simple excision, i.e., enucleation, cannot be curative, even if most sarcomas do not seem to infiltrate surrounding structures.

Indeed, sarcomas respect anatomical borders. Thus, the local anatomy influences tumour growth by setting natural barriers to their extension. In general, sarcomas take the path allowed by least resistance anatomical planes and initially grow within the anatomical compartment in which they arose. Only at a later stage are the walls of that compartment violated (i.e., the cortex of a bone or the aponeurosis of a muscle) and the tumour breaks into another compartment. Most bone sarcomas are bicompartmental at the time of presentation: they destroy the overlying cortex and extend directly into the adjacent soft tissues. STSs may arise between compartments (thus being extracompartmental) or in anatomical sites that are not walled off by anatomical barriers, such as the intermuscular or subcutaneous planes. In the latter case, they remain extracompartmental and only at a later stage break into the adjacent compartment.

There are four basic types of excisions [29], depending on the relationship of the dissection plane to the surface of the tumour. An 'intralesional' excision is performed within the tumour mass and results in removal of only a portion, so that macroscopic tumour is left behind. In a 'marginal' excision, the dissection plane crosses the pseudocapsule of the tumour. Such an excision may leave microscopic disease, and microscopic margins may be either positive or negative, depending on the type of tumour and surrounding tissues. 'Wide' excision entails removing the tumour with a cuff of circumferential healthy tissue. However, the adequate thickness of this cuff varies broadly according to the type of tissue. It should be of some centimetres along the longitudinal plane of the muscle. It can be one centimetre along the axial plane of the muscle. It can be few millimetres, or even less, in proximity of tissues particularly resistant to tumour, such as peritoneum or pleura. If not infiltrated, the underlying structures can be safely preserved. If infiltrated, their removal should always be considered. 'Radical' resection implies removal of the tumour and the whole anatomical compartment in which it is located. Of course, a compartmental resection does not define per se the quality of surgical margins, since it can achieve a wide or a borderline margin, depending on how close the tumour is to the border of the compartment.

The quality of surgical margins is critical and ideally should be always evaluated by both the operating surgeon and the pathologist [30]. The closest margin should be identified and extensively sampled. Microscopically, margins are defined as negative, when the tumour edge is covered by at least one mm of healthy tissue, or positive when the tumour edge is covered by less than one mm of healthy tissue or is found at the inked surface [31–35].

In principle, the aim of surgery is to resect the tumour surrounded by healthy tissue and to avoid positive surgical margins. In fact, the risk of local failure doubles in case of positive margins, despite the use of post-operative RT, with a subsequent impact on distant outcome and survival (Table 55.4). While the initial prognosis mainly depends on the biology of the tumour, once a patient has 'survived' the first period and the systemic risk dependent on tumour biology becomes weaker, the quality of surgery appears as the strongest prognosticator for outcome [31–35]. Two factors can explain the impact of positive surgical margins on survival: a relatively slight increase in the risk of subsequent systemic spread in case of recurrence and a direct impact of local recurrence that may lead to death in some sites [35–36]. In the case of pathological positive margins, re-excision should always be considered whenever feasible [30, 37–39]. This does not apply when a positive margin is planned in advance in order to preserve an important structure for function-sparing (i.e., a motor nerve), provided adequate RT is delivered (especially in the preoperative setting) [40–43].

Table 55.4 Incidence of local recurrence, distant metastases and death in major published series of extremities soft tissue sarcoma, according to microscopic surgical margins

LR, incidence of local recurrence; DM, incidence of distant metastases; CSD, incidence of disease specific death; M+, positive microscopic surgical margins; M−, negative microscopic surgical margins.

The same principles should be applied to tumours located outside the limbs and trunk wall, although wide margins may be more difficult to obtain and a careful balance between morbidity and chances of cure should always be made on a case-by-case basis [44].

The ability to reconstruct large defects by pedicled or free flaps, to restore function by replacing bone, vessels, nerves, and to perform major visceral resections, whenever needed to improve quality of surgery, should be part of proper planning before the surgical procedure is undertaken. Therefore, a careful multidisciplinary approach is needed in all cases for proper treatment delivery [30].

Soft tissue sarcoma

Surgery of STSs primarily consists of the resection of the tumour surrounded by a cuff of healthy tissue [45]. In extremities and trunk walls, this basically implies the resection of surrounding soft tissues, mainly muscles, subcutaneous fat, and skin (Figure 55.4). The necessity to cover the soft tissue loss by a flap transposition depends on several factors, such as the site and size of the defect, exposed structures (bone, vessels, nerves), and functional restoration. Vessels, nerves, and bone are always resected when directly invaded/encased, while their resection has to be discussed on a case-by-case basis when their periosteum, adventitia, or epineurium are infiltrated without invasion of the underlying structure.

Similar principles apply to surgery of retroperitoneal sarcomas [46]. In fact, unlike primary epithelial solid tumours, which are usually confined to a single organ and can generally be removed with resection of that organ, retroperitoneal STS commonly abuts multiple surrounding organs. Paralleling surgery in extremities, tumours should be systematically resected en bloc with surrounding tissues, which at this site are mainly the adjacent viscera even when not overtly involved, to minimize the risk of microscopically positive margins (Figure 55.5). Indeed, not all uninvolved adjacent viscera/structures are routinely resected en bloc with the tumour [47–53]. The objective is to achieve a wide microscopic margin along most surfaces, even by removing additional dispensable organs, while performing what is essentially a marginal excision along critical structures. In general, the ipsilateral kidney,

colon, and mesocolon and at least a portion of the psoas can be safely and relatively easily resected without serious consequences. Resection of the pancreatic body and tail and spleen can usually be performed with a relatively low short-term morbidity. Resection of other structures, including—but not limiting to—the aorta, inferior vena cava, iliac vessels, femoral nerve, diaphragm, duodenum, head of the pancreas, uncinate process, liver, and bone (specifically vertebral bodies) entails significant resections with ensuing greater morbidity, so that it is not performed unless macroscopic invasion is documented. This extended approach has been systematically adopted only in the recent years, with a significant improvement in local control in all patients and of survival in patients affected by low/intermediate grade sarcomas, whose outcome had been dominated by inoperable local recurrences [47–61] (Table 55.5).

Similar principles do apply, as long as it is feasible, also to tumours at other sites (mediastinum, head and neck) [30], a systematic description of which goes beyond the scope of the present text.

Since the STS family is made up of at least 50 histological subtypes, these general principles can be applied differently in selected subtypes, as follows.

Atypical lipomatous tumour/well-differentiated liposarcoma

This low-grade tumour, when arising in the extremity, has a relatively low rate of recurrence, may not recur for a relatively long interval, and has minimal or no risk of distant metastatic spread and death, unless dedifferentiation occurs [62]. In fact, dedifferentiation in general entails a risk of metastatic spread as high as 20%, but in extremities dedifferentiation develops only rarely (less than 5% of cases) [62, 63]. In other words, a well-differentiated liposarcoma in extremities only occasionally poses a life threat. Furthermore, low-grade recurrent atypical lipomatous tumours (ALTs) may grow slowly for years. Therefore, such tumours can be resected with a modest positive margin, especially when preserving limb function is an issue. The same low-grade tumour, however, becomes a life-threatening disease when located to the retroperitoneum, even if lacking areas of dedifferentiation [64]. In fact, as discussed above, local control is an issue for retroperitoneal sarcomas, and patients often die of local regional failures without developing distant
Fig. 55.4 (A) Contrast-enhanced T1 weighted MRI of myxoid liposarcoma of the left thigh, originating in the abductor compartment. The planned resection line is shown in blue. (B) Surgical specimen cut through the longest diameter. The tumour is surrounded by a cuff of healthy tissue.
Fig. 55.5 (A) Contrast-enhanced CT scan of left retroperitoneal liposarcoma. The planned resection line is shown in blue. (B) The surgical specimen. The tumour is covered by the left kidney and colon (and psoas muscle in the back, not shown here).

metastases. An extended surgical approach for well-differentiated liposarcoma located at this site is therefore recommended [44].

Myxoid/round cell liposarcoma

This tumour predominantly occurs in the extremities [65]. It can be found even in the trunk, but almost always as a metastasis from a primary tumour located in extremities. Pure myxoid liposarcoma rarely metastasizes, while the risk increases when a round cell component is present in more than 5% of the tumour [65–68]. At variance with most other sarcomas, metastases can occur in the soft tissues, abdomen, mediastinum, and bone before affecting the lung [65–68]. Chemotherapy and RT may be particularly active [69–71]. Therefore, preoperative therapies, either by single or combined modalities, are often offered to reduce surgical morbidity and increase chances of cure [72, 73].

Dermatofibrosarcoma protuberans

Dermatofibrosarcoma protuberans (DFSP) is a superficial tumour, which infiltrates soft tissues for centimetres beyond the obvious margins of the lesion and can recur locally following inadequate

Table 55.5 Local recurrence-free survival and overall survival in major published series of retroperitoneal soft tissue sarcoma

	Study period	Median FU	No patients	Complete resection (%)	5-years LRFS	5-years OS

resection [74]. However, the more common variety of DFSP has no metastatic potential. The goal of surgery should be to achieve negative margins, often necessitating reconstruction by plastic surgery [74–76]. When cosmetic/function preservation is an issue, limited positive margins may be accepted, and a wider resection postponed when a recurrence occurs. Since DFSP is usually a relatively superficial tumour, resection of muscles deep to the tumour is often unnecessary. Approximately 5–10% of patients with DFSP present as a more aggressive fibrosarcomatous variant, which may more often recur locally and potentially spread [74]. These patients should be treated as those having a 'conventional' sarcoma, with limited positive margins being only occasionally acceptable.

Leiomyosarcoma

This sarcoma may arise from skin, soft tissues, visceral organs, or vessels and it is one of the commonest histological subtypes [77]. The approach to skin leiomyosarcoma is easy, since the invasion of surrounding tissues is limited and the metastatic potential almost nil. On the contrary, soft tissues leiomyosarcoma often presents as large masses and has a systemic risk as high as 50% [77, 78]. An extended soft tissue en bloc resection with the mass is required. Adjuvant treatments are often discussed with the patient, although their impact on local and distant outcome is limited. Gastrointestinal (GI) leiomyosarcomas are rare [79]. They are treated by the resection of the affected GI tract. Adjacent organs are resected only if directly infiltrated. They typically have a high metastatic risk and spread to liver before other organs. Vascular leiomyosarcomas predominantly arise from veins and often abut outside the vessel extending in the soft tissues [80, 81]. The affected vascular tract should be resected en bloc with adjacent soft tissues. Intravascular tumour thrombi may be present and should be removed en bloc with the disease. Frozen margin specimens over the vessel should be taken to ensure free margins. The metastatic risk is significant, although a fraction of them may have a long natural history.

Pleomorphic liposarcoma, unclassified pleomorphic sarcoma, synovial sarcoma

These tumours, although different from a histological and biological standpoint, are usually approached the same way [82–86]. They predominantly affect the extremities and present as large and deeply located masses. They have a significant metastatic risk and are often treated by combined modalities. The surgical approach consists of the standard procedures described above.

Myxofibrosarcoma

This malignant tumour, when located superficially, infiltrates through soft tissue (subcutaneous fat and investing fascia) some centimetres beyond the ostensible margins of the visible or palpable mass. When located intramuscularly, the extension of the infiltration is usually limited by anatomical barriers, although it has a higher propensity to invade them as compared to other histological subtypes. Myxofibrosarcoma most commonly arises in the extremities of elderly individuals. It demonstrates a 30% rate of local recurrence and a 16% rate of distant recurrence [87–90]. Eventually, multiple local recurrences may lead to amputation. Therefore, it is critical to pursue aggressive local therapy. Wide surgical margins (≥2 cm beyond the clinical boundaries of the palpable mass in general and up to 4 cm for the superficial ones) should be the goal of surgery, which often requires complex wound closure or flap reconstruction by a plastic and reconstructive surgeon, as well as

resection/reconstruction of vessels and nerves. RT, either preoperatively or post-operatively (described below), may be considered.

Malignant peripheral nerve sheath tumours

These tumours often arise from a major peripheral nerve, which can be identified macroscopically. They can occur sporadically or in the context of neurofibromatosis type 1 syndrome. The high-grade variant is marked by an early propensity for distant metastases [91–93]. When originating from a peripheral nerve, they also may spread along the nerve fibres proximally or distally. Wider margins at this level should be obtained (if possible at least 4 cm of macroscopic healthy nerve) to limit this loco-regional failure, which eventually may reach the spinal cord. Frozen sections may help ensure the accomplishment of clear margins.

Angiosarcoma

Management of primary and radiation-associated (secondary) angiosarcoma is challenging because of the multifocality of this disease [94–97]. Scalp angiosarcoma is a particularly insidious malignancy. While radical surgery is possible (requiring complex flap reconstructions), it is not uncommon for patients to develop local recurrences immediately outside the margins of resection even if the margins of the initial resection were widely negative, with or without RT. Angiosarcoma is sensitive to systemic chemotherapy and to RT. Since surgery is rarely curative, it should not be considered as the only treatment choice, especially for scalp angiosarcoma. Surgery may be reserved for patients who are experiencing problems with local control (bleeding from a fungating tumour) or who only appear to have a solitary site of disease by both clinical examination and imaging while undergoing systemic therapy.

Epithelioid and clear cell sarcomas

Both of these tumours tend to affect young adults and to occur in distal extremities. At variance with all other histological subtypes, they may give rise to in-transit metastasis along the affected limb and to loco-regional lymph node metastases [98–100]. Accurate staging of the whole limb is mandatory and sentinel lymph node biopsy should be considered as part of the routine approach to primary disease. Their sensitivity to conventional chemotherapy is at best limited. A more aggressive variant of epithelioid sarcoma tends to occur to the limb roots and the trunk and is called proximal-type epithelioid sarcoma [101]. This variant behaves as a very aggressive unclassified sarcoma, having a high risk of hematogenous distant spread. Loco-regional lymph nodes are only rarely involved [102]. Its sensitivity to conventional chemotherapy is higher, but fast progression after response is often observed. If a preoperative treatment is planned, the status of the disease has to be carefully monitored.

Radiation-induced sarcomas

Radiation-induced sarcomas are rare and include a variety of histological subtypes, the most common of which are pleomorphic undifferentiated sarcoma, angiosarcoma, malignant peripheral nerve sheath tumours, and leiomyosarcoma [103, 104]. Beside the inherent characteristics of each histological subtype, they are all marked by a high propensity to locally recur, given the difficulty in obtaining clear margins. In fact, it is very difficult to distinguish tumour infiltration of healthy tissues from radiation-induced changes around the tumour site. The tumour should be excised with as much surrounding tissue as possible. Often, if not always,

this requires plastic surgery and liberal vascular and nerve resection and reconstruction. Systemic chemotherapy and re-irradiation are often considered, given the overall dismal prognosis.

Bone sarcomas

Surgery of bone sarcomas primarily consists of resection of the affected bone, surrounded by healthy tissue whenever needed and feasible [105, 106]. Adequate staging by bone scan and cross-sectional imaging should be performed to understand the extent of the disease in the affected bone and the presence of satellite or skip lesions. Resected peripheral bones are usually replaced by prostheses of variable lengths and complexity [107, 108]. Bone pure allografts can also be used, especially when tendon and joints need to be replaced. In the last years, composed allografts (bone grafts + prostheses) have been successfully used in several conditions [109, 110]. Thus, the rate of primary amputation today does not exceed 10% [107, 110]. The replacement of axial bones (pelvis and spine) is more difficult, while they are frequently affected in adult bone sarcomas. In fact, osteosarcoma and Ewing sarcoma predominantly affect the limbs, while many chondrosarcomas and all chordomas affect central bones.

For tumours located in the pelvis, hindquarter amputations can still be an option, although followed by significant disability. Rehabilitation is difficult and patients often require prosthetics or remain in a wheel chair for the rest of their life. Nevertheless, this is still an option in several presentations. In fact, reconstruction is a challenge for most pelvic tumours. The pelvic anatomy (presence of sciatic and femoral nerves, iliac vessels, sacral plexus, and pelvic viscera) adds to the complexity of the osteo-muscular resection and may sometimes render an amputation more suitable than a conservative procedure.

There are three types of conservative resections [111]. Type I is the easiest and is used for tumours confined in the iliac wing. It consists of resections of the iliac bone without interrupting the continuity between the sacrum and the rest of the pelvic bones of the affected site. Type II is the most complex, since it involves the acetabulum. Different types of reconstruction have been attempted over the years with prosthesis or bone allografts. None of them has proved to be really successful. The failure rate is as high as 30–50% [112, 113]. This should be factored in the decision before surgery is undertaken. Type III involves the pubis and is used for tumours confined to the pubic bone and ileo-pubic and/or ischiopubic branches. No reconstruction is needed as for type I. Tumours may obviously extend beyond one segment of the pelvic bone and the resection include more than one type.

For tumours located to the sacrum, the complexity of the intervention increases with the level of resection, although reconstructions are almost never needed, even for total sacrectomy [114]. For tumours located below S3, the resection is straightforward and followed by a complete recovery of the pelvic functions, if at least both S3 roots are preserved. For tumours located above S3, morbidity depends on the number of roots resected. In fact, if both S2 are preserved, there is still a 40% chance of complete recovery of the pelvic functions. If both S2 roots are transected, the pelvic functions are lost and rehabilitation is needed to live with fecal incontinence and neurologic bladder. From S1 on the resection determines also impairment of the motor/sensitive function of the limbs [115]. For tumours located to the mobile spine, a reconstruction is always needed and usually consists of a segmental arthrodesis obtained

through osteosynthesis and bone grafts. Morbidity is mainly related to the extent of resection in soft tissues, the number of roots and the number of vertebral bones resected [116]. Dorsal vertebral bones resection is followed by more limited morbidity, if compared to lumbar and cervical bones, since the latter always affect the function of at least one of the lower or upper limbs.

Surgery of bone tumours in general and all the more of pelvic/spine tumours should be performed only by a dedicated team with specific expertise in this difficult field.

Osteosarcoma

Osteosarcoma is the most common primary bone sarcoma and is usually marked by a high grade of aggressiveness [117]. It typically occurs during childhood and adolescence. More rarely it can occur in young adults. Histologic variants include low-grade central, conventional, teleangiectatic, small cell, paraosteal, periosteal, and high-grade surface osteosarcoma. In patients over the age of 40, it is usually associated with a pre-existent condition such as Paget's disease or irradiated bone [118, 119]. Paraosteal, periosteal, and low-grade central osteosarcomas tend to occur in the third decade of life. Between 80–90% of the tumours occur in the metaphysis of long bone with the most common sites being the distal femur, proximal tibia, and proximal humerus. Surgery and chemotherapy are the mainstays of therapy. Given the sensitivity of osteosarcoma to chemotherapy, surgery is commonly performed after three to four courses of chemotherapy, which is continued post-operatively [120, 121]. Pathologic evaluation of tumour response to chemotherapy has a significant prognostic value. Parosteal osteosarcoma is a distinct variant of osteosarcoma. Its incidence is estimated to be 4% of all osteosarcomas. It arises from the cortical bone and generally occurs in an older age group and has a better overall prognosis than osteosarcoma, since it may also have a low histological grade of aggressiveness. 50% of cases exhibit overt cartilaginous differentiation. The treatment program may vary according to the grade and be surgery alone for the low-grade variant. Periosteal osteosarcoma is a rare cortical variant of osteosarcoma that arises superficially on the cortex, most often on the tibial shaft, and can also occur in patients over 50 years of age. It may also have a more limited aggressiveness as compared to the more common osteosarcoma [122, 123]. Surgery for all osteosarcomas always consists in the resection of the affected bone. Reconstruction is performed as described above.

Ewing sarcoma/pPNET

Ewing sarcoma represents the prototype of round cell sarcomas. Typically it strongly expresses CD99, and harbours a typical chromosomal translocation that fuses in most cases the *EWSR1* gene on chromosome 22 with a variety of partner genes (*FLI1* in approximately 85% of cases), belonging to the ETS family of transcription factors (Table 55.2). Ewing sarcoma is marked by high aggressiveness and early distant spread. They may occur either in bones or soft tissues. Ewing sarcoma of bone occurs predominantly in the diaphysis or metaphyseal-dyaphyseal portion of long bones of skeletally immature patients. The peak incidence is the second decade of life. It is exceedingly rare in very young patients and in those over the age of 30. Extraskeletal Ewing sarcoma represents approximately 20% of all Ewing sarcomas, tends to occur at an older age, and exhibits the same morphological and molecular features of the

skeletal counterpart. Treatment is made up of surgery, chemotherapy and RT [124, 125]. Given the high sensitivity of these tumours to chemotherapy, the local treatment is almost always preceded by induction chemotherapy. Histopathologic evaluation of tumour necrosis after induction chemotherapy has prognostic value. In general, there is retrospective evidence that adding surgery to chemotherapy and RT improves the final outcome. However, for proximally located or trunk lesions, where surgery may result in excessive morbidity, RT may be delivered as definitive treatment. Surgical resection in selected presentations may also be placed at the end of the chemotherapy program.

Chondrosarcoma

The most useful prognostic tools in chondrosarcoma, both in terms of surgical planning and prognosis, is histological grading [126, 127]. There are a few distinct, relatively rare, histological variants of chondrosarcoma, in addition to the conventional type. These include clear cell, mesenchymal, and dedifferentiated chondrosarcoma. Primary chondrosarcomas are not associated with a pre-existing lesion (90% of the cases). Secondary chondrosarcomas are associated with pre-existing chondroid lesions such as enchondroma, osteochondroma, chondroblastoma, chondromyxofibroma, periosteal chondroma, and synovial chondromatosis (10% of the cases). The majority of conventional chondrosarcomas occur between the ages of 40 and 60. The most common sites are the pelvis, femur, and shoulder girdle. Low-grade chondrosarcomas originating from the limbs can be treated by intralesional curettage and application of local adjuvants, such as phenol, ethanol, and liquid nitrogen. As an alternative for small lesions, radiofrequency ablation and, more recently, cryoablation are occasionally used. Intermediate- and high-grade chondrosarcomas as well as low-grade chondrosarcomas located in the pelvis or shoulder girdle have to be treated by conventional resections and reconstructions. Adjuvant RT is not routinely administered, since chondrosarcoma has long been considered radioresistant. Nonetheless, recent data on the administration of radiotherapy with heavy particles have raised potential benefit for problematic sites. Confirmatory studies are needed to include these new modalities as part of a standard approach. Chemotherapy is not routinely recommended, save for specific subtypes. Dedifferentiated chondrosarcoma may be treated by employing chemotherapy regimens similar to those used for high-grade sarcomas [128, 129]. This is most true of mesenchymal chondrosarcoma, for which chemotherapy regimens similar to those used in Ewing sarcoma may be selected.

Chordoma

Chordomas are definitely rare, affecting 0.1 individuals in 100 000 per year. They occur predominantly between the age of 50 and 70, although the ones located at the base of the skull may occur in young adults. The most common site of origin is the sacrum (it is the most common primary bone tumour of the sacrum), followed by the clivus and base of the skull in general. More rarely it affects the mobile spine. It is never found outside the vertebral bodies. Resection of the affected bone can be challenging because of extension into surrounding soft tissues, spinal cord or central nervous system, viscera, and major vessels. Surgery has always been considered the mainstay of therapy, although often followed by significant long-term morbidity [130, 131]. Only recently, with the introduction of heavy particles, i.e., protons and carbon ions (RT

that allows the delivery of higher doses by sparing normal tissues), combined approaches or radiotherapy alone have been proposed as an alternative to conventional surgery with the goal of reducing surgical sequelae [132, 133]. Confirmatory studies are needed, though the rarity of these tumours, along with their variability in clinical presentation, make studies all the more difficult, especially when the goal is to compare long-term complications from different treatment modalities.

Radiation therapy

Soft tissue sarcoma

In general, limb-sparing surgery relies on complementary RT, to minimize risk of local recurrence, as demonstrated in two pivotal trials--one with brachytherapy (BRT) and one with post-operative external beam radiotherapy (EBRT) [134, 135]. RT reduces the risk of local recurrence from greater than 30% to less than 10% in most series, but does not impact distant failure or overall survival.

EBRT may be delivered preoperatively or postoperatively [136]. When given preoperatively, the goal of radiation is to treat the margins to minimize the risk of recurrence, not necessarily to reduce the size of the tumour per se. A randomized comparison between pre- and post-operative EBRT has been performed. There was no difference in local recurrence rates [137]. Preoperative EBRT was associated with a doubling in the rate of wound complications (35% vs 17%) but with a lower rate of late complications and tissue fibrosis and better functional outcomes. Postoperative EBRT generally covers a larger field (including drain sites) and used a higher dose than preoperative EBRT. This is particularly important in young adults of childbearing age with proximal thigh STS: preoperative EBRT may spare the gonads whereas postoperative radiation may not [136].

Moreover, data from retrospective series suggest that the administration of preoperative RT minimizes the risk of limited close or positive margins [40–43]. Therefore, whenever preservation of function is a goal and the tumour abuts critical structures, preoperative EBRT should be considered.

Brachytherapy (BRT) may be delivered through after-loading catheters placed across the tumour bed at the end of surgery [138]. The goal of BRT is to deliver additional radiation to a close margin (including neurovascular structures) with minimal treatment to surrounding tissue, particularly when further EBRT is no longer feasible. When the final pathologic margins are confirmed, the appropriate catheters may be loaded with radioactive seeds once or twice a day for a defined treatment period concentrated over the close margins. To minimize wound complications, catheters should not be loaded until at least postoperative day five. To minimize the risk of dislodging the catheters, any drains placed at the time of surgery should remain in place until the catheters have been removed.

Intraoperative RT (IORT) has also been studied in extremity STS, but it has failed to improve results of conventional EBRT. It is therefore not routinely used in clinical practice [138].

Patients with small (<5 cm), superficial, well-circumscribed STS resected with a wide margin (>1 cm) of non-neoplastic tissue or a biologic barrier (fascia) may not require RT, provided that they can be reliably followed for local recurrence [139]. The same may apply to low-grade tumours, independent of tumour location and

size. Of note, myxoid/round cell liposarcoma and angiosarcoma are more sensitive to EBRT than all other histological subtypes [71]. Therefore, EBRT is more liberally used in patients affected by these tumours, especially in the preoperative setting.

In retroperitoneal sarcomas (RPS), the role of RT is controversial, in the absence of phase III randomized controlled trial data. While RT unequivocally reduces the risk of local recurrence in patients with extremity STS, this has not been proven in RPS [140]. Furthermore, the proximity of radiosensitive tissues and organs, such as the liver and small intestine, together with the large size of the radiation field, limit its utility. Those who utilize RT generally deliver it preoperatively, when the bulk of the tumour itself displaces uninvolved organs out of the radiation field [141]. There is one ongoing randomized trial assessing the efficacy of preoperative RT in patients with RPS.

IORT has also been studied in RPS, with results similar to those achieved in the extremities [142].

Bone sarcoma

In general, osteosarcoma and adult bone sarcoma (chondrosarcoma and chordoma) are considered radioresistant tumours [143–146]. No randomized trials have been performed to formally address radiation in these tumours. On the contrary, Ewing sarcoma is highly radiosensitive [147]. RT is therefore part of Ewing sarcoma treatment program, while other bone tumours have only been rarely treated by EBRT, and then predominantly in a palliative setting. The introduction of heavy-particle RT has allowed the possibility to increase dose delivery, sparing normal tissues [4]. Both chordomas and chondrosarcoma located to difficult sites (base of the skull and spine) have then been treated with these new methodologies in recent years with promising results [143–146]. Confirmatory studies are needed to understand whether this modality could complement or even substitute for surgery.

Medical therapy

The efficacy of chemotherapy in adult STS has long been confined to the low/intermediate spectrum, with doxorubicin and ifosfamide as the only active drugs, whether used alone or in combination. More recently, some cytotoxics were proven to have significant antitumour activity in selected STS subtypes, while new molecular targeted agents are progressively entering the medical armamentarium. Therefore, medical therapy of adult STS is much broader today. While this evolution is in progress, single-agent doxorubicin might still be regarded as a standard medical therapy by some, while a set of old and new agents are increasingly used at many institutions for 'precision' therapeutic choices. The quality of evidence backing this shift is a limiting factor and a reason for discrepancies across institutions. In fact, STS are a family of rare tumours, so that clinical studies regarding selected histologies are all the more difficult to carry out.

With regard to strategy, medical therapy always needs to be combined with other treatment modalities in localized STS and is considered an essentially palliative modality in advanced STS. This differentiates adult STS from small round blue cell sarcomas of childhood, in which chemotherapy has a comparatively much higher efficacy and an eradicating potential in some presentations. Actually, adjuvant chemotherapy is not standard treatment in adult STS, although, in the high-risk setting, many institutions share the

decision with the patient to undertake it. In addition, chemotherapy may be employed to down-stage localized, surgically problematic STS, possibly in combination with RT. Metastatic STS are treated with chemotherapy, unless surgery of isolated lung metastases is used alone, as is the case when prognostic factors are good. As long as the number of available agents, and regimens, increases, clinical decision-making may be problematic in regard to how many lines of medical therapy should be resorted to in the palliative setting.

Active drugs and regimens in soft tissue sarcoma

Doxorubicin is still regarded as the most active agent in adult STS. It is reasonable to place its response rate at around 20%. In the metastatic setting, median duration of tumour response is slightly less than one year. Ifosfamide was later shown to exert an antitumour activity which can be viewed as essentially similar to doxorubicin. Therefore, the potential for cytoreduction of single-agent chemotherapy, whether doxorubicin or ifosfamide, is low and its prognostic impact is limited in the advanced disease.

Doxorubicin and ifosfamide can be combined, to potentially increase their efficacy. Currently available randomized clinical trials have failed, however, to show any major improvement in the average adult STS patient [148]. However, data from randomized trials point to an increased progression-free survival and response frequency with multiagent chemotherapy. Uncontrolled studies report better results, which suggest a selection bias, by which larger studies might have been less selective, thus diluting what the effect of multiagent chemotherapy may be in some clinical presentations. The toxicity of the combination of doxorubicin and ifosfamide, administered over three to five days with mesna (Uromitexan®) and hydration, and recycled every three weeks, is definitely higher than single-agent chemotherapy with either doxorubicin or ifosfamide. With a full-dose doxorubicin plus ifosfamide regimen, most patients experience profound neutropenia, though lasting a few days, while platelets are relatively spared, with a few patients requiring platelet transfusions. Neutropenic fever is experienced by a substantial number of patients in some cycles, so that granulocyte colony stimulating factors are generally used. Thus, while doxorubicin is a safe standard choice for palliating an advanced disease, a full-dose doxorubicin + ifosfamide regimen may be used when tumour response, or major antitumour activity, is a clinical goal, after considering age, performance status, and co-morbidities. Thus, the combination of doxorubicin plus ifosfamide will be preferred when chemotherapy is used as an adjuvant, or when the goal is to down-stage an advanced, or surgically problematic, localized STS. It may also be an option when any major symptom needs prompt palliation. In general, the good performance status of many adult STS patients—advanced though their disease may be—is an additional factor which tends to favour multiagent chemotherapy to maximize the treatment effect. It goes without saying that there is a high variability across institutions in these treatment choices, depending on whether a conservative or a more aggressive approach is preferred.

Both doxorubicin and ifosfamide can be regarded as wide-spectrum agents across all adult STS histological subtypes. Indeed, while this is true of doxorubicin, ifosfamide seems to have limited activity in leiomyosarcomas [149]. On the contrary, it has major activity in synovial sarcoma. Ifosfamide is generally used in the 6–9 g/sqm dose range every three weeks. When used at doses in the 12–15 g/sqm range, it is termed 'high-dose' [150].

If administered over four to five days, its toxicity profile includes high-grade neutropaenia, though of limited duration. CNS symptoms are uncommon in adults, though minor drowsiness may be a sign. While urothelial toxicity is prevented by the standard administration of mesna, renal damage is generally avoided by appropriate hydration, although signs of tubular toxicity may be encountered. A better toxicity profile is associated with high-dose ifosfamide administered as a prolonged 14-day infusion through a portable external pump, every four weeks [151]. High-dose ifosfamide may be active in a proportion of patients already exposed to standard-dose ifosfamide. This makes it a second-line option in patients previously treated with doxorubicin and ifosfamide. Otherwise, in patients treated with doxorubicin alone, it can be used also at standard doses with the same aim. In patients who responded to doxorubicin, other anthracyclines can be employed in the second-line setting as well, although the top cumulative dose is a limiting factor for treatment duration, so that high-dose ifosfamide may again be an alternate choice. Liposomal doxorubicin may be an option.

Dacarbazine (DTIC) is an agent which was included in the multiagent regimens CYVADIC and its ifosfamide-containing 'upgrade', MAID. Currently, its added value is felt to be limited, so that multiagent first-line chemotherapy is most often doxorubicin plus ifosfamide without dacarbazine. However, an exception may be the use of dacarbazine in leiomyosarcomas, an entity which may be less sensitive to ifosfamide. Thus it may be added to doxorubicin in the first-line therapy of leiomyosarcomas, or it can be used as a further-line single-agent choice in leiomyosarcoma. Its toxicity profile is good with currently available antiemetic coverage. Its oral counterpart, temozolomide, which is converted into its active metabolite in plasma, has been shown to have some activity in leiomyosarcoma as well [152].

In fact, there is currently a trend towards tailoring medical therapy to the histological sarcoma subtype [153]. Amongst cytotoxics, for example, gemcitabine (Gemzar®) has distinct activity in leiomyosarcoma and angiosarcomas [154, 155]. Angiosarcomas are also the only histological subtype in which taxanes have some antitumour activity in sarcomas; low-dose paclitaxel, given every 7 to 10 days, is effective in angiosarcoma [156]. In this histology, the onset of tumour resistance may be relatively fast, but the substantial cytoreduction which can be achieved may be exceedingly useful in combination with surgery and/or RT, especially in the loco-regional advanced setting.

Docetaxel (Taxotere®) was combined with gemcitabine to give rise to the GEMTAX regimen [157]. Given the lack of activity of taxanes in all STS histologies with the exception of angiosarcoma, the assumption is that this combination may exploit a synergy between the two agents. Data are conflicting, however, about the clinical added value of the combination in comparison to gemcitabine alone. GEMTAX seems mainly active in leiomyosarcoma, and possibly pleomorphic sarcoma and angiosarcoma. Of course, tolerability of single-agent gemcitabine is much higher than the combination, so that its use may be all the more interesting for palliation of recurrent, metastatic leiomyosarcoma.

A marine-derived agent which was shown to be active in advanced STS is trabectedin [158]. The two histologies where trabectedin is most active are leiomyosarcomas and liposarcomas, although other subtypes may be sensitive, in particular synovial sarcoma. Indeed, when liposarcomas are split into their two main subtypes, i.e.,

well- and dedifferentiated and myxoid/round cell liposarcomas, the activity profile of trabectedin looks markedly different. In fact, trabectedin shows a definitely higher response frequency in myxoid/round cell liposarcomas [70, 72], a longer duration of response, and a higher chance of a new response after treatment interruption following best response [159]. This has been shown retrospectively, while proof of a peculiar mechanism of action was provided as well. In fact, myxoid/round cell liposarcomas are a translocation-related STS, and trabectedin apparently displaces the fusion protein from target genes, thus displaying a kind of 'targeted' mechanism of action. Myxoid/round cell liposarcomas are a chemosensitive histology, marked by a relatively 'slow' natural history, which adds to the value of therapy per se. Trabectedin is generally well-tolerated, provided patients do not have liver function abnormalities at baseline, in particular cholestasis. Proper dose reductions and delays are suggested for liver alterations during therapy. Steroid premedication and a maximum dose per cycle may be useful to minimize toxicity. This may be limited to fatigue following administration, nausea in some patients, and laboratory evidence of increased transaminases. Major myelosuppression is unlikely, though it may occur and be prolonged, while rhabdomyolysis is exceedingly rare.

A well-known molecularly-targeted agent, imatinib (Gleevec®), has a specific role in STS, namely in DFSP [21]. This is a surgically-curable disease in most cases [74], but there are instances in which medical therapy can be useful because the tumour is locally advanced and cytoreduction can make surgery feasible or, rarely, metastases have developed. Imatinib has a high response frequency, possibly related to the fact that DFSP is a translocation-related STS, with increased stimulation of platelet derived growth factor receptor beta (PDGFRβ) as a result of the fusion protein activity. It is worth distinguishing typical DFSP from its 'fibrosarcomatous' variant. Imatinib is active also in these cases, but the duration of response is shorter [160].

Other highly specific subgroups which may be sensitive to molecularly-targeted therapies include ALK-rearranged inflammatory myofibroblastic tumours, which may be responsive to crizotinib (Xalkori®) [161]. Likewise, malignant PEComas are marked by a degree of disruption of the mTOR pathway and a proportion of these tumours are responsive to mTOR inhibitors [22]. Formal clinical studies are lacking at the moment, and the therapeutic value of these target therapies in these histologies is yet to be defined.

In a randomized clinical trial with broad eligibility criteria, mTOR inhibitors have been shown to slightly prolong progression-free survival in advanced sarcomas when given as a maintenance therapy following best response to standard chemotherapy [162].

The antiangiogenic agent pazopanib (Votrient®) was shown to significantly prolong progression-free survival when given for advanced, previously treated, non-adipogenic STS [163]. It is possible that pazopanib exerts a more specific antitumour activity in selected histologies, namely synovial sarcomas and leiomyosarcomas. Some antitumour activity has also been shown also for other antiangiogenic agents, including sorafenib, sunitinib, cediranib, and bevacizumab. Sunitinib (Sutent®) has been shown to result in tumour shrinkage in alveolar soft part sarcoma and solitary fibrous tumours, possibly through its activity on PDGFR [164, 165]. Cediranib (Recentin®) was also shown to be active in alveolar soft part sarcoma. The combination of temozolomide and bevacizumab (Avastin®) was shown to be active in solitary fibrous tumour [166]. A variety of molecularly-targeted agents are under

investigation today in STSs. Likely, they will provide their best benefit in selected histologies expressing specific biomarkers. The development of new agents in this way, i.e., looking for biomarkers within selected STS subtypes, is challenging due to the small numbers of patients.

Medical therapy in the multidisciplinary treatment strategy of soft tissue sarcomas

Positioning of medical therapy in the treatment strategy of adult STS is problematic and reflects uncertainties in the potential of available agents and regimens.

Chemotherapy was tested as an adjuvant as from the 1970s, with a series of randomized clinical trials employing doxorubicin or doxorubicin-based regimens. These studies varied widely in sample size as well as eligibility criteria. Second-generation trials employed anthracyclines and ifosfamide. An Italian randomized trial tested a full-dose epirubicin plus ifosfamide regimen for five courses vs no medical therapy after surgery. It enrolled around one hundred patients with an advantage in overall survival which led to its early interruption [167]. On longer follow-up, the magnitude of the benefit and its statistical significance decreased. A large randomized trial from the EORTC, of five courses of doxorubicin plus ifosfamide vs no medical therapy after surgery, has been recently reported to be negative [168]. Prognostically, the patient population of this trial was slightly more favourable than the Italian trial. In brief, the largest trials, both of first- and second-generation, have been negative, while some smaller trials provided positive results. The former may have been less selective, as opposed to the latter, which might have highlighted benefits confined to the highest-risk patient subgroups. When published randomized trials of adjuvant chemotherapy were pooled together in a meta-analyses, a statistically significant benefit was shown in terms of overall survival, distant relapse-free survival, and local relapse-free survival. In the last published meta-analysis, the absolute risk reduction was in the range of 5–10% for all these end-points [169]. The main weakness is the presence of large negative trials, as opposed to some positive small studies, with marginal statistical significance [167]. In brief, the absolute benefit is likely limited, in the 10% range, and the uncertainty is high. This is widely felt to justify a policy of shared decision-making with patients in conditions of uncertainty, obviously selecting high-risk presentations. In practice, these are marked by a high malignancy grade, tumour size in excess of 5 cm, and deep location for limb STS. Clinical decisions by analogy may be allowed in rare tumours, so that adjuvant chemotherapy may be proposed also in non-limb sarcomas, including visceral, when the risk is high as well. An anthracycline plus ifosfamide regimen is generally selected, although leiomyosarcomas might benefit more from the combination of doxorubicin with dacarbazine or gemcitabine with docetaxel. Less chemo-responsive histologies are usually excluded, while waiting for more mature data about the activity in the advanced setting of selected molecularly targeted agents for some of them.

When the decision is made to use chemotherapy in the localized disease setting, one may well choose to administer medical therapy before surgery. This may provide benefit in quality of surgical margins or function-sparing surgical options. A randomized trial compared three courses of preoperative full-dose epirubicin plus ifosfamide chemotherapy with the same preoperative treatment followed by two further cycles of the same regimen [170]. No difference was found. Though lacking a no-adjuvant therapy control arm, the results of the treatment arm of the previous Italian randomized trial were reproduced in this study. An option may thus be to administer three cycles of full-dose multiagent chemotherapy, possibly before surgery, to exploit both the systemic potential of adjuvant treatment in high-risk adult STS and the local benefit for subsequent surgery. A currently ongoing trial randomizes patients between three pre-operative cycles of full-dose epirubicin plus ifosfamide and three cycles of a histology-driven chemotherapy. A trial is ongoing in uterine leiomyosarcomas comparing no further treatment after surgery versus four courses of GEMTAX followed by four courses of doxorubicin.

The natural history of a distinct proportion of adult STS is marked by the presence of 'isolated' lung metastases, i.e., in the absence of extrapulmonary disease. Complete surgery of all visible lesions, if feasible, is then standard treatment. The treatment goal is to pursue eradication in a small proportion of these patients and achieve a meaningful disease-free interval in a number of them. It is unknown whether adding chemotherapy might increase the cure rate, although it probably increases relapse-free interval. In these patients, however, medical therapy at relapse might bring the same prognostic benefit in the context of a palliative approach. Prognostic factors for complete surgery of isolated lung metastases are tumour aggressiveness, reflected by the previous relapse-free interval (or the doubling time on serial assessments, if available) and the number of metastases [171]. The value of thresholds is questionable, but a number of metastases of around four or five and a previous relapse-free interval in the range of one to two years may be used to separate patients with a bad or a good prognosis. In the lack of available clinical trials, therefore, many clinicians do not use chemotherapy when prognostic factors are favourable and share the decision with the patient whether to use it or not when prognostic factors are poor. If selected, chemotherapy may be administered preoperatively, with the opportunity to monitor tumour response and thus tailor treatment accordingly.

Chemotherapy is an obvious choice in the advanced metastatic setting, although its benefit may be limited, with median overall survival intervals of less than one year. Median duration of tumour response is in the same range. It cannot be ruled out, however, that an aggressive use of all medical options available, depending on tumour histology, may translate into an effect on survival and quality of life, although obviously within the context of palliative intent. The availability of new agents and their potential in selected histologies definitely encourages the clinician to embark in several 'further-line' medical therapies. The prognostic impact of an aggressive medical approach to the advanced disease is unknown, while its impact on costs and toxicity is obvious. The natural history of metastatic adult STS is marked by a relatively limited extent of disease for long periods of time, as may be the case when metastases are confined to the lungs. Thus, performance status is often preserved along the natural history of an advanced disease. A few symptoms may be dominating, with dyspnoea prevailing, carrying all the palliative problems therefrom. Merging symptomatic measures with reasonable attempts through a specific medical therapy may be the best choice in several cases. However, clinical decision-making is especially challenging when disease is advanced, performance status is good, and convincing histology-driven medical options are potentially available.

Isolated limb perfusion

This treatment is reserved for limb-threatening STS. This procedure involves placing vascular access catheters into the main artery and vein of the affected extremity and perfusing with high-dose chemotherapy (usually melphalan) and tumour necrosis factor alpha (TNFα) under hyperthermic conditions. Isolated limb perfusion (ILP) is generally performed as an open procedure with cutdown directly onto the vessel and is delivered in the neoadjuvant setting.

ILP with chemotherapy alone has uniformly failed in the treatment of unresectable extremity STSs. The addition of TNF-α to this treatment approach has proved to be critical in improving the outcome of locally advanced extremity STS [172].

TNF-α has an early and a late effect; it enhances tumour-selective drug uptake during the perfusion and also plays an essential role in the subsequent selective destruction of the tumour vasculature. These effects result in a high response rate, which translates into limb salvage in most cases. Several single-institution reports have confirmed the safety and efficacy of this procedure.

Medical therapy of adult Ewing sarcomas

Ewing sarcoma may occasionally occur in adults. In adults, extraskeletal presentations are more common than in children. Indeed, extraskeletal Ewing sarcoma may occur to any site, from soft tissues (e.g., of limbs or superficial trunk) to viscera (e.g., kidney, etc.). The overall treatment strategy, including medical therapy, should follow the same principles applied in younger patients and the prognostic impact of treatment should thus parallel in principle what is achievable today in younger ages, though in all series there is an unfavourable prognostic trend as age increases. Likewise, treatment does not change in principle whether the patient has skeletal or extraskeletal disease. Of course, tolerability of treatments may decrease as long as age increases, especially with regard

to the duration of chemotherapy foreseen by standard protocols for skeletal Ewing sarcoma of children and adolescents. In several institutions, a duration of chemotherapy approaching nine courses is often applied. It is not known to which extent the approach to the exceedingly rare subcutaneous Ewing sarcomas might be less aggressive, given their good prognosis.

Active agents are doxorubicin, cyclophosphamide, ifosfamide, vincristine, etoposide, and actinomycin D, so that many of these drugs are usually incorporated in protocols employed both in adults and in children and adolescents [173, 174]. Upfront chemotherapy is often used, followed by surgery of residual localized disease and consolidation chemotherapy. RT is often used in adults, lacking of some constraints in sites which may apply to children.

An open question has to do with the value of high-dose intensification therapy for patients who do not respond optimally to preoperative chemotherapy and for high-risk and metastatic patients. Indeed, there is retrospective evidence that high-dose consolidation therapy may be effective for patients with isolated lung metastases, while disease diffusely metastatic to bone and/or bone marrow is not [175]. However, lacking positive controlled evidence, high-dose therapy is not standard treatment today in any presentation. With regard to extraskeletal Ewing sarcomas, pathologic criteria to assess tumour response to preoperative chemotherapy in bone Ewing sarcoma do not apply [176], and there is uncertainty as to how to stratify prognosis on the basis of the clinical presentation.

Salvage medical therapy may include high-dose ifosfamide, cyclophosphamide + topotecan, temozolomide + irinotecan, or gemcitabine + docetaxel [177–180].

Medical therapy of adult bone sarcomas

Osteosarcoma may occasionally occur in adults. The overall treatment strategy, including medical therapy, should follow the same

baseline

+4 months
Fig. 55.6 Non dimensional tumour response in a chordoma patient to imatinib mesylate.

principles applied in younger patients. Thus, it will include chemotherapy in all cases, with the exception of low-grade osteosarcomas, i.e., paraosteal and periosteal osteosarcoma, and low-grade chondroblastic osteosarcoma of the skull. Clearly, there may be a problem of treatment tolerability depending on age, e.g., ≥ 40. This mainly affects the use of high-dose methotrexate. In fact, in most institutions standard chemotherapy for osteosarcoma includes doxorubicin, cisplatin, and high-dose methotrexate [181]. Randomized evidence in favour of the addition of the latter is lacking, but retrospective studies are available and randomized comparisons have not replicated expected results for standard treatment. High-dose methotrexate may be less tolerated in older patients, so that there are protocols in >40-year-old patients, including high-dose methotrexate only for suboptimally-responding patients. Ifosfamide and etoposide may be added as well in those patients with suboptimal tumour response to preoperative chemotherapy. Aside from high-dose methotrexate, principles of treatment should be the same as in children or adolescents. This means that preoperative chemotherapy is generally used, although with a lack of any randomized evidence supporting the added value of placing medical therapy preoperatively instead of postoperatively. Preoperative chemotherapy is followed by surgery, then by consolidation chemotherapy, which may be tailored to the degree of pathologic response. A macrophage activator, muramil tripeptide, has been associated to some benefit when given upfront in a single randomized trial, with reference to the subgroup receiving ifosfamide (which, however, was shown to be devoid of any added value in the same study), so that its incorporation in standard protocols is still controversial [182]. In metastatic osteosarcoma, treatment is often the same as for localized disease with the addition of surgery of lung metastases, if isolated (i.e., in the absence of extrapulmonary lesions). The prognosis of osteosarcoma patients with isolated lung metastases occurring d'emblée may even parallel prognosis of localized disease when the tumour burden is very low, and in any case benefit from the same approach as for localized disease, plus surgery of lung nodules. When the relapse occurs to the lungs exclusively, the number of lesions and the disease-free interval dictate to which extent further chemotherapy is combined with surgery of metastases, if complete excision of all nodules is feasible [183]. Even the choice of second-line chemotherapy is based on previous treatments and tumour response. High-dose ifosfamide may be an option, while alternate agents are lacking for an effective salvage medical therapy in relapsing osteosarcoma patients, who generally receive virtually all active drugs first-line.

The medical therapy of chondrosarcoma has been poorly investigated [184]. However, it is logical to assume that low-grade chondrosarcomas are poorly responsive to cytotoxic chemotherapy. High-grade chondrosarcomas may have a higher sensitivity to agents used for high-grade sarcomas in general, while it is not yet understood to what extent drugs specifically active in osteosarcoma may be used as well. Mesenchymal chondrosarcomas are aggressive tumours which may display a sensitivity profile such that regimens used in Ewing sarcomas are often used.

Chordomas are poorly sensitive to cytotoxic chemotherapy, with the possible exception of the rare dedifferentiated chordomas. In the last years, molecularly-targeted therapies have been shown to be active in this disease, though their efficacy within the overall treatment strategy is yet to be elucidated. Imatinib has antitumour activity, which is likely related to its anti-PDGFRβ effect [185]. Responses are often unidimensional (Figure 55.6) and

progression-free survival may be in the one-year range. The combination of imatinib with mTOR inhibitors is currently investigated, with evidence of more pronounced dimensional responses. The dual histogenetic profile of chordomas may justify the evidence of activity which was provided for anti-EGFR agents, though it seems to be less remarkable. Strategically, medical therapy may currently find a place in metastatic chordomas as well as locally advanced tumours for which surgery and RT cannot be foreseen, or possibly can be envisaged in case of tumour response.

Michael Brada, Olaf Ansorge, and Claire Blesing

Tumours of the central nervous system

Epidemiology and aetiology

Compared with other cancers, primary neoplasms of the brain and spinal cord in adults are relatively rare. They comprise approximately 1.5% of all cancers. There are an estimated 6.4 new cases per 100 000 people per year and the lifetime risk is 0.6% [1].

The aetiology of most primary brain tumours is unknown; random somatic mutations in glial progenitor cells are thought to be the initiating event in gliomagenesis. Iatrogenic or environmental exposure to radiation is an established cause. For example, radiotherapy (RT) involving the cranium for childhood malignancies results in a 500-fold increased risk for meningioma after 40 years of follow-up compared to the normal population [2]. Genetic tumour predisposition syndromes or phakomatoses often have a nervous system component (Table 56.1). Lifestyle factors are not thought to contribute significantly to brain tumour development.

Classification, pathology, and molecular genetics

The WHO classification of brain tumours

Classification schemes are constantly evolving and aim to integrate historically-determined concepts with insights from molecular biology. Since its inception in 1979, the World Health Organization (WHO) classification of tumours of the central nervous system (CNS) has included a malignancy grading system (WHO grade I, II, III, and IV) that is applied across the diverse range of primary brain tumours. The purpose of the WHO grading system is to provide clinicians with guidance about prognosis. For example, a WHO grade I tumour (pilocytic astrocytoma, meningioma) has generally low proliferative potential and may be cured by surgery alone, whereas a WHO grade IV tumour (glioblastoma) has a high proliferation rate and is usually treated with surgery and adjuvant radio/chemotherapy. Although tumour grade is a strong independent predictor of outcome, it is important to remember that the site of a tumour in relationship to functional domains of the brain is equally important. For example, a benign (WHO grade I) convexity meningioma can be removed completely with resulting cure whilst the same grade I tumour located at the edge of the foramen magnum is relatively inaccessible and may result in fatal brainstem compression. Further, it should be remembered that the WHO grade reflects natural history following surgery, not adjuvant radio/chemotherapy.

The 2007 WHO scheme (Table 56.2) is a histological classification system; brain tumours are classified according to their presumed cell lineage (e.g., astrocyte or oligodendrocyte progenitor cell). This morphological approach is increasingly supplemented by molecular genetic data, and it is becoming clear that the molecular characteristics of histologically identical tumours are more powerful predictors of outcome or treatment response than histology alone. This will be reflected in the forthcoming amendment of the WHO classification scheme [3].

The role of neuropathology in the diagnosis of brain tumours

Modern CT and MRI techniques have revolutionized the initial diagnostic approach to a patient with a suspected brain tumour. However, in the vast majority of cases a biopsy is required to establish the nature of the neoplasm. Often only a small needle biopsy is obtained. In these circumstances the neurosurgeon works with a neuropathologist during the operation to establish whether diagnostic tissue has been obtained. These intraoperative consultations provide instant feedback and, due to the soft texture of most CNS neoplasms, are carried out via touch or squash preparations. The final diagnosis is obtained from tissue sections and molecular genetic data. This is synthesized in a report that may also take into account MRI appearances and possible sampling bias.

Cell of origin and recurrence after therapy

Both morphology and expression of lineage specific markers is used to infer the likely cell of origin of a brain tumour. This underpins the current classification system. A small number of proteins, detectable by immunohistochemistry, allow the distinction of glial, neuronal, and other lineages. Whether tumours arise from dedifferentiated mature cells or lineage-restricted precursors remains uncertain; however, there is increasing evidence supporting the idea that a small number of stem-like cells within an otherwise heterogeneous tumour are responsible for tumour progression, therapeutic resistance, and subsequent recurrence of malignant gliomas. Such 'tumour-initiating cells' are the focus of extensive research. Figure 56.1 shows a model of presumed histogenesis of common brain cancers.

Molecular pathogenesis of brain tumours

Most primary brain tumours occur sporadically; fewer than 5% occur in the context of hereditary tumour predisposition syndromes (Table 56.1). These often manifest with multiple stigmata reflecting the diverse tissues derived from the neuroectoderm. It is noteworthy that sporadic counterparts of familial brain tumours

Table 56.1 Inherited tumour syndromes and their nervous system lesions

Syndrome	Gene	Chr	Nervous system	Skin	Other
NF-1	*NF1*	17q11	Neurofibromas, MPNST, optic nerve glioma (pilocytic astrocytomas), astrocytomas	Café au lait spots, axillary freckling, cutaneous neurofibromas	Iris hamartomas (Lisch nodules), phaeochromocytoma, osseous lesions, leukaemia
NF-2	*NF2*	22q12	Schwannomas (bilateral, vestibular, and peripheral), meningiomas, ependymomas (spinal), astrocytomas, glial hamartias, calcifications	—	Posterior lens opacities, retinal hamartomas
vHL	*VHL*	3p25	Haemangioblastoma	—	Retinal haemangioblastoma, renal cell carcinoma, phaeochromocytoma, visceral cysts
TSC	*TSC1 TSC2*	9p34 16p13	Subependymal giant cell astrocytoma, cortical tubers	Angiofibroma, subungual fibroma, *peau chagrin*	Cardiac rhabdomyoma, duodenal polyps, lung and kidney cysts, renal angiomyolipoma, lymphangioleiomyomatosis
LFS-1	*TP53*	17p13	Astrocytomas (GBM), PNETs	—	Breast ca, sarcomas
Cowden	*PTEN*	10q23	Dysplastic gangliocytoma of the cerebellum (Lhermitte-Duclos), megalencephaly	Trichilemmoma, fibromas	Hamartomatous polyps of the colon, thyroid neoplasms, breast carcinoma
Turcot	*APC hMLH1 hPSM2*	5q21 3p21 7p22	Medulloblastoma, Glioblastoma	Café-au-lait spots (*hMLH1*)	Colorectal polyps
Gorlin	*PTCH*	9q31	Medulloblastoma	Basal cell carcinomas, palmar and plantar pits	Jaw cysts, ovarian fibroma, skeletal abnormalities
MRT	*INI1*	22q11.2	AT/RT	—	Renal rhabdoid tumours

Abbreviations: NF, neurofibromatosis; vHL, von Hippel-Lindau; TSC, tuberous sclerosis; LFS, Li-Fraumeni syndrome; MRT, malignant rhabdoid tumour predisposition syndrome. MPNST, malignant peripheral nerve sheath tumour; GBM, glioblastoma; AT/RT, atypical teratoid rhabdoid tumour; PNET, primitive neuroectodermal tumour.

(e.g., meningiomas, a hallmark of neurofibromatosis type 2) often carry mutations at the same locus (tumour suppressor gene), but manifest at an older age, as predicted by Knudson's two-hit hypothesis.

Insights from high-throughput tissue analyses

Brain cancers (gliomas) were amongst the first neoplasms subjected to systematic genomic and transcriptomic analysis. This has resulted in the identification of molecular subtypes of histologically identical tumours that may guide individualized treatments. However, translation into the clinic remains challenging. A few common themes have emerged from these studies. For example, the evolutionary history of a presumed cell of origin of a primary brain tumour is reflected in the number (and type) of mutations and epigenetic marks. For example, age and site-specific molecular signatures may be observed in glioblastoma, the most common malignant glioma. Mutations in the histone gene *H3F3A* (K27) occur in ~80% of midline glioblastoma in children but are rare in adults. Mutations in IDH1 or IDH2 are seen in young adults, particularly in hemispheric tumours, but are absent in older adults. IDH1/2 glioblastomas often arise from lower grade precursor tumours, whereas EGFR-mutated tumours often present de novo (Figure 56.2).

High-throughput analyses are rapidly evolving and the reader is advised to refer to online resources for up-to-date information [4, 5].

Tumour heterogeneity and evolution of resistance to treatment

The high-throughput datasets described above have two main limitations: they are generally static (reflecting one time-point of a highly dynamic process) and the use of bulk tissue as source material do not (yet) provide information about specific subpopulations of cells that may be most relevant for tumour progression. Tumour cell heterogeneity likely underpins also the emergence of therapy-resistant subclones. Analysis of sequential biopsies allows the construction of temporo-spatial evolutionary trees of genomic changes associated with tumour progression and treatment-induced changes [6]. These studies suggest that, in diffuse gliomas, recurrences not occurring under the selective pressure of temozolomide are seeded by cells derived from the initial tumour at early stages of their evolution, whereas those recurring after chemotherapy show distinct pathways to tumour progression. These observations suggest that it will be difficult to design effective therapies based on the molecular signature of a single (pretreatment) biopsy.

Clinical manifestations of brain tumours

Brain tumours can present with a wide range of clinical symptoms and signs, which are largely dependent on both the location in the brain and the rate of tumour growth. Patients with rapidly growing tumours are more likely to present with headaches due to raised intracranial pressure, seizures, and focal symptoms and signs. In

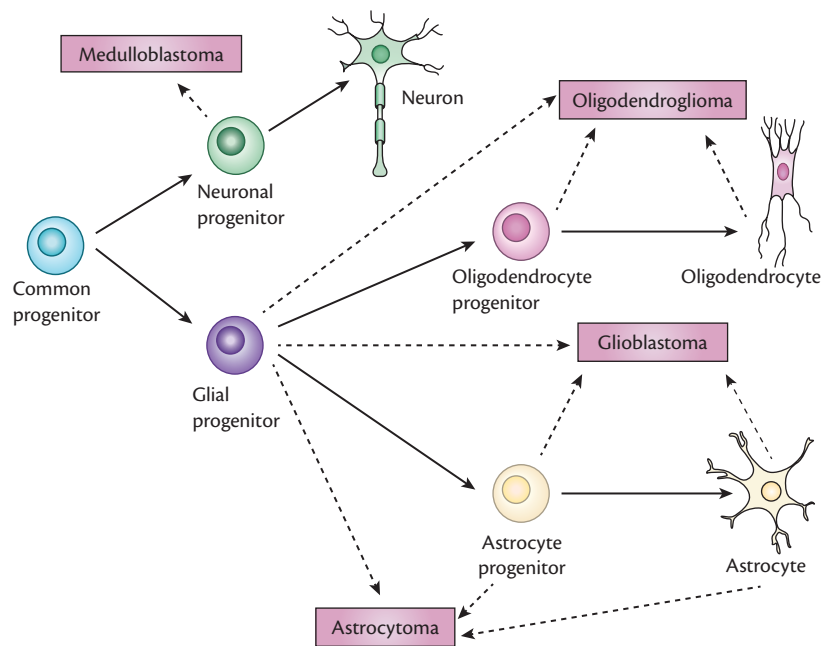

Fig. 56.1 Glioneuronal precursor cells and presumed origin of common brain tumours.

Fig. 56.2 Common molecular signatures of diffuse gliomas in adults. The constellation of a relatively small set of genetic alterations can be used to refine the classification of the main morphological categories of diffuse glioma (oligodendroglioma, astrocytoma, glioblastoma). Primary and secondary glioblastoma are morphologically indistinguishable but genetically distinct. Some of the markers are of prognostic (IDH1/2) or predictive (1p/19q) value (or both). Stratification by tumour genotype will be essential for future trial design.

Abbreviation: G-CIMP, Glioma CpG Island Methylator Phenotype.

contrast, many patients with low-grade gliomas present after a seizure but are otherwise completely well. With the increase in the availability of MRI scanning, asymptomatic tumours are also detected.

Headache, often an early symptom in the patient's history, is rarely the only symptom in a patient without abnormal neurological signs. Headache may be caused by raised intracranial pressure from peritumoural vasogenic oedema or from obstructive hydrocephalus (which occurs more commonly with posterior fossa tumours). Whilst headaches due to raised intracranial pressure have typical features (e.g., more severe when recumbent, associated with vomiting, and possibly visual obscuration), many patients have headaches (especially initially) which do not have any concerning 'red flag' features.

Seizures are a common presenting symptom, but these may be unrecognized focal or partial seizures. Patients can present with less focal signs such as personality or cognitive change. These symptoms are often detected after obtaining a corroborative history from a relative. Rapidly growing gliomas which involve the corpus callosum often present with striking cognitive change and sometimes incontinence, whereas slower growing tumours may present with more insidious cognitive and behavioural change (e.g., with a low-grade orbito-frontal meningioma).

Focal symptoms at presentation depend on the location of the tumour. Dysphasia may occur with lesions in the dominant frontal or temporal lobe and focal weakness or sensory symptoms may occur with lesions located in the frontal or parietal lobes, respectively. Patients may not always be aware of a visual field defect and instead present as a consequence of this (e.g., after repeated driving accidents) or an asymptomatic field defect may be detected on examination.

Compression of the quadrigeminal plate, due to intrinsic tumours in the posterior part of the third ventricle and in the pineal region, leads to palsy of upward gaze, ptosis, and pupillary dilation (Parinaud's syndrome) in addition to hydrocephalus. Tumours affecting the thalamus and basal ganglia tend to cause contralateral motor and sensory deficit and occasional impairment of consciousness.

Neuroradiology

CT and MRI allow non-invasive visualization of the CNS parenchyma as well as the cerebrospinal fluid (CSF) spaces, blood vessels, the adjacent skull, scalp, skull-base, and orbits. In addition to the macroscopic structural and anatomical information provided by standard CT and MRI imaging techniques, functional, ultrastructural, and pathophysiological information can also be obtained with contrast-enhanced techniques, diffusion-weighted imaging, diffusion tractography, perfusion imaging, MR-spectroscopy, and functional MRI. The structural imaging capabilities and, to a lesser extent, these more advanced techniques have made CT and MRI indispensible to the modern practice of neurology, neurosurgery, and neuro-oncology. Nuclear medicine techniques, including PET-CT, have a limited role in neuro-oncology.

The differential diagnosis of ring-enhancing intracranial mass lesions include metastases, glioblastoma multiforme (GBM), acute inflammatory demyelination, bacterial abscess, and a number of other infectious conditions such as toxoplasmosis, tuberculoma, and cysticercosis (Box 56.1). Diffusion-weighted imaging (DWI) can be used to distinguish between a bacterial brain abscess and a tumour by evaluating the diffusion characteristics of the fluid component

---

Box 56.1 Information to consider when generating a differential diagnosis of CNS mass lesions.

1. Age of the patient
2. Clinical presentation
   seizure
   neurological deficit
   headache
   length of history
3. History of a disease or syndrome, e.g., a phacomatosis, AIDS or a known systemic malignancy
4. Location of the lesions
   intra-axial vs extra-axial
   supratentorial vs infratentorial
   gray matter vs white matter vs both
   specific sites: brainstem, spinal cord, pituitary, suprasellar, pineal, intraventricular
   internal auditory meatus/cerebellopontine angle

of the lesion. Pus in bacterial abscesses demonstrates markedly restricted diffusion while necrotic tumour material demonstrates facilitated diffusion, except in rare instances where haemorrhage has occurred into the necrotic tumour centre. The absence of restricted diffusion in the fluid component of a ring-enhancing lesion has a high negative predictive value for excluding a bacterial abscess [7].

MR-spectroscopy is a well-established technique that allows the relative abundance of various metabolites within brain parenchyma to be determined. Standard brain MR-spectroscopy techniques target compounds such as choline, creatine, N-acetyl aspartate, lipids, lactate, various amino acids, and myo-inositol. Certain inferences can be drawn from the relative abundance of these metabolites and it offers information that is complimentary to the information obtained from standard MR imaging and perfusion imaging. MR spectroscopy techniques can be adapted to detect new

target metabolites; for example, much research is currently aimed at MR-spectroscopic detection of 2-hydroxyglutarate (2-HG), an oncometabolite resulting from enzymatic activity of the mutated IDH gene product [8].

Medical management of central nervous system tumours

Patients with brain tumours often develop a number of general medical issues requiring management [9]. Many patients have seizures and need treatment with anti-convulsant medication. Consideration should be given to the potential interaction between enzyme-inducing anti-epileptic drugs, steroids, and some chemotherapy agents. It appears that the use of non-enzyme-inducing agents is increasing. The prophylactic use of anti-epileptic drugs in patients with gliomas who have never had seizures is not currently recommended [10].

Corticosteroids (usually dexamethasone up to 24 mg/daily in divided doses) are commonly used in patients who present with features of raised intracranial pressure and significant neurological deficits. Following debulking surgery, the dose should be reduced rapidly and titrated against symptoms; it should be discontinued where possible to avoid long-term effects, of which proximal myopathy is particularly disabling. Where possible, steroids should not be used prior to biopsy if the differential diagnosis includes primary cerebral lymphoma.

The risk of venous thromboembolism is increased in patients with malignant gliomas [9, 11]. However, the risk of intratumoural haemorrhage whilst on anticoagulation therapy is relatively low [9, 12] and, therefore, unless there are other specific contraindications to anticoagulation therapy or an existing intratumoural haemorrhage, it is reasonable to anticoagulate patients with malignant glioma and venous thromboembolism using low molecular weight heparin.

Many patients with brain tumours suffer with depression associated with the knowledge of the diagnosis of such serious consequence [13]. Patients and their family and friends require intensive psychological support, both in hospital and in the community. In addition, patients should be offered intensive rehabilitation to overcome or to learn to cope with disability caused by the tumour and its treatment.

Surgery for intracranial tumours

Biopsy is used to obtain adequate and representative tissue for histopathology and molecular/genetic diagnosis. This can be performed using stereotactic frame-based or frameless neuronavigation techniques to localize small lesions with precision. Craniotomy and complete resection, debulking, or subtotal resection of the tumour is carried out to reduce mass effect on adjacent structures and prevent or improve neurological deficit. Cytoreduction also helps reduce surrounding brain oedema and steroid intake, thus improving the patient's quality of life and possibly prolonging survival.

Preoperative planning is important and resection can be maximized using functional MRI (fMRI) and diffusion tensor tractography (DTI) [14, 15]. While fMRI is able to highlight localization of function within the cortex, DTI represents the only technique able to elucidate white matter structures in vivo. During tumour resection, these systems become less accurate because of brain shift which occurs as a result of the craniotomy and CSF release. Intraoperative

MR imaging can provide scans of adequate resolution to visualize any residual tumour during surgery [16]. Intraoperative ultrasound provides a less expensive option by providing real-time images of the tumour; however, it is limited by spatial resolution and difficulty in outlining tumour margins [16, 17].

Tumour visualization using high-definition microscopic images and intraoperative fluorescence modules, especially tumour fluorescence derived from 5-aminolevulinic acid (ultraviolet light 440 nm), enables more complete resection of contrast-enhancing malignant glioma. High-definition endoscopes with wide viewing angles complement the microscope by providing excellent illumination and panoramic view, especially for skull-base approaches to look beyond the surgeon's direct field of view. They have revolutionized trans-sphenoidal and extended endonasal approaches [18]; more recently, they have been used to resect intraparenchymal tumours [19].

Radiotherapy for central nervous system tumours

Radiotherapy (RT) plays an integral part in the management of many patients with benign and malignant brain and spine tumours. RT is delivered in multiple daily fractions to minimize side effects to normal tissues. A radical course of treatment may deliver up to 33 fractions with a maximum dose of 60–70 Gy and a palliative course only 2 to 15 fractions. Stereotactic radiosurgery (SRS) is delivered in one to five high-dose fractions as an ablative treatment. This may be used to treat many benign conditions such as vestibular schwannoma, meningioma, arteriovenous malformation, trigeminal neuralgia, pituitary adenoma, as well as limited volume (<20 cm^3) brain metastases.

Chemotherapy is delivered concurrently with RT for indications such as glioblastoma, where temozolomide improves prognosis significantly, leading to 27% of patients living beyond two years and 9.8% beyond five years [20, 21]. For patients with anaplastic oligodendroglioma and 1p19q co-deletion who are treated with RT and procarbazine, lomustine, and vincristine (PCV) chemotherapy, the median overall survival (OS) exceeds 12 years [22]. Thus, attention to reducing the risks of late radiation toxicity in this patient group as well as those with intrinsically good prognosis has become more pertinent [23, 24].

Radiotherapy technique

Planning and delivery of RT include reproducible patient immobilization and a planning CT with the patient in the treatment position. The CT is fused to diagnostic pre- and post-operative MRI or CT [25]. Amino acid-labelled PET-CT is an investigational tool which has shown promise in helping to define recurrent high-grade glioma treated with stereotactic re-irradiation [26]. Gross tumour volume (GTV) and clinical target volume (CTV) are delineated and an appropriate departmental margin to planning target volume (PTV) is calculated using the Van Herk formula [27]. Van Herk formula: CTV-PTV margin = $2.5\Sigma + 0.7\sigma$ (Σ = SD systematic error; σ = SD random error). The critical normal tissue organs-at-risk (OAR) are delineated and a planning organ-at-risk volume (PRV) margin added using the modified van Herk formula, which takes into account the fact that OAR will not be irradiated from all directions. OAR-PRV margin = $1.3\Sigma + 0.5\sigma$ [28].

SRS may be delivered using a modified linear accelerator, multi-headed cobalt (e.g., Gamma Knife®), or a focused robotic arm on a linear accelerator (e.g. CyberKnife®) system. All three systems achieve largely similar dose distributions [29, 30].

Heavy-particle accelerators, such as proton beam, can deliver treatment to large volumes (such as craniospinal axis [CSA]) or localized stereotactic treatment). The dose distribution of the proton beam consists of an entrance region where there is a slowly increasing dose, followed by a rapid rise to a maximum dose (the Bragg peak) and a fall off to near zero. Proton beam therapy is delivered using two to six beams. Proton beam therapy (PBT) is now considered to be superior to photon RT for paediatric CNS tumours due to the lower normal tissue dose; ocular melanomas and chordoma are indications for this approach [31].

Adverse effects of central nervous system irradiation

The acute reactions to CNS irradiation occur during or immediately after a treatment course. These include tiredness, skin reaction (erythema, desquamation), and hair loss, which usually commence three weeks after the start of RT. Neurological deterioration, headache, and nausea, due usually to cerebral oedema, can be controlled with steroids (dexamethasone in doses of 2–16 mg per day). However, these symptoms could also signify ongoing tumour growth.

Delayed radiation reactions may be either 'early delayed' appearing a few weeks to a few months after RT or 'late delayed' starting months to years later [32]. The early delayed reaction is usually one of transient demyelination due to temporary depletion of oligodendroglia [33]. Late delayed damage results from the combination of oligodendroglial loss and endothelial damage, leading to demyelination and necrosis.

The somnolence syndrome represents an early delayed radiation reaction in the brain and in adults is characterized by a transient period of exhaustion at two weeks and drowsiness, lethargy, and anorexia at 4–6 weeks after irradiation.

The incidence and severity of late radiation damage are dose- and volume-dependent and can also be increased by chemotherapy, age, diabetes, and spatial factors. Necrosis appears a median of one to two years following RT, whilst cognitive decline develops over many years [34]. For radiosurgery, the volume of the brain receiving >12 Gy correlates with both the incidence of radiation necrosis and asymptomatic radiologic changes. For fractionated RT without chemotherapy, if the dose per fraction is <2.5 Gy there is a 5% necrosis risk at 72 Gy and 10% risk at 90 Gy [34]. Twice-daily fractionation and fraction sizes of >2.5 Gy have higher and less predictable necrosis risks. Adult survivors of radical brain irradiation at or below the standard tolerance limits may develop neuropsychological sequelae; these have also been described for lower doses of radiation when combined with chemotherapy. Ongoing deterioration at 12 years post-RT can be seen in over 50% of patients with low-grade glioma. White matter hyperintensities and global cortical atrophy were associated with worse cognitive functioning in several domains [35]. Irradiation of the pituitary and hypothalamus may lead to pituitary failure [36]. Cerebrovascular accidents (CVA) occur at increased frequency following brain irradiation.

Radiation carries a risk of the development of new primary tumours within the radiation treatment field. The latency is 7–30 years and the risk is in the order of 0.5–3% at 30 years after RT for benign CNS disease [37]. Patients with tumour-prone conditions such as neurofibromatosis NF1 and NF2, von Hippel-Lindau, and Gorlin's syndromes who receive RT or radiosurgery for benign CNS conditions such as acoustic neuroma have a much higher risk of developing either malignant transformation (e.g., ten-fold risk in acoustic neuroma for NF2 patients) or second malignancy (9.5-fold risk of meningioma for NF2 patients) than those without tumour-prone conditions [37]. RT or radiosurgery should be used with great caution in these patients. Tolerance doses for normal tissues within the CNS have been estimated by the Quantitative Analysis of Normal Tissue Effects in the Clinic (QUANTEC) [38, 39].

Re-irradiation of central nervous system tumours

A meta-analysis of brain re-irradiation (interval between courses, 3–55 months) found no cases of necrosis when the total radiation dose was <100 Gy (normalized to 2 Gy/fraction; a/b ratio, 2) [40]. Data on re-irradiation of the spinal cord in animals and humans suggest partial repair of RT-induced subclinical damage becoming evident about six months post-RT and increasing over the next two years. For re-irradiation of the full cord cross-section at 2 Gy per day after prior conventionally fractionated treatment, cord tolerance appears to increase at least 25% at six months after the initial course of RT based on animal and human studies [41]. For the brain, 50% of repair of damaged tissues after one year can be assumed in order to calculate potential retreatment doses [34, 38, 39, 42].

Chemotherapy

The response of intracranial tumours to chemotherapy depends on drug delivery and the individual sensitivity of tumour cells. Factors influencing drug delivery to CNS tumours include blood flow, permeability across capillaries and cell membranes, and the half-life of the drug. Cerebral capillary endothelial cells differ from endothelium at other sites by the presence of tight intercellular junctions on a basement membrane which lacks fenestrations and which restrict the passage of material across the capillary wall. This is defined as the blood brain barrier (BBB). The ability of a drug to cross the BBB is determined by its molecular weight and lipophilicity, so water-soluble drugs of molecular weight more than 200 kDa penetrate poorly. However, it is the transfer of drugs across the tumour endothelial membrane which is of most relevance to drug delivery. The capillary permeability of brain tumour vasculature varies in different regions of the tumour as well as between tumours, even of the same histological type, and the precise role of the blood-tumour barrier in determining chemoresponsiveness is not known. This blood-tumour permeability results in the enhancement seen on contrast imaging studies; however, the infiltration of tumour cells extends well beyond the enhancing edge on imaging.

The intrinsic cellular chemosensitivity of intracranial tumours relates to tumour histology. Germinomas, primitive neuroectodermal tumours, and primary cerebral lymphomas are chemoresponsive. The management of glial tumours has been transformed over the past 15 years due to the positive additive effect of the alkylating agent temozolomide on survival following surgery and RT for glioblastoma [20, 21]. Temozolomide also has a role to play in monotherapy for some elderly patients with glioblastoma and also patients with recurrent high-grade glioma [43]. Patients with

anaplastic oligodendroglioma have a high response rate to a combination of procarbazine, lomustine, and vincristine (PCV), which has now been shown to improve OS following RT for those patients with 1p19q co-deletion. [22]. Monoclonal antibodies target agents and small molecules such as VEGF inhibitors (bevacizumab and cediranib), and integrin inhibitors which inhibit angiogenesis (cilengitide) are being extensively studied in CNS tumours due to the high vascularity of high-grade gliomas. However, to date these have not impacted on survival for these patients in the adjuvant or recurrent setting [44, 45].

Clinical management of brain tumours
Glioma

High-grade glioma—glioblastoma multiforme

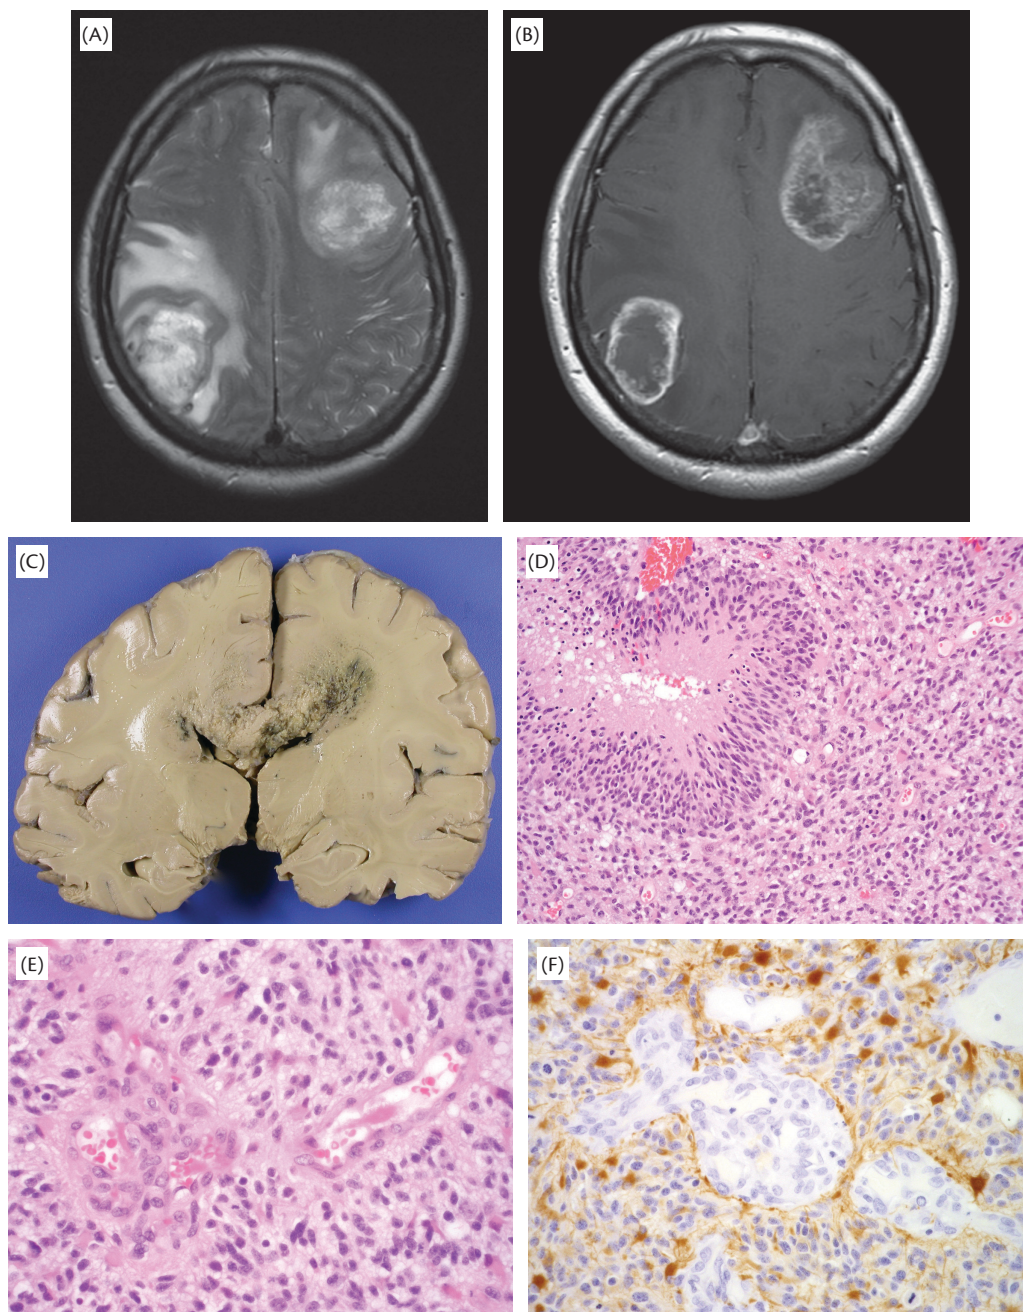
Radiology. The cardinal imaging features of a glioblastoma are irregular peripheral enhancement around an area or areas of necrosis and variable amounts of vasogenic oedema in the surrounding white matter (see Figure 56.3). 99% of glioblastomas are supratentorial. The amount of oedema has a great influence


Fig. 56.3 Multifocal GBM: axial T2-weighted (A) and gadolinium enhanced T1-weighted (B) MR images demonstrate large intra-axial tumours in the left frontal and right parietal lobes. Note the typical imaging features of irregular peripheral enhancement, central necrosis, and surrounding oedema. (C) Macroscopic specimen showing necrotic tumour crossing the corpus callosum. (D) Pseudopalisading microscopic necrosis and (E) microvascular proliferation are characteristic. (F) Tumour cells express GFAP (brown stain), which leaves the proliferating vessels unstained.
Fig. 56.4 Incompletely enhancing GBM: in addition to the peripherally-enhancing tumour seen in the left temporal lobe on the T1-weighted gadolinium enhanced image (B), there is an area of high signal in the left thalamus on the T2-weighted image (A). This area does not show contrast enhancement on the T1-weighted image.

on the amount of mass effect and, when a sizable rim-enhancing lesion has little or no oedema, it is more likely to be a GBM than a metastases or abscess. Other frequent findings are smaller enhancing satellite nodules, spread along white matter tracts such as the corpus callosum and areas of contiguous or non-contiguous non-enhancing solid tumours that correspond histologically to the WHO grade II or III tumour. These areas are better appreciated on MRI (see Figure 56.4) than CT, often involve cortical or deep grey matter structures and their presence indicates a slightly better prognosis [46]. The uncommon glioblastomas with the IDH1 mutation commonly have areas of non-enhancing tumour and most IDH1-mutated tumours involve the frontal lobes [47].

MR spectroscopy of the solid-enhancing portions of the tumour demonstrates a markedly raised choline:NAA ratio and perfusion imaging demonstrates a markedly increased cerebral blood volume (rCBV).

Surgery. High-grade gliomas are diffusely invasive tumours and patients undergo either a biopsy or tumour resection. A biopsy of the enhancing part of the tumour on a T1-weighted post-contrast MRI scan is offered to patients with poor WHO performance status despite being on steroids, and for those with diffuse or multifocal tumours and tumours in deep locations (e.g., thalamus, brainstem). The risk associated with biopsy is relatively low with a negative biopsy rate and mortality of approximately 5% and 1%, respectively [48, 49].

The infiltrating nature of gliomas means they cannot be completely excised and the majority will recur within 2 cm of their original location [50]. The goal of tumour resection is to obtain tissue for histological diagnosis, decompress tumour-mass effect, and extend tumour-free and patient survival. Extent of resection and residual tumour volume correlate with survival and recurrence, with thresholds of 70% and 5 cm^3, respectively [51]. Resection >90% is associated with significantly greater one-year survival (76.5%) than resection <90% [52].

Safe extensive resection has been possible with the aid of intra-operative MR guidance (iMR), intraoperative tumour fluorescence techniques, cortical mapping, and intraoperative high-frequency ultrasound [53]. iMR (either low or high field) achieves greater

extent of resection compared to conventional neuronavigational techniques with a trend towards improved survival [54–59]. 5-aminolevulinic acid (5-ALA)-induced fluorescence has been recently used for better in situ visualization of high-grade gliomas. The patient drinks an oral preparation of the drug three to four hours prior to surgery. ALA is a natural precursor in the haem-biosynthetic pathway and accumulates protoporphyrin IX in malignant cells to allow visualization with a modified microscope emitting blue light (440 nm) compared to surrounding normal brain. A randomized, controlled multicentre trial showed that gross total resection was achieved in 65% patients assigned to 5-ALA arm in comparison to 36% assigned to white light (p <0.0001) with a longer 6-month progression-free survival (41% vs 21.1%) [60]. Since then, studies have shown the superiority of 5-ALA resections compared to conventional white light resection [61, 62] and combined 5-ALA with iMR [63] and 5-ALA with cortical mapping [64] in improving survival. Sodium fluorescein is another fluorescent dye that accumulates in malignant glioma cells and is visualized under 560 nm wavelength fluorescent light source [65]. Recent studies have demonstrated its safety [66] and role in improving gross total resection and quality of life [67].

The median survival for glioblastoma patients is 14 months after maximal resective surgery and adjuvant radiochemotherapy [20]. Further maximal resective surgery following recurrence is offered to patients with a good performance status and who can have further chemotherapy. Surgery in this group of patients is beneficial [68] and improves median overall survival from six months following one resection to 26 months after three or four resections [69]. Because local recurrence is the failure pattern of the current therapeutic strategy for glioblastoma, local drug delivery has emerged as an alternative/adjunct to systemic drug delivery. This is primarily in two forms: implantation of biodegradable BCNU (Gliadel®) wafers along the wall of the resection cavity, and convection-enhanced delivery (CED) of various chemo- and immunotherapy agents.

Gliadel® wafers have been implanted both after primary resective surgery [70] and following tumour recurrence [71] with mixed outcome [72–74]. A recent meta-analysis showing improved survival compared to placebo with no increased incidence of adverse events

[75]. A number of studies using different combination of chemo- and immuno-therapy using CED for recurrent glioma have thus far shown mixed results and failed to show any clinically significant survival advantage [76–78].

Radiotherapy and chemotherapy. Adjuvant RT has an established role following biopsy or resection in the management of patients with malignant glioma due to the high local recurrence rate following surgery alone. In early randomized studies, whole-brain RT (WBRT) was shown to prolong median survival from 18 weeks with no treatment up to 42 weeks after 60 Gy WBRT [79, 80].

With improved contrast-enhanced imaging, current standard practice is to treat the involved field using conformal RT. The optimal total dose is 60 Gy in doses of 1.8–2 Gy per fraction, reducing to 55 Gy for specific tumour locations such as brainstem and optic chiasm. The margin added to the GTV (defined as the enhancing tumour and resection cavity) is based on patterns of failure following RT. Retrospective analyses suggest that over 85% of tumours recur within 2 cm of the GTV [81]. This holds true for patients treated with 60 Gy RT and temozolomide chemotherapy [82, 83]. Serial stereotactic biopsy specimens showed infiltrating tumour cells extending up to 2 cm beyond the enhancing tumour edge [84]. Thus, the recommended CTV is 2 cm beyond the GTV, unless limited by anatomical barriers to tumour growth (skull, ventricles, falx, etc.) [85, 86].

The addition of alkylating agent temozolomide to radical RT (60 Gy) followed by six subsequent cycles has resulted in a significant survival advantage over RT alone, leading to 27% of patients living beyond two years and 9.8% beyond five years vs 11% and 2%, respectively, for RT alone in the EORTC trial [20, 21]. This is now standard of care for patients up to 70 years of age with WHO performance status ≤2. Cytotoxicity of temozolomide is mediated mainly through methylation of the O^6 position of guanine. This DNA damage is rapidly repaired by MGMT. Epigenetic silencing of MGMT has been proposed as a predictive factor for benefit from treatment with alkylating agents. The EORTC study group carried out a post hoc analysis of outcome dependent on methylation of the MGMT gene for 206 out of the 573 patients included in the randomized study. Patients with this genetic alteration had a better two- and five-year survival with temozolomide (48.9%, 13.8%) than for the patients with unmethylated MGMT gene (14.8% and 8.3%) [87]. Methylation of the MGMT gene is a prognostic factor, but its predictive role is still to be quantified in prospective studies.

Two large studies (AVAGlio and RTOG 0825) investigated the addition of the VEGF inhibitor bevacizumab (Avastin®) to RT and temozolomide for glioblastoma. The agent adds to toxicity but failed to demonstrate an OS benefit [44, 45].

Glioblastoma in the elderly. Glioblastoma is a disease that primarily affects the elderly population (>65 years) and the incidence in this group continues to rise [88, 89]. There is class I evidence in the literature that maximal resection of high-grade glioma in the elderly is warranted and yields improved survival without an increase in surgical morbidity [90]. Although the number of patients in the trial was small, resection had an average survival of 24.5 weeks, compared with 12 weeks following stereotactic biopsy [90]. A number of other single-centre studies have shown the same [91–96].

Along with tumour grade and performance status, age is an important prognostic factor for patients with brain tumours. This may be related to age-adapted patterns of care as well as treatment independent intrinsic factors, such as the virtual absence of the good prognostic IDH-1 mutation within tumours in the malignant glioma population aged over 60 [97]. The tolerance of the brain to radiation may also be affected by age. From the Central Brain Tumour Registry of the US, the median age at diagnosis for glioblastoma is 64 and the two- and five-year survival for those over this age is 5.5% and 1.4% compared with 34.3% and 16% for 19–44 year olds [98]. Median survival for elderly patients with high-grade glioma unfit for or declining RT is poor, and in an unselected retrospective group it was ten weeks.

A series of clinical trials have investigated the best treatment for elderly patients. The French study showed that patients over 70 years of age randomized to best supportive care survived 16.9 weeks which was significantly shorter than 29.1 weeks for those treated with focal RT (50 Gy in 1.8 Gy fractions) [99]. A Canadian study looked at a shorter course of 40 Gy delivered in 2.66 Gy fractions compared with 60 Gy in 2 Gy fractions for patients aged over 60; the OS was five months in both arms [100]. Methylation of the MGMT gene occurs in just under half of patients with GBM, and this is also seen in the population over 65 years [101]. Two large phase 3 trials have looked at temozolomide in older patients. The Nordic trial randomized 291 patients over 60 years to four-weekly temozolomide versus hypofractionated RT (34 Gy in 3.4 Gy fractions) or conventional RT (60 Gy in 2 Gy fractions). Survival with temozolomide (8.4 months) or hypofractionated RT (7.5 months) was longer than conventional RT (six months), particularly in those over 70 (p = 0.02) [102]. The German NOA-08 trial included 373 patients aged over 65 with KPS (Karnofsky Performance Status Scale) 60% or higher. Dose-dense temozolomide (100 mg/m², 1 week on, 1 week off) was compared with conventional RT (60 Gy in 2 Gy fractions); survival was similar (8.6 vs 9.6 months HR 1.09) [103]. 60% of the patients in the studies had undergone partial or complete resection. Both studies found that patients with methylation of the MGMT gene treated with temozolomide lived longer (9.7 months) compared with those without the genetic change (6.8 months, HR 0.56).

For patients aged over 70, treatment stratification by methylation status is evidence-based. Those who are methylation MGMT positive can be offered first-line temozolomide, and those without should be offered RT alone using shorter regimens such as 34 Gy in 10 fractions [104]. Patients aged 60–70 and PS 0–1 benefit from combined temozolomide and RT (60 Gy) [21].

High-grade glioma (HGG)—anaplastic gliomas
Anaplastic astrocytoma, anaplastic oligodendroglioma, and anaplastic oligoastrocytoma

Imaging. Like grade II astrocytomas, these tumours generally show relatively uniform high signal on T2-weighted images and relatively low density on CT. The majority (>80%) of anaplastic astrocytomas (AA) (WHO grade III) show at least some contrast enhancement, either a focal nodule of enhancement or patchy areas of enhancement within part of the tumour (see Figure 56.5). This enhancement may be relatively subtle and MRI has a greater sensitivity than CT in this regard. The contrast-enhancing components of the tumours often demonstrate lower signal on T2 than the surrounding non-enhancing areas as seen in Figure 56.5. This corresponds to higher density on CT and a degree of restricted diffusion on DWI—all imaging features of increased cellularity.

While necrosis with peripheral enhancement is not a feature of these tumours, focal areas or well-circumscribed cystic change is
Fig. 56.5 Grade III astrocytoma: axial T2-weighted (A) and gadolinium enhanced T1-weighted (B) MR images demonstrate a large intra-axial tumour in the left frontal lobe. The tumour is of predominantly high signal on T2 and intermediate signal on T1 with a focal area of contrast enhancement indicating the high grade component of the lesion. (C) Atypical glial cells with mitoses set in a fibrillar matrix. (D) Tumour cells express the protein product of the IDH1R132H mutation and have (E) lost nuclear ATRX expression (note preserved staining in endothelial and other non-neoplastic cells). (F) Strong nuclear p53 over-expression suggests the presence of a TP53 mutation. The constellation of these changes is highly characteristic of diffuse astrocytoma (see schematic in Figure 56.2).

occasionally seen. Most AAs are supratentorial; the pons is the most common infratentorial location. MR spectroscopy demonstrate raised choline:NAA ratio and perfusion imaging demonstrate an increased relative cerebral blood volume (rCBV).

Radiotherapy and chemotherapy. Anaplastic gliomas are distinct from glioblastoma in tumour cell genetics. The treatment strategy for anaplastic tumours should therefore be tailored by the presence or absence of these genetic changes. 1p19q co-deletion is seen in 75% of anaplastic oligodendroglioma (AO), 60% of anaplastic oligoastrocytoma (AOA), and 15% of AA, conferring both a better prognosis, as well as higher response likelihood to chemotherapy

when the deletion is present. Methylation of the MGMT gene is present in 70% of AO and AOA and 50% of AA. IDH1 mutation occurs in a similar percentage of cases. Both methylation MGMT and IDH1 mutation are independent predictors of a better prognosis [105].

Given the very long survival of some patients with anaplastic glioma, trials to reduce treatment have been conducted. RT (60 Gy in 1.8–2 Gy fractions treating GTV + 2 cm) was compared with a six-month course of chemotherapy (PCV or temozolomide) for 318 patients in the NOA-04 trial [105]. The progression-free survival (PFS) (30.6 months for RT and 31.9 months for chemotherapy

HR = 1) and OS at 48 months (72% for RT and 65% for chemotherapy) were not statistically different. More patients receiving RT showed a response or stable disease compared with chemotherapy (p = 0.08). Overall, 24% of patients had a partial or complete response and 66% stable disease. Only 50% of patients have so far required second-line treatment. The AA subgroup had the worst prognosis; PFS was 10.8 months with RT and 18.2 months with chemotherapy compared with 52 months for either treatment for AO and AOA. For this poorer prognosis group, the ongoing CATNON/BR14 study is evaluating the role of temozolomide in addition to RT for anaplastic glioma patients without 1p19q loss.

The EORTC 26951 and RTOG 9402 studies of patients with anaplastic oligodendroglioma treated with RT, with or without PCV chemotherapy, did not initially show a survival difference. However, the 12-year follow-up of the EORTC study has shown that the median survival is significantly longer for RT and PCV (42.3 vs 30.6 months; HR 0.75). For the subgroup of patients with 1p19q co-deletion the OS exceeds 12 years with PCV + RT against 9.3 years for RT alone (HR 0.56) [22]. The RTOG 9402 study did not show an OS benefit by adding PCV (median survival 54 months; HR 0.79, p = 0.1), but for those patients with 1p19q co-deletion median survival with PCV + RT was 14.7 vs 7.3 years without chemotherapy (HR 0.59, p = 0.03). No survival benefit was seen for the addition of chemotherapy for patients without 1p19q co-deletion [106].

Management of recurrent high-grade glioma. Most patients with high-grade malignant glioma ultimately fail locally or loco-regionally. In parallel with improvements outlined above in the initial treatments of these tumours, salvage strategies including re-operation, re-irradiation, interstitial brachytherapy, chemotherapy, and use of targeted agents have been developed and may have a role in selected patients [107]. There have been no randomized trials comparing these options. It is important to distinguish recurrence from pseudo-progression which occurs in one-fifth of patients treated with RT and temozolomide [108]. Therefore, adjuvant temozolomide should be continued if the early post-radiation scan suggests pseudo-progression, unless there is evidence of clinical deterioration or further disease progression on subsequent imaging.

Stratifying patients with recurrent disease into prognostic groups is helpful in planning treatment. A minority of patients will be suitable for second surgery or re-irradiation. Park et al. [109] determined prognostic factors for 34 patients who underwent re-operation for recurrent GBM. A validation cohort (109 patients) were scored one point for each of KPS ≤80, tumour volume ≥50 cm³, or tumour in an eloquent area (motor, speech, or middle cerebral artery [MCA] region). Good (zero points), intermediate (one to two points), and poor (three points) prognostic groups had median survivals of 9.2, 6.3, and 1.9 months (p <0.001). Other factors that help in decision making are the histologic grade, relapse-free interval, and local vs diffuse recurrence. At the time of re-resection for high-grade glioma, insertion of carmustine wafers prolongs survival modestly (31 vs 23 weeks with placebo, p = 0.006) [110].

Focal re-irradiation using single-fraction (SRS) or fractionated (fSRT) stereotactic radiation can be used for small volume recurrence. As with surgery, prognostic factors to guide re-irradiation include small tumour volume, young age, good performance status, and treatment-free interval (a radiation repair factor of 50% can be used 12 months after RT). SRS delivering a marginal dose of 15–18 Gy in a single fraction to a tumour size 10–20cm³, results in medial survival of 8–11 months and 22% necrosis rate at re-operation [111]. Tumour volumes up to 50cm³ treated with hypofractionated schedules (e.g., 25–35Gy in 3–7 Gy fractions) result in median survivals of 8–11 months with low necrosis rates [111]. Alternatively, fSRT using 1.5–2 Gy fractions can be used to deliver a total retreatment dose of 36 Gy along with systemic therapy such as bevacizumab giving a median survival of ten months [112] or RT alone up to 45–54 Gy depending on fraction size, previous dose, and time since treatment [42].

Brachytherapy can be used to deliver high localized radiation doses to the resection cavity following re-operation. This treatment is delivered using ¹²⁵I implanted seeds or afterloaded ¹⁹²I seeds or solution (GliaSite). Median survival is in the order of 8–10 months [111]. However, radionecrosis is seen in about 40% of cases.

Systemic therapy has a role to play in recurrent high-grade glioma. A randomized study of 447 patients with recurrent high-grade glioma following initial treatment with RT alone, showed no difference in survival between procarbazine, vincristine, and CCNU (lomustine) (PCV) vs temozolomide (6.7 vs 7.2 months) [113]. For patients who have completed six months of adjuvant temozolomide, re-exposure to that drug following a treatment-free interval of over two months results in a 30% six-month PFS [114]. Dose-dense temozolomide is less effective than conventional dosing in temozolomide-naïve patients [113]. Alternative options include lomustine (CCNU) or carmustine (BCNU) single-agent therapy with a 19% PFS at six months and response rate of 4% [115], or the PCV combination with a median survival 6.7 months and PFS 3.6 months [113].

Bevacizumab alone or in combination with chemotherapy has not been shown to prolong survival in recurrent HGG. Evidence from the phase 2 BRAIN study comparing bevacizumab alone or with irinotecan for 167 patients with recurrent GBM following adjuvant RT and temozolomide showed no difference between the arms with a PFS of 4.2 months and OS of 8–9 months. Steroid doses were reduced in most patients [116]. Bevacizumab appears to reduce permeability with normalization of vessels, reduced oedema, and improved oxygenation, hence the reduced steroid dependence; however, there is a rebound increase in vascular permeability and oedema when this treatment is ceased.

Low-grade gliomas

Imaging. Grade 2 astrocytomas show relatively uniform high signal on T2-weighted MRI images, low density on CT and do not show contrast enhancement (Figure 56.6). They may be well-circumscribed and can resemble an infarct on both imaging modalities. DWI demonstrates facilitated diffusion which provides a reliable distinction from an acute infarct. MR spectroscopy demonstrates an increase in myoinositol and a slightly raised choline: NAA ratio. Perfusion imaging shows a low rCBV. An increase in rCBV is an indication of high-grade transformation and can precede the onset of contrast enhancement by up to 12 months [117]. Larger tumour size at presentation and the growth rate in the first six months predict earlier high grade transformation [118].

Oligodendrogliomas usually involve the cortex and subcortical white matter of the cerebral hemispheres and are often indistinguishable on imaging from grade II or III astrocytomas unless they contain calcification, seen in more than two-thirds of oliogodendroglioma but rarely in astrocytoma. MR spectroscopy and
Fig. 56.6 Grade II astrocytoma: axial T2-weighted (A) and gadolinium enhanced T1-weighted (B) MR images demonstrate a large intra-axial tumour in the right frontotemporal region. The tumour is of high signal on T2 and intermediate signal on T1 with no contrast enhancement.

perfusion findings also overlap with those of grade II and grade III astrocytomas. A small minority of oligodendrogliomas present as intraventricular or extra-axial masses. Compared to astrocytomas, imaging is relatively poor at distinguishing between WHO grade II and III oligodendrogliomas since the presence or absence of contrast enhancement is a less reliable indicator of grade.

Pilocytic astrocytomas are rare in adults compared to children and the anatomical distribution differs with supratentorial lesions outnumbering the cerebellar and brainstem lesions more commonly encountered in children. In the cerebral hemispheres, these tumours usually have a heterogeneous appearance with mixed solid and cystic areas, with avid contrast enhancement of some or all of the solid areas often with focal areas of calcification on CT. Surrounding vasogenic oedema is uncommon. Pilocytic astrocytoma in the cerebrum can resemble various other tumours including oligodendroglioma, glioblastoma, ganglioglioma, and pleomorphic xanthroastrocytoma.

Optic nerve gliomas are usually pilocytic astrocytomas but are usually infiltrative, leading to fusiform enlargement of the optic nerve, often extending to the chiasm and beyond. Contrast enhancement is also more variable in optic pathways pilocytic astrocytomas and is occasionally absent.

Surgery. These low-grade tumours grow continuously [119–121] and may transform into higher grade gliomas, leading to neurological disability and ultimately death. Therefore, surgical management paradigms have changed in the last decade. The shift has been from regular imaging surveillance (with or without a biopsy) to aggressive surgical resection including awake craniotomy with intraoperative neurophysiology mapping as the first treatment option to prolong PFS and OS [122].

To maximize the extent of resection, a craniotomy is performed with the patient awake under local anaesthesia or asleep for the initial craniotomy and then awake after the dura is opened. With the patient awake, intraoperative electrostimulation is now considered the gold standard. Eloquent cortical and subcortical white fibre tracts (motor, somatosensory, optic radiation, language, and spatial cognition) are stimulated to define their relationship to the tumour and preserve them during tumour resection [123]. This has resulted

in reduction in neurological deficit from up to 28% (without awake mapping) to less than 2% with more evidence pointing towards functional mapping-guided resection rather than image-guided resection. Duffau et al. recently introduced the concept of 'supratotal resection' where a tumour is resected with an additional margin beyond the signal abnormality visible on the FLAIR-weighted MRI scan, as it has been shown that isolated tumour cells exist beyond the signal abnormality. This has resulted in a significantly lower rate of anaplastic transformation when compared to a control group who underwent a 'complete' resection [124]. An aggressive surgical approach also results in improvement in quality of life, especially with reduction in seizures.

Pilocytic astrocytomas are grade 1 benign tumours and carry an excellent prognosis. Therefore, the aim of surgery is a complete resection without producing a deficit. In children and young adults the cerebellum is a common site and the tumour presents as a cyst with enhancing mural nodule. A suboccipital craniotomy is commonly performed and the mural nodule excised. The cyst wall is non-neoplastic and need not be removed unless it enhances as well. Invasion of brainstem or involvement of cranial nerves or blood vessels may limit resection. Prognosis is good and the residual tumour may show arrested growth or even spontaneous regression and if there is a recurrence on serial MR imaging, patients can be re-operated upon [125, 126].

Intrinsic low-grade glioma of the brainstem can undergo stereotactic biopsy. Surgical resection is usually not possible given its eloquent location. Some patients require a CSF diversion procedure (endoscopic third ventriculostomy or ventriculoperitoneal shunt) for obstructive hydrocephalus. Resection is indicated for tumours with a dorsal exophytic component in the fourth ventricle or the cerebellopontine angle as these are generally benign and amenable to radical subtotal resection [127].

Subependymomas of the fourth ventricle are approached through a suboccipital craniotomy and telovelar approach and should be resected as fully and safely as possible. Damage to the floor of the fourth ventricle can lead to neurological deficit. Surgery reduces the tumour burden and re-establishes the flow of cerebrospinal fluid [128].

Radiotherapy and chemotherapy. The role of RT in the treatment of low-grade gliomas (grade 2 astrocytoma, oligodendroglioma, mixed oligoastrocytoma) was investigated in two large EORTC randomized trials. EORTC 22844 showed no difference in survival between immediate post-operative RT of 45 Gy with 59.4 Gy in 1.8 Gy fractions [129]. Trial 22845 compared immediate RT (54 Gy in 1.8 Gy fractions) with the same given on tumour progression. Again, the overall median survival (7.2 years) and five-year survival (60%) were the same [130]. There was no difference in the rate of malignant progression between the two arms, but early RT improved PFS from 3.4 to 5.3 years (p <0.0001). RT stabilizes or improves neurological deficit caused by the tumour and often reduces the frequency of seizures which accompany the presentation of low-grade tumours. RT is currently recommended following evidence of tumour progression following surgical excision or biopsy or for symptomatic tumours. The recommended radiation dose is 54 Gy in 1.8 Gy fractions. The extent of disease in these often-unenhancing tumours is usually defined as the region of T2 hyper-intensity on MRI [131], with a 1 cm surrounding margin to give CTV.

From the EORTC studies, five independent poor prognostic factors have been determined: age >40, astrocytoma subtype, tumours >6 cm, those crossing midline, and presence of neurologic deficit before surgery. The presence of three or more risk factors determines a higher risk group with a median survival of three years. The low-risk group (0–2 risk factors) has a median survival of over seven years [132].

Chemotherapy in low-grade glioma has a potential role following RT. The US RTOG 9802 trial treated 251 patients with unfavourable low-grade glioma (age >40 or subtotal resection or biopsy irrespective of age) with RT, 54 Gy in 1.8 Gy fractions. Patients were then randomized to receive six cycles of PCV or no further treatment [133]. Median OS was not statistically different between the arms (>8.5 years vs 7.5 years) as was five-year survival (72% vs 63%). PFS at five years was, however, improved by the addition of chemotherapy (63% vs 46%, p = 0.005). Molecular markers IDH1, methylation MGMT, and 1p19q co-deletion are good prognostic features in low-grade gliomas [134]. Phase 2 studies indicate a potential role for temozolomide in low-grade gliomas, and several intergroup studies comparing RT with temozolomide in low-grade gliomas stratifying by molecular characteristics are in progress.

Brainstem gliomas. Glial tumours may involve any of the structures from the thalamus and hypothalamus through the midbrain to the pons and medulla. In adults, half are diffusely infiltrating non-enhancing low-grade gliomas. When treated with RT, 62% of patients improve and the median survival exceeds seven years. 30% are malignant glioma with poor response to chemo/RT and have a median survival of 11 months. Just under 10% of cases are focal tectal glioma, often presenting with hydrocephalus, and prognosis exceeds ten years without irradiation [135].

Ependymoma

Ependymomas occur more commonly in children than adults, and account for less than 10% of CNS tumours, and typically arise within or adjacent to the ependymal lining of the ventricular system. Tumours may be low grade (1 or 2) or anaplastic (grade 3). In adults, 75% of ependymomas arise within the spinal canal, and up to 10% of patients have spinal metastases. Neuroaxis MRI should be carried out on all patients and CSF cytology should be examined for posterior fossa lesions and all anaplastic tumours.

Imaging. The majority of intracranial ependymomas arise in the wall of the fourth ventricle and these tumours often fill the ventricle and extend through one or more of its outflow foramina into the cisterna magna leading to obstructive hydrocephalus. Signal heterogeneity is common on MRI due to cystic change. Focal haemorrhage, calcification, and avid contrast enhancement is often seen.

Supratentorial ependymomas are usually much larger than fourth ventricular tumours at the time of presentation and most are within the brain parenchyma rather than intraventricular. It is rarely possible to make a prospective radiological diagnosis of a supratentorial ependymoma since their imaging features overlap significantly with those of a number of other lesions including glioblastoma, ganglioglioma, and pleomorphic xanthroastrocytoma.

Radiotherapy. Retrospective studies demonstrate good long-term control following partial or complete tumour excision and RT [136]. There is no clear evidence that prophylactic spinal irradiation prevents isolated spinal metastases, particularly if the primary tumour remains uncontrolled. The consensus view is that ependymomas should be treated with local irradiation to the site of the tumour and the appropriate margin, regardless of tumour grade and site. The technique and doses used are the same as those employed for other low-grade gliomas (54 Gy in 1.8 Gy fractions) increasing to 59.4 Gy in 1.8 Gy fractions for anaplastic tumours outside of the brainstem [137].

The overall five-year survival of adult patients with cranial ependymomas is 67–85% and PFS is 63%. The prognosis is related to the histological grade, the extent of surgical resection, patient age, and performance status [136].

Patients with sub-ependymoma have a good prognosis following resection alone, and adjuvant RT is not routinely given.

Medulloblastoma/primitive neuro-ectodermal tumours (PNET)

Clinical presentation and diagnosis. Patients with medulloblastoma may present with raised intracranial pressure (usually due to hydrocephalus), cerebellar signs, and occasionally brainstem cranial nerve palsies.

Imaging. Medulloblastomas are usually solid, well-circumscribed intra-axial lesions of the cerebellum. The high cellularity of these lesions is reflected in their slightly hyperdense (compared to normal brain parenchyma) appearance on unenhanced CT scan and this corresponds to a slightly hypodense appearance on T2-weighted images and moderate diffusion restriction on DWI. Contrast enhancement is variable with some tumours enhancing avidly and relatively uniformly while some show only patchy enhancement and a small minority show no enhancement at all. Subarachnoid dissemination in the intracranial and spinal canal is a frequent finding.

Surgery. A medulloblastoma is approached by posterior fossa craniotomy and usually removal of the posterior arch of C1. The approach depends on the anatomical location of the tumour but the telovelar approach is the best choice for tumours in the fourth ventricle and avoids post-operative mutism [138]. The goal of surgery is gross total resection and the extent of resection correlates with five-year survival [139–143]. >1.5cm^3 of residual tumour on the post-operative MRI scan in children >3 years with no tumour dissemination correlates with good prognosis [144]. Some patients who present with obstructive hydrocephalus require

preoperative CSF diversion (endoscopic third ventriculostomy or ventriculo-peritoneal shunt) [145, 146].

Radiotherapy. Patients are classified according to extent of disease using the Modified Chang criteria [147]. Those with localized primary disease and negative spinal MRI and CSF cytology are M0. Positive CSF cytology alone is M1, intracranial metastatic disease M2, and macroscopic disease within the spinal area is M3, and outside the CNS is M4. Low-risk patients are those with <1.5 cm^3 post-op residual, >3 years old and M0. All other patients are high risk. Post-operative CSA RT is indicated in all patients regardless of the extent of tumour resection. For M0 disease, the CSA being treated to 35 Gy in 1.66 Gy fractions. The posterior fossa or site of supratentorial primitive neuro-ectodermal tumours (PNET) plus margin is boosted to a further dose of 20 Gy in 1.66 Gy fractions. For patients with M1–M3 disease, the CSA should be treated to a higher dose of 40 Gy in 1.66 Gy fractions and a further boost of 15 Gy in 1.66 Gy fractions to the primary site, and spinal seedlings should be treated with a RT boost to a small volume to the level of spinal cord tolerance (5–10 Gy in 1.66 Gy fractions). UK national guidelines are available from the British Neuro-Oncology Society [148].

Chemotherapy. The use of adjuvant chemotherapy in paediatric medulloblastoma has been extensively tested in sequential intergroup studies; however, there have been no trials in adults. As the natural history of adult medulloblastoma is similar to that in children, similar indications for chemotherapy could be accepted. The regimens used are those tested in randomized trials in children [149].

Prognosis. The extent of disease defined by the Modified Chang criteria, age, completeness of resection, histological subtype, and genetic markers are prognostic indicators [150]. For adults, with low-risk disease treated with the paediatric HIT 2000 protocol (CSA RT 35.2 Gy and boost total 55.2 Gy then lomustine, vincristine, cisplatin chemotherapy), a prospective study of 70 adults showed the four-year survival of 89% [151]. Most patients who relapse do so at the primary site.

The prognosis of patients with metastatic medulloblastoma is poor 23–30% of patients relapse. Up to 10% of patients disease recurs outside the CNS, particularly in the bone marrow and systemic spread may be seen in the absence of a ventricular shunt. Recurrent tumours may be chemoresponsive, although they are rarely curable. Stem cell transplant results in a disease-free survival in 24% of patients at ten years [152].

Pineal tumours

Clinical presentation. Tumours arising from the pineal gland can be germ cell tumours, pineal cell tumours, and gliomas (see Table 56.3). Due to their location, obstruction of the cerebral aqueduct with obstructive hydrocephalus is a common complication. Other features reflect the involvement of adjacent structures, such as the midbrain, hypothalamus, and the brainstem. Compression of the quadrigeminal plate causes paresis of upward gaze and the pupils become unresponsive to light or accommodation (Parinaud's syndrome). Downward gaze paresis usually indicates further inferior tumour extension. The duration of symptoms relates to tumour growth rate, and for slow-growing germinoma could be as long as 20–30 months.

Germinomas make up the majority of germ cell tumours. On CT, germinomas are slightly hyperdense and engulf the normal pineal

Table 56.3 Histology and characteristics of pineal region tumours

Germ cell tumours (GCTs)	Germinoma (equivalent of testicular seminoma) may have ß-HCG up to 50
	Malignant non-germinomatous germ cell tumour (MNGGCT) 80% have αFP>25+/- ß-HCG >50 (yolk sac and choriocarcimoma subtypes)
	Embryonal carcinoma—immature germ cells
	Teratoma—differentiated germ cells
Pineal parenchymal tumours	Pineocytoma (grade I)
	Pineal tumour of intermediate differentiation (grade II or III)
	Papillary pineal tumour (grade II or III)
	Pineoblastoma (grade IV managed with CSA RT as per PNET)
Astrocytic tumours (see section on Glioma)	High-grade astrocytic tumour
	Low-grade astrocytic tumour
	Tectal plate tumour

calcification. Avid uniform contrast enhancement is the rule with germinomas. Metastases to the anterior recesses of the third ventricle are often seen. Pineal germ cell tumours, like their systemic testicular counterparts, may secrete alpha-fetoprotein and human chorionic gonadotrophin into the cerebrospinal fluid and systemic circulation. The presence of αFP is specific for teratoma, while ß-HCG levels may be elevated by either teratoma or germinoma.

Pineal cell tumours, pineocytomas and pineoblastomas, also show enhancement on CT and MRI but in contrast to germinomas, they expand the normal pineal calcification leading to the 'exploded pineal' appearance on CT. Pineoblastomas can grow large and invade surrounding structures.

Diagnosis and staging. Patients with pineal region tumours should have preoperative craniospinal MRI, CSF cytology, as well as serum and CSF αFP and ß-HCG. Key distinctions are made between secreting (αFP>25 and/or ß-HCG >50) and non-secreting germinoma, and between localized and metastatic disease (multifocal cranial disease, positive spine MRI or CSF cytology). Immediate post-operative imaging to define resection extent is recommended. The presence of positive tumour markers along with clinical and neuroradiological picture of germ cell tumour (GCT) is sufficient to start therapy without histological confirmation. All other tumours should have a biopsy at the minimum. UK national guidelines for pineal region tumours are available [148].

Surgery. Surgical management of pineal tumours includes an endoscopic third ventriculostomy and endoscopic tumour biopsy with CSF sampling for tumour markers which is usually the first-line treatment, although occasionally a ventriculoperitoneal shunt may need to be performed [153–156].

Patients who need a surgical resection can undergo four possible surgical approaches: (a) transcallosal interforniceal, (b) transventricular, (c) occipital transtentorial, and (d) infratentorial supracerebellar. For benign or low-grade tumours a complete surgical resection results in excellent long-term recurrence-free survival [157, 158]. The benefit of maximal surgical resection for malignant tumours is less clearly defined and is weighed against the potential

morbidity of an aggressive approach [159, 160] although, a recent meta-analysis showed a graded increase in five-year survival with increasing degrees of resection (84% for gross total, 53% subtotal, and 29% debulking for pineoblastoma) [161].

Chemotherapy and radiotherapy

Germinoma. For patients with non-secreting germinoma, 97% long-term survival has been achieved following CSA RT (24 Gy in 1.6 Gy fractions) followed by a boost of 16 Gy in 1.6 Gy fractions to the primary tumour (in the SIOP CNS GCT 96 study). Long-term outcomes with CSA RT are excellent for patients with metastatic germinoma, (98%) [162]. Attempts to reduce the radiation volume with the addition of chemotherapy and using involved-field RT, resulted in an unacceptably high risk of leptomeningeal relapse [162]. The ongoing European SIOP CNS CGT II study investigates chemotherapy followed by whole ventricular irradiation and a boost for any residual tumour for localized non-metastatic non-secreting germinoma. In the USA, whole ventricular irradiation with tumour boost to a total dose 40–45 Gy is standard of care for localized germinoma.

Malignant non-germinoma germ cell tumour (secreting CGTs) MNGGCT. The prognosis for patients with MNGGCT is poorer than for germinoma. The tumour is less radiosensitive and RT alone is ineffective (20–40% long-term survival). Patients treated following the SIOP 96 protocol with initial chemotherapy (cisplatin or carboplatin, ifosfamide, and etoposide) for 4–6 cycles followed by surgical resection of any residual, and then focal irradiation (54 Gy in 1.8 Gy fractions) for non-metastatic disease had a PFS of 67%. Those with metastatic disease treated with chemotherapy and CSA RT (30 Gy in 1.5 Gy fractions) with a boost to tumour (24 Gy in 1.6 Gy fractions) and spinal metastatic boost (16 Gy in1.6 Gy fractions) have a PFS of 72% [163]. The ongoing SIOP CNS GCT II study is evaluating high-dose chemotherapy for those with high-risk MNGGCT.

Pineal parenchymal tumours (PPT). These compose 30% of pineal region tumours. Surgery for pineocytoma, followed by local RT for residual disease (50–55 Gy), yields a five-year survival of 86%. SRS gave ten-year survival rates of 67% in a small study of eight patients with PPT and should be considered experimental [164]. If surgical resection is complete, an expectant policy can be adopted.

PPT of intermediate differentiation and papillary tumours are rare, and some reports include cases with CSF dissemination. Management should include maximal surgical excision, and local or CSA irradiation depending on disease extent.

Pineoblastoma has a higher risk of leptomeningeal dissemination and should be treated as per PNET above with CSA RT.

Primary cerebral lymphoma

Clinical presentation and diagnosis. Lymphoma infiltrates the white matter tracts to produce an array of symptoms including focal weakness or language deficits, cognitive, and behavioural changes. Lymphoma can also invade the meninges producing cranial nerve deficits and cognitive change. Infiltration of the spinal nerve roots can also cause specific sensory motor deficits or migratory pain syndromes. Systemic involvement (suggested by concurrent 'B' symptoms such as weight loss and fever) is rare in primary cerebral lymphoma.

Uveitis may precede or accompany other neurological features in 5–10% of patients. Patients may present with 'floaters' and blurred vision and infiltrates may be seen on slit lamp examination [165].

Patients with intravascular lymphoma may present to a neurologist with lacunar strokes due to obstruction of the brain arterioles by malignant lymphocytes. Intravascular lymphoma is a systemic non-Hodgkin lymphoma which causes systemic symptoms such as night sweats, hepatosplenomegaly, or pancytopaenia [166].

Diagnosis. UK national guidelines for the diagnosis and management of CNS lymphoma are available [148]. Up to 12.5% of patients with disease apparently confined to the CNS are found to have extraneural involvement. Staging investigations should include an MRI scan of the brain and spine; CT scan of the chest, abdomen, and pelvis; serum LDH and HIV serology; CSF protein, glucose, cytology; flow cytometry; and IG gene rearrangement. Cytological examination of either vitreous or CSF can provide a diagnosis of primary cerebral lymphoma, although the sensitivity of this test is variable [167]. As well as ophthalmic examination and bone marrow histology for all patients, elderly males should undergo testicular ultrasound.

In immunosuppressed patients, examination of the CSF with Epstein–Barr virus (EBV) specific polymerase chain reaction (PCR) primers can be used to aid the diagnosis, although this has a low positive predictive value [168]. In view of the morbidity of treatment, neuropsychological baseline testing should be considered.

Imaging. The most common forms of PCNSL (diffuse large B-cell lymphoma) cause multifocal, relatively well-circumscribed intra-axial mass lesions, mostly in the supratentorial compartment. The disease involves regions that abut the CSF spaces, particularly the periventricular white matter including the corpus callosum. On CT, these tumours are of noticeably higher density than the surrounding brain parenchyma (Figure 56.7) and demonstrate a degree of restricted diffusion on DWI reflecting the high cellularity of these tumours. Avid uniform contrast enhancement and prominent surrounding vasogenic oedema are characteristic. The solid pattern of enhancement indicates the absence of macroscopic necrosis and this is a useful distinguishing feature between PCNSL and GBM. Necrosis has been described in PCNSL in immunosuppressed patients but even in that clinical context it is a rare finding.

A dramatic response to steroid treatment can occur with potentially complete resolution of all the imaging findings—a response that may last for weeks or even months before recurrence in the same or different anatomical locations in the CNS. Treatment with corticosteroids should therefore be avoided before attempting a tissue diagnosis.

Prognosis. The International Extra-nodal Lymphoma Study Group (IELSG) scoring system is based on age (>60 years), performance status (>1), raised LDH, raised CSF protein, and deep brain-matter involvement. High (score 4–5), medium (score 2–3), and low risk (score 0–1) categories gave two-year survival rates of 15%, 48%, and 80% [169].

Surgery. The mainstay of treatment is chemotherapy; therefore, a craniotomy and tumour resection is not warranted [170]. Tissue diagnosis is required prior to starting treatment and a stereotactic biopsy (framebased or frameless) is an excellent means of obtaining tissue.

Chemotherapy and radiotherapy. Chemotherapy is the first-line treatment for patients who are fit. High-dose methotrexate (≥3 g/m²) has good CNS penetration and has the best outcome, particularly if combined with cytarabine and WBRT. Such treatment
Fig. 56.7 PCNSL pre- (A) and post-contrast (B) CT images demonstrate the typical appearance of PCNSL. The lesions in the right frontal lobe and corpus callosum are both in contact with the CSF spaces, are slightly hyperdense on the unenhanced image and show avid, solid enhancement after contrast administration. The florid oedema seen around the right frontal lesion is also a typical feature. (C) Angiocentric growth of large atypical lymphoid cells that (D) strongly express the B-cell marker CD20. (E) T-cell marker CD3 is restricted to small non-neoplastic lymphocytes. (F) The proliferation fraction is very high (MIB-1/KI-67). Most primary CNS lymphomas are of diffuse large B-cell type.

resulted in a 47% three-year survival vs 34% for HD-MTX and WBRT alone in one study [171].

A more recent study of 44 patients given HD-MTX, rituximab, and temozolomide-induction therapy followed by etoposide and cytarabine consolidation therapy without WBRT resulted in a CR rate of 66%, and four-year survival estimate of 65% [172]. This regimen is now being tested in a larger intergroup study.

The ongoing role of WBRT in PCNSL is uncertain. Omission of WBRT (45 Gy) following HD-MTX + ifosfamide resulted in an inferior outcome in terms of PFS (18.3 vs 11.9 months); however, neurotoxicity was seen in 49% of those receiving WBRT against 26%

who did not and OS was unchanged [173]. Unlike other settings, in PCNSL RT at doses of 40 Gy has been associated with late cognitive decline, dementia, ataxia, and urinary incontinence, especially in those >60 years old. The heightened sensitivity to irradiation might be explained by the tumour's highly diffuse, angiocentric growth pattern, as well as that most patients receive high-dose methotrexate, a potent neurotoxin [34].

Consolidation WBRT (45 Gy in 25 Gy fractions) may be considered in patients under the age of 60 following HD-MTX as this reduces the relapse risk from 83% to 25% and improved three-year survival (92% vs 60%) compared with lower-dose WBRT (30.6 Gy)
Fig. 56.8 Multiple meningiomas in a patient with NF2: axial pre- (A) and post-gadolinium (B) T1-weighted MR images demonstrate multiple avidly enhancing durally-based mass lesions. The tumours are isointense to cortex on the unenhanced images and therefore difficult to identify on that image. (C) Macroscopic meningioma specimen, cross section. Note dural base to the left of the image and well-circumscribed nature of the tumour. (D) Whorls and lobules of meningothelial cells are a characteristic feature of these neoplasms.

following CHOD-BVAM [174]. However, WBRT may not have an overall benefit for patients over the age of 60 following chemotherapy, due to the high rate of neurotoxicity; if it is used, a reduced dose of 30.6 Gy in 17 fractions results in the same relapse risk as 45 Gy [174].

WBRT alone has a complete response rate of over 50%, but 61% relapse within the radiation field and median survival is only 11 months. RT has a role to play in patients progressing on, or not tolerating, chemotherapy, where three-year survival rates of 33% and 60% have been seen [175]. A dose of 36 Gy in 1.8 Gy fractions WBRT followed by a 9 Gy boost is often used.

Meningioma

Presenting features. Slow-growing meningiomas may remain clinically silent despite reaching a relatively large size. With more frequent use of MRI, small incidental asymptomatic meningiomas are found. Meningiomas impinging on local brain structures may present with focal neurological deficit and epilepsy; features of increased intracranial pressure occur relatively late. In older patients, an enlarging mass may cause global deterioration of intellectual function and personality changes. Meningiomas of the olfactory groove may cause anosmia; parasellar and suprasellar meningiomas may compress the optic chiasm and result in visual deficit. Clivus and foramen magnum region tumours impinge on

the lower cranial nerves, brainstem, and midbrain, presenting with cranial nerve deficit. Lesions extending into the orbit, cavernous sinus, or compressing the optic apparatus may lead to proptosis with visual deficit and occasionally oculomotor, trochlear, and abducent nerve palsies. Optic nerve sheath meningiomas, which are generally very indolent tumours, present with gradual deterioration in vision.

Imaging. Meningiomas are extra-axial, durally-based tumours with the rare exception of intraventricular meningiomas. Approximately 90% are supratentorial with the convexities and parafalcine regions the most common locations. The commonest growth pattern is the so-called 'globose' meningioma—a sessile or less commonly pedunculated mass attached to the dura (Figure 56.8). Less common are the so called 'en plaque' tumours that have a more carpet-like growth pattern and often an intraosseous component characterized by hyperostosis of the involved bone. The greater wing of the sphenoid bone is the most common location of this type of meningioma.

The majority of meningiomas enhance uniformly and avidly. A 'dural tail' of congested enhancing dura can be seen on MRI in up to 60% of meningiomas. Approximately 20% demonstrate some degree of calcification on CT. Most are relatively isointense to cortex on T1 and T2-weighted images and can therefore be relatively inconspicuous unless contrast-enhanced images are performed.

Heavily-calcified meningiomas are hypointense on all pulse sequences and some histological types of meningiomas such as the microcystic and secretory types can be markedly hyperintense on T2-weighted images. Oedema is commonly seen, especially around larger meningiomas.

Surgery is the mainstay of treatment and the goal of surgery is complete macroscopic resection of the tumour with its dural attachment and also the bone if it is involved. This is dependent on tumour location, consistency, size, relationship and involvement of adjacent neurovascular structures and, in recurrent cases, previous RT or surgery.

The general principles of meningioma surgery are:

1. Early interruption of blood supply to the tumour (consider pre-operative embolization in some cases).

2. Internal tumour decompression (suction, ultrasonic aspirator, coagulation).

3. Arachnoid plane dissection with minimal retraction on adjacent brain (separate the tumour capsule from the surrounding brain, neurovascular structures).

The Simpson classification of meningioma resection is: grade I, complete removal, including resection of dura and bone; grade II, complete tumour removal with coagulation of dural attachment; grade III, complete tumour removal without resection or coagulation of dural attachments; grade IV, subtotal removal; and grade V, decompression. This classification remains useful for evaluating recurrences and in Simpson's series, grade I through to grade IV tumours had recurrence rates of 9%, 19%, 29%, and 40%, respectively, at ten years follow-up [176]. However, a recent study has shown no statistical difference in recurrence rate between grade I to IV resections at five years, so the benefit of more aggressive attempts to resect tumour with dura and bone was negligible compared with simply removing the entire tumour or even leaving small amounts of tumour attached to critical structures [177].

Tumours arising from the convexity can be completely resected with a rim of surrounding normal dura (usually 2 cm) and also any infiltrated bone. The dural defect after resection can be reconstructed using either autologous pericranial flap (vascularized or non-vascularized) or a synthetic dural substitute. The craniectomy defect after bone resection can be replaced either with acrylic or titanium mesh.

Parasagittal and falx meningiomas can be removed in their entirety, although a key factor in this is the anatomical location of the tumour in relation to the superior sagittal sinus (SSS) and the extent of sinus invasion [178]. As part of the preoperative workup it is important to perform a venogram (MR or CT) to assess the patency of the SSS.

A meningioma which only involves the falx can be resected with its base and the defect in the falx replaced either with autologous tissue (pericranium or temporalis fascia) or a synthetic dural substitute. The management of meningioma which involves the SSS is more controversial. Sindou et al. have described a grading system for meningioma based on extent of invasion of the SSS [178]. Depending on the extent of tumour invasion into the SSS they advocate either coagulating the invading tumour or resecting the sinus wall and repairing it directly or with autologous patch or a vein bypass. The final option is sinus resection with no venous bypass. It may be best to leave the residual tumour and follow up with MR imaging; if the residual grows, RT may be used. It is generally agreed that a partially occluded sinus in its anterior one-third can be resected as the risk of a venous infarction is very low. Resection of the posterior two-thirds of a partially occluded sinus carries a high risk of venous infarction.

Tumours of the anterior skull base can be approached by a craniotomy (bifrontal/anterior interhemispheric/pterional/subfrontal) or an extended endoscopic transplanum/transtuberculum approach [179, 180]. A recent meta-analysis showed that an open transcranial approach results in higher resection rate with lower postoperative CSF leak [181].

Lateral sphenoid wing meningioma are similar to convexity tumours and a Simpson grade I resection can be achieved. Medial sphenoid wing meningiomas tend to encase the internal carotid and middle cerebral artery; therefore, a total removal is not possible [182].

Meningiomas at other sites, such as the cerebellopontine angle, the clivus, or the anterior part of the foramen magnum, are accessible through a retrosigmoid /translabyrinthine or far lateral approach. Their removal carries a higher morbidity, especially involving the lower cranial nerves [183]. Some centres perform an endoscopic endonasal transclival approach to resect clival tumours [184, 185].

Radiotherapy is very effective in controlling the growth of surgically inaccessible meningiomas. It is used principally for the treatment of progressive benign (grade I) skull-base meningiomas and recurrent benign meningiomas at other sites not amenable to surgical excision, such as tumours involving but not occluding the venous sinuses.

Many meningiomas remain slow growing without threat to function and there is no evidence to suggest that earlier treatment is associated with better tumour control or survival outcome, although there are no randomized studies to assess this. The decision to proceed with treatment depends on the rate of growth, the presence and progression of neurological deficit caused by the tumour, and the perceived risk from uncontrolled growth.

The optimum treatment approach is the use of fractionated conformal or high precision stereotactic RT, which achieves disease control in most tumours with little or no radiation-induced toxicity [186]. As in other benign intracranial tumours, the GTV is defined on contrast-enhanced MRI (in three orthogonal planes) co-registered with planning CT scan. The PTV incorporates margin around the tumour of 3–5mm. There is no reliable dose response data and most series reporting outcome have used doses between 50 and 56 Gy at 1.8–1.6 Gy per fraction. Intensity-modulated radiation therapy (IMRT), while theoretically allowing for reduced dose to adjacent structures, has not been convincingly demonstrated to improve outcome either in terms of tumour control or toxicity [187]. Similarly, the reported results of proton RT for benign meningiomas are not superior, either in terms of disease control or toxicity, with a suggestion of higher incidence of side effects [188, 189].

The reported actuarial local tumour control following RT of benign meningioma is in the region of 90% at five years and 80–90% at ten years [186, 190, 191] and this is similar following high-precision treatment [186, 187]. The control rate of progressive optic nerve sheath meningiomas can be up to 100% at five and ten years. Similarly, the local control rate of progressive grade I parasellar/cavernous sinus meningiomas can reach 100% at five and ten years [186, 187].

Small meningiomas away from critical structures such as the optic apparatus, brainstem, and cranial nerves have been treated with single fraction radiosurgery with reported five- and ten-year control rates of cavernous meningiomas in the region of 90% at ten years [192]. Hypofractionated RT regimens should only be used with caution within prospective trials.

The evidence for benefit of RT for grade II tumours in terms of achieving long-term disease control is limited to small, largely retrospective, series [186]. While historically the reported recurrence rate is in the region of 90% for subtotally and 50% for completely excised tumours, with the use of MRI a proportion of completely excised grade II meningiomas do not recur and the current policy is to consider fractionated RT to patients with incompletely excised and offer to those with recurrent grade II tumours.

Pituitary adenoma

Clinical presentation. Non-functioning pituitary adenomas become symptomatic due to the involvement of the visual pathways (typically bitemporal hemianopia) or due to hypopituitarism. Rarely, the tumour mass may involve cranial nerves in the cavernous sinus. Spontaneous haemorrhage into such tumours (pituitary apoplexy) results in abrupt loss of vision with severe headache and impaired consciousness. Functioning pituitary adenomas present with features of a pituitary mass and endocrine syndromes such as acromegaly with elevated growth hormone (GH), Cushing syndrome with excess ACTH secretion, and features of excess prolactin secretion in prolactinoma.

Imaging. Pituitary adenomas are usually solid tumours and depending on their size, they can cause expansion of the pituitary fossa and extension into the suprasellar cistern and/or the cavernous sinuses. Macroadenomas can cause chiasmal compression. The tumours are slightly hypointense to normal pituitary tissue on T1-weighted images and slightly hyperintense on T2. They enhance less avidly and somewhat slower than normal pituitary tissue. Gadolinium-enhanced T1-weighted images therefore increase the sensitivity for detecting microadenomas and the sensitivity is further increased if dynamic (rapid sequence) imaging is performed during contrast administration; microadenomas are most conspicuous as relatively non-enhancing nodule surrounded by enhancing pituitary tissue on the early images.

Surgery is the first-line treatment for non-functioning pituitary adenomas. The aim of surgery is to maximally resect the tumour, obtain tissue for histopathology diagnosis, and, importantly, relieve compression on the pituitary and optic chiasm to possibly preserve and restore function.

Surgical access is through the sphenoid sinus either using an endonasal or sublabial approach and takes advantage of the close proximity of the sphenoid sinus to the sella and pituitary tumour. Tumour resection can be performed with the microscope or endoscope. More recently, an endoscopic endonasal approach is preferred by surgeons as it has the added advantage of extended approaches where bone of the rostral, anterior skull-base can be removed (transplanum/transtuberculum) for better access to large suprasellar pituitary tumours [193–196]. This also provides a wide panoramic view without brain and optic chiasm retraction and has a rapid recovery time and lower surgical morbidity and mortality (<1%) [193, 194, 197–200]. A trans-sphenoidal approach improves vision in the majority of patients with complete recovery seen in 35–39% and partial improvement in 50–60% of patients [200–203]. The most common complication after surgery is diabetes insipidus, seen in 15% of patients (up to 2% being permanent) [204, 205].

A trans-sphenoidal approach is now also the treatment of choice for elderly patients compared to a transcranial approach with a significantly lower mortality [202, 206].

Transcranial approaches (pterional craniotomy or subfrontal approach) are usually advocated for tumours with eccentric extensions into the frontal, temporal, or posterior fossa [207, 208]. They are now typically performed as part of a staged procedure after an endonasal trans-sphenoidal approach first.

Radiotherapy. Fractionated RT for progressive unresectable or recurrent pituitary tumours achieves excellent tumour control and, in functioning tumours, normalization of hormone levels albeit with delay of some years [209]. However, pituitary adenomas have an indolent natural history with little threat from a non-functioning adenoma mass to the optic apparatus unless in close proximity to it, and in the absence of local invasion minimal risk to other surrounding neural structures. The current policy is therefore to manage residual non-functioning pituitary adenomas following surgery with a policy of surveillance, which generally consists of annual MRI imaging and, in tumours close to the optic apparatus, regular ophthalmological assessment. RT is recommended at progression, especially if considered as a threat to functions or if enlarging tumour may require further surgery in the future and RT would be aimed at avoiding it.

In patients with residual secreting tumours, the aim is to achieve normalization of hormone levels and this generally means the use of irradiation in the presence of an elevated hormone following surgery regardless of the size of the residual tumour mass. Nevertheless, a debate exists on the relative value of somatostatin analogues and radiation in achieving the normalization of growth hormone. The current cost of life-long use of somatostatin analogues tends to favour RT in patients with apparently normalized GH levels on medical treatment, to allow for its subsequent withdrawal.

The principal RT option for the treatment of pituitary adenomas is fractionated 3D conformal RT using various forms of immobilization (mask or a relocatable frame) combined with image guidance to achieve high precision of treatment. The GTV/CTV-PTV margin is generally in the region of 3–5mm. The majority of functioning and non-functioning adenomas are effectively treated with a dose of 45 Gy in 1.8 Gy fractions [210]. There is no data to suggest dose-response relationship in terms of disease control or the rate of normalization of hormonal levels.

Following fractionated conventional and high-precision stereotactic RT of non-functioning pituitary adenomas, the ten-year control rate is in the region of 90–95% [209–211]. Fractionated RT to pituitary adenomas is associated with 1–2% risk of radiation optic neuropathy and 20–30% risk of developing pituitary hormone deficiency requiring replacement therapy [211, 212]. Although there is an increased risk of stroke associated with stroke mortality [213, 214] and increased risk of second brain tumours presumed at least in part to be radiation-induced [215], the increased risk may also be associated with the pituitary disorder itself.

Small functioning and non-functioning pituitary adenomas have been treated with single-fraction radiosurgery. The overall inferior results compared to conventionally fractionated treatment in terms of tumour control would argue against the routine use of radiosurgery. The current evidence also does not support the hypothesis

that high single radiation doses alter the rate of decline of elevated hormone levels [209].

Craniopharyngioma

Clinical presentation. The presenting features of craniopharyngioma similarly to non-functioning adenomas include symptoms of compression of visual pathways, hypothalamus, and the pituitary. The cystic component of craniopharyngioma can involve frontal and temporal lobes and can extend to the posterior fossa. Craniopharyngiomas can cause raised intracranial pressure due to third ventricular compression and obstructive hydrocephalus; in older patients, this may present with non-specific dementia-like features. Endocrine disturbances in addition to frequent hypopituitarism also include diabetes insipidus, which is unusual in pituitary adenomas.

Imaging. Craniopharyngiomas are predominantly suprasellar multicystic lesions with solid enhancing components. Calcification is seen in most paediatric tumours and up to 50% of adult tumours. The MRI signal characteristics of the fluid contents vary according to the protein content of the cyst fluid and the presence of haemorrhage and can be strikingly hyper- or hypointense on either T1 or T2-weighted images. Larger tumours can cause compression of the optic chiasm and even obstructive hydrocephalus.

Surgery. Surgery has an important role in the management of craniopharyngioma. Two main surgical strategies have been adopted. The first is aggressive surgical resection to achieve a gross total resection. This has been advocated as a curative measure. The second option is subtotal or partial resection, but tumour recurrence is higher with subtotal resection with recurrence rate of 25–100% compared to 0–62% with gross total resection [216–222]. Therefore, RT as an adjuvant to subtotal resection is now recommended. Recent studies have found no significant difference in PFS or OS between gross total resection and subtotal resection with adjuvant RT [223–227]. However, the incidence of surgical complications (panhypopituitarism, diabetes insipidus, and hypothalamic injury) which have long-term sequelae and affect quality of life are less with a conservative approach [225, 228, 229].

The two main surgical access routes for craniopharyngioma are trans-sphenoidal (microscopic or endoscopic) or transcranial (pterional, subfrontal). The trans-sphenoidal approach was traditionally used only for small intrasellar and infradiaphragmatic tumours [217] but over the past few years the advent of extended endoscopic approaches (EEA) has resulted in achieving resection of supradiaphragmatic/suprasellar lesions [230–233]. The initial concern with this approach was the high CSF leak rate, but advancement in closure techniques using a multilayered closure or a vascularized nasoseptal flap has reduced the CSF leak rates to less than 5% [234–236].

The wide panoramic view of the EEA has certain advantages such as lack of brain and optic apparatus retraction/manipulation, excellent visualization of the floor of the third ventricle and anatomy of the suprasellar space. The main limitation of this approach is significant tumour lateral to the carotid arteries. The transcranial approach is preferred by some surgeons with suprasellar tumour extension and is particularly helpful with tumours with significant lateral extension and vascular encasement. A recent meta-analysis and review has shown better gross total resection, less neurological morbidity, better visual outcome, and lesser incidence of diabetes insipidus with an EEA compared to transcranial surgery [237, 238].

A craniopharyngioma with an intraventricular component or completely intraventricular can be accessed through an endoscopic intraventricular approach [155, 239, 240].

Patients who present with acute hydrocephalus secondary to a suprasellar tumour obstructing the third ventricle require urgent surgical intervention by either direct tumour decompression or insertion of an external ventriculostomy. Tumours with a large suprasellar cystic component can undergo endoscopic intraventricular cyst fenestration with insertion of a ventricular access device to facilitate reaspiration if the cyst recurs [239].

Radiotherapy is part of the management of patients with incompletely resected and recurrent craniopharyngioma. While the relatively high recurrence rate of apparently completely excised craniopharyngiomas also suggested the use of irradiation in this group of patients, with improved imaging surveillance is a reasonable alternative with early institution of RT with evidence of tumour progression to avoid the need for additional surgery.

Fractionated high-precision conformal RT is the gold standard (see above). The techniques include multiple non-coplanar fixed-field treatment, IMRT, or arcing techniques. Fractionated radiation is delivered in daily fractions of 1.6–1.8 Gy per fraction to a total dose of 50 Gy in 28–30 fractions [240].

Following conventional RT, the ten-year PFS and OS rates are 75–90% [240, 241]. The results following high-precision fractionated treatment are similar, albeit less mature, with five-year PFS rates over 90% and up to 100% five-year survival [240, 242].

The results of single-fraction radiosurgery are disappointing, with five-year local PFS rates in the region of 60–70% even though smaller tumours tend to be treated with this technique [240]. Hypofractionated regimens should be used with caution as long-term results are not available. There is limited data on the use of protons to assess the comparative efficacy and toxicity.

Before, during, and after RT, 10–20% patients may develop cystic enlargement of the craniopharyngioma, which does not signify treatment failure [243]. If this occurs, and causes visual impairment and/or hydrocephalus, early recognition and treatment in the form of cyst aspiration is essential [243].

Spinal tumours

Clinical presentation

Spinal tumours cause local pain at the site of the lesion and impaired neurological function at and below the spinal level. Pain due to bone or spinal-root involvement is localized to the level of the lesion and may significantly predate other symptoms. It is usually worse at night and coughing or straining may exacerbate it and provoke paraesthesiae or temporary impairment of neurological function. Pain from intramedullary tumours is less severe.

Spinal compression by tumours causes segmental loss of power and tendon reflexes. Below this level it causes impairment of long-tract function, with loss of sensation and motor deficit (paraparesis or paraplegia) with hyper-reflexia and dysfunction in bladder and bowel sphincter control (usually urinary retention and constipation or incontinence). Laterally placed tumours may cause a Brown-Séquard syndrome with loss of motor function ipsilaterally and of sensation contralaterally.

Clinical features may indicate the level of spinal compression due to a tumour but confirmatory radiological investigations are essential. In adults, the spinal cord segmental level differs from that of

the bony vertebral level. Thus, below the level of the axis (C2) in the cervical and thoracic region the approximate segmental level of the cord can be obtained by adding two to the corresponding vertebral level. The spinal cord terminates at the conus medullaris at the level of L1–L2 lumbar vertebrae, so that the lumbar segments of the spinal cord lie at the T11–T12 vertebral levels, with the sacral spinal segments at the L1–L2 level. Below the conus the lumbar and sacral nerve roots form the cauda equina.

Specific syndromes. Spinal tumours may arise within the spinal theca (intradural), in the substance of the cord (intramedullary) or in the subarachnoid space (extramedullary), or they may lie outside the theca (extradural).

Intradural intramedullary tumours (e.g., ependymomas) result in diffuse spinal cord swelling over several spinal segments, often in the cervical or upper thoracic region and can be associated with cyst formation centrally in the spinal medulla. They initially result in loss of local function over several spinal segments, particularly involving crossing spinothalamic tract fibres, as well as pain and subsequent loss of neurological function below the level of the tumour. The cyst may give rise to a syringomyelic clinical picture, with a predominant loss of spinothalamic sensation and impaired tendon reflexes at the level of the tumour. A late, but diagnostic, feature of intrinsic spinal cord tumour is sacral sparing. Tumours in the conus or in the filum terminale cause cauda equina and conus involvement. The cauda equina syndrome typically presents with local pain (rectal or genital), backache, loss of sphincter tone and function, and lower limb flaccid paralysis. Perianal sensory loss (saddle anaesthesia) is a frequent early sign.

Intradural extramedullary tumours (schwannomas or meningiomas) may present with spinal root involvement, pain, and impaired neurological function due to spinal compression. In the cervical region, combined intradural and extradural components are often found, while in the thoracic region tumours are sometimes wholly extradural. Large extraspinal components may present with a mass in the neck or mediastinum.

Extradural tumours, which are most frequently metastatic, present with pain and features of spinal cord compression which are dominated by motor impairment, initially as mild spastic paraparesis. This is accompanied by sphincter disturbance and ascending sensory loss, often starting as paraesthesiae.

Imaging

- *Pilocytic astrocytomas:* These are more common in children and vary from relatively well-circumscribed enhancing lesions with or without juxtatumoural cysts or syrinx formation, most commonly in the cervical cord, to more diffuse lesions that can involve the whole cord with marked expansion of the cord. Widening of the spinal canal is occasionally seen and reflects the slow-growing nature of these lesions.

- *Grade II—IV astrocytomas:* These tumours are characterized by cord expansion and T2 hyperintensity usually involving several adjacent segments. The cervical cord is more commonly involved than the thoracic cord. Contrast enhancement is almost always evident in grade III and IV tumours and subarachnoid spread as well as intratumoural haemorrhage are features that suggest grade IV tumours.

- *Spinal cord ependymomas:* Ependymomas that occur within the spinal cord are usually WHO grade II or III, as opposed to the grade I myxopapillary ependymomas that usually affect the filum terminale. Cord ependymomas also occur more commonly in the cervical cord (Figure 56.9) but are usually better circumscribed than diffuse astrocytomas with avid contrast enhancement. Polar cysts are commonly seen in the superior and/or inferior aspect of the tumour and haemosiderin staining in the cyst walls is responsible for low signal seen in the fundus of the cyst walls on T2-weighted images in up to half of tumours—the so called 'cap sign'. Syrinx formation is also a common feature as in other cord tumours.

- *Spinal cord metastases:* Cord metastases are very rare compared to brain metastases. Unlike cord ependymomas and astrocytomas, metastases are usually quite small (typically less than 1.5 cm in maximum extent) and do not have a predilection for any particular segment of the cord. Avid contrast enhancement and extensive cord oedema extending several segments above and below the tumour are typical features (Figure 56.10).

Surgery. The surgical approach to most spinal tumours is by a non-destabilizing standard posterior laminectomy or laminoplasty performed at the level of the lesion and extended rostral and caudal to it determined by the pre-operative MRI scan. This gives good access to all posteriorly-located and some postero-laterally-located tumours. Tumours located anterior to the spinal cord require more direct open approaches through the mouth, neck, chest, or abdomen [244–247] or endoscopic-assisted to minimize retraction and injury to the spinal cord [248]. Occasionally, even these tumours can be resected through a standard posterior approach with varying degrees of lateral bone resection, dentate ligament division, and gentle cord rotation [245].

In meningioma, the aim of surgery is complete tumour removal, which is usually possible through an exposure by posterior laminectomy and with opening of the spinal theca. The rostral and caudal pole of the tumour is exposed. Depending on the size and consistency of the tumour, it is internally debulked with an ultrasonic aspirator or laser, which facilitates visualization and development of the tumour margins. There is usually a good arachnoid plane which separates the tumour capsule from the spinal cord, nerve roots, or cauda equine rootlets. This plane is developed and the tumour separated off the normal tissue. The dural attachment can either be resected and autologous tissue or synthetic graft sewn, or the base cauterized.

The above basic principles apply to neurofibromas as well. Typically, these tumours arise from the dorsal nerve root and tumour removal requires identification and division of the proximal and distal nerve root tumour attachments. It is possible to preserve the ventral root, which is tightly applied to the ventral tumour surface. Large tumours with dumb-bell–shaped extension through the root sleeve, however, usually necessitate resection of the entire spinal nerve. Patients rarely have a significant nerve deficit due to compensation by adjacent roots.

Intramedullary tumours are generally approached by posterior laminectomy and dural opening. Most centres perform spinal cord monitoring (somatosensory-evoked potentials [SSEP]) and motor-evoked potentials (MEP) to predict potential postoperative neurological deficit, although there is no good correlation between change in amplitude and outcome [249].

Usually a midline myelotomy is performed although with eccentric tumours a myelotomy over its most superficial part causes least
Fig. 56.9 Spinal cord ependymoma: sagittal T2-weighted (A) and gadolinium enhanced T1-weighted (B) MR images demonstrate an avidly enhancing intramedullary tumour in the cervical cord with 'polar' cysts at the superior and inferior aspects of the solid, enhancing component of the tumour. Note the modest amount of cord oedema above and below the cystic components. (C) Perivascular pseudorosettes with (D) strongly GFAP positive processes radiating towards a vessel are characteristic of ependymomas.

neurological damage. The tumour is resected 'inside to outside' using an ultrasonic aspirator. The most important factor governing surgical outcome and extent of resection is the plane between the tumour and the spinal cord. Where a plane can be developed between the tumour and the cord (cavernoma, ependymoma, some low-grade astrocytomas and haemangioblastoma) an attempt at gross total resection is an option. Where the plane is poorly defined (high-grade astrocytoma or some low-grade astrocytoma) a biopsy or subtotal resection is recommended [250]. Cystic component within the tumour can be aspirated or drained.

Recently, 5-ALA fluorescence-guided resection has been performed in ependymoma to visualize the tumour margin and safely achieve maximum tumour resection [251].

Radiotherapy. Primary intramedullary tumours are treated by radical spinal irradiation to spinal cord tolerance doses. The clinical target volume based on MRI should include the whole circumference of the spinal canal and tumour extension with a 1–2 cm margin. The beam may traverse sensitive structures such as the kidneys, small bowel, and lungs, and the chosen technique has to take into account their limits of radiation tolerance. In whole-spine irradiation as part of craniospinal axis radiotherapy, the superior margin is matched to the cervical extension of the whole-brain field. In-field segments and intensity modulation can be used to ensure dose homogeneity throughout the target volume.

Spinal cord tolerance to irradiation. The spinal cord is a 'serial' rather than 'parallel' organ, which means that a small area of damage to the organ can be catastrophic to function. Using conventional fraction sizes of 1.8–2 Gy to the full-thickness cord, the estimated risk of myelopathy is <1% and <10% at 54 Gy and 61 Gy, respectively, with a calculated strong dependence on dose/fraction (a/b = 0.87 Gy). Reports of myelopathy from stereotactic radiosurgery to spinal lesions appear rare (<1%) when the maximum spinal cord dose is limited to the equivalent of 13 Gy in a single fraction or 20 Gy in three fractions [41].

Re-irradiation of spinal cord tumours. Data on re-irradiation of the spinal cord in animals and humans suggest partial repair of RT-induced subclinical damage becoming evident about 6 months post-RT and increasing over the next two years. For re-irradiation of the full cord cross-section at 2 Gy per day after prior conventionally fractionated treatment, cord tolerance appears to increase at least 25% six months after the initial course of RT based on animal and human studies [41].

Spinal ependymomas

Surgery. Gross total resection is the aim of filum terminale and conus medullaris tumours and has a lower risk of a recurrence than subtotal resection [252]. Filum tumours are resected by first dividing the filum above the lesion to prevent retraction and then below

Fig. 56.10 Spinal cord metastases from breast cancer: sagittal T2-weighted (A) and gadolinium enhanced T1-weighted (B) MR images demonstrate an avidly enhancing intramedullary tumour at the T5 level with extensive oedema in the thoracic cord above and below the lesion. The tumour itself is visible on the T2-weighted image as a focus of intermediate signal outlined by the high signal oedema in the swollen cord. Note: no histology.

the lesion. The filum is differentiated from nerve roots by its whiter appearance, vessels on its surface, and, more definitely, by intra-operative stimulation and anal sphincter EMG recording. Tumour of the conus medullaris does not usually invade the conus and can be separated from it. Sometimes a subtotal resection is accepted to prevent damage to the conus.

Intramedullary ependymoma usually have a clear cleavage plane and a complete surgical removal reduces the likelihood of a recurrence [253] but aggressive resection is associated with high complication rate [254].

Radiotherapy. Spinal ependymoma account for 60–80% of spinal gliomas. There are no randomized trials on the role of adjuvant RT following surgical excision; however, total excision has a very good survival (86% at 10 years) and adjuvant RT is not generally used [255]. However, following less radical surgical procedures (partial excision or biopsy alone) if RT (50 Gy in 1.5–2 Gy fractions) is used, 50–60% of patients remain alive and free of tumour progression at five and ten years [256]. Irradiation is confined to the region of the tumour and the margin of potential spread. The use of more extensive irradiation, including brain and whole spinal cord, is not advocated; however, all patients should have imaging of the whole neuroaxis to exclude the possibility of primary intracranial disease with drop spinal metastases.

Anaplastic ependymoma of the spinal cord is rare (5% of spinal ependymoma) and surgical biopsy or excision should be followed by local RT (50–55 Gy in 1.6–1.8 Gy fractions).

Spinal astrocytoma

Surgery. The optimal management of malignant intramedullary spinal cord astrocytomas remains controversial. The principles of surgical approach to these tumours however are the same as other intramedullary tumours. Most AA patients undergo a subtotal resection given the lack of a clear tumour-spinal cord plane and have a decreased OS (38% vs 78%) at four years compared to those who have a complete resection [257]. However, complete resection of a glioblastoma is usually not possible [257, 258]. Surgery carries a high risk of neurological deterioration [258].

Radiotherapy. Since the biological nature of spinal cord high-grade glioma is identical to that of the brain, RT remains a key adjuvant treatment [259]. Radical surgery and RT of spinal GBM is associated with poor survival, similar to historical controls of diagnostic biopsy and RT [257]. The rationale for post-operative RT is equivalent to that for the treatment of intracranial gliomas, treating all high-grade tumours and incompletely resected low-grade tumours due to the high risk of neurological compromise if left untreated. Doses of 50–55 Gy in 1.6–1.8 Gy fractions are administered. For patients with glioblastoma, temozolomide should be given concurrently with the RT as for cranial GBM, and if there is already very poor neurological function due to cord disruption, radiation doses up to 60 Gy could be justified. Neurological deficit due to tumour or surgery is rarely relieved by RT and patients with high-grade tumours have very poor prognosis [260, 261].

Brain metastases

Clinical presentation

Brain metastases are the most common intracranial tumours in adults, accounting for over half of brain tumours. Up to 20% of patients with systemic malignancy will develop brain metastases, but the frequency appears to be increasing with the increased control of extra-cerebral disease from improved systemic therapy that may lack CNS penetration. Most malignant tumours are associated with the development of brain metastases through haematogenous spread. The risk of brain metastases is highest in patients with lung cancer (20% of cases), melanoma (7%), renal cell cancer (7%), breast cancer (5%), and colorectal cancer (1%) [262]. The most frequent presentation is of multiple lesions within the brain parenchyma; less frequent are single metastases or meningeal disease.

Patients with brain metastases present with typical features of a gradually expanding tumour mass and associated oedema with headache, focal neurological dysfunction, cognitive dysfunction, and seizures. Confusional states and multiple neurological deficits are common. Less commonly, intratumoural haemorrhage, obstructive hydrocephalus, or embolization by tumour cells is seen.

Approximately two-thirds of patients presenting with brain metastases have a known underlying primary tumour, usually with metastatic disease at other sites. In the absence of known malignant disease, if imaging suggests brain metastases and the patient is fit enough to undergo treatment, it is necessary to search for a primary cancer (CT chest and abdomen or PET CT). 60% of cases will have an underlying lung cancer. However, in the 25% of cases where no primary is detected, biopsy of the brain metastasis must be undertaken to obtain histological diagnosis.

In some cancer types, genetic modification may be seen in the metastasis not present in the primary cancer. For example, Her-2

overexpression in breast cancer or BRAF mutation in melanoma may occur in the brain lesions, which may determine treatment options which can cross the blood brain barrier (lapatinib and vemurafenib, respectively). Therefore, a biopsy of brain metastases in a patient with known metastatic cancer may be required to direct subsequent treatment.

Imaging

Parenchymal brain metastases are much more common than leptomeningeal metastases. Metastases can occur anywhere in the brain parenchyma but favour the junction of the cortex with the white matter. The vast majority of metastases show contrast enhancement. Necrosis and surrounding oedema are commonly seen, particularly with larger lesions.

Leptomeningeal metastases are more difficult to detect and can be very subtle, even on gadolinium-enhanced MRI. The cerebellar folia, cranial nerves, and internal auditory meatus are common locations for leptomeningeal metastases.

Treatment

The aim of therapy is palliation. Corticosteroids improve symptoms in up to 60 per cent of patients. A randomized trial compared 16 mg with 4 mg of dexamethasone for patients with brain metastases, KPS ≤80, and no impending risk of herniation. There was no difference in degree of KPS improvement between the doses, and toxic effects were worse with the higher dose [263]. Tapering of dose from 4 mg should be carried out over four weeks following palliative treatment. This may be sufficient palliation in patients with extensive systemic metastatic disease when prognosis is 1–2 months. Further treatment should be determined by the patient's overall prognosis. Patients with brain metastases can be divided into three prognostic groups from the RTOG recursive partitioning analysis (RPA) [264]. The RPA has recently been validated for updated treatment modalities stereotactic radiosurgery (SRS) and fractionated stereotactic radiation therapy (fSRT) [265].

Using this analysis, RPA class I tumours (KPS ≥70, <65 years, controlled primary, no extracranial metastases) have a median survival of 7.1 months. Class III tumours, in patients with KPS <70 have a median survival of 2.3 months. For class II, who are neither class I nor III, the median survival is intermediate at 4.2 months. Patients with class I and some class II have a favourable prognosis. Those with limited brain metastases (1–3) and controlled systemic disease have the best overall prognosis with a median survival of over a year; treatment should be focused on eradication or control of the brain metastases, including surgery or radiosurgery.

Patients with an unfavourable prognosis (most in class II and all in class III) should have treatment focused on control of symptoms caused by the brain metastases.

Surgery

Surgery is usually reserved for patients with a single symptomatic accessible metastatic deposit. Following gross total resection alone, local disease control at one year is around 50% [266, 267]. Surgery also has a role in patients with multiple metastases if one is symptomatic or life-threatening (as in the posterior fossa) [268].

Occasionally, patients with two or three lesions that can all be removed by one or more craniotomies are still considered surgical candidates. The aim of surgery is to reduce the mass effect from the lesion and possibly improve neurological deficits. Resecting the metastases reduces the surrounding oedema and, as a consequence, reduces the need for steroid medications and, consequently, their long-term side effects.

However, the decision to proceed with surgery is multifactorial and depends on the patient's age, Karnofsky score, extracranial disease (controlled or progressing), number, size, location, and histological type of metastasis (if known primary) as shown below. Surgery is generally indicated for tumours of ~3 cm, but not for small tumours (<1 cm), and ≤3 lesions (although it is possible to resect the large one if symptomatic and >3 cm). Surgery is generally reserved for superficial or supratentorial lesions, rather than for those in the thalamus, deep basal ganglia, or brainstem. For surgery, patients should generally have KPS ≤ 70, with controlled extracranial disease. Optimal primary tumour types include solid tumours such as those of the breast, colon, or lung, melanoma, and renal cancers rather than lymphoma, small cell lung cancer, or germ cell tumours.

The aim of surgery is en bloc resection, but sometimes this might not be possible depending on tumour location and size. The lesion is localized using a neuronavigation system. Patients undergoing a piecemeal resection have an increased risk of leptomeningeal dissemination compared to en bloc resection [269–271]. Some authors advocate a wider resection incorporating up to 5mm of adjacent brain to reduce local recurrence [272].

Radiotherapy

Favourable prognostic group

Stereotactic radiosurgery, used either alone or in combination with whole-brain irradiation, achieves local tumour control and survival of approximately 11 months, similar to neurosurgical excision [266]. It can be considered a non-invasive alternative to surgery in patients with low-volume brain metastases, particularly where risks of morbidity are high with surgery. The decision to use SRS/fSRT must, however, balance the likely benefits against the risk of complications, including radio-necrosis. Evidence suggests that radio-necrosis becomes more likely as the total brain volume treated increases; if the brain volume receiving >12Gy is >8.5 cm^3, the necrosis rate is 10% [273]. An upper limit of 20 cm^3 has been identified as a reasonable cut-off point for metastatic disease burden to receive SRS [274]. A total volume of 20 cm^3 could accommodate a single tumour of approximately 3.2 cm diameter or a number of smaller tumours.

The addition of whole brain radiotherapy (WBRT) to radiosurgery or surgery for patients with 1–3 brain metastases improves local and distant brain control but there is no difference in median survival (10.7 months) or quality of life from the EORTC 22952 study. Patients treated with radiosurgery alone were found to have better neurocognitive outcomes as compared to patients treated with WBRT and radiosurgery [266]. Radiosurgery to the tumour bed with a 2 mm margin following surgical excision of isolated metastases is an alternative approach to avoid WBRT and reduce local relapse. This technique is currently being tested in intergroup studies [275].

Radiosurgery boost with WBRT may improve local disease control in selected participants compared to WBRT alone, although the median survival of six months remains unchanged for participants with multiple (>3) brain metastases [276].

Unfavourable prognostic group

Whole brain radiation (WBRT) provides effective palliation and can produce neurological improvement in 64–85% of patients. A Cochrane review of 39 randomized trials involving over 10,000 patients concluded that none of the RCTs with altered WBRT dose-fractionation schemes as compared to the standard (30 Gy in ten daily fractions or 20 Gy in four or five daily fractions) found a benefit in terms of overall survival, neurologic function, or symptom control [277]. Case series indicate that the median survival increases by 3–6 months with the use of palliative WBRT; however, the benefit of WBRT as compared to supportive care alone has only been studied in one RCT. The MRC QUARTZ trial group has recently published interim results of a study of patients with non-small cell lung cancer and inoperable brain metastases. The first 151 patients given optimal supportive care, with or without WBRT (20 Gy in five fractions), had a median survival of 50 days and no difference in quality of life scores. 50% of patients were RPA class III [278]. It may be that supportive care alone, without WBRT, is appropriate for some patients, particularly those with advanced disease and poor performance status [279]. In a cohort study of 3459 patients with brain metastases, 17% lived for less than six weeks after their WBRT [280].

Chemotherapy

Systemic chemotherapy administered to patients with brain metastases of chemosensitive tumours, such as lymphoma, teratoma, small cell lung cancer, and breast cancer, can induce clinical responses, particularly in previously untreated patients. More recent evidence has become available on the use of targeted agents crossing the blood brain barrier for brain metastases. The BRAF inhibitor, vemurafenib, has shown activity for melanoma patients who exhibit V600 BRAF mutations with brain metastases. A 50% response rate was seen in non-pretreated patients [281] lasting 8–32 weeks, and a 75% response rate following cranial radiotherapy [282]. Lapatinib is an oral small molecule tyrosine kinase inhibitor also crossing the blood brain barrier that interrupts Her-2 receptor pathways. Its use resulted in prolonged median survival for Her-2 positive breast cancer patients with brain metastases (19 months) compared with trastuzumab (12 months), a monoclonal antibody inhibitor of Her-2 receptor [283].

Metastatic spinal tumours

Although uncommon, spinal tumours may present with symptoms mimicking many benign disorders, frequently delaying diagnosis. These include back pain, sometimes radiating to other parts of the body; loss of sensation, especially in the arms or legs; difficulty in walking; decreased sensitivity; loss of bowel or bladder function; and muscle weakness depending on which nerve or part of the spinal cord is compressed. Spinal tumours progress at different rates. In general, cancerous spinal tumours grow more quickly, and noncancerous spinal tumours tend to develop very slowly. Metastatic tumours to the spine are usually extradural, arising from bony or surrounding soft tissue metastatic masses. Rarely, deposits may be intramedullary. The neurological deficit is the result of the combination of local cord oedema, ischaemia, and direct pressure.

The aim of therapy is functional improvement and pain control. Survival depends usually on the extent of metastatic disease and the tumour type, as well as treatment. The functional outcome after therapy is largely dependent on pretreatment neurologic status. Education for patients and health care staff about symptoms that warrant immediate evaluation to detect malignant spinal cord compression (MSCC) is key to early diagnosis and therapy. A recent study indicates that 62% of patients are ambulatory at the time of diagnosis [284]. Rapid diagnosis and treatment are also key to maintaining or regaining ambulation. MRI of the whole spine should be conducted for suspected cases of MSCC.

Treatment guidelines

Patients are frequently in severe pain. Corticosteroids are the initial treatment in patients with suspected spinal cord compression and usually relieve pain within a few hours; however, opioids are also usually required. Treatment with higher doses than those given conventionally (dexamethasone 4 mg, 6 hourly) results in higher adverse events, but no improved pain control or neurological outcome [285].

Spinal stability should be assessed using the SINS score (spinal instability neoplastic score) which considers disease location at junctions in the spine, mechanical pain, bone lesion type, spinal alignment, vertebral body collapse, and involvement of posterolateral spinal elements [286]. If the spine is unstable (score 13–18) patients should be nursed horizontally in bed, and a surgical approach considered. An indeterminate score 7–12 should involve surgical consultation. An unstable spine will not respond to radiotherapy and should be treated surgically with fixation, or—if there is no epidural disease— with percutaneous vertebroplasty followed by radiotherapy.

The choices of treatment for patients with stable spinal disease include decompressive surgery, radiotherapy, or both. In patients with chemosensitive tumours, chemotherapy may be the initial treatment. Patients with spinal metastasis who do not have acute neurological deterioration may require workup to identify the primary tumour and to obtain histological confirmation of malignancy. The role of surgery is dependent on a number of factors including patient age, histopathology of the primary tumour, number of spinal metastases, and systemic disease (controlled vs uncontrolled). Solitary metastasis with indolent tumours (renal cell cancer, melanoma, some adenocarcinomas, thyroid, and sarcoma) may be candidates for attempted cure with en bloc resection (total spondylectomy) [287–290].

Patients with stable spines, who are able to walk, could be considered for chemotherapy for very chemosensitive tumours (teratoma or lymphoma); radiotherapy alone if the tumour is very radiosensitive (small cell carcinoma, germ cell tumour, lymphoma, leukaemia, and multiple myeloma); or, for the majority of patients, surgical decompression followed by radiotherapy (30Gy in ten fractions). This latter approach results in maintained ambulation in 94% treated with surgery and RT versus 74% for RT alone [291].

Surgical decompression is done through either an anterior approach or a posterior laminectomy. Most cases require a metallic instrumented fixation and fusion to maintain spinal stability. When an anterior approach is employed, an anterior plate spanning one level above and one level below the vertebrectomy defect is generally used to support the cage or cement reconstruction in the vertebral body. In posterior decompression, posterolateral lateral mass or pedicle instrumentation is usually employed, spanning at least two levels above and below the tumour.

In non-ambulant patients with a single area of compression, paraplegia of <48 hours, prognosis of > 3 months, controlled metastatic disease elsewhere, and non-radioresponsive tumours, surgical decompression followed by radiotherapy (20–30Gy) should also be considered. This strategy results in regained ambulation in 62% compared to 19% for RT alone. Survival is similar between both treatment groups [291]. Spinal cord compression by a tumour of unknown primary site or progression of signs despite radiotherapy are also indications for surgery. Laminectomy alone has been shown to be no better than radiotherapy and should not be used.

Patients without the good prognostic features outlined above should be considered for treatment with palliative radiotherapy. Thirty percent of those who are non-ambulatory will regain the ability to walk, but only 2–6% of fully paraplegic patients will do so following radiotherapy alone. This is more likely for patients whose symptoms develop slowly (>2 weeks), treatment is started <12 hours after loss of ambulation, and bladder and bowel function are retained [292].

An optimal radiotherapy regimen has not been defined; in patients with a limited prognosis a dose of 20 Gy in five fractions by direct field is usually adequate. A single fraction of 8 Gy should be considered for patients with MSCC who have progressive neoplastic disease, poor performance status, and survival <6 months. In these patients, there is no benefit in a more protracted course of RT [293]. Prognosis for patients with MSCC who are ambulatory prior to RT is 8–10 months, compared with 2–4 months for non-ambulatory patients.

More radical RT is reserved for solitary lesions such as plasmacytoma (40 Gy in 20 fractions).

Skull base tumours

Clinical features

The most frequent site of primary bone tumours of the skull is the base of the cranium, with rare involvement of other regions. The most common tumours are chordomas and chondrosarcomas, with occasional osteomas, giant cell tumours of the bone, and osteosarcomas. Base of skull (clivus) tumours present with symptoms of local bone destruction (usually pain) and gradually progressive features of cranial nerve, brainstem, or mid-brain compression. Tumours may also invade other surrounding structures, such as the sphenoid sinus, pituitary fossa, orbits, and nasopharynx, with attendant focal clinical features.

Surgery

Surgery is the primary treatment but the tumour site and extensive invasion of surrounding structures make complete excision difficult.

Radiotherapy

The five-year progression-free survival of patients with chordoma treated with photon radiotherapy (50 Gy) after incomplete resection or biopsy alone is 20–30% and the median survival is five years [294].

High-energy charged-particle radiation (protons and helium ions) has been employed in the treatment of skull-base chordomas and low-grade chondrosarcomas. Due to the sharp dose gradient fall off, a higher dose (70 Cobalt-Gy equivalent) can be delivered to the skull-base tumour with reduced risk of normal tissue complications to the brainstem, optic chiasm, and spinal cord compared with photon RT. In addition, the low-dose radiation to normal tissues beyond the target volume is significantly lower with protons, and the rate of second malignancy following proton therapy appears to be half that of conventional radiotherapy (6.45% vs 12%). Published case series of 416 patients with chordoma treated with proton therapy has shown five-year local control and overall survival rates of 69% and 80%, respectively [295]. The results for chondrosarcoma are higher with ten-year local control and survival rates over 98% following 72 Cobalt Gy-equivalent proton therapy [296].

There are concerns about proton therapy, however. The radiobiological effectiveness (RBE) value for proton therapy has been calculated to be 1.1 compared with photon therapy. However, it is possible that the value varies between tumour and normal tissues, so better estimates of RBE for normal tissues are required to be certain of likely long-term risks to normal tissues. The recent developments in photon radiotherapy (IMRT, volumetric modulated arc therapy, relocatable frameless stereotactic immobilization, improved dose optimization and calculation) permit delivery of photon radiotherapy to higher doses. Randomized trials comparing photon therapy and proton treatment for indications such as skull base chordoma and chondrosarcoma should be conducted [297].

Vestibular schwannoma

Clinical presentation

Vestibular schwannomas are benign encapsulated tumours of the eighth cranial nerve, representing 8% of intracranial tumours in surgical series, either as sporadic tumours or as part of neurofibromatosis (NF2). They arise from the vestibular nerve within the internal auditory meatus and commonly present with unilateral progressive deafness. However, symptoms may not occur until the tumour has expanded into the cerebello-pontine angle, causing ataxia and involvement of the trigeminal and facial nerves. The mid-brain and pons may be compressed and hydrocephalus may develop. Large tumours may also involve the adjacent seventh or fifth (trigeminal) nerves with associated clinical signs. Schwannomas may rarely involve the trigeminal, glossopharyngeal, vagus, or hypoglossal nerves and these may also affect the cerebello-pontine angle. They are well-circumscribed, avidly-enhancing solid tumours, but larger lesions can have areas of non-enhancing cystic degeneration.

Vestibular schwannomas are graded according to local tumour extension and size. Histologically, they are highly cellular with interlacing bundles of spindle cells whose nuclei are often in parallel arrays, alternating with lesser-textured, often partially cystic areas.

Surgery

Tumours may be resected by retrosigmoid, subtemporal, or translabyrinthine routes. Given the success with stereotactic radiosurgery in controlling tumours <3 cm with improved facial nerve function (98%) and hearing preservation compared to surgery [298–302], surgery is usually reserved as first-line treatment for tumours >3cm.

Gross total resection with facial nerve preservation remains the ideal goal to lower the rate of recurrence [303–305]; however, this is

also associated with a higher rate of facial nerve palsy with increasing tumour size. A recent large meta-analysis (>11,000 patients) showed 90% facial nerve preservation with tumour <2 cm vs 67% with >2 cm [306]; therefore, most surgeons now accept a subtotal resection with preservation of facial nerve function [307, 308] or follow it with planned radiosurgery [309].

Radiotherapy

Radiotherapy has been employed in the treatment of inaccessible or incompletely excised schwannomas of the eighth and other cranial nerves. Treatment is delivered with stereotactic immobilization and delivered as a single fraction (SRS) or fractionated (fSRT) [310]. The outcomes are similar, with long-term tumour control rates of 93% at ten years and hearing preservation 70% at ten years for SRT (up to 54 Gy in 1.8 Gy fractions) and SRS (<13 Gy to 80% isodose). However, when SRS delivered >13Gy to 80% isodose, this resulted in higher rates of hearing loss (25% preservation at ten years) [311]. The choice of treatment modality is governed by a number of factors. If a vestibular schwannoma is <3.5 cm, watch and wait, SRS, or surgery are options. If it is larger than 3.5 cm or presents with local compressive symptoms, then SRS should not be used, and surgical excision and/or fractionated SRT should be used. The likelihood of hearing preservation following treatment should also be considered in the choice of treatment.

Vestibular schwannoma in neurofibromatosis type II (NF2)

Patients with NF2 are a particular challenge because they usually have bilateral vestibular schwannomas and a higher risk of radiation-induced malignancy. Treatment is indicated when there is brainstem compression, deterioration in hearing, and/or facial nerve dysfunction. Surgery is usually carried out; however, hearing preservation is problematic with bilateral disease. VEGF is highly expressed in vestibular schwannoma in NF2 [312]. Bevacizumab, the monoclonal antibody targeting VEGF, has been used in patients with progressive vestibular schwannoma with NF2. In one study, 55% of 31 patients showed a response in terms of initial tumour reduction and hearing improvement. This improvement was durable; 61% had stable or improved hearing and 54% had stable or reduced tumour size at three years [312, 313].

Choroid plexus tumours

Imaging. Choroid plexus papillomas (CPP) are more common than choroid plexus carcinomas and occur predominantly in the trigone of the lateral ventricles in children. When they occur in adults, the fourth ventricle is the most common location. The tumours have an irregular frond-like outline and usually enhance avidly but heterogeneously. Calcification is seen in approximately 25% of CPP on CT.

Drop metastases are occasionally seen in patients with CPP. Choroid plexus carcinomas typically occur in the lateral ventricles of children under the age of five; although they resemble CPP on imaging, they tend to be larger and show infiltration of surrounding brain. Hydrocephalus is a common complication.

Surgery. Surgery is the treatment of choice in benign CPP and gross total resection is associated with excellent outcome and low recurrence rate. Patients with recurrence are offered further surgery rather than radiation therapy [314, 315].

Radiotherapy. Following incomplete excision, radiotherapy has been employed with variable results [316]. It is recommended as routine treatment only in patients with gross macroscopic residual disease and in those with recurrent tumour and should be delivered by localized irradiation in doses of 50–55 Gy as for low-grade gliomas.

CPP is a rare malignant variety, to be distinguished histologically from metastatic adenocarcinoma and ependymoma. Despite aggressive treatment with surgery, radiotherapy, or chemotherapy, the prognosis is poor with high risk of CSF dissemination. Review of published case series suggests that five-year overall survival is 59.5% and progression-free survival is 37.2%. Treatment with craniospinal axis irradiation resulted in better outcomes than focal irradiation [317].

CHAPTER 57

Tumours of the eye and orbit

Daniel G. Ezra, Geoffrey E. Rose, Jacob Pe'er, Sarah E. Coupland, Stefan Seregard, G.P.M. Luyten, and Annette C. Moll

Introduction to adult tumours of the eye and orbit

Eyelid tumours

Tumours of the eyelid are the most frequent seen in ophthalmic practice and the periocular skin is one of the commonest sites for non-melanoma skin cancers. Numerous tumour types arise from the eyelid, as it is contains many different tissues that are capable of undergoing benign or malignant transformation. The eyelid skin is extremely thin (less than 1 mm), but contains all of the normal skin elements, as well as the adnexal elements, such as fine hairs, and rudimentary sebaceous and sweat glands. Beneath the skin is the orbicularis oculi muscle, under which lies the tarsal plate that provides support for the meibomian glands. The bulbar surface of the tarsal plate is lined with conjunctiva that is tightly adherent to the substantia propria [1].

Eyelid tumours are thought to account for 5% of all non-melanoma skin cancers [2], and, whilst prevalence data is limited, about 60 000 malignant eyelid tumours are diagnosed annually in the US [3].

Symptoms and signs

As the face is the most examined area of the body, patients will often present early having noticed a lump in the eyelid region, although some such tumours may be neglected, particularly in the elderly. Periocular tumours are usually slow growing, with local invasion and disruption of normal anatomical structures a feature of malignancy. This disruption is particularly evident at the lid margin, where the complex and close arrangement of structures is disrupted even by very small tumours. In contrast, benign lesions may distort, but do not destroy, normal structures. Although patients will only very rarely present with pain, this important symptom might suggest bony invasion as a result of late presentation, or perineural invasion by malignant tumours, particularly squamous cell carcinoma (SCC).

Conjunctival invasion or pagetoid spread is a particular feature of sebaceous carcinoma and can commonly present with symptoms of a red or sore eye suggestive of blepharitis; as such, the clinician should consider conjunctival biopsy in all patients having persistent unilateral ocular surface 'inflammation'. Areas of diffuse induration are a feature of eyelid tumours and scirrhous cutaneous lesions can commonly cause eyelid retraction and cicatricial ectropion.

Clinical history, examination, and imaging

The central objective in the evaluation of any eyelid lesion is to differentiate between benign and malignant lesions. The most important feature of the history is that of progressive growth: benign lesions and the more common malignant tumours, such as basal cell carcinoma (BCC), are usually indolent in nature and typically grow slowly. In contrast, more aggressive tumours such as melanoma can proliferate more rapidly. Other features suggestive of malignancy include irritation, crusting, bleeding with minor trauma, and failure of any such lesion to heal within 3–4 weeks.

A full examination should include the skin, conjunctiva, eyelid margin, and eyelashes. Although examination can be done with magnifiers or other aides, it is usually performed using slit-lamp biomicroscopy by specialists. Other systems, such as dermatoscopy, also have a particular role for pigmented lesions. The nature of the lesion should be examined, including the tarsal conjunctiva and ocular surface, and a full orbital examination performed where orbital invasion is suspected. Rolled 'pearly' borders and indurated or hardened areas are suggestive of malignancy (e.g., BCC), as is a loss of mobility over the underlying structures.

The lymphatic drainage from the medial end of the eyelids is to the submandibular nodes and that of the lateral ends to the preauricular nodes; all assessments of eyelid tumours should include examination of these lymph node groups. This is particularly important where more aggressive malignancies (such as melanoma, SCC, or sebaceous carcinoma) are suspected. Examination of periocular cutaneous sensation is particularly important with SCC that has a predilection for perineural invasion that can cause periocular pain or numbness.

Imaging is imperative where larger tumours appear to be involving the orbit: CT has advantages over MRI, providing thinner cuts with less motion artefact, better details of bone involvement, and greater inherent contrast within the orbital structures. In some cases, however, MRI may be of value in imaging anterior orbital structures, as it offers better differentiation of soft tissues.

Malignant tumours

BCC is the most common malignant eyelid tumour in Caucasians [4]. The age-adjusted incidence of BCC in men and women is equal and about 14 per 100 000 per year [5]. BCCs typically appear on sun-exposed areas, being most common on the lower eyelid (50%), followed by the medial canthal area (36%), and are rarer on the upper lid (8%) or lateral canthus (6%); this periocular distribution is explained by the shielding of upper lid skin by the eyebrow and plication of the upper eyelid skin when the eye is open [6]. In addition to sun exposure, patients on long-term immunosuppression are at a higher risk of developing skin cancers (with BCC being the

most common). Xeroderma pigmentosum is an autosomal recessive condition, with an inability to repair cellular damage due to UV exposure, and affected patients develop pigmented lesions early in life followed by the appearance of BCCs. Gorlin's, or basal cell naevus, syndrome is an autosomal dominant condition characterized by the development of numerous BCCs, especially on the sun-exposed areas such as face and hands [6].

Several different histological subtypes of BCC are described, which underlie differences in clinical presentation, and include nodular, ulcerative, cystic, morphoeic, and pigmented BCCs. The most common BCC (60%) is nodular, that presents as a raised nodule with well demarcated, pearly, and telangiectatic borders; with growth, the centre may become ulcerated and umbilicated. Morphoeic BCCs are the second most common lesion and can look innocuous, with borders that are difficult to identify and a surface that may be sore or crusted. BCCs can often present as pigmented lesions and hence should enter the differential diagnosis for a periocular pigmented lesion. Occasionally BCCs can present as a cystic lesions containing mucinous material and, without biopsy, these can be difficult to distinguish from other benign periocular cysts.

BCCs very rarely metastasize and their morbidity arises from local invasion into adjacent tissues, with neglected tumours invading the orbit or mid-face.

Sebaceous carcinoma is a malignancy arising from the meibomian glands, sebaceous glands aligned vertically in the tarsus and being unconnected with hairs [1]. The incidence of this tumour varies widely with geographical location, forming ~9% of periocular malignancies in the West but 30–40% in Southern and Eastern Asia, and described as 'more common than BCCs' in some reports [8]. Unlike sebaceous adenomas, sebaceous carcinoma is only rarely related to Muir-Torre syndrome [9]. This tumour usually presents in older patients, most commonly in their seventies, and three-quarters occur in women. It can masquerade as other conditions, such as recurrent chalazion, chronic unilateral conjunctivitis or blepharitis. The correct histological diagnosis can also be difficult to determine, with up to a half of biopsies being misinterpreted as SCC. Metastasis is estimated at 8% and can develop up to five years after initial treatment of the eyelid lesion [10].

Sebaceous carcinoma has a propensity for intraepithelial, pagetoid spread which is believed to increase the risk of invasion and metastasis. All cases of sebaceous carcinoma require mapping biopsies of the bulbar and tarsal conjunctiva to exclude pagetoid spread and, if epithelial involvement is identified, surgical clearance might require orbital exenteration [11].

SCCs are related to chronic sun exposure, commonly presenting as ulcerated or hyperkeratotic lesions. A well-described feature is the development of a cutaneous horn or scaly surface. The differential diagnosis for these lesions includes fast-growing keratoacanthomas or actinic keratoses. SCC arising primarily on the exposed bulbar conjunctiva is commonly associated with immunosuppression due to HIV infection. Periocular skin SCC behaves similarly to SCC occurring elsewhere, with low metastatic potential and low mortality. Local spread to regional lymph nodes may occur in a quarter of patients and a lymph node assessment is essential if SCC is suspected. Death is usually a result of perineural invasion, often through the frontal nerve, into the CNS (8%) or due to distant metastasis (6%) [12].

Cutaneous melanoma of the eyelid is rare, comprising 1% of all melanomas [13]. Risk factors for melanoma are similar to those of other malignant tumours—including sun exposure, a family history, fair skin, and older age. Periocular radiotherapy is also a risk factor, particularly for patients previously treated for retinoblastoma who may have required high dose external beam radiotherapy. Lentigo maligna melanoma is the most common head and neck form of cutaneous melanoma, and is also the most common form of eyelid melanoma. Whilst these lesions often occur *de novo*, up to a half of melanomas arise from a predisposing lesion such as lentigo maligna (i.e., in situ melanoma), congenital naevus, and rarely, a naevus of Ota [14]. Eyelid melanomas can also arise from an extension of a conjunctival melanoma crossing the muco-cutaneous junction and invading the adjacent skin. Some evidence suggests that eyelid melanoma might have a more favourable prognosis than other melanomas of the head and neck [15].

Merkel cell tumours, which typically occur in elderly females, progress at an extraordinarily rapid rate of growth, often doubling in size within two or three weeks. They require aggressive therapy by wide surgical clearance, but still carry a relatively poor prognosis.

Principles of management

Periocular skin tumours present unique difficulties in management due to the proximity of the globe and orbital contents, and the high density of regional innervation also makes perineural spread a significant problem for some tumour types. Although only 15–20% of lid lesions are malignant [4], an accurate clinical diagnosis and determination of malignant potential can be challenging. If there is any doubt, an incisional biopsy should be taken as an initial step, unless a sentinel lymph node biopsy is planned, when this should be performed prior to tumour manipulation.

Whilst there is significant variation in the practical management of these tumours, the universal principle is to eradicate the tumour with maximal preservation of function and physical appearance. After correct diagnosis, it is essential to ensure adequate clearance of the tumour. To this end, excision is usually performed with histological clearance either as a two-stage procedure (using frozen section and fast paraffin techniques) or by using Mohs' micrographic surgery. Mohs' surgery, both by limiting loss of normal tissues and by increasing the proportion of tumour-free survivors, is becoming increasingly popular as the treatment of choice for periocular BCCs—particularly in high-risk areas, such as the inner canthus, or with morphoeic tumours. Additional difficulties are presented with sebaceous carcinoma, where multiple conjunctival mapping biopsies are required to evaluate the presence or extent of any pagetoid tumour spread.

Defects are generally reconstructed using combinations of direct closure techniques, flaps or free grafts, although small defects can often be left to heal spontaneously over a few weeks. Orbital invasion is a devastating complication of eyelid tumours and the patient will generally require orbital exenteration. Whilst exenteration improves survival outcomes for most tumours, there is evidence that it has no impact on survival in melanoma [14].

The proximity of the eye globe makes 5-fluorouracil and imiquimod less tolerated as treatment options for periocular BCCs, as they can cause significant ocular surface inflammation. Other modalities, such as radiotherapy and cryotherapy, also have a role in more conservative treatment.

Orbital tumours

Malignant tumours of the orbit arise as primary disease, by secondary direct spread from the paranasal sinuses or lacrimal sac, or as metastases from remote primary tumours. The US National

Cancer Institute reports an annual incidence of periocular malignancy—albeit of the eye *and* orbit—to be up to 1 in 100 000, with 13% arising under the age of 20 years and a fifth arising in each of the decades from 55 and 65 years of age [16]. Orbital malignancy equally affects men and women, with an estimated cumulative lifetime risk of 0.08% [16].

Symptoms and signs

The presentation of orbital tumours varies with the predominant location of the mass: for example, anterior masses generally causing a visible and palpable localized eyelid swelling and displacement of the globe. In contrast, tumours in the posterior half of the orbit cause progressive proptosis and are often associated with ill-defined periocular swelling. This swelling, often worse on wakening, is both due to displacement of normal orbital fat and due to vascular congestion at the orbital apex. True binocular diplopia is a common feature of orbital malignancy and can arise from restriction of globe movements by sheer tumour bulk, or by malignant infiltration of the three nerves supplying the extraocular muscles. Ptosis is usually due to eyelid swelling, but more rarely arises from tumour invasion of the upper branch of the oculomotor nerve within the orbit. Optic neuropathy—with reduced visual acuity, reduced colour perception, or visual field impairment—is rare with orbital malignancy, but can arise from compression of the optic nerve. Malignancies of the lacrimal drainage system and the maxilla, that may secondarily invade the orbit, are often associated with a watering eye and, more rarely, with ipsilateral epistaxis.

Orbital malignancies are typically painless unless associated with bone erosion, the exception being lacrimal gland carcinoma—commonly accompanied by chronic ache that is thought to arise from perineural infiltration [17]. Cancers arising in the paranasal sinuses will commonly cause pain that may be referred to the head or the teeth. Periocular sensory loss, whilst a good guide to the location of an orbital lesion, is most commonly due to non-malignant processes [18].

Clinical history, examination, and imaging

A thorough medical history should be taken, as the progression of symptoms provides a good idea of the likely diagnosis. This is well illustrated with orbital apex syndromes, where loss of multiple functions (e.g., ocular motility, periocular sensation, and visual impairment) occur within hours, the apex lesion is probably inflammatory or vascular. In contrast, a step-wise progression over months is probably a malignant infiltration sequentially impairing the many nerves at the apex. Clearly a history of systemic malignancy is important, even if many years before, and the enquiry should also address epiphora, nasal symptoms or surgery, and dental or pharyngeal pain.

Ophthalmic examination should include an assessment of orbital signs and also a check for intraocular malignancy that can spread outside the globe. Likewise, it is imperative to check the nasal space and search for regional lymphadenopathy. Where the length of history is uncertain, reference to past photographs can be valuable; a sole photograph is best for such comparison, as downward displacement of the resting lower lid—with an apparent 'rising sun' corneal configuration—is one of the earliest signs of proptosis.

Whilst most tumours in the orbit will cause proptosis or eyelid fullness, certain malignant tumours—such as metastatic breast or lung carcinoma—can generate a desmoplastic scirrhous response with secondary enophthalmos, or eyelid 'hangup' on downgaze due to fibrosis of the levator muscle [19]. Facial weakness is another—easily-overlooked—periocular clinical sign that is of particular importance with periocular malignancy, as it can occur as a result of malignant infiltration of the preauricular lymph nodes.

Thin-slice CT is the primary investigation of choice for orbital disease as it demonstrates in fine detail the micro-invasion of cortical bone, tumour calcification, and defines the macroscopic extent of disease. MRI can be a useful secondary imaging for soft-tissue detail within the skull-base, details of meningeal involvement, and the assessment of water content within abnormal tissues. Ultrasonography has a minor role in orbital disease: it is invaluable for imaging intraocular disease and measuring tumour dimensions, at assessing the scleral thickness for tumour invasion, and—using the Doppler colour imaging mode—for the assessment of blood-flow within the orbital tissues.

Immunohistochemical studies of the biopsy tissue may help identify the site of the primary tumour. Likewise, specific blood tests may be indicated for various systemic malignancies.

Orbital tumours in adults

Lymphoma is the main orbital malignancy, and will be discussed separately below. Lacrimal gland carcinoma is very rare, but sadly involves younger people and carries a poor prognosis [2]. Adenoid cystic carcinoma is the commonest epithelial malignancy, but others include primary adenocarcinoma, mucoepidermoid carcinoma, or SCC. Malignant mixed tumours arise within previously benign pleomorphic adenomas and may present with recent change in a longstanding known orbital asymmetry. These tumours often cause some inflammatory signs with pain and, because of this risk, any 'dacryoadenitis' lasting for more than three months should be considered for biopsy. Incisional biopsy is performed through the upper lid skin crease and, if proven to be carcinoma, consideration given to the macroscopic removal of tumour with later high-dose (about 5500 cGy) fractionated radiotherapy to both the orbit, superior orbital fissure, and anterior cavernous sinus—treatment for the latter two sites reducing recurrence due to perineural spread of the tumour. Implantation brachytherapy has been used to treat the tumour 'bed' but it does not treat the critical areas of the superior orbital fissure or cavernous sinus. Orbital exenteration and deliberate breach of the lateral wall should probably be avoided, as it does not improve survival [20], and tends to seed tumour into the cranial diploe with relentless recurrence of disease. Exenteration might, however, have a role in treating these patients where combined with preoperative intra-arterial chemoreductive therapy—the current suggested regimen is cisplatin and doxorubicin—and later radiotherapy [21].

The orbit is not infrequently invaded by malignancy arising in the globe such as choroidal melanoma, eyelids (commonly BCC), or the paranasal sinuses. Invasive malignancies of sinus origin include squamous carcinomas, lymphomas, adenocarcinomas, esthesioneuroblastomas, and melanomas. Orbital invasion by these tumours tends to be manifest as restriction of ocular motility and displacement of the globe. Such cases usually require partial or complete orbital exenteration during resection of the primary site of disease, together with adjunctive radiotherapy in many cases.

Metastases, whilst common within the choroid, comprise a minority of orbital malignant diseases. Some of the commonest
Fig. 57.1 Primary acquired melanosis presented as diffuse superficial conjunctival pigmentation with corneal involvement.

Fig. 57.2 Large conjunctival melanoma on the temporal bulbar conjunctiva.

primary sites are the breast, cutaneous melanoma, prostate, and lung. Whilst most metastases will generally present with rapidly progressive and painful proptosis that looks rather 'inflammatory', scirrhous carcinoma of breast or lung can cause enophthalmos. With secondary melanomas, the growth may be so rapid that the lesion looks like a well-defined benign lesion such as cavernous haemangioma—but the history should clinch the correct diagnosis. Clearly, these patients must be managed in a multidisciplinary team.

Conjunctival melanoma

Conjunctival melanoma is a rare tumour of middle-aged and older persons, mostly in Caucasians and more commonly in males, with an annual incidence of 0.2–0.8 per million in Caucasian populations [22, 23]. Conjunctival melanoma is unilateral and arises most commonly in the perilimbal, interpalpebral, and bulbar conjunctiva, plica semilunaris, and caruncle (Figures 57.1 and 57.2). Conjunctival melanoma arising from primary acquired melanosis or conjunctival melanocytic intraepithelial neoplasia (PAM/C-MIN) with atypia is most common (70%). However, it may be multifocal and may appear simultaneously or sequentially in different parts of the conjunctiva. Conjunctival melanoma that arises from a naevus or *de novo* appears clinically as a solitary pigmented or non-pigmented vascularized nodule, commonly in the limbal area.

The definitive diagnosis of conjunctival melanoma is made by histopathological examination. Most cases can be diagnosed with confidence by light microscopic features. Four types of atypical melanocytes have been described in conjunctival melanoma: small polyhedral, spindle, balloon, and round epithelioid cells with eosinophilic cytoplasm. The invasive melanoma is often accompanied by conjunctival melanoma in situ in the adjacent epithelium. Any breeching of the basement membrane by atypical melanocytes in conjunctival melanoma in situ should be considered as microinvasive melanoma. Atypical melanocytes within the epithelium of subepithelial cysts can give rise to multiple foci of invasive melanoma [24].

If in doubt, immunohistochemical stains such as HMB-45 or Melan-A can be used to highlight the neoplastic melanocytes, and Ki-67 proliferation index may help to differentiate melanoma from naevi. BRAF mutations are found in about half of conjunctival melanomas while BRAF mutations are seldom encountered in uveal melanomas [25].

There are several histopathological features that predict adverse prognosis in conjunctival melanoma, including depth of invasion measured with an ocular micrometer from the basement membrane to the deepest point of invasion. Other histological prognostic factors are pagetoid spread, mixed cell tumours versus spindle cell tumours, lymphatic invasion, high mitotic count, and high cell proliferation indices. The presence of previous primary acquired melanosis (PAM) does not appear to be a prognostic indicator [26].

The primary treatment of conjunctival melanoma is surgical excision of the entire tumour when possible. When limbal and scleral involvement are suspected, scleroconjunctivectomy can be considered [27]. Most surgeons will add adjuvant treatment, including cryotherapy, ruthenium brachytherapy, and proton beam radiotherapy. Topical mitomycin C and topical interferon alpha-2b have also been used successfully as adjuvant treatment, especially in melanoma originating from PAM with atypia [28]. Exenteration of the orbit is reserved only as a palliative treatment for advanced stages.

Local recurrence of conjunctival melanoma, when treated by surgical excision alone, has been reported in 56–65% of patients, and nearly half develop more than one recurrence. Risk factors for local recurrences are melanoma originating in PAM with atypia, located other than at the limbus and bulbar conjunctiva, involvement of surgical margins, and failure to perform adjuvant therapy. Local recurrences are managed as primary melanoma.

Conjunctival melanoma may spread locally via 'in-transit' metastases to local lymphatics within the conjunctiva. Spread of conjunctival melanoma to the nasolacrimal duct, the nasal cavity and paranasal sinuses, has been attributed to shedding of exfoliated melanoma cells in the tear film. Rarely, conjunctival melanoma invades the eyeball or the orbit. Conjunctival melanoma can metastasize to any organ in the body; in half of them regional lymph nodes (preauricular and submandibular) will be involved before systemic spread. The rate of conjunctival melanoma-related mortality ranges, according to several studies, between 12–19% in five years and 23–30% in ten years. The most important clinical risk factors are tumour location and tumour thickness. Tumour locations with high risk of metastases are non-bulbar conjunctival melanomas, i.e., those in the palpebral conjunctiva, fornices, plica,

and caruncle. The critical thickness is 0.8 mm, above which there is continuous worsening in prognosis with increasing tumour thickness [29, 30].

Uveal melanoma

Uveal melanoma is distinctly different from cutaneous melanoma. The incidence is stable rather than increasing. Most data argue against ultraviolet radiation as a significant cause of uveal melanoma, and the molecular mechanisms operating in uveal melanoma are not akin to those identified in cutaneous melanoma. Significant advances have been made in treatment of the primary disease with a number of eye-preserving options now available. Mortality has, however, remained unchanged with nearly half of patients ultimately developing metastatic disease. To date, no treatment for disseminated uveal melanoma has proven efficacious in a randomized clinical trial.

Aetiology

Uveal melanoma arises from the melanocytes of the uveal tract, i.e. from the neural crest-derived, non-epithelial, pigment-containing cells of the choroid, ciliary body, and iris stroma. Melanoma of the eye and ocular adnexa, so-called ocular melanoma, comprises about 5% of all melanoma and more than 85% of ocular melanoma is of uveal origin [31]. Only 5% of uveal melanoma arises from the iris; the vast majority of uveal melanoma originates from the choroid posterior to the equator. It is widely assumed that most lesions arise from uveal naevi that have transformed into melanoma. Because the prevalence of uveal naevi is 4–6.5% in the general population, the risk for a naevus without atypical features to develop into a melanoma is markedly low. Individuals with syndromes like oculo(dermal) melanocytosis are at an increased risk to develop uveal melanoma [32], but the majority occur in patients with no apparent predisposing condition. Most cases present in a sporadic setting and familial uveal melanoma is distinctly uncommon, although an increasing number of families with germline BAP-1 mutations and familial uveal melanoma are now being reported [33, 34]. There are a few case reports of families with the familial atypical multiple mole melanoma syndrome (FAMMM) with some family members featuring an associated uveal melanoma [31]. A possible link, albeit probably not strong, between uveal and cutaneous melanoma is supported by data indicating a 75% increased risk for patients with uveal melanoma to develop skin melanoma [35]. Also, case-control studies suggesting that atypical (dysplastic) naevi are more prevalent in patients with uveal melanoma. Nevertheless, the incidence of uveal melanoma is largely stable in many countries and does not parallel the rapid increase seen in cutaneous melanoma [36, 37]. Although there are a few reports of uveal melanoma being more frequent in welders, occupational exposure to ultraviolet radiation has not been associated with uveal melanoma [38]. A few case-control studies on sunlight, and hence ultraviolet radiation, exposure have generated conflicting results [39]. Moreover, unlike cutaneous or conjunctival melanoma, mutations in the BRAF and NRAS genes are uncommon events in uveal melanoma [27, 40, 41]. Uveal melanoma is much more prevalent in Caucasians than in African Americans, perhaps by as much as a 20-fold difference in the age-adjusted incidence rate. In largely Caucasian populations, the annual incidence ranges approximately from 5–10 cases per million [31, 38]. Notably, uveal melanoma is a disease of the middle-aged and elderly and is rare in children and young adolescents [42]. There are some data suggesting that predisposing conditions like oculo(dermal) melanocytosis are more frequent in young patients with uveal melanoma [42]. Bilateral disease is an extremely uncomment event, without a clear association to any known genetic predisposition [43].

Signs and symptoms

Approximately 70–87% of patients with uveal melanoma experience symptoms at the time of referral to an ocular oncologist [44]. A substantial proportion of patients are diagnosed with uveal melanoma following a routine ophthalmological examination or fundus photography for an unrelated condition. When symptoms are present, these are generally non-specific and include metamorphopsia (distorted vision in which straight lines appear wavy), blurred vision, a visual field defect and, rarely, ocular pain. Generally, a uveal melanoma grows slowly and symptoms accumulate over a considerable period of time. Nevertheless, an associated serous retinal detachment may sometimes progress rapidly and cause a sudden onset of symptoms. An iris melanoma is located on the anterior iris surface and as such recognizable to the patient or relatives as a brown spot on iris. Diffuse iris melanoma with raised intraocular pressure may sometimes cause iris atrophy and a change in iris colour (typically to a greenish hue) that sets the eye apart from the fellow eye; i.e., iris heterochromia.

Diagnosis

Although initial misdiagnosis of a uveal melanoma by an ophthalmologist reportedly occurs in one of four patients [45], an ophthalmologist specialized in ocular oncology can make the diagnosis by clinical appearance assisted by non-invasive techniques in 95% of cases. The most frequently used non-invasive technique is ultrasonography. This is available in frequencies ranging from 10–50 MHz featuring different resolution and depth penetration. Other techniques like fluorescein angiography, optical coherence tomography, indocyaninine green angiography, and MRI may provide additional information. The typical choroidal melanoma is a 10–15 mm dome-shaped or mushroom-shaped (this signifies a rupture of Bruch's membrane) solid tumour with a colour ranging from greyish to dark brown, but rarely black (Figure 57.3). Many lesions are clinically non-pigmented (whitish) and larger lesions may feature an associated serous retinal detachment. The diffuse choroidal melanoma is a rare subtype (1–3% of choroidal melanoma), typically a flat pigmented lesion extending to more than one quadrant of the ocular fundus. This subtype is notoriously difficult to diagnose for the inexperienced physician, but carries a significant mortality and a tendency to grow extrasclerally. Other rare subtypes include the annular (ring-like) ciliary body melanoma and the retroinvasive melanoma which may invade the optic nerve. Sometimes, lesions like peripheral choroidal haemorrhagic retinopathy, choroidal metastases, uveal effusion syndrome, hamartoma of the retinal pigment epithelium, posterior scleritis, choroidal haemangioma and subretinal haemorrhage may simulate a posterior uveal melanoma.

Uveal melanoma is almost unique among cancers in that the clinical diagnosis often is not verified by cytological or histopathological examination. For tumours large enough to warrant
Fig. 57.3 Enucleated eye with large (15 × 15 × 12 mm) choroidal melanoma. The tumour is mushroom-shaped and the retina is partially detached.

enucleation, the clinical diagnosis is highly accurate at 99.7% [46]. For smaller uveal melanoma or clinically atypical tumours, any diagnostic uncertainty can be resolved by any of a range of biopsy techniques. Although symptoms like progressive visual field loss and blurred vision are not specific for uveal melanoma, they usually lead to a prompt ophthalmological examination. Nevertheless, significant delays in referral to a dedicated ocular oncology centre remain a concern [45]. Small indeterminate melanocytic lesions are sometimes observed for growth before treatment is initiated, in particular when treatment is likely to be associated with significant visual loss. Features of indeterminate melanocytic lesions of the choroid, such as thickness greater than 2 mm, subretinal fluid, orange pigment within the tumour, clinical symptoms, location within 3 mm of the optic disc, acoustic hollowness by ultrasonography, and absence of a halo are associated with increased risk for growth [27] (Figure 57.4). The risk
Fig. 57.4 Juxtapapillary choroidal naevus with significant characteristics predicting growth.

for growth is more than 50% at five-years follow-up when two or more risk factors are present [27]. Although not always appropriate, growth of indeterminate melanocytic lesion of the choroid is then often used as a surrogate measure for malignant transformation. Because uveal melanoma is distinctly rare, but choroidal naevi occur in approximately 4–6.5% of a Caucasian population, the features predictive for growth help to identify the very few lesions at significant risk for malignant transformation. It is widely assumed that uveal melanoma may metastasize when quite small and given the impact early treatment may have on visual function, this has generated significant controversy of when to treat small melanocytic lesions [47].

Management of primary disease

In the US, there has been a dramatic shift towards the use of eye-preserving options for uveal melanoma. During 1973–74, nearly all patients with uveal melanoma had surgery, almost always enucleation of the eye, but in 2004–2006 only ~25% of patients with uveal melanoma had surgery as the first option. Radiotherapy, largely episcleral brachytherapy, has become much more common as the first line of treatment in up to 62.5% of patients [48]. This change has been stimulated by evidence that survival is not compromised for patients with medium-sized tumours who have primary radiotherapy rather than enucleation and by the introduction of standardized plaques for episcleral brachytherapy as a result of the Collaborative Ocular Melanoma Study (COMS) [49]. Another of the COMS trials showed that pre-enucleation radiotherapy for uveal melanoma provided no survival benefit [50]. Treatment is not standardized among centres and patients with similarly-sized tumours may receive different treatment. Enucleation is a reasonable option for many large tumours and tumours adjacent to the optic disc where poor visual outcome is expected. Episcleral brachytherapy using a radioactive plaque (Figure 57.5) may be performed under local anaesthesia or general anaesthesia. A range of radionucleotides with different characteristics are available (Table 57.1), but ruthenium-106 is more widely used in Europe and iodine-125 in North America. Tissue penetration is greater for iodine and centres with access to both radionuclides often use ruthenium for small and medium-sized tumours and iodine for larger tumours. Typically, tumour regression is slow and may take 6–9 months to become apparent. Local recurrence may occur after many years and periodic monitoring of the irradiated tumour, typically for life, is therefore important. A number of side effects occur following

Fig. 57.5 Ruthenium-106 applicator for episcleral brachytherapy. The outer surface includes a silver lining to minimize radiation to normal tissue. The inner surface contains the radioactive source and is molded to fit the curvature of the eye. Two eyelets allow for suturing the radioactive plaque to the scleral surface.

Table 57.1 Radionuclides in current use for episcleral brachytherapy of uveal melanoma

Element	Nuclide	Energy (MeV)	Half-life
Iodine	I-125	2.40	59 days
Ruthenium	Ru-106	6.55	374 days
Iridium	Ir-192	1.46	74 days

Box 57.1 Complications following episcleral brachytherapy

Ocular perforation
Uveal effusion
Diplopia
Choroidal atrophy
Radiation-induced cataract
Radiation optic neuropathy
Radiation retinopathy
Neovascular glaucoma
Scleral melting

plaque radiotherapy (Figure 57.6) and radiation retinopathy is seen in up to half of eyes treated (Box 57.1), but this complication is also frequent after any form of teletherapy.

A juxtapapillary choroidal melanoma is difficult to treat with episcleral brachytherapy and may alternatively be managed with proton beam radiotherapy. Some centres use this technique as the first option for most uveal melanoma [51]. To avoid significant side effects from radiation, large tumours may be fragmented and removed by a vitreous cutter (endoresection) after radiotherapy [52]. Primary endoresection not preceded by radiotherapy is highly controversial, although a histopathological study of eyes enucleated after primary endoresection suggest that tumour seeding is a rare event [53, 54]. Some tumours may also be managed by trans-scleral local resection (exoresection), often combined with plaque radiotherapy, which reduces the rate of local tumour recurrence [55]. Alternative radiation techniques to treat uveal melanoma include fractionated stereotactic radiotherapy and single-fraction radiosurgery. Primary transpupillary thermotherapy is now rarely used as the sole therapy
Fig. 57.6 Choroidal melanoma 6.5 years after iodine brachytherapy. There is significant tumour regression, but also side effects, such as choroidal atrophy and radiation optic neuropathy.

because of an increased risk for local recurrence and is now typically combined with brachytherapy [56]. A circumscribed iris melanoma has traditionally either been observed (because of the excellent prognosis for this subgroup) or surgically excised. A diffuse iris melanoma is often monitored until any raised intraocular pressure cannot be controlled by topical or oral medication, or diode laser cyclo-photocoagulation. For this subtype, surgical intervention typically entails enucleation of the eye. Recently, proton beam irradiation for both subtypes of iris melanoma has been advocated as an alternative to enucleation or local excision. Irradiation may subsequently be combined with a shunt to control intraocular pressure [57].

Follow-up

Patients with uveal melanoma treated with an eye-preserving option are usually monitored for life at regular intervals. This includes comparison with standardized pre-treatment fundus photographs and often ultrasonography. Patients with extrascleral growth found at or after enucleation may need periodic imaging of the orbit to exclude an orbital recurrence. Fine stippled episcleral pigment deposits, which may appear a few years after brachytherapy for uveal melanoma, may be pigment lodged in macrophages rather than extrascleral tumour growth [58]. Although an effective treatment for metastatic uveal melanoma is still lacking, an increasing number of ocular oncologists advise periodic extraocular monitoring for metastatic disease. Uveal melanoma preferentially disseminates to the liver and systemic monitoring is usually confined to this site.

Management of systemic disease

Metastases are detected at the time of diagnosis in less than 1% of patients with uveal melanoma. Nevertheless, prolonged follow-up reveals disseminated disease in more than half of patients at 35 years after diagnosis. Although most patients with metastatic disease are identified during the first five years after diagnosis, 20–33% of deaths even after 15 to 35 years following the diagnosis of uveal melanoma are attributable to melanoma [59]. The liver is involved in 90% of metastatic uveal melanoma and frequently the presenting site of widespread disease. Traditionally, patients with systemic uveal melanoma often received treatment similar to patients with systemic cutaneous melanoma, but therapy is now more specific. Current strategies to manage systemic uveal melanoma include partial hepatectomy, radiofrequency ablation, selective internal radiotherapy, immunotherapy (e.g., ipilimumab), targeted therapies, liver chemoembolization, intrahepatic arterial chemotherapy, systemic chemotherapy, or combinations of the above [60].

Quality of life

The diagnosis of ocular cancer generates significant anxiety and depression in patients. Symptoms like fatigue and insomnia are prevalent [61]. There are some data to suggest that anxiety diminishes faster after diagnosis in patients with enucleation than in patients managed by brachytherapy [62]. Visual function is initially better in patients with brachytherapy, but this difference is reduced over time as radiation-related side effects emerge [62]. Differences between individuals may be significant and there is scope for personalized treatment [63] in particular, as a consistent survival benefit for radical treatment such as enucleation has not been shown.

Histopathology

For many decades, the cell type of uveal melanoma has been known to correlate with prognosis. Traditionally, tumour cells are characterized as spindle or epithelioid depending on their morphology and prognosis is poorer for tumours with epithelioid cells. Tumours may be described as containing a mixed cell type when both spindle cells and epthelioid cells are present, but there is no consensus as to how many epithelioid tumour cells make a melanoma an epitheloid melanoma. Uveal melanoma may occasionally be largely necrotic, but the original cell type is usually discernible. When a choroidal melanoma grows it will eventually rupture Bruch's membrane causing a mushroom or collar-stud appearance. The retina is typically eroded rather than frankly invaded by a choroidal melanoma. Likewise, the sclera is often only minimally invaded by a choroidal melanoma, but tumour cells may gain access to one or more of the routes taken by nerves and vessels which traverse the sclera and then reach the surface of the eye. By histopathological examination, the tumour cells of medium-sized and larger tumours invade trans-scleral emissary canals in more than half of cases and extrascleral growth is evident in 8% of cases [46]. Similarly, intravascular tumour growth is found in nearly 40% of eyes following enucleation for uveal melanoma. In most cases this occurs within the tumour proper or away from the tumour, but within the eye [64]. All intraocular vascular channels are presumed to be part of the blood vasculature as lymphatics have not been detected within the eye. This is consistent with tumour seeding from uveal melanoma believed to be almost exclusively haematogenous. A number of histopathologic parameters have been found to correlate with prognosis including nucleolar size, the number of cycling tumour cells, tumour cell mitotic count, extravascular matrix patterns (particularly the presence of closed connective tissue loops), microvascular density, and tumour-infiltrating macrophages [65–70]. Eyes with irradiated tumours may be secondarily enucleated for local recurrence or ocular complications or both. Typically, these irradiated tumours feature secondary changes like obliterated blood vessels and tumour cells with intracytoplasmatic vacuolization [71]. Although the number of cycling tumour cells is much reduced after radiotherapy there may be still be proliferating tumour cells present in eyes enucleated for ocular complications but with clinically- regressed tumours [72, 73]. Intriguingly, data suggest that in 40% of eyes enucleated for presumed failed brachytherapy, the clinically increased tumour size cannot be histopathologically confirmed [71].

Prognosis

Although significant progress has been made in the management of the primary uveal melanoma, prognosis for life has largely remained unchanged [74]. Notably, the mortality rate is higher than for patients with cutaneous melanoma and nearly half of patients with uveal melanoma will die with metastatic disease [31]. Most of these will die during the first five years after diagnosis [75], but some patients develop systemic disease several decades after diagnosis [76]. It is widely assumed that tumours spread when quite small, usually several years before diagnosis, and that metastases then remain unnoticed in the liver for many years [47, 77]. When metastatic disease becomes clinically evident, the median survival is 6–12 months, but 22% of patients survive more than four years after diagnosis of metastases [59, 78]. Most patients have hepatic metastases as the first site of presentation of disseminated uveal melanoma [78]. Large tumours, anteriorly- located tumours (except iris melanoma which have an excellent prognosis), tumours with specific extracellular matrix patterns and tumours containing epithelioid cells, cells with large nucleoli or a large proportion of cycling tumour cells carry a worse prognosis [66, 67, 77]. Moreover, tumours with chromosomal aberrations like monosomy 3 and gain of chromosome 8q are associated with poor survival [79, 80]. These latter findings have prompted a surge in using prognostic tumour biopsies to make tissue or cells available for molecular testing. Fluorescence in-situ hybridization FISH has been used extensively to study chromosomal abnormalities, but the technique lacks standardization and results have not always been consistent [81]. Increasingly sophisticated methods, like multiplex ligation probe dependent amplification, now more reliably predicts survival [82, 83]. Nevertheless, tumour significant heterogeneity for chromosomal aberrations across the tumour necessitates multifocal tumour sampling [84, 85]. Gene expression profiling has also been able to identify a subgroup of uveal melanoma associated with a very high mortality rate [86]. This method has recently evolved into a commercially available platform for molecular prognostic testing in patients with uveal melanoma validated by a large set of patents [87, 88]. To date, there is no independent study comparing the prognostic accuracy of gene expression profiling with that of DNA-based techniques. It could be argued that there is no use in genetic testing for uveal melanomas if there is no successful treatment for metastatic disease. Speaking against this line of thought is the increasing pressure from patients to know whether they have a 'good' or 'bad' uveal melanoma. Further, the frequency of screening can be adjusted according to whether the patient is at high or low risk of developing disseminated tumour. Those patients at high risk can be screened more intensively (possibly with techniques of greater resolution, e.g., MRI) with the aim of detecting the metastases earlier and allowing possibly for surgical removal. Finally, those patients at high risk of metastatic uveal melanoma will be those to consider for clinical trial enrolment, including those trials in adjuvant therapy [89].

Lymphoproliferative tumours

Conjunctival lymphomas

Conjunctival lymphoid tumours may be subdivided into reactive lymphoid hyperplasia, atypical lymphoid hyperplasia, and the more common conjunctival lymphoma. These tumours belong to

the group of ocular adnexal lymphomas that may affect also the orbit and eyelids.

Conjunctival lymphomas usually occur in adults and can present as an isolated primary lesion of the conjunctiva; however, in up to one-third of patients it is a manifestation of systemic lymphoma that can be present simultaneously with the conjunctival disease or during follow-up. Lymphomas may involve additional ocular sites, mainly the orbit. Most patients are symptomatic, presenting with a conjunctival mass or irritation and, less commonly, ptosis, epiphora, proptosis, and diplopia. Lymphomas of the conjunctiva appear as an elevated pink mass, commonly termed a 'salmon patch' (Figure 57.7). These lesions are commonly located at the bulbar conjunctiva and fornix, usually hidden by the eyelids. Biopsy is needed to establish the histopathological diagnosis, i.e., to differentiate lymphomas from reactive lymphoid hyperplasia and to subtype the lymphoma [90]. The vast majority of the conjunctival lymphomas are low-grade non-Hodgkin B-cell lymphoma, usually extranodal marginal zone B-cell lymphoma. Other subtypes are diffuse large B-cell lymphoma, follicular lymphoma, mantle cell lymphoma, plasmacytoma, and lymphoplasmacytic lymphoma [90].

In all cases of conjunctival lymphoma, systemic evaluation should be performed to determine the extent (or stage) of the disease. Conjunctival lymphomas are treated using surgical excision, cryotherapy, low-dose external beam radiation, and brachytherapy. Recently, intravenous or intralesional rituximab has been used [91]. Since many low-grade conjunctival lymphomas are indolent or progress very slowly, observation and periodic follow-up has been advocated. The mortality rate of conjunctival lymphoma is usually low; however, this is dependent on the lymphoma subtype and the stage of the disease at presentation.

Lymphoma of the retina

Vitreoretinal lymphoma

Vitreoretinal lymphoma (VRL) is a lymphoma of high-grade malignancy, usually of B-cell type, which is often associated with cerebral disease. CNS lymphoma (CNSL) may occur prior to, concurrently, or subsequent to the ocular disease.

Clinical features

VRL most often affects elderly patients (i.e., over the age of 60 years) and the incidence is dramatically increasing. Infrequently, however, they are seen in younger, possibly immunocompromised,

Fig. 57.7 Diffuse conjunctival lymphoma presented as elevated pink mass occupying most of the bulbar conjunctiva and lower fornix.

individuals (Table 57.2). VRL are bilateral in about 60–90% of patients but are often asymmetrical at presentation. The eye is involved in about 20% of primary CNSL, but the brain ultimately becomes involved in about 80% of VRL arising initially in the eye.

Usually VRL can be distinguished from uveitis clinically, although there are overlaps, which may be pronounced in eyes with a large component of reactive inflammation. Lymphomatous deposits initially accumulate around the retinal blood vessels and can be visible ophthalmoscopically as perivascular sheathing, mimicking vasculitis. Multiple, tiny, cream-coloured deposits can develop, resembling peripheral drusen or a white-dot syndrome. These may result in punched-out, atrophic retinal pigment epithelium (RPE) lesions. The lymphomatous infiltrations become more extensive, eventually involving the full thickness of the retina, which, on ophthalmoscopy, becomes opaque. The tumour cells seem to permeate the RPE, accumulating as clumps in the subretinal space on Bruch's membrane. The overlying RPE atrophies, leaving a fine pigment dusting over the amelanotic tumour surface. Fluorescein angiography (FA) shows a variety of features, such as staining of subretinal deposits, RPE window defects, diffuse RPE mottling or stippling, and rarely, vascular leakage and macular oedema [92]. The so-called leopard skin appearance on FA is considered to be pathognomic for VRL.

Histology, immunohistology, and genetics of vitreoretinal lymphoma

In most centres, diagnostic pars plana vitrectomies are performed to establish the diagnosis of VRL. The laboratory techniques applied to achieve diagnosis consist of cytology, immunohistochemistry, flow cytometry, polymerase chain reaction (PCR) for clonality analysis, and cytokine profiling.

Histologically, VRL can be subtyped in most cases as a diffuse large B-cell lymphoma (DLBCL) [90]. VRL is characterized by a subretinal or perivascular retinal infiltration of pleomorphic medium-to-large sized cells with minimal basophilic cytoplasm, indented or folded nuclei, and prominent, often multiple, nucleoli. Atypical mitotic figures can be seen.

Immunohistochemically, VRL are characterized by the following expression profile: positivity for B-cell antigens (CD79a, CD20, PAX-5), as well as for BCL-2, MUM1/IRF4, OCT2, BOB.1, BCL-6+/-, CD10-/+, Pu.1-/+. They are usually monotypical for IgM on immunohistochemistry [93]. Staining with Ki-67 shows that the tumour cell growth fraction is very high (i.e., about 80–90%). Clonality assessment can also be performed on DNA extracted from VRL using PCR directed against the immunoglobulin heavy and light chains in B-cell lymphomas, and against the T-cell receptor in the case of rare T-cell lymphomas.

Treatment of vitreoretinal lymphoma

The treatment of VRL remains controversial and varies considerably between centres, including external beam radiotherapy, intravitreal therapies (with or without CNS radiotherapy), and autologous bone marrow transplantation with chemotherapy. Low-dose external beam radiotherapy induces clearance of the vitreous opacities and regression of the subretinal tumour deposits, leaving behind areas of atrophy. In time, there can be radiation-induced complications such as retinopathy and cataract. Intraocular methotrexate is effective [94]. Rituximab has recently been shown to induce regression of VRL, whether given intravitreally or systemically, although recurrence is common [91]. Intraocular rituximab seems to be

Table 57.2 Summary of the clinical, morphological, immunophenotypical, and genotypic features of the various types of intraocular lymphoma

Lymphoma	Clinical features	Most common subtype	Morphology	Immunoprofile of neoplastic cells	Genotype	Putative cell of origin
Vitreoretinal	60–70 years 'Floaters' Painless decrease in VA Subretinal infiltrates Often bilateral RPE changes on FA CNS involvement (70–80% of patients)	DLBCL	Medium large cells with minimal cytoplasm and prominent nuclei. Often admixed macrophages	CD79a+ CD20+ PAX5+ BCL2+ MUM1/IRF4+ BCL6+/− CD10−/+ OCT2+ BOB1+ Pu1− High Ki−67 rate: >80%	Very high somatic IgH mutation load Few ongoing somatic mutations Chromosomal translocations in 50%: t(14;18)(q31;q21)	Two different types: (a) Early post–germinal centre B cell = DLBCL of ABC type (b) Germinal centre cell = DLBCL of GCB type
Choroidal	50–60 years Blurring of vision Metamorphopsia Clear vitreous Diffuse thickening of choroid Usually unilateral Extraocular extension No CNS involvement	*Primary:* EMZL	Small centrocyte–like cells with varying plasmacellular differentiation Few admixed reactive T–cells Necrosis rare	CD79a+ CD20+ BCL2+ CD43+/− IgM+ CD5− CD23− CyclinD1− CD10− Low Ki−67 rate: 5−15%	Moderate somatic IgH mutation load Few ongoing somatic mutations Chromosomal abnormalities: t(11;18)(q21;q21)	Post–germinal centre (memory) B cell
Choroidal	Previous history of systemic NHL Decrease in VA Possibly bilateral	*Secondary:* Dependent on systemic NHL	Dependent on systemic NHL	Dependent on systemic NHL	Dependent on systemic NHL	Dependent on systemic NHL

Abbreviations: VA, Visual acuity; FA, fluorescein angiography; IOP, intraocular pressure; CNS, central nervous system; DLBCL, diffuse large B-cell lymphoma; EMZL, extranodal marginal zone B-cell lymphoma; NHL, Non Hodgkin lymphoma; CD, cluster of differentiation; ABC, activated B-cell type; GCB, germinal centre B-cell type; t(N1;N2), chromosomal translocation between chromosome N1 and N2. #, represents features of only one case.

well-tolerated by the eye and the risks of this treatment are the same as any invasive procedure (i.e., endophthalmitis, haemorrhage, and cataract).

Prognosis

As mentioned above, approximately 80% of patients with primary VRL subsequently develop lymphoma of the brain, spinal cord, or meninges. Whether this is the result of metastatic spread or multifocal tumour development is not known at present. Whether ocular treatment influences the prognosis for survival is also not clear. There is some evidence that early systemic treatment for VRL delays the onset of CNS disease, prolonging survival [90, 95]. The onset of cerebral disease in VRL portends a poor prognosis.

Uveal lymphoma

Lymphoid proliferations of the uvea can be divided into two main groups: primary uveal tumours and secondary intraocular manifestations of systemic lymphoma. Primary uveal lymphoma is rare and can be further divided according to location: primary choroidal lymphoma, primary ciliary body lymphoma, and primary iridal lymphoma, with the first being the most common.

Primary choroidal lymphoma

Primary choroidal lymphoma was first described in 1920, and occurs as a unilateral tumour in the absence of systemic disease at diagnosis. Due to the usual low-grade nature of these tumours, they were previously erroneously termed reactive lymphoid hyperplasia or uveal pseudotumours. Subsequent investigations including clonality analysis using PCR have provided evidence that the majority of these tumours are low-grade B-cell lymphomas. Most primary choroidal lymphomas can be sub-typed as extranodal marginal zone B-cell lymphomas (EMZL), with clinical, morphological, immunophenotypical, and genetic features similar to EMZL in other locations [reviewed in 96].

Secondary choroidal lymphomas

Intraocular lymphoma secondary to disseminated, systemic NHL is usually confined to the choroid [97]. Rarely, systemic lymphoma can present with anterior segment disease such as pseudohypopyon or iris infiltration.

The most common systemic lymphoma subtype involving the choroid is DLBCL. This is followed by multiple myeloma, extramedullary plasmacytoma, lymphoplasmacytic lymphoma/immunocytoma, marginal zone B-cell lymphoma of either the gastric mucosa or lung, and B-cell chronic lymphocytic leukaemia.

The treatment of patients with secondary intraocular lymphoma is dependent on the underlying systemic NHL and the extent of its dissemination. Similarly, the prognosis of the patients is associated with this and the response to therapy.

Metastatic tumours to the eye

Haematogenous dissemination of tumour cells from primary carcinomas in other parts of the body can form secondary tumours most frequently in the choroid (Table 57.3). Less frequent tumours can develop in the iris and ciliary body. Increased incidence of these primary carcinomas and prolonged survival had led to an increased incidence of metastatic tumours to the eye. The metastatic lesions involve both eyes in 25% of the cases and often multiple lesions can

Table 57.3 Primary sites of choroidal metastases

Males (n= 137)	Females (n = 287)
Lung 40%	Breast 70%
Unknown (30%)	Lung (10%)
Gastrointestinal (10%)	Unknown (10%)
Kidney (5%)	Others (<5%)
Prostate (5%)	Gastrointestinal (<5%)

be observed. The frequent primary sites are breast cancer in females and lung cancer in males [98].

Clinical signs

The clinical signs and symptoms depend on the location of the tumour. Tumours located in the iris are often without signs or symptoms and appear as a small gray or gelatinous lump. Patients with posteriorly-located choroidal lesions often complain of vision loss, blurring, or visual disturbances. Indirect ophthalmoscopy will show an irregular and ill-defined, commonly pale yellow, slightly elevated lesion with exudative retinal detachment. Ultrasonography will usually show a relative flat lesion, sometimes lobulated with high internal reflectivity on the A-scan. In difficult cases, fine-needle aspirate biopsy can be of help when the diagnosis cannot be made with non-invasive techniques. In those cases with suspected choroidal metastases and with an unknown primary tumour, a CT-scan of the thorax and abdomen is indicated to rule out the most common primary tumours.

Treatment and prognosis

Survival of the patient strongly depends on the primary tumour. Since the primary tumours are widely disseminated the prognosis of these patients are poor, particularly with primary lung carcinoma and gastrointestinal carcinomas. The primary goal for the treatment is to preserve vision and palliate pain. Most patients will be treated locally with external beam irradiation, while others are treated with systemic chemotherapy or hormone therapy [99, 100].

Thyroid cancers

Thyroid cancers account for less than 1% of all malignancies but are the most frequent cancers of the endocrine organs. The commonest type of thyroid cancer is papillary carcinoma, accounting for 60% of cases, followed by follicular carcinoma (15% of cases). Papillary thyroid cancer may be induced by exposure to radiation. Thyroid cancer typically presents as an asymptomatic thyroid nodule, usually diagnosed by fine needle aspiration biopsy. Treatment is typically by total or near total thyroidectomy, followed by the administration of radio-iodine to destroy any remaining thyroid tissue (followed by long-term thyroid replacement therapy).

Medullary thyroid carcinoma (MTC) arises from parafollicular C cells and comprises 5–10% of all thyroid cancers. Hereditary autosomal dominant forms are associated with germline point mutations in the *RET* proto-oncogene and occur as part of multiple endocrine neoplasia (MEN) type 2A or 2B, or as isolated familial medullary carcinoma. MTCs typically present with a solitary thyroid nodule, accompanied in 50% of cases by cervical lymphadenopathy, and can be associated with unusual hormonal effects, including secretory diarrhoea. The diagnosis is often made by fine needle aspiration biopsy and elevated serum calcitonin. Treatment is by total thyroidectomy, followed by monitoring of serum calcitonin levels (and long-term thyroid replacement therapy). Testing for the presence of *RET* mutations (see Chapter 13.10) allows family testing, with prophylactic thyroidectomy recommended for affected individuals. Rare thyroid tumours include: anaplastic carcinomas, which present as a rapidly enlarging and fixed thyroid mass, sometimes with local pain and are typically rapidly fatal; sarcomas; and primary lymphomas which usually also present as a rapidly enlarging thyroid mass in a patient with Hashimoto's thyroiditis. Squamous cell carcinomas may also present as an enlarging thyroid mass. Much information on the evidence base for the optimum diagnosis and management of thyroid cancers can be found in published guidelines [1–4].

Primary thyroid follicular epithelial tumours

See Table 58.1.

Aetiology

Excessive stimulation of the thyroid by thyroid-stimulating hormone (TSH) accounts for the higher proportion of follicular carcinomas compared with papillary carcinomas in iodine-deficient areas. The thyroid-stimulating antibodies of Graves' disease do not increase the risk of developing thyroid cancer, but incidental thyroid tumours that arise in this disorder may behave more aggressively because of activation of TSH receptors. Low-dose external beam radiation (10–1500 cGy) to the head and neck increases the risk of papillary thyroid cancer 10 to 30 years after exposure. Higher thyroid

Table 58.1 Classification of thyroid malignancies

Primary thyroid follicular epithelial tumours	Differentiated (papillary, follicular)
	Poorly differentiated (insular, other)
	Undifferentiated (anaplastic)
C-cell epithelial tumours	
Primary non-epithelial tumours	Lymphoid origin (lymphoma, plasmacytoma)
	Mesenchymal cell origin (sarcoma)
	Other (teratoma)
Secondary nonthyroidal tumours	Metastases
	Extension of tumour from adjacent structures

radiation doses, including those arising from radio-iodine given for treatment of hyperthyroidism, are not associated with an increased risk of malignancy because thyroid cells are destroyed rather than transformed. However, death from thyroid cancer, which is an unusual outcome, may be slightly increased by radio-iodine treatment, suggesting an effect of radiation on tumour dedifferentiation. In Belarus, the incidence of papillary carcinomas in children and young adults has increased 60-fold after the disastrous release of radio-iodine and other radionuclides from the Chernobyl nuclear reactor. The increase has been greatest in those aged less than four years at the time of exposure and is due to the potent mutagenic effects of radio-iodine on the growing thyroid gland.

Familial forms of papillary and follicular carcinomas exist but are unusual (less than 5% of cases). There are also associations with familial adenomatosis polyposis, including the Gardner syndrome variant (OMIM [Online Medelian Inheritance in Man] 175100), Cowden's disease (multiple hamartoma syndrome, OMIM 158350), Peutz-Jeghers syndrome (OMIM 175200), the Carney complex (OMIM 160980), and ataxia-telangiectasia (OMIM 208900). Papillary carcinomas do not arise from hyperplastic nodules or adenomas. In about one-third of these tumours one of several distinct rearrangements of the *RET* proto-oncogene, a member of the receptor tyrosine kinase family, occurs. The resulting chimeric oncogenes are termed *RET/PTC* (for papillary thyroid carcinoma). *RET/PTC3* is particularly linked to radiation. Around 40% of papillary carcinomas have mutations in the *BRAF* gene which encodes a serine-threonine kinase, and these tumours tend to be more aggressive and present more often with extrathyroidal invasion. Less than 10% of papillary carcinomas have mutations in the *NTRK1* oncogene.

Activation of the *RAS* oncogene occurs in around 20% of follicular and papillary thyroid cancers. Combinations of *RET, BRAF,* and *RAS* mutations do not occur in the same tumour, implying activation of the MAPK cascade as a critical step in carcinogenesis. Follicular carcinomas probably arise, at least in some cases, from follicular adenomas. Rarely, follicular carcinomas are associated with activating mutations of the genes encoding the TSH receptor or G α-protein, similar to those found in toxic adenoma. Anaplastic carcinoma may arise in a papillary or follicular carcinoma and is associated with mutations of several genes including *CTNNB1* and the p53 tumour suppressor gene.

Epidemiology

Papillary microcarcinomas are tumours less than 1 cm in diameter that occur in up to 36% of autopsy specimens and up to 24% of surgical thyroidectomies. Clearly, most of these do not become malignant. Excluding tumours that are found coincidentally, the annual incidence of thyroid follicular epithelial cancer is around 4 per 100 000. In iodine-sufficient countries, more than 80% of these are papillary carcinoma, about 10% are follicular carcinoma, and 5–10% are anaplastic carcinoma. Women are two to four times more likely to develop thyroid cancer than men, and the peak incidence is between 30 and 50 years of age.

Clinical features

Most patients present with an asymptomatic thyroid nodule; this may be noticed by themselves or their relatives, or sometimes the nodule is detected during physical examination for another complaint. The difficulty in making a diagnosis arises because thyroid nodules are frequent, and only about 5% of palpable thyroid nodules are malignant. Diffuse or multinodular thyroid enlargement occurs in around 10% of the population and is four times more common in women than in men. Solitary thyroid nodules occur in up to 5% of the population and are usually hyperplastic or colloid nodules; 5–20% of them are neoplastic, but this figure includes follicular adenomas as well as malignant tumours.

It can be seen that determining which thyroid nodules are malignant poses a dilemma that has been exacerbated by the widespread use of ultrasound examination of the neck. Up to 60% of adult thyroids have nodules detectable by high-resolution ultrasound scanning. Another problem is determining which nodules warrant investigation in a multinodular goitre. It seems reasonable to perform fine needle aspiration biopsy of so-called dominant nodules, as well as those nodules in which there are any suspicious ultrasonographic features (microcalcification, hypoechogenicity, and nodular hypervascularity) and any nodules that have demonstrated recent change in size.

There are usually no symptoms or signs to indicate that a solitary thyroid nodule is malignant because most tumours progress slowly and present before disease is advanced. Age and sex are important considerations, since a malignancy is more likely in a solitary nodule when the patient is a child or an adolescent, is over 60 years old, or is a man between the ages of 20 and 60 years. Previous exposure to radiation and a family history of thyroid cancer should also arouse suspicion. A carcinoma is more likely if the nodule has grown recently or is hard, irregular, or fixed on palpation. Clinical assessment should include careful examination of the cervical, submental, and supraclavicular lymph nodes. Late-presenting features include hoarseness, dysphagia, or dyspnoea which may indicate local invasion, but these symptoms can occasionally occur with an enlarging benign goitre. Rarely, the diagnosis only becomes apparent when metastatic disease is detected in bone or lung. The relatively indolent presentation of papillary and follicular thyroid carcinoma contrasts with that of anaplastic carcinoma in which a rapidly enlarging and fixed thyroid mass occurs, sometimes with local pain. Extension to the oesophagus, trachea, and/or recurrent laryngeal nerves is frequent, and the overlying skin may also be infiltrated.

Pathology

There are several variants of papillary thyroid carcinoma united by their characteristic cytological features (Figure 58.1). The nuclei are large, clear ('Orphan Annie', after the eyes of the cartoon character), and have longitudinal grooves and invaginations of cytoplasm (Figure 58.1A). Two-thirds of tumours are unencapsulated and display papillary and follicular structures; the remainder are the encapsulated, follicular, tall cell, sclerosing, and clear cell variants.

The encapsulated variant has a better-than-average prognosis and the tall cell variant a worse prognosis. Half of papillary carcinomas contain degenerate calcified papillae, termed psammoma bodies. The tumour is multicentric in up to 80% of cases if the resected thyroid is examined carefully.

Metastasis is via the lymphatics, and local lymph nodes are infiltrated in 40–50% of cases (more in young patients). Distant metastases are found in less than 5% of patients at presentation, with the lung being the most common site. Follicular carcinoma is characterized by follicular differentiation with a solid growth pattern and without the nuclear features of papillary carcinoma. The tumour is encapsulated, but there is invasion of the capsule and vessels (Figure 58.1B). This invasion is the crucial feature which distinguishes follicular carcinoma from follicular adenoma, self-evidently a distinction only possible by histological examination. Minimally and widely invasive subtypes are recognized, the
Fig. 58.1 Histopathological features of thyroid follicular epithelial carcinoma. (A) Papillary carcinoma with a central papilla, which has many overlapping and pleomorphic nuclei. Nuclear pallor and grooves are seen. (B) Anaplastic thyroid carcinoma is seen with poorly defined, pleomorphic cells. No overt papillary or follicular features are present. (C) Follicular carcinoma, showing microfollicles, is seen within the bone (calcified tissue at top).

latter having a worse prognosis. When 75% or more of the tumour cells exhibit oxyphilic staining due to mitochondrial accumulation, it is called a Hürthle (or oncocytic) cell carcinoma, which probably also has a worse prognosis. Lymph node metastases with oncocytic tumours are unusual, as is multicentricity in the thyroid. Metastasis occurs via the bloodstream, typically to bone and lungs.

When follicular differentiation is poor or absent, the tumour is classified as an insular carcinoma with a poor prognosis. In anaplastic carcinoma there is no capsule, the cells are atypical, including spindle, multinuclear, and squamoid forms, and mitoses are frequent (Figure 58.1C).

Diagnosis

Thyroid epithelial cancers generally fail to affect thyroid function. However, this should be evaluated in all patients presenting with a thyroid nodule; a low circulating level of TSH strongly suggests an autonomous benign nodule. Anaplastic carcinoma may occasionally cause hypothyroidism, but the most frequent cause of an elevated level of TSH with a hard, nodular thyroid is Hashimoto's thyroiditis (OMIM 140300). Some of the glands in these cases are so irregular that a malignancy may be suspected. There is no increased or decreased risk of thyroid epithelial carcinoma in Hashimoto's thyroiditis, but thyroid lymphoma almost always occurs in association with autoimmune thyroiditis. Therefore, any dominant or atypical area in a Hashimoto's goitre requires careful evaluation. Thyroid peroxidase and/or thyroglobulin antibodies occur in about a quarter of patients with thyroid follicular epithelial carcinoma, coincident with the presence of a lymphocytic infiltrate which, in turn, is associated with a slightly more favourable prognosis. Although the serum thyroglobulin concentration is extremely useful in follow-up, as discussed below, this investigation is useless in

diagnosis; levels may not be elevated with some cancers and, even when elevated, cannot be causally distinguished from those that occur in benign adenoma, multinodular goitre, Graves' disease (OMIM 275000), or destructive thyroiditis.

Neither radionuclide nor ultrasound imaging are able to diagnose malignancy accurately. Radionuclide scanning can be performed with Tc pertechnetate or radio-iodine (^{131}I or ^{123}I), with similar information being obtained from either nuclide. Most thyroid cancers fail to take up radionuclide ('cold' nodules), but the more frequent benign lesions such as colloid nodules, cysts, adenomas, and thyroiditis behave similarly. About 20% of nodules have normal or increased radionuclide uptake. Malignancy cannot be excluded with these appearances, however. The only exception is when the nodule is 'hot' and the surrounding thyroid tissue fails to take up radionuclide, indicating the presence of a toxic adenoma which is almost invariably benign. This type of nodule will cause suppression of TSH and will be suspected from routine testing of thyroid function. In summary, radionuclide scanning usually adds little to the diagnosis.

The role of ultrasonography is more controversial but it is increasingly being used in the initial evaluation. Predicting the presence of malignancy based on the echo pattern of the tumour, and more recently using colour-flow Doppler imaging, may be successful in up to 80% of cases, but this depends on the operator having considerable experience. As well as the poor specificity of ultrasonography, the technique is so sensitive that many small unsuspected nodules will be uncovered, complicating the evaluation. Ultrasonography is useful for accurate measurement of thyroid and nodule size, which can be helpful in monitoring patients, for detecting lymphadenopathy, and for guiding biopsy, although this procedure is usually performed without imaging. Fine needle aspiration biopsy is undoubtedly the current technique of choice

for investigation of a thyroid nodule. Local anaesthetic is not needed because the procedure causes little discomfort. It is usual to take two to six biopsies to increase the sample yield. Essentially three diagnoses are possible: benign (65–75% of specimens), malignant (5%), and indeterminate (20–30%), but an experienced cytopathologist is needed to obtain reliable results. Papillary carcinoma is readily diagnosed by fine needle aspiration biopsy, and medullary carcinoma and lymphoma can also be detected by the use of immunohistochemical staining, although lymphoma frequently requires core or open biopsy for confirmation.

Follicular carcinomas cannot be distinguished cytologically from follicular adenomas, and these tumours account for the bulk of needle aspiration specimens labelled indeterminate (or suspicious). Open biopsy is the only secure diagnostic method in this setting. About 15% of biopsies reported in experienced centres are considered unsuitable for diagnosis. It is relatively simple to repeat the biopsy, but a persistently equivocal biopsy should be grounds for considering surgery since malignant tumours will be found in about a half of these cases. A cyst may be aspirated during biopsy. If this fails to reaccumulate and no lesion remains palpable, a malignancy is highly unlikely, but recurrence of a cyst may indicate malignant disease and require surgery for definitive diagnosis. Overall, the sensitivity and specificity of fine needle aspiration biopsy is greater than 90%.

Molecular diagnosis

The most common molecular alterations in thyroid cancer include *BRAF* and *RAS* point mutations and *RET/PTC* and *PAX8/PPAR*γ rearrangements. These genetic alterations are found in more than 70% of all papillary and follicular thyroid cancers. The diagnostic role of *BRAF* mutations has been studied most extensively. The *BRAF V600E* mutation can also be used for tumour prognostication as this mutation may be associated with a higher rate of tumour recurrence and tumour-related mortality. The use of these and other emerging molecular markers are expected to improve accuracy of diagnosis, allowing for more individualized surgical and post-surgical management. However, we are a little time away before these investigations become routine in the majority of thyroid clinics.

Treatment

Surgical excision

A total or near total thyroidectomy should usually be performed since thyroid carcinomas are often bilateral and removal of thyroid tissue facilitates subsequent ablation by radio-iodine. Unilateral total lobectomy is indicated for microcarcinoma. In papillary carcinoma, the central lymph nodes should be dissected, as should all palpable nodes. Central lymph node removal is also indicated in follicular carcinoma with histological evidence of extrathyroidal spread.

Radio-iodine therapy

After surgery, radio-iodine can be administered to remove any remaining thyroid tissue, which then allows thyroglobulin or iodine whole body scanning to be used in follow-up to detect metastases. This treatment also destroys occult carcinoma and, by scanning after ablation, metastatic disease is revealed. Local policies vary, but in most centres an ablation dose of 1100 MBq to 3700 MBq I is given one to three months after surgery. Recent studies have shown an equivalent outcome after either 1100 or 3700 MBq, with the higher dose having more adverse effects, so the lower dose is preferable for low-moderate risk tumours [5].

A pretreatment scan is not required because virtually all patients have persistent thyroid remnants no matter how apparently complete the surgery was. Radio-iodine ablation is indicated in all patients with a tumour >4 cm diameter, or any tumour size with gross extra-thyroidal extension, or with distant metastases present, whereas it is not indicated for a tumour ≤1 cm diameter and on histological examination the diagnosis is a classical papillary or follicular variant carcinoma, or a follicular minimally invasive carcinoma with no angioinvasion or invasion of thyroid capsule [2]. Disease presentations between these descriptors require careful consideration and discussion with the patient. There are persuasive arguments that low-risk patients with papillary carcinoma may not benefit from radio-iodine ablation and clinical staging scores (see below) may help to identify such patients.

In approximately 15% of patients, a second treatment dose of iodine is necessary to achieve ablation. Iodine exposure, including iodine-containing contrast media, may prevent accumulation of iodine during treatment. High levels of stimulation by TSH are required to produce maximum uptake of iodine; this has been achieved traditionally by a period of three to four weeks without thyroxine replacement and can thus lead to the development of severe hypothyroid symptoms. The short action of liothyronine, 20 μg three times daily, as a replacement is therefore preferable in the weeks before scanning and iodine treatment, because only two weeks are needed when this is stopped to increase endogenous TSH (which should be >30 mU/L). Even this short period without thyroid hormone may be troublesome for the patient. Recombinant TSH suitable for intramuscular administration is now available and can be given without cessation of thyroid hormone replacement. This is now the preparation method of choice in patients without high-risk disease or a recurrence, or in those who cannot tolerate hypothyroidism clinically, and it offers a better quality of life during treatment.

Systemic therapy for radio-iodine resistant thyroid cancer

Until recently, doxorubicin has been considered a systemic treatment by default, albeit with limited systematic evaluation of clinical benefit. The introduction of biologics, specifically tyrosine kinase inhibitors (TKIs), has radically altered this landscape. The pathways that are most likely targeted include the *BRAF V600E* mutation, which is present in approximately 45% of papillary thyroid cancer but is less common in follicular thyroid cancer [6]. *RAS* mutations are more common in follicular thyroid cancer, with mutations in *HRAS, NRAS,* or *KRAS* detectable in approximately 40% of FTC [7]. A number of TKIs and other biologics have been tested in thyroid cancer, including cediranib, lenalidomide, cabozantinib, dabrafenib, trametinib, everolimus, lenvatinib, pazopanib, selumetinib, sunitinib, vandetinib, and vemurafenib, although sorafenib is the only FDA-approved drug available for standard therapy in differentiated thyroid cancer (see section below on MTC concerning approval of vandetanib).

Most drugs have been primarily been evaluated in phase II trials in radio-iodine-resistant differentiated (not MTC or undifferentiated) thyroid cancer. However, sorafenib was approved based on data from the DECISION study in 417 patients treated with either sorafenib or placebo [8]. The primary endpoint of improved progression-free survival (PFS) was met with sorafenib at 10.8 months vs placebo at 5.8 months. Responses were seen in 12% with sorafenib and 0.5% with placebo, and stable disease in 42%

and 33%, respectively. Toxicities, including hand-foot syndrome, fatigue, and diarrhoea, were common, as when sorafenib is used in hepatocellular carcinoma, although these were considered manageable. To date, there are results from phase II studies suggesting that second-line TKI therapy may be helpful, although there are no studies demonstrating an optimal sequence, nor any prospective data validating predictive biomarkers. The likeliest target that may prove useful is the *BRAF V-600E* mutation, in which case one of the BRAF inhibitors might be considered.

Long-term thyroid replacement therapy

The last aspect of treatment is to maintain the patient for life on levothyroxine. This is given to high-risk patients at doses sufficient to suppress levels of TSH to below 0.1 mU/L, because TSH is a growth factor for thyroid carcinoma. In almost all patients, satisfactory suppression of TSH can be achieved without inducing thyrotoxic symptoms. The effective levothyroxine dosage is 2.2–2.8 µg/kg body weight, i.e., doses average between 150µg–200µg per day. The optimum level of TSH is unknown, but higher levels of TSH (0.1–0.5 mU/L) can be accepted in low-risk patients, and some form of risk stratification within the first year after initial treatment is helpful in determining the degree of TSH suppression to be aimed for [2].

Anaplastic carcinoma

Anaplastic carcinoma is usually rapidly fatal. The tumour rarely takes up radio-iodine. Surgery has a very limited role in relieving obstructive symptoms, and external beam radiotherapy is useful for short-term palliation. The place of chemotherapy remains to be fully established, although individual patients may achieve a partial remission with treatment, usually given as some combination of paclitaxel or docetaxel, doxorubicin and cisplatin, with or without radiotherapy [4].

Follow-up

Lifelong follow-up is recommended for papillary and follicular cancer because they may recur many years after apparent cure. Serum thyroglobulin measurement and ultrasound of the neck should be performed 9–12 months after initial resection and radio-iodine ablation to provide a baseline measurement for follow-up [2]. Detectable levels of thyroglobulin after thyroid ablation indicate persistent or recurrent disease. Measuring thyroglobulin levels is especially valuable after recombinant TSH stimulation, as the rise in TSH will promote thyroglobulin production and exaggerate any increase. This is particularly useful in initial follow-up and in following high-risk patients; in those at low risk who have a negative neck ultrasound thyroglobulin may be measured routinely without TSH stimulation. If thyroglobulin is detectable, the patient should have a whole body iodine scan and any recurrent disease can then be treated with a therapeutic dose of 5500 MBq I. It is usual to perform a diagnostic total body scan after initial radio-iodine ablation. If there is residual radio-iodine uptake, SPECT-CT scanning may provide useful localization information in some cases [2].

Repeated scans thereafter have now been superseded by measurement of thyroglobulin and low-risk cases may be assessed adequately by thyroglobulin measurement alone. The only exception is in the patient with thyroglobulin antibodies that interfere with many assays for thyroglobulin. If this is the case, repeated scans are the only way to ensure that the patient remains free of disease, although some argue monitoring the thyroglobulin antibody level fall is a surrogate marker for the thyroglobulin level itself. Ultrasonography is useful to confirm the presence of loco-regional recurrence without distant metastases, and these tumour deposits are best dealt with surgically. For metastatic disease, usually in the lung, treatment with radio-iodine can be repeated every four to six months, but there is little benefit above a cumulative dose of 18 500 MBq. Bone metastases may respond to iodine or external beam radiotherapy. The best survival in metastatic thyroid cancer occurs in young patients with small metastases, indicating the overall value of early treatment for this disease.

Prognosis

At least nine scoring systems have been advocated to assess prognosis in papillary and follicular carcinoma, of which the TNM classification system is now the most popular. These systems generally take into account the age and sex of the patient, tumour characteristics (especially size, extension, and metastases), and completeness of excision.

With appropriate treatment the rate of recurrence of papillary carcinoma is about 15%, and the cause-specific death rate is approximately 5% at 20 years. In other words, 85% of these patients present with features of the group with the best prognosis, i.e., achieving a score of less than six in the system described in Table 58.2. In follicular carcinoma, the cause-specific survival rate is 80% at 20 years after treatment and 70% at 30 years. However, in the subgroup with metastases at presentation the ten-year survival is only 20%. The median survival time for anaplastic carcinoma is four to 12 months and those with distant metastases at presentation have a median survival time of only three months.

Special problems in pregnancy

A solitary nodule in a pregnant woman should be evaluated by fine needle aspiration biopsy. If the biopsy suggests malignancy and the nodule is growing significantly, surgery can be undertaken in the second or third trimester, but otherwise this is best deferred until after delivery. Women receiving radio-iodine ablation should avoid pregnancy for at least six months after all radioactive treatment has been administered.

Table 58.2 The predictive value of a scoring system in determining outcome in papillary carcinoma. The scoring system is used to divide patients into four prognostic groups. The overall score is the sum of the following: 3.1 (if ≤39 years old) or 0.08 × patient age (if ≥40 years old); 0.3 × size of tumour in centimetres; 1, if resection is incomplete; 1, if there is extrathyroidal extension; 3, if there are metastases

Score	20-year survival (%)
<6	99
6–6.99	89
7–7.99	56
≥8	24

A patient with a past history of thyroid cancer on suppressive doses of levothyroxine who becomes pregnant is likely to require an increased dose of levothyroxine during their pregnancy in order to keep the TSH level suppressed. After delivery of the baby their levothyroxine dose can be reduced to pre-pregnancy levels.

Primary thyroid lymphoma

Less than 5% of thyroid malignancies are non-Hodgkin's B-cell lymphoma (OMIM 605027). The peak incidence is between 50 and 80 years of age, and women are affected three times more frequently than men. The typical presentation is a rapidly enlarging thyroid mass in a patient with Hashimoto's thyroiditis. The clinical features may suggest anaplastic carcinoma. The diagnosis can be made by fine needle aspiration biopsy and confirmed by large needle or open biopsy. Accurate staging is then necessary to plan treatment, which may include external beam radiotherapy and anthracycline-based lymphoma chemotherapy. Intensive treatment has produced eight-year survival rates of over 90%. Recent results with rituximab, a monoclonal antibody directed against B cells, have shown some evidence of therapeutic benefit.

Medullary carcinoma of the thyroid

MTC was first described in 1959 by Hazard and colleagues as a distinct entity [9]. It can occur in a sporadic (about 75%) and a hereditary (about 25%) form. As of today, surgery is the only curative treatment. Current research is therefore concentrating on alternative treatment modalities.

Epidemiology

MTC is a rare malignancy. Reliable data regarding the incidence of MTC do not exist but it is believed that MTC accounts roughly for about 5% to 10% of all thyroid malignancies (<http://www.baets.org.uk/guidelines/>).

Hereditary medullary thyroid carcinoma

The aetiology of hereditary MTC is well known although our understanding of the pathogenesis is still incomplete. Clinically, three different forms of hereditary MTC are distinguished, namely familial MTC (FMTC), multiple endocrine neoplasia 2A (MEN 2A), and MEN 2B (Table 58.3), often also summarized as MEN 2 [10].

Molecular biology and pathology

Germline *RET* mutations in MEN 2

Germline mutations of the *RET* proto-oncogene have been shown to be associated with all three types of hereditary MTC. They can roughly be divided into extracellular and intracellular mutations. With regard to the extracellular mutations, one of five particular cysteine codons in exon 10 (C609, C611, C618, and C620) or exon 11 (C634) is affected in the majority of cases. In rare instances, mutations in exon 5 or exon 8 may be found. In contrast, intracellular mutations in exons 13–16 associated with MEN 2 always affect non-cysteine amino acids.

Association of *RET* genotype with disease features

While about 85% of MEN 2A have a codon 634 mutation, only 30% of FMTC families have a codon 634 mutation [11]. Actually, it would appear that the distribution of mutations among the cysteine codons is more even in FMTC families. Even though some mutations have only been found in patients with FMTC and not in MEN 2A patients, it is not recommended that these patients should forego phaeochromocytoma and pHPT surveillance.

The most common mutations associated with MEN 2B are located in the intracellular tyrosine kinase domain and affect non-cysteine amino acids. The most common of these mutations (>95%) is found in exon 16 (M918T) [14]; the next common, in exon 15 (A883F), probably accounts for approximately 2–3% of MEN 2B cases [15]. These two mutations have not yet been reported in patients with MEN 2A or FMTC. There does not appear to be any clinical difference between M918T cases and A883F ones. There are some rare

Table 58.3 Phenotypes in familial medullary thyroid carcinoma (FMTC), MEN 2A, and MEN 2B

Clinical Findings			FMTC		MEN 2A	MEN 2B	
Medullary thyroid carcinoma	70–100%	90–100%	100%				
Phaeochromocytoma		–		40–60%	40–60%		
Primary hyperparathyroidism	–		15–25%	–			
Ganglioneuromatosis		–		–		+	
Intraoral neuromas		–		–		>90%	
Neuromas of the lips		–		–		>60%	
'Bumpy lips'			–		–		>95%
Medullated corneal fibres	–		–		+		

MEN 2A, multiple endocrine neoplasia type 2A.

MEN 2B, multiple endocrine neoplasia type 2B.

– Phenotype is not part of the syndrome.

+ Phenotype is not part of the syndrome; the frequency, however, is not well documented.

Source: data from Brauckhoff M et al., Premonitory symptoms preceding metastatic medullary thyroid cancer in MEN 2B: An exploratory analysis, *Surgery*, Volume 144, Issue 6, pp. 1044–1050, Copyright © 2008 Elsevier; and Gimm O., Familial Endocrine Conditions, in Hubbard JG et al. (Eds.), *Endocrine Surgery: Principles and Practice*, Springer Science and Business Media, New York, USA, Copyright © 2009.

reports of patients with *RET* double-mutations and a MEN 2B-like phenotype [12, 13].

Despite great advances in the study of genetics and genotype-phenotype association in MEN 2, unanswered questions remain. For instance, the onset of carcinogenesis can differ in family members harbouring the same mutations. In addition, it is unknown why some family members develop phaeochromocytomas and/or pHPT while others do not. GFR alpha 4 has been reported to be a modifying factor [16].

Sporadic medullary thyroid carcinoma

From the clinical point of view, the term sporadic indicates the absence of any family history of MTC or MEN 2 component tumours. However, the term sporadic MTC should only be used if no MEN 2-specific germline *RET* mutation was found [12].

Most recently, mutually exclusive somatic mutations in *RET* and *RAS* have been reported recently in about 90% of sporadic MTCs, suggesting that these oncogenes are predominant drivers [17].

Medullary thyroid carcinoma

MTC derives from the parafollicular C-cells. It is therefore sometimes even named C-cell carcinoma. C cells produce calcitonin and staining with calcitonin is the best diagnostic criterion. Less well-differentiated tumours, especially metastases, may show weak or absent calcitonin staining. CEA is the second most important hormone produced by C cells. Both calcitonin and CEA are used as blood tumour markers. Beside calcitonin and CEA, MTC may synthesize various other hormonal or non-hormonal substances, for example polypeptide hormones (adrenocorticotrophin [ACTH], somatostatin, vasoactive intestinal peptide), bioactive amines and enzymes (dopamine, histaminase, serotonin), amyloid, melanin, or nerve growth factor.

MTC is typically a circumscribed, rounded tumour that occurs in the middle or upper third of the thyroid lobe, where the concentration of C cells is greatest. Macroscopically, MTC is solid, firm, and usually not encapsulated. Calcification is often present. Microscopically, partial encapsulation of the tumour may be seen, but usually there is clear microscopic evidence of infiltration into the surrounding tissue. Amyloid deposition is a typical, but not invariable, feature. Structurally, MTC is a great imitator. Hereditary MTC is often multicentric whereas sporadic MTC is usually unicentric.

C-cell hyperplasia

In hereditary MTC, C-cell carcinoma seems to occur after development of C-cell hyperplasia (increased number of C cells). According to the WHO, the most accepted definition of C-cell hyperplasia is defined as more than 50 C-cells per low-power field [18]. This morphological (neoplastic) change is rarely seen in sporadic MTC. However, exceptions are reported in either instance and C-cell hyperplasia has also been reported in healthy individuals (reactive). Thus, C-cell hyperplasia is not a reliable finding in distinguishing hereditary from sporadic MTC.

TNM classification and staging

TNM classification and staging for MTC can be found on the website of the American Cancer Society: <http://www.cancer.org/cancer/thyroidcancer/detailedguide/thyroid-cancer-staging>.

Molecular diagnosis

Apparently sporadic medullary thyroid carcinoma

Today, it is standard practice that every new patient with apparently sporadic MTC should undergo germline mutation analysis of *RET* (Figure 58.2). Following genetic counselling that should be offered to any patient with MTC, patients can be easily screened by analysing DNA extracted from peripheral blood leucocytes (Figure 58.2A).

The reasons for advocating a consequent screening procedure are diverse. After exclusion of a germline *RET* mutation, these individuals, and subsequently their family members, can be excluded from further screening procedures for MTC or accompanying disorders (e.g., phaeochromocytoma). Therefore, it may very well be justified to screen a 70-year-old female with MTC for *RET* mutation, not for her own risk but to exclude the possibility that her descendants are at risk (Figure 58.2B).

RET mutation analysis should begin with exons 11 and 10 where mutations are found most often. If no mutations are found, exons 13, 14, and 15 followed by exons 5 and 8 need to be analysed. Analysis of exons 16 and 15 seems to be indicated if MEN 2B is suspected.

A hereditary background is highly unlikely, although possible, if analysis of all exons mentioned above is negative for specific *RET* mutations. To exclude administrative errors, a confirmation of the test would be desirable but is not established in all countries.

Known MEN 2 family

Given the current state of knowledge, any patient with MEN 2-specific *RET* mutation must be assumed to be at high risk of developing MTC.

Diagnosis and staging

The female to male ratio of both sporadic and hereditary MTC is approximately 1:1. Both sporadic and hereditary MTC can present clinically with a morphological change of the thyroid, possibly palpable during physical examination but almost never causing any functional disorder of the thyroid. The majority of patients (50–80%) with sporadic MTC and also those with hereditary MTC who are not diagnosed by screening procedures (= index patients) usually have lymph node metastases at the time of diagnosis. Thus, cervical lymph node metastases may be the initial symptom of MTC. In advanced stages, symptoms may arise from effects caused by extensive production of calcitonin, especially diarrhoea.

MTC is not just one type of thyroid cancer; it is a special form with its own biological behaviour and, therefore, needs to be treated differently from other thyroid cancers. Therefore, the diagnosis of MTC should be made preoperatively if possible. Reoperation due to avoidable incorrect initial treatment is not only accompanied by a higher morbidity rate but the chance of biochemical cure is certainly lower [19].

Fine needle aspiration cytology

In the case of suspected cancer based on clinical evaluation or ultrasound, a fine needle aspiration cytology (FNAC) either of the thyroid or regional lymph nodes should be performed [20].

Calcitonin and carcinoembryonic antigen

Before *RET* was identified as the MEN 2 disease-causing gene, all at-risk patients had to be screened via calcitonin. This is best

(A)

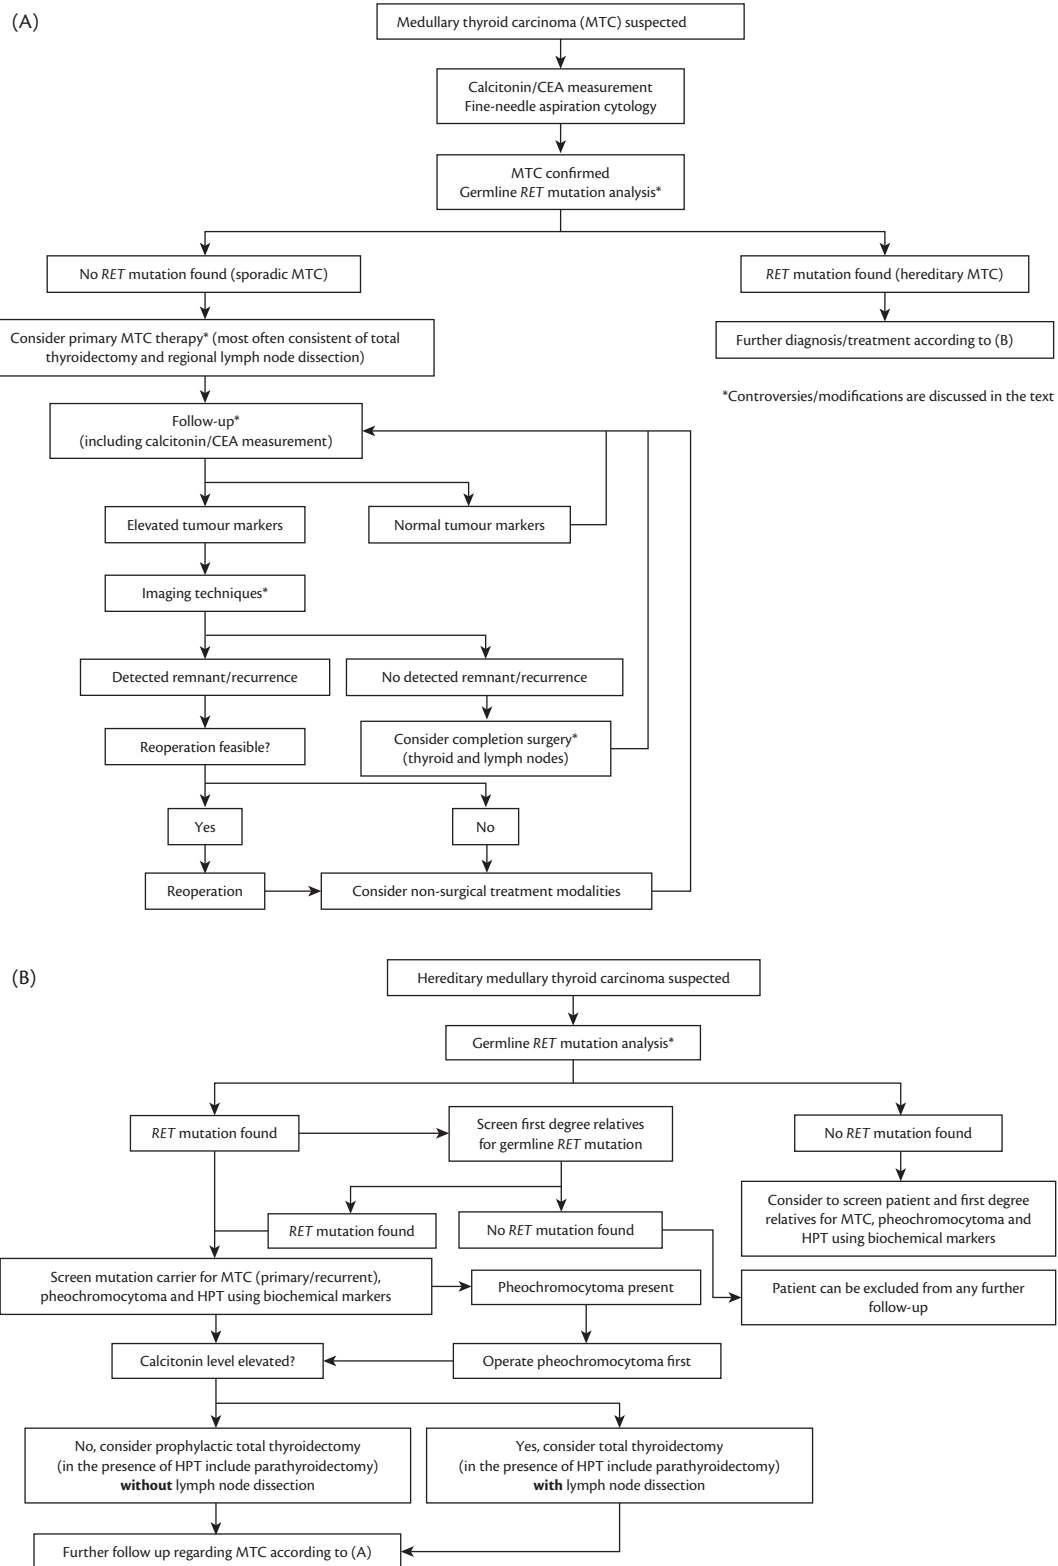
(B)


Fig. 58.2 (A) Diagnostic and therapeutic strategy in apparently sporadic MTC. (B) Diagnostic and therapeutic strategy in suspected hereditary MTC.

done by measuring basal calcitonin. Calcitonin can even be stimulated with either calcium (2 mg/kg body weight of 10% Ca^{2+} injected intravenously in 1 min) or pentagastrin (0.5 µg/kg body weight, diluted in 5–10 ml sterile saline, injected intravenously in 5–15 s) or a combination of both. Calcitonin levels are determined immediately before and 2 and 5 minutes after injection of the provocative reagent. Stimulation of calcitonin seems to be of most value in patients when the diagnosis MTC is questioned (e.g., if no thyroid nodule is found or if basal calcitonin is only slightly elevated). A variety of other conditions (e.g., pregnancy, contraceptive

pill, renal failure, liver disease, and various tumours including lung, breast cell tumours, and hepatomas) can cause elevated calcitonin levels. However, if calcitonin can be stimulated more than two or three times of the basal calcitonin levels, the diagnosis MTC is very likely. Whereas calcitonin remains an important diagnostic tool in sporadic MTC and index patients with hereditary MTC, the diagnosis of hereditary MTC in screening patients is currently made by *RET* analysis (Figure 58.2B). In these patients, the measurement of calcitonin levels may be useful in determining the extent of surgery since lymph node metastases seem to be rare if basal calcitonin levels are within the normal range (Figure 58.2B) [21].

Carcinoembryonic antigen (CEA) may also be elevated in some patients. In this regard, it should be mentioned that any patient with elevated CEA level should be considered to have MTC after exclusion of more common diseases (e.g. colon cancer). CEA is not as sensitive as calcitonin and cannot be stimulated.

Special considerations in MEN 2B patients

In contrast to other MEN 2 patients or patients with sporadic MTC, MEN 2B patients develop a specific phenotype (Table 58.3). However, when patients with MEN 2B develop their specific phenotype (around age 3–8 years) [22], most already have developed metastasized MTC. Recent research has therefore looked for symptoms that may allow earlier diagnosis. It has been found that children with MEN 2B obviously very soon (around the age of six months) develop gastrointestinal symptoms, in particular constipation. In addition, these patients often lack the ability to develop tears [22]. Whether the combination constipation and 'dry eyes' would justify genetic screening for MEN 2B has not yet been shown.

Surgical management

Surgery is the treatment of choice as primary therapy as well as for recurrent MTC.

Thyroid gland

In both sporadic and hereditary MTC, total thyroidectomy is generally accepted as the adequate therapy.

Lymph node metastases

The prognostic significance of lymph node metastases is widely accepted [23] and the majority of non-screening patients have lymph node metastases at diagnosis. Thus, there is general agreement to perform at least a cervicocentral lymphadenectomy as the minimal extent of lymph node dissection [12]. Of course, compartments involved by macroscopic lymph node metastases have to be dissected. According to the recommendation by the British Thyroid Association and the Royal College of Physicians, any patient with pT2–4 tumour or palpable neck lymph nodes should undergo bilateral lateral lymph node dissection (<http://www.baets.org.uk/guidelines/>). Some consider a lateral lymph node dissection only necessary in patients with basal calcitonin levels >400 pg/ml (ca. 177 pmol/l) [12] while others recommend a bilateral lateral lymph node dissection if basal calcitonin levels are higher than 200 pg/ml (ca. 58 pmol/l) [24].

In any case, the surgical technique of the lymph node dissection should be performed in a systematic manner, i.e., that the removal of all lymph nodes in one region should be performed en bloc with the surrounding adipose tissue while preserving vital vessels, nerves and muscles. Any form of 'berry-picking', i.e., the removal of only macroscopic enlarged lymph nodes should be restricted to reoperations once a region has been cleared systematically. This approach is justified by several studies showing that the systematic approach is superior in achieving biochemical cure (normalization of the post-operative calcitonin level) since it removes even normal lymph nodes that very well may carry metastases.

Distant metastases

Surgery is also the treatment of choice to treat distant metastases. However, biochemical cure has never been achieved and the focus should be put on palliation [25]. Thus, the indications to operate on distant metastases are either to eliminate local symptoms or to prevent complications caused by the metastases.

Special considerations in MEN 2 patients

In any patient with MEN 2, total thyroidectomy is mandatory. In non-screening patients, routine cervicocentral lymph node dissection is recommended [12]. Screening patients may or may not have pathological calcitonin levels and patients with normal basal calcitonin levels may forego central lymph node dissection as the risk of having lymph node metastases is very low [21]. This is also the reason why surgery should preferably be performed before calcitonin levels turn pathologic. Here, the patient's age and the specific mutation may be of help guiding the time when to operate [26]. According to the British Thyroid Association and Royal College of Physicians, patients with MEN 2A are recommended to undergo surgery before the age of five years while patients with MEN 2B should undergo surgery as soon as the diagnosis is made, preferably within the first year of life when MTC might already be present but lymph node metastases unlikely.

Phaeochromocytoma, which may be present in about 50% in both MEN 2A and MEN 2B, can be present at the time the diagnosis of MTC is made but often occurs metachronously. In only up to about 10% of patients, symptoms caused by a phaeochromocytoma (palpitation, nervousness, hypertension either paroxysmal or sustained) precede MTC. It is especially important to rule out the coexistence of a phaeochromocytoma that needs to be operated prior to an MTC operation because of the risk of an intraoperative hypertensive crisis. This can best be done by measuring plasma-metanephrines [27]. The sensitivity/specificity of urinary-metanephrines is almost as good. The British Thyroid Association and Royal College of Physicians recommend this biochemical workup even in the absence of a positive family history or symptoms (<http://www.baets.org.uk/guidelines/>). Virtually all patients with elevated metanephrines do have an adrenal abnormality on CT. Due the fact that phaeochromocytoma in MEN 2A and MEN 2B patients is often bilateral (synchronously or metachronously), surgery should be as restrictive as possible [28]. Surgery should be performed in an attempt to remove all adrenal medullary tissue while preserving cortical function. This technique decreases the need for long-term steroid replacement or, even worse, the occurrence of an Addisonian crisis. If performed appropriately, the risk of recurrence is low. In this regard, it needs to be emphasized that phaeochromocytomas in MEN 2A and MEN 2B are malignant in less than 5%.

Up to 20–30% patients with MEN 2A will develop primary hyperparathyroidism (pHPT). The association of parathyroid disease with MEN 2A is regarded as being genetically determined and not a response to elevated calcitonin levels. pHPT is rarely present

when MTC is diagnosed. Thus, pHPT is most often diagnosed during follow-up of patients operated on for MTC. As in sporadic cases, calcium and parathormone should be measured to diagnose pHPT. There is no need for prophylactic parathyroidectomy. Once pHPT is diagnosed or when operating on the thyroid gland, all four parathyroids should be identified and all enlarged parathyroids (rarely more than one) should be removed. In the rare event of enlargement of all four parathyroids, the least single pathological gland needs to be identified. The least pathological part should either remain in situ or should be autotransplanted into the sternomastoid muscle. Similar results could be achieved with either technique. In MEN 2B, pHPT is not more often present than in the general population.

Residual/recurrent medullary thyroid carcinoma

Even if primary therapy in a patient with sporadic MTC consists of total thyroidectomy and bilateral lymph node dissection, normal calcitonin levels can only be achieved in up to 40–50% (Figure 58.2A). There is general agreement that post-operative elevated calcitonin levels indicate residual tumour. However, despite elevated calcitonin levels, imaging techniques often fail to detect residual C cells. This situation probably reflects the limitations of imaging techniques available today since they fail to detect micrometastases. Common sites for distant metastases are lung, liver, and bone.

Localization and confirmation

Imaging studies are recommended in patients with a basal calcitonin levels of ≥150 pg/ml (= 44 pmol/L) [12]. For the detection of loco-regional and mediastinal metastases, CT is recommended. Concerning liver metastases, multidetector-CT or MRI is advised. In patients having basal calcitonin levels <150 pg/ml (~ 44 pmol/L), the indication to perform imaging studies should be made on an individual basis.

Larger metastases might very well be detectable using CT or MRI. Occult metastases, however, are rarely detectable using either technique. Due to the nature of C-cell metastasis (multiple, micronodular, involving the whole organ), laparoscopy has been successfully used to identify liver metastases [29]. Less invasive techniques used successfully include ^{99m}Tc-dimercaptosuccinic acid (DMSA), ^{131}I-MIBG, ^{111}In- or ^{99m}Tc-octreotide, and ^{18}FDG-PET (<http://www.baets.org.uk/guidelines/>) [30]. However, no single diagnostic technique is able to reliably demonstrate the full extent of disease in patients with recurrent or metastatic MTC.

If in doubt, a localized remnant/recurrent tumour should be subject to FNAC if accessible.

Reoperation

The indication for reoperation may be given: (1) if primary therapy did not consist of total thyroidectomy and either if the post-operative calcitonin level is elevated in patients with sporadic MTC or in any patients with hereditary MTC regardless of the post-operative calcitonin level; and (2) in cases of proven or suspected residual lymph node metastases. If a patient with sporadic MTC underwent less than total thyroidectomy, indication for reoperation is not necessarily given if the thyroid remnant is small and calcitonin levels after stimulation are within normal levels [31]. However, in the case of elevated calcitonin levels, completion

thyroidectomy and/or loco-regional lymph node dissection is recommended. In contrast, in hereditary MTC a completion of the thyroidectomy is always advised since every single C cell has the potential of developing MTC.

If either lymph node metastasis or recurrent disease is proven by imaging techniques/FNAC, the indication for reoperation is given in most cases.

In the presence of distant metastases, the extent of reoperation should be evaluated individually. In addition to the patient's age and general condition, the tumour dynamic should be taken into account. The latter can be assessed by looking at the doubling-time of both calcitonin and CEA (see prognosis).

Radiation

MTC is generally not very sensitive to radiation. Although there are some studies reporting a reduced risk of local recurrence after radiation, surgery should be performed if feasible. The reasons are the disadvantages of radiation:

1. Many patients experience distressing long-term side effects of cough and dryness due to the high doses needed.

2. Scarring of the neck makes assessment of future local recurrence (clinically and using imaging techniques) and reoperation difficult.

A plausible consensus is as follows:

1. If surgical treatment appears successful (defined as normal calcitonin level after stimulation), there is no need for radiation.

2. In cases of biochemical or clinical evidence of persistent/recurrent disease, reoperation would be the preferred treatment.

3. Radiation should be avoided until local disease is either symptomatic or rapidly progressing, and not amenable to reoperation.

4. In some rare instances, a combination of 'debulking' surgery and radiotherapy may be appropriate.

5. Radiation may be useful in treating symptomatic distant metastases, such as bone metastases.

Radio-iodine treatment

Because MTC does not derive from follicular cells, there is no uptake of radio-iodine and therefore no indication to treat these patients with radio-iodine.

Chemotherapy and other treatment modalities

Some experimental studies with chemotherapy are promising. Currently, one of the best results has been achieved by combining dacarbazine, fluorouracil, and doxorubicin [12].

New therapeutic approaches such as TKIs have been studied in recent years. For vandetanib, an inhibitor of vascular endothelial growth factor receptor (VEGFR), the epidermal growth factor receptor (EGFR), and the RET-tyrosine kinase, a significantly prolonged PFS has recently been shown in a phase III study [32]. However, the rate of adverse side effects (such as diarrhoea, rash, nausea, hypertension, headache) requiring intervention was quite high (26–56%). In animal studies, an improved efficacy was shown combining radioimmunotherapy and antiangiogenic therapy [33]. Concerning irinotecan, a reduced toxicity was shown when using octreotide-marked liposomes in comparison to 'free' irinotecan in in vitro studies [34]; clinical results have not yet been published.

Molecular-targeted therapy is most promising and we should expect new treatment options in the near future.

Prognosis

Most long-term studies report a five-year survival rate of 80–90% and a ten-year survival rate of 60–70%. Probably more than 50% of all patients with sporadic MTC will die of their disease.

Like most cancers, prognosis has been shown to depend on tumour stage [35]. Besides tumour stage, post-operative calcitonin level is the most powerful prognostic factor. In this regard, the term 'biochemical cure' needs to be explained. 'Biochemical cure' simply demonstrates the absence of pathological calcitonin levels after treatment. It does not necessarily mean that the patient is really cured (without tumour). Indeed, rising levels of calcitonin after apparent 'biochemical cure' have been reported although reoperation rarely had to be performed in these cases. In contrast, falling calcitonin levels have been observed without treatment. In these instances, falling calcitonin levels may indicate a dedifferentiation of the MTC with consequent decreased calcitonin expression rather than spontaneous regression. CEA levels seem to correlate inversely with calcitonin and correlate most likely better with the overall tumour mass in patients with less-differentiated MTC [36].

It has repeatedly been shown that the prognosis can be well assessed by looking at the doubling-time of both calcitonin and CEA [37, 38]. A doubling-time of less than six months correlates with a poor prognosis while one more than two years correlates with a good prognosis.

Follow-up

Following surgery, all patients need lifelong replacement of levothyroxine (L-T4). The dose of L-T4 should be adjusted according to periodic measurements of serum thyrotropin (TSH) that should be within the normal range. Patients who undergo treatment for MTC have to be followed-up lifelong in intervals usually between 6–12 months. Shorter follow-up might be justified if tumour progression is suspected. In this respect, there is generally no difference between sporadic and hereditary cases. However, it is unknown whether screening patients who underwent prophylactic thyroidectomy and histologically only showed C-cell hyperplasia need to undergo follow-up at all. In the case of follow-up, the basal calcitonin should be measured yearly. There is controversy about whether basal calcitonin or CEA levels correlate with the amount of disease (see prognosis), but agreement that elevated post-operative levels almost generally indicate persistent disease. If either basal or stimulated calcitonin level is abnormal, further investigations may be indicated to localize the residual disease. If medical management is not altered as a response to calcitonin levels in individual cases, there is no need to subject the patient to repeated tests.

Adrenal tumours

Adrenocortical tumours

The adrenal cortex comprises 90% of the normal adult adrenal gland and weighs up to 4 g. It consists of three zones: the outer zona glomerulosa (15% of the cortex), which expresses the enzyme 18-oxidase and can thus secrete aldosterone; the middle zona fasciculata (75% of the cortex); and inner zona reticularis which express the enzyme 17α-hydroxylase and can secrete cortisol, androgens, oestrogens, and weak mineralocorticoids. Tumours arising from the adrenal cortex are divided into benign and malignant; either can be functioning or non-functioning, the latter being a not uncommon incidental finding during abdominal imaging with either CT or MRI scanning. The great majority of adrenocortical tumours are benign and hormonally silent (non-functioning). Functioning tumours of the zona glomerulosa and fasciculata give rise to Conn's and Cushing's syndrome, respectively. Virilizing and feminizing tumours, probably arising from the zona reticularis, are more rare; however, tumours secreting combinations of adrenocortical steroids have also been described [39, 40].

Cushing's syndrome

Epidemiology

Cushing's syndrome is due to an adrenal adenoma in 10–30% of cases and shows a marked female preponderance of 4–5:1. Adrenal adenomas may occur at any age; bilateral adenomas are rare, but occur as part of familial adenomas [39].

Aetiology and pathogenesis

The cause of these tumours is essentially unknown, but adenomas have developed in a setting of chronic ACTH excess and micronodular adrenal hyperplasia [39, 40]. Loss of function of a tumour suppresser gene, the *MEN1* gene, and steroidogenic acute regulatory (STAR) protein mRNA are under investigation [41].

Pathology and biology

Adenomas are usually small (average diameter of 4 cm), encapsulated, and consist of mixtures of compact zona reticularis and clear zona fasciculata-type cells (see Figure 58.3). In Cushing's syndrome associated with primary adrenocortical disease, increased cortisol secretion suppresses ACTH synthesis and secretion, therefore inducing contralateral adrenal cortex atrophy [42].

Diagnosis and staging

Patients with adrenal adenomas usually present with the gradual onset of symptoms and signs of hypercortisolism. The presence of proximal myopathy, vascular fragility, and thin skin can be used to clinically differentiate them from other pseudo-Cushingoid states [43]. Benign adenomas are usually pure cortisol secretors, and hirsutism and other androgenic effects are usually absent. However, components of the syndrome due to mineralocorticoid excess (hypertension, hypokalaemia) and virilization have been described.

The mainstay of diagnosis of Cushing's syndrome is the demonstration of inappropriate and excessive secretion of cortisol [42, 43]. Measuring the 24-hour excretion of urinary free cortisol (UFC) was previously used, but is of low sensitivity. However, the 2 mg/day low-dose dexamethasone suppression test (LDDST), measuring the 9 am serum cortisol before and after the administration of dexamethasone 0.5 mg strictly six-hourly for 48 h, has a 98% sensitivity in demonstrating autonomy in cortisol secretion using a cut-off cortisol value for suppression of 50 nmol/l. All patients with adrenal adenomas fail to show suppression [43] (Figure 58.5). As a screening test, measurement of the 9 am serum cortisol after dexamethasone 1 mg at midnight has very high sensitivity but rather low specificity.

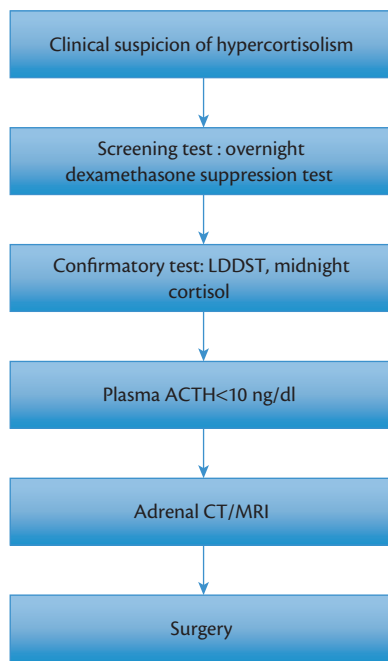
The differential diagnosis is made from the other causes of Cushing's syndrome, pituitary adenoma (Cushing's disease) and ectopic ACTH-secretion, by measurement of ACTH levels which are persistently very low or undetectable [42, 43].
Fig. 58.3 High power photomicrographs of four adrenal tumours. Each is stained with haematoxylin and eosin and magnified ×400. (A) Adrenal adenoma causing Cushing's syndrome. [1] Note uniform, large clear cells resembling those from the zona fasciculata. [2] Atrophic adrenal cortex adjacent to the adenoma. (B) Adrenal aldosteronoma with typical spironolactone bodies. (C) Adrenal carcinoma with nuclear pleomorphism (D) Adrenal phaeochromocytoma. [1] Typical pleomorphic cells with cytoplasmic basophilia and background vascularity. [2] Finely granular cytoplasm indicative of plentiful chromaffin granules (characteristic chromogranin staining).
Fig. 58.4 Typical macroscopic appearance of three adrenal tumours (A) Adrenal cortical adenoma causing Cushing's syndrome: the adrenal gland weighing 14 g (normal 4–6 g for a surgically excised gland) in the medial aspect (left) of which is a well-circumscribed adrenal cortical adenoma measuring 2 × 1.5 cm. (B) Adrenal cortical carcinoma causing Cushing's syndrome. [1] A very large cortical carcinoma (9 cm) removed at postmortem examination. The specimen is attached to the inferior vena cava, which has been opened as far as the right atrium and ventricle. [2] An adrenal cortical carcinoma weighing 240 g. The tumour is encapsulated and composed of brown tissue with extensive areas of haemorrhage in the centre of the tumour. (C) Adrenal phaeochromocytoma: a well-defined adrenal tumour composed of slightly variegated pink tissue with extensive central necrosis.


Fig. 58.5 Algorithm for suspected hypercortisolism.

By means of CT and MRI it is possible not only to localize the tumour, but to distinguish possible malignancy based on imaging characteristics (see Figure 58.6). Iodocholesterol and NP-59 radio-nuclide isotope scans are rarely used nowadays [44, 45].

Management

The treatment of choice is laparoscopic adrenalectomy with overall morbidity being very low when performed by an experienced surgeon [46]. Post-operatively, the contralateral atrophic adrenal gland may take from weeks to years to recover; it is therefore important to cover the surgical procedure with hydrocortisone 50–100 mg six-hourly for two to three days, and thereafter maintain the patient on standard steroid replacement with hydrocortisone (10 mg, 5 mg, 5 mg daily), until gradual normalization of the hypothalamo-pituitary-adrenal axis is obtained. Patients should be followed up and cortisol replacement should be increased during stress. Appropriate diagnosis and surgical treatment of adrenal adenomas is associated with a cure rate approaching 100% and a normal survival curve [47].

Conn's syndrome (aldosterone-producing adenomas)

Classification

Aldosterone-producing adenomas (APAs) are the most common form of primary hyperaldosteronism, which also includes bilateral hyperplasia of the zona glomerulosa (idiopathic hyperaldosteronism, IHA), primary adrenal hyperplasia (PAH, where the zona glomerulosa of one adrenal becomes hyperplastic and histopathologically resembles unilateral IHA, but biochemically behaves as APA), adrenal carcinoma, and two genetic familial varieties (type 1 which is called glucocorticoid-remediable aldosteronism [GRA] and type 2 variant which is not glucocorticoid sensitive).
Fig. 58.6 CT scans of (A) left-sided adrenal adenoma and (B) a massive right-sided adrenal carcinoma, both associated with the clinical and biochemical features of Cushing's syndrome.

Epidemiology

Approximately 0.5–2% of unselected hypertensive individuals have primary hyperaldosteronism due to an adrenal adenoma. IHA is much more common, but may be simply one end of the spectrum of low-renin hypertension. There is a 2:1 female to male incidence in adenomas, which seem to congregate in the age range of 30 to 50 years. By contrast, IHA is seen predominantly in men in sixth decade of life.

Aetiology and pathogenesis

Increasingly, sporadic adenomas have been associated with mutations of sodium/potassium channels leading to constitutive activation of hormonal secretion. After a discrete adenoma has been removed, the non-tumourous adrenal cortical zona glomerulosa is often found to be histologically hyperplastic, with multiple small cortical nodules and even a second adenoma [48].

In terms of familial forms, the molecular basis of GRA is known. It is a rare, autosomal dominant disorder resulting from a heritable mutation that causes the fusion of genes encoding the promoter for 11β-hydroxylase and aldosterone secretion, and is under ACTH control [48, 68]. Studies in type 2 variant of familial hyperaldosteronism show loss of heterozygosity of the MEN1 gene, but further studies are needed [68].

Pathology

The typical Conn's tumour is less than 2 cm and microscopically composed of mixture of zona glomerulosa, zona fasciculata cells, and hybrid cells with characteristics of both layers (see Figure 58.3B)

Diagnosis and staging

Patients with Conn's adenomas classically present with the triad of hypertension, hypokalaemic alkalosis, and muscle weakness. Spontaneous hypokalaemia occurs in 80%; but patients can be normokalaemic at the start, and develop hypokalaemia within three to five days of initiation of a liberal sodium intake (150 mEq/day). Hypokalaemia in a setting of a low to moderate dose of potassium-wasting diuretics can also be indicative. Symptoms induced by hypokalaemia are weakness, muscle cramping, paraesthesia, tetany, polyuria, and polydipsia due to hypokalaemia-induced nephrogenic diabetes insipidus. In IHA there may be less severe hypokalaemia or even normokalaemia.

The diagnosis of primary hyperaldosteronism (PA) is based on the demonstration of high-normal or frankly elevated levels of aldosterone with concomitantly suppressed plasma renin activity (Figure 58.7). There is no single specific and sensitive screening test. Random plasma aldosterone/renin activity can be used for screening, with high accuracy, also leading to a marked increase in a detection rate in PA [69, 70] (see Figure 58.7). Some authorities specify renin/aldosterone ratios suggestive of Conn's syndrome, but is should be recognized that these are very assay- and unit-dependent.

In the next step it is important to differentiate Conn's syndrome from hyperplasia, as the former is amenable to surgical treatment while the latter is usually treated medically. Basal levels of potassium, renin, and/or aldosterone are poor discriminators. Differentiating can be made by examining the response of serum aldosterone to 4-h ambulation between 8 am and 12 pm. As with adenomas, the tumour is ACTH-sensitive and aldosterone falls over the morning, while IHA is angiotensin-dependent and therefore aldosterone rises. However, the test has a low accuracy [48]. Adenomas also produce an excess of 18-hydroxycorticosterone, an intermediate precursor of aldosterone that facilitates the biochemical diagnosis. 18-hydroxycorticosterone levels are also elevated in glucocorticoid-sensitive hyperaldosteronism (GSA) [49].

Adrenal imaging with CT or MRI scan also plays a role in distinguishing these two entities, but even in expert hands the small size of many of these tumours, plus the presence of adrenal incidentalomas, suggest that it is only diagnostic in young patients with a nodule >1cm on one side and a normal contralateral adrenal. A more accurate technique is venous catheterization with sampling of both adrenals for aldosterone and the inferior vena cava to demonstrate a gradient, with a simultaneous cortisol sample to ensure correct placement within the adrenal veins (an aldosterone/cortisol ratio of >4:1 between the affected and unaffected site is indicative of an adenoma). This method has a near 100% sensitivity and a positive predictive value of 90%, but requires expert interventional radiology [44].

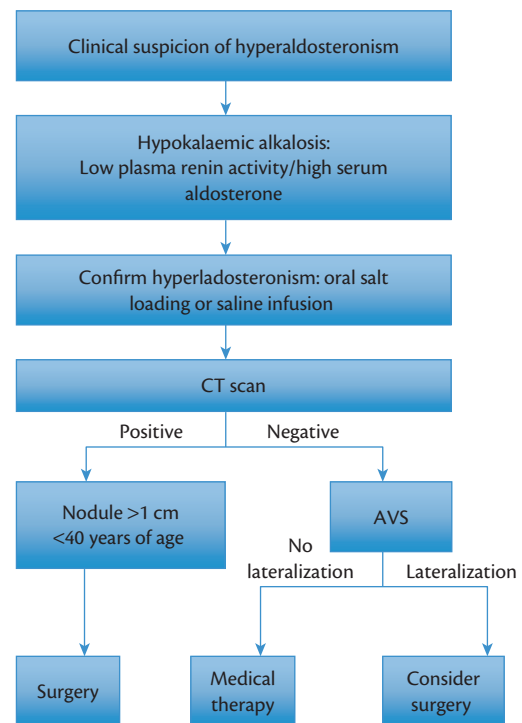
NP-59 I-iodomethyl-19-norcholesterol scintigraphy under dexamethasone suppression has also been used to distinguish adenoma from hyperplasia. Unilateral NP-59 uptake is regarded as sufficient evidence of an adenoma, while in IHA neither gland is visualized, but the test is now rarely used [45].


Fig. 58.7 Algorithm for suspected hyperaldosteronism.

Management

Having distinguished between an adenoma and IHA, a four- to six-week course of treatment with spironolactone should be given (100–400 mg daily) to assess reversibility of blood pressure, replete potassium levels, and desuppress the contralateral adrenal in patients with adenomas. Laparoscopic adrenalectomy is the treatment of choice as these tumours are relatively small [46]. One year post-operatively, 70% of patients are normotensive, falling to 50% after five years; however, normal potassium balance is permanent. Patients with GSA are treated with dexamethasone, while patients with carcinomas have an overall poor prognosis but may initially respond to mitotane.

Adrenal carcinoma

Epidemiology

Malignant neoplasms of the adrenal cortex account for 0.05–0.2% of all cancers and occur in two peaks; the first peak before the age of five and the second in the fourth to fifth decade. There is a female predominance, accounting for 65–90%, while bilateral tumours have been reported in 2–10% of the cases. These tumours account, in general, for one-third of adrenal tumours presenting with Cushing's syndrome [40, 50, 51].

Aetiology and pathogenesis

Adrenal carcinomas (AC), apart from sporadic variants whose pathogenesis remain unclear, have been described in siblings and can be associated with several syndromes. This implies a high probability that there may be an inherited component, seen in the Li–Fraumeni syndrome (germline mutations of p53 tumour suppressor gene). There is also evidence to suggest that environmental pollutants may

play a causative role in some forms of childhood AC [52]. Rarely, AC can arise from ectopic adrenocortical tissue and from patients with uncontrolled congenital adrenal hyperplasia [44, 51].

Microbiology and pathology

Adrenal carcinomas are large (90–95% larger than 6 cm), encapsulated tumours with areas of haemorrhage, necrosis, calcification, and signs of local invasion (Figure 58.3B).

Histologically, pleomorphic, lipid-deplete cells, with varying mitotic activity, nuclear atypia and hyperchromasia, aneuploidy (83% of all carcinomas), as well as invasion of the capsule (Figure 58.3C). Staging of adrenal carcinomas depends on tumour size, nodal involvement, invasion of adjacent tissue, and the presence of metastases [40, 50, 51, 53, 54] (Table 58.4).

Diagnosis and staging

Approximately 50% of adult carcinomas are non-functional, and most of these patients first present with advanced metastatic disease to lungs, liver, or bone, before primary diagnosis is established. In 50% of patients a palpable abdominal mass and abdominal or flank pain is present. Sometimes tumours are discovered as 'incidentalomas'. Unlike adrenal adenomas, which predominantly secrete cortisol, carcinomas often secrete a variety of other steroids, mainly androgens (androstenedione, dehydroepiandrosterone sulphate [DHEAS]). This is especially the case in children, where isolated Cushing's syndrome is seen only in 3%. The majority present with virilization (40%) or the combination of Cushing's syndrome and virilization (50%). Virilization can cause isosexual precocious puberty in young girls [40, 50, 51]. An elevated blood pressure is seen in >50% of childhood adrenal carcinomas, mostly associated with cortisol hypersecretion. The median age at diagnosis in children is 4.3 years, with girls predominating over boys (5.3/1) below the age of four years [52].

Cushing's syndrome presents in 30% of adults (20–30% of cases of adrenal Cushing's are due to a carcinoma), virilization in 20%, and the combination of the two in 10 to 20%. Feminization and hyperaldosteronism are relatively rare manifestations; even rarer are hypoglycaemia and polycythaemia [40].

Diagnosis

The diagnostic tools are those used for Cushing's syndrome due to an adenoma, while measurement of adrenal androgens facilitates the diagnosis. Imaging with either CT (the presence of a large unilateral adrenal mass with irregular borders) or MRI scanning is often virtually diagnostic of an adrenal carcinoma (Figure 58.6B). On imaging, such tumours exceed 6 cm, although 16% may be less than 6 cm and resemble adenomas.

Management

Untreated, the median survival in adrenocortical carcinomas is less than three months. Patients with functional adrenal carcinomas present at earlier phase, and therefore have better prognosis. More than 50% of adrenal carcinomas are metastatic at the time of diagnosis. Radical excision with en bloc resection of any local invasion or distant metastasis if possible prolongs survival [71, 72].

The mainstay of pharmacotherapy is mitotane, which acts by blocking adrenal steroid 11β-hydroxylation and altering extra-adrenal metabolism of cortisol and androgens, but also exerts a direct tumouricidal effect. At high doses, if not limited by side-effects, it controls hypercortisolism in 50–60% of patients, although objective tumour responses (>50% reduction in tumour bulk) occur in less than 20% of such patients [55]. However, the extent to which mitotane can increase the length of time between recurrences remains to be assessed [56, 73, 74]. The dose should be rapidly increased, dependent on side effects and a therapeutic range of 14–20 mg/L is optimal; this should be monitored as levels below this are less effective, while above this toxic side effects are limiting. Hydrocortisone replacement may need to be added, with high doses often being required. Mitotane increases cortisol-binding globulin (CBG) so monitoring must be with salivary cortisol or UFC.

Metyrapone and the antifungal agent ketoconazole can be used to control cortisol secretion [56]. Chemotherapy is of limited efficacy, but the combination of etoposide, platinum, and doxorubicin is marginally more effective than streptozocin. Other regimens may be attempted, but none is in widespread use. Targeted therapy with IGF1 receptor antagonism has been tried but appears to

Table 58.4 Staging of adrenocortical carcinoma

Stage	T, N, Mα	Macfarlane (1958) [53]	Lee et al. (1995) [54]
I	T1, N0, M0	Tumour <5cm, confined to the adrenal gland	T1 (<5cm), N0, M0
II	T2, N0, M0	Tumour >5cm, confined to the adrenal gland	T2 (>5cm), N0, M0
III	T1 or T2, N1, M0 T3, N0, M0	Tumour confined to the adrenal gland with involvement of local lymph nodes, or, tumour extending beyond the adrenal gland but not invading adjacent organs	T3/T4 (local invasion as shown by histological evidence of adjacent organ invasion, direct tumour extension to IVC, or tumour thrombus within the IVC or renal vein) and/or N1 (positive renal lymph nodes), M0
IV	T3 or T4, N1, M0 any T, M1	Tumour extending beyond the adrenal gland, invading adjacent organs, and involving local lymph nodes, or any tumour with metastases	T1-4, N0-1, M1 (distance metastases)

Abbreviations: T, Tumour; N, lymph node; M, Metastases; 0, negative.

Reproduced with permission; and adapted from *Surgery*, Volume 118, Issue 6, Lee JE et al., Surgical management, DNA content, and patient survival in adrenal cortical carcinoma, pp. 1090–1098, Copyright © 1995 Published by Mosby, Inc., with permission from Elsevier, <http://www.sciencedirect.com/science/journal/00396060>. Based on radiology, intraoperative evaluation, and permanent-section histopathological evaluation of the resected specimen.

be ineffective. Combining mitotane with cytotoxic chemotherapy shows no prolongation of survival, but requires further study [75].

Radiotherapy to the tumour bed can be used, in case of a high risk for local recurrence [40, 55, 56, 76].

In general, the great majority of patients show local invasion, with or without metastases, and despite aggressive surgical therapy the five-year survival is currently only 15–25% [40, 50, 55, 56]. A five-year survival rate of 46% has been described in patients with adrenal carcinoma in whom complete margin-negative tumour resection was achieved irrespective of adjuvant mitotane treatment [54], while others have advocated that immediate adjuvant long-term therapy with mitotane may also be beneficial [57, 73].

Virilizing tumours

Epidemiology

Virilizing adrenal tumours are rare, more common in childhood, but may present at any age and predominantly in women (75%). When present, they are usually carcinomas.

Microbiology and pathology

Virilizing adrenal tumours are well-encapsulated. Tumours secrete a variety of adrenal androgens proportionally with tumour size (mainly DHEAS, as well as testosterone and androstenedione), but a combined pattern with glucocorticoid and mineralocorticoid excess is seen in older patients with more malignant tumours. Small lesions are more often benign than larger ones, but the distinction is often less clear cut than for cortisol-producing adenomas and even large tumours may well be benign [58].

Diagnosis and staging

Signs and symptoms are mainly due to the excess androgen production. Young prepubertal women present with virilization and accelerated growth, while adult women experience menstrual irregularities, male-type alopecia, hoarseness of the voice, increased libido, and/or increased muscle mass. In men, symptoms may be minimal, except in childhood when they can induce isosexual precocious puberty [58].

The differential diagnosis is between congenital adrenal hyperplasia (CAH) in young girls and the polycystic ovary syndrome (PCO) in adult females.

Baseline testosterone levels >6 nmol/l are suggestive of the presence of a tumour, but there is significant overlap with values obtained from patients without tumours; however, a tumour is unlikely if androgens suppress following dexamethasone administration [59].

In women with PCO the onset of symptoms usually dates from puberty and is progressive, in contrast to women with tumours whose presentation is more acute. In CAH patients 82% have some sort of unilateral mass, while only 11% have bilateral adrenal enlargement, thus limiting the diagnostic specificity of adrenal imaging [59].

In cases of tumours, adrenal imaging with CT or MRI scanning will identify most of these tumours, which are usually greater than 2 cm; simultaneous adrenal and ovarian venous catheterization and sampling is rarely necessary.

Management

These tumours grow slowly and metastasize late. Surgical excision is the treatment of choice while the role of radiotherapy has not been clearly defined. Mitotane has also been used as adjunctive treatment, although at present there is no effective tumouricidal agent. Symptoms and signs of virilization may regress with cyproterone acetate or flutamide.

Feminizing tumours

Epidemiology

Feminizing adrenal tumours are rare, constituting less than 10% of adrenal tumours, 90% being seen in males, aged 25–45 years. Clearly, this figure may be an underestimate, as signs of hyperoestrogenism are clearly more subtle in women [60].

Microbiology and pathology

Feminizing adrenal tumours are always malignant although cases of benign tumours have been described in childhood suggesting adenoma-to-carcinoma transformation. There are no microscopic criteria to distinguish malignant from benign tumours. The majority of these tumours are large, often weighing more than 1 kg. Functionally, they produce oestrogenic steroids such as oestradiol, oestrone, and oestriol, and most of them have elevated levels of urinary oestrogens [60, 61].

Diagnosis and staging

In males, tumours present with gynaecomastia and evidence of hypogonadism. Half of patients may have a palpable abdominal mass. In females, isosexual precocious puberty may be seen in childhood, although normal menstruation is not achieved due to the unopposed oestrogen action on the uterus; elderly women can present with the acute onset of postmenopausal bleeding [60]. The elevated oestrogen levels are unresponsive to dynamic endocrine tests, ACTH-stimulation, GnRH-analogue, and dexamethasone suppression, although tumours with positive 'chorionic' and 'pituitary-gonadotrophin' tests have been described. Adrenal imaging with CT or MRI scanning will almost always identify such tumours.

Management

Surgical excision is the only available treatment; although there are a few studies describing partial responses of such tumours to non-specific cytotoxic chemotherapy or mitotane, experience is limited. The overall prognosis is poor [61].

Incidentally-discovered adrenal masses

Epidemiology

Adrenal masses are found in around 4% of patients imaged with CT scanning for reasons other than suspected adrenal pathology; such lesions are referred to as adrenal 'incidentalomas'. The majority are not diagnosed in life, considering their prevalence is four-fold greater at autopsy, but incidence has been increasing proportionally to the increased use of imaging interventions [62, 77]. They occur equally in both sexes, and are rare under the age of 30 years; their prevalence increasing with age. They are more common in the obese, diabetics, hypertensives, and patients with MEN 1 [50, 62]. The majority are benign adenomas, with the majority of the rest comprising adrenal carcinomas, phaeochromocytomas, and secondary metastases.

Management

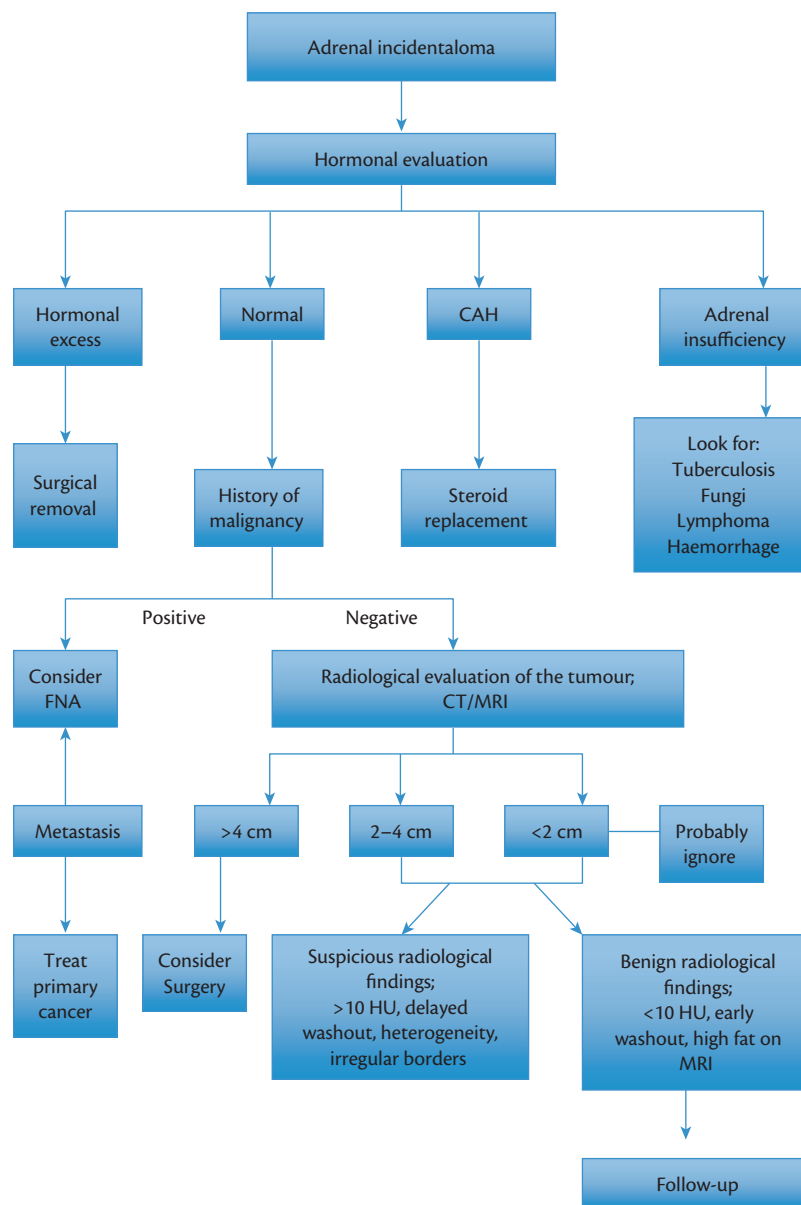
See Figure 58.8. Lesions can be unilateral- or bilateral-differential diagnoses in Tables 58.5 and 58.6. The diagnostic approach in


Fig. 58.8 Algorithm for an incidentally-discovered adrenal mass.

Table 58.5 Differential diagnosis of unilateral adrenal mass.

	(4) Haemorrhage
	(5) Bilateral metastases

patients with adrenal incidentalomas should focus on two main questions: whether the lesion is malignant, and whether it is hormonally active, in order to decide on the treatment if needed.

In case of bilateral 'incidentalomas' which represent 11–16% of lesions, the differential diagnosis is very broad, and clinical and biochemical evaluation is important given the potential for the presence of congenital adrenal hyperplasia (11% of all cases). However, there is also the rare occurrence of primary adrenal insufficiency due to bilateral destruction by solid tumour metastases, haematological malignancy, haemorrhage, or infectious (CMV, mycobacterium, fungal) or granulomatous disease [59, 62].

All patients should undergo biochemical assessment regardless of history and clinical findings [59, 78–80]. The majority of 'incidentalomas' are benign cortical adenomas, either non-secretory or of low secretory capacity [62]. Increasing data suggest that many apparent non-secretory adrenal adenomas do in fact show low-grade cortisol secretion, which may have metabolic effects, but whether all should then be removed is controversial. In the case of an adrenal mass which has been deemed hormonally non-secretory, the possibility of primary or metastatic malignancy must be excluded. Attempts to separate benign from malignant lesions on the basis of size (greatest diameter) criteria have been shown to be of limited value [62]. Therefore, the initial radiological investigation recommended to differentiate between adenomas and non-adenomas is unenhanced CT with the use of an attenuation value of ≤10 Hounsfield units (HU) highly indicative of a benign adenoma. In case of a higher baseline attenuation value, delayed contrast-enhanced CT studies should be performed with rapid washout indicative of a benign tumour [44, 78, 80]. MR should be considered when CT is inconclusive, as in-phase/out-of-phase imaging can be used to indicate a high fat content and hence benign behaviour [44, 62].

Fine needle aspiration under CT guidance may be used only in selected cases suspicious of metastases (after biochemical exclusion of phaeochromocytoma), because it is not useful in separating benign from malignant primary adrenal tumours [59, 62, 78]. Furthermore, suspected malignant adrenal tumours should *not* undergo biopsy because of the risk of dissemination.

Adrenocortical scintigraphy ^{131}I-6β-iodomethylnorcholesterol has been used but now is mainly of historical interest [63, 81].

All adrenal tumours with suspicious radiological findings, most functional tumours, and all tumours more than 4 cm in size that lack characteristic benign imaging features should be surgically excised [78–80]. Adrenal tumours may increase in size, develop overt or subclinical hormone secretion or feature malignant transformation. Therefore, radiological and hormonal follow-up should be recommended to the patients. More investigations are needed for the establishment of long-term follow-up protocols [77, 79]. For masses that appear to be benign (<10 HU; washout, >50% by MRI), small (<3 cm), and completely nonfunctioning, probably all that is required is one further imaging at 3–6 months [79].

Adrenomedullary tumours

Phaeochromocytomas and paragangliomas

Neuroendocrine tumours originated from chromaffin adrenal cells are called phaechromocytomas, while those arising in extra-adrenal sympathetic and parasympathetic paraganglia are called paragangliomas. The majority (80%) of tumours are located intra-adrenally, while sympathetic paragangliomas are in the abdominal preaortic sympathetic plexuses, paravertebral sympathetic chain, organ of Zuckerkandl, and, rarely, urinary bladder. Parasympathetic paragangliomas are most commonly found in the head and neck (HNPGLs) [64, 82].

Such tumours usually store and secrete catecholamines. They present a heterogeneous group of chromaffin cell neoplasms with different ages of onset, secretory profiles, locations, and potential for malignancy according to underlying genetic mutations [83].

Epidemiology

Phaeochromocytomas are rare tumours, showing no sexual predominance, occurring at any age, although most commonly in the third and fourth decades. A significant number of phaeochromocytomas (>50%) are found at autopsy having escaped diagnosis in life [87]. Tumours account for less than 1% of cases of hypertension, but importance of diagnostics is in potential lethal consequences if unrecognized and untreated [64, 65, 83]. Their prevalence is much higher in incidentalomas (4.2–6.5%), and therefore all adrenal incidentalomas should be screened for phaeochromocytoma irrespective of the presence of catecholamine excess [83].

Aetiology and pathogenesis

Phaeochromocytomas and sympathetic paragangliomas usually produce catecholamines or their metabolites. HNPGLs rarely produce significant amount of catecholamines (less than 5%) Catecholamines are metabolized within tumour cells: noradrenaline to normetanephrine and adrenaline to metanephrine [82]. Significant intra-tumour metabolism of catecholamines occurs in large tumours; conversely, small lesions can be disproportionally symptomatic because of high concentrations of catecholamines [64].

Relative catecholamine levels differ in different tumours; most phaeochromocytomas secrete noradrenaline predominantly, while in MEN 2 the secretory product is adrenaline. Dopamine, metabolized to 3-methoxytyramine, is seen in some succinate dehydrogenase (SDH)-B-related paragangliomas [82, 83]. Phaeochromocytomas may produce vasoactive peptides that reduce vascular responsiveness; thus, some patients with high catecholamine levels can be completely asymptomatic, while in others adrenoceptor blockade is ineffective in controlling hypertension [64].

Most phaeochromocytomas are sporadic, but 30% are hereditary. Three classical syndromes, connected to a loss of function in tumour suppressor genes and inherited in an autosomal dominant pattern, are associated with adrenal phaeochromocytoma: Von Hippel-Lindau (VHL) syndrome, multiple endocrine neoplasia type 2 (MEN 2), and neurofibromatosis type 1 (NF1). The MEN 2 syndrome, NF1, and VHL show prevalence of phaeochromocytomas in 40–50%, 1 % and 15% of patients, respectively. Phaeochromocytomas may be the only manifestation in about 25% of carriers of a MEN 2A mutation and in about 40% of carriers of the VHL syndrome. Mutations of all four SDH complex subunits (A, B, C, and D), and of the succinate dehydrogenase assembly factor 2 (*SDHAF2*) predispose to paragangliomas, while mutations of the transmembrane protein 127 (*TMEM127*) and the *MAX*-gene are associated with susceptibility to phaeochromocytomas and paragangliomas. In general, these traits are inherited in an autosomal dominant pattern, with SDH-D being inherited from the father due to imprinting [82, 83].

Microbiology and pathology

Lesions vary in size, are well encapsulated, and highly vascular (Figure 58.3C). Microscopically, all phaeochromocytomas and paragangliomas display similar histopathological characteristics (Figure 58.3D).

Approximately 10–20% of tumours are malignant. Signs of capsular invasion and vascular penetration are not proof of malignancy, which is clear if metastatic lesions to the bone, liver, lungs, and within the tumour bed are present. Paragangliomas are more likely to show malignant behaviour, as are tumours in the context of SDH-B mutations [64, 82].

Diagnosis and staging

Patients with phaeochromocytomas present with a diversity of symptoms, due to secreted catecholamines and other active substances.

The classic triad of severe headache, diaphoresis, and palpitations carries a high degree of specificity (94%) and sensitivity (91%) for phaeochromocytoma in the hypertensive population. Symptoms may vary in frequency and duration. Other symptoms in acute attack include tremor, pallor, weakness, nausea, and panic attacks. The hypertension is sustained in 50% of patients, paroxysmal in about 35% but absent in approximately 10–20%. Orthostatic hypotension can occur because of hypovolaemia and impaired arterial and venous constriction responses. Hypertensive crises with induction of anaesthesia, hypertensive encephalopathy, or spells suggestive of seizure disorder should all evoke suspicion of an underlying phaeochromocytoma. Cardiovascular and cerebrovascular complications can occur, including sudden left ventricular failure, pulmonary oedema, dysrhythmias, circulatory shock, myocardial infarction, dilated cardiomyopathy, cerebral infarction, and intracranial haemorrhage. Less specific signs and symptoms such as heat intolerance, weight loss, carbohydrate intolerance, pyrexia of unknown origin, and constipation mimicking pseudo-obstruction and paralytic ileus, have been described.

Other active secreted substances have been described: ACTH, vasoactive intestinal peptide, parathyroid hormone or parathyroid-hormone-related protein secretion [61].

Certain drugs can precipitate a hypertensive crisis in the presence of a phaeochromocytoma, which include tricyclic antidepressants, anti-dopaminergic agents (such as sulpiride and metoclopramide), and naloxone. β-adrenoreceptor blockers can also precipitate a hypertensive crisis if not preceded by adequate α-adrenoreceptor blockade.

Diagnosis is made by the demonstration of inappropriately high circulating plasma free or urinary fractionated metanephrines, followed by anatomical localization with imaging techniques due to the variable location of these tumours (Figure 58.9).

Biochemical testing should be performed in symptomatic patients, in patients with adrenal incidentalomas, or those in an increased hereditary risk [82]. Initial testing should include measurement of urinary or plasma metanephrines, or both if available. Measurement of plasma-free and urinary metanephrines show similarly high specificity, but overall plasma levels offer higher sensitivity [83].

If plasma metanephrines are more than four-fold above the upper reference limit there is a close to 100% probability of a tumour. Levels above the normal range but less than this can be seen in patients with acute, debilitating, non-endocrine illness [66]

and can be discriminated from true phaeochromocytomas by the clonidine suppression test. Raised urinary dopamine and high levels of 3-methoxytyramine may indicate malignancy, the latter being typically raised in paragangliomas [82, 83].

After biochemical diagnosis confirmation, anatomical localization is necessary due to the variable location of these tumours. CT scanning is very accurate in the detection of adrenal phaeochromocytomas with sensitivities ranging from 93–100%, although it lacks in specificity as it fails to distinguish between phaeochromocytomas, adrenal adenomas, and myelolipomas (Figure 58.10). MRI is a superior method in detecting adrenal and extra-adrenal tumours, demonstrates a bright hyperintense signal on T2 settings [44, 84]. Whole-body MRI may be included in initial anatomical imaging, especially in case of a strong clinical suspicion of extra-adrenal or extra-abdominal lesions [83].

To functionally confirm an adrenal mass as a phaeochromocytoma, prior to surgery, ^{123}I-meta-iodobenzylguanidine (^{123}I-MIBG) scintigraphy is helpful, and will identify some 80–90% of phaeochromocytomas. Considering the method shows reduced sensitivity in detecting paragangliomas, familial paraganglioma syndromes, and metastases, additional PET scanning with a range of labelled ligands (^{18}F-FDG, FDOPA, ^{11}C-HED) provides an alternative functional imaging approach with improved resolution over scintigraphy [82, 83]. In general, FDG-PET is most readily available, and is particularly useful for identifying tumours in patients with SDH mutations. However, ^{123}I-MIBG has the advantage that in patients with malignant tumours it can assess suitability for ^{131}I-MIBG therapy.

Management

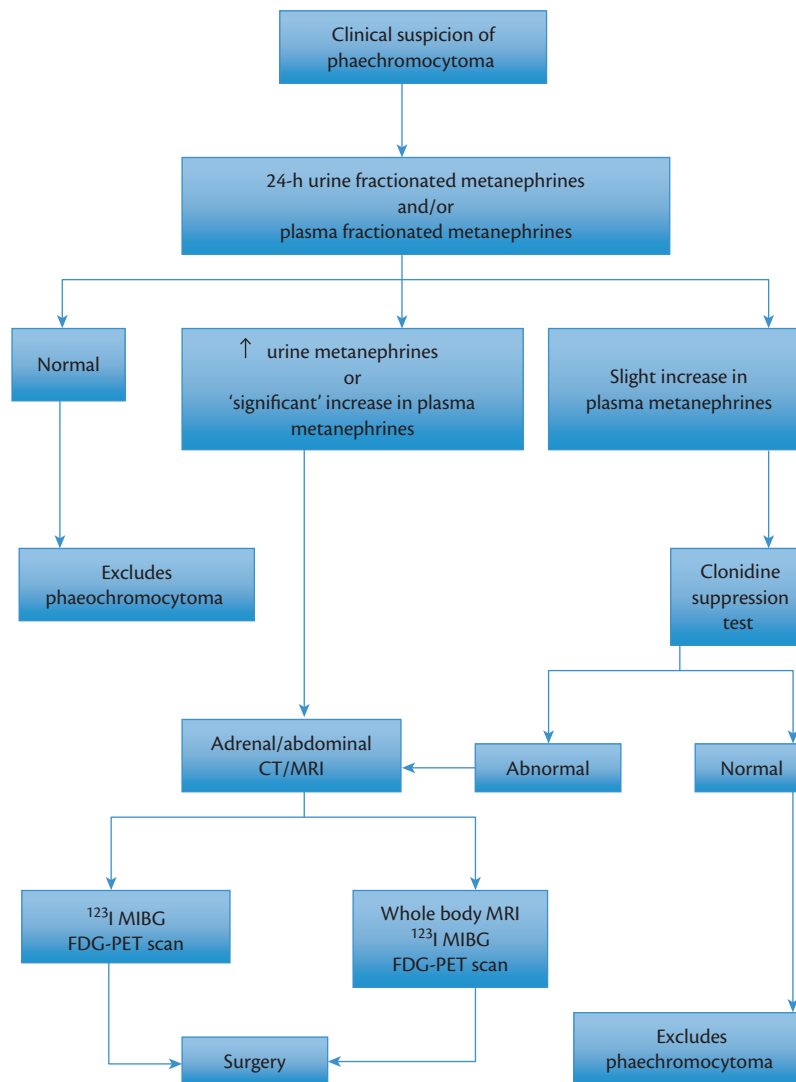
Laparoscopic surgery is first choice technique for resection of adrenal and extra-adrenal tumours. The possibility of cortical-sparing surgery in hereditary syndromes with frequent bilateral disease, in order to avoid medical adrenal replacement therapy, remains controversial because of possible disease recurrence. Preoperatively, all patients should be given adequate alpha-blockade to achieve expansion of the intravascular volume and a reduction the frequency and severity of intraoperative pressor episodes. At least two weeks prior to surgery patients are started with oral phenoxybenzamine, usually at a dose of 1 mg/kg. Alternatives include calcium channel blockers and selective α1-adrenoreceptor blocking agents such as doxazocin or terazosin. However, significant elevations of blood pressure can still be seen during surgical manipulation of the tumour and thus nitroprusside should be available during operation. Beta-adrenoreceptor blockade may be used for control of tachyarrhythmias and angina, but always after prior α-adrenoceptor blockade, otherwise unopposed catecholamine induced vasoconstriction can result in dangerous blood pressure elevations. Patients with phaeochromocytomas have a high volume requirement both during and after surgery and plasma expanders may be necessary. Perioperatively, the use of morphine or phenothiazines should be avoided as these agents can precipitate hypertensive crises or hypotension. Enflurane and isoflurane are the anaesthetics preferentially used as they do not sensitize the myocardium to catecholamines and minimize the risk of arrhythmias. Post-operatively, the blood pressure may remain elevated for a few weeks and around 75% of patients become normotensive. Surgical mortality is now extremely low with adequate preparation and thus complete cure is the rule in patients undergoing elective procedures.


Fig. 58.9 Algorithm for suspected phaeochromocytoma.

Post-operative follow-up is necessary, not only for patients with identified mutations of disease causing genes, but for all patients because there is currently no reliable pathological technique which can rule out the potential for malignancy or recurrence.

Fig. 58.10 CT scan of a large right-sided and smaller left-sided adrenal phaeochromocytoma.

Malignant phaeochromocytomas

Malignancy is diagnosed in terms of metastatic spread, which may occur years (median 5.6 years) after surgical excision. As mentioned, there are no histopathologic features to predict malignancy. There is a greater tendency to malignancy with paragangliomas, tumours in young people, female sex, large, familial lesions, and those associated with other endocrine or neoplastic disorders. These tumours are usually associated with increased dopamine and methoxytyramine secretion. There is no definitive consensus on therapy aimed at the tumour; ^{131}I-MIBG is used for patients with positive scintigraphy [82, 85]. Chemotherapy with a combination of cyclophosphamide, vincristine, and dacarbazine (CVD) is preferred in patients with negative ^{123}I-MIBG scintigraphy and in those with rapidly progressing tumours, regardless of MIBG uptake. The CVD combination can provide tumour regression and symptom relief in up to 50% of patients, but the responses are usually short and are seen in only 30% of patients [64, 82, 86]. Only a third of patients will respond to either of treatments; CVD and ^{131}I-MIBG [82], and it is unclear as to whether survival is increased. Temozolomide can be used as a second-line chemotherapeutic agent, while targeted therapy with sunitinib has shown some responses, albeit short-lived

[83]. Radiation therapy may provide palliation in patients with skeletal lesions [82]. There have also been a number of reports of treating inoperable primary and metastatic lesions with technically challenging embolization [67]. The five-year survival of patients with malignant phaeochromocytomas is 20%; however, there are patients who have survived for 20 years or longer [83].

Pituitary tumours

Pituitary tumours account for approximately 10% of clinically apparent intracranial neoplasms. Significant advances have improved the diagnosis and management of these tumours, including imaging of the pituitary by nuclear magnetic resonance, radio-immunoassay of circulating pituitary hormones, the advent of microsurgical techniques, immunocytochemistry, refinement of techniques for administering external pituitary irradiation, and new drug therapies.

Classification of pituitary neoplasms

Neoplasms of the pituitary (Box 58.1) may be divided into adenomas or carcinomas (which may be either functioning or non-functioning in terms of pituitary hormone production), craniopharyngiomas, other primary tumours, and metastatic malignancies. A number of parapituitary neoplasms occur (Table 58.7). The term pituitary carcinoma should not be used unless metastases within the nervous system or spinal cord separate from the primary tumour (or outside the neuroaxis) are found, and this is very rare.

Pituitary adenomas

Pituitary adenomas can be classified on the basis of their anatomical, histological, or functional characteristics (Tables 58.8 and 58.9). Anatomically, microadenomas are defined as tumours of less than 10 mm in diameter (the maximum diameter of the normal gland), and larger tumours are defined as macroadenomas. Modern classification based upon immunocytological and ultrastructural features of the tumour cell identifies the five major cell types of the anterior pituitary:

1. the lactotroph, producing prolactin;

2. the somatotroph, producing growth hormone (GH);

3. the corticotroph, producing adrenocorticotrophic hormone (ACTH);

4. the thyrotroph, producing thyroid stimulating hormone (TSH); and

5. the gonadotroph, producing luteinizing hormone (LH) and follicle-stimulating hormone (FSH).

Similarly, adenomas which immunostain for these hormones but do not secrete them can be identified. Some adenomas are

Box 58.1 Classification of pituitary neoplasms

negative to immunostaining for all the anterior pituitary hormones (null-cell adenomas) and a small percentage immunostain for more than one anterior pituitary hormone (plurihormonal adenomas). Prolactin-cell and null-cell adenomas occur most commonly, followed by GH-cell adenomas. Glycoprotein hormones (luteinizing hormone, follicle-stimulating hormone, and thyroid-stimulating hormone) are less commonly associated with adenoma formation; sometimes the tumours stain for and secrete the α-subunit.

Functional classification of pituitary adenomas

The functional classification of pituitary adenomas is discussed below in order of their frequency (Table 58.8).

Pituitary tumours associated with hyperprolactinaemia

These tumours vary from microadenomas, which more commonly present in women, to macroadenomas. Although prolactinomas occur less frequently in men, when they do, they tend to be larger, present at a mean of a decade later, and are more likely to be associated with compression effects. Patients with macroprolactinomas usually have prolactin levels >3000 mU/l (normal up to 360 mU/l). True prolactinomas are only occasionally associated with lower circulating prolactin levels between 2000 and 3000 mU/l. Some large non-secreting pituitary tumours may also cause mild hyperprolactinaemia (<2000 mU/l) [88]. Intrasellar and suprasellar craniopharyngiomas, meningiomas, or any other parapituitary lesion may also cause a mild hyperprolactinaemia (<2000 mU/l) [89]. Mixed prolactin- and GH-secreting tumours occur, so that

Table 58.8 Pituitary adenomas and their relative incidence (per cent) in surgical material

Prolactin-cell (lactotroph) adenomas	28
Null-cell (non-functioning) adenomas	26
Growth hormone-cell (somatotroph) adenomas	15
Corticotroph-cell adenomas	14 (45% silent)
Plurihormonal adenomas	12
Gonadotroph-cell adenomas	4
Thyrotroph-cell adenomas	1

some patients with hyperprolactinaemia may have the features of acromegaly.

Pituitary tumours associated with no elevation of circulating anterior pituitary hormones

These tumours tend to be macroadenomas and present with local pressure effects. They also may present with features of hypopituitarism.

Pituitary tumours associated with high levels of circulating growth hormone

These tumours cause acromegaly and/or gigantism and are commonly macroadenomas. They tend to be more aggressive and rapidly enlarging in younger patients. Approximately 35% of patients with acromegaly also have hyperprolactinaemia, which is due either to a plurihormonal tumour or a large somatotroph adenoma compressing the pituitary stalk. Less than 1% of patients with acromegaly have a large pituitary full of hyperplastic somatroph cells rather than a tumour, associated with elevated levels of GH-releasing hormone, usually from a carcinoid tumour of the pancreas or lung.

Pituitary tumours associated with Cushing's syndrome

Cushing's disease may be associated with normal or elevated ACTH levels, but in Nelson's syndrome (enlargement of the pituitary and skin pigmentation following bilateral adrenalectomy) the level of ACTH is invariably greatly elevated. Corticotroph adenomas are frequently microadenomas. Only rarely are they large, and in these circumstances they may be highly invasive.

Pituitary tumours associated with high gonadotrophin(s)

Pituitary tumours may secrete FSH alone, which is more common than LH secretion alone or both LH and FSH. They usually present as macroadenomas with space-occupying symptoms.

Pituitary tumours associated with thyrotoxicosis and high levels of thyroid-stimulating hormone

The tumours are usually macroadenomas and may also secrete prolactin.

Pituitary carcinomas

Primary carcinomas of the anterior lobe are very rare indeed and originate in adenohypophyseal cells. Most frequently they are non-secreting, but may secrete ACTH, prolactin, or GH.

Craniopharyngiomas

These tumours account for 2–5% of all intracranial neoplasms and arise in the remnants of Rathke's pouch, which is the dorsally directed outgrowth of the foetal stomatodeum [90]. They are more frequently suprasellar than intrasellar. They may be solid or cystic and are usually benign. These tumours present with hypopituitarism due to compression of the hypothalamus or, in the case of intrasellar tumours, the anterior pituitary. They most frequently present in children, but can occur throughout life. Suprasellar tumours may present with diabetes insipidus, and some patients have mild hyperprolactinaemia (see above).

Other primary tumours of the pituitary

Sarcomas of the pituitary occur. These are very rare and may occasionally be seen after irradiation of the pituitary.

Metastatic malignancies

Secondary tumours of the pituitary and parapituitary region are infrequent and rarely recognized clinically. They occur most frequently in patients with primary tumours of the breast, but bronchial, prostatic, and colonic neoplasms may also metastasize here.

Hypothalamic and parapituitary neoplasms

These are shown in Table 58.7.

Epidemiology of anterior pituitary tumours

Most pituitary tumours have an equal sex incidence, exceptions being tumours that secrete prolactin and ACTH, which are more common in women. They may occur at any age, although the greater frequency is between 30 and 50 years. A UK population-based study found the prevalence of pituitary adenomas to be 77.6/100 000 population, with a preponderance of prolactinoma (57%), and lower rates of the other subtypes (non-functioning adenoma [28%], acromegaly [11%], and Cushing's disease [2%]) [91].

Aetiology of anterior pituitary tumours

The aetiology of pituitary tumours is largely unknown and it is probable that there are various causes for their development. All cell types in the pituitary can become neoplastic.

Genetic factors play a role in some tumours, such as those associated with MEN type 1 or type 4 or Carney complex caused by mutations in the PRKAR1A gene. More recently, familial isolated pituitary adenoma (FIPA) has been shown to be associated with mutations in the tumour suppressor AIP gene in 20% of cases [92].

Clinical aspects of non-functioning pituitary tumours

These tumours most frequently present as large masses associated with local pressure effects. Microadenomas may be diagnosed incidentally on brain imaging performed for another disease. Rarely, because of bleeding into the pituitary tumour, they may present with the acute onset of headache associated with visual disturbance and meningism due to blood in the cerebrospinal fluid—pituitary apoplexy, which can be rarely fatal due to sudden hypopituitarism.

Clinical features

Local pressure

Headache is the most frequent symptom. It may be due to stretching of the dura above the pituitary. If there is upward extension of the pituitary tumour, pressure on the optic chiasm results in a bitemporal field defect. A decrease in visual acuity may occur due to optic atrophy, which may be irreversible if the pressure on the chiasm is long-standing [93].

Lateral extension of the tumour may cause interference of the function of the third, fourth, or sixth cranial nerves.

Hormonal changes

These occur with great frequency in patients with pituitary tumours. The most common cause of hypopituitarism is a pituitary tumour in adults and a craniopharyngioma in children. In progressive hypopituitarism, there is usually a characteristic order in the development of trophic-hormone deficiency. Usually, GH and LH secretions fail first, followed later by that of FSH, ACTH, and TSH. Prolactin deficiency is rare.

GH deficiency causes short stature in children and sometimes, but not always, retarded skeletal development. There are a number of important features of GH deficiency in adults, including impaired psychological well-being, increased abdominal adiposity, and reduced muscle strength (Box 58.2), and we now recognize that these are frequently reversible when GH is administered to adults.

In men with gonadotrophin deficiency, there is decreased libido, impotence, and a decrease in sperm count. Testicular size decreases and the testes may become soft. In addition, there is loss of pubic, axillary, and facial hair in both sexes. In women, a decrease in libido may occur and dyspareunia or amenorrhoea due to decreased oestrogen secretion is also seen. Infertility is common in both sexes. Prolactin deficiency is rare, and most commonly pressure by a functionless tumour on the pituitary stalk results in elevation of circulating prolactin levels. Hyposecretion of TSH in children causes growth retardation. In adults, when hypothyroidism develops, the swelling of the subcutaneous tissue is less prominent in pituitary

hypothyroidism than in the primary form of the disease. Secretion of ACTH is associated with the features of corticosteroid deficiency, but in pituitary ACTH deficiency there is pallor of the skin, unlike most causes of primary adrenal failure. Deficiency of antidiuretic hormone causes diabetes insipidus. Cranial diabetes insipidus most commonly occurs after pituitary surgery. Patients with hypopituitarism may have anaemia associated with hypogonadism.

Investigation of patients with pituitary disease

Assessment of pituitary function

Anterior pituitary function

It is essential to assess and correct anterior pituitary function before testing that of the posterior pituitary. This is because cortisol and thyroxine deficiency may decrease the symptoms of diabetes insipidus by decreasing the glomerular filtration rate.

Basal serum hormone levels of thyroxine, cortisol, prolactin, LH, FSH, TSH, testosterone, or oestradiol should be assessed.

The insulin hypoglycaemia test is the standard way of assessing ACTH and GH reserves and is safe if adequate precautions are taken.

Posterior pituitary function

Posterior pituitary function is tested with a water-deprivation test, prior to which other causes of polyuria (including diabetes mellitus, chronic renal failure, hypercalcaemia, and hypokalaemia) must be excluded, as these impair the efficiency of antidiuretic-hormone action.

Neuro-ophthalmological investigation

Neuro-ophthalmological examination, particularly formal perimetry, aids diagnosis, determines type and timing of treatment, and serially helps to follow the progress of the disorder.

Radiological investigation

Magnetic resonance imaging

MRI with dedicated pituitary sequences (thin slices, small field of view, and dynamic contrast acquisition) is recommended as the routine examination for evaluating pituitary and parapituitary tumours. Post contrast and thin section dynamic contrast enhanced pituitary MRI imaging has significantly improved diagnostic accuracy. A pituitary microadenoma and macroadenoma are shown in Figures 58.11 and 58.12.

Surgical management of anterior pituitary tumours

Trans-sphenoidal pituitary surgery, using either the fully endoscopic endonasal or trans-septal approach, by an experienced pituitary neurosurgeon has revolutionized the management of pituitary tumours. Successful surgery is more likely to be achieved for microadenomas than for macroadenomas (in the treatment of acromegaly, for example, 80–85% of microadenomas have safe GH levels after surgery, but this figure falls to 50–60% for macroadenomas). Mortality is very low (<1%) and complications—haemorrhage, cerebrospinal fluid leak, and meningitis—are rare (1% each). Hypopituitarism is seen after trans-sphenoidal surgery and the frequency with which this complication is seen depends on the size of the pituitary tumour.

Box 58.2 Characteristic clinical features of growth hormone deficiency in adults

Increased fat mass
Reduced lean body mass
Decreased extracellular water
Low bone density
Impaired cardiac function
Poor physical performance
Impaired psychological well-being
Fig. 58.11 A left-sided pituitary microadenoma is shown on MRI.

Transfrontal surgery, involving the lifting of a bone flap and frontal lobe retraction, has a greater morbidity and mortality than trans-sphenoidal surgery. The main indication for it is the decompression of the optic chiasm in patients with a large and inaccessible suprasellar extension (greater than 2 or 3 cm). Surgery using this route virtually never results in complete removal of the tumour and subsequent radiotherapy is necessary as 80% of tumours will recur.

Radiotherapy management of anterior pituitary tumours

External beam radiotherapy has been used for many years in the treatment of pituitary tumours to good effect [94]. Many studies have demonstrated the effectiveness of gamma knife radiosurgery in non-functional pituitary tumours with significant decreases in tumour dimensions occurring one year following treatment.
Fig. 58.12 A large extrasellar pituitary tumour (non-functioning) with suprasellar extension is shown on MRI.

Hypopituitarism following radiotherapy develops rarely and late, but this means that after radiotherapy patients need a yearly assessment of pituitary function. Less than 5% of pituitary adenomas recur if external pituitary irradiation is given. Late malignancy in the field of irradiation is reported to occur at 1.9% at 20 years, but these data are based on small numbers [95].

Functioning pituitary tumours

Prolactinoma

In women, prolactinomas tend to present earlier than in men. Furthermore, in women they tend to be smaller at presentation. Therefore, local effects of a pituitary tumour secreting prolactin occur commonly in men. In these patients pituitary function may also be affected as described above.

Symptoms of hyperprolactinaemia

High prolactin levels cause amenorrhoea or oligomenorrhoea, galactorrhoea, and infertility in women in the reproductive phase of life and relative or absolute impotence in men. Patients also have acne, a greasy skin, and hirsutism because prolactin enhances adrenal androgen secretion. In men, galactorrhoea is less frequent and gynaecomastia is a rare feature. Soft testes may eventually occur and testosterone levels, particularly in those patients who have long-standing hyperprolactinaemia, tend to fall, due to hypopituitarism.

Diagnosis of prolactinoma

The diagnosis is made by taking one or two basal, unstressed, blood samples for prolactin estimation. Once drugs and hypothyroidism have been excluded, hypothalamo-pituitary disease is by far the commonest cause of hyperprolactinaemia.

Management of prolactinoma

The aims of treatment are to reduce prolactin levels to normal, remove the tumour mass with the preservation of anterior pituitary function, and not cause significant side effects, particularly hypopituitarism. The choice of therapy depends on the size of the tumour, the presence of local complicating factors, the degree of elevation of serum prolactin, and the expertise that is locally available. In all but the largest tumours compressing local structures, medical treatment with dopamine agonists should be attempted as first-line therapy. In a large proportion of patients (85–90%) this will suppress prolactin levels to normal without side effects and will cause a resumption of normal gonadal function without the risk of hypopituitarism.

Medical therapy

Dopamine agonists are first-line therapy for prolactinomas. These drugs suppress prolactin by stimulating dopamine receptors present on the prolactin-secreting cells of the pituitary tumour. They can be used either on its own as primary therapy or as an adjunct in the treatment of patients with macroprolactinomas whose levels of prolactin are not adequately normalized by surgery or pituitary irradiation. Most experience has been gained with bromocriptine (an ergot alkaloid that works as a long-acting dopamine agonist) and cabergoline—a longer acting dopamine agonist administrable once or twice per week.

Surgery

Pituitary surgery is only indicated when medical therapy has either failed to reduce the prolactin level to normal or is not tolerated by the patient. Prolactinomas may re-develop after surgery.

Radiotherapy

External pituitary irradiation is also used in the treatment of prolactinoma [96]. It is clear that it arrests tumour growth, prevents further enlargement subsequently during pregnancies, and gradually decreases the circulating levels of prolactin. It may take between five and ten years to reduce prolactin levels to normal when off medical therapy.

Acromegaly

If GH hypersecretion occurs before fusion of the epiphyses, gigantism results. If secretion occurs after fusion, the acromegaly syndrome develops often over many years and this is much more common than gigantism as most tumours occur during adulthood.

Clinical features

Symptoms directly related to excessive GH secretion are numerous (Table 58.10).

Additionally, type 2 diabetes mellitus may occur in 30% of patients with acromegaly because GH hypersecretion results in hyperinsulinism and insulin resistance. Patients with persistent hypercalcaemia usually have multiple endocrine adenomas involving the pituitary and parathyroid glands and parathyroid hyperplasia may be seen.

Diagnosis of acromegaly

The chemical diagnosis of acromegaly is made by an oral glucose tolerance test (75 g), during which GH levels fail to suppress to <0.33 mcg/l. GH stimulates the production of insulin-like growth

Table 58.10 Presentation of acromegaly based on 310 patients

Presenting chief complaint	Frequency (%)

factor 1 (IGF-1) and levels of this peptide are almost invariably raised at diagnosis. This peptide, in contrast to GH, does not show wide variations during the day.

Investigations

Radiology

99% of patients have a pituitary tumour detectable on MRI scanning. Formal visual field testing should also be carried out.

Biochemical investigations

GH levels should be assessed in samples obtained five or six times throughout the day.

Management of acromegaly

Acromegaly is a disease which approximately halves life expectancy [97]. Increased mortality is due to cardiovascular and cerebrovascular causes related to hypertension and diabetes mellitus [97] and to respiratory causes. Mortality is also increased for malignant causes and, in particular, the incidence of colonic cancer is significantly increased [98]. Therefore, it is important to treat patients with acromegaly once the diagnosis has been made. Suppression of mean GH levels to <1mcg/l are not associated with increased mortality [97].

Surgery

Definitive treatment usually involves trans-sphenoidal surgery. The best results follow surgery for microadenomas where there has been an early diagnosis and prompt definitive therapy. In experienced hands, up to 85% of patients with microadenomas can expect to be cured by trans-sphenoidal surgery. Larger tumours, and most particularly tumours which extend out of the sella turcica, are cured by trans-sphenoidal surgery in less than 40% of patients.

External beam pituitary irradiation

If surgery is unsuccessful at reducing GH to safe levels, external beam pituitary irradiation is considered afterwards. Several studies suggest that the response of GH to pituitary irradiation is dependent on the pre-irradiation GH concentration and the length of time after treatment. GH levels continue to fall up to at least 15 years after external pituitary irradiation.

Medical treatment

The long-acting somatostatin analogues, octreotide and lanreotide, may be used post-operatively for patients not biochemically cured by surgery. They normalize GH and IGF-1 levels in approximately 40% of post-operative patients. Medical treatment is used whilst awaiting the effects of external pituitary irradiation in those patients not completely cured by surgery. Pegvisomant, a GH-receptor antagonist, is used in those resistant to somatostatin analogues. Cabergoline, usually at a dose of 3 mg weekly, may also be effective (in 20–30% of cases) in reducing GH levels in conjunction with somatostatin analogues.

Cushing's disease

Cushing's disease is applies to inappropriate elevation of circulating free glucocorticoids caused by a pituitary adenoma secreting ACTH.

Clinical features

The clinical features include a rounded, plethoric face, and central obesity. Myopathy induces wasting of the arms and legs. Loss of

libido, amenorrhoea, and galactorrhoea may occur, particularly if there is associated prolactin production by a pituitary tumour. Hirsutism and acne also occur. In patients with long-standing Cushing's syndrome, vertebral collapse occurs as a result of osteoporosis. Psychiatric manifestations, particularly depression, are seen in 50–60% of patients with this syndrome.

Differential diagnosis and investigation

There is no single, reliable test for the diagnosis of Cushing's syndrome, which may be difficult because intermittent, mild, and atypical forms of the disease occur [99]. Firstly, Cushing's syndrome must be diagnosed and secondly, the differential diagnosis must be established. Diagnosis is achieved with a low-dose dexamethasone test (0.5 mg six-hourly for 48 h) where there is failure of suppression of serum cortisol to <50 nmol/l after dexamethasone. In the differential diagnosis of Cushing's syndrome, the level of ACTH is important. It is undetectable in patients with adrenal adenoma or carcinoma. The major diagnostic problem involves differentiating Cushing's syndrome due to ectopic ACTH production by occult neoplasms from Cushing's disease (Table 58.11). Cushing's disease is suggested, if, when giving the patient dexamethasone 8 mg daily for 48 h (2 mg six-hourly), there is a >50% suppression of plasma cortisol. Unfortunately, some patients with ectopic ACTH production may show such suppression, while 10% of patients with Cushing's disease fail to suppress. Ectopic ACTH secretion is suggested by the presence of hypokalaemia, provided the patient is not taking diuretics.

Management of Cushing's disease

Surgery

Trans-sphenoidal pituitary surgery is the first-line treatment option for patients with Cushing's disease. Cure rates vary according to the criteria used but the immediate post-operative cure rate is 70 to 80% with an experienced neurosurgeon level when biochemical cure is defined as a circulating cortisol level <50 mU/l post-operatively.

Pituitary irradiation

Pituitary irradiation using the standard technique described above is most frequently indicated after unsuccessful surgery. Pituitary irradiation is particularly effective in the treatment of children with Cushing's disease.

Table 58.11 Response to tests used to differentiate ectopic ACTH secretion from Cushing's disease

	Ectopic ACTH (% of cases)	Cushing's disease (% of cases)
Hypokalaemia <3.2 mmol/l	100	10
Diabetes mellitus	78	38
Dexamethasone 8 mg/day (no suppression)	89	22
No response to metyrapone	50	36
CRH test excessive response	0	>90

Abbreviation: CRH, corticotrophin-releasing hormone.

Medical treatment

Medical treatment may be used as an adjunct to surgery and radiotherapy while the effects of radiotherapy are awaited or, alternatively, for the preoperative treatment of patients. Metyrapone, an 11β-hydroxylase inhibitor, inhibits the synthesis of cortisol. Mitotane is an adrenolytic agent which may be used together with metyrapone in patients who are not responding adequately to this drug alone. It has a slow onset of action. Side effects include hypercholesterolaemia, and cerebellar ataxia because of its incorporation into cerebellar neurones. Both metyrapone and mitotane may result in adrenal insufficiency and so require careful monitoring of cortisol levels. Patients may require hydrocortisone replacement. Most recently, the somatostatin analogue, pasireotide, which stimulates somatostatin receptor subtypes 2 and 5 has been licensed for use in patients with Cushing's disease who fail to be biochemically cured. It is effective in ~30% of cases but may cause deterioration in glucose tolerance.

Gastroenteropancreatic neuroendocrine neoplasms

Introduction

Neuroendocrine neoplasias (NEN) of the gastroenteropancreatic (GEP) system are rare (incidence 1–4/100 000 worldwide) and affect both sexes equally. Although derived from endocrine precursor cells, less than half of all patients present with a classical functional hormone hypersecretion syndrome caused by the excessive and unregulated secretion of peptide hormones, neuropeptides, or neurotransmitters. In contrast to other epithelial tumours of the GEP-system, symptoms related to tumour burden usually develop late and are associated with advanced tumour stages, whether or not the symptoms are related to hormone hypersecretion (functioning NEN) or to tumour mass effects (e.g., small bowel obstruction, bile duct occlusion). Insulinomas are an exception to this rule because they manifest themselves at an early tumour stage in most cases with a specific and rather easily recognized clinical syndrome. Less than 10% of all patients present with a specific family history, whereby the GEP primary is almost exclusively located in the foregut (especially in the pancreas, duodenum, stomach, and bronchus). This hereditary tumour syndrome is termed 'multiple endocrine neoplasia, type 1' (MEN 1).

Tumour classification

Gastroenteropancreatic neuroendocrine neoplasias (GEP-NEN) are classified according to:

- primary tumour localization within the GEP-system
- tumour stage according to UICC (Union for International Cancer Control)/ AJCC (American Joint Committee on Cancer)/ENETS (European Neuroendocrine Tumor Society)
- tumour grading according to the Ki67-proliferative index
- functionality (i.e. a clinically manifest hormone hypersecretion syndrome)
- association with the MEN 1-syndrome.

30–40% of all tumours cause specific symptoms and syndromes (see Table 58.12) related directly to the excessive release of their functional secretory products (e.g., gastrin or serotonin) [100]. As a general rule, hindgut tumours (i.e., NEN originating from the colorectum)

are almost always non-functional. By contrast, midgut tumours present with carcinoid syndrome in many cases and then are usually metastatic, while foregut tumours—if hormonally active—present with either the Whipple's triad (symptoms known or likely to be caused by hypoglycaemia, low plasma glucose measured at the time of the symptoms, and relief of symptoms when the glucose is raised to normal), a Zollinger–Ellison syndrome or, more rarely, with glucagonoma syndrome or Verner–Morrison syndrome (see Table 58.12).

In the recent years, the WHO has published a new classification of NEN specifically addressing GEP-NEN (Table 58.13). This classification largely relies on the classification proposals made by ENETS and has been confirmed by several studies [101, 102]. It is important to realize that the proliferative capacity as indicated by either mitotic count or Ki67-labelling index by immunohistochemistry is now considered a most important prognostic factor of GEP-NEN. Thus, GEP-NEN with a proliferative capacity of no more than one mitosis per high power field (HPF) or no more than 2% Ki67-positive tumour cells are considered grade 1 (G1) neuroendocrine tumours (NET-G1) and may still be labelled with the traditional term 'carcinoid tumour'. GEP-NEN with an intermediate proliferative capacity of 2 to 20 mitoses per HPF or 3–20% Ki67-positive tumour cells are classified as grade 2 (G2) neuroendocrine tumours (NET-G2); the term 'carcinoid' is, however, no longer considered appropriate for these NET-G2. Finally, NEN with more than 20 mitoses or more than 20% Ki67-positive tumour cells are now termed grade 3 (G3) neuroendocrine carcinomas (NEC-G3) according to WHO, ENETS, AJCC, and UICC. WHO-grading according to Ki67-index or mitotic count as well as TNM (tumour node metastasis)-classification have proven to provide significant prognostic stratification (Table 58.14).

The efforts towards a clinically and prognostically relevant classification for NEN have also lead to a NEN-specific TNM-classification by ENETS which was largely adopted by the AJCC and the UICC; the latter varies from the ENETS proposal only for early stage appendiceal and pancreatic NEN [103–105].

Almost 90% of all GEP-NEN are well differentiated, as reflected by their slow rate of growth. In cases where there is a family history, tumours of the parathyroid and the pituitary can also occur (MEN 1). However, the subgroup of highly proliferative, poorly differentiated, and rapidly progressing neuroendocrine carcinomas (NEC-G3; see Tables 58.13 and 58.14) exists and requires an appropriately modified diagnostic and therapeutic approach.

Aetiology and frequency

Since cells of the diffuse endocrine system can be found anywhere within the GEP-system, primary NEN can also be found in essentially any GEP localization. However, in approximately 6–10% of all cases an advanced, metastatic NEN is found and no explicit primary tumour organ can be identified in spite of extensive and sensitive clinical investigation (CUP, cancer of unknown primary). Depending on the primary tumour localization the frequency of NEN varies considerably; however, NEN of the stomach, the appendix, and the rectum represent the most frequent NEN and by far the majority of them are early stage, non-metastatic tumours (10–15% of all NEN each) [106]. In contrast, small intestinal and pancreatic NEN, while also representing approximately 15% of all GEP-NEN each, are mostly advanced metastatic tumours. Other localizations such as duodenum (~ 4%), colon (~ 5%), and oesophagus (<1%) are much rarer [107].

NEN metastasize by lymphatic and hematogenous spread to numerous localizations; almost any location in the body has been described as a metastatic site (e.g., orbits, heart, breast, skin, adrenal glands, etc.) in addition to the most frequent sites as listed in Table 58.15.

The majority of neuroendocrine GEP tumours are sporadic without a family history of a hereditary syndrome. With the exception of a small subgroup of patients, until now no clear genetic cause has been found for the sporadic form [108, 109]. In contrast, most patients with multiple neuroendocrine neoplasia-type 1 possess a genetic defect of the so-called *MEN 1* or *menin* gene (90%). Studies have shown that *menin* acts as a tumour-suppressor gene. Therefore, *menin* modifications may affect the cellular replication of neuroendocrine cells [109–113].

Histology, routine laboratory testing, and neuroendocrine cell biology

Independent of the functional state, conventional histology of GEP-NEN typically shows a homogeneous array of small round cells, each with a uniform nucleus and cytoplasm, but mitoses are rare. The low proliferation index can be determined immunohistochemically using antibodies against the proliferation marker Ki67 (usually less than 5% of cells are proliferating) (Figure 58.13). Higher proliferation rates correspond to less differentiated NET-G2 and, in some cases, even to poorly-differentiated neuroendocrine carcinomas of the small- or large-cell type. In the common form of well-differentiated neuroendocrine tumours (NET-G1/2), malignancy can only be diagnosed by the detection of distant metastases or tumour invasion into neighbouring structures (e.g., nerve sheaths, blood and lymph vessels, or lymph nodes) [114]. Most NETs produce multiple gastrointestinal hormones, neurotransmitters, and neuropeptides. However, only some of the hormone-active components are released into the bloodstream. Thus, if immunoreactivity for various peptide hormones is demonstrated in the tissue section, this neither necessarily implies their release into the bloodstream nor a clinical manifestation of a functional hypersecretion syndrome. By contrast, chromogranin A (a packaging protein of secretory granules), is synthesized and released in almost all tumour cells. Hence, both immunohistologic as well as laboratory blood tests should be restricted to the use of chromogranin A as a broad-spectrum marker for the presence of neuroendocrine tumours. Only in selected cases, defined by a specific history suggesting the excessive release of a given hormone, are specific hormone determinations of use [100]. NEN cells are characterized by a cell type-specific synthesis of secretory vesicles. These vesicles are characterized by a specific vesicular envelope (membrane) and content (core). To release the vesicular content into the bloodstream, second messenger systems (for example, calcium, cGMP, or cAMP) are required. These second messengers permit the release of hormones, neuropeptides, and neurotransmitters in an 'on demand' or regulated fashion. While peptide hormones and neuropeptides, together with the so-called packaging proteins of the granin family (e.g., chromogranin A), are contained in secretory granules, neurotransmitters are mainly contained within neuroendocrine small synaptic-like vesicles [100].

Adequate histopathological diagnosis requires the use of immunohistochemical techniques based on molecular markers for these two types of vesicles. Chromogranin A is used both immunohistochemically and serologically to identify secretory granules (Figure 58.13). For neuroendocrine small synaptic-like vesicles, synaptophysin is now established as a routine immunohistochemical

Table 58.12 Hormone hypersecretion syndromes in NEN: syndrome characteristics, mediators, and diagnostic testing

Syndrome/tumour	Secreted hormone(s)	Primary tumour	Diagnostic test	Symptoms
Carcinoid syndrome (classical)	Serotonin (substance P, neuropeptide K, tachykinines)	Small intestine (mostly ileum), bronchial system, pancreas (rarely), rectum (extremely rarely)	5-HIAA in 24-hour- urine (acidified), serum chromogranin A (CgA)	Facial flushing (85%), secretory diarrhoea (75%), carcinoid heart disease (Hedinger's syndrome; 25%), wheezing (<10%)
Carcinoid syndrome (atypical)	Histamine (bradykinines)	Stomach (rarely)	Methylimidazole acetic acid in 24-hour- urine	Facial flushing, wheezing
Zollinger–Ellison syndrome (ZES) or gastrinoma	Gastrin	Duodenum (30%), pancreas (70%)	Serum gastrin, secretin-test, gastric 24-hour-pH-metry	Recurrent peptic ulcer disease (atypically localized, multiple), secretory diarrhoea, steatorrhoea, maldigestion
Insulinoma	Insulin (rarely proinsulin)	Pancreas	Serum glucose, serum insulin, serum proinsulin (rarely), C-peptide, 72-hour-fasting-test	Whipple's triad: fasting (hyperinsulinaemic) hypoglycaemia, neuroglycopaenia, reversibility after glucose application
Glucagonoma	Glucagon	Pancreas	Serum glucose, serum glucagon	Diabetes mellitus, necrolytic migratory erythema, anaemia, malnutrition (weight loss)
Verner–Morrison syndrome or VIPoma	VIP	Pancreas (90%)	Serum VIP, venous blood gas analysis	WDHA-syndrome: watery diarrhoea, hypokalaemia, achlorhydria, metabolic acidosis, occasionally facial flushing
Somatostatinoma	Somatostatin	Pancreas (50%), duodenum (periampullary region, 50%)	Serum somatostatin	Steatorrhoea, diarrhoea, cholelithiasis, diabetes mellitus
Ectopic ACTHoma	ACTH	Bronchial system	Serum ACTH, cortisol in 24-hour- urine dexamethasone suppression test	Cushing's syndrome
Non-functioning NET (G1/2)	None, causing clinical symptoms	Whole GEP-system	Serum chromogranin A (CgA)	None
Non-functioning NEC (G3)	None, causing clinical symptoms	Whole GEP-system	Neuron-specific enolase (NSE), serum chromogranin A (CgA)	None

Abbreviations: 5-HIAA, 5-hydroxy-indole acetic acid; ACTH, adrenocorticotrophic hormone; VIP, vasoactive intestinal peptide.

marker molecule with the highest sensitivity for the diagnosis of a neuroendocrine neoplasm (Figure 58.13). Due to their poor specificity regarding neuroendocrine neoplasms, neuron-specific enolase (NSE) and CD56 (NCAM) should be abandoned as immunohistologic markers for NEN.

Clinical syndromes

Neuroendocrine specific symptoms and syndromes are caused by the excessive release of hormones, neuropeptides, and neurotransmitters. As already pointed out, hormone hypersecretion is mainly observed from a primary tumour located in the pancreas and duodenum, whereas neurotransmitters and neuropeptides are mainly released by tumours located in the distal small intestine. Specific hormone hypersecretion (i.e. functional) syndromes, the respective hormones or amines thought to mediate the symptoms, and the laboratory tests are summarized in Table 58.12.

Non-specific symptoms are frequently observed in GEP-NEN with abdominal pain (50–60% of all patients), unexplained weight loss (20%), fatigue (15%), small bowel obstruction (~12%), gastrointestinal bleeding (~10%), night sweats (~8%), jaundice (~4%),

Table 58.13 Classification of neuroendocrine neoplasms according to WHO 2010 [214–216]

WHO 2010	Histological differentiation grade	Grading Ki67-index mitotic rate	WHO 2000 (old)
NET-G1	Well differentiated	≤ 2% <2/10HPF	WDET/C
NET-G2	Well differentiated	3–20% 2–20/10HPF	WDET/C
NEC-G3 - Large cell phenotype - Small cell phenotype	Poorly differentiated	>20% >20/10HPF	PDEC
Exception: NET-G3	Well differentiated	>20% >20/10HPF	Increasingly described novel subgroup

Abbreviations: G1/2/3, grade; HPF, high power field (40-fold magnification); NET, neuroendocrine tumour; NEC, neuroendocrine carcinoma; PDEC, poorly differentiated endocrine carcinoma; WDET, well differentiated (neuro-)endocrine tumour; WDEC, well differentiated (neuro-)endocrine carcinoma.

and fever of unknown cause (~2%) as the most frequent symptoms ultimately leading to the diagnosis of a NEN.

Specific aspects of diagnosis and therapy of GEP-NEN

Functional tumours

Neuroendocrine neoplasms of the pancreas, duodenum, and stomach

NEN of the pancreas have also been called islet-cell tumours or endocrine pancreatic tumours (EPT). Since many of these tumours produce hormones (e.g., gastrin and vasoactive intestinal polypeptide [VIP]) that are not found in the normal untransformed endocrine pancreas, it is assumed that these tumours derive directly from transformed pancreatic stem cells. The

Table 58.14 Prognosis of GEP-NEN according to WHO-classification and TNM-staging groups

	GEP-NEN	Small intestine	Pancreas
Prognostic factor	5-YSR	5-YSR	5-YSR
G1	80–90%	90–95%	85–90%
G2	65–80%	70–85%	60–80%
G3	10–33%	20–50%	15–35%
Stage I–IIIa 'limited disease'	80–90%	85–95%	75–90%
Stage IIIb–IV 'extensive disease'	50–70%	60–75%	50–60%

Abbreviation: 5-YSR, 5-year survival rate.

Table 58.15 Sites and frequency of metastases of NEN

Localization	Frequency
Lymphonodular	~80%
Hepatic	~70%
Peritoneal	~20%
Osseous	~10%
Pulmonary	up to 10%
Other intra-abdominal organs	up to 7%
CNS	up to 3%

tumorigenesis of duodenal and gastric neuroendocrine tumours is even less clear [115].

Insulinoma/hypoglycaemia syndrome

The incidence of insulin-secreting neuroendocrine tumours, or insulinomas, is approximately 0.1–0.4 per 100 000 of the population worldwide, affecting both sexes equally [116]. Insulinomas can occur at any age. Most insulinomas (approximately 90%) are small (less than 2 cm), non-metastatic, and occur as solitary tumours. They are almost exclusively confined to the pancreas. Multiple, synchronously- or metachronously-occurring insulinomas are observed in only a few cases (less than 7%). In all of these, MEN 1 has to be excluded [110, 116–120]. In cases of malignant insulinoma, the 10-year survival rate is less than 30% [116]. Moreover, in these cases, the release of insulin into the bloodstream may lead to less functionality due to the secretion of incompletely-processed 'immature' insulin.

Diagnosis

To diagnose an insulin-secreting neuroendocrine tumour, the first step is to take the patient's history (reports of psychiatric and neurological symptoms, alterations or even loss of consciousness, e.g. related to hypoglycaemia), and the second is to perform a 72-hour fasting test combined with repeated determinations of glucose and insulin levels. In this context, C-peptide determinations to exclude exogenous insulin administration may be unnecessary. The test is diagnostic if the fasting glucose level is less than 2.5 mmol (45 mg/dl) with inappropriately high levels of insulin more than 70 pM (486 µIU/mL) and C-peptide (more than 500 pM) [121]. Alternatively, diagnostic challenge tests using a euglycaemic hyperinsulinaemic-clamp method [122] or diazoxide or calcium stimulation may be used in doubtful situations [121, 123, 124]. The localization of insulinomas is often difficult due to their small size (1–2 cm in diameter). For preoperative localization, endoscopic ultrasound (EUS) has the highest sensitivity (85%) [125]. A similar sensitivity is observed for the more invasive and rarely required procedure of intra-arterial calcium stimulation and selective portal venous sampling [121]. Other procedures such as transabdominal ultrasound (US), computed tomography (CT), and magnetic resonance imaging (MRI) detect less than half of all cases [126]. Similarly, somatostatin-receptor scintigraphy (SRS) has a low sensitivity in benign cases. This is best explained by the low expression of somatostatin-receptor subtypes-2 and -5 bound by somatostatin analogues such as octreotide [127]. However, in malignant insulinomas, sensitivities for SRS of up to 90% have been reported [128]. Positron emission tomography (PET)-scanning
Fig. 58.13 Histological diagnosis of neuroendocrine tumours. (A) Conventional haematoxylin and eosin (H&E) staining of an ileal NET. (B) Immunohistochemical detection with antibodies against chromogranin A. (C) Synaptophysin. (D) Ki67; note that chromogranin A and synaptophysin antibodies react exclusively with tumour cells. Ki67 positivity is observed in a few tumour cells.

using either Gallium-68-DOTATOC/TATE (Ga-DOTATOC/TATE) or even the glucagon-like peptide-1(GLP-1)-analogue exendin-1 may provide more sensitive and specific means for insulinoma detection currently under development [128]. So far, no convincing data exist to include metaiodobenzylguanidine (MIBG)-scintigraphy into tumour staging. Intraoperatively, palpation as well as intraoperative ultrasound (IOUS) both detect insulinomas with a high degree of sensitivity (approximately 90%) (see Figure 58.14 which shows diagnostic images of a pancreatic neuroendocrine tumour with metastases to the liver).

Therapy

Curative tumour resection represents the therapy of choice: experienced centres report a cure rate of 90%; the procedures may involve open or laparoscopic resection of tumour, the latter for pancreatic tail insulinomas in particular. In patients with unresectable and metastatic disease (approximately 10%), symptomatic antisecretory therapy with diazoxide (a membrane, hyperpolarizing, potassium-channel opener) and one of the somatostatin analogues (SSA), octreotide or lanreotide, can improve hypoglycaemia (see Table 58.17) [129]. However, somatostatin analogues have to be used cautiously as reduced glucagon release may interfere with counter-regulatory mechanisms [130]. The somatostatin receptor-non-specific SSA pasireotide as well as the mTOR inhibitor everolimus may provide additional, off-label treatment for symptom control in otherwise uncontrolled patients [130]. To further control symptoms and with antiproliferative intent, the nitrosourea streptozocin in combination with 5-fluorouracil (5-FU) or doxorubicin can be effectively used (see Table 58.18) [131–133]. Tumour-volume reduction by embolizing liver metastases can be

employed in patients with extensive liver metastases [134–136]. Prognosis relates to tumour stage, differentiation, and proliferation. The 10-year survival rate for patients with metastatic disease is under 30% [116].

Gastrinoma/Zollinger–Ellison syndrome

Gastrin-secreting neuroendocrine tumours, or gastrinomas, are epithelial tumours characterized by the excessive release of gastrin into the bloodstream, which gives rise to the Zollinger–Ellison syndrome [137]. This syndrome, initially described by Zollinger and Ellison, consists of a triad of extensive peptic ulcerations in the upper gastrointestinal tract, excessive acid secretion in the stomach (combined in some cases with secretory diarrhoea), as well as solitary or multiple islet-cell tumours of the pancreas or duodenum (see Figure 58.15A and 58.15B). Gastrinomas usually become manifest between the third and fifth decades of life, although they are also occasionally observed during childhood. Up to 25% of all gastrinomas occur in association with MEN 1 [110, 117–120, 138–140]. At the time of presentation, about two-thirds of all patients already have metastatic disease [126, 141, 142]. Approximately 30–50% of all gastrinoma primaries occur extrapancreatically, with the primary (or primaries) located in the duodenal wall. Due to their small size, they are often missed endoscopically as well as surgically [125]. The prognosis for patients with extrapancreatic primaries appears to be better than that for patients with intrapancreatic tumours.

Clinical features

Multiple, small (less than 1 cm) peptic ulcerations are found in the oesophagus, stomach, post-bulbar duodenum, and even proximal jejunum. Approximately one-third of all patients complain of secretory diarrhoea in the presence, or even absence, of peptic
Fig. 58.14 Imaging diagnosis of a pancreatic neuroendocrine tumour metastatic to the liver. (A) Abdominal CT showing the larger of the two pancreatic primaries (arrowheads, right) and liver metastases (arrows, left). (B) Somatostatin receptor scintigraphy with two pancreatic tumours (small arrowheads) and liver metastases (small arrows). (C) Image fusion of CT and SRS indicating that part of the liver metastasis (arrowheads) is devoid of somatostatin receptors, probably representing necrotic tissue. The metastasis in the right liver lobe (arrows) was not detected by the abdominal CT. Note that the spleen on the right shows unspecific uptake.

ulcerations. Secretory diarrhoea is caused by the excessive release of hydrochloric acid which leads to protein denaturation in the intestinal lumen and wall. This in turn leads to a partial villous atrophy as well as malabsorption and steatorrhoea.

Diagnosis

Based on the clinical features given above, the final diagnosis is made by both laboratory testing and imaging procedures. The biochemical diagnosis is traditionally established if: unstimulated gastric acid secretion (BAO, basal acid output) exceeds 15 mval/h (more than 5 mval/h after partial gastric resection) together with an increased gastrin level of more than 150 pg/ml; high serum gastrin levels (more than 1000 pmol/ml) exist, and achlorhydria or hypochlorhydria is excluded [123, 143]. In patients with moderately high gastrin levels (150 to 1000 pg/ml) the diagnosis is made using a secretin-challenge provocation test (2 U/kg body weight). An increased gastrin level of

more than 200 pg/ml is pathognomonic. In rare cases, a gastrinoma can be only diagnosed by a pathological secretin test in the absence of a raised basal gastrin concentration [144]. However, positive secretin tests together with hypochlorhydria have been reported in only a few cases. The use of 24-hour transnasal pH-metry presenting unregulated pH-decrease below 4, particularly at night, may replace gastric acid secretion measurement.

Hypergastrinaemia is most often observed in patients treated with proton-pump inhibitors and H 2-receptor antagonists, and, less commonly, in patients with chronic atrophic gastritis, pernicious anaemia, hypercalcaemia, short-bowel syndrome, and renal failure. Usually the serum gastrin level does not exceed 500 pg/ml. However, in these cases, the secretin test will be negative. Due to the high frequency of MEN 1 associated with gastrinomas, serum prolactin, calcium, and phosphate concentrations should be analysed in parallel for the diagnosis of a prolactinoma and/or primary hyperparathyroidism [120, 140].

Imaging procedures

After the biochemical diagnosis has been established, the location and size of the primary, its local spread, as well as lymph node and liver metastases have all to be considered. Intrapancreatic gastrinomas are usually less than 2 cm in diameter at initial diagnosis. Between 80 and 90% of tumour lesions can be detected in the so-called gastrinoma triangle (cranial axis: cystic and common bile duct; caudal axis: distal two-thirds of the duodenum and medial axis: border of the pancreatic head and body). Most are located at the right side of the superior mesenteric artery. In those patients with a primary tumour located outside the pancreas (especially duodenum), the diagnosis is even more difficult. Only the EUS and SRS (see Figure 58.13) imaging modalities possess sensitivities between 85 and 90% [125, 128]. When these two procedures are combined, almost all tumours are detectable. For IOUS and intraoperative palpation, sensitivities range from 70 to 90%. In cases of suspected duodenal gastrinomas, intraoperative transduodenal illumination has the highest sensitivity, even allowing the detection of lesions in the few millimetre range. US and CT usually suffice for the detection of liver metastases (Figure 58.16). However, SRS and MRI represent the most sensitive methods for detecting the bony metastasis most frequently observed in neuroendocrine foregut tumours.

Therapy

The therapy of choice is surgery with a curative intent. Postoperative cure has been reported in more than 50% of cases (40–90%) [145]. In contrast to sporadic gastrinomas, patients with MEN 1 should be submitted to surgery only in selected cases [121, 145]. This stems from the finding that patients with MEN 1 develop multiple tumours at different times. In addition, different clinical courses are observed between families. Thus, symptomatic therapy with antisecretory agents represents the first treatment of choice (see Table 58.17) [141, 146, 147]. About 50% of all patients are not amenable to curative surgery. Provided tumour progression is evident, these patients should be treated with systemic chemotherapy using streptozocin in combination with 5-FU or doxorubicin. Objective response rates of approximately 50% have been reported, together with a survival benefit of 12 years in two phase-III studies [131, 133]. An alternative or sequential treatment option—particularly for pancreatic NET—is targeted treatment by either everolimus or sunitinib which have both proven a substantial prolongation of progression-free survival of pancreatic NET in phase III trials (see Table 58.18) [131, 133].
Fig. 58.15 Endoscopic appearance of NET-manifestations. (A) Small bulbar duodenal ulcer in Zollinger–Ellison syndrome (ZES). (B) Atypical, postbulbar duodenal ulcer in ZES (arrow), recognize small intestinal Kercking's folds. (C) Small ileal NET (arrow). (D) Large ileal NET protruding into the caecum (arrow).
Fig. 58.16 Imaging diagnosis of a pancreatic NET metastatic to the bone. (a) Scintigraphic bone scan (SRS) showing a faint uptake in a bony metastasis located in the left shoulder (arrow). Note that the primary tumour and the liver metastasis had been resected. (b) No bony lesion was visualized in the left proximal humerus on conventional radiography. (c) However, magnetic resonance imaging of the left shoulder demonstrated a bony metastasis in the left humerus. Note that a bony metastasis can be missed by conventional radiography.

Patients who are unresponsive to chemotherapy and who have a functional tumour state unresponsive to extensive acid suppression with proton-pump inhibitors (PPIs) may be subjected to embolization of liver metastases, provided the major tumour burden is confined to the liver [134–136]. It is debatable whether embolization has to be performed with or without a chemotherapeutic agent (e.g., streptozocin or doxorubicin) coupled to an embolizate [146].

VIPoma/Verner–Morrison syndrome

NETs secreting vasoactive intestinal polypeptides (VIP) (VIPomas) occur in later life, affecting women slightly more often than men. Tumours are usually localized in the pancreatic head. They are clinically characterized by extreme secretory diarrhoea caused by the excessive release of VIP, which results in dehydration, hypochlorhydria/achlorhydria, and hypokalaemia [121]. This syndrome was first described by Priest and Alexander followed by Verner and Morrison one year later. Since the diarrhoea clinically resembles cholera, VIPoma is also termed 'pancreatic cholera' or WDHA syndrome (watery diarrhoea, hypokalaemia, and achlorhydria/acidosis). Whereas secretory diarrhoea presents the diagnostic hallmark, other symptoms include dehydration (100%), weight loss (100%), abdominal pain (60%), and flushing (20%). VIPomas are also observed in a small percentage of patients with MEN 1. Diagnosis is made on the basis of a stool volume of more than 1 litre as well as an increased VIP plasma concentration. Hypokalaemia (100%), hypochlorhydria (70%), hypercalcaemia (40%), and hypoglycaemia (20%) are also observed.

Imaging procedures

Tumours are usually large (more than 3 cm) at presentation, often located in the pancreatic tail, and are metastatic in two-thirds of all cases. Conventional imaging procedures such as US, CT, and MRI usually suffice to determine the tumour extent [121].

Antisecretory treatment using somatostatin analogues, such as octreotide or lanreotide, represent the therapy of choice (see Table 58.17). A reduction of the stool volume is usually observed within hours. In advanced cases, unresponsive to somatostatin analogues, (chemo)embolization for liver metastases, cytoreductive therapy using streptozocin together with 5-FU or doxorubicin, or debulking surgery may be considered (see Table 58.18) [148, 149]. For proliferation control, targeted treatments may also be considered (see 'Medical therapy' section below). For resectable tumours, surgery with a curative intent represents the therapy of choice [141, 147].

Somatostatinoma

Due to its many and varied functions, somatostatin secreted by neuroendocrine tumours (somatostatinomas) may cause diabetes mellitus, diarrhoea/steatorrhoea, gallstones, and hyperchlorhydria. In addition, weight loss might also be found as a characteristic clinical feature [121]. However, a large series of somatostatin-producing NET has not been able to identify any patient presenting with the postulated specific clinical syndrome, thus challenging the latter [121]. Somatostatin-producing NEN are considered slow growing in comparison to other functional neuroendocrine tumours. Diagnosis is made by the detection of increased serum somatostatin levels. Primary tumours are often found at a pancreatic or duodenal, mostly periampullary, location. At first presentation, pancreatic somatostatin-producing NEN are frequently already large in size and metastatic (90%). Thus, conventional imaging procedures allow complete staging of the tumour extent. Extrapancreatic tumours are usually smaller in size and metastatic in only 50% of cases. Extrahepatic somatostatinomas are often found in the duodenum, especially in the region of the papilla. In the latter case, an association with von Recklinghausen's (neurofibromatosis type 1, NF1) disease has been described. Tumours in the duodenal wall are difficult to localize; therefore, conventional imaging procedures, with the exception of endoscopy and endoscopic ultrasound, may miss the lesion. Due to its common location in the foregut, surgical exploration may be considered in well-documented patients whose diagnosis is based solely on the results of biochemical testing. Treatment strategies adhere to the principles of pancreatic NEN.

Glucagonoma

Glucagon-secreting neuroendocrine tumours (glucagonomas) may present with skin lesions. A typical skin rash of necrolytic migratory erythema is observed, together with reduced glucose tolerance or diabetes mellitus. Moreover, thrombotic complications, anaemia, and psychiatric disturbances are often found. Serum concentrations of all amino acids, especially those generated by gluconeogenesis, are reduced and thus rather pronounced weight loss is frequently observed due to protein catabolism. Diagnosis is made on the basis of an increased serum glucagon level of more than 1000 pg/ml. Most primary tumours are found in the pancreas (especially body and tail). An association with MEN 1 has to be considered [121]. At presentation, tumours are usually already large (5–10 cm) and can be localized as mentioned above. Therapy includes the standard regimens used to treat other neuroendocrine tumours. Diabetes mellitus can usually be treated with oral antidiabetics; only 25% of patients require insulin treatment. Peri- and postoperative antithrombotic therapy is necessary to prevent thrombotic complications in patients undergoing surgery. Somatostatin analogues can improve skin lesions, but do not affect diabetes mellitus. Chemotherapy and targeted therapies as employed for the treatment of other pancreatic neuroendocrine tumours may be considered (see Tables 58.17 and 58.18) [147, 148, 150].

ACTH-producing tumours

Both well-differentiated and dedifferentiated neuroendocrine tumours may secrete ACTH, leading to a paraneoplastic Cushing's syndrome. In some rare cases, a Zollinger–Ellison, or even a carcinoid syndrome, may coexist. The prognoses for patients varies. These tumours are often large at presentation, proliferate variably, and may therefore not be amenable to curative or even debulking surgery. However, some small undifferentiated neuroendocrine carcinomas in the lung may present at early stage with a paraneoplastic Cushing's syndrome. Therapy with somatostatin analogues or chemotherapy using streptozocin and either 5-fluorouracil or doxorubicin may be of use in the case of NET (G1/2) [147, 148, 150]. In dedifferentiated NEC (G3), treatment with cisplatin and etoposide (VP-16) appears to be palliative in only a few cases. Non-suppressibility of cortisol by dexamethasone is diagnostic. ACTH may be either normal (but elevated with respect to the cortisol concentration) or elevated. Since tumours are large, conventional imaging procedures suffice for tumour staging in most cases. Therapy should be palliative, treating Cushing's syndrome with ketoconazole or metyrapone (see Tables 58.17 and 58.18) [151]. In the case of bronchial NEN, however, tumour localization may be difficult as the tumour is small and manifests clinically with a Cushing's syndrome. In these cases, SRS or either Ga-DOTATOC/TATE- (for NET) or fluoro-18-D-glucose-FDG PET/CT (for NEC) may be of help [152]. Differentiation of Cushing's syndrome and pituitary-derived Cushing's disease may be difficult.

Growth hormone-releasing hormone-secreting neuroendocrine tumours

Growth hormone-releasing hormone (GHRH)-secreting neuroendocrine tumours (GHRHomas) are extremely rare. They occur primarily in the pancreas (30%), lung (50%), and small intestine (10%), with most pancreatic GHRHomas located in the pancreatic tail. Some 30% of all GHRHomas occur together with MEN 1. At presentation, tumours are usually larger than 5 cm and, relatively commonly, occur together with gastrinomas. Based on the hypersecretion of GHRH, acromegaly is the leading clinical sign. Diagnosis is usually made by detecting the presence of both a pancreatic tumour and acromegaly. Cushing's syndrome together with Zollinger–Ellison syndrome can be observed in approximately 40% of all patients. However, most cases are diagnosed retrospectively after pituitary surgery for a supposed growth hormone (GH)-secreting pituitary tumour, since histology identifies somatotrophic hyperplasia rather than adenoma tissue. Biochemical testing should demonstrate non-suppressibility of GH by an oral glucose load in addition to a low GHRH concentration. Tumour localization and treatment are the same as for glucagonomas, with somatostatin analogues as the preoperative first-line treatment [121].

Other functional tumours

Due to the extremely low incidence of other functional neuroendocrine tumours (e.g., neurotensinomas), the reader is directed to Öberg [141] and Kulke and Mayer [153].

Neuroendocrine tumours of the intestine

Carcinoid syndrome/'serotoninomas'

Neuroendocrine tumours of the distal small intestine are characterized by the synthesis and release of low molecular-weight neurotransmitters (e.g., serotonin) as well as neuropeptides (e.g., tachykinins). When released in an unregulated mode and in excessive amounts into the bloodstream, these secretory compounds as well as many other (so far unidentified) factors lead to the so-called carcinoid syndrome. Approximately 80% of all neuroendocrine tumours of the distal small intestine (midgut origin) become functional when metastases are formed (see Figure 58.15C and 58.15D). Typically, these tumours grow slowly, reflecting WHO-grade 1 or 2. Usually, this slow tumour progress leads—even in metastatic disease—to a median overall survival (especially in the elderly) of up to 10 or even 20 years [154–156] . Therefore, patients with midgut tumours have a better prognosis compared to those with foregut tumours (see Table 58.14). The incidence of NET of the small intestine (formerly termed carcinoids of the midgut) is approximately 1.0 per 100 000 of the population worldwide, affecting middle or older ages and both sexes equally [154]. Primary tumours are usually small (less than 1 cm), solitary to multiple, and thus often escape imaging procedures (see 'Diagnosis' section below). Ileal and jejunal carcinoids are common and metastasize earlier than the most common appendiceal and rectal neuroendocrine tumours.

Diagnosis

Diagnosis is first accomplished by a clinical history of at least one of the symptoms observed in the carcinoid syndrome [157]. Symptoms of the carcinoid syndrome vary, with diarrhoea and flushing observed in approximately 80% of all patients at initial presentation [154, 157]. Bronchial wheezing as in asthma is observed in only less than 10% of all cases [154, 157]. Flushing is characterized by a reddening of the upper part of the body, particularly affecting the face, neck, and the upper part of the sternum; teleangiectasias may remain permanently in some patients. In advanced cases, functional NET of the small intestine can manifest with severe flushing, leading to a loss of consciousness combined with low or high blood pressure, all contributing to the clinical picture of the so-called malignant flush. Together with an endocardial fibrosis (30–40% of all cases), cardiac arrhythmias and severe right heart insufficiency are observed [154, 157]. In patients with local disease, the 10-year survival rate is more than 80% while it decreases to 50–60% in metastatic patients [155, 158]. With the advent of effective antisecretory treatment, endocardial fibrosis is often the life-limiting factor, progressing independently of symptom control.

Biochemical diagnosis is made by the determination of 5-hydroxyindoleacetic acid (5-HIAA) levels in urine (sampled for 24 h) and chromogranin A levels in serum (see Table 58.12). To avoid false-positive 5-HIAA results, certain precautions concerning food intake, prior and during urine sampling, have to be observed. This includes the avoidance of foods containing serotonin, such as pineapples, bananas, cheese, etc. [142, 159]. Imaging diagnosis is made by transabdominal ultrasound and computed tomography. For identification of the primary tumour, classic enteroclysis according to Sellink can be used. Somatostatin receptor scintigraphic scan (SRS) and the even more sensitive Ga-DOTATOC/TATE-PET/CT will be useful for identifying metastases and also the primary. MRI is useful for detecting small volume and diffuse metastatic disease to the liver or the bones; the use of liver-specific imaging techniques (contrast-media enhanced or diffusion weighted imaging) can significantly improve imaging results and thereby influence therapeutic management decisions (Figure 58.17) [121].

Therapy

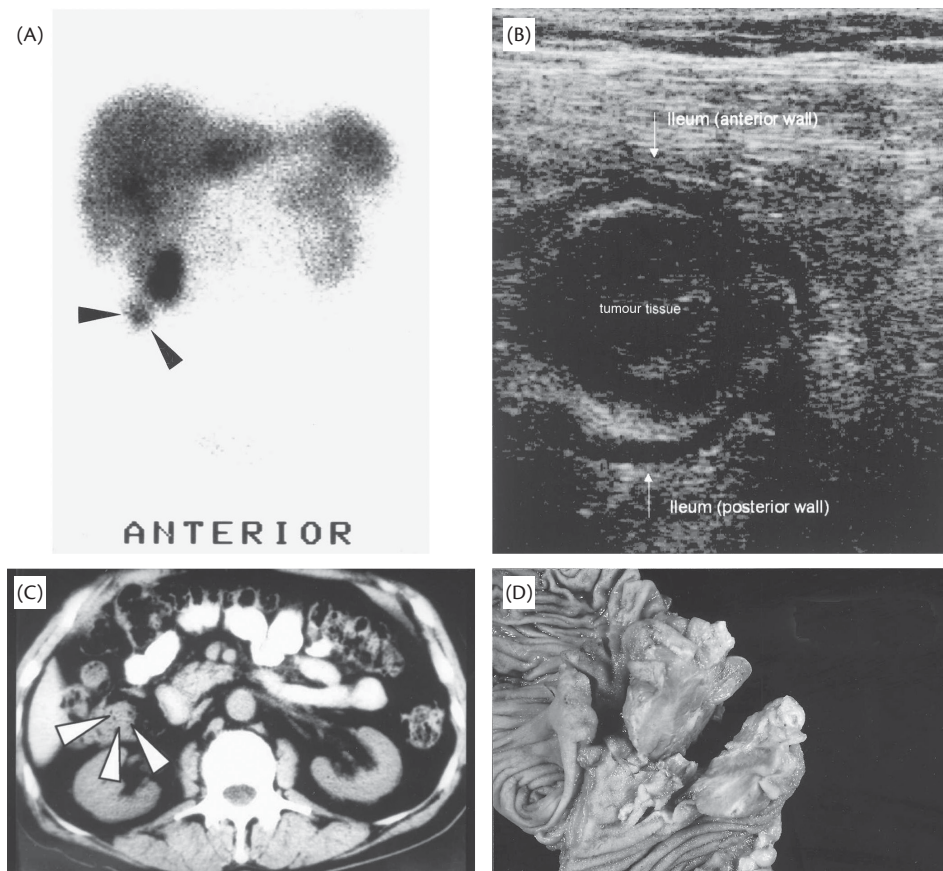
Locally or locoregionally confined NEN of the small intestine should in general be surgically (but not endoscopically) resected [160]. Appendiceal carcinoids—a special subgroup—are observed during 0.3% of all appendectomies [155]. These tumours are practically always non-metastatic and are cured by surgery. Tumours tend to calcify with increasing age, especially when located in the tip of the appendix. Neuroendocrine tumours located in the appendiceal base (10%) have a worse prognosis. Despite a tumorous infiltration of the serosa and surrounding fatty tissue, only tumours larger than 1–2 cm in diameter appear to become metastatic and therefore these should be resected using surgical oncological techniques [121, 156]. In practical terms, appendiceal carcinoids incidentally found by appendectomy should only be considered for reoperation when they are larger than 1 cm, located at the appendiceal base, and infiltrating neighbouring structures. Tumour infiltration by the mesoappendix and vessels, however, is a clear indication for (extended) ileocaecal resection. An extended right hemicolectomy should be performed in cases of extensive lymph node metastasis [121]. In the elderly patient, even metastatic tumours tend to grow extremely slowly. Thus, surgery should only be considered in this subgroup of patients when obstructive tumour growth is either imminent or apparent. If somatostatin analogue therapy is planned, surgery combined with a prophylactic cholecystectomy should be performed to prevent the development of cholecystolithiasis (gall-stone formation is one of the possible side effects of somatostatin and its analogues).


Fig. 58.17 Imaging of a neuroendocrine ileal primary. (A) Positive somatostatin receptor scintigraphic scan (SRS) in a neuroendocrine tumour of the ileum (arrowheads). (B) Abdominal CT of the abdomen demonstrating the neuroendocrine tumour in the ileum. Note that SRS was used for guided diagnostics in (A), i.e., CT was performed after localization of the tumour by SRS. (C) Transabdominal ultrasound also demonstrating the ileal primary. (D) Resected specimen demonstrating the ileal primary.

The value of debulking surgery, particularly in patients with multiple liver metastases, is questionable [121, 158, 161–163]. Perioperative treatment with somatostatin analogues is highly recommended for patients with a carcinoid syndrome, as a carcinoid crisis may be provoked during intraoperative tumour manipulation. Patients who are not candidates for surgery should be treated primarily with biotherapy (namely, somatostatin analogues and interferon-a), provided tumour progression has been verified during a treatment-free observation period (usually for longer than 3–6 months) (see Tables 58.17 and 58.18) [147, 164–166]. Only in patients unresponsive to biotherapy may chemoembolization or even chemotherapy be tried (Figure 58.18). However, only low response rates (less than 30%) are observed using the latter therapeutic regimen (see also 'Medical therapy' section for further details) [132, 141, 147, 167].

Non-functional neuroendocrine tumours of the pancreas and intestine

Introduction

Symptoms and signs

Non-functional neuroendocrine tumours are characterized by the hypersecretion of polypeptides or peptides (e.g., chromogranin A or pancreatic polypeptide (PP)) not causing a specific clinically manifest symptomatology [123, 141, 142, 168]. Approximately 50–65% of all neuroendocrine tumours are non-functional.

Primaries are most commonly located in the rectum and pancreas; however, they can also be found in other locations such as the small and large intestine and even in the ovary, prostate, and liver. Non-functional NEN manifest clinically only when a luminal obstruction of the intestine, the bile duct, or even of the urinary tract is observed, or when larger tumor masses are observed. In some cases, abdominal pain can be the presenting symptom due to metastatic mesenteric root infiltration. In this case, intestinal absorption is often impaired. Rectal NEN are usually small (more than 1 cm), yellow-greyish in colour, and located in the submucosa. Almost all rectal NEN occur 4–13 cm proximal of the dentate line as solitary tumours [121]. Often, they are removed endoscopically.

Diagnosis

Due to the lack of functionality/hormonal activity, specific symptoms and syndromes are missing. Therefore, patients present at the first visit with unspecific symptoms related to:

1. liver metastases (protrusion of the right upper abdomen and/or abdominal pain due to an extended liver capsule);

2. gastrointestinal obstruction, an acute abdomen, complete or incomplete mechanical obstruction;

3. obstruction of the biliary and/or pancreatic tract (jaundice, acute pancreatitis); and

4. fatigue and weight loss.
Fig. 58.18 Imaging diagnosis of liver metastases. (A) Computed tomogram of multiple liver metastases visualized using an intravenous contrast agent. (B) Angiographic detection also demonstrates multiple hypervascularized metastases of variable size. Note the large lesion in the upper left of the image. Hypervascularized lesions can be treated by (chemo)embolization.

The initial diagnosis of a non-functioning NET is frequently made by the ultrasonic detection of liver metastases in patients presenting with non-specific abdominal symptoms. After histological diagnosis staging with standard imaging modalities (US, CT, or MRI) provides information on the extent of tumour spread and tumour volume [121, 153, 169]. Recently, SRS and PET/CT have been increasingly used as the first imaging procedure since most non-functional tumours are positive by this functional imaging procedure [154, 157, 142, 169]. A whole-body scan allows 'guided diagnostics' for consecutive, selective imaging procedures or even allows somatostatin receptor imaging and cross-sectional imaging at the same time ('one-stop imaging') (see Figure 58.14). Non-functional NET of the stomach, duodenum, and pancreas are best visualized using EUS, since this has the highest sensitivity for detecting primary tumours and local infiltration, particularly when larger vessels and lymph nodes are involved. US, CT, and MRI are utilized for determining the extent of distant metastases [110, 144].

Therapy

Since the natural clinical course of non-functional tumours is similar to that of functional tumours, therapy follows the same guidelines as for the latter [144].

NEN of the stomach

Gastric NEN are an increasingly diagnosed entity due to frequent endoscopic procedures of the upper gastrointestinal (GI)-tract (Table 58.16). However, they provide a rather heterogeneous group of organ-specific neoplasms according to their pathophysiologic association to hypergastrinaemia (types 1 and 2), their association with chronic atrophic gastritis and hypochlorhydria (type1, ECLoma) or with a Zollinger–Ellison syndrome of a MEN-1-associated gastrinoma (type 2), their sporadic occurrence (types 3 and 4), and their proliferative capacity according to a Ki67-index below 20% (G1 or 2, type 3) or higher than 20% (G3, type 4, see Table 58.16). The diagnosis is usually endoscopic, followed by EUS, US, CT, MRI, and somatostatin receptor imaging for staging in cases of suspected advanced stages. The therapy is usually oncologic resection (which may include endoscopic resection in early stage cases of type 1 and 2 gastric NET if larger than 1 cm but smaller than 2 cm). The palliative treatment options adhere to the general principles of treatment of advanced NEN although data are almost unavailable [110, 144].

Principles of the therapy of GEP-NEN

Surgery

For all GEP-NEN, surgery represents the therapy of first choice bearing the only potential for long-term cure. In patients with a known primary tumour and only local spread, radical surgery has to be performed to remove the primary as well as lymph nodes following the same standard oncological procedures used for resecting adenocarcinomas within the GI tract [158, 161–163, 170]. Liver transplantation may only be considered in very few and highly

Table 58.16 Subclassification of gastric NEN

	Type 1	Type 2	Type 3	Type 4
Prevalence of all gastric NEN [%]	70–80	5–6	10–20	<5
Tumour characteristics	Small (<1–2 cm), in 65% multiple, 78% polypoid	Mostly small (<1–2 cm) and multiple, polypoid	Solitary, large (>2cm), polypoid and ulcerated	Solitary, large (>2cm), polypoid, mostly ulcerated
Associated disease	Chronic atrophic gastritis (CAG)	Gastrinoma and ZES MEN 1	None	None
WHO classification	G1/2-NET	G1/2-NET	Mostly G2-NET	G3-NEC
Serum gastrin levels	↑	↑↑	Normal	Normal
Gastric pH	↑↑	↓↓	Normal	Normal
Metastases [%]	2–5	5–15	30–80	50–100
Estimated tumour-related deaths [%]	0	<10	25–30	60–95

selected instances of unresectable hepatic metastases arising from intestinal or pancreatic GEP-NET (G1/2) with lasting evidence of absent extrahepatic disease (possible only after successful and complete primary tumour resection) [160, 171–179].

Medical Therapy

Medical treatment of GEP-NEN generally covers two biological aspects of the disease: control of hormone hypersecretion symptoms (i.e. functionality, Table 58.16) and control of proliferation.

While specific symptom management (i.e. anti-hormonal) needs to be considered according to the respective functional syndrome (Table 58.17), medical antiproliferative treatment (Table 58.18) is considered according to NEN-grading and primary tumour localization. In any case, surgical resectability needs to be ruled out prior to treatment initiation.

Biotherapy

The use of pharmacologically modified biological peptides (such as the somatostatin analogues (SSA) octreotide, lanreotide, or pasireotide) and recombinant human interferon-α (IFN-α) or its PEGylated form (PEG-IFN-α) is usually termed biotherapy in contrast to chemotherapy. Although biologically, biotherapy also represents a targeted approach against specific NET-cell targets, SSA and IFN-α are usually not included in the term 'molecular targeted therapy' (see 'Molecular targeted therapy' section).

Somatostatin analogues

Somatostatin analogues (SSA) are synthetic derivatives of human somatostatin-14, with half-lives ($t\frac{1}{2}$, 180–210 min) greatly exceeding that of the naturally occurring somatostatin ($t/\frac{1}{2}$, 2–3 min). Somatostatin and its analogues (octreotide, lanreotide, and pasireotide) inhibit the release of hormones, neuropeptides, and neurotransmitters from neuroendocrine cells of the GEP system by activating somatostatin receptors on the surface of NET cells. While octreotide and lanreotide act primarily through somatostatin receptors subtype 2 and 5, pasireotide is less selective and also binds to subtypes 1 and 3; by this pasireotide may mediate additional effects for symptom and proliferation control currently

Table 58.17 Symptom management for functioning NEN

Carcinoid syndrome CS	Somatostatin analogues (SSA) effectively control hypersecretion of serotonin and other mediators of CS
	Somatostatin receptor subtype-specific SSA:
	◆ Octreotide: 50–500 µg s.c. bid or tid
	◆ Octreotide long-acting release LAR: 10–30 mg i.m., monthly
	◆ Lanreotide autogel: 60–120 mg deep s.c., monthly
	◆ Peri-interventional continuous i.v. infusion: initial 100 µg bolus, then 50 µg per hour; not approved but common practice
	Somatostatin receptor-non-specific SSA:
	◆ Pasireotide: 600–1200 µg s.c. bid; not approved
	Interferon-alpha (IFN-α) effectively controls hypersecretion of serotonin and other mediators of CS:
	◆ IFN-α2b: 3–5 Mio Units s.c., three times weekly
	◆ PEG- IFN-α2b: 90–180 µg s.c., once weekly
	Tryptophane hydroxylase inhibitor telotristate etiprate specifically inhibits synthesis of serotonin: not approved, under development
Insulinoma syndrome (Whipple's triad)	Diazoxide controls insulin hypersecretion by inhibiting K_{ATP}-channels:
	◆ 25–150 mg bid or tid
	SSA may control insulin hypersecretion:
	Somatostatin receptor subtype-specific SSA:
	◆ Octreotide and lanreotide: for dosing see CS
	Somatostatin receptor-non-specific SSA may very effectively control insulin hypersecretion:
	◆ Pasireotide: 600–1200 µg s.c. bid; not approved, under development
	Everolimus may provide additional control of insulin hypersecretion in refractory cases not amenable to surgical treatment:
	◆ 5–10 mg p.o. daily; not approved, individual approach
Zollinger–Ellison syndrome ZES (gastrinoma)	Proton-pump inhibitors (PPI) very effectively control gastric acid hypersecretion of ZES:
	◆ Pantoprazole: 40 mg p.o. tid, up to six times daily
	◆ Omeprazole: 40 mg p.o. tid, up to six times daily
	◆ Esomeprazole: 40 mg p.o. tid, up to six times daily
	Sufficient gastric acid suppression may be monitored by use of 24-hour pH-metry
	SSA may control hypersecretion of gastrin in cases of insufficient control by PPIs
	Somatostatin receptor subtype-specific SSA:
	◆ Octreotide and lanreotide: for dosing see CS
Glucagonoma syndrome	Standard antidiabetic treatment
	SSA effectively control hypersecretion of glucagon
	Somatostatin receptor subtype-specific SSA:
	◆ Octreotide and lanreotide: for dosing see CS

Table 58.17 Continued

Verner–Morrison syndrome (VIPoma)	SSA effectively control hypersecretion of VIP
	Somatostatin receptor subtype-specific SSA:
	◆ Octreotide and lanreotide: for dosing see CS
	Additional standard antidiarrhoeal treatment may be necessary:
	◆ Loperamide: 2–4 mg p.o. tid
	◆ Tinctura opii 1%: titrate according to effect
	Monitoring of blood bicarbonate/base excess by blood gas analysis and subsequent substitution of bicarbonate may be required in individual cases
Atypical carcinoid syndrome	SSA may effectively control hypersecretion of histamine
	Somatostatin receptor subtype-specific SSA:
	◆ Octreotide and lanreotide: for dosing see CS
	Anti-histaminic drugs may provide some additional anti-histaminergic symptom control
Ectopic Cushing's syndrome (ACTHoma)	Ketoconazole can provide control of steroid hormone synthesis until definitive treatment:
	◆ 50–300 mg p.o. tid according to effect
	SSA may provide some additional control of ACTH hypersecretion
	Somatostatin receptor subtype-specific SSA:
	◆ Octreotide and lanreotide: for dosing see CS
	Somatostatin receptor-non-specific SSA effectively control ACTH hypersecretion in Cushing's disease and may be tried in refractory cases of peripheral, autonomous ACTH secretion:
	◆ Pasireotide: 600–1200 µg s.c. bid; not approved, under development
Somatostatinoma	No specific antisecretory treatment available
	Standard antidiabetic treatment in case of diabetes mellitus
	Standard endoscopic (ERCP) or surgical treatment for gall stone disease

under investigation. Hence, specific symptoms caused by the excessive release of secretory products can be inhibited. SSAs represent the therapy of choice for the carcinoid syndrome. A subcutaneous injection of 0.05 or 1.0 mg of octreotide three times per day will usually control diarrhoea and flushing within a few hours in 50–90% of patients [147, 148, 164, 166, 180, 181]. SSA has also proved effective in control of peptide hormone secretion in glucagonomas or VIPomas (Table 58.16). Depot formulations given either intramuscularly (octreotide) or subcutaneously (lanreotide) every four weeks have been shown to control symptoms (see Table 58.16) [148]. The development of gallstones during long-term SSA therapy is observed in 10–60% of all patients [148]; however, only a small percentage of these patients become symptomatic. Further side effects include a temporary exocrine pancreatic insufficiency and initial abdominal pain, which subsides after several days of treatment [141, 147, 148]. In some cases (especially with high dosages), substitution of pancreatic enzymes due to long-term exocrine pancreatic insufficiency may have to be initiated. Pasireotide, due to its less selective mode of action may cause additional side effects, such as disturbances of glucose homeostasis including diabetes mellitus. Occasionally, a complete or partial response with SSA therapy has been observed in well differentiated G1/2-NET [148]. In general, however, SSA treatment has been demonstrated to significantly increase progression-free survival in NET from the midgut (PROMID-trial with octreotide) [182] or of gastrointestinal and pancreatic origin (CLARINET-trial with lanreotide) [147, 148, 164, 165, 183, 184]. The median time to progression varies between 14 months in the PROMID trial and 32.8 months during treatment in the CLARINET trial; However, these trial designs are not directly comparable and thus the results cannot directly be compared.

Therefore—beyond antisymptomatic treatment—SSA may also be considered for long-term antiproliferative control in patients who do not need a cytoreductive strategy although not all countries have approved these drugs for that indication. In late 2014, the US FDA approved lanreotide for the treatment of patients with unresectable, well- or moderately- differentiated, locally-advanced or metastatic GEP-NETs to improve progression-free survival.

Interferon-α

Interferon-α (IFN-α) represents an alternative treatment to the use of SSA as monotherapy for metastatic neuroendocrine tumours of the GEP system [150, 185, 186]. Apart from its known antiviral action, an antiproliferative effect for IFN-α has also been demonstrated [186, 187]. Studies show that IFN-α has a direct action on the cell cycle as well as on chromogranin A expression. In contrast to SSA, control of symptoms takes several days to develop [141]. Similar to SSA, stable disease can be observed in about half of all patients in whom tumour progression had been documented prior to treatment; an objective response (mostly partial remission) may, however, be observed in up to 20% of treated NET patients. A clinical response can be achieved using 5 million units of IFN-α three times per week. In contrast to SSA, side effects are more significant, including influenza-like symptoms (fatigue, myalgia, arthralgia, and headache) [141, 148, 165]. Furthermore, latent autoimmune diseases can become manifest during IFN-α treatment. Myelotoxicity, neuropsychiatric abnormalities, and fatigue syndromes may also have to be considered as side effects. In relation to the location of the primary tumour, patients with NET of the small intestine tend to respond better to IFN-α treatment than those with pancreatic or other gastrointestinal NET [141].

Table 58.18 Antiproliferative medical treatment for NEN

Systemic therapy for NET (G1/2)	
Biotherapy SSA	Somatostatin analogues (SSA) prolong regression-free survival in both small intestinal and pancreatic NET Somatostatin receptor subtype-specific SSA: ◆ Octreotide long-acting release LAR: 10–30 mg i.m. monthly ◆ Lanreotide autogel: 60–120 mg deep s.c. monthly treat until PD Side effects: nausea, vomiting, mild diarrhoea or steatorrhoea, elevated liver enzymes, gall stones, hair loss, disturbed glucose tolerance, bradycardia (rarely)
Biotherapy Interferon-alpha	Interferon-alpha (IFN-α) may induce a tumour-control in 30-40% of pNET ◆ IFN-α2b: 3–5 Mio Units s.c. three times weekly ◆ PEG- IFN-α2b: 90–180 µg s.c. once weekly treat until PD (not approved by authorities) Side effects: flu-like syndrome, fever, chills, myalgia, cephalgia, fatigue, weight loss, anaemia, leukopaenia, thrombocytopaenia, symptoms of depression, activation of autoimmune diseases
Molecular targeted therapy: Everolimus	Everolimus induces SD/PR in app. 70% and prolongs PFS against placebo from 4.6 to 11.0 months ◆ Everolimus: 10 mg daily treat until PD Side effects: stomatitis, rash, pruritus, fatigue, cephalgia, infections, oedema, loss of appetite, diarrhoea, nausea, dysgeusia, epistaxis, anaemia, thrombocytopaenia, hyperglycaemia, pneumonitis, weight loss
Molecular targeted therapy: Sunitinib	Sunitinib induces SD/PR in app. 70% and prolongs PFS against placebo from 5.5 to 14.0 months ◆ Sunitinib: 37.5 mg daily treat until PD Side effects: diarrhoea, nausea, vomiting, anorexia, stomatitis, rash, dysgeusia, hand-foot-syndrome, hair-colour-changes, fatigue, epistaxis, neutropaenia, thrombocytopaenia, hypertension, insomnia, weight loss
Molecular targeted therapy: Bevacizumab	Bevacizumab may induce prolonged PFS as a reserve medication alone or in combination with SSA or TMZ: ◆ Bevacizumab (in combination with SSA) 15 mg/kg BW, i.v. over 1–2 hours, on day 1 repeat on day 21, treat until PD (not approved by authorities) ◆ Bevacizumab (in combination with TMZ) 5 mg/kg BW, i.v. over 1–2 hours, day 1 repeat on day 15, treat until PD (not approved by authorities) Side effects: allergic reactions, nausea, vomiting, fatigue, cephalgia, thrombosis, arterial hypertension, proteinuria, wound healing defects, spontaneous GI-perforations, tumour-associated bleeding episodes
Chemotherapy: Streptozocin-based	Combination chemotherapy of streptozocin (STZ) with either 5-fluorouracil (5FU) or doxorubicin (DOX) induces PR in 30–40% and SD in additional 20–30% ◆ STZ/5FU: STZ 500 mg/m² BSA, i.v. over 1 hour, days 1–5 5FU 400 mg/m² BSA, i.v. as bolus, days 1–5 repeat both on day 43, treat until best response or for 9 cycles ◆ STZ/DOX: STZ 500 mg/m² BSA, i.v. over 1 hour, days 1–5 DOX 50 mg/m² BSA, i.v. over 1 hour, days 1 and 22 repeat both on day 43, treat until best response or for 9 cycles CAVE: cumulative DOX-dose: 500 mg/m² Side effects: nausea, vomiting, diarrhoea, constipation, mucositis, hand-foot-syndrome, renal insufficiency, leukopaenia, neutropaenia, thrombocytopaenia, anaemia, cardiotoxicity (DOX)
Chemotherapy: Temozolomide-based	Combination chemotherapy of temozolomide (TEM) with capecitabine (CAP) induces PR in 40–70% and SD in additional 20% ◆ TEM 200 mg/m² BSA, dialy p.o., days 10–14 CAP 750 mg/m² BSA, bid p.o., days 1–14 repeat both on day 29, treat until PD (not approved by authorities) Side effects: nausea, vomiting, diarrhoea, mucositis, hand-foot-syndrome, fatigue, anaemia, leukopaenia, neutropaenia, thrombocytopaenia, herpes viridae infections, elevated liver enzymes This may also be applied to NET-G3 or NEC with a Ki67-index below 55%

Table 58.18 Continued

Systemic therapy for NEC (G3)	
Chemotherapy: Cisplatin-based	Combination chemotherapy of cisplatin with etoposide (VP16) induces CR/PR in 60–70% NEC with TTP of app. 9–11 months
	◆ Cisplatin 45 mg/m² BSA, i.v. over 1–2 hours, days 2 and 3
	Etoposide 130 mg/m² BSA, i.v. over 1–2 hours, days 1–3
	repeat both on day 29, treat until PD (not approved by authorities)
	Side effects: nausea, vomiting, diarrhoea, mucositis, hand-foot-syndrome, distal polyneuropathy, hearing loss, renal insufficiency, leukopaenia, neutropaenia, thrombocytopaenia, anaemia
Chemotherapy: Oxaliplatin-based	Combination chemotherapy of oxaliplatin (OX) with either 5-fluorouracil (5FU) and folinic acid (FOL) or capecitabine (CAP) may induce tumour control in 30–40% of rapidly progressing pNET or such with high tumour load
	◆ FOLFOX: OX 85 mg/m² BSA, i.v. over 2 hours, day 1
	FOL 200 mg/m² BSA, i.v. over 2 hours, days 1 and 2
	5FU 400 mg/m² BSA, i.v. as bolus, days 1 and 2
	5FU 600 mg/m² BSA, 22-hour-infusion, days 1 and 2
	repeat both on day 15, treat until PD (not approved by authorities)
	◆ CAPOX: OX 130 mg/m² BSA, i.v. over 2 hours, day 1
	CAP 1000 mg/m² BSA, bid p.o., days 2–15
	repeat both on day 21, treat until PD (not approved by authorities)
	Side effects: nausea, vomiting, diarrhoea, constipation, mucositis, hand-foot-syndrome, distal polyneuropathy, leukopaenia, neutropaenia, thrombocytopaenia, anaemia, mild renal insufficiency
Chemotherapy: Irinotecan-based	Combination chemotherapy of irinotecan (IRI) with 5-fluorouracil (5FU) and folinic acid (FOL) may induce tumour-control in 30–40% of NEC as a second-line therapy
	◆ FOLFIRI: IRI 180 mg/m² BSA, i.v. over 2 hours, day 1
	FOL 400 mg/m² BSA, i.v. over 2 hours, day 1
	5FU 400 mg/m² BSA, i.v. as bolus, day 1
	5FU 1200 mg/m² BSA, 46-hour-infusion, days 1 and 2
	repeat both on day 15, treat until PD (not approved by authorities)
	Side effects: nausea, vomiting, diarrhoea, mucositis, hand-foot-syndrome, distal polyneuropathy, oropharyngel dyskinesia, leukopaenia, neutropaenia, thrombocytopaenia, anaemia

SSA and IFN-α combination therapy

A combination of IFN-α with SSA has been used to control symptoms as well as tumour-cell proliferation. So far, a synergistic effect has been demonstrated only in a relatively small number of cases. However, patients with progressive disease treated with monotherapy can be prescribed combination therapy, albeit for a limited time [188–190, 191].

Molecular targeted therapy

Molecular targeted therapy addressing signal transduction pathways within the NET cell have recently become a treatment option for well-differentiated G1/2-NET. Their mode of actions include inhibition of growth factor signalling (sunitinib, everolimus), inhibition of metabolic signalling (everolimus), inhibition of proliferation and induction of apoptosis (sunitinib, everolimus), and inhibition of angiogenesis (sunitinib, everolimus).

Everolimus

Recently, the mTOR-inhibitor everolimus has been extensively studied in G1/2-NETs that were not amenable to curative surgical treatment. The RADIANT-3 trial in advanced pancreatic NET demonstrated a significantly prolonged duration of progression-free survival in everolimus-treated EPT patients in comparison to placebo-treated patients of 11 versus 5 months when actively progressing patients were treated; this led to authority approval of everolimus in progressive pancreatic NET [192]. In non-pancreatic NET everolimus has also been extensively studied and showed some effect in combination with octreotide in patients with progressive non-pancreatic NET; predefined statistical significance was, however, not met in this placebo-controlled phase III trial although longer follow-up is underway. Everolimus is therefore under further investigation in the treatment of non-pancreatic NET as is the mTOR-inhibitor temsirolimus [193].

Sunitinib

In a study design similar to that used with everolimus, the multiple tyrosine kinase inhibitor sunitinib was studied in progressive non-functioning pancreatic NET (G1/2) in a phase III trial and demonstrated good efficacy with a prolongation of progression-free survival from 5 months in the placebo arm to approximately 11 months in the treatment group [190]. Although—as with the mTOR-inhibitors—some toxicities have to be considered, this has led to authority approval of the substance for proliferation control of progressive pancreatic NET (G1/2) [194].

Bevacizumab

The anti-vascular endothelial growth factor (VEGF)-antibody bevacizumab has also been applied to NET in several phase-II trials and is currently under investigation for this indication [195]. The mostly hypervascularized NET treatment with this antibody has

led to the proof of concept of antiangiogenic treatment in NET in a study combining pancreatic and intestinal NET [196].

Chemotherapy

In the early 1980s, chemotherapy represented the only systemic therapeutic option for the treatment of GEP-NET (G1/2). Based on the relatively high response rates (approximately 50%) achieved in the treatment of non-metastatic and metastatic insulinomas, the initial monotherapy with streptozocin has been extended to the treatment of patients with other neuroendocrine tumours, and in various drug combinations [131–133, 197]. Published data on a variety of combination therapies have demonstrated objective response rates for pancreatic NET ranging from 30 to 60%. By contrast, NET of the midgut have lower response rates (10–30%) [167]. The duration of remission is considerably shorter for patients with midgut tumours compared to those with pancreatic NET (less than 2 years). So far, the most comprehensive study of NET of the foregut showed that a combination of streptozocin together with doxorubicin is slightly superior to a combination of streptozocin plus 5-fluorouracil [133]. These findings are in contrast to those of an earlier study by the same group, which demonstrated similar response rates for both treatment regimens [131]. Thus, based on the lower side effects associated with 5-fluorouracil, streptozocin together with 5-fluorouracil is favoured by most centres [198].

In recent years, an oral combination regimen of temozolomide and capecitabine has been suggested to have efficacy in pancreatic and non-pancreatic NET. Objective radiological response rates of up to 70% and disease stabilization in the majority of the remaining patients have been observed, thus leading to a new treatment option in progressive NET. However, authority approval is not available; a prospective controlled trial is currently accruing patients in the US cooperative groups [199].

In metastatic poorly differentiated NEC (G3), a combination treatment using etoposide (VP-16) and cisplatin led to response rates in approximately 50% of patients [197]. However, objective response (in some cases even complete remissions) lasted only a few months (about 3 months) and was complicated by considerable side effects including nausea, leukopaenia, thrombocytopaenia, anaemia, and neuropathy. Other platinum-based regimens such as FOLFOX or CAPOX may be considered due to less toxicity and probably equal efficacy although no controlled comparative trial data are available [200]. As second-line treatment temozolomide- or irinotecan-based treatments have been suggested but not tested in prospective phase III trials [201].

Loco-regional and locally ablative therapies
(Chemo) embolization

Because of the frequent hypervascularization of neuroendocrine hepatic metastases, superselective occlusion of the hepatic artery represents a therapeutic option for both the control of symptoms and control of proliferation of liver metastases. During the last decade, superselective embolization, with or without chemotherapeutic agents coupled to microspheres, has shown response rates ranging from 30 to 80%. However, in inexperienced hands this technique can lead to a mortality rate of more than 5%. Studies have suggested that a combination of chemoembolization together with systemic chemotherapy can lead to response rates of up to 80% [134–136]. These promising data have still to be evaluated in prospective studies. Additional locally ablative treatment options such as radiofrequency ablation (RFA), catheter-guided [192]-Ir-irradiation (after-loading), or SIRT (selective intra-arterial radionuclide therapy with ^{90}Y) may be performed in experienced centres [190].

Peptide receptor-mediated radionuclide therapy (PRRT)

Overexpression of somatostatin receptors on the surface of tumour cells of NEN (most of them being NET-G1/2) has opened the option of peptide receptor-mediated radionuclide therapy as a highly tumour-specific treatment modality. Using either ^{90}Yttrium or ^{177}Lutetium as cytotoxic radioemitters, a tumour tissue-specific systemic treatment has become available for NET from any origin as long as there is sufficient somatostatin receptor expression on the tumour tissues evident on somatostatin receptor imaging. Retrospective and prospective cohort studies as well as one phase II trial have provided evidence for good efficacy for symptom and tumour growth control of NET in response to this treatment modality. Progression-free survival ranges from 12 months in progressive NET to over 4 years in pretreatment stable NET. Side effects like nephro-, myelo-, and gastrointestinal toxicity need to be considered but are usually well manageable. Since hitherto there are no comparative data of PRRT versus medical treatment options available, a clear-cut recommendation of when to apply PRRT within the sequelae of systemic treatments in NET is, as of now, still not possible [202–205].

Selective internal radionuclide therapy (SIRT)

A combination of a trans-arterial hepatic loco-regional treatment and locally applied radiotherapy can be achieved by combining a trans-arterial catheter approach to otherwise uncontrollable liver disease caused by NET with the advantage of radionuclide-covered microbeads or resin. The latter lead to arterial tumour vessel occlusion and the radionuclide (^{90}Yttrium) additional tumour irradiation. This approach may achieve additional control of liver disease in some advanced NET patients in experienced centres [182].

Carcinoid heart disease (CHD, Hedinger's syndrome)

Up to 30% of patients with mostly small intestinal NET suffering from the carcinoid syndrome experience an endocardial fibrosis mediated by serotonin and other mediators released by (mostly hepatic) tumour manifestations into the systemic circulation. This endocardial fibrosis can lead to thickening and retraction of the leaflets of the right ventricular valvular system and, by this mechanism, to severe life-limiting right heart failure [206]. To date, right heart valvular surgery is available for interdisciplinary treatment of this severe condition in experienced cardiothoracic surgical centres; however, a catheter-based approach to right heart valvular replacement has been reported recently [143, 207–209].

Experimental and future approaches

Novel substances like telotristat etiprate [210], pasireotide [211], temsirolimus [196], and pazopanib [212] are currently under investigation for a potential role in medical NEN treatment as well as several combination treatments with the aim to improve efficacy while not increasing toxicity. Also some comparative trials comparing either chemotherapy to targeted therapy or somatostatin analogue treatment to PRRT are currently recruiting and will provide important information in the future on the role of specific treatments within the therapy sequelae in individual patients—a hitherto unclear issue [121, 159, 213].

Summary

For appropriate prognostic and therapeutic stratification of GEP-NEN, adequate histopathological grading according to WHO criteria (Ki67-index) and clinicopathological staging according to either ENETS or UICC criteria is essential. Early and metastatic GEP-NEN can be treated by various modalities. Resection (mostly surgical but also—if accessible and feasible—endoscopic) represents the main treatment of choice, allowing the only cure of NEN disease. In patients with functional unresectable tumour disease, the control of hypersecretion (i.e. the control of symptoms) is best achieved using biotherapy with secretory inhibitors such as somatostatin analogues and interferon-α. However, in patients with documented tumour progression or where there is a lack of symptom control provided by the current biotherapy, an increase in the dose of the somatostatin analogues may be employed. Alternatively, a combination of somatostatin analogues with interferon-α can be successful in some cases. Patients with metastatic disease confined primarily to the liver and displaying significant functionality can be additionally treated by loco-regional or locally ablative techniques. Patients with pancreatic NET (G1/2) should be treated antiproliferatively when there is documented tumour progression. In such cases, streptozocin-based combination chemotherapy or molecular targeted treatments are available. There is increasing evidence that small intestinal NET (G1/2) may benefit from the antiproliferative treatment with somatostatin analogues independently from control of functionality. However, in this group fewer options are available as compared to pancreatic NET in case of progression. PRRT provides an effective antiproliferative (and in some cases symptomatic control) treatment option for all somatostatin receptor-positive NET. Novel treatments and combination as well as sequential treatments are currently under investigation. In patients with NEC-G3, platinum-based combination remains the cornerstone of treatment except for the few early resectable cases. Regular, long-term follow-up visits are essential in patients with GEP-NEN.

Cancer of unknown primary site

Nicholas Pavlidis and George Pentheroudakis

Introduction to cancer of unknown primary

Cancer of unknown primary (CUP) is considered to be a neglected and orphan disease, refractory to standard chemotherapy and of a short survival in the majority of cases. In general, both diagnostic and therapeutic approaches for these patients remain a real dilemma for practising oncologists and a continuum issue for the health care system. Clinical, translational, and basic research is still a challenge for several specialized centres worldwide. For optimal diagnosis and treatment, CUP multidisciplinary teams should be established in major referral hospitals. Today, evidence-based guidelines are of paramount importance for the optimal management of these patients and for health economic policies.

CUP represents a heterogeneous group of histologically-confirmed metastatic malignancies for which a thorough medical history and a careful physical examination along with an extensive diagnostic workup fail to detect the primary site. These tests consist of full blood count, biochemistry tests, urinalysis, stool occult blood testing, specific immunohistochemistry, imaging technology (chest X-ray, computed tomography (CT) of the thorax, abdomen and pelvis, mammography and positron emission tomography (PET) in some cases) [1, 2]. Although molecular technology with multigene profiling platforms offers high sensitivity in detecting the primary site, their use in daily practice has not yet been introduced [3].

According to NICE (National Institute for Health and Clinical Experience) the definition of CUP is divided into: (a) malignancy of undefined primary origin (before comprehensive investigation); (b) provisional carcinoma of unknown primary (before specialist review and further specialized investigations); and (c) confirmed carcinoma of CUP (no detection of primary despite (a) and (b) investigations) [4].

Epidemiology

The median age at presentation is 65 years and males are affected more commonly than females. In general, CUP accounts for 2.3–4.2% of all human malignancies and it represents the seventh to eighth most common cancer and the fourth most frequent cause of death [1, 2]. The annual age-adjusted incidence per 100 000 population in the US is 7–12 cases, in Australia 18–19 cases, and in The Netherlands 5.3–6.7 cases (Table 59.1). CUP represents approximately 40 000 new cases per year in the US and 2500 in The Netherlands [5–7].

CUP is not very well-defined as a discrete classification within the International Classification of Disease (ICD) nomenclature. The ICD codes used for CUP registrations are ICD C77–C80 [8].

Recent data from the Sweden Family Cancer Database suggest that the cause of death in CUP patients frequently matched the cancer diagnosed in a family member, implying that the metastasis had probably undergone a phenotypic change of the primary cancer. The strongest data were correlated with lung, kidney, liver, and ovarian cancers, although independent significant association was also found with other malignancies such as colorectal, pancreatic, breast, and prostate cancer [9].

An increased risk of subsequent cancers in CUP patients has been reported in both Swedish and Swiss cancer databases, ranging from 1.4–1.69 (standardized incidence ratio). Significant excess risks were observed for cancer of prostate, oral cavity, pharynx, and skin [10–12].

Biologically, CUP follows a process of type 2 progression (a malignant clone to begin with) and not of a type 1 (from a premalignant lesion to malignant lesion) [13].

CUP patients carry a unique natural history which is not similar to patients diagnosed with known primary cancers. It is characterized by an early dissemination (50% of CUP patients present with multiple sites of metastases), a short history of symptoms and signs related to metastatic lesions, an aggressive behaviour, and an unpredictable metastatic pattern. The unpredictable metastatic pattern refers to the differences in the incidence of metastatic sites at diagnosis, between known and unknown primary tumours. Pancreatic cancer presenting as CUP has a four- to five-fold higher

Table 59.1 Incidence of CUP worldwide

Country	Incidence %
Switzerland	2.3
USA	2.3
Finland	2.5
UK	2.6
Japan	3.0
Russia	3.6
Netherlands	4.0
Australia	4.2

incidence of presenting with bone and lung involvement as compared to known primary pancreatic tumours [1, 2].

Molecular biology

Chromosomal instability, oncogenes, and oncoproteins

Aneuploidy is seen in 70–90% of solid tumours and probably reflects derangements of chromosomal replication during cell division. Hedley et al. established aneuploidy in 70% of 152 CUP, without any relationship to patterns of metastatic involvement or survival [14]. Abnormalities of the short arm of chromosome 1 (1p) were reported in 12 of 13 CUP, a finding consistent with the common occurrence of 1p structural alterations in advanced solid tumours [15].

Oncogenes are overexpressed or amplified in many solid tumours. The encoded proteins favour malignant transformation and survival by activating cellular proliferation, inducing cell migration, inhibiting apoptosis, and promoting neoangiogenesis. C-Myc, Ras, and human epidermal growth factor receptor (EGFR) (HER)-2 proteins were studied by immunohistochemistry (IHC) in 26 cases of CUP and were over-expressed in less than a third of cases for any of the studied proteins [16]. Hainsworth et al. examined 100 CUP and similarly observed HER-2 overexpression in 11% of specimens, with no differences in overall survival (OS) between patients with overexpressing and non-overexpressing HER-2 tumours [17]. Fizazi et al. found HER-2 IHC overexpression in only two of 56 CUP cases (4%); with no association of HER-2 status with histological differentiation, treatment activity, or clinical outcome [18]. Rashid et al. reported HER-2 IHC expression in 68% and overexpression in 24% of 76 cases of CUP [19]. Van de Wouw et al. also observed IHC HER2 overexpression in 16 of 45 CUP cases (35%) [20].

EGFR is a transmembrane protein that recently came under scrutiny after accumulating knowledge of its role in malignant transformation. Fizazi et al. reported IHC EGFR protein overexpression in two of 56 CUP specimens (4%), whereas Rashid et al. reported it in 46 of 76 CUP samples (61%) [18, 19]. These discrepant results serve to emphasize the heterogeneity of this group of tumours. Both studies, however, failed to establish any correlation between EGFR protein staining and clinicopathological parameters or prognosis. Dova et al. studied 50 patients with CUP and found EGFR protein expression in 74% of tumours (12% with overexpression) with no prognostic utility and with absence of activating mutations in exons 18, 19, 21 [21].

In IHC studies, Fizazi et al. reported c-Kit protein overexpression in six of 56 CUP samples (11%), while Rashid et al. reported it in three of 76 cases (4%) [18, 19]. Dova et al. screened 50 CUP specimens and found c-Kit protein overexpression in 13%. Moreover, we observed no activating mutations in exon 11 of the c-*kit* and exons 12 and 18 of the *PDGFR* genes by means of PCR-single strand conformational polymorphism (SSCP) [21, 22]. In all studies, c-Kit protein expression failed to demonstrate prognostic utility for response to therapy or survival.

MET is a transmembrane receptor that is activated upon binding of hepatocyte growth factor and has been incriminated in relaying survival signals to the interior of cancer cell upon therapeutic blockade of other receptors such as EGFR and HER2. Recently, Stella et al. screened 23 patients with CUP and reported presence of activating mutations in eight tumours (30%) [23]. The CUP mutation rate of MET (30%) is strikingly higher than that reported for other known primary tumours (4%).

Tumour- and metastasis-suppressor genes and proteins

Tumour-suppressor genes encode proteins that suppress malignant transformation, survival, and metastatic dissemination by maintaining the integrity of cellular DNA and by controlling vital cell cycle processes, with the 'guardian of the genome', p53, being the most investigated. Briasoulis et al. studied IHC p53 expression in 47 patients with CUP and found strong immunoreactivity in 24 (53%) suggesting accumulation of a mutated, abnormally stable protein [24]. The expression of p53 protein by itself had no prognostic value for treatment benefit or survival. Van de Wouw et al. found no prognostic value of IHC p53 detection, present in 23 of 48 tumours [48%] in a relatively large series of CUP patients from the Netherlands, whereas Bar-Eli et al. reported p53 exon 5–9 gene mutations in 6/15 CUP (26%) [20, 25].

Metastasis-suppressor genes have been recently recognized as genes that modulate the capability of the malignant clone for systemic dissemination without affecting the primary tumour malignant transformation process. Loss of function of the metastasis-suppressor KiSS-1 was seen in several human malignancies and was correlated with advanced stage and poor prognosis. Dova et al. screened 50 cases of CUP for KiSS-1 gene mutations by PCR-SSCP and direct sequencing and found only one mutated sample (242C>G resulting in P81R) [26].

Angiogenesis and hypoxic phenotype

Hillen et al. reported that tumour microvessel density was an adverse prognostic factor for outcome in 39 patients with liver metastases of unknown primary [27]. In a more recent study, van de Wouw et al. found no prognostic value of IHC CD34 (a microvessel density marker) and VEGF-A IHC detection (26%) for the outcome of 46 patients with CUP [20]. Karavasilis et al. studied the expression of VEGF-A, the main protein mediating angiogenesis, and thrombospondin-1 (TSP-1), an inhibitor of vessel formation, in 81 patients with CUP [28, 29]. Strong expression of VEGF and its inhibitor, TSP-1, was seen 83% and 20% of tumours, respectively. Rashid et al. recently observed VEGF expression by IHC in half of 75 CUP [19]. Despite reliance on neoplastic vessels, tumours are relatively hypoxic compared to normal tissues. Recently, Koo et al. reported a hypoxic phenotype, defined by IHC expression of Hypoxia-Inducible Factor 1a (HIF1a), Glucose Transporter 1 (GLUT1), and COX2, in 25% of 69 patients with CUP tumours [30]. In those patients, the tumoural hypoxic phenotype was significantly associated with worse survival.

Collectively, these data draw the picture of a highly-active angiogenic profile of CUP metastases. Although these features are not different from those seen in several advanced malignancies of known primary site, they provide a sound basis for implementation of therapies modulating angiogenesis.

Pharmacogenomics and circulating tumour cells

Pentheroudakis et al. studied the presence of circulating tumour cells (CTC) in 24 patients with CUP by immunofluorescent detection of cytokeratins CK 8, 18, 19, leukocyte antigen CD45, and nuclear antigen DAPI [31]. CTC were observed in 15 out of 24 (62.5%) evaluable patients (median 1 CTC/million peripheral

blood mononuclear cell (PBMNC), range 0–20), while nine had no detectable CTC. The presence and number of CTCs at various cut-offs had no prognostic utility for OS or progression-free survival (log rank p > 0.05).

Souglakos et al. extracted mRNA from 62 paraffin-embedded CUP tumours and applied qRTPCR in order to study the transcription of DNA-repair, hypoxia, and cell-cycle control genes [32]. Among ten studied genes, the DNA repair gene ERCC1, the angiogenesis regulator TXR1, and the hypoxic factor HIF1a were significantly associated with patient outcome, though not with response to chemotherapeutic agents.

The cancer of unknown primary site genetic signature hypothesis

What does one mean by the term 'genuine' CUP? This refers to the possibility that a CUP tumour may possess not only a genetic signature specific for the primary site (since it unavoidably did originate somewhere in the body) but also a second genetic signature that is primary-independent, pro-metastatic, and possibly CUP-specific. This CUP multigene expression signature may be responsible for the early spread of the malignant clone to metastatic sites, regression of the primary, and distinct natural history from other common tumours and fulminant course of the disease. Whether there is a 'core' CUP signature common in all CUP tumours remains to be seen.

Overall, the search for a molecular CUP signature relied on rather random studies of single genes or proteins and did not disclose presence of a molecular trait that is a consistent CUP characteristic (Table 59.2). It is very likely that the CUP signature is complex and multigene, in which case multiplex or genome-wide expression profiling platforms should be utilized in order to identify it. In addition to genes being transcribed to messenger RNA, the complex mosaic of microRNAs, 20-nucleotide short RNA segments which regulate the translation of mRNA, is an additional layer of complexity worth investigating [33].

Pathology

Histologically, CUP is categorized into four major types. The most common type is adenocarcinoma of well- to moderate-differentiation (50%), followed by poorly or undifferentiated adenocarcinomas (30%), squamous cell carcinoma (15%), and undifferentiated neoplasms (5%). With modern immunohistochemistry undifferentiated neoplasms can be better characterized as non-specified carcinomas, neuroendocrine tumours, lymphomas, germ-cell tumours, melanomas, and sarcomas, or embryonal malignancies (Table 59.3) [1, 2].

The main diagnostic goal in CUP patients is to identify the primary site. The tools for this investigation include diagnostic pathology with specific immunohistochemistry, molecular technology, imaging technology, endoscopic workup, and occasional serum tumour markers. Molecular technology with gene profiling assays is not in routine use due to high cost and doubtful contribution to patients' outcome.

Light microscopy

Light microscopic examination, using routine staining with haematoxylin and eosin or other staining, i.e., mucicarmine, Alcian Blue, or periodic acid-Schiff, is only able to characterize cell morphology

Table 59.2 Selected publications of molecular aberrations reported in CUP

Investigator	Method	No of CUP	Molecular aberration
Hedley	Karyotypic analysis	152	Aneuploidy in 70%
Hainsworth	IHC	100	HER2 overexpression in 11%
Rashid	IHC	76	HER2 overexpression in 24%
Dova	IHC PCR	50	EGFR overexpression in 12% No EGFR gene amplification nor activating mutations
Dova	IHC PCR	50	cKIT overexpression in 13% No cKIT or PDGFR activating mutations
Stella	PCR	23	MET activating mutations in 30%
Van de Wou	IHC	48	p53 overexpression in 48%
Karavasilis	IHC	75	VEGF-A overexpression in 83% TSP1 overexpression in 20% MMP2 overexpression in 49% MMP9 overexpression in 36%
Koo	IHC	69	Hypoxic phenotype (HIF1a/ GLUT1/COX2 +) in 25%
Pentheroudakis	IF	24	CTC present in 62%
Souglakos	PCR	62	Prognostic significance for ERCC1, TXR1, HIF1a mRNA

and tumour differentiation, but it is unsuccessful in identifying the primary site.

Immunohistochemistry

Immunohistochemical investigations by using a series of monoclonal or polyclonal antibodies against several structural tissue components are very useful in identifying the tumour origin in

Table 59.3 Histological classification of CUP with the ICD-0 morphology code

Adenocarcinoma (M8140/3)	
◆ Well to moderately differentiated	50%
◆ Poorly differentiated or undifferentiated	30%
Squamous cell carcinoma (M8070/3)	15%
Undifferentiated neoplasms	5%
◆ Non-specified carcinoma	
◆ Neuroendocrine tumours (M8246/3)	
◆ Lymphomas (M9590/3)	
◆ Germ cell tumours (M 9064/3O)	
◆ Melanomas (M 8720/3)	
◆ Sarcomas (M 8800/3)	
◆ Embryonal malignancies (M 9070/3)	

Table 59.4 An immunohistochemistry algorithm for CUP diagnosis

Step 1 (detects broad types of cancer)	
Tumour type	Immunoperoxidase stains
Carcinoma	Pan-Cytokeratin, EMA
Lymphoma	CLA, (CD45RB), EMA (±)
Sarcoma	Vimentin, desmin, S100, alpha-smooth muscle actin, myoD1, CD34, c-kit, CD99
Melanoma	S100, HMB45, Melan-A
Step 2 (detects broad types of carcinoma)	
Carcinoma type	
Adenocarcinoma	Light microscopy, PAS, CK7, CK20
Squamous cell carcinoma	CK5/6, p63
Neuroendocrine carcinoma	Chromogranin, synaptophysin, PG9.5, CD56
Germ-cell carcinoma	PLAP, OCT4, AFP, HCG
Step 3 (detects origin of adenocarcinoma)	
Adenocarcinoma type	
Breast cancer	ER, GCDFP-15, mamaglobulin, CK7+/CK20-
Ovarian cancer	CA125, mesothelin, WT1, ER, CK7+/CK20-
Endometrial cancer	CK7+/CK20-, CA125, ER
Prostate Cancer	PSA, PAP, CK7-/CK20-
Colon cancer	CDX2, CEA, CK7-/CK20+
Pancreatic cancer	CK7+/CK20±, CA 125, mesothelin
Liver cancer	Hepar-1, AFP, polyclonal CEA, CD10, CD13
Lung cancer	TTF1, CK7+/CK20-
Kidney cancer	CD10, CK7-/CK20-
Thyroid cancer	TTF1, thyroglobulin

metastatic adenocarcinomas or poorly differentiated carcinomas. Antibodies against cytokeratins, and especially against CK7 and CK 20, have opened up a helpful diagnostic avenue (Table 59.4) [34, 35].

Chromosomal diagnosis

The detection of chromosomal abnormalities could be helpful in specific cases as in germ cell CUP (detection of an isochromosome of the short arm of chromosome 12i (12p) or a deletion in 12p), peripheral neuroectodermal tumours, or in Ewing's sarcomas (translocation t [11, 22] [q 24; q 12] [36, 37].

Diagnostic investigations

Imaging

Computed tomography

The sensitivity of whole-body CT-scans to detect a primary site is around 30–35%, recognizing that small lesions can be missed by CTs. CT scans are also used for CUP staging [38].

Magnetic resonance imaging

MRI is very useful in identifying mainly occult breast primary tumours. Its sensitivity could be as high as 60% [39].

[111]In Octreoscan

This is useful in detecting neuroendocrine CUP tumours expressing enhanced somatostatin receptors [40].

Mammography

Mammography is used to detect breast primary sites in women with isolated axillary lymph node involvement by an adenocarcinoma. However, its sensitivity is not as high as MRI of the breast [41].

FDG-PET/CT-scan

FDG-PET/CT scans have proven to be useful in CUP patients for the detection of primary site [42, 43]. In a recent meta-analysis, in a total sample size of 433 patients, the overall primary tumour detection rate, pooled sensitivity, and specificity of FDG-PET/CT scans were 37%, 84%, and 84%, respectively. The most common primaries discovered are those of head, neck, and lung [44]. NICE UK recommendations offer 'FDG-PET/CT scan for CUP patients presenting with cervical lymphadenopathy with no primary tumour identified on ear, nose and throat panendoscopy, if radical treatment is considered to be an option' [4].

Endoscopy

Endoscopic investigations should be limited to CUP patients with particular symptoms or signs, i.e., bronchoscopy in patients with haemoptysis or cough and negative imaging studies, or colonoscopy in patients with constipation, diarrhoea or overt blood loss. Extensive endoscopic evaluation in the absence of clinical or laboratory findings should be avoided, since sensitivity is extremely low [1, 2].

Serum tumour markers

Measurement of serum tumour markers has no diagnostic, prognostic, or predictive value in CUP patients.

Routine evaluation of epithelial serum tumour markers (CEA, CA 15-3, CA 19-9, and CA 125) might show non-specific overexpression, since almost 70% of patients express more than two markers in their serum.

However, some serum markers could be helpful in certain clinicopathological subsets, i.e., AFP or β-HCG in poorly-differentiated carcinomas with midline distribution, PSA in men with unique osteoblastic metastases, CA 125 in primary peritoneal adenocarcinoma, or CA 15-3 in women with isolated axillary nodal adenocarcinoma [45].

Multidisciplinary management of clinicopathological subsets

CUP is a heterogeneous group of diseases that is classified as favourable, specific, or good prognosis subsets and unfavourable, non-specific, or poor prognosis subsets. This classification is based on age, sex, histopathology, clinical presentation, and organ or tissue involvement. This classification offers great help to the practising oncologist for both diagnostic and therapeutic management and provides at the same time prognostic and predictive value (Table 59.5) [1, 2].

Prognostic and predictive factors

Several prognostic factors have been reported for patients diagnosed with CUP. From various multivariate analyses, significant

Table 59.5 Clinicopathological subsets and patients

Favourable or specific CUP subsets	Unfavourable or non-specific CUP subsets
Women with serous-papillary adenocarcinoma of peritoneal cavity	Adenocarcinoma metastatic to the liver or other organ
Women with adenocarcinoma involving only axillary lymph nodes	Malignant ascites from a non-papillary adenocarcinoma
Poorly-differentiated carcinoma with midline distribution	Multiple cerebral metastases from adenocarcinoma or squamous cell carcinoma
Squamous cell carcinoma involving cervical lymph nodes	Multiple lung or pleural metastases from adenocarcinoma
Neuroendocrine carcinoma of unknown primary	Multiple metastatic bone disease from an adenocarcinoma without a serum PSA elevation.
Adenocarcinoma with a colon-cancer profile	Squamous-cell carcinoma of the abdominal cavity
Men with blastic bone metastases and elevated serum PSA levels	
Patients with limited disease	
Melanoma of unknown primary with localized nodal disease	

Reprinted from *Critical Reviews in Oncology/Hematology*, Volume 69, Issue 3, Pavlidis N and Fizazi K, Carcinoma of unknown primary (CUP), pp. 271–279, Copyright © 2009 Published by Elsevier Ireland Ltd., with permission from Elsevier, <http://www.sciencedirect.com/science/journal/10408428>.

adverse prognostic indicators related to histology, clinical picture or serum markers have been identified. Among them, these factors are male sex, age >64, PS >1, number of metastatic sites, liver metastases, poorly-differentiated histology, weight loss, lymphopaenia, leukocytosis, elevated serum LDH, elevated alkaline phosphatase levels, and low albumin levels [46, 47].

Classification of clinicopathological subsets

Women with serous papillary adenocarcinoma of the peritoneal cavity

This subset is also called primary peritoneal adenocarcinoma and accounts for 7–20% of all pelvic or peritoneal serous papillary cancers. It seems to affect women three to seven years older than ovarian carcinoma patients, with a median age of 55–65 years.

The clinical manifestation of this disease is similar to stage III or IV ovarian cancer patients. The main symptoms and signs are abdominal pain and distention, ascites, and palpable masses. Signs of constipation with intestinal obstruction are more commonly seen in late stages. The disease is predominantly located in the peritoneal, mesenteric, omental, and ovarian surfaces as well as in pelvic and retroperitoneal nodes. Visceral organs are involved in less than 15% of the cases.

Serum CA 125 is a useful tumour marker since it is elevated in up to 90% of patients. Histopathologically, these are serous papillary adenocarcinomas, with or without psammoma bodies. Almost half of these patients are diagnosed with poorly-differentiated tumours. Immunohistochemistry is positive for pancytokeratins, CK7, epithelial membrane antigen, CA 125, B 72.3, ER, mesothelin, and WT 1 [48].

Women with isolated axillary nodal metastases from adenocarcinoma

This CUP subset affects women with a mean age of 52 years, most commonly postmenopausal. A quarter of these patients have a positive family history for malignancy. They present with axillary lymphadenopathy of either N1 (48%) or N2-3 disease (52%).

The detection of an occult primary tumour in the breast can be achieved by MRI or mastectomy in 60% and 70% of cases, respectively. Ductal carcinomas are the most common histology (83%) with a good to moderate differentiation in the majority of the patients. Oestrogen and progesterone receptors are expressed in around 40%, while HER 2 is overexpressed in 30% [49].

Poorly-differentiated carcinoma with midline distribution

This is a predominantly male disease occurring at a median age of 56 years. It presents with nodal involvement of midline distribution affecting mainly mediastinal, retroperitoneal, or supraclavicular lymph nodes. In some cases, peripheral nodes, lung, or pleural metastatic lesions can also be observed. These tumours are relatively aggressive with rapid growth. Elevated alpha-fetoprotein and β-chorionic gonadotropin levels are found in less than 20% of the patients.

Histologically, these tumours are characterized as poorly differentiated or undifferentiated carcinomas without the expression of any specific immunoperoxidase staining, apart from the presence of an i(12p) chromosomal abnormality-favouring germ cell tumour in some patients [50].

Squamous cell carcinoma involving cervical lymph nodes

This subset represents 5% of patients and affects middle-aged or elderly mainly male patients with a strong history of tobacco and alcohol abuse. Clinical presentation is characterized by unilateral enlargement of upper or middle cervical lymph nodes.

Histopathology is compatible with squamous cell carcinoma. Occasionally, the detection of Epstein–Barr or human papilloma virus, with the support of molecular techniques, could be helpful in distinguishing nasopharyngeal from oropharyngeal primary tumours [51, 52].

Neuroendocrine carcinomas of unknown primary

CUP neuroendocrine tumours account for 13% of all neuroendocrine tumours and are diagnosed as low-grade or high-grade malignancies. High-grade neuroendocrine tumours are the most common, representing almost 80% of all cases. These are poorly-differentiated tumours with disseminated disease and a rapidly-growing behaviour. Low-grade tumours are mainly located in the liver and manifest with symptoms associated with secretion of vasoactive peptides.

Histologically, they are diagnosed with small cells with little cytoplasm and dark nuclei, positive for neuroendocrine immunohistochemical stains (chromogranin, synaptophysin, PGP 9.5, CD56) [53].

Adenocarcinoma with a colon cancer profile

This CUP subset has recently been described and refers to patients with a mean age of 58 years who present with predominantly liver and peritoneal metastases and less commonly with lungs, pleura bones, or ovarian secondary lesions. Laboratory investigations show a normal colonoscopy and histology compatible with adenocarcinoma or poorly-differentiated adenocarcinoma stained with CK20, CDX2, and CEA [54, 55].

Men with blastic metastases and elevated serum PSA

This is a very rare CUP subset consisting of male patients with osteoblastic metastases, localized or diffuse bone pains, elevated serum PSA levels, and a histology revealing metastatic adenocarcinoma with a positive staining for PSA marker [1, 2].

Patients with limited disease

Patients with this subset are presented with: (a) a single lesion in several sites, i.e., lymph nodes, skin, liver, bone, lung, brain, or adrenal gland; or (b) with isolated inguinal lymphadenopathy, mainly of squamous cell histology [1, 2].

Melanoma of unknown primary with isolated nodal disease

This subset accounts for 3.2% of all melanoma patients. Clinically, it presents either as local nodal or as visceral metastatic disease. Cases with local nodal disease present with localized symptomatology, in contrast to the visceral type where more systemic symptoms and signs are present. Histopathology with light microscopy and immunohistochemistry reveal features of a melanoma [56].

Unfavourable or non-specific subsets

The incidence of the unfavourable group accounts for 80% of all CUP patients. The most common subset in this group is that of metastatic liver disease. Other organs involved by metastatic lesions are lymph nodes (35%), lungs (31%), bones (28%), and brain (15%). The most frequent histologic malignancy is adenocarcinoma (64%) followed by undifferentiated carcinoma (20%), neuroendocrine (9%), and squamous cell carcinoma (3%). These patients present with miscellaneous symptoms and signs related to the underlying metastatic organ [1, 2, 57, 58].

Treatment of clinicopathological subsets

Women with serum papillary adenocarcinoma of the peritoneal cavity

These women should be treated as FIGO stage III ovarian carcinoma with optimal surgical cytoreduction followed by platinum/taxane systemic chemotherapy. Data derived from a systemic review of 25 clinical series of a total of 579 patients with primary serous peritoneal adenocarcinoma showed response rates and survival similar to serous ovarian cancer. Median response rate was around 80% (53–100%) with clinical and pathological complete responders of 50–70% and 10–15%, respectively. The feasibility of optimal surgical debulking ranged between 13–79% of patients. Mean overall survival is 30 months (15 to 42 months) with longer survival seen more often in patients who underwent optimal debulking [48].

Women with isolated axillary nodal metastases from adenocarcinoma

The management of these patients includes locoregional and systemic treatment. Locoregional therapy is identical to stage II or III breast cancer. For patients with N1 disease (mobile nodes), axillary clearance followed by either simple mastectomy or breast irradiation should be offered. Adjuvant chemotherapy followed by endocrine treatment should be provided for premenopausal women, while postmenopausal women should receive only endocrine therapy with tamoxifen or aromatase inhibitors.

For patients with N2 disease (fixed nodes), neoadjuvant chemotherapy should be considered. In non-responding or elderly patients, radical radiotherapy is recommended. For patients with positive hormone receptors, adjuvant endocrine treatment should be provided. In addition, trastuzumab should be added to HER-2 positive patients according to the guidelines for stage III breast cancer.

Prognostic data from a recent systematic review including 24 clinical studies with 689 patients in this subset, demonstrated that prognosis is similar to stage II–III breast cancer. Two important prognostic factors were: (a) the number of involved axillary nodes and (b) the absence of residual gross disease.

Loco-regional failure in locally irradiated patients is around 15–25% and mean five-year overall survival is 72% with a median follow-up of 62 months. The impact of adjuvant systemic treatment at three-year overall survival is estimated to be approximately 22%. One should keep in mind that all therapeutic data in these patients are based on type 3 level of evidence [49].

Poorly differentiated carcinoma with midline distribution

Although these patients have a relatively poorer outcome comparing to germ cell tumours, they should still be treated with platinum-based combination chemotherapy. A systematic review of ten published studies and 703 patients reports response rates of 50% (42–64%) with 20–25% complete responses. Median survival is 12 months (8–15 months) and almost 10–15% of patients can enjoy long-term DFS. Favourable prognostic factors are: (a) low tumour burden, (b) absence of visceral disease, (c) good performance status, (d) female gender, and (e) platinum-based regimens [50].

Squamous cell carcinoma involving cervical lymph nodes

This subset of CUP patients should be managed according to locally advanced squamous carcinoma of the head and neck. Loco-regional treatment with radiotherapy to the pharyngeal axis and bilateral neck with or without radical neck dissection is recommended. Concurrent chemotherapy is also used in most cases.

The most prominent prognostic factors are lymph node stage and extracapsular spread followed by other less important factors such as good performance status, young age, absence of weight loss, and low-grade histology. Five-year survival or long-term disease control is around 50–60%, while the majority of these patients are considered cured [51].

Neuroendocrine carcinoma of unknown primary

Treatment provided to high-grade and low-grade neuroendocrine CUP tumours differs between patients. Patients with high grade neuroendocrine tumours are managed with platinum-based chemotherapy regimens containing mainly etoposide. Overall response rates are around 50–70% with 15–20% complete responders, a median survival of 15.5 months (range 12–40 months) and a two–year survival rate of 33–50%. On the contrary, patients with low-grade tumours are treated with somatostatin analogues or chemoembolization and can exhibit a median survival of 40 months and a five-year survival rate of 35–45%.

The above data are retrieved from a recent systematic review of 39 studies including 500 patients diagnosed with neuroendocrine carcinoma of unknown primary [53].

Adenocarcinoma with a colon-cancer profile

This favourable subset of patients is treated with colorectal chemotherapy regimens. Overall response rate is up to 70% with some complete responders. Median survival is around 20–24 months [54, 55].

Table 59.6 Treatment recommendations and prognosis in favourable CUP subsets

CUP subsets	Therapeutic recommendations	Prognosis
Women with serous papillary adenocarcinoma of the peritoneal cavity	Optimal surgical debulking followed by platinum-based combinations	Mean overall survival is 30 months and is 2–6 months less compared to primary ovarian cancer. Optimal debulking offers long-term survival of 15–42 months
Women with adenocarcinoma involving only axillary lymph nodes	Axillary nodal dissection, mastectomy or breast irradiation followed by adjuvant chemotherapy and/or endocrine treatment according to the biological characteristics	Mean 5-year overall survival is 72%. The impact of adjuvant systemic treatment is 22% at 3-year survival
Poorly differentiated carcinoma with midline distribution	Chemotherapy with platinum-containing regimens	Median survival is 12 months (8–15 months) and 10–15% are long-term disease-free survivors
Squamous cell carcinoma involving cervical lymph nodes	Neck dissection and/or irradiation of bilateral neck and head-neck axis. Concurrent chemotherapy seems to be beneficial for N_2 or N_3 disease	5-year survival or disease control is 50–60%. Most of these patients are considered cured
Neuroendocrine carcinomas of unknown primary	Platinum—etoposide combination chemotherapy for poorly differentiated tumours and somatostatin analogues for low-grade tumours	High-grade tumours: median survival is 15.5 months, 2– year survival: 33–50%. Low-grade tumours: median survival 40 months 5-year survival: 35–45%
Men with blastic bone metastases and elevated PSA	Endocrine treatment with LHRH agonists and/or antiandrogens	
Adenocarcinoma with a colon cancer profile	Colorectal chemotherapy regimens	Median overall survival is 20–24 months
Patients with limited disease	Surgical excision ± radiotherapy	Long-term survivors
Melanoma of unknown primary with isolated disease	Surgical treatment with local radiotherapy and adjuvant chemo-immunotherapy	Median survival: 24–165 months 5-year survival: 29–76% 10-year survival: 19–63%

Men with blastic bone metastases and elevated serum PSA levels

These patients should be treated empirically with androgen suppression treatment similar to metastatic prostate cancer [1, 2].

Patients with single operable metastatic deposit

This rare entity should be treated with local excision, with or without radiotherapy [1, 2].

Melanoma of unknown primary with localized nodal disease

Patients with localized disease should be treated surgically. Local radiotherapy as well as adjuvant chemoimmunotherapy are recommended post-operatively. Prognostically, two groups of patients have been described: localized nodal disease group and the metastatic visceral group. Survival rates differ substantially between these two groups. Localized nodal disease has a median survival between 24 and 165 months and a five-year and ten-year survival between 29–76% and 19–63%, respectively. The metastatic visceral group exhibits a median survival between three and 13 months and a five-year survival of 6–18%. Lymph node number, female gender, age, and surgical management are considered as favourable prognostic factors [56].

Table 59.6 summarizes the therapeutic recommendations and prognosis of favourable CUP subsets.

Unfavourable or non-specific subsets

Unfavourable subsets constitute a majority (75–80%) of CUP patients. Unfortunately, most of these subsets remain relatively unresponsive to systemic chemotherapy. Despite the availability of several cytostatic drugs active in various solid tumours, there is no evidence that chemotherapy benefits this particular group of patients. Although responses can be seen, survival benefit is lacking [57].

The most common agents in current use are platinum compounds, mainly cisplatin or carboplatin, and taxanes, either paclitaxel or docetaxel. Other drugs used in combination are gemcitabine, oxaliplatin, capecitabine, vinorelbine, etoposide, or anthracyclines. The most frequent combinations used as first-line treatment include carboplatin, cisplatin, paclitaxel, docetaxel, gemcitabine, or etoposide. In general, response rates vary between 20–40% with very few complete responders. OS is 9–11 months and 1-year survival is around 30% [59].

Table 59.7 Palliative regimens for unfavourable CUP patients

Drugs	Dosage
Carboplatin	AUC 5 Q 3 weeks
Paclitaxel	175 mg/m^2, Q 3 weeks
Carboplatin	AUC 5 Q 3 weeks
Docetaxel	75 mg/m^2, Q 3 weeks
Cisplatin	60–75 mg/m^2, Q 3 weeks
Gemcitabine	1000 mg/m^2, Q 3 weeks
Cisplatin	75 mg/m^2, Q 3 weeks
Etoposide	100 mg/m^2 days 1–3, Q 3 weeks
Irinotecan	160 mg/m^2, Q 3 weeks
Oxaliplatin	80 mg/m^2, Q 3 weeks
Irinotecan	100 mg/m^2, Q 3 weeks
Gemcitabine	1000 mg/m^2, Q 3 weeks
Oxaliplatin	85–130 mg/m^2, Q 3 weeks
Capecitabine (oral)	2000 mg/m^2, days 1–14, Q 3 weeks

The subset of patients with mainly liver metastases is one of the most common unfavourable subsets. The results from five studies published with more than 700 patients showed that the response rate was less than 20% and the median survival was 5.5 months [57]. Some authors claim that since 2000, with the availability of newer drugs, response rates and OS have been improved. Here, one should be cautious since CUP patients enrolled in clinical trials are selected patients with younger age and better performance status [60].

Nevertheless, according to the available guidelines, unfavourable CUP patients of relatively young age and good performance status should be considered for platinum-based chemotherapy. Alternatively, best supportive care should be recommended [61]. Table 59.7 demonstrates commonly used low-toxicity palliative chemotherapy regimens for poor-risk CUP patients.

Conclusion

The description and management of CUP is a constantly evolving story, encompassing, as it does, evolution in novel imaging and genomic classifiers of disease. As stated in the early chapters of this book, the ultimate key to this heterogeneous set of diseases may come from massive DNA sequencing efforts and the discovery of druggable, actionable, driver mutations.
