Cytokines play important roles in immune modulation. Many cytokines, including IL-2, IL-3, IL-4, IL-6, IL-10, IL-12, tumor necrosis factor-α (TNF-α), macrophage colony-stimulating final factor, and IFNs, have been studied for their roles in tumor treatment. Some cytokines (IL-2 and IFN-α) have been approved by the U.S. Food and Drug Administration (FDA) specifically for the treatment of melanoma and renal cell carcinoma, although enthusiasm for use has waned given the systemic toxicity profile (139,140). Ovarian cancer ascites is rich with cytokine expression, and the study of this ascitic fluid should help us gain a better understanding of the complex immune interactions between tumor and host. A recent analysis showed ascites to be high in proinflammatory cytokines IL-6, IL-8, and the immune suppressive cytokines IL-10, CCL22, and TGF-B in most samples. Interestingly, high IL-6 expression predicted residual disease after debulking and was highest at recurrence (141).

Interferons

Although the full extent of action of IFN in patients with ovarian cancer is unknown, several mechanisms have been proposed: (a) stimulation of NK cells and macrophages, both of which are known to have antitumor properties (21); (b) antiangiogenic effects; and (c) inhibition of expression of dysregulated oncogenes (such as *HER2/neu*), thereby improving the responsiveness of cisplatin-resistant cells (142). A Gynecologic Oncology Group Study evaluated administration of systemic IFN-α to patients with advanced ovarian cancer in which patients with measurable disease showed a low response rate of approximately 10% (143). The role of intravenous IFN-α as a maintenance treatment after initial surgical resection and chemotherapy was also evaluated in a randomized phase 3 study and showed no benefit (144). Systemic IFN-α was also associated with frequent dose-limiting toxicity. Because of the poor response rate and frequent toxicity of systemic administration, further studies were focused on IP administration of IFN-α. Multiple clinical trials with IP IFN therapy were carried out, leading to a randomized trial (by the Southwest Oncology Group) of adjuvant IP IFN-α in stage III ovarian cancer patients who showed no evidence of disease after primary surgery and chemotherapy (145). The trial was closed early, but there was no difference between the study arms with regard to progression-free survival ($p = 0.56$). In cervical cancer, monotherapy with IFN-α had minimal activity (146). Studies evaluating intralesional IFN in human papillomavirus (HPV)–associated diseases (cervix and vulvar cancer) have waned as directly targeted immunologic approaches against the virus have emerged. Nonetheless, a study utilizing intralesional IFN = alpha 2b in high-grade cervical intraepithelial neoplasia showed a 60% response rate. Treated patients also expressed more Th1 (IFN-γ, TNF-α, IL-2) cytokines, with a significant reduction in the viral load of high-risk HPV ($p = 0.0313$) (147).

Interleukin-2

IL-2 is a T-cell growth factor that plays a central role in the immune system, with data showing IL-2-induced $CD4^+$ T-cell expansion in patients with HIV infection (144) as well as clinical responses in renal cell cancer and malignant melanoma, resulting in FDA approval of IL-2 in treatment for these tumors (148,149). It has been shown to activate tumor-associated macrophages and upregulate IFN-stimulated genes (150). Because of the toxicity of intravenous IL-2 administration, studies in ovarian cancer focused on IP administration. A phase 2–3 study (151) of IP IL-2 in patients with laparotomy-confirmed persistent or recurrent ovarian cancer after ≥6 courses of prior platinum-based chemotherapy reported an overall response rate of 25.7%, with an overall 5-year survival probability of 13.9%. A more recent study shows that IP IL-2 administration in patients with ovarian cancer increases $CD4^+$ CD25 high T cells that highly express FOXP3 and suppress Treg cells. This suggests that IL-2 has a critical role in maintaining the Treg pool as well as enforcing Treg cell

tumor trafficking in humans, and may lend itself to combination studies of other agents targeting different immune checkpoints (152,153). A disadvantage of frequent administration of intravenous high-dose IL-2 is the occurrence of dose-limiting side effects. Therefore, delivery of IL-2 from an expression plasmid has been evaluated for the treatment of ovarian cancer. IP treatment of ovarian tumors with an IL-2–expressing plasmid resulted in an increase in local IL-2 levels, a change in the cytokine profile of the tumor ascites, and a significant antitumor effect in a mouse model (154). An *in vitro* study on colorectal cancer showed the ability of plasmids expressing murine IL-2 to enhance the antitumor activity of viral vector immunization against a cancer mucosa antigen, showing the tolerability and possibility of combining plasmid-derived IL-2 production with other immunotherapeutic strategies as well (155).

Interleukin-12

IL-12 is a cytokine produced mainly by activated monocytes, tissue macrophages, and B cells. It can induce IFN-γ and together with IL-2 becomes a potent activator of CTLs and NK cells (156,157). Whereas IL-4 and IL-10 mediate the development of Th2-type immunity, IL-12 initiates the differentiation to the Th1 phenotype. In addition, IL-12 production can be negatively or positively regulated by cytokines. For example, IL-10 and IL-4 have been shown to inhibit the production of IL-12 (158), whereas IL-2 and IFN-α enhance its production. In addition, IL-12 has potent antimetastatic and antitumor effects in several murine tumor models, as well as in human tumor cells *in vitro* and *in vivo* (159). Ascitic IL-12 had been shown to be an independent prognostic factor for adverse outcome in ovarian cancer (160), although later there was uncertainty over this finding as a result of a possible statistical flaw (161). A phase 2 GOG clinical trial (162) evaluated intravenously administered recombinant human IL-12 in patients with recurrent or refractory ovarian cancer. Myelotoxicity and capillary leak syndrome were the major adverse events. Partial response rate was 3.8%, with no complete responders. Recent focus has shifted to evaluating the administration of IL-12 expressing DNA. Two studies have evaluated this strategy in patients with malignant melanoma, showing response of greater than 30% in 5 of 12 patients receiving intratumoral injections; or CR in 2 of 19 and PR or stable disease (SD) in 8 of 19 patients using electroporation of plasmid coding IL-12 (163,164).

ANTIBODY-MEDIATED THERAPY OF CANCER

Antibodies are the primary mechanism for eliminating infectious pathogens from the bloodstream. The effect of most commonly used vaccines against infectious agents is thought to be primarily a consequence of antibody induction with subsequent complement-mediated inflammation and cytotoxicity (156). In addition, tumor antigen-specific autoantibodies are found in the sera of patients with solid tumors, and generally increase with tumor burden (165,166). As one example, the presence of p53 autoantibodies was detected in 41.7% of patients with serous cancer, and detectable p53 antibodies were associated with improved OS ($p = 0.04$; HR, 0.57; 95% CI, 0.33 to 0.97) (167). It is unknown whether this finding represents a biomarker for prognosis, or whether the antibodies exert immunologic control of tumor. Another example is found in the presence of natural antibodies (i.e., prior to vaccination or administration) in paraneoplastic syndromes. In a series of 100 patients with small cell lung cancer, patients with autoantibodies causing the Lambert–Eaton myasthenic syndrome had improved survival (19.6 months) versus those who were antibody negative (8.9) (168). In platinum-resistant ovarian cancer patients, another study showed that anti-MUC1 IgM antibodies correlated with OS at both early ($p = 0.052$) and late ($p = 0.009$) time points (169). These results provide the possibility that functionally effective antibodies may confer a survival advantage. The possibility that these represent a biomarker for better outcome instead cannot be excluded from this data. The ability of antibodies to mediate protection from tumor recurrence has also been suggested in experimental animal models (170). The administration of monoclonal antibody 3F8 against GD2 or induction of GD2 antibodies by vaccination after challenge with EL4 lymphoma (which expresses GD2) showed prolonged survival in mice receiving antibody ($p < 0.004$) or vaccination ($p < 0.008$) (170). Trials in gynecologic cancers have included the

administration of murine or humanized antibodies directly targeting tumor-associated antigens, indirect approaches utilizing anti-idiotypic antibodies, or antibodies conjugated to radionuclides, cytokines, or other immunotoxins. The greatest success in the antibody-mediated treatment of cancer to date has come from a series of monoclonal antibodies against antigens expressed at the cell surface of cancer cells, with clinical efficacy in both the advanced disease and the adjuvant settings. Monoclonal antibodies are produced by hybridoma cells. They have evolved from simple murine-derived antibodies with recombinant engineering techniques that now permit monoclonal antibodies of various sizes, configurations, valences, and target effector functions (171). Examples of agents of their efficacy continue to grow and include an ever-increasing list such as rituximab, ibritumomab, and tositumomab for B-cell lymphomas; gemtuzumab for acute myelocytic leukemias; alemtuzumab for chronic lymphocytic leukemias; cetuximab for colorectal and head and neck squamous cell carcinomas; and trastuzumab for breast cancer (171,172). Several mechanisms of action have been postulated: (1) monoclonal antibodies can mediate effector cells by having an activating or suppressive function in pathways such as with CTLA-4 (53), (2) they may target tumor supportive molecules such as VEGF with bevacizumab (173), or (3) they may recognize tumor-specific receptors and by binding may activate or repress signaling pathways. Preclinical studies suggest that antibodies may have the most efficacy in the adjuvant setting. Because many gynecologic cancer patients are initially rendered free of detectable disease by surgery and/or chemotherapy after initial diagnosis, the administration of effective mAbs or vaccines with antibodies as part of the effector repertoire would have broad applicability. There are a variety of potential antigen targets for antibodies on gynecologic cancers. Screening for this purpose was traditionally limited to surface antigens because antibodies recognize antigens primarily at the cell surface. A previous study screened a series of 40 mAbs against 25 common antigens that are potential targets for antibody-mediated immunotherapy, as listed in **Table 15.3** (70,174,175). The antigens expressed by ovarian and endometrial cancers are similar, and quite different from those expressed by melanomas, and similar to, although not the same as, those expressed by prostatic cancers. The 18 excluded antigens (including CEA and *HER2/neu*) were expressed in one or zero of five specimens. The expression of these antigens on normal tissues is essentially restricted to apical epithelial cells at luminal borders, a site that appears not to be accessible to the immune system. In addition to these overexpressed tumor-associated antigens, other targets have included overexpressed growth factor receptors (e.g., *HER2/neu* [erbB2], epidermal growth factor receptor [EGFR], VEGF); and mutated tumor suppressor genes (e.g., *p53* and *BRCA-1*). Binding of mAb to these antigens may have antitumor effect generated through a variety of possible mechanisms including: (a) antibody-mediated recruitment of human effector mechanisms *in situ*, ADCC against the tumor cells; (b) development of tumor-specific CTLs; (c) activation of the complement system; (d) stimulation of granulocytes cytotoxic to the cancer cells; and (e) induction of an anti-idiotypic antibody that can elicit active immunity.

TABLE 15.3 Potential Antigens for Antibody-Directed Therapy

	Antigen (mAb)[a]							
Tumor	sTn (CC49)	sTn (B72.3)	TF (49H.8)	Le^y (3S193)	Le^y (BR96)	GM2 (696)	Globo-H (Mbr1)	MUC-1 (HMFG
Ovarian	4/5	3/5	5/5	4/5	99/133[b]	5/5	18/19	5/5
Endometrial	4/5	2/5	4/5	3/5	2/5	5/5	4/5	3/5
Melanoma	0/5	0/5	0/5	0/5	0/5	10/10	0/10	0/5
Small cell Lung	0/5	0/5	0/5	2/5	1/5	6/6	4/6	2/5

[a] All the tumor tissues were stained by avidin-biotin complex immunoperoxidase methods (173). Figures are the number of tumor specimens with >50% positive tumor cells by immunohistochemistry.

[b] From Federici MF, Kudryashov V, Saigo PE, et al. Selection of carbohydrate antigens in human epithelial ovarian cancers as targets for immunotherapy: serous and mucinous tumors exhibit distinctive patterns of expression. Int J Cancer. 1999;81(2):193–198.

[c] From Kabawat SE, Bast RC, Welch WR, et al. Immunopathologic characterization of a monoclonal antibody that recognizes common surface antigens of human ovarian tumors of serous, endometrioid, and clear cell types. Am J Clin Pathol. 1983;79(1):98–104.

The extensive expression of CA-125 in over 80% of serous and endometrioid ovarian cancers has been well documented since the early 1980s (176). Following the successful cloning of CA-125 and identification of it as a complex mucin, it has been termed MUC-16 (177,178). Multiple efforts focusing on MUC 16 as a logical target for immunotherapy are underway.

Antibody Conjugates

In an attempt to add to the efficacy of unconjugated antibodies, efforts have been made to optimize the antitumor activity by conjugating with radionuclides, toxins, cytotoxic drugs, or second antibodies. The choice of conjugates and specific antibodies is influenced by features such as antigen internalization, lysosomal degradation, shedding, and heterogeneity of expression. The mechanism can be complex in that for some, internalization is a prerequisite for cellular toxicity, whereas in others, it may result in reduced efficacy and increased host toxicity due to intracellular catabolism (179).

Radionuclides

A variety of radionuclides have been conjugated with antibodies for imaging and treatment. The optimal radionuclide for cancer therapy is dependent on many factors (180). Radioconjugates with β (i.e., ^{131}I and ^{90}Y) and α (i.e., ^{211}At and ^{212}Bi) emitters have been proposed for regional therapy of peritoneal implants (181). Estimates of dosimetry suggest that adequate therapy (i.e., 20 Gy) could be delivered to tumors with a depth <300 μg using ^{211}At, <0.1 cm using ^{131}I, and <1 cm using ^{90}Y when conjugated to antibodies. The relatively low radiation dose makes the IP delivery route attractive in the setting of ovarian cancer, placing the source close to the tumor implants in the case of ovarian cancer. Delivery of effective radiation dose is greatly influenced by the extent of tumor binding, depth of tumor penetration, catabolism, and relative distribution between tumor and normal tissues. Antibody-radionuclide conjugates have been successfully developed for non-Hodgkin lymphoma, resulting in drug approvals with CD20 targeted agents (182). Randomized clinical data in ovarian cancer are sparse, with two larger studies having been reported. A randomized trial of 251 patients with stage Ia or Ib grade 3, or Ic, or grade 2 ovarian cancer with no macroscopic residual disease were randomized to IP radioactive chromic phosphate (32P) versus cisplatin and cyclophosphamide chemotherapy. The cumulative incidence of recurrence at 10 years was 35% (95% CI, 27% to 45%) versus 28% (95% CI, 21% to 38%), favoring chemotherapy (p = ns). The toxicity profile of 32P was worse (183).

The SMART study was a large randomized trial that evaluated IP yttrium-90-labeled HMFG1 murine monoclonal antibody in patients with ovarian cancer after a surgically defined complete remission. The MUC 1 antigen targeted by ^{90}Y-muHMFG1 is well established as an immunotherapy target, and is overexpressed on 90% of adenocarcinomas, including ovarian cancer. The phase 2 data supporting the use of ^{90}Y-muHMFG1 administered intraperitoneally in patients in first remission was promising, with a Cox model estimate of 10-year survival at 70% compared to 32% of case-matched controls (p = 0.003) (184). Patients were stratified using a second surgical assessment, as disease status at second look remains a powerful predictor of ultimate progression-free and OS (185). Despite the strong preclinical and clinical data supporting this approach, at a median follow-up of 3.5 years, relapses occurred in 98 versus 104 patients (p = ns). Although there is no randomized evidence supporting the efficacy of radioconjugates in gynecologic malignancies to date, the number of candidate agents for investigation continues to increase.

Immunotoxins, Drugs, and Cytokines

Drugs, toxins, and cytokines conjugated to mAbs have been evaluated in numerous cancers. Immunotoxins incorporate an antibody-binding domain and a toxin joined by a chemical cross-linker, peptide, or disulfide bond. The specific targeting afforded by mAbs and the relative potency of the toxin moiety present potential therapeutic advantages. Early conjugates, which have generally not been successful, linked antibodies to standard anticancer drugs such as doxorubicin or vinblastine. It is generally not possible to deliver comparable levels of cytotoxic agents as intravenous administration using this approach. This field is advancing by replacing murine antibodies with humanized versions and conjugating agents that are both specific and functional at lower doses (57,186). Multiple agents are being evaluated, although none have proven effective in gynecologic tumors to date.

Other Selected Clinical Trials with Monoclonal Antibodies

Monoclonal Antibodies for Patients with Ovarian Cancer

CA-125, a tumor-specific antigen that is found in 97% of patients with late-stage ovarian cancer, was first described by Bast et al. (176) as an antigen that is elevated in the serum of patients with epithelial ovarian cancer. CA-125 has been cloned and identified as the mucin MUC-16 (187), as shown in **Figure 15.2**. Studies have shown that MUC-16 has a variety of functions and contributes to ovarian cancer cell growth, survival, and invasiveness (188). Recent data suggest that expression is extended to digestive tract adenocarcinomas, and moderate expression likewise correlates with poor survival ($p < 0.001$) (189). The sheer size of the MUC-16 complex has made selecting appropriate sequences for incorporation into vaccines difficult, and initial studies focused on antibodies that could be raised against CA-125. In addition to antibodies targeting CA-125 for patients with ovarian cancer, others have been directed toward EGF, Her2/neu, and VEGF (see **Table 15.4**). (The role of antivascular agents is discussed in Chapters 23, 20, and 21 for the treatment of ovarian, cervical, and endometrial cancers.)

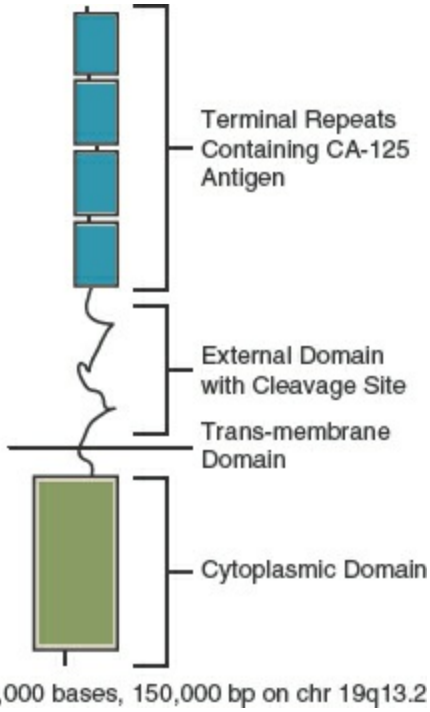

Figure 15.2 Proposed MUC-16 structure

TABLE 15.4 Monoclonal Antibodies for Patients with Ovarian Cancer

Antibody	Target	Results	References
Oregovomab	CA125	No benefit. PFS 1st line 13.3 vs. 10.3 months, p = 0.71	(190)
Abagovomab	CA125	No benefit. HR for PFS 1.099 (95% CI, 0.919–1.315; p = 0.301); OS 1.150 (95% CI, 0.872–1.518; p = 0.322).	(191)
Matuzumab	EGF	No benefit. Phase 2 trial (n = 75) with no activity.	(192)
Trastuzumab	Her 2/neu	No benefit. 45 Her 2 + patients had RR 7.3% with PFS 2 months.	(193)

Monoclonal Antibodies for Patients with Cervical and Endometrial Cancers

There are no approved antibody strategies targeting antigens in cervical or endometrial cancers to date. VEGF-targeted approaches are ongoing in patients with cervical carcinoma and endometrial cancer, and these are discussed in the appropriate chapters. EGF-targeted approaches have also been evaluated in patients with cervical cancer. EGFR is overexpressed in 85% of patients with invasive cervical cancer (194). Cetuximab is a chimeric IgG1 mAb that antagonizes normal ligand receptor interactions. A phase 2 trial by the Gynecology Oncology Group evaluated single agent cetuximab in 38 patients. No clinical responses were detected (195). Cetuximab was also evaluated in 76 patients in combination with cisplatin chemotherapy in treated and chemotherapy-naïve patients. Response rates of 9% and 16%, respectively, were seen, with no evidence that there is any advantage to cetuximab over cisplatin alone (196).

CANCER VACCINES

Vaccines continue to be evaluated as an approach to immunotherapy (197–201). Similar to experiences in other immunogenic tumors (202), vaccines have shown limited efficacy as monotherapy in patients with advanced recurrent disease. Current efforts to improve vaccines are directed broadly toward: (a) optimizing the choice of antigens; (b) improving vaccine delivery systems to maximize the magnitude and quality (phenotype and polarization) of antibody and T-cell responses; and (c) developing combinatorial approaches with adoptive T-cell or immunomodulation therapy to maximize activation and function of vaccine-primed effector cells *in vivo*.

Vaccines Designed Primarily to Generate Antibody Responses

Most current vaccines seek to generate cellular responses (often with an accompanying humoral or integrated response). However, based on the cell surface target antigen selection process appropriate for antibody recognition described earlier, and advances in the chemical and enzymatic synthesis of carbohydrate and glycopeptide antigens and optimization of adjuvant use, the exploration of a variety of synthetic antigen vaccines with antibody production as one end point has been performed. In one example, a pilot trial of a heptavalent vaccine-KLH conjugate (GM2, GLOBO-H, LeY, TN-MUC1, Tn(c), sTn and TF) plus QS-21 in patients with epithelial ovarian, fallopian tube, or peritoneal cancer in a second or subsequent remission was evaluated (200). Fluorescence-activated cell sorting (FACS) and CDC analysis showed increased reactivity against MCF7 cells in 7 of 9 patients, with some increase seen in all patients. This led to Gynecology Oncology Group Trial 255 (NCT00693342), which was a randomized trial in ovarian cancer patients with second or third complete clinical remission receiving either the adjuvant alone (OPT-821) or the multivalent antigen construct + OPT-821. The end point was the proportion of patients who were disease-free at 12 months (35% vs. 50%). 171 patients were enrolled and randomized. The estimated hazard ratio for PFS of the vaccine conjugate + opt-821 to the opt-821 reference arm was 0.98 (95% CI, 0.71 to 1.36). At a current follow-up of 34 months, the median OS for the opt-821 arm was 47 months and had not yet been reached for the vaccine conjugate + opt-821. Therefore, the study did not meet its primary PFS endpoint, and the secondary OS endpoint requires further follow-up (203).

On the basis of this lack of activity, additional to the development of vaccine now seek to produce cellular or integrated responses.

Vaccines Primarily Designed to Produce Cellular or Integrated Responses

There are a wide range of options for augmenting the immunogenicity of the antigenic targets for T-cell immunity, and this remains the primary goal for tumor immunotherapy (204,205). This now includes the possibility of genetically modifying T cells themselves to express both tumor-associated antigens and DC-activating molecules (205). For the antigens, the options include (a) the full proteins or MHC-restricted peptides modified by amino acid substitutions to increase immunogenicity; (b) genes or mini-genes for these proteins or peptides used as DNA vaccines; or (c) genes expressed in viral or bacterial vectors. Costimulatory molecules, cytokines, or molecules targeting antigens to particular processing compartments can be incorporated into these vaccines. DNA vaccines are appealing in this regard because of ease of production, versatility, and adaptability to such combinations (190). Most of these approaches can also be applied to expressing these antigens in APCs, such as DCs, that are then used to vaccinate the patient. Furthermore, because many tumor-rejection antigens detected by T cells in experimental animals are individually unique (mutated), a variety of individualized vaccines are being tested. Whole-cell vaccines can be prepared from a specific patient (if accessible tumor is available), and immunogenicity may be increased by the use of an immunologic adjuvant and transduction with genes for cytokines or costimulatory molecules, or treatment with haptens such as dinitrophenyl (DNP) (206). Other approaches attempting to increase the immunogenicity of unique and shared antigens include the use of heat shock proteins that may

carry the full range of cancer peptides, and DNA or messenger RNA vaccines that may be obtained from smaller biopsy specimens (207). See **Table 15.5** for further information.

TABLE 15.5 Select Vaccines for Patients with Ovarian Cancer

Vaccine	Target	References
DC	Tumor derived, DC tumor cell hybrids, HLA restricted antigens	(208–210)
NY-ESO-1 (proteins, peptides, epigenetic potentiation)	CT antigen	(75, 211–213)
GM-CSF secreting vaccines	Inducing T cells, expansion of T and B lymphocytes	(214)
Farletuzumab	Folate Receptor Targeting	(215)
MUC-1 targeted	MUC-1 (recent Trial NCT01521143 terminated 2015 prior to completion)	(216)

CT, cancer testis; DC, dendritic cell; HLA, human leukocyte antigen.

WHOLE TUMOR VACCINES

Several groups have used viruses to increase tumor cell immunogenicity for whole tumor cell vaccination. An alternative approach to deliver effectively whole tumor antigen is by using DCs. Although whole tumor vaccines offer distinct advantages, some drawbacks warrant consideration. First, surgical procurement of large numbers of autologous tumor cells may not be possible in many patients. Alternatives to this limitation exist, including use of allogeneic cell lines or the use of tumor mRNA. RNA electroporation of DCs is a convenient approach to generate a potent tumor vaccine (206). An additional concern with whole tumor vaccination relates to the inclusion of a large number of "self" antigens, which could potentially drive tolerogenic responses, that is, expand Treg rather than cytotoxic lymphocyte responses. Other work has demonstrated that DCs can be polarized *ex vivo* with the use of IFNs, TLR agonists, or p38 mitogen-activated protein kinase inhibitors to drive cytotoxic lymphocytes and Th17 effector cells at the expense of Treg activity (217). On the other hand, if immunization is successful, there may be increased concern for breaking tolerance to "self" antigens, leading to immunopathology. To date, pilot studies with whole tumor vaccines have reported no autoimmunity in patients with ovarian cancer.

NEOANTIGEN VACCINES

Advances in next-generation sequencing and epitope prediction now permit the rapid identification of mutant tumor neoantigens. This has led to efforts in utilizing these mutant tumor neoantigens for personalizing cancer immunotherapies. Indirect support for this approach comes from studies demonstrating that (i) infusion of autologous *ex vivo* expanded TILs can induce objective clinical responses in metastatic melanoma (218) and (ii) the relationship between pretherapy $CD8^+$ T-cell infiltrates and response to checkpoint blockade in melanoma (219). Deep-sequencing technologies permit easy identification of the mutations present within the protein-encoding part of the genome (the exome) of an individual tumor, allowing for prediction of potential neoantigens. Several preclinical and clinical studies have now confirmed the possibility of identifying neoantigens on the basis of cancer exome data (220–223). Although there are limitations to probing the mutational profile of a tumor in a single biopsy (224,225), it is evident that the vast majority of neoantigens occur within

exonic sequence, and do not lead to the formation of neoantigens that are recognized by autologous T cells (225,226). Consequently, a robust pipeline for filtering the cancer exome data is essential. Epitope presentation of neoantigens by MHC class I molecules may be predicted using previously established algorithms that analyze critical features such as the likelihood of proteasomal processing, transport into the endoplasmic reticulum, and affinity for the relevant MHC class I alleles. To predict epitope abundance, gene and/or protein expression levels can also be integrated into the analysis. It therefore appears useful to stimulate neoantigen-specific T-cell responses in cancer patients using two possible approaches. The first is to synthesize long peptide vaccines that encode a set of predicted neoantigens. The second approach is to identify and expand preexisting neoantigen-specific T-cell populations to create either bulk neoantigen-specific T-cell products or TCR-engineered T cells for adoptive therapy.

ADOPTIVE CELLULAR THERAPY

Effective cancer immunotherapy is dependent on the presence of large numbers of antitumor lymphocytes with appropriate homing and effector functions that enable them to seek out and destroy cancer cells *in vivo*. The adoptive transfer of *ex vivo* expanded tumor-reactive T cells holds the potential of achieving this condition in a short period of time, as shown in **Figure 15.3**. Clinical trials testing spontaneous or induced polyclonal or oligoclonal T cells conducted in the past have provided crucial lessons that can guide further optimization. The use of *ex vivo* expanded TILs has yielded the best clinical immunotherapy results to date. The advantages of TIL-based adoptive therapy include the presence of spontaneously occurring T cells with natural avidity against tumors that have escaped thymic deletion; the use of a polyclonal population of T cells that can limit immunologic escape of tumors; and the natural selection of patients whose tumor microenvironment is already conducive to T-cell homing. Initial studies using TILs in the treatment of metastatic melanoma during the late 1980s and early 1990s demonstrated objective antitumor responses, but these were short-lived. Based on animal studies showing that host lymphodepletion before T-cell transfer enhances persistence of T cells and antitumor response, a scheme of incremental lymphodepletion through high-dose nonmyeloablative chemotherapy and whole body radiation was tested. Infused cells were both long-lived and highly penetrating, showing regression of voluminous metastatic tumors, with recent reports showing up to 16% complete response and 72% overall objective response rates with maximal lymphodepletion and radiation. T-cell persistence correlated with long-lasting responses (120,202). Although these are phase 1 studies accruing a highly selected cohort of patients with metastatic melanoma, with preexisting antitumor immunity, whose tumors yield tumor-reactive TILs, the results clearly demonstrate the power of adoptive immunotherapy and dispel the assumption that immunotherapy can control only small tumors (227). Interestingly, adoptive transfer of $CD8^+$ clones expanded *ex vivo* to large numbers, and transferred following lymphodepletion, did not result in objective tumor response in melanoma, indicating that polyclonal T cells, a mixture of memory and effector cells, and $CD4^+$ cells are necessary for tumor rejection (228).

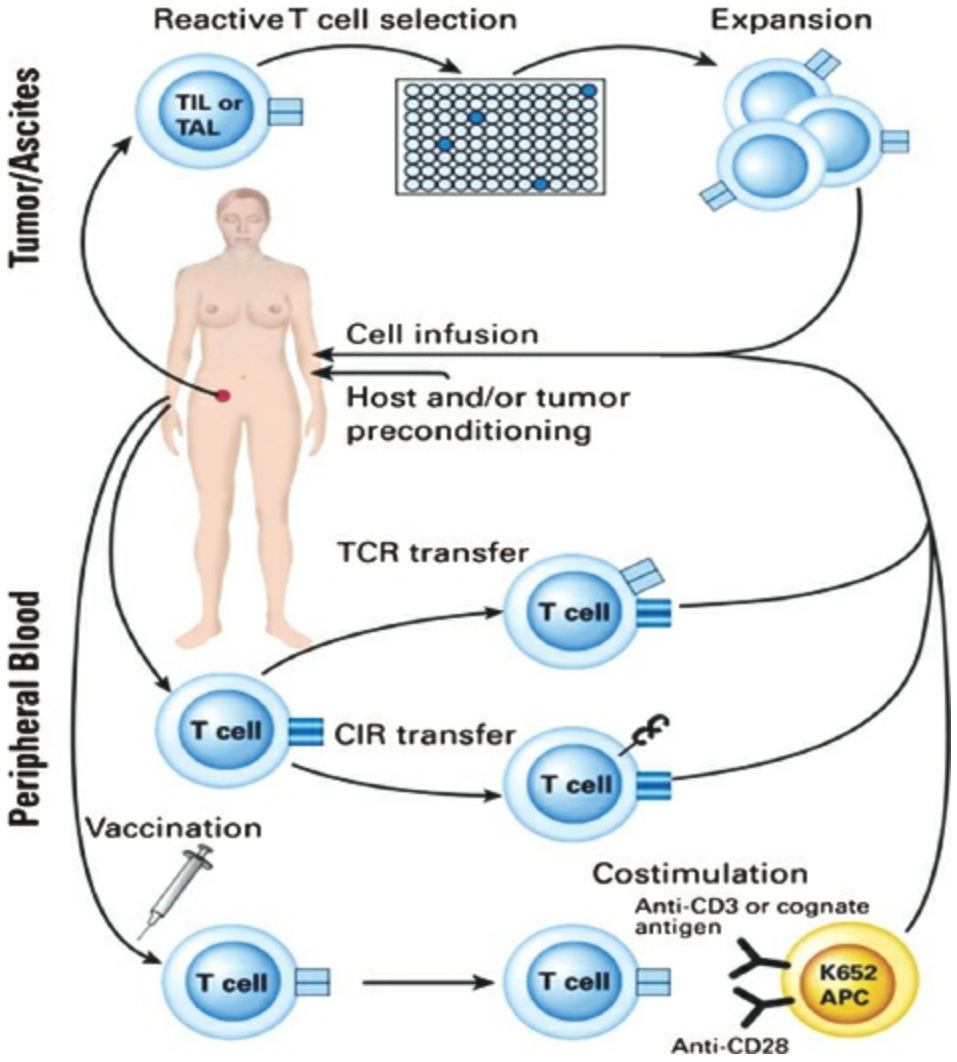

Figure 15.3 Cellular therapy
Source: From Kandalaft LE, Powell DJ Jr, Singh N, et al. Immunotherapy for ovarian cancer: what's next? J Clin Oncol. 2011;29:925–933, with permission.

Although TIL-based adoptive therapy has been tested mainly in melanoma or in hematologic malignancies, there is evidence that it also presents an important opportunity in ovarian cancer. In the early 1990s, ovarian cancers were found to yield reactive TILs after IL-2 culturing *in vitro* that might be amenable to adoptive transfer (229,230). Moreover, pilot clinical trials of adjuvant therapy with adoptive transfer of tumor-derived lymphocytes expanded *ex vivo* with IL-2, following surgical debulking and frontline chemotherapy, showed a marked survival advantage (231,232). Stage III EOC patients treated with consolidation adoptive transfer of expanded TILs after completion of cisplatin-based frontline chemotherapy (n = 13) had a 3-year OS rate of 100%, whereas 3-year OS in a control group of patients (n = 10) receiving only chemotherapy was 67.5% ($p < 0.01$). The 3-year disease-free survival of the patients in the TIL group and in the control group was 82.1% and 54.5%, respectively. Although these results can be limited by the lack of randomization, they nevertheless support the feasibility of adoptive therapy for ovarian cancer (231).

Optimization of adoptive TIL therapy is a matter of intense investigation, currently directed at: (a) optimizing methods to select tumor-reactive TIL and expand them under optimal costimulation conditions that allow preferential expansion of specific T-cell phenotypes; and (b) optimizing host and/or tumor conditioning. As shown in the melanoma trials, although infused cells had an effector phenotype ($CD27^-$ $CD28^-$ $CD45RA^-$ $CD62L^-$ $CCR7^-$), TILs that persist at 2 months in association with tumor regression were characterized by a less differentiated phenotype ($CD27^+$ $CD28^+$ $CD45RA^+$ but $CD62L^-$ $CCR7^-$) and longer telomeres (233–237). These results argue that use of memory rather than effector cells may

be more convenient for adoptive transfer (238), which has been confirmed by mouse models (239). Because TILs comprise a large number of tumor-reactive effector cells, identification of culture conditions that preferentially expand memory phenotypes is a priority. Recent technological advances with the development of artificial APCs (aAPCs) expressing a variable repertoire of costimulatory molecules and cytokines have generated new opportunities to provide the desired costimulatory molecules and cytokines to re-educate TILs, improving their potency and function *in vivo*. More recent work has described the development of a next-generation K562-based aAPC platform capable of expressing multiple gene inserts, including HLA-A2, CD64 (the high-affinity Fc receptor), CD80, CD83, CD86, CD137L (4-1BBL), and CD252 (Ox40L), and a variety of T-cell supporting cytokines (240). Cell-based aAPCs have proven to be more efficient at activating and expanding $CD8^+$ $CD28^-$ T cells, and antigen-specific T cells, than the magnetic bead-based aAPC (240).

One strategy to overcome the daunting task of raising large numbers of tumor-reactive T cells is by engineering T cells to redirect their specificity. This can be accomplished by transducing lymphocytes to express a cloned TCR with a high affinity for tumor-associated epitopes. In this case, the cloned heterodimeric TCR is transduced to mixed peripheral blood T cells isolated from the patient, creating a large amount of bispecific T cells, which are polyclonal with respect to their original TCR, but potentially monoclonal for the cloned TCR (if recombination with endogenous TCR is minimized) (241). Alternatively, T cells can be transduced with a chimeric immunoreceptor.

In the setting of advanced cervical cancer, adoptive T-cell therapy appears to be a promising option. In a study by Stevanović et al. (242), HPV oncoprotein-reactive T-cell cultures generated from TILs were administered to patients. Three out of nine treated women attained objective tumor responses, with durable remissions in two patients.

An alternative strategy to engineer T cells with redirected specificity is through genetic modification to recognize antigens in an MHC-unrestricted fashion through the use of chimeric antigen receptors (CAR), fusion genes encoding an extracellular domain that specifically binds to tumor epitopes through a single chain variable fragment (scFv) antibody, linked to intracellular signaling modules that mediate T-cell activation (57,241,243,244). The tumor binding function of CAR is usually accomplished by the inclusion of a single chain variable fragment (scFv) antibody, containing the V_H and V_L chains joined by a peptide linker of about 15 residues in length. In principle, universal targeting vectors can be constructed, because the scFvs bind to native cell surface epitopes and bypass the requirement for MHC restriction (245,246). Thus, in comparison with TCRs, CARs have two major advantages: (a) their HLA-independent recognition of antigen, which makes them broadly applicable regardless of the subject's HLA and regardless of the level of HLA expression on tumor cells, and (b) their signaling, which redirects T-cell cytotoxicity and permits T-cell proliferation and survival upon repeat antigen exposure. A potential drawback stems from their potential immunogenicity, if scFv are nonhuman. This can be averted by using human scFv.

A large number of CARs targeting diverse tumors have been developed (reviewed elsewhere) (241,247), and initial testing was done primarily in hematologic malignancies. Some of the ovarian tumor antigens and CARs investigated *in vitro* and *in vivo* in T lymphocytes are FBP (248,249), MUC1 (250), HER2, and mesothelin (251). The first study of adoptive transfer of CAR T cells in ovarian cancer (252) that was reported demonstrated safety, but no clinically evident tumor responses were seen. This was likely due to low expression of the transgenic CAR, and poor persistence of the transferred T cells (252). Persistence can be dramatically improved by using human scFv and by adding costimulatory signaling capabilities to the intracytoplasmic domain of CARs (253). One issue that must be addressed with CARs is that signaling through the cytosolic domain of the usual scFv-TCRz single chain construct does not fully replicate the multichain TCR signaling complex. This is solved by incorporating additional signaling modules in the cytoplasmic domain of the chimeric receptor. Efficient lentiviral and tissue culture technology also now enables highly efficient transduction of primary T cells (254). Other preclinical studies in which the T cells were engineered to express an MUC-16–specific CAR were associated with complete eradication of orthotopic ovarian xenografts (253). Additional studies evaluating T cells targeting other ovarian cancer–associated targets such as folate receptor, mesothelin, and NY-ESO-1 are ongoing.

Reports also indicate that T cells that are expanded *ex vivo* to maintain more stem-like T-cell populations, known as T stem cell memory (Tscm) cells, are capable of a more sustained response by replenishing effectors (255). A clear benefit of transferring less mature, more stem-like cells is likely due to the increased persistence and replenishing capability of

these cells *in vivo*. Next-generation autologous car-T cell (ACT) protocols are focused on (i) using less mature cells up to and including hematopoietic stem cells to provide a long-lasting, potentially life-long supply of effector T cells engineered against tumor antigens by TCR genes; (ii) incorporation of suicide genes in the gene-modification that could add an extra level of safety; (iii) incorporation of switch receptors that allow recognition of multiple antigenic targets; (iv) conversion of inhibitory signaling (e.g., *via* the PD-1 receptor) into an agonist signal by modifying the costimulatory domain of CAR T cells against the ligand; and (v) genetic labeling with bioluminescence imaging and positron emission tomography reporter genes to allow real-time visualization of transgenic T cell traffic into the tumor and its correlation with antitumor responses (256).

In preparation for the ACT, patients usually receive lymphodepleting conditioning chemotherapy, and low- or high-dose IL2 is administered after the transfer for T-cell expansion. As ACT becomes more common, it becomes very important that all centers are familiar with potential adverse events that may occur and its management. Cytokine release syndrome, typically occurring between postinfusion days 2 and 10, manifested as fever, hypotension, and respiratory insufficiency, can be managed with tocilizumab, an IL6-receptor antagonist and general supportive treatment in an intensive care unit setting. High-dose steroids are administered to life-threatening cases. Patients who have undergone multiple cycles of chemotherapy in the past may end up with persistent pancytopenia, and therefore, it is advisable to decrease the dose of conditioning chemotherapy and cryopreserve stem cell reserve for backup.

INNATE IMMUNE AGONISTS

In addition to vaccines, several strategies targeting recognition of cancers by the innate immune system have been explored in ovarian cancer. These strategies include type I IFN discussed earlier, TLR agonists, and microbial agents such as oncolytic viruses and bacteria.

TLR Agonists

TLRs recognize signature molecules broadly shared by various pathogens, which leads to production of type I IFNs and maturation of APCs. TLR ligands are being explored as anticancer agents in ovarian cancer (257). VTX-2337 (motolimod) is a small molecule agonist of TLR8, which has been evaluated in combination with liposomal doxorubicin in a phase 1 study in patients with advanced ovarian cancer. The study had evidence of safety and immune activation with clinical benefit (258). A phase 2 study evaluating motolimod in combination with liposomal doxorubicin is ongoing (NCT01666444), and an additional study is currently evaluating a triple combination of motolimod, liposomal doxorubicin, and the PD-L1 targeting antibody durvalumab (NCT02431559).

Oncolytic Viruses

Oncolytic viruses are viruses that have an inherent preferential predilection for replication in cancer cells as opposed to normal tissues. In addition to having tumor-debulking properties, the viruses serve as strong activators of innate immunity through provision of TLR agonists, release of tumor antigens and danger signals, and production of type I IFN. Several trials using oncolytic viruses administered intraperitoneally have been conducted in patients with advanced ovarian cancer, with most of the studies demonstrating good tolerability and durable disease stabilization in some patients (259–265). These studies suggest that IP oncolytic viruses present a viable therapeutic strategy in ovarian cancer, although for optimal efficacy, their evaluation in combination with other modalities (e.g., chemotherapy, other immunotherapies) is likely warranted.

Listeria

Live-attenuated *Listeria monocytogenes* (Lm)–based vaccines use a genetically modified form of the bacteria. Several studies have explored Lm-based vaccine encoding HPV-16 E7 protein in the setting of advanced cervical cancer. A prospective phase 2 study conducted in India was designed to evaluate the safety and efficacy of this vector (ADXS11-001) with and without cisplatin chemotherapy in patients with advanced cervical cancer. The results, presented at the ASCO 2014 meeting, demonstrated a 36% 12-month survival and an 11% response rate, suggesting that ADXS11-001 is an active agent in recurrent cervical cancer (266). A GOG phase II trial (protocol 265) evaluating the use of ADXS11-001 in the treatment of persistent or recurrent squamous or nonsquamous cell carcinoma of the cervix is ongoing (267).

CONCLUSIONS

Many patients with cervical, endometrial, or ovarian cancer who eventually develop treatment-resistant disease can initially be rendered free of clinically detectable disease by surgery, radiation therapy, and/or chemotherapy for varying periods of time. This setting, where the targets are circulating tumor cells or micrometastasis rather than bulk disease, is ideal for treatment with immune-based interventions. Significant advances have been made in the field of cancer immunotherapy over the last decade. It has been equally important to identify tumor antigens with immunogenic potential, as well as the application of a variety of approaches to augment the antitumor response in particular, using immunomodulatory strategies such as checkpoint blockade. Although there is clear evidence of long-lasting benefit in isolated groups of patients, there are numerous steps to take to continue to improve the outcomes for patients: (1) biomarkers for response must be developed, such as characterization of predictive genomic signatures, (2) broadening early success with checkpoint blockade by targeting Ox 40, ICOS, and others; (3) consideration of combinations with other modalities such as radiation, chemotherapy, or cryotherapy , to enhance antigen presentation, (4) consideration of the use of oncolytic viruses, (5) combinations with a variety of targeted agents exploiting the immune-modulating effect of the targeted drugs, and (6) evaluation of agents targeting other immune inhibitory mechanisms such as regulatory T cells, IDO, and MDSCs.

We must move ahead with discovery-oriented translational research in the form of clinical trials that quickly assess alternative vaccine strategies, immunomodulation approaches, combination strategies, immunologic monitoring methods, and tumor escape mechanisms. The key to success will depend on the continued development of organized multidisciplinary groups with the adoption of standardized patient populations (e.g., second or third remission), as well as standardized monitoring to enable the comparison of single variables such as the constitution of an antigen (protein, peptide, viral vectors, or DNA); the method, frequency, and intensity of antigen delivery; the effect of different adjuvants; and the characteristics of the effectors. In concert, a combination of strategies with the aim of achieving an integrated response (antibody and T-cell effectors) along with immunomodulatory approaches seems most likely to provide a meaningful clinical benefit in the future.

CHAPTER 16 Clinical Trials Methodology and Biostatistics

Mark F. Brady, Jeffrey C. Miecznikowski and Virginia L. Filiaci

Clinicians make treatment recommendations daily. These recommendations arise from culling information from standardized clinical guidelines, published reports, expert opinion, or personal experiences. The synthesis of information from these sources into a particular recommendation for an individual patient is based on a clinician's personal judgment. But what constitutes reliable and valid information worthy of consideration? It has long been recognized that properly planned and conducted clinical trials are important sources of empirical evidence for shaping clinical judgment. This chapter begins by describing a general system for classifying clinical study designs. The components of a clinical trial and essential considerations for developing new trials are then presented. Because translational research (TR) objectives are incorporated into many modern cancer trials, some issues related to design and analyses of these components are also presented.

CLASSIFICATION OF STUDY DESIGNS

In general, a clinical study is any experiment involving human subjects that evaluates an intervention that attempts to reduce the impact of a specific disease in a particular population. The term clinical trial is usually limited to prospective studies where individuals receive an intervention and then followed to assess their health status. When an intervention is applied to prevent the onset of a particular disease, the trial is classified as a primary prevention trial. For example, a primary prevention trial may evaluate healthy lifestyles or a vitamin supplement in a population of individuals who are considered to be at risk of a particular disease. Secondary prevention trials evaluate interventions that are applied to individuals with early stages of a disease to reduce their risk of progressing to more advanced stages. Tertiary intervention trials are aimed at evaluating interventions that reduce the risk of morbidity or mortality due to a particular disease.

Clinical trials that evaluate methods for detecting disease in a preclinical state are called **screening trials**. Early detection may mean diagnosing a malignancy in an early stage (e.g., the use of mammography in the detection of breast cancer) or in a premalignant state (e.g., the use of Papanicolaou smear in the detection of cervical intraepithelial neoplasia). There are typically two types of interventions in a screening trial. The first intervention is the screening program (e.g., annual mammograms) that involves individuals who appear to be free of the disease. However, once the disease is detected in an individual, a secondary intervention (e.g., surgery) is performed in hopes of stopping the disease from progressing to more advanced stages. Consequently, screening trials require *both* interventions to be effective. An effective screening procedure is useless if the secondary intervention does not alter the course of the disease. On the other hand, an ineffective screening procedure would cause the secondary intervention to be applied indiscriminately or too late for the treatment to be effective.

Nonexperimental studies (or **observational studies**) can be classified into three broad design categories: cohort (or **prospective**), case–control (or **retrospective**), and **cross-sectional**. In cohort studies, individuals are initially grouped

according to their exposure status, which can be based on environmental, genetic, lifestyle, or therapeutic treatment factors. These individuals are then followed to determine who develops the disease of interest. The aim of these studies is to assess whether the exposure is associated with the incidence of the disease under study. This design is in contrast to the case–control study that retrospectively identifies individuals on the basis of whether they have the disease and then measures and compares their exposure histories. General discussions of case–control studies tend to use the term exposure, but this term can encompass the status of a particular protein or genetic biomarker. Measuring exposure may be as simple as questioning the individuals about their personal or employment history, or it may involve a more sophisticated assessment such as analyzing the individual's biologic specimens for biomarkers. Though the case–control study has drawbacks, it has the advantage of often being less expensive, easier, and quicker to perform than a cohort study, especially when the disease is rare. The power of the case–control design is clearly demonstrated in the study reported by Herbst et al. (1) that demonstrated that mothers taking diethylstilbestrol during pregnancy increases the risk of vaginal cancers occurring in their daughters exposed *in utero*.

There is a special type of case–control study that is nested within a cohort of exposed and unexposed individuals. For instance, suppose a large prospective clinical trial is conducted within a specific population and blood or tissue samples are banked for each of the individuals who were enrolled into the study cohort. After the study has been completed, the investigators may be interested in determining whether a biomarker is associated with the subjects' outcome. Instead of assessing the biomarker for all the individuals in the cohort study, when the outcome is uncommon it is usually more efficient to assess the new biomarker in those individuals who experienced the outcome of interest (cases), and only a subset of those who did not experience the outcome (controls). In this type of study, the case–control study is said to be **nested** within a cohort study.

There are several approaches to selecting the controls from the cohort, and each approach offers advantages and disadvantages. First, controls can simply be a randomly selected subset of all of the control subjects. This is the traditional case–control procedure. Alternatively, one or more controls could be randomly selected from the subset of controls that have risk factors matching each case (individual matching). This is the matched case–control design. The variables that are selected for matching should be associated with the disease and the exposure of interest. These variables are considered potential confounders. Matching on variables that are only associated with the exposure will undermine the efficiency of the study design. The goal of matching is to increase the study's efficiency by forcing cases and controls to have similar distributions of the confounders. Because time at risk of developing a disease (e.g., age) is frequently associated with both risk of disease and exposure, nested case–control studies frequently match on the time that an individual is at risk. In this case, each case is matched to a control that has been at risk of developing the disease for at least as long as the time until the matched case developed the disease. While the most often stated reason for matching is to reduce confounding, it actually tends to provide an important increase in efficiency. It is important to recognize, however, that following the matching process the selected controls are no longer representative of the controls in the target population. In particular, the distribution of the confounding variables and the exposure (e.g., the new biomarker of interest) in the control sample will be shifted toward that of the cases (2). Matched case–control studies can provide valid estimates of the conditional relative odds of the new biomarker for diseased cases versus the controls; however, estimating the marginal or absolute effects of the biomarker in the target population requires complex weighting procedures (3).

The **case–cohort design** provides another approach to selecting individuals from an established cohort (4). All of the individuals in the cohort who develop the disease outcome are selected and designated as cases. Then a subcohort of individuals is randomly selected from the entire cohort, which provides the controls. One of the primary advantages of the case–cohort approach is that the same subcohort can be used for the analyses of multiple disease outcomes. In contrast, a matched case–control study would need to identify matches for each of the cases that is selected for each type of outcome studied.

It should be noted that the goal of the cross-sectional study is to describe the prevalence of a disease and an exposure in a population during a specific period of time. These studies can often be conducted more quickly and less expensively than both the cohort or case–control studies, but they are seldom used when the time between exposure and disease onset

is long, as it is for cancer.

COMPONENTS OF A CLINICAL TRIAL

Objectives

In clinical oncology research, the ultimate purpose is to accomplish a defined objective, whether it be to develop a treatment plan that puts the patients into a disease-free state, reduce the risk of cancer recurrence, or allow patients to return to their normal lifestyle within a reasonable period of time. When it comes to a particular clinical trial, however, objectives need to be more precisely defined. In general, they typically incorporate three elements: the interventions to be evaluated, the "yardstick" to be used to measure treatment benefit (see End Points), and a brief description of the target population (see Eligibility Criteria). These three elements (i.e., "what," "how," and "who") should be stated in the most precise, clear, and concise terms possible. An open dialogue among expert investigators remains the most effective approach for establishing the objectives of any clinical trial.

End Points

The end points of a trial typically consist of a measurable and reproducible entity in the patient's disease process that can be used to assess the efficacy of an intervention. A study may assess more than one end point, but in these instances the end point of primary interest should be clearly specified or else the study design should carefully reflect the complexity of interpreting multiple outcomes. End points can also be a composite measure of multiple outcomes. For instance, some studies assessing health-related quality of life aggregate patient-reported scores from several related items or domains that are all considered components of a larger concept called quality of life.

End points should be a valid (unbiased) measure of the treatment effect on the disease process. They should not be susceptible to a systematic error that favors one treatment, which would lead to biased estimates of the treatment's effect. For instance, trials assessing time to disease progression, in which the schedule for CT scans is different for each treatment group, are susceptible to assessment bias. Second, the measurement of an end point should be reliable and not susceptible to subjective interpretation. Third, end points that are directly relevant to the patient are preferable, although valid surrogate end points are considered indirectly relevant to the patient. Finally, end points which are not too expensive or inconvenient for the patient are preferred. It is not always possible for a single end point to exhibit all of these characteristics simultaneously. For example, avoiding death is very relevant to a patient with a lethal disease like advanced gynecologic cancer. Also, survival can usually be measured very reliably. However, most cancer patients will not only receive the treatments prescribed by the study, but after exhibiting signs of disease progression, they also receive other anticancer therapies. In this case, the validity of overall survival (OS) comparisons is suspected because they not only reflect the effects of the study treatment, but also the effects of other therapies that are external to the study.

End points may be classified as: categorical (e.g., clinical response), continuous (e.g., serum CA-125 values), or time-to-event (e.g., survival time). A time-to-event end point includes both time (a continuous measure) and censoring status (categorical measure). The data type influences the methods of analysis.

Measurement Errors

The susceptibility of an outcome to measurement errors is an important consideration when choosing an end point. These can be characterized as random or systematic errors. Random error refers to variation that occurs among measurements that is not predictable, and appears to be due to chance alone. For example, a serum sample could be divided into 10

aliquots and submitted to the laboratory for CA-125 determinations. If the laboratory returns nearly the same value for each aliquot, then the associated random error is low, and the measurement may be deemed reproducible. On the other hand, if the CA-125 values vary considerably among aliquots, perhaps because of inconsistent laboratory procedures, then individual values may be considered unreliable. In this case, taking the average CA-125 measurement across all 10 aliquots is expected to be a better estimate of the patient's true CA-125 value than any single measurement.

Deviations from the true value that occur in a regular fashion are termed systematic errors, or bias. For example, suppose an investigator initiates a randomized trial comparing two treatments with time to disease progression being the primary end point. The protocol indicates that the patient should be assessed after each cycle of therapy. However, suppose that a treatment cycle duration is 2 weeks for one treatment group and 4 weeks for the second treatment group. Using a more intense assessment schedule for the group being treated on 2-week cycles would tend to detect progressions earlier than in the group being treated every 4 weeks. Therefore, the time to failure comparison between treatments would systematically favor the treatment group with a longer interval between assessments.

When there are recognized sources of error, it is important that the study design implements procedures to avoid or minimize their effects. For example, random error in many cases can be accommodated by either increasing the number of individuals in the study (the sample size), or in some cases by increasing the number of assessments performed on each individual. Systematic measurement error cannot be addressed by increasing the sample size. In fact, increasing the sample size may exacerbate the problem because small systematic errors in large comparative trials contribute to the chances of erroneously concluding that the treatment effect is statistically significant. The approaches to controlling sources of systematic error tend to be procedural. For example, treatment randomization is used to control selection bias, placebos are used to control observer bias, standardized assessment procedures and schedules are used to control measurement bias, and stratified analyses are used to control biases due to confounding. For an extensive description of biases that can occur in analytic research, see Sackett, 1979 (5).

Surrogate End Points

Surrogate end points do not necessarily have direct clinical relevance to the patient. Instead, surrogate end points are often intermediate events in the etiologic pathway to other events that are directly relevant to the patient (6). The degree to which a treatment's effect on a surrogate end point predicts the treatment's effect on a clinically relevant end point is a measure of the surrogate's validity. The ideal surrogate end point is an observable event that is a necessary and sufficient precursor in the causal pathway to a clinically relevant event. Additionally, the treatment's ability to alter the surrogate end point must be directly related to its impact on the true end point. It is important that the validity and reliability of a surrogate end point be established and not simply presupposed (7,8). Surrogate end points are sometimes justified on the basis of an analysis that demonstrates a statistical correlation between the surrogate event and a true end point. However, while such a correlation is a necessary condition, it is not a sufficient condition to justify using a particular surrogate as an end point in a clinical trial. For example, CA-125 levels following three cycles of treatment of ovarian cancer have been shown to be associated with OS (9). However, it has not (yet) been demonstrated that the degree to which any particular treatment reduces CA-125 levels reliably predicts its effects on clinically relevant end points, like overall survival.

Primary End Points in Gynecologic Oncology Treatment Trials

The United States Food and Drug Administration organized a conference to consider end points for trials involving women diagnosed with advanced ovarian cancer (10). Meta-analyses were presented that indicated that progression-free survival (PFS) can be considered a valid end point for trials involving women with advanced ovarian cancer. However, while the general validity of PFS for predicting OS has been established, PFS comparisons in a particular study can be biased because of differences in disease assessment schedules among treatment groups, either intentionally or unintentionally. In

contrast, overall survival time is generally not susceptible to this source of bias.

The progression-free interval (PFI) may be a reasonable end point in trials involving patients with early or locally advanced cancer. The difference between PFI and PFS resides in how patients, who die without any evidence of disease progression, are handled in an analysis. Patients who die without evidence of progression are censored at the time of their death in a PFI analysis, but are considered an uncensored event in a PFS analysis. If deaths due to non-cancer–related causes are common, then selecting PFI as the study end point will generally increase the study's sensitivity for detecting active treatments. In this case, however, the analysis needs to consider procedures that will account for treatment-related deaths, as well as deaths from competing causes, which may occur prior to disease recurrence. Simply censoring the time to recurrence in these cases can make a very toxic treatment appear more effective than it actually is.

A number of studies have provided evidence that a new treatment increases the duration of PFS, but not OS. For example, OVAR 2.2, a second-line treatment trial involving patients with platinum-sensitive ovarian cancer, indicated that carboplatin and gemcitabine significantly decreased the hazard of first progression or death by 28% (hazard ratio = 0.72, p = 0.003) when compared to carboplatin alone (11). However, there was no appreciable difference between the treatment groups with regard to the duration of OS (hazard ratio = 0.96, p = 0.735). Also, three trials evaluating maintenance bevacizumab for first- or second-line treatment of ovarian cancer reported significant prolongation in the duration of PFS (12–14), but no difference in overall survival. PFS may be a good surrogate for OS, but it appears to be susceptible to a small but not insignificant chance of false-positive prediction. Despite this, it is very rare for the results of an oncology trial to indicate that a new treatment prolongs OS but does not delay the onset of recurrence or progression.

It seems reasonable to expect that an anticancer treatment that prolongs survival should exert its influence by delaying the onset of new or progressive disease. This has prompted some investigators to recommend using both PFS and OS as trial end points (15–17). Specifically, trials involving patients with advanced stage cancer are designed to assess OS in the final analysis, but PFS is monitored at scheduled interim analyses. If the trial's evolving evidence indicates that there is insufficient PFS benefit, then the trial may be stopped early with the conclusion that the treatment has insufficient activity to warrant further investigation in the target population. This procedure tends to halt trials of inactive treatments early, but continues trials of active agents to completion.

To date, PFS has not been formally validated for use in trials involving patients with metastatic cervical, endometrial, or vulvar cancers. In the absence of a formally validated surrogate end point, OS or symptom relief remain reasonable end points. Because relief from symptoms is susceptible to assessment bias, trials utilizing these end points should use validated instruments (see Measurement Errors) and consider blinding the study treatments whenever possible.

Response (disease status) assessed via reassessment laparotomy following treatment has been proposed for use as a study end point in ovarian cancer trials (18). The justification is that those patients with no pathologic evidence of disease are more likely to experience longer survival than those with evidence of disease. The principal drawback to this end point is that reassessment laparotomy is a very onerous procedure for the patient; many patients refuse reassessment surgery, or the surgery may become medically contraindicated. Even among patients of surgeons who are strong proponents of reassessment surgery, the percentage of patients not reassessed is typically greater than 15%. These missing evaluations can significantly undermine the interpretability of the study.

In summary, the ideal primary end point provides valid and reliable evidence about the intervention's impact on the disease. It is, itself, either clinically relevant to the patient, or a validated surrogate of a clinically relevant outcome. It should be convenient and cost-effective to measure. Unfortunately, in some trials, these features are not always available simultaneously. If a surrogate end point is used, then its validity should be established, not presumed.

Eligibility Criteria

The eligibility criteria serve two purposes in a clinical trial. The immediate purpose is to define those patients with a particular disease, clinical history, and personal and medical characteristics who may be considered for enrollment. The subsequent purpose of eligibility criteria is typically evident after the clinical trial is completed and the results are available.

At this time physicians need to carefully consider to whom the results apply. Therefore, during study development, investigators should be cognizant of the generalizability of any results that are ultimately reported. A potentially useful approach for determining the necessity of a particular eligibility criterion is to clearly identify its function. In addition to defining the target population, there are four distinct functions that an eligibility criterion may serve: benefit-morbidity equipoise (safety), homogeneity of benefit (scientific), logistics and regulatory compliance (19).

Ideally, each patient who meets the eligibility criteria of a clinical trial would be asked to participate. However, this is seldom possible for multiple reasons. **Figure 16.1** displays common restrictions that can limit the entry of patients to a clinical trial. In particular, restricted access to the study may contribute to distorted sampling from the target population, which is called selection bias. For example, participating investigators at university hospitals might tend to enroll disproportionately more patients with cancer who have undergone more aggressive initial cytoreductive surgeries than their counterparts at community hospitals.

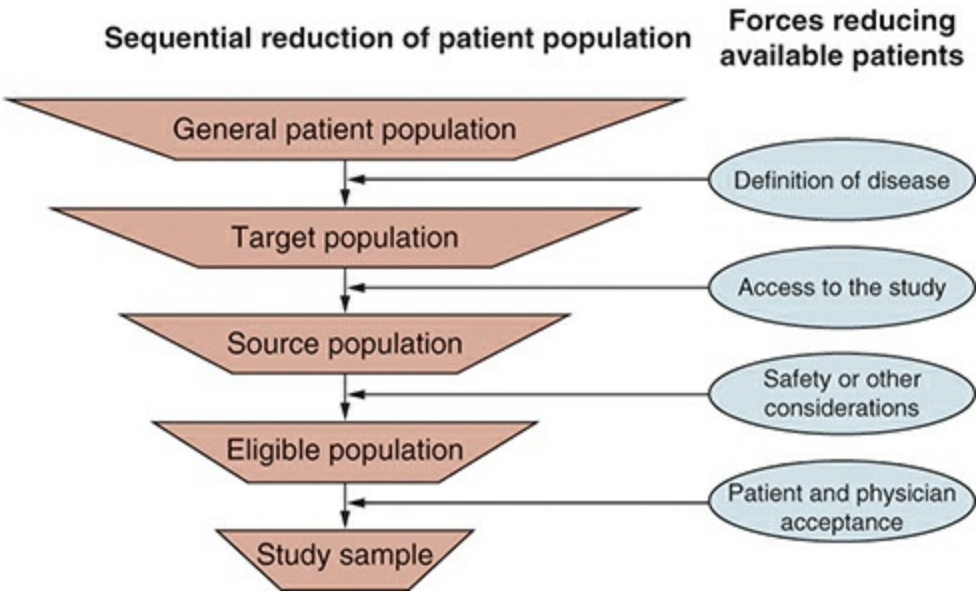

Figure 16.1 Sequential reduction of patient population

Eligibility criteria applied for safety are in place to eliminate patients for whom the risk of adverse effects from treatment is not commensurate with the potential for benefit. An example of this may be to restrict eligibility to patients with normal organ function based on concern that a trial therapeutic may be too toxic in such patients. Eligibility criteria may also be warranted when there is a scientific or biologic rationale for a variation in treatment benefit across patient subgroups, particularly if the effect of a new therapy may be expected to be dramatically inconsistent across the entire spectrum of the target population, so much so that statistical power can be compromised (19). One example of this type of exclusion criterion is found in GOG Protocol 152 (A Phase 3 Randomized Study of Cisplatin [NSC#119875] and Taxol [Paclitaxel][NSC#125973] with Interval Secondary Cytoreduction versus Cisplatin and Paclitaxel in Patients with Suboptimal Stage III & IV Epithelial Ovarian Carcinoma). This study was designed to assess the value of secondary cytoreductive surgery in patients with Stage III ovarian cancer. All patients entered into this study were to receive three courses of cisplatin and paclitaxel. After completing this therapy they were then randomized to either three additional courses of chemotherapy or interval secondary cytoreductive surgery followed by three additional courses of chemotherapy. The eligibility criteria excluded patients who had only microscopic residual disease following their primary cytoreductive surgery, because there is no scientific reason to expect that interval cytoreduction would be of any value to patients with no gross residual disease. In addition, the desire to accrue a study population with homogeneous prognosis is a common reason for eligibility criteria. In fact, eligibility criteria should be as broad as possible to enhance generalizability.

Eligibility criteria based on regulatory considerations include those institutional and governmental regulations that require a signed and witnessed informed consent and study approval by the local Institutional Review Board. These

restrictions are required in most research settings and are not subject to the investigator's discretion. Finally, they can be justified by logistic considerations. For example, a study that requires frequent clinic visits for proper evaluation or toxicity monitoring may restrict patients who are unable to arrange reliable transportation. The potential problem with such a restriction is how it is structured. A criterion requiring that the patient have a car at her disposal is probably too restrictive, because some patients from resource-poor areas may not have access to private transportation. Such a restriction tends to erode the generalizability of the trial by oversampling from resource-rich communities.

Many biostatisticians believe that eligibility criteria in oncology trials tend to be too restrictive and complicated (19,20). Overly restrictive or complex eligibility criteria hamper accrual, prolong the study's duration, and delay the reporting of results, and therefore should be avoided. The Medical Research Council has demonstrated that it is possible to conduct trials with simple and few eligibility criteria (21). As an example, the International Collaborative Ovarian Neoplasms (ICON 3) trial compared standard carboplatin or cisplatin–adriamycin–cyclophosphamide regimen to paclitaxel plus carboplatin in women with newly diagnosed ovarian cancer. This trial employed only six eligibility criteria, three of which were for safety (fit to receive chemotherapy, absence of sepsis, and bilirubin less than twice the normal level). This was in sharp contrast to GOG Protocol 162 (A Phase 3 Randomized Trial of Cisplatin (NSC #119875) with Paclitaxel (NSC #125973) Administered by Either 24-Hour Infusion or 96-Hour Infusion in Patients with Selected Stage III and Stage IV Epithelial Ovarian Cancer), which had 34 eligibility criteria.

PHASES OF THERAPEUTIC INTERVENTION TRIALS

The traditional approach to identifying and evaluating new drugs has relied on sequential evidence from phase 1, 2, and 3 clinical trials. Each of these study designs stem from very distinct study objectives. Phase 2 trials build on the evidence gathered from phase 1 trial results, and similarly phase 3 trials build on phase 2 and phase 1 trial results. The investigation of a given treatment may be halted at any phase, due to safety and/or efficacy issues. Depending upon the underlying investigation, the time from the initiation of a phase 1 trial for a given treatment to the completion of a phase 3 trial often spans several years. Trials can also include multiple phases. Although this may cut down on the overall duration as compared to developing and running individual trials, additional upfront development time is increased, with no guarantee that the additional phases will ever complete.

Phase 1 Trials

The purpose of a phase 1 trial is to determine an acceptable dose or schedule for a new therapy as determined by toxicity and/or pharmacokinetics. Because of the limited number of patients involved in phase 1 trials, outcome measures such as response and survival are not the primary interests in these studies. In general, the phase 1 trial marks the first use of a new experimental agent in humans. Most escalate dose or schedule of the new agent either after a prespecified number of consecutive patients have been successfully treated or within an individual as each dose is determined to be tolerable.

The usual phase 1 trial of a cytotoxic agent attempts to balance the delivery of the greatest dose intensity against an acceptable risk of dose-limiting toxicity (DLT). The conventional approach is to increase the dose of the new agent after demonstrating that a small cohort of consecutive patients (three to six) was able to tolerate the regimen. However, once an unacceptable level of toxicity occurs (e.g., two or three patients experiencing DLT), the previously acceptable dose level is used to treat additional patients to provide further evidence that the current dose has an acceptable risk of DLT. If this dose is regarded as acceptable, it is called the recommended dose level (RDL) for further development. The RDL should not be confused with the maximum tolerated dose (MTD). The MTD is a theoretical concept used to design phase 1 trials, whereas the RDL is an *estimate* of the MTD, and may or may not be accurate.

Alternative strategies for estimating the MTD have been proposed. The primary motivation for these newer strategies is to reduce the number of patients treated at therapeutically inferior doses and to reduce the overall size of the study. One of

these alternatives implements a Bayesian approach and is referred to as the continual reassessment method (CRM) (22). It has the attractive feature of determining the dose level for the next patient based on statistical modeling of the toxicity experience of previously treated patients. While the traditional approach has been criticized for treating too many patients at subtherapeutic doses and providing unreliable estimates of the MTD, CRM has been criticized for tending to treat too many patients at doses higher than the MTD (23). Refinements to CRM have been proposed (24) and found to have good properties compared to alternative dose-seeking strategies (25).

Another family of designs termed the accelerated titration design (ATD) allows doses to be escalated within each patient and incorporates toxicity or pharmacologic information from each course of therapy into the decision regarding whether or not to pursue further escalation (26). Both the modified-CRM and ATD designs can provide significant advantages over the conventional phase 1 design. Finally, phase I studies to identify doses for combinations of agents may require the consideration of potential pharmacokinetic or pharmacodynamic interactions (27).

Other phase I study designs are often utilized for trials involving precision therapies. These studies often incorporate a biomarker end point that signals either the activation or deactivation of a targeted pathway. As the dose is increased for small cohorts of individuals, the biomarker is measured and toxicity monitored simultaneously. Then, statistical models are used to determine a safe dose where the targeted pathway is consistently activated or inhibited (28).

Even though the majority of phase 1 trials in cancer research follow what has been described above, alternative phase 1 trials may arise in other settings such as medical device trials, prevention trials, education intervention trials, behavior modification trials, in which the first phase of investigation may actually utilize healthy subjects, such as studies designed to determine the utility of a new educational intervention on smoking cessation. The phase 1 trial may simply be utilized as an approach toward gaining some experience with the intervention prior to moving forward to the next phase of investigation.

Phase 2 Trials

Once a dose and schedule for a new regimen have been determined, the reasonable next step is to seek evidence that the new regimen is worthy of further evaluation in a prespecified patient population. The principle goal of a phase 2 trial is to prospectively quantify the potential efficacy of the new therapy. Because a phase 2 trial treats more patients at the RDL than in a phase 1 trial, it also provides an opportunity to more reliably assess toxicities. A phase 2 trial is often referred to as a screening trial because it attempts to judiciously identify active treatments worthy of further study in much the same way a clinician screens patients for possibly a more extensive disease evaluation. The study should have adequate sensitivity to detect active treatments and adequate specificity for rejecting inactive treatments. A phase 2 trial may evaluate a single new treatment or incorporate randomization to evaluate several new therapies or treatment schedules simultaneously.

Traditionally, phase 2 trials have been designed as a single-arm trial, but the randomized phase 2 trial has been utilized with increasing frequency. However, investigators should consider several factors when designing the phase 2 trial as a single-arm or a multi-arm randomized trial. While the required sample size is smaller for the single-arm trial, strong and sometimes unwarranted assumptions are required in the design (29). Single-arm trials assume that the probability of response to standard treatment in the target population is known with certainty, which is often suspect, because of unanticipated or unknown differences between the study sample and historical sample(s). For instance, there may be differences in the patients' prognoses unintentionally introduced by the study's eligibility criteria or changes in patient referral patterns. Differences in the response assessment schedule, the modalities for evaluation, or the definition of response may change over time and therefore distort comparisons with historical results. Therefore, whenever possible, we prefer the randomized controlled phase 2 design of a novel agent against an accepted standard treatment. However, when the probability of response to standard treatment is widely accepted to be very low (e.g., <5%), a single-arm trial makes sense.

Phase 2 trials can have a single-stage or a multistage design. In a single-stage design, a fixed number of patients are

treated with the new therapy. The goal of the single-stage design is to achieve a predetermined level of precision in estimating the end point. Although precision is one important goal in cancer trials, investigators and trial experts aim to reduce the number of patients exposed to inferior (or inactive) therapies. For this reason, many phase 2 cancer trials use multistage designs. Multistage designs implement planned interim analyses of the data and apply predetermined rules to assess whether there is sufficient evidence to warrant continuing the trial. These rules are in place to stop accrual in trials with regimens having less than the desired activity while allowing regimens having at least a minimally acceptable level of activity to proceed to completion. Two-stage designs that minimize the expected sample size when the new treatment has a clinically uninteresting level of activity have been proposed for single-arm studies (30) and multi-arm studies (31). In the cooperative group setting there is often a need for flexibility in specifying exactly when the interim analysis will occur. This is because of the significant administrative and logistic overhead of coordinating the study in several clinics. Therefore, designs that do not require the interim analyses to occur after a precise number of patients are entered are useful particularly in the multi-institutional setting (32).

Regardless of the measure of treatment efficacy, toxicity is a secondary end point in phase 2 trials. This approach is not likely to be appropriate in phase 2 trials of very aggressive treatments in which stopping rules may explicitly consider both response and the cumulative incidence of certain toxicities (33–35). Bayesian designs that permit continuous monitoring of both toxicity and response have also been proposed (36). Other designs account for simultaneous assessment of two outcomes (e.g., response rate and survival), also referred to as a bivariate outcome (37).

The approach to clinical trials utilizing biomarker-driven selection and molecularly targeted therapies is discussed below.

Phase 3 Trials

The goal of a phase 3 trial is to prospectively and definitively determine the effects of a new therapy relative to a standard therapy in a well-defined patient population. Phase 3 trials are also used to determine an acceptable standard therapy when there is no prior consensus on the appropriate standard therapy. It is useful to distinguish phase 3 objectives as having an efficacy, equivalency, or non-inferiority design consideration. An **efficacy** design is characterized by the search for an intervention strategy that provides a therapeutic advantage over the current standard of care. An **equivalency** trial seeks to demonstrate that two interventions can be considered sufficiently similar on the basis of outcome such that one can be reasonably substituted for the other. **Non-inferiority** trials seek to identify new treatments that reduce toxicity, patient inconvenience, or treatment costs without significantly compromising efficacy.

Efficacy Trials

From the outset of efficacy trials, it is recognized that the benefit of a novel treatment (which is being evaluated) may be accompanied by an increased risk of toxicity, inconvenience, or financial cost, when compared to the standard of care. However, it is hoped that the benefits will be sufficiently large to offset these drawbacks. This is illustrated in **Figure 16.2**. Suppose treatment A is the standard of care for a particular target disease population. The quantitative *difference in efficacy* between treatments with respect to a particular outcome (B-A) can be described on a horizontal axis as in **Figure 16.2**. If we are reasonably certain that the difference between treatments is less than zero (left of 0), then we would consider treatment A to be better. On the other hand, if the treatment difference is greater than zero (right of 0), then we would conclude that the new treatment, B, is better. Furthermore, we can use dotted lines on this graph to demarcate a region in which the difference between A and B is small enough to warrant no clinical preference for A or B. Consider the results from a trial expressed as the estimated *difference between treatments* and the corresponding 95% or 99% confidence interval (CI) superimposed on this graph. The CI depicts those values of the treatment difference that can be reasonably considered consistent with the data from the trial. When the CIs are sufficiently broad that the data cannot distinguish between the treatments being tested, the trial is determined to be inconclusive (**Fig. 16.2**). This is a typical

consequence of a small trial. On the other hand, if the CI entirely excludes the region where treatment A is better than treatment B, then we can conclude that treatment B is significantly better than treatment A (**Fig. 16.2**). Note that in this case the lower bound of the CI may extend into the region of clinical indifference, but the CI must exclude the region below (left of) 0 difference.

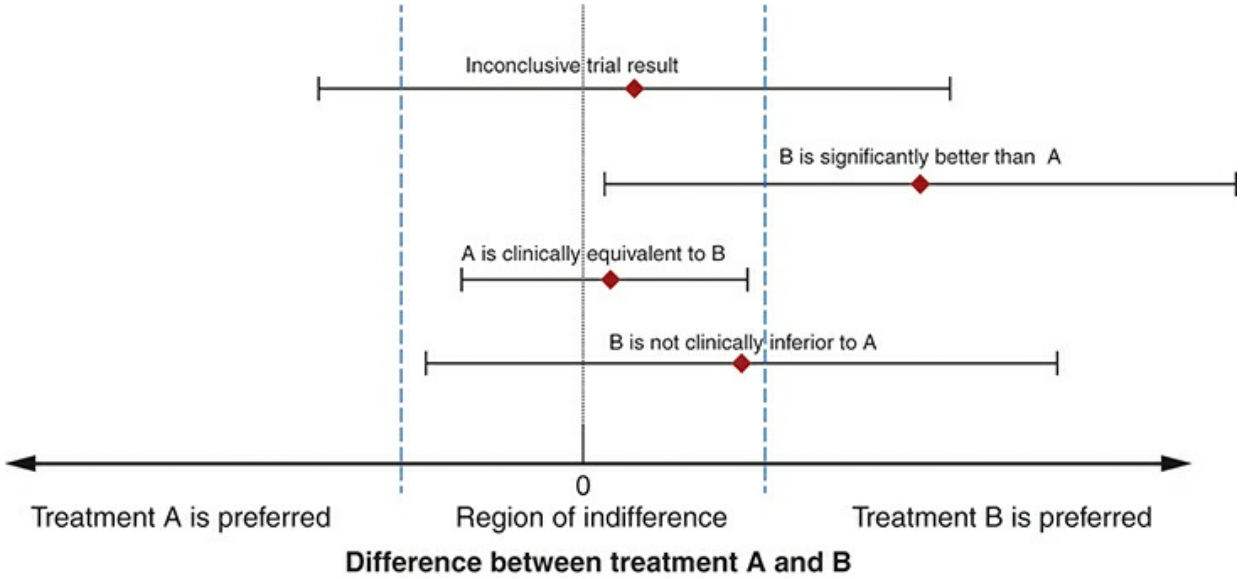

Figure 16.2 Graphical representation of the point estimates and confidence intervals describing the difference in efficacy between the standard treatment (A) and a new experimental regimen (B) from five hypothetical trials

When an efficacy trial fails to demonstrate that a new experimental regimen is statistically superior to the control regimen, this should not be interpreted as demonstrating that these regimens are equally effective. Even though the estimated difference between two treatments may be near zero, the CI may not rule out treatment differences that are clinically relevant. Therefore, we advocate cautious interpretation from efficacy studies that conclude "therapeutic equivalency" when only a small difference between treatments with regard to the outcome is observed. Careful inspection of the CIs, such as those in **Figure 16.2**, is appropriate, as well as where one personally considers where the region of clinical indifference is located.

Equivalency Trials

The equivalency study design is perhaps a misnomer, because it is impractical to generate enough data from any trial to definitively claim that the two treatments are equivalent. Instead, an investigator typically defines the limits for treatment differences that can be interpreted as clinically irrelevant. If it is a matter of opinion for what differences in effect sizes can be considered clinically irrelevant, this issue can become a major source of controversy in the final interpretation of the trial results. Bioequivalency designs are occasionally conducted to demonstrate that two treatments exert similar influence on the expression of a biomarker. In this case, an investigator should have some notion about the acceptable range of biomarker expression that can be considered clinically equivalent. These studies are designed so that, within tolerable limits, the treatments can be considered as having similar biologic effects.

Non-inferiority Trials

A non-inferiority study design may be considered when the currently accepted standard treatment is associated with significant toxicity and a new and less toxic treatment becomes available. The goal of this type of study is to demonstrate

that substituting the new treatment for the current standard treatment does not compromise efficacy appreciably (38–41). Referring to **Figure 16.2**, the trial seeks to provide sufficient evidence to be reasonably certain that the difference between A and B lies above the lower boundary of the indifference region. This lower boundary is often called the "non-inferiority margin." If the CI for the difference in efficacy fails to exclude the region where the standard regimen, A, is preferred, then there is insufficient evidence to conclude that the new regimen is not inferior to standard treatment.

The justification for the non-inferiority margin selected in a particular study is often controversial. If this margin is set too low, then the study has an unacceptably high probability of recommending an inferior treatment. If it is too high, then the trial utilizes too many clinical and financial resources. To select an appropriate margin of non-inferiority it is important to recognize that even though a non-inferiority trial may explicitly compare only two treatments, implicitly there is a third treatment to be considered. For example, suppose that several historical studies indicate that treatment A is better than a placebo for treating a specific disease. In this case, the goal of a non-inferiority study is to demonstrate that a new experimental treatment, B, does not significantly compromise efficacy when compared to the currently accepted active standard treatment, A. However, it should also demonstrate that B would have been better than a placebo, if a placebo had been included in the current trial. In other words, the current trial will directly estimate the effectiveness of B relative to A, but it must also indirectly consider the effectiveness of B relative to the previous control treatment (placebo in this case). This indirect comparison relies on obtaining a reliable and unbiased estimate of the effectiveness of the current active control to the previous control from previous trials.

Sometimes the margin of non-inferiority is expressed as a proportion of the effectiveness of A relative to the previous standard treatment. For example, a non-inferiority study could be designed to have a high probability of concluding that a new treatment retains at least 50% of the activity of the standard regimen, A. Note that an investigator may wish to be highly confident that none of the efficacious benefits of the current standard treatment be sacrificed. In this case, the margin of non-inferiority is set at 0 (**Fig. 16.2**) and the design is the same as the efficacy trial. Indeed, an efficacy trial can be considered a study in which the investigator is willing to accept the new treatment B, only if the trial results indicate that B is statistically superior to A.

Obtaining reliable estimates for the activity of the currently accepted active standard treatment can be a very troublesome aspect of non-inferiority oncology trials. For example, cisplatin 75 mg/m^2 and paclitaxel 135 mg/m^2 infused over 24 hours was the first platinum–taxane combination to demonstrate activity in the treatment of advanced ovarian cancer (42). Subsequently, several trials were conducted to assesses whether carboplatin could be safely substituted for cisplatin (43–45) or whether Taxotere could be substituted for paclitaxel (46). However, there has been some controversy about the amount of benefit provided by paclitaxel (47). An investigator can reasonably ask: "what is the effect size of paclitaxel and how much of this effect can I be reasonably certain is preserved by Taxotere?"

Randomized Trials

There are several design features to consider when developing a phase 3 trial concept. One important feature to consider is treatment randomization. The randomized clinical trial (RCT) has several scientific advantages. First, both the known and unknown prognostic factors tend to be distributed similarly across the treatment groups when a trial implements randomized treatments. Second, a potential source of differential selection bias is eliminated. This bias could occur when there is an association between treatment choice and prognosis—it need not be intentional. When a physician's interest in a trial or a patient's decision to participate in the trial depends on the assigned treatment, a nonrandom association between treatment and prognosis can be introduced. Finally, randomization provides the theoretical underpinning for the significance test (48). In other words, the probability of a false-positive trial as stated in the study design is justified with randomization. It is important to recognize that the advantages provided by randomizing the study treatments are forfeited when all of the randomized patients are not included in the final analyses.

It is sometimes argued that because many factors influencing prognosis are known, perhaps other approaches to allocating treatments can be considered, and statistical models used to adjust for any imbalances in prognosis. However,

the conclusions from this type of trial must be based on the completeness of knowledge about the disease and acceptability of the modeling assumptions. If the disease is moderately unpredictable with regard to the outcome, or the statistical model is inappropriate, then the conclusions are suspect.

Kunz and Oxman (49) have compared the results from overviews of randomized and nonrandomized clinical trials that evaluated the same intervention, and reported that nonrandomized studies tended to overestimate the treatment effect compared to randomized trials by 76% to 160%. Schulz et al. (50) compared 33 randomized controlled trials that had inadequate concealment of the random treatment assignments, to those studies that had adequate concealment. They found that even those with inadequate concealment tended to overestimate the treatment effect (relative odds) by 40%. Some investigators do not appreciate the importance of concealment and will go to considerable lengths to subvert it (51). When the randomization technique requires pre-generated random treatment assignments, one must guarantee that the investigators, who are enrolling patients, do not have access to the assignment lists.

It should be acknowledged that the patient–physician relationship can occasionally be challenged by introducing the concept of treatment randomization (52). Patients may prefer a sense of confidence from their physician regarding the "best" therapy for them. However, physicians involved in an RCT must honestly acknowledge that the best therapy is unknown and that an RCT is preferable to continued ignorance. One survey of 600 women seen in a breast clinic suggests that 90% of women prefer their doctor to admit uncertainty about the best treatment option, rather than give them false hope (53).

Randomization Techniques.

The simplest approach to randomization is to assign treatments based on a coin flip, sequential digits from random number tables, or computerized pseudorandom number generators. On average, each individual has a defined probability of being allocated to a particular study treatment, when they enter the study. While this approach is simple, the statistical efficiency of the analyses can be enhanced by constraining the randomization so that each treatment is allocated an equal number of times. Permuted block randomization is sometimes used to promote equal treatment group sizes. A block can be created by shuffling a fixed number of cards for each treatment and then assigning the patients according to the random order of the deck. After completing each block there are an equal number of patients assigned to the treatment groups. For example, consider a trial comparing treatments A and B. There are six possible ways the block can be ordered when the block size is four: AABB, ABBA, BBAA, BABA, ABAB, and BAAB. A sufficient number of assignments for an RCT can be created by randomly selecting a series of blocks from the six distinct possibilities.

There are three features of blocked randomization to be considered. First, the probability of a particular treatment being allocated is not the same throughout the study, as in simple randomization. Taking the example above, every fourth treatment is predetermined by the previous three allocations. Second, the use of small blocks in a single-clinic study may undermine concealment and allow an investigator to deduce the next treatment. This potential problem can be corrected by continually changing the block size throughout the assignment list. Third, large block sizes can undermine the benefits of blocking. As block sizes increase, the procedure resembles simple randomization.

The statistical efficiency of the study can be further enhanced by stratifying patients into groups with similar prognoses and using separate lists of blocked treatments for each stratum. This procedure is called stratified permuted block randomization. It is worth noting that using simple randomization within stratum would defeat the purpose of stratification, because this is equivalent to using simple randomization for all patients. Likewise, trials that stratify on too many prognostic factors are likely to have many uncompleted treatment blocks at the end of the study, which also defeats the intent of blocking (54).

When it is desirable to balance more than a few prognostic factors, an alternative is dynamic treatment allocation; one particular type being minimization. Whereas stratified block randomization will balance treatment assignments within each combination of the various factor levels, minimization tends to balance treatments within each level of the factor, separately. Each time a new patient is entered into the study, the number of individuals who share any of the prognostic characteristics of the new patient is tabulated. A metric, which measures the imbalance of these factors among the study

treatments, is computed as if the new patients were allocated to each of the study treatments in turn. The patient is then allocated to the treatment that would favor the greatest degree of balance (55). In the event that the procedure indicates equal preference for two or more possible treatment allocations, simple randomization can be used to determine the individual's treatment assignment. Regardless of the degree of imbalance, however, this randomization process should not be deterministic. Instead, the treatments that restore the greatest degree of balance are more likely to be allocated.

Concealment during the randomization process refers to the procedure in which the assigned study treatment is not revealed to the patient or the investigator until after the subject has successfully enrolled onto the study. The purpose of concealment is to eliminate a bias that can arise from an individual's decision to participate in the study depending on the treatment assignment (56). Concealment is an essential component of RCTs.

Blinding is a procedure that prevents the patient or physician from knowing which treatment is being used. In a single-blinded study, the patient is unaware of which study treatments she is receiving. A double-blinded study results in a situation in which neither the patient nor the health care provider is aware of that information. One purpose of blinding is to avoid measurement bias, particularly differential measurement bias (see End Points section). This type of bias occurs when the value of a measurement is influenced by the knowledge of the treatment being received. It can occur when the measurement of an end point is in part or totally subjective. Most methods for assessing pain are subjective, and require treatment blinding to promote the study's validity.

Oncology trials frequently do not implement blinding for several reasons. It is rather difficult to blind treatments when various treatment modalities are used (e.g., surgery versus radiation therapy, or intravenous versus oral administrations), when good medical practice is jeopardized (e.g., special tests are required to monitor toxicity due to particular treatments), or when it is logistically difficult (e.g., the evaluating physician must be kept isolated from the treatment of patient). In the absence of blinding, care should be taken that the method of measuring the end point is precisely stated in the protocol and consistently applied to each patient uniformly. Trials that assess quality of life or relief from symptoms should give serious consideration to treatment blinding. Schulz et al. (57) have reviewed 110 RCTs published between 1990 and 1991 from four journals dedicated to obstetrics and gynecology. Thirty-one of these trials reported being double-blinded. Schultz et al. conclude that blinding should have been used more often, despite frequent impediments. Moreover, blinding seemed to have been compromised in at least three of the trials where it was implemented.

Placebos blind the patient, and usually the physician as well, as to whether they are receiving an experimental or inert treatment. Placebos are frequently used in trials where there is no accepted standard treatment and the end point is susceptible to measurement bias. The use of a placebo is also important when the end point can be affected by the patient's psychological response to the knowledge of receiving therapy, combined with a belief that the therapy is effective. This phenomenon is aptly named the "placebo effect." In such circumstances, the use of a placebo provides a treatment-to-control comparison that measures only the therapeutic effect. Note that the "placebo effect" is a distinctly different type of measurement bias from those that have been previously discussed. Careful ethical considerations must precede the use of a placebo or sham procedure in any clinical trial (58).

Trials with Historical Controls

The strict definition of a phase 3 trial does not necessarily require concurrent controls (i.e., prospectively enrolled patients assigned the standard treatment) or randomization (i.e., random treatment allocation). However, these two features are almost synonymous with phase 3 trials today.

The principal drawback from inferring treatment differences from a historically controlled trial is that the treatment groups may differ in a variety of characteristics that are not apparent. Differences in outcome, which are in fact due to differences in characteristics between the groups, may be erroneously attributed to the treatment. Although statistical models are often used to adjust for some potential biases, adjustments are possible only for factors that have been recorded accurately and consistently from both samples. Shifts in medical practice over time, differences in the definition of the disease, eligibility criteria, follow-up procedures, or recording methods can all contribute to a differential bias. Unlike

random error, this type of error cannot be reduced by increasing the sample size. Moreover, the undesirable consequences of moderate biases may be exacerbated with larger sample sizes. When a trial includes *concurrent* controls, the definition of disease and the eligibility criteria can be applied consistently to both treatment groups. Also, the standard procedures for measuring the end point can be uniformly applied to all patients.

Factorial Designs

Factorial designs are used when several interventions are to be studied simultaneously. The term *factorial* arises from historical terminology in which the treatments were referred to as factors. Each factor has corresponding levels; for example, an investigator may wish to compare a study agent administered at three dose levels: high dose, medium dose, and none. The total number of factor combinations being studied is the product of the number of levels for each factor or treatment. For example, a trial that evaluates treatment A at three levels and treatment B at two levels is called a 3-by-2 (denoted 3 × 2) factorial design. If the relative effects due to the various levels of treatment A are independent of the levels of B, the two treatments (A and B) can be evaluated simultaneously. The factorial design provides a significant reduction in the required sample size when compared to trials that study A and B separately. The key assumption necessary for a factorial design is that all treatments can be given simultaneously, without interaction or interference.

The most commonly utilized factorial design is the 2 × 2 factorial design that includes two distinct treatment regimens at each of two factor levels. For example, suppose individuals entering a cancer prevention trial are randomly assigned to receive vitamin E (placebo-A or 50 mg/day) and beta carotene (placebo-B or 20mg/day) in a study designed as a 2 × 2 factorial. In this case, the factors are vitamin E and beta carotene, whereas the respective factor levels are placebo-A or 50 mg/day for vitamin E, and placebo-B or 20 mg/day for beta carotene. There are four treatment combinations. In a standard 2 × 2 design, the main effect of vitamin E can be ascertained by utilizing information from each of the four treatment groups. In some studies, however, the main effects may be of secondary importance compared to the "interaction" between each factor. An interaction exists when the effect due to one of the factors (i.e., treatment A) depends on the level of the other factor (treatment B). In drug discovery, a "positive" interaction may imply a synergistic effect of two drugs in combination; that is, the effect of the combination therapy is greater than the sum of the individual additive effects. Reliable tests of an interaction require a relatively large number of patients in each of the four treatment groups. If potential treatment interaction cannot reasonably be ruled out or there is interest in possible interactions, then attention to the statistical power of such tests is an important part of designing and interpreting the study results (59).

HYPOTHESIS TEST

A hypothesis is a conjecture based on prior experiences that leads to refutable predictions (60). A hypothesis is frequently framed in the context of either a null or an alternative hypothesis. In a therapeutic efficacy trial, a null hypothesis may postulate that a treatment does not influence patients' outcome. The alternative hypothesis is that a particular, well-defined treatment approach will influence the patients' outcome to a prespecified degree. These hypotheses cast the purpose of the trial into a clear framework. During the study design, the investigators select a test statistic from an appropriate statistical procedure (e.g., an F-statistic from an analysis of variance, or a chi-square statistic from a logistic model) that evaluates the degree to which the study data support the null hypothesis. A type I error is committed when the null hypothesis is in fact true, but the test statistic leads the investigator to incorrectly conclude it is false. Committing the type I error would be disastrous if it means discontinuing the use of an active control treatment that is well tolerated and substituting an experimental therapy that is more toxic, but in reality, no better. A type II error is committed when the null hypothesis is not true, but the test statistic lead the investigator to erroneously conclude that it is true. Type II errors commonly occur in studies that involve too few subjects to reliably estimate clinically important treatment effects. Prospectively specifying the null hypothesis, the appropriate statistical method for the analysis, the test statistic, and quantifying the acceptable

probabilities of type I error (i.e., α-level) and type II error are essential elements for determining the appropriate design and sample size for a particular trial.

p-Value

At times statisticians play the role of the conservative physician, cautiously prescribing a significance test only when it is appropriate. There is a general concern that the *p*-value is overused, even abused, and overemphasized. A common misconception is that the *p*-value is the probability that the null hypothesis is true. The null hypothesis is either true or false, and so it is therefore not subject to a probability statement. It is the inference that an investigator makes, based on his data, that is susceptible to error. The *p*-value is simply the probability that the test statistic would be as extreme or even more extreme, if the null hypothesis was in fact true (see Hypothesis Test section).

Misconceptions about the *p*-value may arise in part from a poor distinction between the *p*-value and the α-level of a study (61). The α-level is the probability of the test statistic rejecting the null hypothesis when it is true. It is specified during the design phase of the study, and is unaltered by the results obtained. The *p*-value results from a statistical test performed on the observed data.

TRANSLATIONAL RESEARCH

Many modern clinical trials involve the systematic collection and banking of biologic materials from the participants. These materials may include serum, plasma, urine, buccal cells, or tumor tissue, which are collected and stored in a biorepository. The biologic materials together with the clinical data can then be used to understand how a biologic effect translates into the treatment effect on the patient population. This translation gives rise to the concept of translational research (TR). In TR, discoveries in laboratory science are translated into practical applications. The flow of information from TR studies is a two-way street: (1) more complete understanding of tumor biology and (2) more effective treatments for patients.

The goal in this section is to provide clinical and laboratory scientists with some fundamental information needed to design, implement, and analyze the data from TR studies. The following sections develop the concepts for: (1) biomarker discovery and verification, and (2) biomarker validation. Insights are provided into the goals and expectations a researcher can have when performing a biomarker study. With this knowledge at hand, the reader can avoid some of the mistakes, errors, and biases that have plagued TR and have led to false, misreported, or misleading reports.

It is important to understand that biomarkers can be used to diagnose a disease, to assess prognosis, to select appropriate treatments (predictive), or to assess treatment outcomes (surrogate end point). Thus, biomarkers can be incorporated into many aspects of clinical practice and research once validated. There are two types of biomarker validation to consider: analytic and clinical validation. Analytic validation refers to obtaining evidence that the biomarker assay result is reproducible under a variety of conditions and that the assay is shown to accurately measure the intended analyte. This is essential before a biomarker can be clinically validated. Clinical validation involves demonstrating that the biomarker is "fit for purpose." That is, it functions properly for its intended use as a diagnostic, prognostic, treatment selective, or surrogate marker. The rigor needed to evaluate the clinical utility of a biomarker has recently been emphasized in light of several failed attempts at validating complex biomarkers (62–64).

Biospecimen Collection

The biologic specimens used in a study are typically gathered either prospectively or retrospectively. In the prospective approach, patients are identified and followed forward in time. There are several advantages with the prospective

approach. First, patient enrollment can focus on enrolling individuals only from the intended target population. Second, the procedures for collecting and preparing specimens can be tailored to the intended laboratory procedures. Third, the quality control procedures for collecting the clinical data can target those data items that are required for the specific study objectives. Fourth, the patient's treatment and follow-up assessments can be standardized and optimized in accordance with the goals of the study. When samples are retrospectively collected, the laboratory analysis is performed using previously archived specimens that may have been originally collected for another intended purpose. The investigator using a retrospective approach is a prisoner to the procedures that were set down before the current study goals were contemplated; therefore, they may not be optimal for his or her intended objectives. For instance, the samples may have come from patients who are not representative of the target population. This reduces the validity of the study results. The specimens may have been obtained, prepared, or stored using outdated or less-than-optimal procedures for laboratory tests. This could introduce biases in the measurements or reduce the power of the study.

Biomarker Development Process

A widely used definition of a biomarker is: "A characteristic that is objectively measured and evaluated as an indicator of normal biological processes, pathogenic processes, or pharmacologic responses to an intervention" (65). Biomarkers can be measurements of macromolecules (DNA, RNA, proteins, lipids), cells, or processes that describe a normal or abnormal biologic state in a patient. From the paradigm of TR described above, biomarkers can inform investigators about a patient's disease diagnosis, prognosis, prediction of response to therapy (i.e., effect modifier), or prediction of a clinical outcome (i.e., surrogate end point).

Generally speaking, biomarkers can be diagnostic, prognostic, or predictive. A diagnostic biomarker is designed to identify the presence of a disease or other condition, while a prognostic biomarker is an indicator that helps researchers in predicting the course of a patient's disease. Prognostic biomarkers are used to estimate the risk of a future clinical outcome; examples include: state of the disease, histology of the tumor, or patient's performance status. A biomarker may also be deemed predictive, and as such, it can be used to modify the estimated risk of a future outcome only when a particular type of treatment is taken. In breast cancer patients, examples of predictive biomarkers are: estrogen receptor status when the treatment is tamoxifen, or HER2/neu status when the treatment is trastuzumab. The phrase "treatment selection marker" may be preferable terminology for a predictive biomarker, to avoid confusion with other uses of the word predictive. For immediate purposes here, predictive markers are viewed as a special class of prognostic markers and we primarily focus on prognostic biomarker studies in general. Only in the section describing studies involving targeted therapies will the distinction be made.

In the following sections, a common biomarker development strategy is discussed that includes: (1) Biomarker discovery, and (2) Biomarker validation. In short, these steps are presented in **Table 16.1** (Discovery and Test Validation Stage) (66).

TABLE 16.1 Biomarker Development for HT Technologies

Classifier Development Phase

- Probe Discovery: Identify a subset of genes/proteins associated with the clinical outcome of interest.
- Probe Verification: Confirm measurements on selected genes/ proteins using alternate laboratory techniques, like IHC or Rt-PCR.
- Classifier Development: Use the confirmed genes/proteins to develop a model (classifier) that appears to predict clinical outcome.

Classifier Verification Phase

- Model Verification: Confirm the model's properties using a small independent sample of individuals or cross-classification techniques.
- Document Classifier: Document the computational procedures and criteria for

interpreting the lockdown model.

Classifier Validation

- Validation: Evaluate the model's predictive accuracy in a sample of individuals representative of the target population. Any changes to the procedures or the lockdown model to improve the classifier will require further validation.

For additional information, see National Research Council. Evolution of Translational Omics: Lessons Learned and the Path Forward. Washington, DC: The National Academies Press, 2012.

Discovery Phase

Regardless of whether the samples were retrospectively or prospectively collected, many studies are designed to discover biomarkers with clinical utility, from among many potentially useful biomarkers.

Since the invention of microarray technology and related high-throughput (HT) technologies, researchers have been able to compile large amounts of information and an enormous pool of potential biomarkers. These so-called HT platforms have become commonly used experimental platforms in the biologic realm (67). A HT platform is designed to measure large numbers (thousands or millions) of signatures in a biologic organism at a given time point. These platforms are a function of the postgenomic era and are often used to determine how genomic expression is regulated or involved in biologic processes. The technologies in **Table 16.2** use hybridization and sequence-based platforms such as gene expression microarrays and RNA-Seq to obtain data matrices.

TABLE 16.2 A Summary of Discovery Platforms, the Material Analyzed in the Platform, and the Recent Cancer Biomarker Discovery Studies using the Given Platform

Platform	Material	Cancer studies
aCGH microarray	DNA	Albertson et al. (68), Hodgson et al. (69), Pollack et al. (70), Albertson (71), Albertson et al. (72), Hackett et al. (73), Garnis et al. (74), Veltman et al. (75), Pinkel and Albertson (76), Rossi et al. (77), Idbaih et al. (78)
Gene expression microarray	mRNA	Ramaswamy et al. (79), Gordon et al. (80), Tibshirani et al. (81), Statnikov et al. (82), Glas et al. (83), Van't Veer et al. (84), Sotiriou et al. (85), Michiels et al. (86), Barrier et al. (87), Miecznikowski et al. (88)
RNA - Seq	Transcriptomics	Levin et al. (89), Pflueger et al. (90)
DNA methylation	DNA	Portela and Esteller (91)
Mass spectrometry	Peptide/proteomics	Paweletz et al. (92), Koopmann et al. (93), Kolch et al. (94), Lan et al. (95), Diamandis (96,97)

Several of the common HT assay platforms used in experiments designed for cancer diagnosis are listed in **Table 16.2**. These platforms were chosen to illustrate the diversity of platforms available for interrogating DNA, RNA, or proteins.

Preprocessing HT Platforms

In short, preprocessing algorithms are required in nearly all of the HT technologies listed in **Table 16.2**. This is due to the fact that HT platforms measure both biologic signal and technical signal. Therefore, the goal of preprocessing algorithms is removal of the technical signal. This technical signal can be considered in terms of background correction and

normalization to adjust across experiments. The background corrections and normalization account for technical artifacts that can occur due to either the array construction or laboratory procedures that introduce systematic errors in the signal on individual arrays or across arrays. Often these preprocessing techniques are specific to the platform employed (e.g., Miecznikowski et al. [98]), and therefore it is impractical to review all of the available preprocessing methods here.

Type I Error and Multiple Testing

The experiments performed in the HT discovery phase often have a goal of simply narrowing down the genome or proteome to a subset of potentially relevant biomarkers. In this sense, the scientists are performing a data reduction where the goal is to choose a subset of markers from the HT scope that are related to or associated with clinical outcome. The association with outcome is assessed using a null hypothesis for each biomarker and summarizing "significance" with a *p*-value. In this case, the interpretation of each *p*-value differs slightly from a study with a single null hypothesis (See Hypothesis Test and *p*-value sections).

When the type I error is limited to 5% for a single hypothesis, there is only a 1-in-20 chance of rejecting that null hypothesis, if it is in fact true. When 10,000 null hypotheses are tested, as may be typical in some HT studies even if all of the null hypotheses were true, one would expect 500 null hypotheses to be rejected at the 5% significance level. The large number of false rejections would make the downstream analysis of confirmation and verification frustrating and impractical.

Therefore, during the discovery phase of an HT experiment, the goal is to limit the Type I error rate. That is, HT studies are designed to limit the number of false-positives, denoted by V in **Table 16.3A**. **Table 16.3B** lists some alternative approaches to controlling the Type I error rate during the discovery phase of the experiment. Statistically significant or interesting markers are determined from hypothesis testing in light of controlling one of the Type I error rates listed in **Table 16.3B**.

TABLE 16.3A A Summary of Results from Analyzing Multiple Hypothesis Tests

	H_0 Retained	H_0 Rejected	Total
H_0 True	U	V	M_0
H_0 False	T	Q	M_1
	M - R	R	M

M_0 and M_1 are considered as fixed (unknown) parameters representing the number of true nulls and the number of true alternatives, respectively. The random variables U and Q represent the number of the correct decisions, whereas the random variables T and V represent the number of incorrect decisions. V is the number of false-positives.

TABLE 16.3B Summaries of Type I Errors Using Random Variables Defined in Table 16-3A

Abbreviation	Name	Quantity
FWER	Family wise error rate	Pr(V ⩾1)
k-FWER	Generalized family wise error rate	Pr(V ⩾k)
FDR	False discovery rate	E[V/R]
k-FDR	Generalized false discovery rate	E[VI(V ⩾k)/(MAX(R,1))]
PCER	Per comparison error rate	E[V]/M
TPPFP	Tail probabilities for the proportion of false-positives	Pr(V/R) >q

Pr( ), probability of; E[ ], expectation of.

Confirmation and Verification

To have reasonable power in light of multiple testing, the Type I errors in **Table 16.3B** tend to be more liberal (more likely to reject null hypotheses) than standard scientific significance testing procedures. Thus, any markers from the discovery phase should be confirmed or verified using other methods, such as immunohistochemical (IHC) assays or reverse transcription polymerase chain reaction (RT-PCR). These verification platforms could use either the same samples from the discovery phase or a new independent set of samples. The goal for this step is to confirm that the biomarker signal from the discovery platform is accurately measuring the expression of the desired gene, protein, or RNA.

Including a confirmation step ensures researchers that their discovery markers can be confirmed using other platforms. This provides some reassurance in the ability of the markers to be confirmed on independent samples from possibly different institutions with, possibly, differing methods of assessment. Methods that describe how to correlate RT-PCR and IHC signals with their microarray counterparts can be found in Press et al. (99), van den Broek and van de Vijver (100), McShane et al. (101), Esteban et al. (102).

In certain IHC assays, the results should be performed by at least two different observers who are blinded to the clinical data. This may alleviate the subjectivity in these experiments, because IHC assays require selection of best regions to score, and subjective measurements of staining intensity and percentage of stained cells.

Validation Phase

Various statistical models can be fit using the data in the discovery phase. At the end of the discovery phase, there should be a complete specification of the marker assay method and model, and thorough documentation of the (final) lockdown model. The fully specified precise lockdown model will be evaluated using a validation dataset. Note, for example, that this must include specifying all coefficients in the classification model and any of the rules for deciding the level of a biomarker.

Validation in biomarker experiments should always involve an independent dataset, that is, data from patients who were not included in any of the discovery dataset(s). Note that internal validation procedures such as cross-validation, bootstrapping, or other data resampling methods are useful to give insights into issues such as bias and variance of regression parameter estimates and stability of the model derived. In these internal validation procedures, some portion of the data is held out (test set), while a model is built on the remaining portion (training set). A limitation of these internal procedures is that there may be biases that affect the training and test sets equally. For example, if the set of specimens for confirmation are collected in the same laboratory, processed by the same technician, and run on the same equipment, then peculiarities of the data (equipment, lab, and technician) will be shared between the samples used to develop the model and the samples used to evaluate the model.

Even with the requirement of an independent dataset, there may still be levels of validation evidence. For example, a lower level of validation evidence may be independent sets of specimens and clinical data collected at a single institution using carefully controlled protocols, with samples from the same patient population. Meanwhile, a higher level of validation evidence would be independent sets of specimens and clinical data collected at multiple institutions.

Additionally, it should be stressed that the independent validation dataset must be relevant to the intended use of the candidate biomarker test. Patients in the independent dataset should have the same type of disease, the same stage, and should be in the same clinical setting in which the candidate test should be used in the future. Ideally, the specimens for independent confirmation will have been collected at different points in time, at different institutions, from different patient populations, with samples processed in a different laboratory to demonstrate that the test has broad applicability and is not over-fit to any particular situation.

Publicly Available Data

Publicly available datasets can help with the development process; furthermore, they can fill in gaps regarding knowledge of systems biology; for example, providing the proteomics story when an individual investigation generates only genomic data. They can be used in an integrative analysis and a meta-analysis. These meta-analyses can strengthen the conclusions drawn from an individual researcher's study. They may also offer insights from other study populations. As DNA microarray technology has been widely applied to detect gene activity changes in many areas of biomedical research, development and curation of online microarray data repositories are at the forefront of research endeavors to use and reuse this mounting deluge of data. Several representative repositories of microarray datasets are available (**Table 16.4**). A somewhat recent comparison of the available microarray databases was provided in Gardiner-Garden and Littlejohn (106). Computer programs like Anduril (107) provide procedures for organizing, storing, and analyzing massive genomic data. Statistical packages in R have also been created that allow users to easily import data from database like ArrayExpress into Bioconductor packages (108).

TABLE 16.4 Repositories of Microarray Datasets

ArrayExpress (103)	http://www.ebi.ac.uk/arrayexpress/
Gene Expression Omnibus (GEO) (104)	http://www.ncbi.nlm.nih.gov/geo/
Center for Information Biology Gene Expression Database (CIBEX) (105)	http://cibex.nig.ac.jp/data/index.html
TCGA	http://tcga-data.nci.nih.gov/tcga/tcgaHome2.jsp or https://gdc-portal.nci.nih.gov/

Concordant with the development of online data repositories, researchers have developed specific data standards required for microarray analysis. The data standard concept describes the minimum information about a microarray experiment (MIAME) that is needed to enable the interpretation of the results of the experiment and to potentially reproduce the experiment (109). MIAME compliance will ensure that biologic properties of the samples and the phenotypes that were assayed were correctly recorded, thus ensuring that the data can be quickly assessed for its suitability in studying new questions. The public repositories including ArrayExpress (103), GEO (110), and CIBEX (105) are all designed to hold MIAME compliant microarray data.

Especially exciting for oncologists, multiple platforms of microarray data from The Cancer Genome Atlas (TCGA) are now available. The TCGA project is further described in Stratton et al. (111), but, in short, represents one of the first large-scale attempts to study the multiple types of genetic mutations involved in multiple cancer types from different cohorts of patients. Initially, the pilot projects studied glioblastoma multiforme and ovarian serous cystadenocarcinoma, but have now expanded to cover roughly 25 different cancer types. For each cancer type, the patient cohorts (collected from different sites) include several hundred individuals, and the platform techniques include gene expression profiling, copy number variation profiling, single nucleotide polymorphism (SNP) genotyping, methylation profiling, and microRNA profiling. These data have been made publicly available, making TCGA dataset a great resource for research using meta-analysis and integrative analysis techniques that were not previously available.

DEVELOPING TR STUDIES AND REPORTING RESULTS

Guidelines have been developed to promote accurate and complete reporting of results from biomarker studies. Throughout this section, the importance of having well-defined questions for the proposed data is stressed. In other words, serious thought, planning, and discussions among a team of scientists are necessary in order to successfully perform biomarker analysis including discovery, verification, and validation.

In the discovery phase it is important that the proposed technology has been validated; for example, technical replication studies in Strand et al. (112), Callesen et al. (113), Leyland-Jones et al. (114), De Cecco et al. (115), Hicks et al. (116), Benton et al. (117), Freidin et al. (118), Lawrie et al. (119). During the discovery phase, it is also important to consider differences in material preparation; for example, frozen tissue samples versus paraffin-embedded tissues as discussed in Nowak et al. (120), Mittempergher et al. (121). During the verification phase these issues may also play a role; however, other concerns may arise, such as the level of concordance in signal necessary between the discovery platform and the verification platform. Ultimately, after discovery and verification, a lockdown model is carried forth to validation. This so-called lockdown model can be interpreted in a decision theoretic setting; each future sample must be classified or the outcome predicted based only on the model and a given sample signal from the intended technology.

In the validation phase, it is important to note that there is a major difference between answering *a priori* defined hypotheses and providing conclusions from exploratory analyses. Conclusions drawn from exploratory data analysis are descriptive results and typically need to be confirmed in a validation dataset, while an *a priori* hypothesis leads to stronger conclusions and does not necessarily need an external validation. Care should be given in reporting unanticipated significant effects, as these are most likely due to chance and thus unlikely to be validated in other studies. Most importantly, researchers should keep in mind that, in the long term, the success of biomarker studies should be measured by clinical improvement in patient outcomes.

A prodigious number of prodigious number of biomarker studies reported in the literature; however, a surprising number of these results are irreproducible. The reasons for these discrepancies may lie in differences in methodological procedures, inadequate control of false-positive findings, improper validation procedures, variability in the patient sampling, or any number of other differences in study design, conduct, or analytical procedures. Many published studies lack adequate information that would allow an evaluation of quality or comparability. To promote clear and complete reporting of biomarker studies, the REMARK guidelines have been developed (122). These guidelines make specific recommendations for preparing TR presentations, reports, and publications with regard to describing patient and sample characteristics, assay methodology, study design, methods of data analysis, and results. While these recommendations have been distilled into bullets in **Table 16.5**, useful additional information can be found in the REMARK document (122).

TABLE 16.5 REporting Recommendations for Tumor MARKer Prognostic Studies (REMARK)

Introduction
1. State the marker examined, the study objectives, and any prespecified hypotheses
Materials and methods
Patients
1. Describe the characteristics (e.g., disease stage or comorbidities) of the study patients, including their source and inclusion and exclusion criteria. 2. Describe treatments received and how they were chosen (e.g., randomized or rule-based).
Specimen characteristics
1. Describe type of biologic material used (including control samples) and methods of preservation and storage.
Assay methods
1. Specify the assay method used and provide (or reference) a detailed protocol, including specific reagents or kits used, quality control procedures, reproducibility assessments, quantitation methods, and scoring and reporting protocols. Specify whether and how assays were performed blinded to the study end point.

Study design

1. State the method of case selection, including whether prospective or retrospective and whether stratification or matching (e.g., by stage of disease or age) was used. Specify the time period from which cases were taken, the end of the follow-up period, and the median follow-up time.
2. Precisely define all clinical end points examined.
3. List all candidate variables initially examined.
4. Give rationale for sample size; if the study was designed to detect a specific effect size, give the target power and effect size.

Statistical analysis methods

1. Specify all statistical methods, including details of any variable selection procedures and other model-building issues, how model assumptions were verified, and how missing data were handled.
2. Clarify how marker values were handled in the analyses; if relevant, describe methods used for cut-point determination.

Results

Data

1. Describe the flow of patients through the study, including the number of patients included in each stage of the analysis (a diagram may be helpful) and reasons for dropout. Specifically, for both overall and for each subgroup extensively examined, report the number of patients and the number of events.
2. Report distribution of basic demographic characteristics (at least age and sex), standard (disease-specific) prognostic variables, and tumor marker, including numbers of missing values.

Analysis and presentation

1. Show the relation of the marker to standard prognostic variables.
2. Present univariate analyses showing the relation between the marker and outcome, with the estimated effect (e.g., hazard ratio and survival probability). Preferably provide similar analyses for all other variables being analyzed. For the effect of a tumor marker on a time-to-event outcome, a Kaplan–Meier plot is recommended.
3. For key multivariate analyses, report estimated effects (e.g., hazard ratio) with confidence intervals for the marker and, at least for the final model, all other variables in the model.
4. Among reported results, provide estimated effects with confidence intervals from an analysis in which the marker and standard prognostic variables are included, regardless of their statistical significance.
5. If done, report results of further investigations, such as checking assumptions, sensitivity analyses, and internal validation.

Discussion

1. Interpret the results in the context of the prespecified hypotheses and other relevant study; include a discussion of limitations of the study.
2. Discuss implications for future research and clinical value.

CLINICAL TRIALS INVOLVING TARGETED THERAPIES

A clinically useful biomarker can identify patients with diseases that are either resistant or sensitive to a specific targeted therapy. As such, they can be used to improve the efficiency of a study and provide more precise treatment for specific subgroups of patients. This concept is illustrated in **Table 16.6**. Suppose the probability of response to standard treatment is 20% in the general patient population. Furthermore, suppose that 20% of the individuals in the general patient population are very responsive to a new targeted treatment, such that, when the targeted agent is added to the standard treatment, the probability of response is 60% among this sensitive subgroup, but unchanged in the nonsensitive subgroup. If the new treatment is combined with standard treatment in the general population, regardless of their sensitivity status, then the expected probability of response would only be 28% (i.e., 20% of population has 60% response rate, and 80% has 20% response rate = $0.20 \times 0.60 + 0.80 \times 0.20 = 0.28$). If a randomized trial was now designed to compare standard treatment versus standard treatment with the new agent, then over 1,000 patients would need to be enrolled to reliably detect this size of a treatment effect (**Table 16.6**). On the other hand, if the study used a perfectly accurate biomarker (sensitivity = 100% and specificity = 100%) to restrict enrollment to treatment-sensitive patients, then only 60 patients would be needed for the study (**Table 16.6**) and the expected number of patients needed for screening would be about 300. In the real world, biomarkers are seldom perfect. A biomarker with 80% sensitivity and 80% specificity could still be used to increase the prevalence of treatment-sensitive patients (e.g., **Fig. 16.3**). In this case, the probability of response to the standard regimen with the new targeted agent in the enriched study population would be 40% ($0.50 \times 0.60 + 0.50 \times 0.20 = 0.40$). The two-arm trial designed with this imperfect biomarker to select sensitive patients would require 220 enrolled patients in order to reliably detect the difference in response rates (**Table 16.6**), and the expected number of patients needed for screening would be about 688.

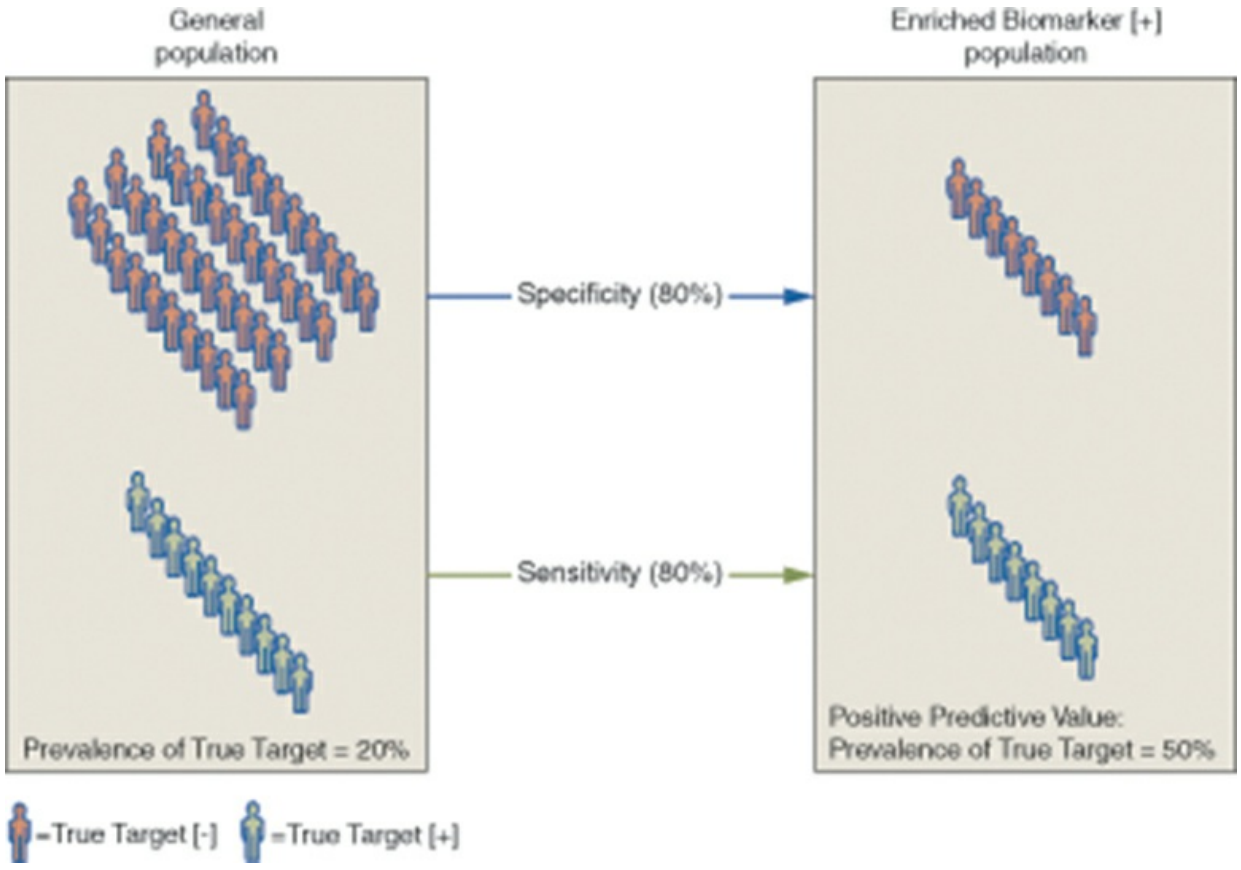

Figure 16.3 Hypothetical biomarker-based enrichment study

TABLE 16.6 Required Sample Size for a Randomized Trials with a Target Prevalence 5 20%

Patient Population	Probality of Response		Sample Size	Screen Size	Assumptions	
	Standard Therapy (P_0)	Standard Therapy (P_1) + Targeted			Sensitivity	Specificity
Ideal Target Population	0.2	0.6	60	300	100	100
General Population	0.2	0.28	1022	1022	—	—
Enriched Population	0.2	0.4	220	688	80	80

In any study design where a biomarker is used to enrich the study sample with individuals considered most likely to respond, it may not be possible to differentiate between an ineffective treatment and a clinically invalid biomarker. Misspecification of the treatment target and misclassification of the tumor state are fundamental reasons for study failure. There can be a mismatch between the agent and the patient selection process in an enrichment design because of inadequate understanding of a potentially complex biologic pathway, or the true target of the agent under study, or use of an invalid surrogate end point biomarker (**Fig. 16.4**). A successful study depends on the degree to which the biomarker accurately measures the true state of the treatment's target(s). Ideally, measuring the agent's effect through the biomarker should measure the agent's effect through the targeted pathway (highlighted in indigo in **Figure 16.4**). If the treatment can influence the disease through pathways that are not captured by the biomarker, then the activity of the agent will be underestimated and potentially missed. For example, in ovarian cancer, mutations in the *BRCA1* and *BRCA2* genes identify tumors likely to respond to a class of agents referred to as Poly-ADP ribose polymerase inhibitors (PARPi). However, responses to PARPi have been observed among patients with no *BRCA* mutations (123). This suggests that markers of other biologic pathways will be needed to identify PARPi-sensitive tumors, such as markers for methylation of the *BRCA* genes or other types of dysfunction in the homologous recombination mechanism. Therefore, if the biomarkers that are used to define PARPi sensitivity included only *BRCA* mutation status, then sensitivity is sacrificed. On the other hand, if the markers for determining PARPi sensitivity include inconsequential mutations in the *BRCA* genes, specificity is diminished. In enrichment studies, loss of sensitivity and specificity decreases the predictive value of the marker, which in turn decreases the chances that a study will identify active targeted agents (**Table 16.6** and **Fig. 16.3**). The schema for a biomarker-enriched randomized phase 2b or 3 trial is presented in **Figure 16.5**. The "Umbrella design" generalizes this enrichment approach. In this case, multiple potentially predictive biomarkers are prioritized for study and all of these biomarkers are assessed in each patient enrolled onto the study. If the patient's tumor expresses the biomarker with the highest priority, treatment is then randomly assigned to her as either an appropriate targeted therapy or standard therapy. If the patient's tumor does not express the biomarker with the highest priority, but does express the biomarker with the second highest priority, then treatment with another appropriate targeted therapy or standard treatment is randomly assigned to her. This process cascades sequentially through each of the biomarkers under study in order of their priority. Individuals who do not express any of these biomarkers are either placed on a study involving a non-targeted therapy or are considered off study. The schema for the Umbrella design is depicted in **Figure 16.6**. It is important to recognize that these study designs cannot be used to demonstrate that the biomarker is, in fact, clinically predictive. For use in a phase 3 trial, this assumption of clinical predictiveness must be justified with data from external studies.

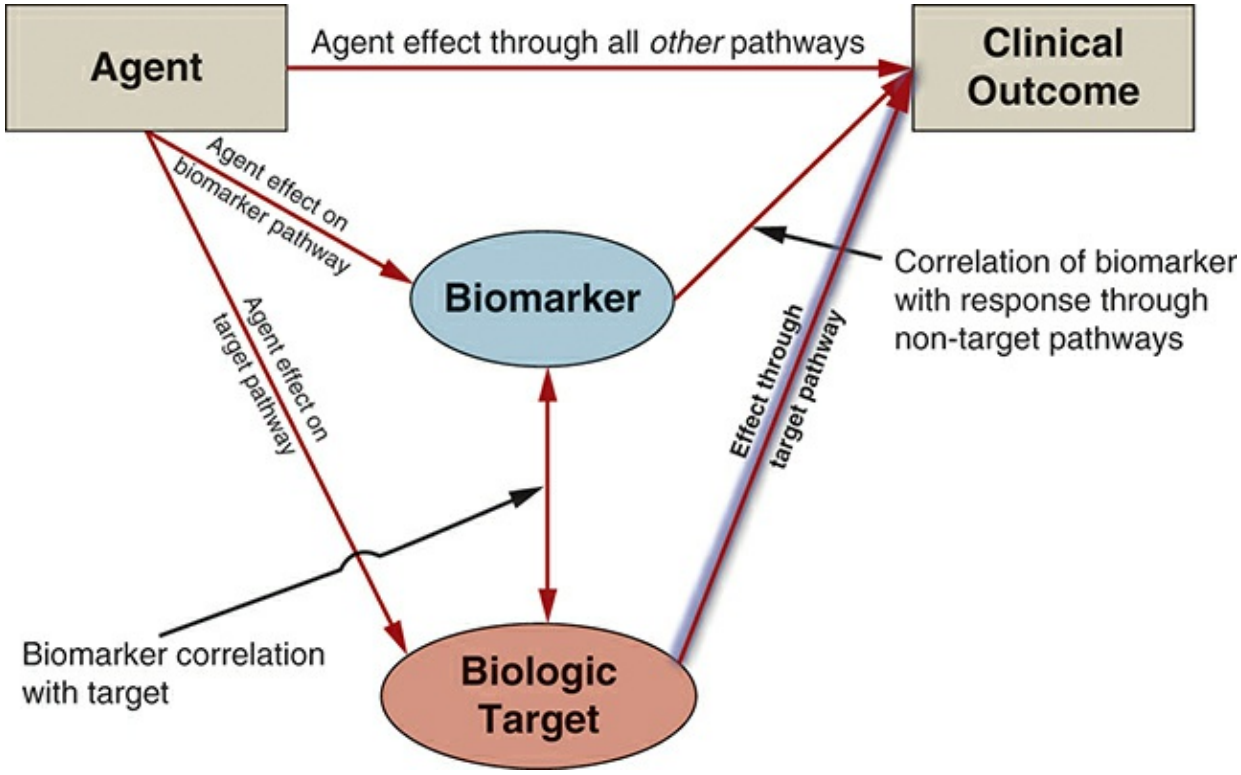

Figure 16.4 Schematic of the causal relationships and correlations between treatment, biomarker, biologic target, and clinical outcome

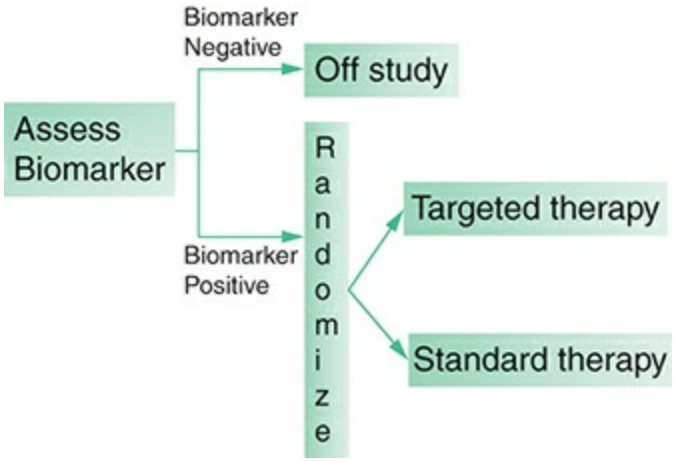

Figure 16.5 Phase 2b or 3 biomarker-enriched randomized treatment trial

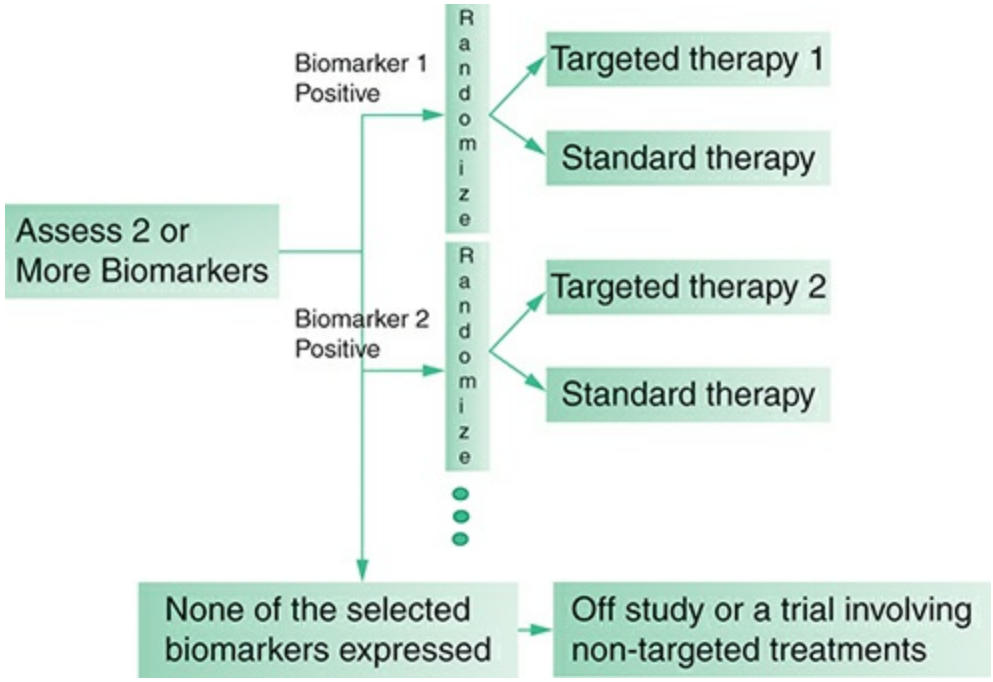

Figure 16.6 Phase 2b or 3 umbrella trial

When it is necessary for a phase 3 study to demonstrate both that the biomarker is predictive and that the treatment is effective in the target population identified by the biomarker, there are several alternative designs (124). One approach randomizes treatment for all patients from the target population and prospectively stratifies the random treatment assignment based on discrete values of the biomarker value. This design assesses a treatment effect in each of the discrete biomarker levels. Other designs randomize between treatment strategies, such as assay-directed treatment versus standard therapy. These designs can be very inefficient and are generally not recommended (125). Study designs that adaptively modify the patient population when a planned interim analysis indicates that the biomarker identifies a subgroup of patients who are unlikely to respond, or that utilize surrogate end points in a lead-in randomized phase 2 (seamless phase 2/3) study have also been proposed (126,127). Currently, adaptive designs for targeted therapies are an area of intense biostatistical research.

Careful planning is necessary for incorporating biomarkers into clinical trials. The appropriate choice of the trial design that incorporates a biomarker into a clinical trial depends on (1) the study's objectives, (2) how well the agent's mechanism of action is understood, (3) how well the role of the target is understood, and (4) how well the selected biomarker captures the state of the drug's true target(s).

CONCLUSION

The complexity of clinical trial design, conduct, analysis, and reporting has increased considerably over the past 60 years, since randomized treatment trials and public screening trials first began. It is difficult for a single clinician to consider initiating a large-scale clinical study because it often requires extensive collaboration with other physicians, as well as professionals from disciplines such as biology, statistics, ethics, psychology, and economics.

CHAPTER 17 Cost-Effective and Value-Based Gynecologic Cancer Care

Laura J. Havrilesky, Shalini L. Kulasingam, Elizabeth L. Jewell and David E. Cohn

OVERVIEW OF COST, QUALITY, AND VALUE IN HEALTH CARE

The cost of health care in the United States continues to rise and is expected to encompass 20% of the gross domestic product by 2020. Despite rising costs, there has not been a commensurate increase in the quality of care delivered in the United States. For this reason, there has been increasing pressure on health systems and providers to demonstrate "value," defined by high-quality and cost-effective care. In this chapter, we will review the historical backdrop that has led to the current level of scrutiny being applied to health care providers to deliver value-based (high-quality and cost-conscious) care. We will define value in health care and describe current and proposed methods to measure value. We will review the methodology of cost-effectiveness analyses (CEAs) and the current evidence regarding the cost-effectiveness of specific interventions in gynecologic cancers.

Cost and Comparative Effectiveness

Given that the ideal infrastructure for measuring value does not yet exist, how can we conduct outcomes-based research with the goal of improving health care quality? Comparative effectiveness research (CER) is defined by the National Academy of Medicine (NAM, previously named the Institute of Medicine) as "the generation and synthesis of evidence that compares the benefits and harms of alternative methods to prevent, diagnose, treat and monitor a clinical condition, or to improve the delivery of care." With this broad definition, the NAM provides a framework for CER to exist, for example, in the development of a model to better understand the potential impact of an intervention (generation of evidence) or in the form of the comparison of two existing treatments of a condition (synthesis of evidence). Congress, in the American Recovery and Reinvestment Act (ARRA) of 2009, appropriated $1.1 billion to jump-start the nation's efforts to accelerate CER. Furthermore, ARRA created the Patient-Centered Outcomes Research Institute (PCORI), a public–private organization charged with setting national priorities for CER.

As the field of CER has become integrated into health care policy and coverage decisions, there has concurrently been increasing concern that CER will lead to denial of certain health care interventions. As a result of concerns raised about resource rationing and the devaluation of life in health states with a high burden of disability, the Affordable Care Act (ACA) of 2010 stated that "The Patient-Centered Outcomes Research Institute (PCORI) . . . shall not develop or employ a dollars per quality-adjusted life year (or similar measure that discounts the value of a life because of an individual's disability) as a threshold to establish what type of health care is cost-effective or recommended." (1) This means that

PCORI, the institute that was created in response to concerns about the high cost of health care in the United States, is prohibited from sponsoring studies that include considerations of cost-effectiveness. Despite this, experts have argued that the funding of CER still provides quality evidence for employment in standard CEAs and will therefore ultimately inform the question of value in health care (2).

Summary

With increasing pressure to control the costs and improve the quality of health care, measurement of value will be an important means by which different treatments can be critically evaluated.

DEFINING AND MEASURING VALUE IN ONCOLOGY

Value can be defined broadly as the desirable health outcomes achieved per monetary unit spent (3). The United States is currently transitioning to a value-based reimbursement system to replace the current system of payment for services provided. In March 2013, the National Commission on Physician Payment Reform published recommendations to transition to a blended payment system (4). These recommendations include elimination of stand-alone fee-for-service payment to medical practices and a transition to an approach based on quality and value. By 2019, physicians will enter an alternative payment model (APM) track or a Merit-Based Incentive Payment System (MIPS) track based on eligibility (5). These impending changes in the reimbursement of medical care make it imperative that physicians understand the principals of defining quality and value in health care.

Status Quo Measurement of Value in Health Care

Health care quality measures have come into the spotlight on a national level as directed by the Patient Protection and ACA, with the goal of understanding and optimizing the correlation between health care spending and quality care. To this end, mandatory reporting of quality measures was included in section 2701 of the ACA (1). However, the implementation of an effective and clinically relevant reporting system is limited by the complex process by which these quality measures are identified, vetted, and applied.

On April 16, 2015, the US Senate passed legislation to repeal the Sustainable Growth Rate formula, which governed provider payment under Medicare's Physician Fee Schedule (6). In its place, the enactment of the Medicare Access and Children's Health Insurance Program Reauthorization Act of 2015 has accelerated the movement toward value-based rather than volume-based payments by 2019 through the introduction of two tracks: the MIPS and APM. Under MIPS, four weighted categories (quality, resource use, clinical practice improvement activities, and meaningful use of electronic health record technology) are used to calculate an overall MIPS score, which is linked to provider payment adjustment based on performance. Providers can also opt out of MIPS by choosing to participate in an APM, which utilizes bundled payment arrangements for episodes of care and accountable care organizations to financially incentivize controlling cost growth while maintaining quality care over time. The Department of Health and Human Services (DHHS) announced goals for 30% of Medicare payments to be value based by the end of 2016 and 50% by the end of 2018 (7). However, many of the quality measures used in these value-based payment models have yet to be fully defined.

Other potential opportunities to achieve value in health care may be related to the elimination of the use of therapies that are not cost-effective (e.g., those that are more expensive, less effective, or both, than alternative treatments). While there is no established agency in the United States that evaluates the cost-effectiveness of health care interventions, such models do exist in the United Kingdom, Canada, Australia, France, and Germany through "value determination" reviews (8). An additional focus on value through the reduction in readmission rates has gained increasing attention; readmissions are a

major contributor to health care costs and are estimated to account for approximately $17 billion annually (9); it is estimated that up to 75% of all readmissions are preventable (10). As such, the US government has made reducing readmissions a priority to improve patient care, reduce health care spending, and therefore increase value. To address this goal, the Hospital Readmissions Reduction Program was established to limit reimbursements to hospitals with excess readmission ratios. Additionally, the Bundled Payments for Care Improvement initiative was established to determine payments based upon episodes of care (rather than for individual services) when patients are readmitted within 30 days of their index hospitalization (11–14).

Proposed Methods of Value Measurement in Oncology Care

In this section, we will describe two innovative methods that have been proposed for assessment of value in oncology health care.

ASCO Value Framework

A high proportion of all health care spending occurs in oncology. While in the past, patients with insurance may have been shielded from the increasing costs of cancer treatments beyond their responsibility for out-of-pocket copayments, changes in the structure of insurance policies with shared payment plans have led to an increasing experience of "financial toxicity," resulting in lower quality of life and an increasing rate of bankruptcy due to health care expenditures. Evidence indicates that cancer patients want information about the comparative effectiveness of available treatments as well as information on their relative costs. ASCO's Value in Cancer Care task force, first convened in 2007, has identified lists of common practices in oncology that were considered "low value" due to their expense and a lack of high-level evidence supporting their use (15,16). These lists, developed as part of the American Board of Internal Medicine Foundation's "Choosing Wisely" campaign, included avoidance of unnecessary imaging following an early-stage cancer diagnosis, avoidance of the provision of prophylactic antiemetic and bone marrow support regimens in low-risk settings, and avoidance of routine screening studies in patients with a low life expectancy. Of note, in 2013 the Society of Gynecologic Oncology published its own "top five" list of low-value interventions to avoid: (1) the screening of asymptomatic, low-risk women for ovarian cancer, (2) the use of Pap smear as a surveillance strategy for endometrial cancer, (3) the performance of colposcopy for low-grade squamous intraepithelial lesion Pap smear results in patients with a history of cervical cancer, (4) the use of routine surveillance imaging in patients with a history of gynecologic cancers, and (5) the delay of palliative care for women with advanced or relapsed cancer (17).

In 2015, the task force presented a framework for comparing the relative clinical benefit, toxicity, and cost of novel treatments in the medical oncology setting. The purpose of the framework is "to provide a standardized approach to assist physicians and patients in assessing the value of a new drug treatment for cancer as compared with one or several prevailing standards of care" and to provide oncologists with "information and physician-guided tools necessary to assess the relative value of cancer therapies as an element of shared decision making with their patients." The ASCO "value framework" was designed to define the value of medical interventions for the treatment of malignancy for which there exists phase III randomized controlled trial (RCT) data to inform outcomes. The framework provides the tools to calculate the net health benefits (NHBs) of a novel therapy (compared with standard of care therapy) for advanced or metastatic cancer using four criteria: (1) clinical benefit based on improvement in overall survival (OS), progression-free survival (PFS), or response rate; (2) toxicity differences; (3) symptom palliation; and (4) treatment-free interval. The clinical benefit calculation employs ASCO-assigned importance weights for OS (using a multiplier of 16), PFS (multiplier 11), or response rate (multiplier 8). In its current form, the framework assigns importance weights based on the opinions of task force members. The maximum possible NHB score for each therapy is 130 points. NHBs are intended to be presented alongside the drug-acquisition cost and, if available, the patient's out-of-pocket cost for each therapy. Value snapshots are

calculated differently for treatments with curative intent as compared with those for metastatic disease. Figure 17.1 depicts an example of a value snapshot constructed using the ASCO format for the comparison of standard chemotherapy with chemotherapy plus bevacizumab for recurrent, platinum-resistant ovarian cancer, using the AURELIA clinical trial results (18).

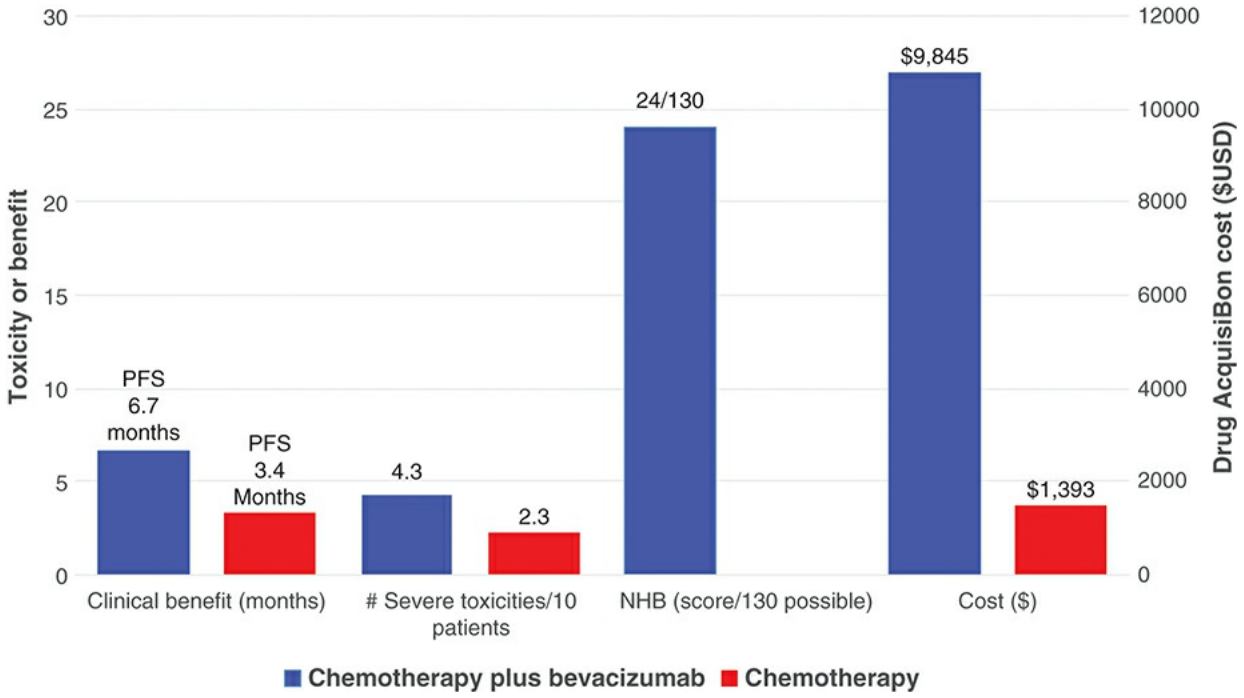

Figure 17.1 Utility Scores Elicited from Members of the Public and Cervical Cancer Survivors for Health States Related to the Treatment of Newly Diagnosed Cervical Cancer

ASCO presents the framework as a starting point for conversations about value between oncologist and patient and points out that the presentation of such data is a responsibility of all practitioners of oncology. An open comment period regarding the value framework was solicited, and it is anticipated that future iterations may include a more transparent, evidence-based foundation of the weighting methods used to calculate NHB.

The Porter Value Framework

Harvard Business School economist Michael E. Porter argues that the definition and demonstration of value are integral to reining in costs and to overall health care reform. He states, “the absence of comprehensive and rigorous outcome and cost measurement is arguably the biggest weakness standing in the way of health care improvement” (3). He argues that surrogate measures of quality, such as the measurement of compliance to guidelines or even of patient satisfaction, do not necessarily indicate quality of care. In order to truly assess quality, the outcomes important to each disease must be defined and measured.

In an effort to begin to define high-quality outcomes, Porter has developed an idealized outcomes measures hierarchy, in which specific health outcomes are multitiered and defined for each disease. In oncology, the highest priority is assigned to survival, followed by functional status achieved, recovery times following treatment, effects of the treatment process on function and quality of life, and sustainability of the cancer-free state. In the Porter value framework, costs are defined as they apply to a full optimal “cycle of care” for a given medical condition, usually representing periods of a year or more. Responsibility for outcomes and reimbursements is shared by all participating providers for a given heath condition.

Ultimately, Porter argues, “Improving value requires either improving one or more outcomes without raising costs or lowering costs without compromising outcomes, or both.” (19). Porter’s strategic agenda for a high-value health care

delivery system includes six components: (1) organization of care in disease-related integrated practice units; (2) measurement of outcomes and costs for every patient; (3) bundled payments for care cycles; (4) integration of care delivery across facilities; (5) expansion of services across geography; and (6) building an enabling information technology platform.

Conclusions—Value in Health Care

Significant progress has been made in the understanding of "value" in health care. Additionally, recent developments in the measurement and quantification of value have led to an expanded effort to tie quality, outcomes, and value-based cancer care to payment models for health systems and providers. Continued understanding of the factors that drive value will be critical to cancer care, including that related to gynecologic cancers. In 2015, the Society for Gynecologic Oncology (SGO) had begun to develop strategies for the development of an APM for endometrial cancer, and subsequently ovarian cancer. This SGO effort is critical in that the DHHS's MIPS and APM programs will be implemented on or after January 1, 2019. Development of a cancer-specific strategy by experts in treating these diseases is critical to the ultimate relevance and success of any APM.

PRINCIPALS OF HEALTH ECONOMIC ANALYSES

This section will introduce basic types of health economic studies. The term "cost-effectiveness analysis" is commonly used as a catchall term for any health economic analysis. In fact, there are several distinct forms of health economic evaluation, including CEA, cost-utility analysis (CUA), and cost-minimization analysis (CMA). CEA and CUA are the most frequently used health economic analyses. CEAs compare alternative interventions using a cost per unit of effectiveness such as a year of life gained (20). CUAs examine cost, effectiveness, and preferences for health outcomes. CMAs compare only cost (20).

Cost-Effectiveness Analyses

CEA is defined by the UK's National Institute for Health and Clinical Excellence (NICE) as an economic study design in which the consequences of different interventions are measured using a single outcome (e.g., years of life gained, deaths avoided) (21). A CEA is used to help prioritize the allocation of resources and to decide between two or more treatments or interventions. It compares a standard of care strategy with its more costly alternatives in terms of the additional cost per unit of effectiveness. Units of effectiveness in oncology CEA are most commonly expressed as additional survival time but may also be expressed in other terms; for example, the number of adverse events or additional procedures avoided or the number of cases of cancer prevented. This type of study is commonly used when a decision or health policy maker is operating within a given budget and is considering a limited range of options (20). When an intervention costs more and is also more effective than its alternative, the cost-effectiveness comparison is expressed as an incremental cost-effectiveness ratio (ICER), or the ratio of the difference in costs to the difference in effectiveness between two strategies.

Cost-Minimization Analyses

In some cases, alternative medical decisions have approximately equivalent effectiveness but potentially different costs. In such cases, the effectiveness component of a CEA may not be needed. CMAs assume comparable effectiveness between strategies and choose a preferred strategy based on the mean cost of each (22). For example, a decision analysis comparing the costs of three different surgical approaches to endometrial cancer staging assumed equal survival outcomes

between strategies and therefore did not incorporate effectiveness (23).

Cost-Utility Analyses

CUA is a form of CEA in which effectiveness is adjusted based on the quality of life that is associated with each strategy. In CUAs, *utilities* are the measurement used for quality of life and represent the preferences of an individual or a society for a particular health outcome. A utility is a number between 0 and 1, with 1 representing perfect health and 0 representing death. The most common metric used for comparison of strategies in a CUA is a quality-adjusted life year (QALY). The QALY quantifies both differences in survival and in quality of life between strategies. In an oncology CUA, the QALY is usually derived as the product of the length of survival in a specific health state and the utility representing the quality of life in that state. For example, 1 year of additional survival in a health state of utility 0.8 is equivalent to 0.8 QALYs. CUAs are preferred when both morbidity and mortality are affected by the proposed medical intervention or when quality of life related to the intervention being examined is a major concern. QALYs are the recommended outcome for health economic analyses if utility scores are available (24).

Methods for Development of a Health Economic Decision Model

This section will address specific methods used in the development of a health economic decision model, with an emphasis on the two most common types of models, CEA and CUA.

Define the Model's Perspective

The perspective of a health economic model is the first important consideration as costs are calculated differently based on the perspective taken. Most CEAs are performed from a third-party payer or a societal perspective. In a third-party-payer perspective model, costs assumed by an insurance company or by Medicare are incorporated. These may include professional fees for encounters and procedures, reimbursements to the hospital or ambulatory surgical center for postoperative care, or reimbursements for home health or rehabilitation care. A societal perspective is usually most appropriate as it accounts not only for all costs included from a third-party-payer perspective, but also for costs related to a patient's lost productivity and the caregiver's expense. For example, if one surgical approach results in a faster return to work, this will be associated with less cost that is due to lost productivity. Use of the societal perspective has led to the recognition that minimally invasive surgery results in cost savings to society (23,25). Other perspectives of health economic models include the *patient* and *hospital* perspectives. A hospital perspective model might be used to inform the decision to purchase expensive equipment such as robotic surgery platforms or an intraoperative radiotherapy facility.

Define the Question

Once the model's perspective has been determined, the clinical problem, standard approach, and any alternatives must be defined (26). The alternatives to the intervention of interest should always include a standard of care approach or even a "do nothing" approach. Next, a conceptual model for the analysis is developed, which outlines the possible consequences of each intervention. Decision models are often used as the conceptual framework for CEAs and have become an integral part of CEA studies.

Develop a Decision Tree

A simple decision tree begins with a *decision node* representing the primary clinical decision being examined. Two or more strategies may be examined using one decision tree. The subsequent nodes in the tree are termed *chance nodes* and define the probability of each possible clinical event that follows from the initial decision. For example, if the decision node concerns the clinical question of whether to accept a blood transfusion, the first chance node may define the probability that the patient will be infected with a blood borne infection such as HIV if she accepts. Another chance node may define the risk of death if transfusion is refused (Fig. 17.2). Probabilities defined at chance nodes are usually derived from the literature or from clinical trial data. At the end of each branch of a decision tree is the *terminal node*, at which a payoff representing the effectiveness of that strategy occurs. In the blood transfusion example, the terminal nodes define three states: life, death, or life with a blood borne infection such as HIV. The payoff for life is 1, for death is 0, and for infection is a utility representing a lifetime spent with the infection. The expected value of each strategy, or its effectiveness, is calculated as the weighted average of the probabilities and payoffs associated with each terminal branch of the tree. The strategy resulting in the highest expected value is said to be the most effective. The payoff in an oncology model is usually expressed as a survival time. In a CUA, the effectiveness might be the product of survival time and the quality of life–based preference score, or utility.

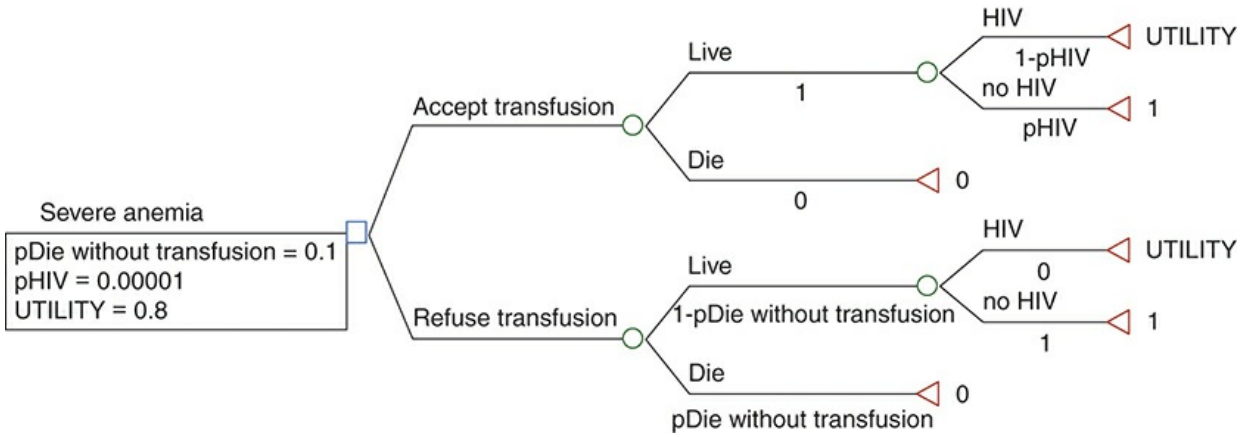

Figure 17.2 Simple decision tree representing the choice to accept or refuse a blood transfusion for severe anemia. The blue square is the decision node, green circles are chance nodes, and the red triangles are terminal nodes. Probabilities of events are depicted beneath each branch. Payoffs are listed to the right of terminal nodes. Three parameters are modeled as variables and have been given numeric values defined beneath the decision node: pHIV is the probability of being infected with HIV should the patient accept a transfusion. pDie Without Transfusion is the probability of death from severe anemia without a transfusion. UTILITY is the quality of life-related value of living with HIV, where 0 represents death and 1, perfect health.

Once all possible clinical events and their probabilities and payoffs have been defined by chance nodes, the costs of tests, treatments, and adverse events may be incorporated at each node. The cost associated with each strategy is calculated as a weighted average of the costs and probabilities associated with each branch of the tree.

Analysis of Model

After cost and effectiveness information have been collected and incorporated into the model, the analyses are performed. Results of cost-effectiveness models are expressed in terms of a comparison of two or more strategies. When one strategy is both more costly and less effective than an alternative strategy, it is said to be *dominated* and should not be considered. Likewise, a strategy that is both more effective and less costly is considered to be *dominant* and should be the treatment of choice. In these two cases, a numeric cost-effectiveness quantification is not needed. When one strategy is both more costly and more effective than an alternative, an ICER is calculated. This is expressed as the difference in the

mean cost divided by the difference in the mean effectiveness between strategies.

The ICER for comparison of intervention A with intervention B is defined as

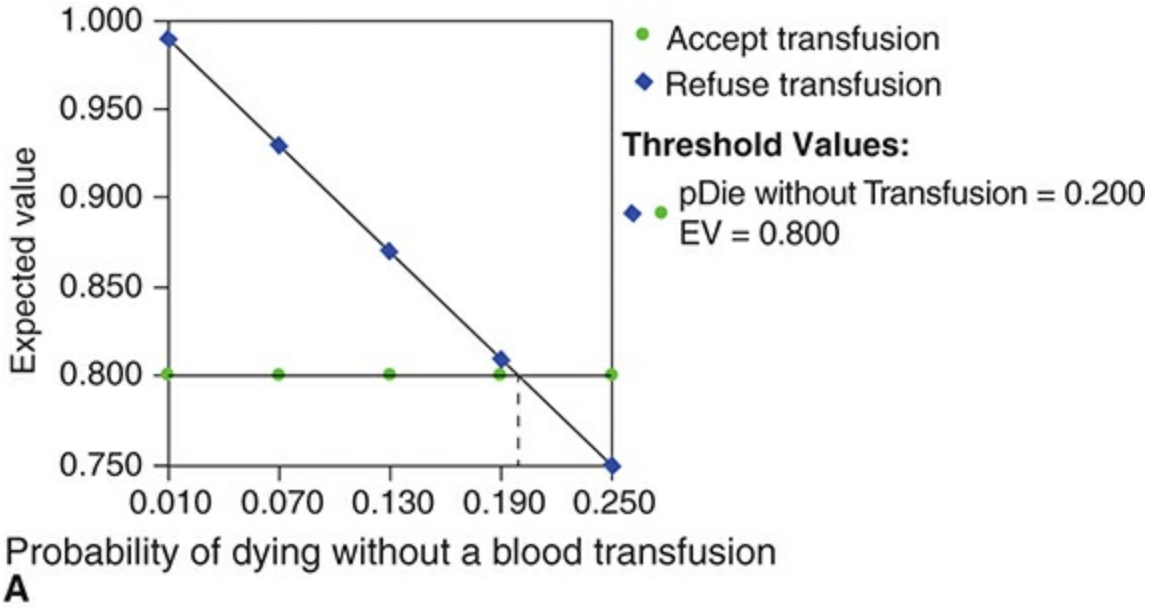
$$\text{ICER} = \frac{\text{Cost}_A - \text{Cost}_B}{\text{Effect}_A - \text{Effect}_B}$$

It is important to note that the ICER is *not* estimated by dividing the cost of one intervention by the measure of its own effectiveness. This average cost-effectiveness ratio is not comparable to the ICER and is not a useful metric in CEAs (27).

In the United States, an intervention has traditionally been considered cost-effective relative to an alternative strategy if the ICER is less than $50,000 per year of life saved (YLS)/QALY (22). Although ICER thresholds of $50,000 per YLS are theoretically used in decision making, they are not strictly applied. Social norms may raise this value such that interventions costing up to $100,000 or even greater per QALY have sometimes been considered cost-effective (28). The term "cost-effective" does not mean that a strategy saves money but rather that the additional cost of the intervention is worthwhile, usually from the perspective of society.

Sensitivity Analyses

Uncertainty in health economic analyses may exist about such input parameters as cost, survival, or clinical probabilities. To assess the impact of such uncertainty on the findings of a decision model, a sensitivity analysis can be performed. The simplest form of sensitivity analysis is a one-way analysis. Estimates are varied one parameter at a time to evaluate the impact changes make on the outcome or conclusions of the model (29). For example, in the simple model describing the decision to accept or refuse a blood transfusion, varying the probability of death due to anemia or the utility related to quality of life with HIV has an impact on the expected value of each decision (Fig. 17.3A, B). Likewise, a two-way sensitivity analysis can be performed to evaluate the impact of varying two model parameters simultaneously (Fig. 17.3C). When variation in the key parameters of a model over their confidence intervals or expected range of values does not change the model's results, the model is said to be insensitive to these variations and its conclusions can be more strongly interpreted. Models whose outcomes change significantly when key estimates are varied over a clinically reasonable range should be interpreted with caution.



A

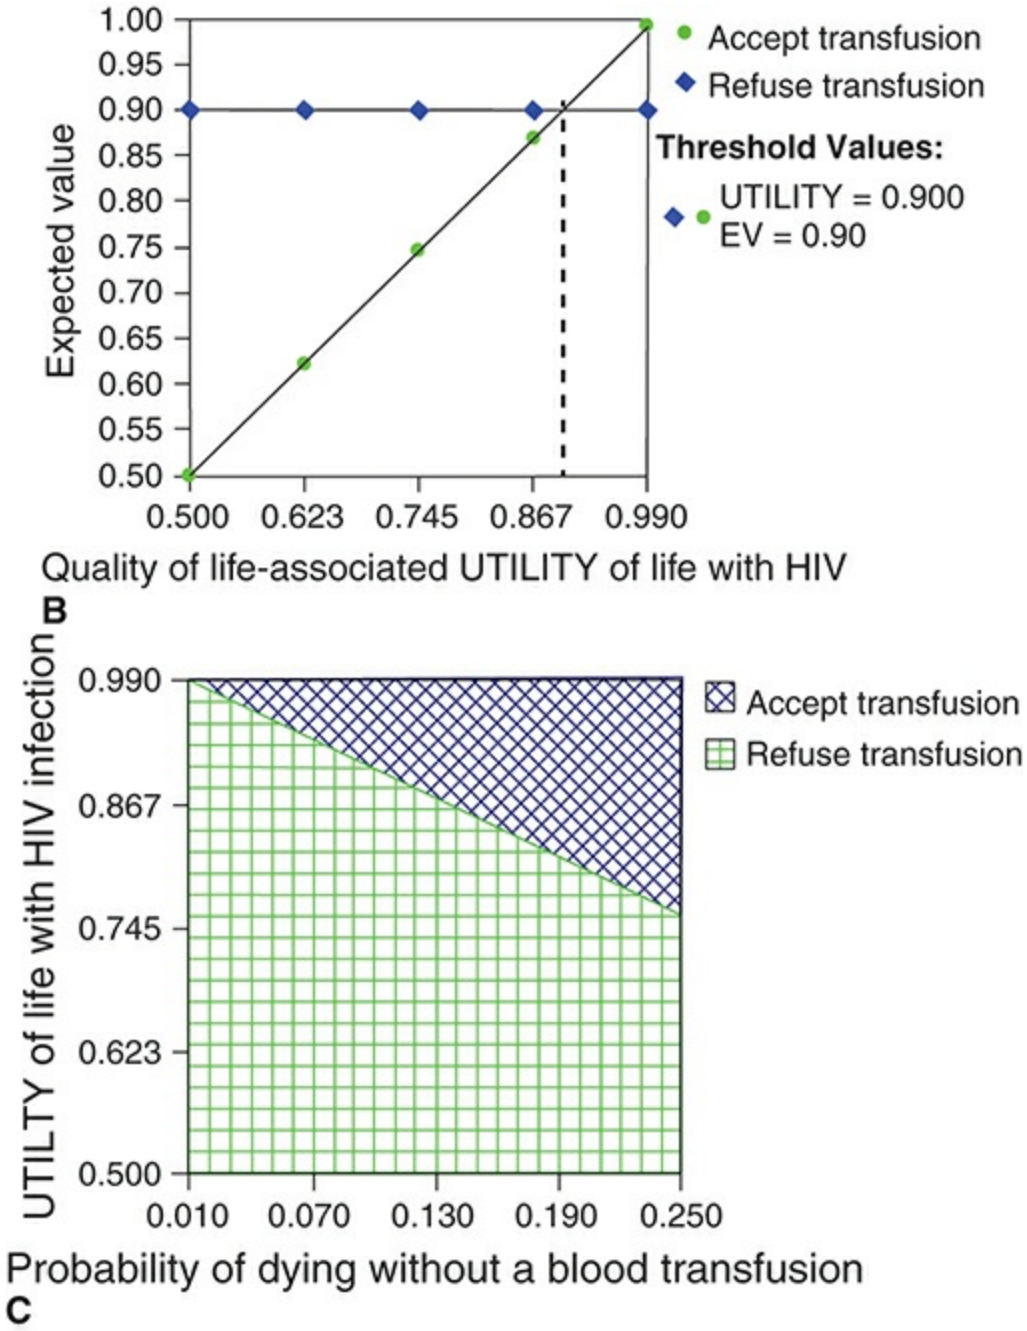


Figure 17.3 A: One-way sensitivity analysis on the probability of death from anemia without a blood transfusion. When the probability of death from anemia exceeds the threshold value of 0.2, the expected value of accepting the transfusion exceeds that of refusing transfusion, and the correct choice is to accept the transfusion. B: One-way sensitivity analysis on the quality of life-related utility of living with HIV. When the utility exceeds the threshold value of 0.9, the expected value of accepting the transfusion exceeds that of refusing transfusion, and the correct choice is to accept the transfusion. C: Two-way sensitivity analysis in which the utility associated with HIV infection and the probability of death without transfusion are varied simultaneously. The blue shaded area represents values for which acceptance of a transfusion results in the highest expected value (payoff) and is the preferred choice. Green shaded area represents combinations for which refusal of transfusion is the preferred choice.

Most clinical models are fairly complex and may warrant the use of multiple simultaneous sensitivity analyses. In a

Monte Carlo probabilistic sensitivity analysis, each variable in the model can be sampled from a probability distribution representing its value (30). Sampling parameter values from probability distributions (rather than from a simple range of values) places greater weight on likely combinations of parameter values. Multiple sampling simulations of the model may then be run, each of which results in an individual cost-effectiveness comparison or estimate. Multiple simulations allow for construction of a cost-effectiveness scatterplot and the ability to express confidence intervals around the ICER estimate (Fig. 17.4), which effectively allows quantification of the total impact of uncertainty on the model and the confidence that can be placed in the analysis results.

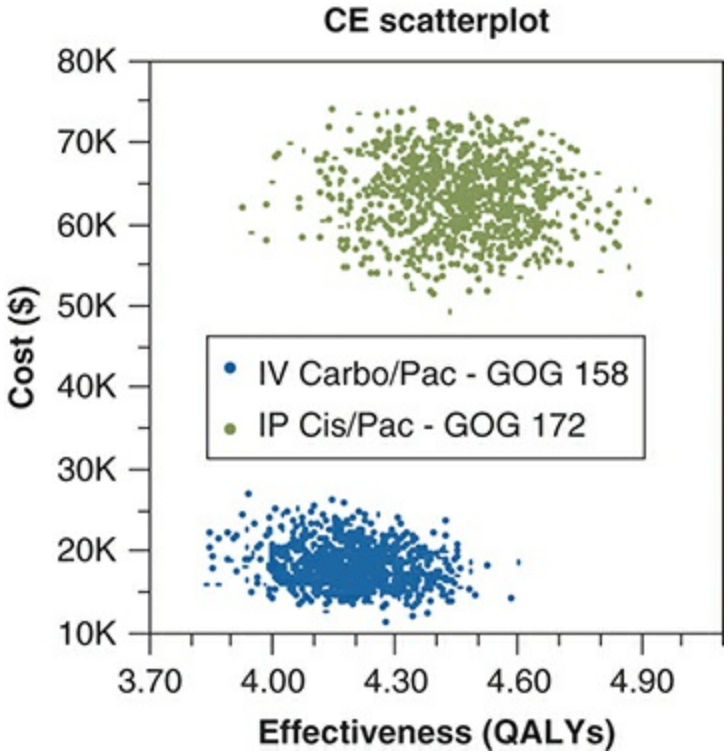

Figure 17.4 Cost-effectiveness scatterplot resulting from a Monte Carlo probabilistic sensitivity analysis for a model comparing intravenous carboplatin/paclitaxel to intraperitoneal cisplatin/paclitaxel and intravenous paclitaxel for advanced ovarian cancer. The simulation was repeated 10,000 times with sampling of key model parameters (cost, survival, probability of adverse events) from probability distributions. This simulation resulted in an estimate of 95% confidence intervals to surround the primary incremental cost-effectiveness ratio estimate. QALY, quality-adjusted life year.

INPUT DEVELOPMENT FOR HEALTH ECONOMIC MODELS

The following section details methods for the development of input data for health economic models.

Estimation of Costs

Cost Definitions

The costs incorporated into a CEA depend on the study's perspective. The standard CEA or CUA is performed from a societal perspective (22). However, alternative perspectives include those of the patient, hospital, or a third-party payer. In a societal perspective analysis, the costs included are all of those borne by society and should therefore include both direct and indirect costs. Direct costs include direct medical costs (e.g., professional and hospital costs, diagnostic tests and procedures) and direct nonmedical costs (such as travel to receive care). Indirect costs account for lost productivity due to time off work for illness, both for the patient and any caregivers. When a health economic model is performed from a nonsocietal perspective, the scope of the costs included may be narrower. For example, in an analysis performed from a third-party-payer perspective, lost productivity would not be included.

Costs versus Charges

When performing a health economic analysis, it is important to distinguish costs from charges. Charges represent what the provider or hospital asks an individual to pay for a service, and not the reimbursement provided by either a private third-party payer or Medicare. Because reimbursements by the Centers for Medicare and Medicaid Services (CMS) are generally considered to approximate the cost of providing a service, it is standard to use national Medicare reimbursements to approximate the costs of medical tests, procedures, or services in a health economic analysis (31). If a Medicare reimbursement is not available for a particular aspect of medical costs, charges may be used to calculate costs using a cost-charge ratio. Cost-charge ratios allow a calculation of the proportion of hospital charges that represent cost to the hospital. Cost-charge ratios are specific to individual hospital departments and may be available from CMS (http://www.cms.gov).

Surgical Costs

Health economic analyses in gynecologic oncology may include an estimate of the costs of surgical procedures. CMS reimbursements may be used to approximate these costs from a societal perspective. Direct surgical costs include professional fees (surgeon, anesthesiologist, pathologist), the cost of hospital recovery, and the costs of any tests or procedures performed in the postoperative period. Postoperative outpatient care is usually part of a global fee that includes the first 90 days of postoperative care and is therefore not included separately. Likewise, the reimbursement for recovery in the hospital or ambulatory surgery center is usually determined by a CMS code, and this reimbursement covers tests and inpatient care. However, additional procedures performed postoperatively are associated with additional professional fees.

Costs of Hospitalization

The cost of a hospitalization may be estimated for health economic models using the Diagnosis Related Group, a CMS code that takes into account the primary diagnosis and the patient's comorbidities and is used to determine the reimbursement Medicare provides to the hospital. An alternative method for estimating the cost of an inpatient hospital stay is to use the Agency for Healthcare Research and Quality's Healthcare Cost and Utilization Project Nationwide Inpatient Sample (http://www.hcup-us.ahrq.gov/). This large all-payer public database provides inpatient data from a national sample of over 1,000 hospitals in 44 states and is released annually. Mean and median charges and costs of all hospitalizations for a specific primary or secondary diagnosis can be obtained by entering the International Classification of Diseases, Ninth Revision (ICD-9) codes. Results can be stratified by demographic information.

Outpatient Treatment Costs

Outpatient treatments in gynecologic oncology often refer to chemotherapy. Cost tabulation should include the CMS reimbursements for the individual chemotherapy drugs and any other medications infused based on the designated J code for each drug. Tests performed routinely over the course of a cycle of treatment should also be included. Finally, the costs of infusion at an outpatient facility should be included using appropriate current procedural terminology codes.

Adverse Events

When two or more strategies are compared using a health economic model, it is critical that the adverse events associated with each strategy be accounted for. Specifically, when severe adverse events result in additional medical or nonmedical costs, these costs should be incorporated as well. For example, if one chemotherapy strategy results in a higher rate of febrile neutropenia, the cost of a hospitalization for this diagnosis should be incorporated into the cost of each strategy in proportion to the probability of the event in each treatment group. Adverse events whose frequencies are not significantly different between strategies or that do not generate additional cost (e.g., grade 1 anemia) may reasonably be omitted from a CEA. However, models should adjust for quality of life differences resulting from adverse events.

Cost Collection as a Component of Phase III Trials

While many cost-effectiveness studies are performed following completion of the clinical trials from which the data are derived, such analyses are ideally planned and executed in conjunction with prospective phase III trials. The International Society for Pharmacoeconomics and Outcomes Research Task Force on Good Research Practices recommends that collection of health economic data should be fully integrated into phase III studies (31). In a phase III trial, prospective economic data are usually collected by accounting for differences in health resource utilization between treatment groups. Ideally, this might include an accounting of all health-related encounters in each treatment group. However, logistical considerations during trial planning often require prioritization as to which data elements will be collected. Therefore, it is often appropriate to choose to focus on “big ticket” items as well as resources that are expected to differ between treatment arms. Resource utilization collection is accomplished by means of subject diaries in which outpatient and inpatient encounters as well as travel and caregiver time may be recorded. Once resource utilization collection is accomplished, national fee schedules and reimbursements are generally used to assign costs to each element.

Modeling Effectiveness

Effectiveness in CEA should be reported in units of relevant clinical outcomes. For example, in oncology studies, effectiveness might be expressed as the number of cases of cancer prevented, the number of unnecessary surgical procedures avoided, or the number of cancer recurrences prevented. However, it is most common in oncology CEA to quantify effectiveness using survival. Thus, in CEAs, the comparison of alternative strategies might be described in terms of the cost per additional year of life, or QALY, saved. While OS is a standard outcome in both CEA and clinical trials, PFS may also be reported.

Modeling Survival

Survival outcomes may be modeled in several ways. One simple method is to assign a survival time (e.g., mean survival in years) to each relevant branch of a simple decision tree. While this method accomplishes the assignment of a survival “value” to each branch of the model, it does not account for additional costs or changes in quality of life that may need to be applied only to subjects who are still alive at a later time. For example, it may be useful to apply the cost of additional

cycles of treatment or adverse events to only those individuals remaining alive or progression free at a specific time point. An alternative, and more common, method is to use a modified Markov state transition model to represent survival (see Construction of a Markov Natural History Model section). When a modified Markov approach is used, costs of events that are applied only if a subject is alive or has relapsed may be applied at each relevant time point. Likewise, changes in quality of life during or after treatment may also be quantified. In the context of comparing effectiveness results of a prospective clinical trial, raw survival data can be used to model Kaplan–Meier survival curves directly (Fig. 17.5).

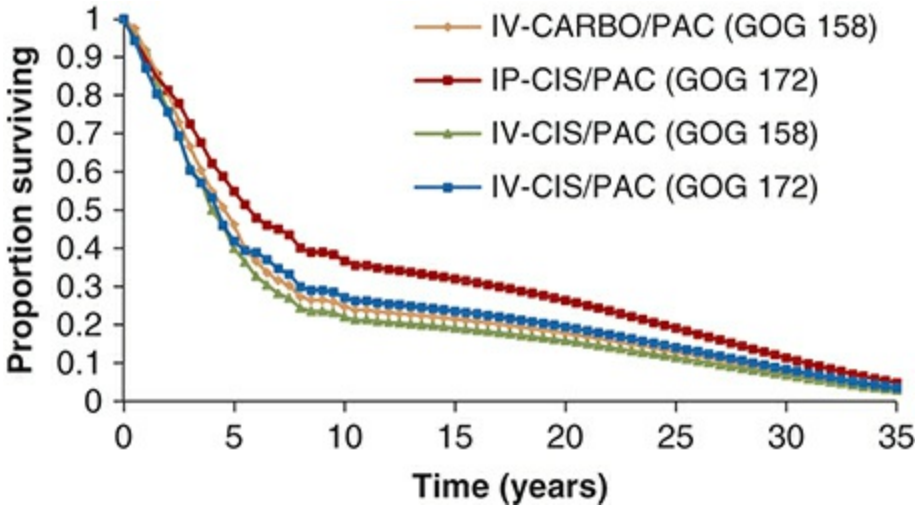

Figure 17.5 Survival curve output from a modified Markov state transition model designed to compare the cost-effectiveness of chemotherapy regimens studied in two randomized phase III trials.

Modeling Quality of Life

Medical interventions in oncology may improve quality of life without extending life or may extend life but worsen quality during treatment. Economic analyses that are based only on cost and efficacy do not fully account for the value of many treatments and interventions. CUAs account for the morbidity, physical well-being, and emotional well-being associated with medical treatments. CUAs may be used when the interventions being considered affect both quality of life and survival or when there is no expected difference in survival but a difference in quality of life is anticipated (20).

In CUAs, quality of life is represented by a utility. A utility is a measure of the desirability or preference that individuals or societies place on a given health outcome (32,33). Utility scores are usually linked to judgments about the value of a particular health state. The anchor health states are 0 for death and 1 for perfect health. Applying utility scores to a cost-effectiveness model allows the outcome of the economic analysis, now the CUA, to be reported in QALYs.

Eliciting Preferences for Calculation of Utility Scores

Use of utility scores in a cost-utility model requires a defined health state for each distinct outcome of the intervention and its alternative (34). For example, health states of interest in an ovarian cancer CUA may include (1) newly diagnosed ovarian cancer starting primary chemotherapy; (2) completed primary therapy, no evidence of disease; (3) progressive

disease on treatment; or (4) end-stage ovarian cancer. Descriptions of health states are needed to derive utilities. The description of each health state includes information about levels of physical health, emotional health, activities of daily living, and overall well-being (35). A rater provides preferences for each health state and a utility score is created. Raters are selected according to the perspective of the study. For example, if a societal perspective is taken, then representatives of the general population should be used to score the preference (22). The preferences of individuals with conditions of interest (such as patients) or of physicians are important ancillary information that might be incorporated into studies performed from alternative perspectives, but these cannot be substituted for societal preferences when the model's perspective is societal (26). Several rigorous formal approaches to the direct measurement of preferences and calculation of utility scores for health states have been developed, of which the most commonly used are the standard gamble (SG) and the time trade-off (TTO) methods.

The TTO method presents the rater with a choice between two health states, both of which have a certain outcome (36). Raters choose between a set number of years of life in a certain health state (i.e., with disease) and a shorter number of years of life in perfect health. The shortest period of time in perfect health that a rater would accept in exchange for a lifetime in the diseased state determines the utility score. For example, if the rater would accept living the next 20 years (but no less) in perfect health instead of living the next 30 years in the diseased health state, the utility score for the health state would be 20/30 or 0.67. The TTO method is relatively easy for raters to comprehend.

In the SG, raters are asked to choose between two alternatives: one with a guaranteed outcome and an alternative containing uncertainty or a "gamble." The guaranteed outcome is the less-than-perfect health state that is being rated. The alternative consists of a treatment that has two possible results: perfect health, with a probability of p, or a worst state (such as death) with a probability $1–p$. The value of p is then varied until the rater is indifferent between the choices of the alternative outcome. While there is some debate concerning consistency of results between the SG and TTO, they are both considered standard methods for eliciting utilities (33,34,37).

Use of Quality of Life Instruments and Health Status Classification Systems to Derive Utilities for CER

Measuring preferences for health outcomes using the direct SG and TTO methods is not a simple exercise and is beyond the scope of most clinical trials for which a CUA might be desirable. There exist a number of prescored health status classification systems to allow indirect assignment of utilities based on questionnaires, and calibrated using prior studies of societal preferences. For example, EuroQoL-5D (EQ-5D) is a simple questionnaire in which raters report no problem, some problem, or a major problem in five dimensions: mobility, self-care, usual activities, pain/discomfort, anxiety/depression (38). The ratings are scores from 0 (dead) to 1 (perfect health) and have been measured against the TTO technique on a random sample of 3,000 members of the adult population in the United Kingdom (39). The score obtained from the EQ-5D may be directly applied to health economic models and is the method preferred by the UK NICE.

The Functional Assessment of Cancer Therapy (FACT) is a 33-item scale developed to measure quality of life in patients undergoing cancer treatment (40). It is commonly used in RCTs of gynecologic cancers. The FACT consists of a core instrument (FACT-G) that can be supplemented by various subscales based on the malignancy of interest. While conversion of FACT scores to utilities has been studied, these methods have not been fully validated (41).

To date, the TTO and SG methods are the most accepted methods to develop utility scores. Although the use of quality of life instruments eases the labor intensiveness of collecting preferences using the TTO and SG methods, many question the validity of the use of indirect methods such as quality of life instruments to construct CUAs. At present, there is no clearly superior method for determining utility scores, either direct or indirect methods. Moreover, some believe that utilities should best be derived from patients as patients really know their disease condition best (42). Others feel that the preferences of the general public are most relevant because society as a whole must delegate distribution of its health care resources (43). As economic analyses evolve, the limitations of preference ratings should be examined and a consistent method of developing utility scores should be determined to allow for better comparisons to be made across cost-utility

studies.

MODELING APPROACHES TO SCREENING FOR GYNECOLOGIC CANCERS

In the following section, methods for the development of natural history models of cancer and their use in screening decision analyses will be described. The current state of evidence for cervical and ovarian cancer screening as informed by the current literature as well as simulation modeling will then be reviewed.

Modeling the Natural History of Cancer

In order to evaluate the effectiveness of a proposed cancer screening test for which no phase III clinical trials have been completed, a model can be created that simulates the natural history of the disease with and without screening. The simplest model is a decision tree. Although decision trees are useful for modeling outcomes that occur over a short period of time, such as a year, they can become unwieldy when trying to model a disease that occurs over a longer period or that involves recurrent events such as multiple episodes of screening or multiple cycles of treatment. Markov models are used for events that recur or occur in a predictable manner over time (44). They are particularly well suited to depicting the events associated with cancer, especially cancers that have a screening component.

Construction of a Markov Natural History Model

For creation of a Markov model, the natural history of a cancer is broken up into a defined, mutually exclusive, and exhaustive set of states. For cervical cancer, these states could include Well, Human Papillomavirus (HPV) Infection, Preinvasive Disease, Undetected Invasive Cancer (Stages I though IV), Detected Invasive Cancer (Stages I though IV), Cancer Death, and Death from Other Causes. For epithelial ovarian cancer, which does not have a universal preinvasive state, natural history states might include Well, Undetected and Detected Invasive Cancer (Stages I through IV), Cancer Death, and Death from Other Causes (Fig. 17.6). Once the states have been defined, movement (usually referred to as "transition") between the states is defined based on knowledge of the cancer's natural history. The probabilities of moving from one state to another over a fixed period of time are then used to populate the model. These are usually obtained from the epidemiologic literature, an analysis of an epidemiologic study, or expert opinion. Together, the states, allowed transitions and probabilities constitute the model. Once programmed, the model can be used to calculate different outcomes such as the lifetime risk of developing or dying from cancer. The outcomes are usually calculated for a cohort (or cohorts) of women who are assumed to enter the model at a given age and are then followed until death or a later age (i.e., 100 years).

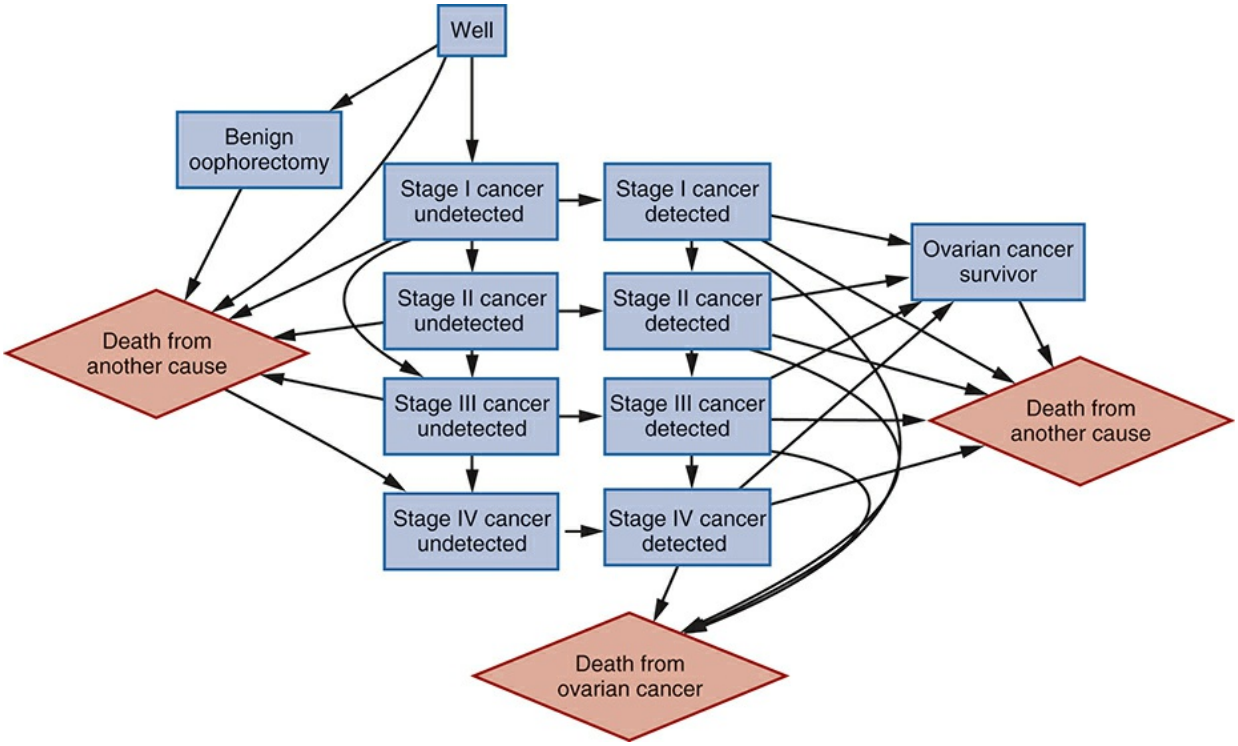

Figure 17.6 Influence diagram for models of the natural history of ovarian cancer. Arrows represent allowed transitions between health states. Diamonds represent terminal states.

Calibration

An important step in developing a model is obtaining probabilities or estimates for key variables (referred to as parameters) from the literature. However, often there are few available estimates, estimates of varying degrees of quality, or even no existing estimates for a given model parameter. The selection of a given clinical estimate is important since this affects the credibility of the model's aggregate result. Calibration is a process that involves comparing the model-predicted results with observed data to ensure a reasonably good fit of one to the other. Model calibration involves several steps: (1) identification of calibration endpoints (for cancer this usually means age-specific cancer incidence, but can also include stage distribution and age-specific mortality curve); (2) establishment of criteria for determining how well the model-predicted data fit the observed data (this may be visual inspection or using a statistical goodness of fit test); (3) adjustment of the set of model input parameters (i.e., probabilities); and (4) comparison of model-predicted outcomes to observed outcomes using the prespecified criteria and repeating steps 3 and 4 until a satisfactory calibration is achieved (45,46).

Validation

Model validation (confirmation that the calibrated model predicts results that are consistent with observed results from screening trials) can be achieved in a number of ways. The most robust method is to compare model-predicted outcomes with actual outcomes. For example, Havrilesky et al. constructed a natural history model accounting for the observed heterogeneity of epithelial ovarian cancers. Validation was performed by simulating the prevalence screen phase of the UK Collaborative Trial of Ovarian Cancer Screening (UKCTOCS) ovarian cancer screening trial. The model predicted the stage distribution of cancers detected by screening and the positive predictive value of the multimodality prevalence screen

within their reported 95% confidence intervals (47). To the degree that simulated results do not reproduce those observed in a clinical trial, the question arises whether there are key input parameters or model structural differences that affect the conclusions. A model can then be revised to determine whether the prediction is improved in an iterative process. Usually, the initial decision to conduct a modeling study is based on the fact that there is no observed data that exist to answer a given question. In this case, model validation is achieved by comparing the results from models built by different, independent groups, to evaluate for similarity. This approach has been adopted by the Cancer Intervention and Surveillance Modeling Network (CISNET). CISNET is a consortium of National Cancer Institute–sponsored investigators who use statistical modeling to study cancer control interventions in prevention, screening, and treatment and their effects on population trends in incidence and mortality. The models in this consortium were independently developed and have been calibrated to US data. The results from modeling studies conducted by members of the CISNET consortium have been used by the U.S. Preventive Services Task Force to inform their recommendations for colorectal and breast cancer (48,49).

Simulation of Screening

The impact of screening, diagnosis, and treatment can be tracked using a Markov model. Markov models can be programmed to keep a count of the outcomes associated with diagnosis, treatment, and screening. Examples include the average number of false-positive or false-negative screening test results, the number of diagnostic procedures such as colposcopy or laparoscopy performed, number of preinvasive lesions detected, and treatments. Other important outcomes include cancer incidence, stage distribution, and mortality. If the cohort of women is modeled over a sufficiently long period of time, the model can be used to calculate life expectancy, lifetime costs, and quality-adjusted life expectancy.

Cervical Cancer

For cervical cancer, modeling has played a particularly prominent role in informing decisions regarding which screening and triage tests to adopt, how frequently women should be screened, and whether the addition of vaccination to screening is cost-effective. This prominent role is due to the fact that trials of new screening tests include follow-up and treatment that often differs from clinical practice or are conducted in non-US populations with different screening histories. Modeling studies can also be used to project both short- and long-term results from trials. For example, trials for the HPV vaccines used cervical intraepithelial neoplasia (CIN) grade 2 or higher as primary outcomes. However, cancer incidence and death are more important outcomes for policy makers. Modeling has been used to estimate the potential cost-effectiveness of adding vaccination to screening. More recently, modeling has been used to justify the expanded coverage of HPV vaccines to include boys. The following sections describe how models of HPV and cervical cancer have been used to enhance clinical data and inform policies regarding screening and vaccination for cervical cancer prevention.

Questions Addressed by Cervical Cancer Models

Appropriate age to begin/end and screening interval with cytology.

A mathematical model of cervical cancer, developed in the 1980s by David Eddy, was used to examine the relationship between Pap smear screening interval and cancer incidence (50). This modeling study showed that screening every 2 or 3 years would result in 95% to 99% of the cancer reduction benefit of screening every year, but with lower costs and fewer procedures. In terms of the ages to begin and end screening, these have for the most part been based on epidemiologic data showing that cancer incidence peaks in the late 30s to mid-40s but that the incidence of CIN peaks in the 20s (51,52).

More recently, modeling has been used to help inform changes to recommendations regarding the age to begin or end screening but also to quantify the trade-offs in terms of burdens and benefits of screening at different ages. An example is from Canfell et al. who modeled the impact of changing the UK screening guidelines to begin at age 25 years instead of age 21 years (53). They found that if the age to begin screening was delayed until 25 years, the lifetime risk of cancer would be minimally affected (cumulative lifetime incidence decreasing from 0.63% to 0.61%) due to the low incidence of cancer in young women (53). More recently, Kulasingam et al. modeled the impact of varying the age to begin screening in 1-year increments from age 15 to 25 years on cancer incidence and mortality (54). They showed that screening in the teens was associated with a high number of additional diagnostic procedures, but very small reductions in lifetime risk of cancer, when compared with beginning screening in the 20s. In terms of the age to end screening, Canfell et al. showed that further reductions in lifetime incidence of cancer (from 0.63% to 0.56%) could be achieved if screening were extended from age 64 to 79 years and conducted at 5-year intervals (53). Kulasingam et al. estimated the impact of continuing to screen a cohort of women who had been screened every 3 years since age 21 beyond age 65 years and also showed incremental reductions in cancer, but large increases in additional procedures. Importantly, these studies illustrate how modeling can be used to examine issues related to age that epidemiologic studies may not be able to answer.

Use of HPV testing in screening.

Modeling studies have examined the cost-effectiveness of adding HPV DNA testing (with either polymerase chain reaction–based tests or hybrid capture 2) to screening programs (55). Strategies examined include cotesting (simultaneous testing with both cytology and HPV DNA, with referral for treatment if either is abnormal), HPV testing followed by triage using cytology if the HPV DNA test is abnormal, and testing with cytology followed by triage using HPV DNA for those with abnormal cytology results. Of the different strategies that have been compared for cost-effectiveness, one in particular showed promise: HPV DNA testing followed by triage based on cytology for women with positive HPV results (56,57). Subsequently, two large randomized trials of primary HPV testing support the use of HPV testing as the primary screening test compared with cotesting with cytology and HPV or cytology alone. The ARTISTIC (A Randomised Trial In Screening To Improve Cytology) trial was a randomized trial that compared cotesting with cytology and HPV DNA to cytology alone (58). The trial was conducted in a UK population of 25,410 women aged 20 to 64 years. The results from three rounds of screening conducted over 6 years were used in combination with a decision model to compare the following screening strategies: (1) screening with cytology alone; (2) screening with HPV followed by triage of HPV-positive women with cytology; (3) screening with HPV followed by triage with genotyping for HPV-16/18 or cytology for other high-risk HPV-positive women; and (4) cotesting with cytology and HPV. The model predicted that primary screening with HPV DNA (strategies 2 or 3) is more effective and potentially cost-saving compared with screening with cytology alone (59).

In the United States, the Addressing the Need for Advanced HPV Diagnostics (ATHENA) study is a prospective 3-year cervical cancer screening trial of 47,208 women aged 21 years and older that compared the performance of the cobas HPV test (Roche Molecular Diagnostics, Pleasanton, CA), which detects 12 HPV types and also provides separate results for HPV-16 and -18, alone and in combination with cervical cytology (60). An analysis restricted to women aged 25 years and older showed that primary screening with HPV, and use of genotyping and cytology for triage of HPV-positive women, was more sensitive with a similar positive predictive value than cytology using an ASCUS cut-point for referral to colposcopy. Based, in part, on these results, the Food and Drug Administration (FDA) in 2014 approved the use of the cobas HPV test as a stand-alone screening test for cervical cancer screening in women aged 25 years and older. Interim guidelines on the use of this test recommend immediate colposcopy for women who are HPV-16 and/or -18 positive or the use of cytology for triage of women who are positive for the other 12 HPV types (61). To date, modeling studies of this new strategy have not been conducted; however, such studies will be needed to quantify the potential impact on cancer and cancer deaths that this new screening option will have compared to currently recommended strategies, namely, screening every 3 years with cytology beginning at age 21 years and ending at age 65 years or switching to cotesting every 5 years beginning at age 30 years.

Quantifying the impact of HPV vaccination.

Two types of models have been used to explore HPV vaccine effectiveness: Markov state transition cohort models (described above) and dynamic transmission models, with a third category—hybrid models—that uses a combination of the two (62). Dynamic models track population changes over time by taking into account births as well as deaths. Importantly, dynamic transmission models also account for how infection with HPV depends on patterns of sexual behavior and the distribution of infection in the population (63). As such, a strength of dynamic models is that they can be used to determine herd immunity, explore the relative value of vaccinating boys in addition to girls, and explore how sexual mixing patterns (how men and women form partnerships and how these affect transmission) affect the age at which vaccination should begin and age(s) for catch-up programs (i.e., vaccination offered to girls and/or women who are not part of the optimal age group but who may still derive a benefit). A recent modeling study conducted using multiple, independently developed HPV and cervical cancer hybrid, Markov and fully dynamic models concluded that vaccination of girls prior to the age of sexual debut has the potential to considerably reduce the burden of CIN and cervical cancer (64). This is especially true if a long duration of vaccine efficacy and high vaccine coverage are modeled. Vaccine price has also consistently been shown to impact the cost-effectiveness of adding vaccination to screening or adding HPV vaccines to existing vaccine programs. Indeed, if HPV vaccines are priced below certain thresholds for different countries, HPV vaccination could potentially be cost-saving compared with not screening (65). Of note, across a range of analyses, vaccination of girls only prior to onset of sexual activity, as opposed to vaccination of boys and girls plus catch-up vaccination, has been shown to have the most attractive cost-effectiveness profile. However, under conditions of low coverage, as has occurred in the United States, extending vaccination to boys is potentially cost-effective (66). Based on these results, and survey data showing low uptake of the HPV vaccines in the United States, the Centers for Disease Control and Prevention Advisory Committee on Immunization Practices (ACIP) decided to extend HPV vaccine recommendations to include boys in addition to girls in 2009 (67). In 2015, the FDA approved a nonavalent HPV vaccine targeted against seven high-risk and two low-risk HPV types associated with approximately 80% of cervical cancers. Modeling by Brisson et al. was conducted to determine the impact of recommending this vaccine in a US population and was included in the recommendation for use of this vaccine by the ACIP (68). Their modeling study predicts that use of the 9vHPV in both males and females will be cost-saving when compared with 4vHPV if the cost of the new vaccine is at most $13 greater than the cost of the 4vHPV vaccine. The 9vHPV was cost-saving in a number of scenarios, and the cost per QALY gained did not exceed $25,000 in any scenario across a range of assumptions about HPV natural history, cervical cancer screening, vaccine coverage, vaccine duration of protection, and health care costs. However, the cost-effectiveness of the 9vHPV was sensitive to assumptions about cost of the vaccine.

Screening in the era of HPV vaccines.

The issue of whether and how screening should change in the era of HPV vaccines is complex and will depend on a number of factors that are still unknown. These include, but are not limited to, the performance of cytology and HPV tests in vaccinated women, whether predicted reductions in CIN and cancer are achieved, and whether vaccination will affect screening behavior, in particular screening participation. Under the assumption that vaccines will markedly reduce cancer incidence and mortality, potentially cost-effective approaches to screening vaccinated cohorts of women include strategies that use a less frequent screening interval, delayed age of first screening, and/or use of a strategy based on HPV DNA testing followed by cytology (56,69). Of note, preliminary modeling to examine the impact of cross protection and broad spectrum vaccines suggests that far fewer screens than currently recommended will be needed to continue to achieve significant reductions in cervical cancer (70). However, with low vaccine coverage continuing to be an issue in the United States, changes to screening for vaccinated cohorts have yet to be instituted and may well be decades off (71).

Modeling has been used extensively in cervical cancer to inform how we should approach screening and add HPV vaccination programs to screening programs. Given the development of new tests for cervical cancer and new vaccines that cover more HPV types than the first generation of HPV vaccines, modeling will continue to play a key role in

determining the most effective and cost-effective strategies for prevention of cervical cancer.

Ovarian Cancer

Because the majority of ovarian cancers are diagnosed at an advanced stage, there has been considerable interest in designing screening strategies to diagnose and treat women earlier in the hopes of improving survival outcomes. Several key parameters may impact the success of any cancer screening program: (1) Availability of effective treatment for screen positive individuals; (2) Sufficiently high disease prevalence; (3) Existence of an effective screening test; and (4) Acceptable cost or cost-effectiveness of the screening program. Each of these parameters is addressed below in the context of development of a screening test for epithelial ovarian cancer.

Effectiveness of Treatment

Pathologic and genetic data now suggest that epithelial ovarian cancer is a heterogeneous disease, with a number of different precursor lesions. Many high-grade serous ovarian cancers likely originate in the fallopian tubes, whereas some clear cell and endometrioid lesions may originate in the endometrium. Because there is no universal, clearly defined precursor lesion for all epithelial ovarian cancer, the target lesion for the screening tests that are currently in phase III trials is stage I disease. Targeting early-stage disease may be appropriate because survival from epithelial ovarian cancer diagnosed at stage I is encouraging. Women with stage I disease with low-risk features may be cured without the need for adjuvant treatment, while those with higher risk stage I disease may still achieve excellent outcomes following three to six cycles of platinum- and taxane-based chemotherapy (72).

Disease Prevalence

Perhaps the biggest challenge to development of a successful ovarian cancer screening program is the low prevalence of this disease. The lifetime incidence of ovarian cancer in the United States is approximately 1.4%. In postmenopausal women, the most likely target population for a screening program, its prevalence is approximately 40 per 100,000 women. Disease prevalence has a direct impact on the achievable positive predictive value of a screening test, which defines the number of diagnostic procedures or surgeries that would be required to diagnose one case of ovarian cancer. Expert opinion suggests that the minimal acceptable positive predictive value for an ovarian cancer screening test should be 10%. To achieve this value in the postmenopausal population, a screening test needs to have a specificity exceeding 99.6%.

Effectiveness of Screening Test

To date, no screening test for ovarian cancer has been proven effective in reducing mortality from this disease. Two large randomized trials have recently been performed to evaluate screening strategies utilizing the CA125 serum test and transvaginal ultrasound. The Prostate, Lung, Colorectal and Ovarian (PLCO) screening trial randomized 78,216 women to either usual care or a combination of annual CA125 for six consecutive years and annual transvaginal ultrasound for four consecutive years (73). After a median follow-up of 12.4 years, there was no difference in ovarian cancer mortality between the screened and unscreened groups. However, there was evidence of possible harm due to the screening intervention, in the form of a 15% rate of serious adverse events among women with false-positive screening tests who underwent surgical procedures. The authors concluded that simultaneous screening with CA125 and ultrasound does not reduce ovarian cancer mortality and may introduce harms (74).

A second large screening trial, the UKCTOCS study, randomized 202,638 postmenopausal women to no intervention, annual transvaginal ultrasound, or a multimodality algorithm incorporating annual CA125 and second-line transvaginal ultrasound. Mortality was 15% lower, but not statistically significantly so, in the multimodality screening group. However,

a planned analysis excluding all cancers diagnosed during the prevalence screen of the trial demonstrated significant ovarian cancer mortality reduction. The authors concluded that further clinical follow-up was needed to make judgment about both the clinical efficacy and cost-effectiveness of the screening algorithm (75).

Comparative Effectiveness of Screening

Several groups have used mathematical modeling to determine the likely success and cost-effectiveness of screening strategies. Skates and Singer designed the first reported stochastic simulation model of the natural history of ovarian cancer. This model suggested that screening using CA125 could potentially save 3.4 years of life per case of cancer detected (76). Urban et al. subsequently modified the Skates and Singer model and performed a cost-effectiveness assessment of several screening strategies. The authors reported that multimodality screening with CA125 followed by transvaginal ultrasound only if CA125 was positive or doubling was potentially cost-effective compared with single test strategies and no screening (77).

More recent screening models have incorporated new data about the pathophysiology and progression of ovarian cancer. Havrilesky et al. constructed a natural history model that, based on the physical proximity of the ovaries to upper abdominal organs such as small bowel and omentum, allowed progression of stage I cancers either to stage II or directly to stage III (78). Disease incidence, mortality, and stage distribution were calibrated to reflect Surveillance, Epidemiology, and End Results (SEER) data. A modified version of this model was designed to account for the heterogeneity of ovarian cancer by modeling aggressive and indolent phenotypes with different rates of progression (47). These models highlighted factors that are important to the success of a screening program. For example, increasing the frequency of screening had a more favorable impact on reducing cancer mortality than increasing the sensitivity of the individual screening test. However, due to the increased cost of screening more frequently, increasing the frequency actually reduced cost-effectiveness. Both models reinforced the important link between specificity and positive predictive value. An annual screening test with a sensitivity of 85% and specificity of less than 99% would have a positive predictive value not exceeding 4%. However, at a specificity of 99.9%, the positive predictive value for annual screening was excellent at 22%. Annual screening of a population of women aged 50 to 85 years at average risk of ovarian cancer with a test at 85% sensitivity and 95% specificity was predicted to improve life expectancy 2.92 days on average, with an ICER of $73,469 per YLS compared with no screening. However, simulated screening of a “high risk” population of women aged 50 to 85 years with a relative risk of developing ovarian cancer of 2 resulted in an improvement in the predicted ICER to $36,025/YLS when compared with no screening. In sensitivity analysis, key factors in achieving a cost-effective screening test (defined as an ICER of less than $50,000 per YLS) were an inexpensive test, a very high test specificity, and infrequent (annual or less) testing. Screening appeared to be potentially most cost-effective when the test specificity was well above 99% and the testing interval was annually or less frequently (78).

These prior models confirm that very high test specificity is required to achieve acceptable positive predictive values, while mortality reduction is sensitive to screening frequency. Annual screening for ovarian cancer appears to be potentially cost-effective in high-risk populations and at very high screening test specificities. For women at average risk, both long-term mortality data and final analysis of the costs of the multimodality screening algorithm in the UKCTOCS trial are critical to any assessment of the costs, benefits, and potential cost-effectiveness of currently available screening strategies. Moreover, because none of the health economic models of screening performed to date have taken quality of life into account, any health economic assessments of ovarian cancer screening would be premature.

COST-EFFECTIVENESS OF THERAPEUTICS IN GYNECOLOGIC CANCERS

In the next section, the value and cost-effectiveness literature regarding therapeutic interventions for gynecologic malignancies are reviewed.

Ovarian Cancer

Chemotherapy for Newly Diagnosed Ovarian Cancer

The standard treatment for ovarian cancer is primary surgical staging with maximum possible cytoreduction followed by chemotherapy.

Introduction of taxanes.

The first cost-effectiveness studies in ovarian cancer chemotherapy were performed in response to the introduction of taxanes into the front-line chemotherapy regimen for this disease. Two independent RCTs, conducted by the Gynecological Oncology Group (GOG 111) and the European-Canadian Intergroup (OV-10), demonstrated that cisplatin plus paclitaxel as primary chemotherapy is superior to previous therapy of cisplatin plus cyclophosphamide in clinical response rate, PFS, and OS (79–81). When first introduced, paclitaxel–cisplatin was a more expensive therapy than the old standard of cyclophosphamide–cisplatin. A number of cost-effectiveness investigations were performed using data from GOG 111. From the perspective of a US oncology practice, the total drug costs for cisplatin plus paclitaxel were four times higher than those for cisplatin plus cyclophosphamide ($9,918 vs. $2,527; year of costing not specified) (82). Compared with cisplatin plus cyclophosphamide, the incremental costs per year of life gained for cisplatin plus paclitaxel therapy were $19,820 for inpatient treatment and $21,222 for outpatient treatment. These incremental costs fall well within the generally accepted cost-effective range for new therapies.

Carboplatin and paclitaxel are now both marketed as generics; older studies are therefore less applicable than when originally published. Given the current low cost of paclitaxel, any clinically superior regimen using this drug is also likely to be found cost-effective. Chan et al. have recently performed an economic analysis based on results of a phase III Japanese GOG trial (83) demonstrating that weekly dose-dense paclitaxel is cost-effective compared with an every 3-week regimen in the setting of primary treatment (84).

Intraperitoneal chemotherapy.

The NCCN guidelines for ovarian cancer recommend intraperitoneal (IP) chemotherapy as primary/adjuvant therapy for optimally debulked (<1 cm) stage II or greater ovarian cancer treatment (85). Several phase III clinical trials have identified advantages of the use of IP chemotherapy for adjuvant treatment of stage III ovarian cancer; the most recent of these studies demonstrated an OS advantage of 16 months in the IP arm at the expense of increased risk of adverse events and a significant reduction in quality of life (86). Long-term follow-up of GOG trials shows that the survival advantage associated with IP chemotherapy persists past 10 years (87).

Two analyses have evaluated the cost-effectiveness of IP chemotherapy for the primary treatment of stage III ovarian cancer. When comparing IP with intravenous (IV) chemotherapy, Bristow et al. reported that IP chemotherapy was potentially cost-effective compared with IV, with an ICER of US$37,454 per QALY (88). Havrilesky et al. reported an estimate of US$180,022 per QALY when using a 7-year time horizon, which was consistent with the current duration of survival results from GOG 172 (89). However, when the time horizon was extended to a lifetime under the assumption that any survival advantage realized with IP chemo would persist over that period, the ICER of IP chemotherapy dropped to US$32,053 per QALY. While both studies informally incorporated quality of life based on the FACT surveys administered to patients enrolled on GOG trials of chemotherapy, neither performed a validated utility assessment. Conclusions that may be drawn from these studies are that IP chemotherapy is potentially cost-effective for women with

stage III disease, but that more formal incorporation of quality of life and investigation of less costly outpatient IP regimens, as were incorporated into the more recently accrued GOG 252 trial, would strengthen this conclusion (88,89).

Bevacizumab.

Bevacizumab is an anti–vascular endothelial growth factor inhibitor of angiogenesis and is FDA approved for treatment of a number of different cancers, including platinum-resistant ovarian cancer. With regard to the primary treatment of ovarian cancer, the ICON7 and GOG 218 phase III clinical trials of newly diagnosed ovarian cancer independently and simultaneously reported a small 2- to 6-month OS advantage to the addition of bevacizumab to primary combination of carboplatin/paclitaxel, followed by 14 to 22 additional cycles of consolidation bevacizumab in the absence of progression (90,91). Even prior to the initial presentation of the data in ovarian cancer, questions were raised about the cost of universal bevacizumab. Cohn et al. performed CEAs examining the likely clinical benefit of bevacizumab and the cost of the drug as well as its associated adverse events. These analyses demonstrated that there was no reasonable scenario under which bevacizumab could be considered cost-effective by existing measures (92,93). A subset analysis of the ICON7 data revealed that the main benefit of bevacizumab appears to be confined to women with high-risk disease such as those suboptimally cytoreduced and those with stage IV disease (90). While ideally treatment of a smaller subset of women with ovarian cancer who are most likely to benefit would make this drug more cost-effective, initial attempts at modeling this scenario did not demonstrate this to be a cost-effective alternative (94).

Consolidation therapy.

Consolidation regimens that have been studied for ovarian cancer include paclitaxel and bevacizumab; both have a proven PFS benefit but neither has demonstrated an OS benefit. Lesnock et al. performed a CEA of consolidation therapy following carboplatin/paclitaxel, comparing 12 months additional paclitaxel to 17 cycles of additional bevacizumab. Clinical data were derived from the PFS results of GOG 178 and GOG 218. Consolidation therapy with paclitaxel was found to be cost-effective; bevacizumab consolidation was dominated (less effective and more costly) by paclitaxel consolidation (95).

Treatment of Recurrent Ovarian Cancer

Most women with ovarian cancer will achieve clinical remission following primary treatment but will eventually experience recurrence.

Platinum-sensitive recurrence.

Patients who experience recurrence more than 6 months after completing a first-line chemotherapy regimen are considered to have “platinum-sensitive” ovarian cancer and have an excellent response rate when re-treated with platinum agents (96,97). Two large RCTs have compared the use of single-agent therapy with combination regimens for platinum-sensitive ovarian cancer. These studies identified a PFS advantage for the combination regimens of gemcitabine plus carboplatin and paclitaxel plus platinum chemotherapy regimens (as well as an OS advantage for paclitaxel plus platinum) compared with platinum alone, and the authors suggested that the combination regimens should be considered standard of care (98,99).

Based on these two studies, Havrilesky et al. designed a Markov state transition model that evaluated the optimal treatment strategy for patients with recurrent platinum-sensitive ovarian cancer. Paclitaxel plus carboplatin had an ICER of $15,564 per additional progression-free year compared with single-agent carboplatin, while gemcitabine plus carboplatin has a less attractive ICER of $278,388 per additional progression-free year compared with paclitaxel plus carboplatin (100). Given that both carboplatin and paclitaxel are now available as generic drugs in the United States, their cost advantage is not surprising. Neurological and hematological toxicities of the regimens were incorporated into a sensitivity analysis that varied the severity and costs associated with treatment. Over a reasonable range of utility scores, paclitaxel

plus carboplatin was still cost-effective compared with carboplatin alone, and gemcitabine plus carboplatin remained non-cost-effective (100). These results must be interpreted on an individual basis with an individual's prior adverse event profile in mind; for example, it is unlikely that a patient with severe neurotoxicity due to prior taxane treatment would be re-treated with the same drug.

Platinum-resistant recurrence.

Recurrent ovarian cancer that occurs within 6 months of completing a first-line chemotherapy regimen has a poor prognosis, with cure being very unlikely. Rocconi et al. performed a CEA of treatment options for recurrent platinum-resistant ovarian cancer and concluded that only best supportive care (no chemotherapy) was clearly cost-effective, while second-line monotherapy was possibly marginally cost-effective (ICER $64,104 per YLS) as well (101). Even without incorporation of toxicity rates and costs, the authors found that combination chemotherapy regimens were never cost-effective for platinum-resistant disease due to unfavorable ICERs.

Finally, bevacizumab is now FDA approved for platinum-resistant recurrent ovarian cancer based on the results of the AURELIA trial which demonstrated superior PFS when bevacizumab was added to standard of care single-agent chemotherapy (18). Cost-effectiveness evaluations are forthcoming but as yet unpublished in this clinical setting.

Targeted therapies.

In the era of personalized medicine, the use of molecular and/or genomic tumor testing to individually tailor cancer treatments has become popular. However, very few targeted treatments have been demonstrated to perform better than nontargeted treatments. The exception in ovarian cancer is the use of polyADP ribose polymerase inhibitors. Women with germline BRCA mutations have been shown to have significantly improved PFS when treated with maintenance olaparib following standard chemotherapy for platinum-sensitive recurrence. In a study by Secord et al., BRCA testing performed specifically to direct the use of maintenance olaparib for platinum-sensitive disease did not appear to be cost-effective when compared with no testing (102). However, consideration of genetic testing is now recommended for all women with ovarian cancer. As germline and/or somatic tumor testing become more prevalent and the costs of targeted agents drop, targeted therapies should become increasingly attractive from an economic standpoint.

Cervical Cancer

Primary Treatment

The standard treatment of cervical cancer has been established for very early-stage and locally advanced-stage disease. However, there is continued debate over the appropriate treatment of stage IB2 disease (103). Current options include primary surgery with radical hysterectomy and lymphadenectomy followed by tailored chemoradiation, primary chemoradiation, and primary chemoradiation followed by simple hysterectomy. The choice of therapy depends on many factors including available resources, costs, patient characteristics, and physician and patient preferences.

Two groups have developed health economic models to inform the treatment of stage IB2 cervical cancer. Rocconi et al. developed a decision model with a third-party-payer perspective to compare three strategies: (1) radical hysterectomy followed by tailored therapy; (2) primary chemoradiation; and (3) neoadjuvant chemotherapy followed by simple hysterectomy. Radical hysterectomy was the least costly strategy per survivor at $41,212; chemoradiation and neoadjuvant chemotherapy followed by simple hysterectomy cost $43,197 and $72,613 per survivor, respectively (104). The authors concluded that radical hysterectomy is the most cost-effective treatment for stage IB2 cervical cancer.

In a second analysis, Jewell et al. used a modified Markov state transition decision model from a third-party-payer perspective to compare primary chemoradiation with primary radical hysterectomy with tailored adjuvant therapy (RH?TA)

for the treatment of stage IB2 cervical cancer. Patients undergoing completed radical hysterectomy were divided into three risk groups to determine adjuvant treatment based on surgical pathologic risk features. Adverse events and their costs were included. The model predicted 5-year OS of 79.6% in the RH+TA arm and 78.9% in the chemoradiation arm. The mean cost of RH+TA was $27,840 compared with $21,403 for chemoradiation. The ICER comparing RH+TA with chemoradiation was $63,689 per additional YLS (105). While Rocconi et al. found RH+TA therapy to be the least expensive option, Jewell et al. found that RH+TA was the costlier treatment option in the base case. The difference in the outcomes of the two decision models may be related to differences in assumptions about the frequency of adjuvant radiotherapy and in cost estimates for radiotherapy. These studies demonstrate how the assumptions, inputs, and design of a model are critical to its results.

Use of Radiation Therapy in Cervical Cancer

Intracavitary radiation treatment is recognized to play a significant and important role in the standard radiotherapy treatment of cervical carcinoma. The majority of centers worldwide use either low dose rate (LDR) or high dose rate (HDR) methods. Randomized trials have confirmed the apparent equivalence of HDR and LDR in terms of the incidence of adverse effects, tumor control, and survival (106). HDR is becoming more prevalent, possibly based on its outpatient nature, the ability to treat a greater number of patients, the ability to treat tumors at different sites, and the perceived cost savings to the health care system due mainly to the outpatient nature of the treatment. However, HDR treatment costs per insertion are frequently greater than those for LDR, and increasing attention is now being paid to thorough health economic analysis by health care professionals in an attempt to reduce escalating health care costs.

Jones et al. undertook a formal analysis of LDR versus HDR brachytherapy from a Canadian hospital perspective (107). Fixed and direct costs arising from equipment purchases, equipment maintenance fees, patient care, and operating costs including the staff, hospitalization, and operating room costs of LDR and HDR insertions were incorporated into a cost model. This study demonstrated that the LDR technique is less expensive when treating up to 80 patients per year. However, the ability to treat a significantly greater number of patients and the potential to treat other sites made use of an HDR unit a more reasonable choice for high-volume centers where over 80 cervical cancer patients are treated annually.

Recurrence and Metastasis

Following the publication of the phase 3 GOG 240 trial, which demonstrated a significant, 3.7-month OS advantage to incorporation of bevacizumab into the chemotherapy treatment of advanced and recurrent cervical cancer, several authors have assessed the economic impact of bevacizumab in cervical cancer treatment. Minion et al. developed a Markov-based decision model and estimated the ICER of therapy with bevacizumab to be $295,164/QALY (108). Phippen et al. performed a similar analysis in their model, identifying an ICER of $155,000/QALY (109). Both groups identified the cost of bevacizumab as the main constraint on the cost-effectiveness of the new regimen.

Preferences for Treatment and Its Effects

Jewell et al. elicited preferences for calculation of utility scores from cervical cancer survivors and from women without cancer. The authors created descriptions of health states that included detailed information about available treatments for early-stage cervical cancer. Surgical scenarios ranged from minimally invasive radical hysterectomy with low-risk pathology requiring no additional treatment to aborted radical hysterectomy due to locally advanced disease followed by primary chemoradiation and brachytherapy. Primary chemoradiation (including teletherapy and brachytherapy) was also evaluated. Physical and emotional aspects of each treatment were outlined and, where appropriate, details about initial postoperative recovery, outpatient whole pelvic radiation, outpatient chemotherapy, and inpatient brachytherapy were described in each health state scenario. Common side effects were incorporated into each description. The TTO method

was used. Health states describing primary chemoradiation were less preferred than those describing primary surgery, regardless of whether postoperative adjuvant chemoradiation was described (Table 17.1). Even in health scenarios with similar 5-year survival, subjects ranked surgery followed by tailored adjuvant treatment as equivalent or slightly preferred over primary chemoradiation. Subjects ranked a minimally invasive approach as most preferred, suggesting that an overnight hospitalization, smaller incision sites, and faster return to activities of daily living are preferred (110). Preferences were also elicited for adverse events related to treatment; subjects ranked severe radiation-related events such as radiation proctitis and gastrointestinal fistula as the least preferred outcomes (111).

TABLE 17.1 Utility Scores Elicited from Members of the Public and Cervical Cancer Survivors for Health States Related to the Treatment of Newly Diagnosed Cervical Cancer

Rank	Treatment	Mean	95% Confidence Intervals
1	Minimally invasive radical hysterectomy No adjuvant treatment	0.94	0.89–0.99
2	Radical hysterectomy Low-risk features No adjuvant treatment	0.89	0.82–0.97
3	Radical hysterectomy Intermediate-risk features No adjuvant treatment	0.89	0.82–0.96
4	Radical hysterectomy Intermediate-risk features Adjuvant chemoradiation	0.80	0.72–0.89
5	Radical hysterectomy High-risk features Adjuvant chemoradiation High dose rate brachytherapy	0.78	0.69–0.87
6	Primary chemoradiation	0.76	0.66–0.85
7	Aborted radical hysterectomy due to extent of disease Primary chemoradiation	0.68	0.57–0.79

Endometrial Cancer

Endometrial cancer is a disease in which outcomes research can be challenging; despite the high incidence of disease, the event rate (recurrence or death) is low. As such, randomized clinical trials for low- or intermediate-risk disease require a large number of subjects and long-term follow-up to demonstrate significance. CER approaches, therefore, may be quite relevant in endometrial cancer. CER in endometrial cancer spans aspects of surgical management, the use of adjuvant radiation and chemotherapy, surveillance for disease recurrence, and the evaluation and management of individuals at risk for or diagnosed with Lynch syndrome–associated cancers.

Preoperative Testing

The use of preoperative imaging in patients with clinical stage I endometrial cancer has, in certain circumstances, been demonstrated to identify disease that might not be amenable to resection. While certain authors supported the strategy of preoperative computed tomography (CT) in patients planned to undergo surgery for endometrial cancer, others questioned the effectiveness and cost of this intervention. Bansal et al. performed a study evaluating patients with endometrial cancer who underwent a preoperative CT of the abdomen and pelvis (112). In 7/250 (3%) of patients, the CT results led to an alteration of the surgical plan. In patients with high-risk histology (serous, clear cell, and sarcoma), the plan was changed in up to 13% of cases. When the cost of imaging was incorporated into their model, the authors estimated that more than

$17,000 was expended to alter the management of one patient. As such, the authors argued that routine preoperative CT in patients with clinical stage I endometrial cancer was not cost-effective.

Laparotomy versus Minimally Invasive Surgery

Over the last few decades, minimally invasive surgery has been incorporated into the management of many malignancies, including endometrial cancer. Randomized trials of laparotomy versus laparoscopy were reported from the Netherlands (113), Australia (114), and the United States (115), all demonstrating similar oncologic outcomes between groups. These trials demonstrated that laparoscopy was associated with a modest improvement in quality of life compared with laparotomy (116,117). Investigators from the Netherlands evaluated the cost of treatment relative to survival and quality of life of subjects undergoing laparotomy or laparoscopic staging of their endometrial cancer (118). Despite a slightly increased cost for minimally invasive surgery (higher operative costs but lower hospital stay costs), total laparoscopic hysterectomy remained cost-effective because of the low rate of complications seen in the minimally invasive arm compared with laparotomy. This group also performed a meta-analysis of 12 trials of laparoscopic endometrial cancer surgery and reached the conclusion that laparoscopy was cost-effective compared with laparotomy (25).

Laparoscopy versus Robot-Assisted Laparoscopy

In 2006, the FDA cleared the first computer-aided (robotic) surgical system for hysterectomy. There has subsequently been a rapid incorporation of robotic surgery into gynecologic cancer practices, mainly for the treatment of endometrial cancer. Initial reports of this surgical approach demonstrated feasibility and acceptable toxicity. However, the initial purchase price of the robot (greater than $1 million), yearly maintenance contract (greater than $100,000 annually), and limited use of disposable instruments add a fixed cost to this procedure over laparoscopy or laparotomy. Given the expense of robotic surgery, analyses of the cost of robotic surgery have been published, often with differing conclusions. Initially, Bell et al. described a series of patients who underwent abdominal, laparoscopic, or robotic staging for endometrial cancer, with the robotic approach being found less costly compared with laparotomy, but not significantly more expensive than laparoscopy (119). Subsequent to this report, other approaches have been utilized to assess the cost-effectiveness and comparative effectiveness of robotic surgery compared with other surgical approaches. Barnett et al. utilized decision modeling from the perspectives of both society and the hospital (with and without the cost of the purchase of the robot incorporated) to assess the impact of surgical approach (laparotomy, laparoscopy, and robotic) for staging of endometrial cancer (23). These authors concluded that while laparoscopy is the least expensive approach, the decreased societal cost associated with an early return to normal function makes robotic surgery less expensive than laparotomy. In sensitivity analysis, when the costs of disposable instruments and equipment are minimized to less than one half their current cost, robotic surgery becomes the least costly approach. The modeling approach with sensitivity analyses is critically important in helping to understand which factors drive cost in endometrial cancer surgery and to acknowledge that the perspective from which the analysis is taken significantly impacts the conclusions that can be drawn. Additionally, a population-based CER analysis was undertaken by Wright et al. describing more than 2,400 women who underwent minimally invasive surgery for endometrial cancer, 58% robotically and 42% laparoscopically (120). These authors found similar rates of complications but an increased cost with robotic surgery and concluded that longer-term outcome data regarding robotic surgery are necessary before this approach should be considered standard for the management of endometrial cancer. Collectively, the data regarding robotic endometrial cancer surgery suggest an increased cost, decreased morbidity compared with laparotomy, and cost-effectiveness that varies based on the perspective from which the data are interpreted.

Lymphadenectomy for Surgical Staging

Following two randomized trials suggesting that lymphadenectomy for unselected endometrial cancer does not improve survival outcomes (121,122), the role of this procedure in the routine management of endometrial cancer has undergone increased scrutiny. Various strategies have been proposed to identify patients who are at highest risk for metastasis to the lymph nodes, generally incorporating tumor grade, depth of myometrial invasion, histology, and tumor size. Kwon et al. found that as tumor grade increases, lymphadenectomy is more cost-effective than its omission, mainly due to the reduced rate of radiation in node-negative patients (123). Modeling of grade 3 endometrial cancer by Havrilesky et al. demonstrated that lymph node dissection had an ICER of $40,183/QALY compared with no lymph node dissection (124). Cohn et al. modeled grade 1 cancers and found that even in this group of patients at low risk for lymph node metastasis, routine lymphadenectomy was cost-effective compared with a strategy of selective lymphadenectomy, based on the assumption of a lower rate of adjuvant radiation in the surgically staged patients (125). Conversely, Lee et al. demonstrated that when preoperative prediction models classified patients as low risk, selective lymphadenectomy was less costly and more effective than routine lymphadenectomy (126). Havrilesky et al. modeled a hypothetical test that could reliably predict lymph node metastasis, finding that such a test could be cost-effective as long as it was fairly inexpensive (127). Collectively, the cost-effectiveness data suggest that strategies to select a high-risk group for lymphadenectomy are more likely to be cost-effective. Sentinel lymph node mapping is a technique recently incorporated into endometrial cancer staging that reduces the number of lymph nodes removed while retaining sensitivity to identify metastatic disease (128). The cost-effectiveness of sentinel lymph node mapping compared with full lymph node dissection for endometrial cancer has not yet been formally reported.

Surveillance for Endometrial Cancer Recurrence

Given that the OS of women with endometrial cancer is approximately 85%, investigators have challenged the notion that routine intermittent surveillance for pelvic examination and vaginal cytology (with or without chest imaging) is cost-effective or even necessary for most women with endometrial cancer. In support of the trend toward decreased intensity of surveillance, it has been estimated that the cost of routine vaginal cytology to identify a single asymptomatic recurrence is more than $44,000 (129). Whether the identification of these asymptomatic individuals leads to improved outcomes is even less certain (130).

Lynch Syndrome

It is estimated that 2.3% of patients with endometrial cancer have Lynch syndrome as the cause of their disease (131). Given the relatively low prevalence of the disease, the ability to distinguish these patients from all those with sporadic disease would be enormously beneficial, as the probands and their families could be introduced to prevention and screening interventions that might decrease the risk of dying from Lynch-related malignancies. However, the clinical Amsterdam criteria are relatively insensitive and nonspecific in identifying Lynch syndrome. Thus, many institutions have begun utilizing immunohistochemistry (IHC) for the DNA mismatch repair genes as an initial screen for Lynch syndrome. Health economic studies of this strategy have demonstrated that utilizing IHC in patients with a first-degree relative with a Lynch-associated cancer is cost-effective (132). Other investigators have shown that the routine use of IHC with genetic testing for patients, with a triage to genetic testing based on a proband's age <60 years, is more cost-effective than other screening strategies (133). Additionally, the cost-effectiveness of strategies to prevent the disease in probands with known Lynch syndrome has been evaluated. Kwon et al. demonstrated that in this population, annual surveillance with endometrial biopsy, pelvic ultrasound, and CA125 at 30 years plus risk-reducing hysterectomy and oophorectomy at 40 years is the most effective strategy, though substantially more expensive than preventative surgery alone or screening alone, with an additional $194,000 spent per increase in year of survival compared with the next best strategy (134). The cost-effectiveness of risk-reducing surgery has also been confirmed by Yang et al., who demonstrated that this intervention is more cost-effective than either yearly examination or yearly invasive screening for malignancy (135).

CHAPTER SUMMARY

Gynecologic oncology provides a rich opportunity to investigate the cost-effectiveness and value of various diagnostic, therapeutic, screening, and preventative strategies. While the field is still relatively young, substantial knowledge about these strategies has been gained through CER techniques and modeling. Continued investigation with refinement of tools for the investigation of value-based gynecologic cancer care is needed to advance the state of knowledge.

KEY POINTS

1. There is increasing pressure on health systems and providers in the United States to demonstrate "value," as defined by high-quality and cost-effective care.
2. CER provides the framework for studies that compare the potential harms and benefits of strategies to prevent, diagnose, or treat gynecologic malignancy.
3. Health economic studies, including CEA and CUA, compare medical interventions on the basis of their relative costs as well as their potential harms and benefits.
4. A key factor in the development of a cost-utility model is the incorporation of quality of life, which requires a preference-based utility. The utility may be derived using a variety of quality of life–related instruments. Use of the utility allows the results of a model to be expressed in QALYs, which are a standard effectiveness outcome.
5. The results of health economic decision models are highly dependent on their perspective and the assumptions made in their construction.
6. Uncertainty in health economic models is best described using multiple sensitivity analyses.
7. There is a growing body of evidence to guide clinical and resource allocation decisions in gynecologic oncology.

SECTION III
Disease Sites

CHAPTER 18 Vulva

Emily Penick, Sushil Beriwal, Edward J. Wilkinson and John W. Moroney*

INTRODUCTION

Malignant tumors of the vulva are rare and account for less than 5% of all cancers of the female genital tract. In 2015, there were an estimated 5,150 new cases of and 1,080 deaths from invasive vulvar carcinoma in the United States (1). Because of its low incidence, most primary care providers will never encounter a patient with vulvar cancer. Although a rare patient with vulvar cancer will present without symptoms, most women with vulvar cancer initially present with complaints such as vulvar irritation, pruritus, pain, or a mass that does not resolve. The interval between the onset of symptoms and the diagnosis of cancer can be protracted if a woman who is embarrassed by new vulvar symptoms delays seeking care, or if a physician prescribes empiric topical therapies without a proper physical examination or tissue biopsy confirmation. Jones and Joura (2) evaluated the clinical events preceding the diagnosis of squamous cell carcinoma of the vulva and found that 88% of patients had experienced symptoms for more than 6 months, 31% of women had three or more medical consultations before the diagnosis of vulvar carcinoma, and 27% had applied topical estrogen or corticosteroids to the vulva.

The vulva is covered by keratinized squamous epithelium; accordingly, most malignant vulvar tumors are squamous cell carcinomas (SCCs). Consequently, our current understanding of the epidemiology, spread patterns, prognostic factors, and survival data for vulvar cancer is largely derived from experience with SCCs. Malignant melanoma is the second most common cancer of the vulva. Although there is some consensus regarding the behavior and treatment of vulvar melanoma, its rarity has thus far precluded robust, prospective clinical trials. A number of other malignant tumors, both epithelial and stromal in origin, arise from normal vulvar tissue and are discussed in detail later in this chapter. Finally, the vulva may be secondarily involved with malignant disease originating in the cervix, bladder, anorectum, colon, breast, or other organs.

The traditional therapeutic approach to vulvar cancer has been radical surgical excision of the primary tumor and inguinofemoral lymphadenectomy. Experience has shown that survival is improved with the administration of postoperative radiation therapy (RT) to selected patients deemed to be at high risk for locoregional failure. More recently, the use of neoadjuvant radiotherapy (RT) with concomitant radiosensitizing chemotherapy (CT) has proven to be effective in treating vulvar cancer patients for whom radical surgery would be either too morbid or technically not feasible. New surgical techniques, including sentinel lymph node (SLN) biopsy, hold the promise of better outcomes for patients with early disease. An individualized approach to vulvar cancer management, often employing multiple modalities in an effort to achieve disease control with better cosmetic results and sexual function, is now the norm. This chapter deals with these and other topics pertinent to the principles of management of women with vulvar cancer.

ANATOMY

The vulva consists of the external genital organs—including the mons pubis, labia minora and majora, clitoris, vaginal vestibule, and perineal body—and their supporting subcutaneous tissues. The vulva is bordered superiorly by the anterior abdominal wall, laterally by the labiocrural fold at the medial thigh, and inferiorly by the anus. The vagina and urethra open onto the vulva. The mons pubis is a prominent mound of hair-bearing skin and subcutaneous adipose and connective tissue that is located anterior to the pubic symphysis. The labia majora are two elongated skin folds that course posterior from the mons pubis and blend into the perineal body. The labia minora are a smaller pair of skin folds medial and parallel to the labia majora that extend inferiorly to form the margin of the vaginal vestibule. Superiorly, the labia minora separate into two components that course above and below the clitoris, fusing with those of the opposite side to form the prepuce and frenulum, respectively. The skin of the labia minora contains sebaceous glands near its junction with the labia majora, but it is not hair-bearing and it has little or no underlying adipose tissue. The clitoris is supported externally by the fusion of the labia minora (prepuce and frenulum) and is approximately 2 to 3 cm anterior to the urethral meatus. It is composed of erectile tissue organized into the glans, body, and two crura. Two loosely fused corpora cavernosa form the body of the clitoris and extend superiorly from the glans, ultimately dividing into the two crura. The crura course laterally beneath the ischiocavernosus muscles and attach to the ischial rami.

The vaginal vestibule is situated in the center of the vulva and is homologous to the male distal urethra. It has squamous mucosal epithelium that is demarcated bilaterally and posteriorly by the junction with the keratinized epithelium at Hart's line, located on the medial labia minora and inferiorly on the perineal body. The vagina, urethra, periurethral glands, minor vestibular glands, and the Bartholin's glands open onto the vestibule. Anteriorly, the minor small vestibular glands are located beneath the vestibular mucosa and open onto its surface, predominantly on the more anterior vestibule. The vestibular bulbs, a loose collection of bilateral erectile tissue covered superficially by the bulbocavernosus muscle, are located laterally. The Bartholin glands, two small, mucus-secreting glands situated within the subcutaneous tissue of the posterior labia majora, have ducts opening onto the posterolateral portion of the vestibule. The perineal body is a 3 to 4 cm band of skin and subcutaneous tissue located between the posterior extensions of the labia majora. It separates the vaginal vestibule from the anus and forms the posterior margin of the vulva.

Vascular Anatomy and Neurologic Innervation

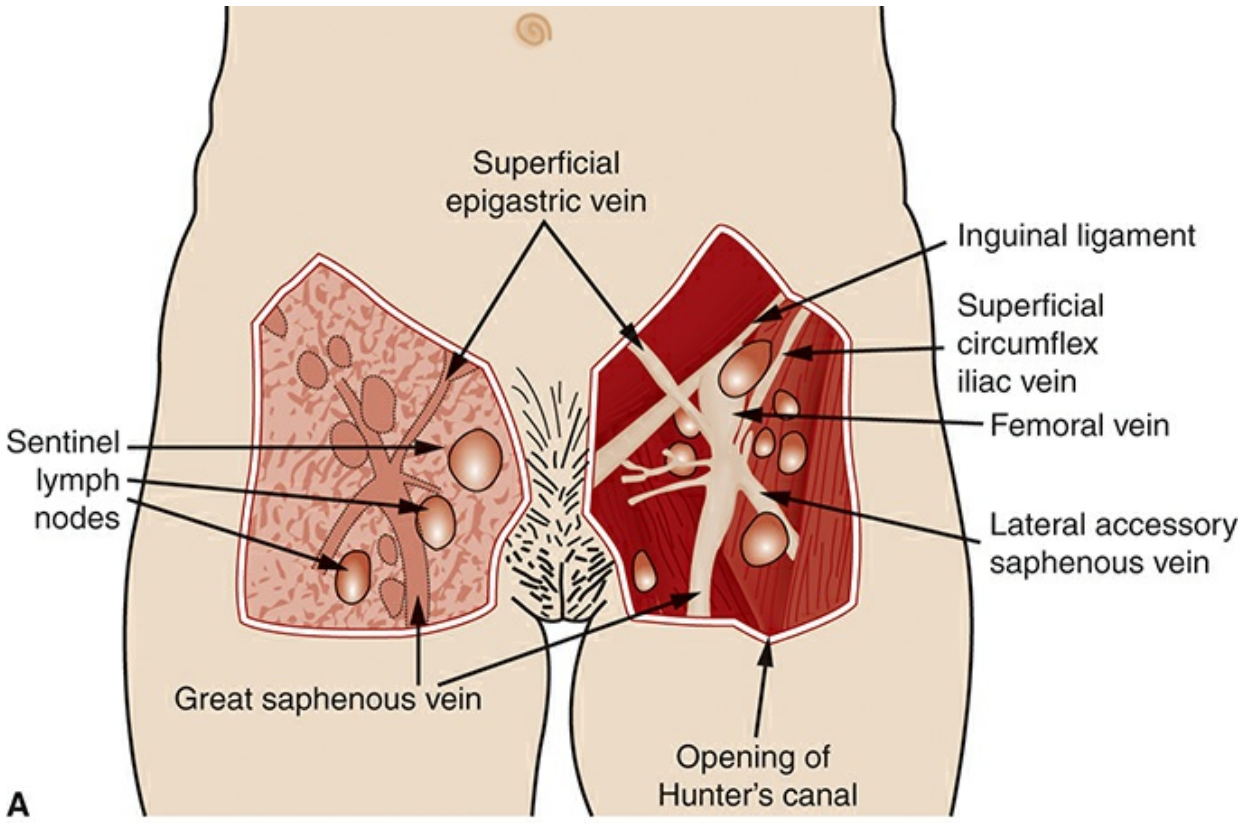
The vulva has a rich blood supply derived primarily from the internal pudendal artery, which arises from the anterior division of the internal iliac (hypogastric) artery, and the superficial and deep external pudendal arteries, which arise from the femoral artery. The internal pudendal artery exits the pelvis and passes behind the ischial spine to reach the posterolateral vulva, where it divides into several small branches to the ischiocavernosus and bulbocavernosus muscles, the perineal artery, artery of the bulb, urethral artery, and dorsal and deep arteries of the clitoris. Both external pudendal arteries travel medially to supply the labia majora and their deep structures. These vessels anastomose freely with branches from the internal pudendal artery. Innervation of the vulva is derived from multiple sources and spinal cord levels. The mons pubis and upper labia majora are innervated by the ilioinguinal nerve (L1) and the genital branch of the genitofemoral nerve (L1–2). Either of these nerves may be easily injured during pelvic lymph node dissection, with resulting paresthesias. The pudendal nerve (S2–4) enters the vulva parallel to the internal pudendal artery and gives rise to several branches that innervate the lower vagina, labia, clitoris, perineal body, and their supporting structures.

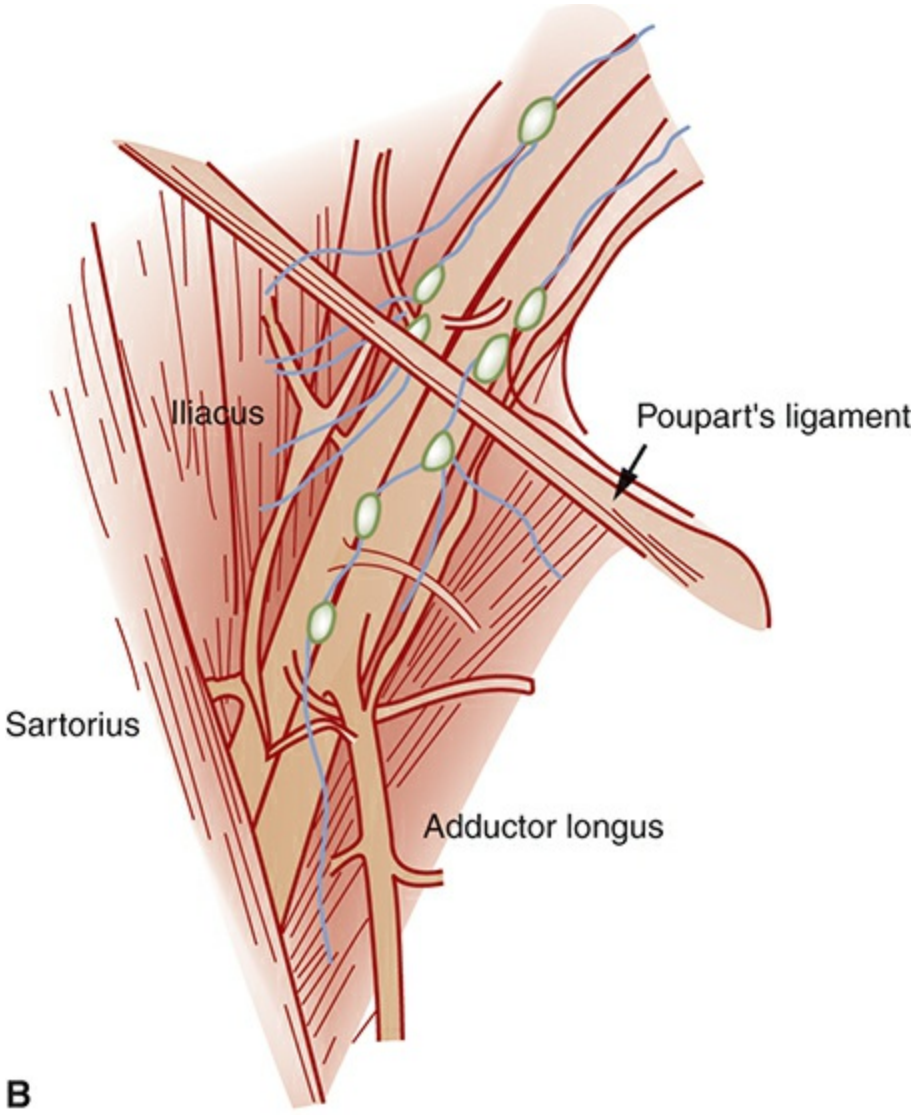
Groin Anatomy and Lymphatic Drainage

Vulvar lymphatics run anteriorly through the labia majora, turn laterally at the mons pubis, and drain primarily into the superficial inguinal LNs. Dye studies by Parry-Jones demonstrated that vulvar lymphatic channels do not extend laterally to the labiocrural folds and do not cross the midline, unless the site of dye injection is at the clitoris or perineal body (3).

The vulvar lymphatics drain to the superficial inguinal LNs located within the femoral triangle formed by the inguinal ligament superiorly, the border of the sartorius muscle laterally, and the border of the adductor longus muscle medially.

There are 8 to 10 inguinal LNs lying along the saphenous vein and its branches between Camper's fascia and fascia overlying the femoral vessels (Fig. 18.1A–C) (3). The first draining LN is the SLN and can be identified using various lymphatic mapping techniques. The SLN is frequently found medial to the femoral vein just above the adductor muscle. Second echelon LNs may be in the groin or pelvis. The Cloquet's node, or the most superior inguinal LN, is located under the inguinal ligament. Lymphatic drainage from the SLN is sequential to the external iliac, common iliac, and aortic LNs (Fig. 18.1A–C).





Iliacus
Poupart's ligament
Sartorius
Adductor longus
B

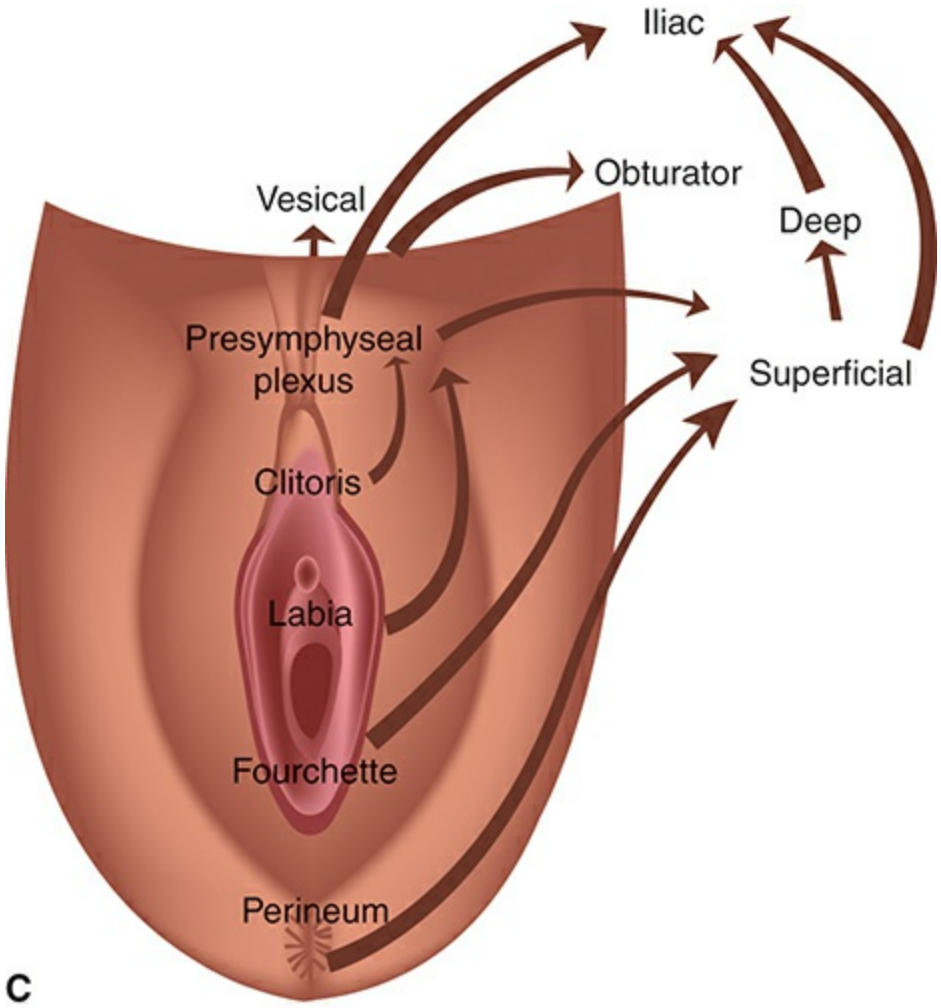


Figure 18.1 These historic figures illustrate some of the problems depicting the lymphatic anatomy of the groin accurately. A, B: Vessels, muscles, and nerves. A: Sentinel nodes; however, this is based on location rather than a mapping procedure, which is misleading. B: Nodes between the femoral artery and the vein. Lymph nodes between the vessels are common in the pelvis but not in the groin. C: Direct drainage from the clitoral area of the vulva to pelvic lymph nodes. This drainage pattern is not observed with preoperative or intraoperative lymphatic mapping studies.

The fossa ovalis is a crescent-shaped terminus of the fascia lata and the site where vascular and lymphatic structures meet with the femoral vessels. The cribriform fascia is a term widely used in the literature describing the anatomy of the groin and is said to cover the fossa ovalis. The cribriform fascia is hard to identify and is more of a “lamina” than an actual fascia. SLN biopsy with lymphatic mapping deemphasizes the need to identify the cribriform structure and focuses the surgeon’s attention on functional *in vivo* surgical anatomy rather than textbook descriptions of LN locations (3).

EPIDEMIOLOGY

An estimated 5,150 women were diagnosed with vulvar cancer in the United States in 2015, and approximately 1,050 died of the disease. Vulvar SCC accounts for approximately 3% to 5% of all gynecologic malignancies and 1% of all carcinomas in women, with an incidence rate of 1 to 2 per 100,000 women (1). Most vulvar cancers occur in postmenopausal women in the seventh decade, although more recent reports have identified a trend toward younger age at diagnosis (4,5). Earlier observational studies suggested associations between hypertension, diabetes mellitus, and obesity

and vulvar carcinoma; however, subsequent analyses have not confirmed the prognostic significance of these diagnoses (5).

NATURAL HISTORY (PATTERNS OF SPREAD)

Several infectious agents have been proposed as possible etiologic agents in vulvar carcinoma, including granulomatous infections, herpes simplex virus, and, most notably, human papillomavirus (HPV). HPV infection is present in virtually 100% of women with cervical cancer. The relationship between HPV infection and vulvar cancer is much less straightforward. This is likely due to the different etiologic pathways that are believed to be responsible for vulvar cancer. These different etiologic pathways are discussed in detail in the chapter on preinvasive disease; however, because of subject matter overlap, some of the data related to HPV and invasive squamous cell carcinoma of the vulva are discussed here.

Vulvar condyloma acuminata have a well-described relationship with HPV as the causal agent, most commonly HPV-6 or -11, and strong associations between vulvar condylomas and the later development of vulvar cancer have been identified (6). The role of HPV in the development of premalignant and malignant lesions of the vulva has become clearer as molecular techniques for HPV detection and mutational analyses have improved. Earlier studies identified HPV DNA in both invasive and carcinoma *in situ* lesions via immunohistochemistry. More recent studies have used DNA detection methods such as polymerase chain reaction and *in situ* hybridization to detect high-risk serotypes (7). Among HPV serotypes, HPV-16 is the most common; however, many other serotypes, including -18, -33, and -52, have been reported. HPV DNA can be identified in approximately 85% to 97% of intraepithelial lesions (HSIL/VIN 2–3), but is seen in 10% to 69% of invasive lesions (8). Such a wide range of associated HPV is seen in association with HSIL/vulvar intraepithelial neoplasia (VIN) and invasive vulvar carcinoma primarily because of differences in detection methods, with newer molecular methods having greater sensitivity and specificity. There are also differences between studies regarding the distribution of HSIL/VIN subtypes (usual or differentiated) and histologic types of carcinomas. This work continues in clinical investigations. In a recent clinical trial of 12,021 women using a 9-valent HPV vaccine, the number of HPV-related external genital biopsies was reduced by 92.3% for follow-up to 54 months (9).

Although HPV DNA is associated with most intraepithelial lesions (85% to 97%), it is much less commonly seen in association with invasive lesions (~27% to 50%) (8,10). Marked differences between HPV positivity in VIN and vulvar cancers are also seen with respect to age. Basta et al. (11) conducted a retrospective case control study examining the coexistence of HPV and the incidence of both VIN and stage I vulvar cancer. HPV infection was present in 61.5% of cases of VIN and vulvar cancer in women aged 45 years or less, and in 17.5% of women older than 45 years.

In 2004, the International Society for the Study of Vulvovaginal Disease (ISSVD) proposed a modified terminology for VIN as two distinct processes: the “usual type (uVIN) encompasses high-grade lesions (VIN 2 and 3) and are caused by HPV (12). The differentiated type of VIN (dVIN) is not caused by HPV. VIN1 lesions are considered to be condyloma and should be managed accordingly as discussed by the 2011 American College of Obstetrician Gynecologists (ACOG)–American Society for Colposcopy and Cervical Pathology (ASCCP) (13). The most common VIN type occurs more frequently in younger women, tends to be multifocal, and has association with HPV serotypes 16, 33, and 18. In contrast, dVIN is less common (2% to 10% of all VIN), generally not related to HPV, and is shown to be unifocal and associated with other vulvar dermatoses such as lichen sclerosus and lichen planus (10,14).

The incidence of HPV-associated VIN has been increasing over the past 20 years, particularly in women of reproductive age, with the highest frequency reported in women aged 20 to 35 (15). The development of condyloma acuminatum/genital warts is attributed to infection with HPV-6 or -11, with the median time between infection and development of lesions at 5 to 6 months. In patients with a history of cervical or vaginal cancer, the vulva should be examined as part of a surveillance exam. In those patients with a history of VIN or lichen sclerosus, self-examination with a mirror should be taught (16).

Chronic immunosuppression and tobacco smoking have also been linked as cofactors for the development of invasive vulvar cancer. Vulvar cancer incidence is increased in female renal transplant patients, as well as women with HIV and AIDS (17,18). Smoking is an independent risk factor for the development of SCC of the vulva, although the reason for this is unclear. One hypothesis is that genetic variations in T-cell-mediated IL-2 responses among smokers may explain differential susceptibility to the development of squamous vulvar carcinomas (19).

Chronic vulvar inflammatory lesions, such as vulvar dermatoses, including lichen sclerosus (LS), lichen planus, lichen simplex chronicus (including squamous cell hyperplasia), and vulvar intraepithelial neoplasia (HSIL/VIN 2–3 (usual as well as differentiated types), particularly dVIN, have been suggested as precursors of invasive squamous cancers (15). Carli et al. (16) suggested a possible role of LS as a precursor to vulvar cancer, based on their observation that 32% of vulvar cancer cases not related to HPV were associated with LS. More recently, in a pathologic reevaluation of patients with a diagnosis of LS who were followed clinically for a minimum of 10 years, van de Nieuwenhof and colleagues identified concordant diagnoses of LS in 58/61 patients who did not progress to cancer, and concordant diagnoses of LS in only 29/60 patients who were identified with a subsequent diagnosis of vulvar cancer. Most patients reclassified as having something other than LS were considered to have dVIN (25/31 patients). This study highlights dVIN as a uniquely at-risk histology that deserves prompt treatment and close follow-up. Differentiated VIN is often found in lesions, previously diagnosed as LS, that have progressed to vulvar SCC (15). In a more recent long-term follow-up study of women with LS, those identified with LS had a progressively increased frequency of vulvar SCC with increasing duration of the disease. In this study, most squamous carcinomas were superficially invasive. At 24 months of follow-up, 1.2% had carcinoma, whereas at 300 months, 36.8% had carcinoma (20). Despite this association, however, LS is not considered a true premalignant condition like HSIL/VIN 2–3. Standard clinical management of LS, including chronic, as-needed topical steroid use, periodic surveillance examinations, and selective biopsies of discrete lesions, has been reported to reduce the risk of vulvar carcinoma (21).

Vulvar lichen planus (LP), like LS, is also recognized as being associated with an increased risk of a subsequent diagnosis of vulvar SCC. In a long-term Finnish study (follow-up >43 years) evaluating more than 12,144 women with LS and 9,030 women with LP, both diagnoses were associated with an increased risk of vulvar carcinoma. Among women with LS, many of those who subsequently presented with vulvar carcinoma presented within 5 years of the beginning of the study, with 993 (8%) women subsequently having carcinoma. Among women with LP, 919 (10%) subsequently developed carcinoma (22).

In a study of 405 patients noted to have VIN 2–3, Jones et al. (23) found that 3.8% of patients had developed invasive cancer despite therapy, and 10 untreated patients developed invasive cancer between 1.1 and 7.3 years (mean, 3.9 years) from the time of initial observation. In a recent retrospective study of 240 women with vulvar squamous lesions, 213 with HSIL/VIN 2–3 were treated with surgical excision. Among these patients, 21 (9.8%) were found to have an associated invasive squamous carcinoma within the surgical specimen. Most tumors were superficial, varying in size from 0.1 to 2 cm. On follow-up, 25% of the patients with positive margins had local recurrence of HSIL, whereas 16.6% of those with negative surgical margins were identified with a recurrence (22). Although some intraepithelial lesions regress spontaneously, it appears that a significant number persist or progress to invasive cancer.

Differentiated VIN is recognized as a precursor of vulvar SCC and is associated with LS in many cases. In a retrospective study involving 240 patients with vulvar squamous lesions, 27 were found to be dVIN, and 19 of these cases (70.4%) had associated SCC (22). In a retrospective study of 18 dVIN cases, 14 were found to have associated SCC, and of these, 12 had associated vulvar LS (24). Trimble et al. (25) postulated that SCC of the vulva may represent a final common endpoint of heterogeneous etiologic pathways. According to their studies, two histologic subtypes, those with basaloid or warty features, are associated with HPV, whereas keratinizing squamous carcinomas are not. Furthermore, basaloid or warty carcinomas are associated with classic risk factors for cervical carcinoma, including age at first intercourse, lifetime number of sexual partners, prior abnormal Pap smears, smoking, and lower socioeconomic status. Keratinizing squamous carcinomas are weakly linked to these factors, and in some cases not at all.

Mitchell et al. evaluated 169 women with invasive vulvar cancers and noted that second genital squamous neoplasms

occurred in 13% of cases. The risk of a second primary tumor was significantly increased in cancer cases with HPV DNA, intraepithelioid growth pattern, or adjacent dysplasia (26). These observations support the concept that some squamous lesions may be initiated by neoplastic etiologies that produce change within the entire field of the lower genital tract (field effect). The obvious clinical implication of this observation is that a patient with an established squamous lesion of the vulva, vagina, or cervix needs to be evaluated and monitored for new or coexistent lesions at other genital sites.

Vulvar cancers metastasize in three ways: (a) local growth and extension into adjacent organs, (b) lymphatic embolization to regional lymph nodes in the groin, and (c) hematogenous dissemination to distant sites. Inguinal node metastasis can be predicted by the presence of multiple risk factors, including tumor diameter, higher histologic grade, depth of stromal invasion, and lymph-vascular space invasion (27). Clinically important observations regarding nodal metastases include the following: (a) Inguinal nodes are the most frequent site of lymphatic metastasis; (b) In-transit metastases within vulvar epithelium and deep tissues are exceedingly rare, suggesting that most initial lymphatic metastases represent embolic phenomena; (c) Metastasis to the contralateral groin or deep pelvic nodes are unusual in the absence of ipsilateral groin metastases; (d) Nodal involvement generally proceeds in a stepwise fashion from the superficial inguinal to the deep inguinal and then to the pelvic nodes (27).

Spread beyond the inguinal lymph nodes is considered distant metastasis (stage IVB). The occurrence of such metastases are due to either sequential lymphatic spread to secondary and tertiary nodal groups or as a result of hematogenous dissemination to more distant sites, such as bone, lung, or liver. Distant metastases are uncommon at initial presentation and are usually seen in the setting of recurrent disease.

CLINICAL PRESENTATION

Most women with vulvar cancer present with pruritus or vulvar discomfort and a recognizable, exophytic or endophytic ulcerated lesion. Selecting the most appropriate site for biopsy in women with condyloma, chronic vulvar LS, multifocal high-grade squamous intraepithelial lesions (VIN 3), or Paget's disease can be difficult, and multiple biopsies may be required. Optimal management for any patient presenting with a suspicious lesion is to proceed directly to biopsy under local analgesia. Tissue biopsies should include the cutaneous lesion in question and representative contiguous underlying stroma, so that the presence and depth of invasion (DOI) can be accurately assessed. Because DOI is a central issue in the management of vulvar cancer, punch biopsies are encouraged and shave biopsies are generally discouraged in the diagnosis of vulvar lesions. If invasion is suspected and a punch biopsy fails to confirm the clinical suspicion, then an incisional or excisional biopsy should be performed. Primary care physicians should be encouraged not to excise an entire lesion if avoidable, in order to facilitate a subsequent sentinel node procedure by a gynecologic oncologist. Figure 18.2 illustrates an early-stage vulvar cancer.

Figure 18.2 Early-stage vulvar cancer.

DIAGNOSTIC EVALUATION

The evaluation of a patient with vulvar cancer must consider the clinical extent of disease and the presence of coexisting medical illnesses. Initial evaluation should include a detailed physical examination with measurements of the primary tumor, assessment for extension to adjacent mucosal or bony structures, and clinical evaluation of the inguinal LNs. It is helpful to record the distance from vital structures such as the clitoris, urethral meatus, and anus, since these structures limit the ability to obtain adequate surgical margins. Diagnostic imaging is not required in women with small primary lesions and normal body habitus. In obese women, the inguinal nodes are difficult to palpate, and imaging may help identify the presence of lymphadenopathy. Patients with large or fixed tumors, and those who are difficult to examine in the clinic, may benefit from an exam under anesthesia with cystourethroscopy and proctosigmoidoscopy. Figure 18.3 illustrates an advanced tumor, for which such an approach can help determine resectability.

Radiographic studies that have been described as beneficial are computed tomography (CT), magnetic resonance imaging (MRI), positron emission tomography (PET), ultrasound, and single photon emission CT. While newer imaging modalities can benefit treatment planning, it is also important to note that published series are small, and no individual modality has been shown to be superior to others in terms of detecting metastatic or recurrent disease (28–31). The best modality might differ depending on the practice situation and skills of the diagnostic imaging consultants. Suspicious lymph nodes should be biopsied if the findings would alter the surgical plan. Because neoplasia of the female genital tract is often multifocal, evaluation of the vagina and cervix, including cervical cytologic screening, should always be performed in women with vulvar neoplasms (32). Lymphoscintigraphy (LSG) is discussed later in this chapter.

Figure 18.3 Advanced vulvar cancer.

STAGING

The International Federation of Gynecology and Obstetrics (FIGO) adopted a modified surgical staging system for vulvar cancer in 1989, which was revised in 1995 and more recently in 2009 (Table 18.1). The 2009 revision was performed to address issues such as the lack of a useful prognostic spread among stages, and significant prognostic heterogeneity

among stage III patients. After the 1995 revision, much has been learned about the significance of the number of involved nodes, the size of inguinal metastases, and nodal morphology (33,34).

TABLE 18.1 Integrated 2009 FIGO and AJCC Staging System for Squamous Cell Carcinoma of the Vulva

FIGO		AJCC		
		T	N	M
		Tis: No invasion past basement membrane (not in FIGO system)		
I: Tumor confined to the vulva				
1A	Lesions ≤2 cm in size, confined to vulva or perineum and with stromal invasion ≤1 mm, no nodal metastasis	T1a	N0	M0
1B	Lesions >2 cm in size or with stromal invasion >1 mm, confined to the vulva or perineum, with negative nodes	T1b	N0	M0
II	Tumor of any size with extension to adjacent perineal structures (1/3 lower urethra, 1/3 lower vagina, anus), with negative nodes	T2	N0	M0
III	Tumor of any size with or without extension to adjacent perineal structures (1/3 lower urethra, 1/3 lower vagina, anus), with positive inguinofemoral lymph nodes	T1 or T2	N1 – N3	M0
IIIA	(i) 1 – 2 lymph node metastasis(es) (<5 mm), or (ii) 1 lymph node metastasis (≥5 mm)	T1 or T2	N1a = (i) N1b = (ii)	M0
IIIB	(i) 3 or more lymph node metastases (<5 mm) or (ii) 2 or more lymph node metastases (≥5 mm)	T1 or T2	N2a = (i) N2b = (ii)	M0
IIIC	Positive nodes with extracapsular spread	T1 or T2	N2c N3 = inguinal skin ulceration or fixed nodes	M0
IV	Tumor invades other regional (2/3 upper urethra, 2/3 upper vagina), or distant structures	T3 = any size, involves upper urethra, bladder, rectum, bone		
IVA	Tumor invades (i) upper urethral and/or vaginal mucosa, bladder mucosa, rectal mucosa, or fixed to pelvic bone, or (ii) fixed or ulcerated inguinofemoral lymph nodes	T3		M0
IVB	Distant metastasis: includes pelvic nodes	T1, T2, or T3		M1

AJCC stage groupings	
Stage	T, N, M combination
0	Tis, N0, M0

IA	T1a, N0, M0
IB	T1b, N0, M0
II	T2, N0, M0
IIIA	T1 or T2, N1a or N1b, M0
IIIB	T1 or T2, N2a or N2b, M0
IIIC	T1 or T2, N2c, M0
IVA	Either T1 or T2, N3, M0 or T2, any N, M0
IVB	any T, any N, M1

The technique recommended by the ISSVD, the International Society of Gynecologic Pathologists (ISGYP), the College of American Pathologists (CAP), and the World Health Organization (WHO) to assess depth of stromal invasion is to measure from the base of the epithelium (epithelial–stromal junction) at the nearest superficial dermal papillae to the deepest point of tumor penetration. These definitions and methods of measurement are supported by the recent CAP-ASCCP Lower Anogenital Squamous Terminology (LAST) project (Fig. 18.4) (35).

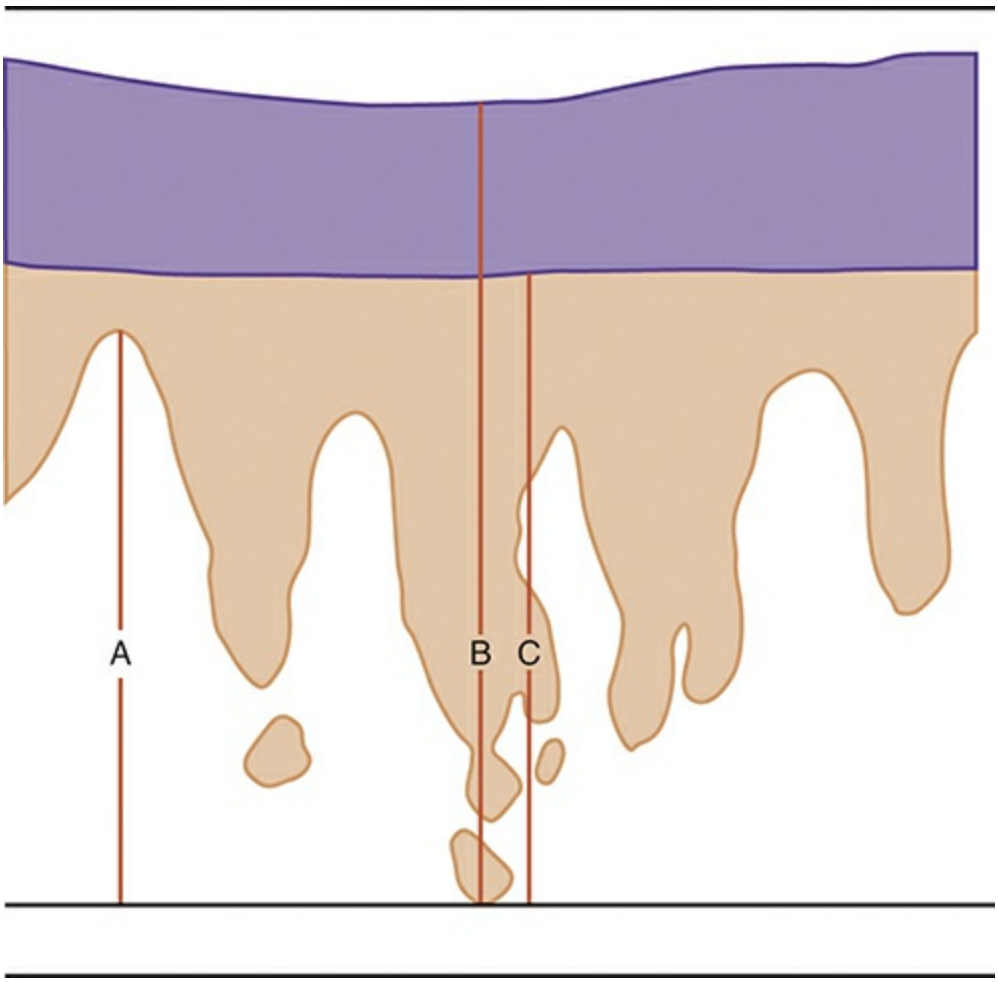

Figure 18.4 Methods for measurement of vulvar superficially invasive carcinomas. Depth of invasion. A: The measurement from the epithelial stromal junction of the most superficial dermal papillae to the deepest point of invasion. This measurement is defined as the depth of invasion and is used to define stage IA vulvar carcinoma. B: The measurement is the thickness of the tumor from the surface of the lesion to the deepest point of invasion. C: Measurement is from the bottom of the granular layer to

the deepest point of invasion. This is also defined as thickness of the tumor in cases where there is a keratinized surface. The International Society of Gynecological Pathologists and the World Health Organization recommend that both the depth of invasion and the thickness of tumor, as well as the method of measurement, be defined in the pathology reports.

Among SCCs limited to the vulva, those with a DOI ≤ 1 mm are associated with a <1% risk for lymph node metastasis. Tumors with a DOI of 1.1 to 3 mm are associated with lymph node metastases in 6% to 12% of patients, and approximately 15% to 20% of tumors with a DOI of 3.1 to 5 mm are associated with positive lymph nodes (36).

In the 2009 revision, all stage I and stage II patients by definition have uninvolved LNs. With respect to inguinal lymphadenectomy, there is no clear definition of how many LNs constitute an adequate evaluation. SLN biopsy is not mentioned as a requirement; however, the emphasis on the size of micrometastases in stage III implies that an SLN biopsy is performed either alone or as part of a lymphadenectomy.

The 2009 staging system added three pathologic groupings within stage III (a, b, and c), each of which contains prognostic significance. These three groups are the number of positive nodes, the size of the largest inguinal node metastasis, and the presence or absence of extracapsular extension. These pathologic features have been shown in multiple studies to be the strongest predictors of mortality related to vulvar cancer (34,37). The other notable difference in the 2009 schema is the absence of stage difference based on unilaterality versus bilaterality of groin involvement; any groin metastasis is considered to be stage III disease. The 2009 FIGO staging guidelines for vulvar cancer were devised with correlation for the American Joint Committee on Cancer (AJCC) tumor node metastasis (TNM) classification scheme (Table 18.1) (34). Tumor assessment is based on physical examination, with endoscopy in cases of bulky disease. Nodal status is determined by the surgical evaluation of the groin. The presence or absence of distant metastases should be determined on the basis of an individualized diagnostic workup based on the patient's clinical presentation (33).

Because of the infrequent incidence of vulvar melanoma, there has historically been a paucity of data to guide staging algorithms for patients with this disease. Recent data, however, support an assertion that AJCC staging guidelines (updated in 2010) for cutaneous melanoma should be applied to vulvar melanoma. Moxley et al. examined 77 cases of vulvar melanoma from five academic medical centers, applying the 2002 modifications of the AJCC staging system for cutaneous melanoma, Breslow thickness, and Clark level to all patients. Breslow's thickness was associated with recurrence (p = 0.002) but not survival; however, the AJCC-2002 staging system was predictive of overall survival (OS) (p = 0.006) in patients with vulvar melanoma (38). It is important that primary tumor thickness (using Breslow's method) and nodal status are the primary determinants of survival in this disease. Also important, however, are the presence or absence of ulceration and mitotic rate; these descriptors also factor prominently in the staging of cutaneous melanoma (Tables 18.2A and 18.2B).

TABLE 18.2A TNM Staging Categories for Cutaneous Melanoma

Classification	Thickness (mm)	Ulceration Status/Mitoses
Tis	NA	NA
T1	⩽1	a: Without ulceration and mitosis < 1/mm^2 b: With ulceration or mitoses ⩾ 1/mm^2
T2	1.01–2	a: Without ulceration b: With ulceration
T3	2.01–4	a: Without ulceration b: With ulceration

T4	>4	a: Without ulceration b: With ulceration
N	**No. of metastatic nodes**	**Nodal metastatic burden**
N0	0	NA
N1	1	a: Micrometastasis[a] b: Macrometastasis[b]
N2	2–3	a: Micrometastasis[a] b: Macrometastasis[b] c: In-transit metastases/satellites without metastatic nodes
N3	4+ metastatic nodes, or matted nodes, or in-transit metastases/satellites with metastatic nodes	
M	**Site**	**Serum LDH**
M0	No distant metastases	NA
M1a	Distant skin, subcutaneous, or nodal metastases	Normal
M1b	Lung metastases	Normal
M1c	All other visceral metastases	Normal
	Any distant metastasis	Elevated

LDH, lactate dehydrogenase; NA, not applicable.

[a]Micrometastases are diagnosed after sentinel lymph node biopsy.

[b]Micrometastases are defined as clinically detectable nodal metastases confirmed pathologically.

Clinical staging includes microstaging of the primary melanoma and clinical/radiologic evaluation for metastases. By convention, it should be used after complete excision of the primary melanoma with clinical assessment for regional and distant metastases.

PATHOLOGY

Most vulvar malignancies arise within squamous epithelium. Although the vulva does not have an identifiable transformation zone, as the cervix does, squamous neoplasms arise most commonly on the labia minora, clitoris, posterior fourchette, perineal body, or medial aspects of the labia majora. Within the vulvar vestibule and fourchette, squamous neoplasia may arise where keratinized stratified squamous epithelium transitions to the nonkeratinized squamous mucosa of the vestibule, also known as Hart's line (39).

Most vulvar squamous carcinomas arise within areas of epithelium associated with a recognizable epithelial cell abnormality. Approximately 60% of cases have adjacent HSIL (VIN 3). In cases of superficially invasive squamous carcinoma of the vulva, the frequency of adjacent HSIL (VIN 3) approaches 85% (14). Lichen sclerosus, usually with associated hyperplastic features, dVIN, or HSIL (VIN 3) can be found adjacent to vulvar SCC in 15% to 40% of the cases (40,41). Granulomatous disease is also associated with vulvar SCC; however, this is not a commonly associated finding in the United States. Thus, vulvar SCC precursors can be considered in distinct groups: those associated with HPV, "usual" VIN, and those that are not (e.g., those associated with LS, chronic granulomatous disease) (see Epidemiology section).

EPITHELIAL CARCINOMAS

Squamous Cell Carcinomas

Stage I squamous carcinomas of the vulva with a DOI of 3 mm have a LN metastasis rate averaging 12%. Tumors with a DOI of 5 mm or more have a LN metastasis rate of at least 15%. Tumors with a DOI ≤ 1 mm carry little risk of LN metastasis (42). DOI and tumor thickness are separately defined and measured because considerable variations can exist among measurements from various superficial points in tumors of approximately 1 mm (41). When evaluating an ulcerated tumor thought to be superficially invasive, measurement from the surface of the ulcer, rather than from the adjacent dermal papillae as recommended for the DOI measurement, may result in serious underestimation, and understaging, of the tumor. When there is epithelial acanthosis, thickening, or hyperkeratosis, measurement of invasion from the overlying

surface epithelium of the tumor, that is, measuring the thickness of the tumor rather than DOI, can result in overstaging. With large tumors, and some tumors with invasion deeper than 1 mm, thickness may be the only reliable measurement because of the lack of identifiable adjacent dermal papillae (41).

In addition to tumor stage and depth or thickness, other pathologic features include vascular space invasion, growth pattern of the tumor, grade of the tumor, and tumor type. Vascular space involvement can be defined as tumor within an endothelial lined vascular space. Strict pathologic criteria require that the tumor be attached to the wall of the vessel, but this is not observed in all cases. Vascular space involvement by SCC of the vulva is associated with a higher frequency of LN metastasis and a lower overall 5-year survival rate. No reliable methods unambiguously predict LN metastasis by quantitation of vascular space involvement by tumor.

Tumor growth pattern influences the rate of LN metastasis and survival in tumors >1 mm in DOI. In stage IA vulvar carcinomas, tumor growth pattern does not influence the risk of node involvement. Three factors describe tumor growth patterns: confluent; compact (pushing pattern); and fingerlike (or spray or diffuse), a pattern also described as poorly differentiated (36). Confluent growth is defined as a tumor mass composed of interconnected tumor >1 mm in dimension (Fig. 18.5). Confluent growth is characteristic of deeply invasive SCCs that are associated with stromal desmoplasia, resulting in fibrovascular stromal changes adjacent to the interconnected cords of tumor.

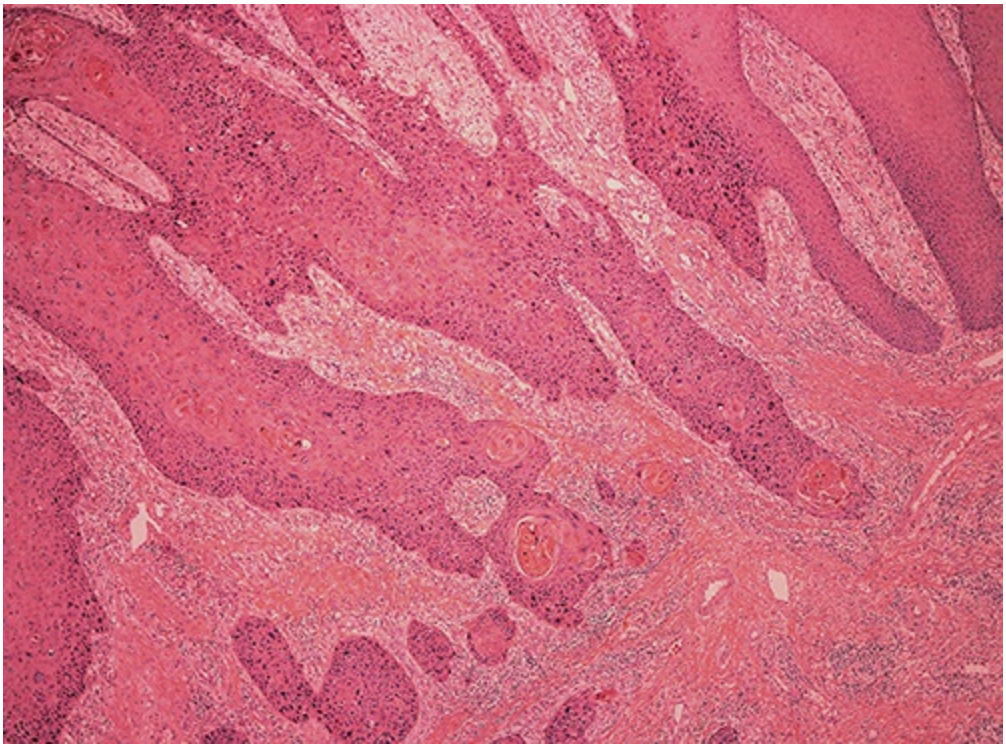

Figure 18.5 Confluent pattern of invasion. The tumor has a compact, pushing growth pattern with a well-defined tumor-dermal interface. The tumor diameter exceeds 1 cm, and has fingerlike growth pattern, with small, variable-sized tumor nests within the adjacent dermis. The adjacent dermis has a desmoplastic, fibrotic appearance.

Compact (pushing; well differentiated) growth is squamous tumor growth that maintains continuity with the overlying epithelium and infiltrates as a well-defined and well-circumscribed tumor mass, without islands of infiltrating tumor remote from the tumor mass. Tumors with compact growth typically have a thickness ≤5 mm and rarely invade vascular space. They are characteristically well differentiated, with the tumor cells resembling the squamous cells of the adjacent and overlying epithelium. There is usually minimal stromal desmoplasia, although there may be a lymphocytic inflammatory cell infiltrate (39).

Fingerlike (spray or diffuse; poorly differentiated) growth is characterized by a trabecular appearance, with small

islands of poorly differentiated tumor cells found within the dermis or submucosa deeper than the bulk of the tumor mass. Tumors with this growth pattern are typically associated with a desmoplastic stromal response (Fig. 18.6) and a lymphocytic inflammatory cell infiltrate. In tumors with a DOI <5 mm, the fingerlike pattern of growth is associated with a higher frequency of inguinal lymph node metastasis (39).

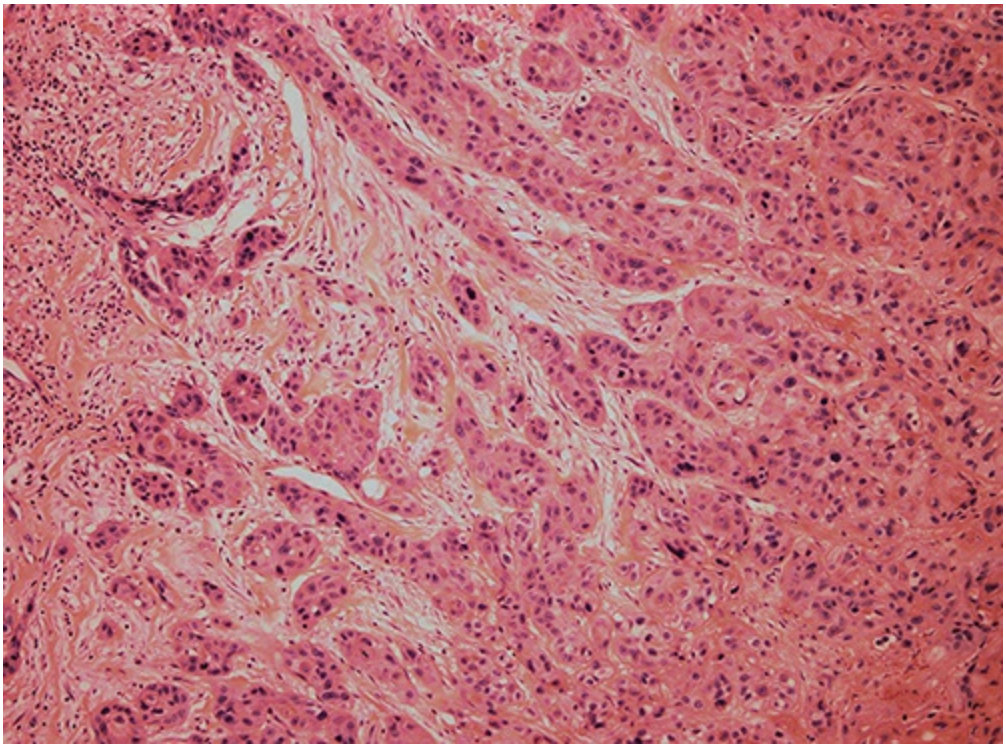

Figure 18.6 Fingerlike growth. The tumor forms small nests surrounded by a desmoplastic stroma.

In some cases, a single tumor may have both compact and fingerlike growth patterns. Mixed patterns, in our experience, are more commonly encountered in frankly invasive vulvar carcinomas and are rarely seen in superficially invasive tumors. The Gynecologic Oncology Group (GOG) has referred to tumors with a compact pattern of growth as well differentiated, and to tumors with the fingerlike pattern of growth as poorly differentiated. Using this terminology, the GOG proposed the following grading system for vulvar SCC:

- Grade 1 tumors are composed of well differentiated tumor and contain no poorly differentiated element.
- Grade 2 tumors contain both patterns, with the poorly differentiated portions making up one-third or less of the tumor.
- Grade 3 tumors also contain both components, with the poorly differentiated portion composing more than one-third but less than one-half of the tumor.
- Grade 4 tumors have one-half or more of the tumor composed of the poorly differentiated elements.

The ISGYP Committee of Terminology for Non-neoplastic Epithelial Disorders and Tumors recommended that the following information be included in the pathology report of all excised vulvar SCCs, information also supported by the CAP, and often used by tumor registries (43):

1. Depth of tumor invasion in millimeters
2. Thickness of the tumor in millimeters

3. Method of measurement of the DOI and thickness
4. Presence or absence of vascular space (lymphatic) involvement by tumor
5. Diameter of the tumor, measured from the specimen in the fresh or fixed state
6. Clinical measurement of the tumor diameter, if available

Several histopathologic types of vulvar SCC are recognized. The usual types include SCC, keratinizing type; SCC, nonkeratinizing type; basaloid carcinoma; and warty (condylomatous) carcinoma (42). Less common types include acantholytic SCC, SCC with tumor giant cells and spindle cell squamous carcinoma, SCC with sarcoma-like stroma, sebaceous carcinoma, verrucous carcinoma, and other rarer types (41,42).

Adenoid squamous carcinoma (pseudoangiosarcomatous carcinoma, acantholytic SCC, pseudoglandular SCC) refers to SCCs with pseudoglandular features. These tumors are characterized by small gland-like spaces within a tumor that otherwise appears to be a poorly differentiated SCC. It is considered a highly aggressive variant of vulvar SCC (44). This tumor should be differentiated from adenosquamous carcinomas that contain an obvious adenocarcinoma component (40). Adenoid squamous carcinoma does not contain sialomucin, but adenosquamous carcinoma typically does contain mucin within the adenocarcinoma component.

SCC with tumor giant cells has multinucleated tumor giant cells intermixed within the squamous carcinoma. This tumor may resemble amelanotic melanoma. SCC with tumor giant cells, unlike melanoma, does not express S100 antigen, HMB45, or Melan-A on immunoperoxidase studies. This tumor does express low molecular weight keratin, similar to other squamous carcinomas (45).

Sebaceous Carcinoma of the Vulva

These tumors, which arise from the sebaceous glands of the vulvar skin, may be associated with VIN. This rare tumor is aggressive. The tumor cells are relatively large, with large nuclei, and prominent nucleoli with prominent cytoplasm. The cytoplasm, related to its lipid content, has a finely vacuolated appearance. The tumor may have the appearance of a SCC intermixed with sebaceous elements. Deep invasion and lymph node or other metastases may be present on initial presentation (46,47).

Spindle Cell Squamous Cell Carcinomas

These tumors consist of poorly differentiated neoplastic epithelial cells that have an elongated spindle shape and may mimic a spindle cell melanoma or a sarcoma (Fig. 18.7) (48). SCC with spindle cell stroma is associated with a sarcoma-like stromal/dermal response that may mimic a primary sarcoma. Spindle cell SCCs can be differentiated from sarcomas by immunoperoxidase techniques. Like other SCCs, the spindle cell variant contains keratin and lacks the antigens distinctive to sarcomas of various origins. S100 antigen, HMB45, and Melan-A are usually immune-reactive in a spindle cell melanoma and lacking in a spindle cell squamous carcinoma.

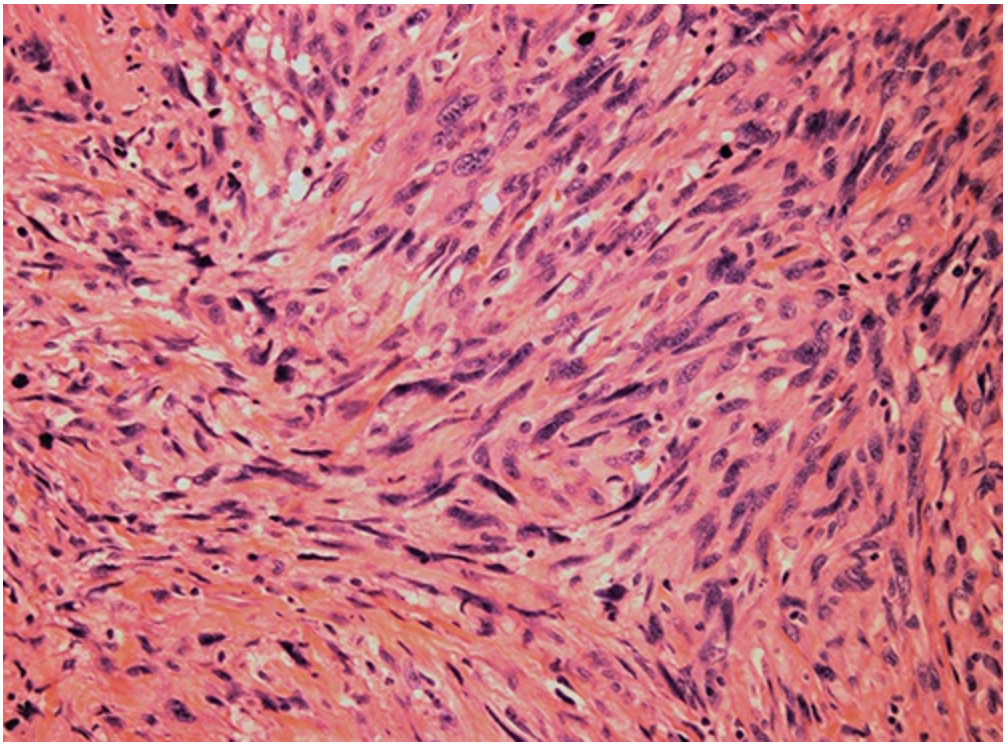

Figure 18.7 Spindle cell squamous carcinoma. The tumor cells have a spindle shape and poorly defined cell junctions.

Verrucous Carcinoma

Verrucous carcinoma of the vulva typically presents as an exophytic appearing growth that can be locally destructive. Clinically, it may resemble condyloma acuminatum. The so-called Buschke-Lowenstein giant condyloma is classified as a variant of verrucous carcinoma by WHO (42). Microscopically, verrucous carcinoma is characterized by well differentiated epithelial cells. The tumor growth pattern is characterized by a "pushing" tumor–dermal interface with minimal stroma between the acanthotic epithelium (Fig. 18.8). The surface is often hyperkeratotic, and there may be parakeratosis. Observed mitoses are characteristically normal. Within the dermis, a mild lymphocytic inflammatory cell response is usually seen. Vascular space involvement by tumor is characteristically lacking. Because of its excellent prognosis, strict histologic criteria should be used in the diagnosis of verrucous carcinoma. Squamous carcinomas with focal verrucous features should not be described or diagnosed as verrucous carcinoma.

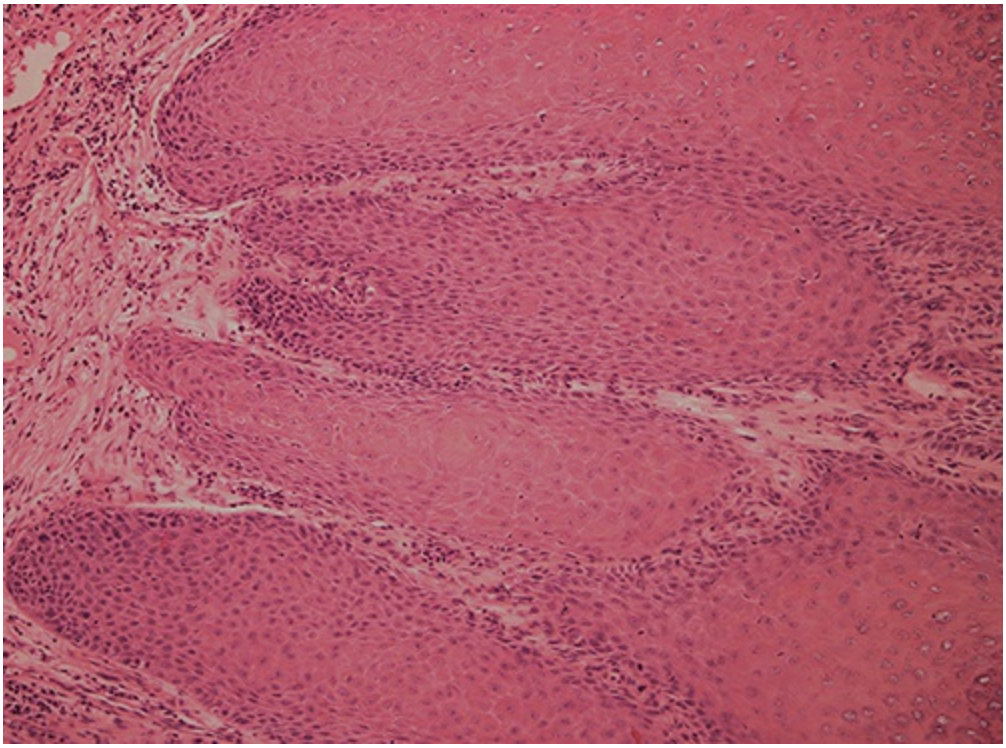

Figure 18.8 Verrucous carcinoma. The epithelial cells are well differentiated, and the tumor has a "pushing border" with a delicate vascular core between the epithelial elements.

Verrucous carcinomas are characteristically diploid, unlike typical SCCs of the vulva, which are usually aneuploid by DNA analysis. The major differential diagnosis of verrucous carcinoma includes keratoacanthomas, pseudocarcinomatous hyperplasia, epithelioid sarcoma, and malignant rhabdoid tumor.

Basal Cell Carcinoma

Basal cell carcinoma (BCC) is a relatively rare tumor in the vulva, accounting for 2% to 4% of infiltrative neoplasms (49). These tumors are most commonly found in elderly women with a median age of 75 years, as compared with 67 years of age for SCCs, as noted in a recent study (50). The tumor may be a plaque or papule. Vulvar BCC most commonly arises on the labia majora and is typically relatively small, ranging from 0.2 to 2.5 cm, with a median size ≤0.85 cm in a recent study of 35 cases (50). The surface of the tumor appears granular and is well circumscribed.

The epithelial cells composing BCC are typically small and vary in form, with small hyperchromatic nuclei that may exhibit some nuclear pleomorphism. These tumors may have a variety of growth patterns (e.g., trabecular, insular), although peripheral nuclear palisading is a relatively consistent finding. BCCs often have an intraepithelial component that is contiguous with the infiltrative component, if present.

Metatypical Basal Cell Carcinoma

This is a variant of BCC that usually occurs at mucocutaneous junctions. The term *basosquamous carcinoma* is applied to these tumors because of their microscopic features, which include BCC intermixed with a SCC component. Nuclear pleomorphism is usually seen in metatypical BCC and in the basal cell and squamous cell components of the tumor. The deeper tumor cells, close to the underlying stroma, have the greatest degree of nuclear pleomorphism and the more prominent squamous features. These tumors have a more aggressive clinical behavior than typical BCC (39).

The differential diagnosis of metatypical BCC includes basaloid SCC, Merkel cell tumor of the skin, and metastatic

small cell carcinoma. Basaloid SCC can be distinguished by its lack of characteristic basal cell growth pattern, and the presence of intracellular bridges. Nuclear pleomorphism is typically much greater in basaloid SCC than in BCC. BCCs express BerEP4 on histochemical study, an antigen not expressed by basaloid SCCs (41). Basaloid SCCs are typically associated with HPV-16, which is not typically associated with BCC. Merkel cell tumors and other neuroendocrine tumors of the vulva are typically subcutaneous or dermal nodules, and not intraepithelial lesions (see section on neuroendocrine tumors).

Neuroendocrine and Neuroectodermal Tumors: Merkel Cell Tumors and Peripheral Neuroectodermal Tumor/Extraosseous Ewing Sarcoma

High-Grade Neuroendocrine Carcinoma/Merkel Cell Tumor

The WHO classifies high-grade neuroendocrine carcinoma tumors into three categories: small cell neuroendocrine carcinoma (small cell carcinoma/SCNEC); large cell neuroendocrine carcinoma; and Merkel cell tumor (51). Although SCNEC tumors are well recognized in the lung, vagina, and cervix, they are extremely rare in the vulva. The WHO recommends that the term "small cell carcinoma" be used only for high-grade neuroendocrine tumors of small cell type, which would be a very rare finding in the vulva. Most of the high-grade neuroendocrine carcinomas reported in the vulva are Merkel cell tumors of the skin that typically occur within the dermis. They are rare, and may have a deceptive appearance as single or multiple cutaneous nodules. Ulceration may occur. The tumors may occur concurrently with vulvar SCC and/or VIN (51). These tumors can be divided into two major types: those composed predominantly of small, relatively uniform cells with little cytoplasm and a hyperchromatic, punctate nuclear chromatin pattern. The second type has cellular features resembling low-grade neuroendocrine tumors, with round to polygonal cells, little cytoplasm, and pale finely granular nuclear chromatin. Both types usually have a high mitotic count. Merkel cell tumors can also be subclassified as carcinoid-like (trabecular), intermediate type, and small cell (oat cell) type. By immunohistochemistry (IHC), these tumors typically express neuron-specific enolase (NSE), NCAM/CD56, cytokeratin CAM 5.2, cytokeratin 20, and AE1/AE3 (51). They may also express synaptophysin and chromogranin. Cytokeratin study, such as with cytokeratin 20, demonstrates a distinct perinuclear cytoplasmic dot. Dense core neurosecretory granules are seen by electron microscopy. These features differentiate it from BCC or SCC (41). Merkel cell tumors frequently have both regional LN and distant metastases, and are associated with a poor prognosis.

Peripheral Neuroectodermal Tumor/Extraosseous Ewing Sarcoma

Peripheral neuroectodermal tumor (PNET) is a rare neuroendocrine vulvar neoplasm that has been reported in children, and women of reproductive age. The tumor may present as a subcutaneous or polypoid mass in the labia minora or majora, and clinically may resemble a Bartholin's cyst, or be ulcerated. On microscopic examination, the tumor is circumscribed multi-lobulated, and contain small cells with hyperchromatic nuclei and scant cytoplasm. Some cells have small nucleoli, and mitotic figures are usually common, with mitotic counts from 3 to exceeding 10 per 10 high power fields (HPFs). Numerous patterns of growth may be seen with highly cellular undifferentiated areas, areas with cyst formation containing eosinophilic proteinaceous material, Homer-Wright rosettes, and follicle-like structures. The cells of PNET have periodic acid-Schiff (PAS) staining cytoplasm that digests with diastase, and typically express CD99 and vimentin. Although, as in Merkel cell tumors, focal reactivity for synaptophysin and NSE may be present, cytokeratin reactivity is absent but may be focally immuno-reactive in some cases; dense core neurosecretory granules, as seen in

Merkel cell tumor by electron microscopy, are not present (52–54).

Urothelial/Transitional Cell Carcinoma

Urothelial carcinoma may be a primary tumor of the vulva, usually arising within the Bartholin's glands. More commonly, urothelial carcinoma is metastatic to the vulva, having arisen within the bladder or urethra. In rare instances, the tumor presents as a Paget-like lesion of the vulva (see section on Paget's disease) (55). Microscopically, urothelial carcinomas are composed of relatively uniform cells; nuclear pleomorphisms may be marked in high-grade urothelial neoplasms. The cytoplasm is eosinophilic without apparent inclusions or keratin formations, although focal keratin formation may be seen. The tumors may exhibit papillary-like growth.

Adenocarcinoma and carcinoma of Bartholin's glands: Most primary adenocarcinomas of the vulva arise within Bartholin's glands. Adenocarcinoma may also arise from other glands or skin appendages of the vulva, including sweat glands and Skene's glands (42). Invasive vulvar Paget's disease has also given rise to adenocarcinoma (Fig. 18.9). Primary malignant tumors arising within Bartholin's glands include SCC (88%) and adenocarcinoma (12%) (56).

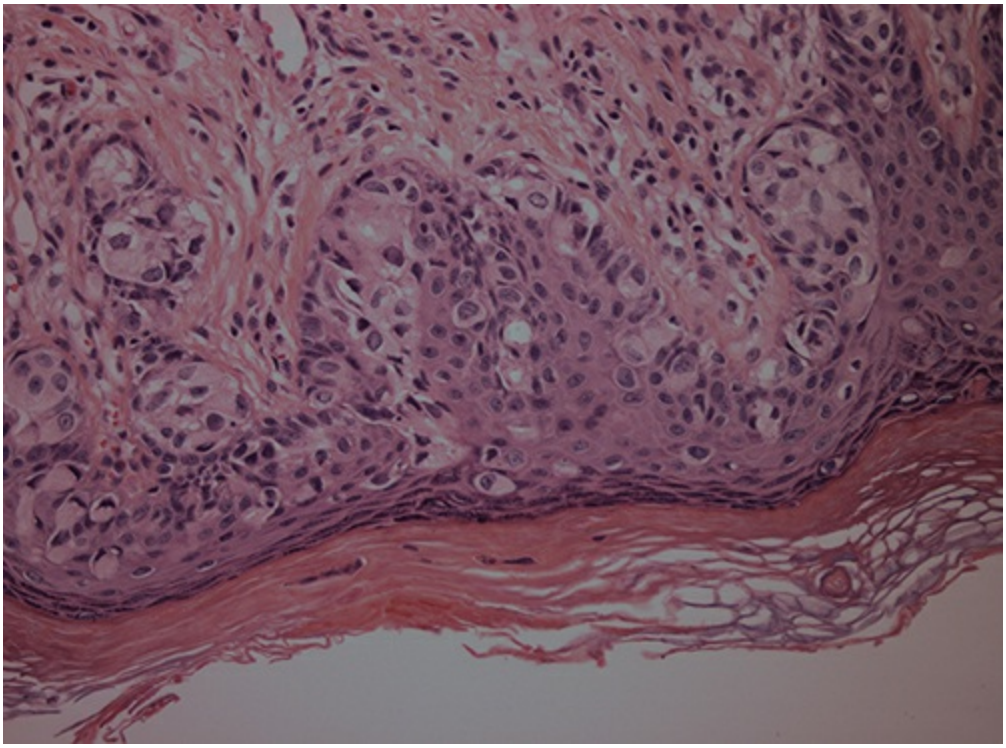

Figure 18.9 Paget's disease. The large cells with prominent cytoplasm and large nuclei represent the intraepithelial Paget's cells. A few small gland-like intraepithelial structures are formed by the Paget's cells.

Carcinomas of Bartholin's glands generally occur in older women and are rare in women younger than 50. Therefore, it is generally advisable to excise an enlarged Bartholin's gland in women 50 years of age or older, especially if there is no known history of prior Bartholin's cyst. If a cyst is drained and a palpable mass persists, excision of the gland is indicated.

Primary carcinomas within Bartholin's glands are usually solid tumors and are often deeply infiltrative. A variety of histologic types of adenocarcinoma have been described within Bartholin's glands, such as mucinous, papillary, and mucoepidermoid carcinoma tumor types, in addition to adenosquamous, squamous, and transitional cell carcinoma. Adenocarcinoma of Bartholin's glands is typically immuno-reactive for carcinoembryonic antigen (CEA). Histopathologic features that identify a carcinoma arising in Bartholin's glands include a recognizable transition from a Bartholin's gland to tumor. The histopathologic tumor type must be consistent with origin from a Bartholin's gland, and the tumor must not

appear to be metastatic to gland. These malignancies are characteristically deep and difficult to detect in their early growth. Approximately 20% of women with primary carcinoma of Bartholin's glands have metastatic tumor to the inguinal lymph nodes at the time of primary tumor diagnosis (56).

Vulvar Paget's Disease and Paget-like Lesions.

Vulvar Paget's disease typically presents as an eczematoid, red, weeping area on the vulva, often localized to the labia majora, perineal body, clitoral area, or other sites. This disease typically occurs in older, postmenopausal Caucasian women, although it has been described in a premenopausal woman (56a,b). Because of its eczematoid, erythematous and/or ulcerated appearance, it is not unusual for vulvar Paget's disease to be misdiagnosed as eczema or contact dermatitis. Approximately 15% of women with vulvar Paget's disease have underlying primary adenocarcinoma, usually arising within apocrine glands or the underlying Bartholin's glands. The Wilkinson and Brown etiologic classification of vulvar Paget's disease divides Paget's disease into two main groups: those of cutaneous origin and those of noncutaneous origin (55). The two most common types of noncutaneous Paget's disease are those associated with colorectal adenocarcinoma and those associated with bladder urothelial carcinoma. Women with Paget's disease of the colorectal type usually present with a lesion that involves the perianal skin, and this lesion is a manifestation of underlying colon or rectal adenocarcinoma. Women with Paget-like disease (pagetoid urothelial intraepithelial neoplasia [PUIN]) typically present with a lesion involving the periurethral area and vulvar vestibule (55,57). In these cases, there is associated bladder and/or urethral urothelial carcinoma, with extension of the neoplastic urothelial cells to the epithelium of the vulva. In cases of PUIN, wide local excision is an acceptable surgical treatment because there is no associated underlying cutaneous adenocarcinoma. The tumor cells are from the bladder and/or urethra, representing an intraepithelial transitional cell neoplasm extending from the bladder and/or urethra (55).

Cutaneous Paget's disease is most commonly a primary intraepithelial neoplasm, and in such cases, the intraepithelial Paget's disease may have an associated invasive Paget's disease. In rare cases, cutaneous Paget's disease may be a manifestation of an underlying cutaneous adenocarcinoma (55). Cutaneous Paget's disease is characterized by the presence of Paget's cells found within the involved epithelium. A Paget's cell is relatively large, with a prominent nucleus that typically has coarse chromatin and a prominent nucleolus. On hematoxylin and eosin (H & E) staining, the cytoplasm is distinctly pale compared with the surrounding keratinocytes. The cytoplasm may be vacuolated or appear foamy, and typically is somewhat basophilic (Fig. 18.9).

Paget's cells of cutaneous origin are rich in CEA, which can be identified with immunoperoxidase techniques. Paget's cells also express cytokeratin 7 (CK-7) and gross cystic disease fluid protein 15 (GCDFP-15) (55). Paget's cells infrequently express CA-125, and estrogen receptor is generally negative. Immunohistochemical staining for CK-7 is useful in many cases to identify the Paget's cells that are strongly CK-7 positive, whereas the adjacent epithelial cells are negative. Invasive Paget's disease ≤1 mm in DOI has reportedly little risk for recurrence (58).

The differential diagnosis of Paget's disease of cutaneous origin includes PUIN/Paget's disease of urothelial origin, Paget's disease of colorectal origin/or other related adenocarcinoma, superficial spreading malignant melanoma, pagetoid reticulosis, and the pagetoid variant of VIN, which are keratinocytic cells resembling Paget's cells. These can all be differentiated by immunoperoxidase techniques because melanomas do not express cytokeratin, but usually express S100 protein, HMB45, and Melan-A, which are absent in Paget's cells (55). The Paget-like cells in PUIN express uroplakin-2 and uroplakin-3, whereas uroplakins are not expressed in Paget's disease of cutaneous origin. The PUIN lesions do not express GCDFP-15. In a study of 15 cutaneous Paget's disease and 3 PUIN cases, GATA-3 was found to be reactive in both lesions and did not distinguish between them (59). Adenocarcinoma cells of colonic, anal, or rectal origin express CEA, as well as caudal homeobox (CDX), whereas Paget's disease of cutaneous origin does not express CDX. HSIL (VIN 3) of pagetoid type may microscopically resemble Paget's disease or melanoma, but the cells of LSIL or HSIL (VIN 1, VIN 2–3) do not express CEA, S100, or melanoma antigen (55,57).

Vulvar Malignant Melanoma.

Malignant melanoma of the vulva accounts for approximately 9% of all primary malignant neoplasms on the vulva, and vulvar melanoma accounts for approximately 3% of all melanomas in women. This tumor occurs predominantly in Caucasian women, with approximately one-third of the cases occurring in women younger than 50; the mean age at diagnosis is 55 years (60). Peak frequency occurs between the sixth and seventh decades, and the highest incidence is in women 75 years of age or older, where the age-specific incidence is reported to be 1.28/100,000 (61). The most common presenting symptom is bleeding; however, symptoms may include pruritus, pain, dysuria, and a palpable mass (62,63). The tumor may arise from a preexisting pigmented lesion or from normal-appearing skin. The primary site on the vulva may be the clitoris, labia minora, and labia majora, where melanomas occur with approximately equal frequency (64). The tumor may be elevated, nodular, or ulcerated. Although tumors are usually pigmented, approximately one-fourth are amelanotic (Fig 18.10). In the clinical setting, the differential diagnosis includes pigmented condyloma acuminatum, pigmented HSIL VIN, atypical genital nevus, melanosis of the vulva, or other malignant tumors, including malignant soft tissue tumors.

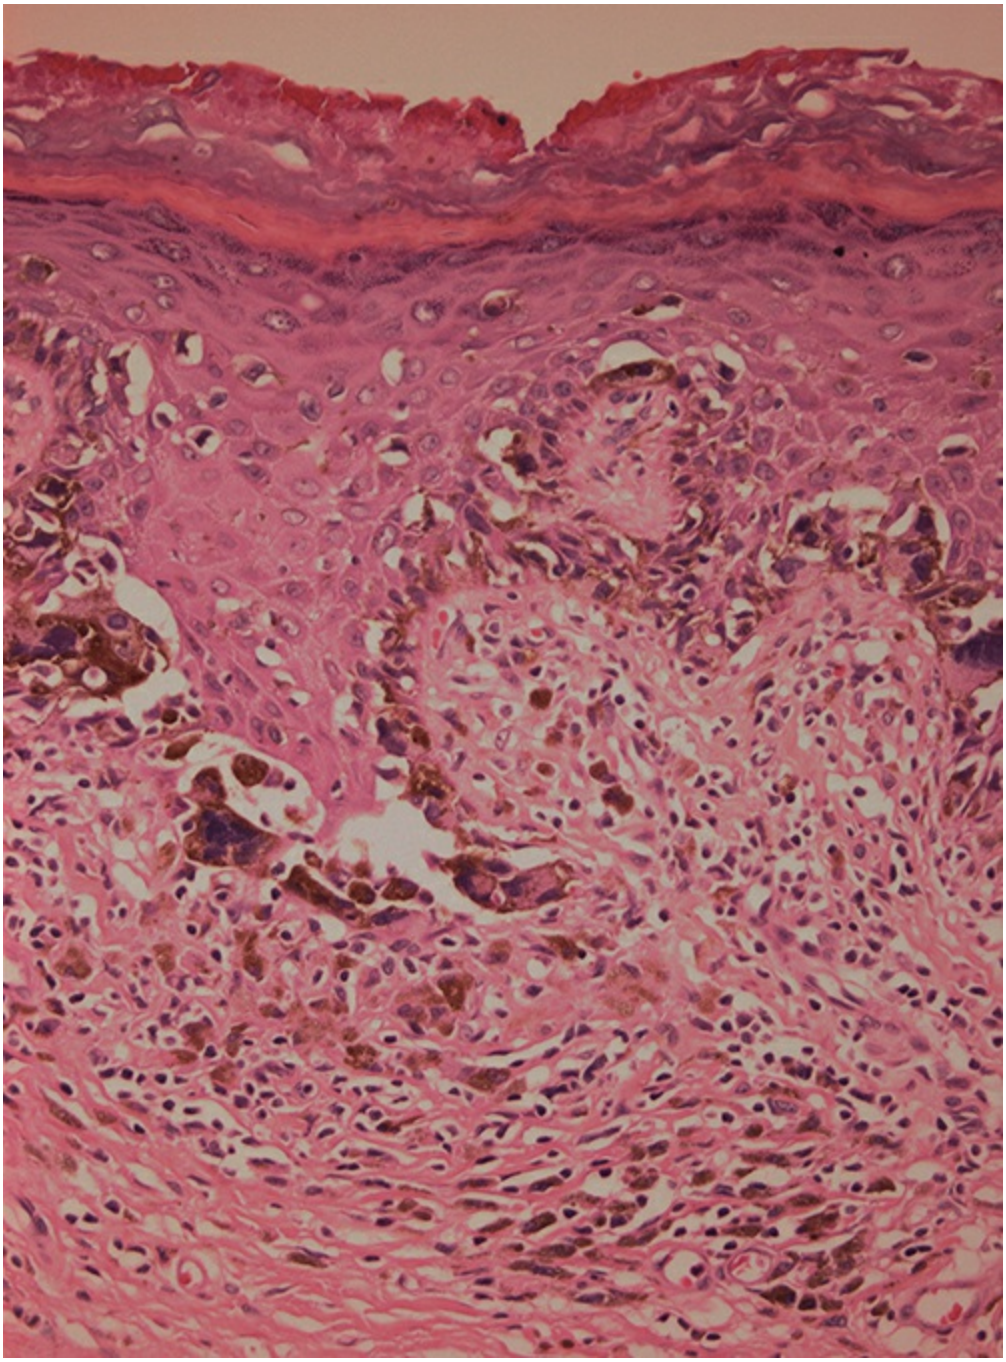

Figure 18.10 Malignant melanoma. The tumor is within the dermis and contains dark melanin pigment. Junctional growth is seen within the overlying epithelial dermal junction.

Historically, vulvar malignant melanomas have been subclassified histopathologically into three categories: superficial spreading malignant melanoma, nodular melanoma, and mucosal lentiginous melanoma, which is also referred to as mucosal/acral lentiginous melanoma (65). Mucosal lentiginous melanomas are the type most commonly reported on the vulva, accounting for over one-half of the cases in larger series (61,65). Nodular melanomas are second in frequency, accounting for approximately one-fifth of the cases, and have the overall worst prognosis of the melanoma types, usually related to the greater thickness and deeper invasion at the time of presentation. Although it can be useful to be aware of these histopathologic categories because of persistent use in some centers, their clinical utility is limited, replaced by more objective and reproducible pathologic tumor characteristics such as DOI, ulceration, and mitotic rate (66).

Tumor thickness is the most important measurement in evaluating malignant melanoma. Historically, Clark's levels and

Breslow's thickness definitions, which describe the extent of dermal and subcutaneous involvement by invasive melanoma lesions, were used to triage patients with T1 lesions into different prognostic groups for treatment (64). More recently, however, the 2009 AJCC Melanoma Staging and Classification update (seventh edition) recommended discontinuation of the use of these methods for characterization of T1 invasive melanoma lesions (66).

Melanomas arising in the vulva may metastasize to other sites within the lower female genital tract, including the cervix, vagina, urethra, and rectum. Distant metastasis is common with disseminated disease. Survival after recurrence is poor, approximately 5%.

Vulvar Sarcomas

Leiomyosarcoma

Leiomyosarcoma (LMS) is the most frequent primary vulvar sarcoma, although sarcomas of the vulva are relatively rare. It occurs in women in the fourth or fifth decade of life and most commonly arises in the labia majora or Bartholin's gland area. The tumors are generally larger than 5 cm in diameter when first diagnosed, presenting as an enlarging mass. It may be deep within the subcutaneous tissue and painful in some circumstances.

On microscopic examination, these tumors are composed of interlacing spindle-shaped cells, sometimes with an epithelioid appearance. Histopathologic criteria for malignancy require at least three of the following features: size >5 cm, evidence of infiltrative growth into adjacent tissue, cytologic atypia of a moderate to severe degree, and mitotic count > 5 mitoses per 10 high power fields (HPFs). In cases with minimal pleomorphism, but with most of the other criteria, it is generally accepted that the diagnosis of LMS can be made with a mitotic count of 10 or more per 10 high power fields (HPFs). Tumors that have an infiltrating border or nuclear atypia with pleomorphism and mitotic count of 5 or more per 10 HPFs are classified as LMS (67).

Malignant Fibrous Histiocytoma

Malignant fibrous histiocytoma (MFH) arises from histiocytes with fibroblastic differentiation. It is considered the second most common sarcoma of the vulva and has its peak frequency in women of middle age. MFH typically presents as a solitary mass that may appear somewhat brownish or pigmented, secondary to areas of focal hemorrhage within the tumor.

On microscopic examination, the tumor is characterized by a complex interlacing cellular growth pattern with marked nuclear pleomorphism, including multinucleated cells and large bizarre cells. Abnormal mitotic figures may be apparent. On immunoperoxidase study, these tumors contain α_1 antitrypsin and α_1 antichymotrypsin. MFH is typically infiltrative, and may involve the underlying fascia. Involvement of the fascia is associated with a higher risk of local spread and distant metastasis (68).

Epithelioid Sarcoma

Epithelioid sarcoma may arise within the labia majora, subclitoral area, and clitoris. Its microscopic features may resemble squamous carcinoma, malignant melanoma, malignant rhabdoid tumor, or lymphoma. Epithelioid sarcoma is usually relatively superficial, arising in and involving the reticular dermis, but it may occur in deeper structures (69).

On microscopic examination, the tumor is nodular and may have areas of necrosis. The tumor cells have an epithelioid appearance with eosinophilic cytoplasm, but there may be metaplastic components, including cartilage and bone. On immunohistochemistry, this tumor contains cytokeratin, which does not distinguish it from epithelial tumors, but is of value in differentiating it from malignant melanoma or other types of soft tissue tumors. Epithelioid sarcoma rarely

metastasizes, although local recurrence is a risk. Immunoperoxidase studies are of value in differentiation, but not in differentiating epithelioid sarcoma from malignant rhabdoid tumor. The distinction of these two tumors is based primarily on microscopic features (69).

Malignant Rhabdoid Tumor

Malignant rhabdoid tumor has been described in the vulva, and, like epithelioid sarcoma, may be relatively superficial and contain tumor cells with an epithelioid appearance with eosinophilic cytoplasm. Unlike epithelioid sarcoma, malignant rhabdoid tumors have relatively pleomorphic nuclei. Metaplastic elements are usually not present. Malignant rhabdoid tumor also has eosinophilic cytoplasmic inclusions, which are not present in epithelioid sarcoma. These inclusions give some of the cells the appearance of signet ring cells. Malignant rhabdoid tumor has a lobulated architecture but lacks necrosis or granulomatous features, which are often found in epithelioid sarcoma (70,71).

Aggressive Angiomyxoma

Aggressive angiomyxoma is a primary soft tissue tumor of the vulva and pelvis that occurs predominantly in women of reproductive age. It is locally aggressive but rarely metastatic (72). It typically presents as a deep soft tissue mass or pelvic mass, sometimes mimicking a Bartholin's cyst or inguinal hernia. In the pelvis, it may displace other pelvic organs and may be best appreciated on radiologic studies.

This tumor is typically poorly circumscribed and difficult to discriminate from adjacent soft tissue. On microscopic examination, the tumor has many blood vessels. It consists predominantly of spindle- to stellate-shaped cells, with relatively small uniform nuclei representing predominantly fibroblasts and myofibroblasts. Mitotic figures are very rare. The tumor stroma varies from myxoid to densely collagenous. Nerves, small glandular structures with mucin-secreting columnar cells, and other epithelial elements may be found trapped within the tumor. The differential diagnosis is as for angiomyofibroblastoma (AMF), summarized next.

AMF

AMF is a rare, benign tumor of soft tissue origin that occurs predominantly in the female genital tract. When involving the vulva, it usually presents as a soft subcutaneous mass, but may occasionally be pedunculated (73).

On microscopic examination, the tumor usually has well-demarcated borders. Variable cellularity is present, with an edematous appearance. The cells are spindle shaped, plasmacytoid or epithelioid in appearance, and mitotic figures are rare. Cells are present in most cases and may be clustered about blood vessels. The tumor is vascular, with small- to medium-sized vessels. Some inflammatory cells, commonly lymphocytes or mast cells, may be seen around the vessels.

Tumors Metastatic to the Vulva

Most metastatic tumors to the vulva involve the labia majora or Bartholin's glands. In the vulva, they most often present as multiple intradermal or subcutaneous nodules but may present as a Bartholin's gland mass (74–76). Metastatic tumors account for approximately 8% of all vulvar tumors, and in approximately one-half of the cases the primary tumor is in the lower genital tract, including the cervix, vagina, endometrium, and ovary. Cervical carcinoma is the most common origin of contiguous metastasis. Local metastasis secondary to contiguous involvement of the vulva from urothelial carcinoma of the bladder or urethra, or anorectal carcinoma, may involve the vulva and present as a Paget-like lesion (see Paget's disease and Paget-like lesions in this section) or a vulvar or groin node mass. Remote metastases have been observed from tumors arising in breast, kidney, stomach, lung, and other sites (76).

PROGNOSTIC FACTORS (INFLUENCING CHOICE OF TREATMENT)

Prognostic information collected during the diagnostic workup of SCCs of the vulva serves as a basis for both patient counseling and treatment decisions. Fundamental decisions regarding goals of therapy (cure vs. palliation) and sequencing of primary treatment (primary surgery vs. chemoradiation (CRT)) should be based on four factors: (a) historical and demographic risk factors; (b) characteristics of the primary tumor, including location, laterality, size (cm), DOI, lymph-vascular space invasion and margin width; (c) clinical ± radiographic assessment of the inguinal LNs; and (d) probability of distant metastatic disease.

After resection of the primary tumor and surgical evaluation of the inguinal LNs, additional information obtained from intraoperative observations and the final pathologic specimens serve to guide decisions regarding adjuvant therapy. The most important prognostic factors for the adjuvant management of SCC of the vulva have been incorporated into the FIGO and AJCC staging systems (Table 18.1). Among the many factors that affect recurrence risk and disease-specific mortality, nodal status, particularly the number of positive nodes, size of the largest metastasis, and the presence or absence of extracapsular extension, are the most important (77). It is impossible to accurately detect LN involvement on physical exam; therefore, the FIGO staging of vulvar cancer changed from a clinical to a surgical and histopathologic approach, with evaluation of extranodal extension (ENE) also taken into account. Each of the above risk factors is discussed in relation to its temporal presentation (presurgical vs. postsurgical resection). Prognostic factors associated with the resection specimen and inguinal lymph node evaluation following surgery are also discussed.

Presurgery

DOI, tumor size, and lymph-vascular space invasion are the primary determinants of a patient's risk for nodal metastases, and the presence of nodal involvement is the single most important determinant of disease-specific mortality. Multiple studies have demonstrated a direct correlation between lymph-vascular space invasion, increasing stromal invasion, and the presence of involved inguinal LNs (78–80).

Postsurgery

Following surgery, intraoperative findings and final pathologic analysis are used to estimate recurrence risk and subsequently guide decisions regarding adjuvant therapy. Among the many pathologic findings (in addition to tumor size, lymph-vascular space invasion, and DOI) that have been shown to affect recurrence risk, surgical nodal status is the most important (78–80).

Risk of local recurrence (LR), although associated with tumor size and extent, is also related to the adequacy of the surgical resection margins. Heaps et al. (81), in their analysis of formalin-fixed tissue specimens, were able to demonstrate a sharp rise in the incidence of LR for tumors with microscopic margins <8 mm. They suggested that this would correspond to a minimum margin of 1 cm in fresh, unfixed tissue. These observations were confirmed in a retrospective multivariate analysis of clinical data by Chan et al. (80), who showed that pathologic margin distance ≤8 mm is an important predictor of LR; de Hullu et al. (82) reported nine LRs among 40 patients with tumor-free margins ≤8 mm compared with no LRs among 39 patients with margins >8 mm. To aid the surgeon in planning surgical margins of resection, Hoffman et al. (83) measured the radial occult microscopic spread of tumor in patients with invasive SCC of the vulva. They found that the gross and microscopic peripheries of most cancers were approximately the same; however, ulcerative tumors with an infiltrative pattern of invasion were more likely to extend beyond what is grossly apparent. The prognostic impact of ENE has also been evaluated. ENE is the dissemination of LN metastasis through the lymph node

capsule and into the surrounding soft tissue. A study performed by Luchini et al. (84) evaluated the presence of ENE, with those individuals with ENE having significantly higher rates of all-cause mortality.

The single most important prognostic factor for recurrence and OS in women with vulvar cancer is metastasis to the inguinal LNs; most recurrences happen within 2 years of primary treatment (77,79). A number of imaging modalities have been studied for the preoperative evaluation of inguinal LN metastasis, including MRI, CT, PET, SPECT, and ultrasound. Currently, there is no imaging modality with a sufficiently high negative predictive value to allow for exclusion of surgical groin LN evaluation (85,86).

GENERAL MANAGEMENT

Historical Background

Development of the en bloc technique of radical vulvectomy with bilateral inguinofemoral lymphadenectomy during the 1940s and 1950s was a dramatic improvement over prior surgical options, and greatly enhanced survival, particularly for women with smaller tumors and negative LNs (87). In this era before effective RT that could provide local and regional disease control, the ability to successfully resect vulvar tumors reduced the occurrence of terminal progression dominated by intractable pain, immobility, malodorous drainage, and bleeding. Long-term survival of 85% to 90% can now be routinely obtained with radical surgery. Unfortunately, en bloc radical vulvectomy with inguinofemoral lymphadenectomy is associated with very morbid postoperative complications such as wound breakdown, lymphedema, disfigurement, and loss of sexual function. Appropriate indications for this procedure in the primary treatment of vulvar cancer are very rare.

Presently, smaller vulvar tumors can be acceptably managed by less radical, double or triple incision surgical approaches, and many authors have proposed more limited resections for certain subsets considered to represent early or low-risk disease (88). The advantages of such approaches include retention of a significant portion of the uninvolved vulva, preservation of body image and sexual function, less operative morbidity, and fewer complications later. Multimodality programs that incorporate radiation, surgery, and chemotherapy have now been validated in women with high-risk tumors, based on success with similar approaches in women with squamous cancers of the cervix and anus (88,89).

Sentinel Inguinal Lymph Node Biopsy

The SLN is defined as the first draining LN of a tumor, and can be identified using a lymphatic mapping technique. This is based on the observation that peritumoral injection of a liquid-based material results in superficial cutaneous lymphatic channel absorption of this material followed quickly by transport to the SLN. Either a vital blue dye, or radiocolloid, or both, can be used to facilitate SLN identification by direct visualization and/or detection of low levels of radioactivity by a handheld radiation detection device or imaging study (Figs. 18.11 and 18.12). The modern SLN concept was first described by Morton and colleagues in patients with cutaneous melanoma; shortly thereafter, it was described in patients with vulvar cancer (90,91). Preliminary experience with both intraoperative lymphatic dye and radioisotope injections confirmed that the SLN of the vulva is always in the inguinal LN basin and can be identified in most patients (92,93). This early experience supported the concept that the successful assessment of lymphatic metastases may ultimately be accomplished with resection/biopsy of one or two SLNs.

Figure 18.11 Transdermal localization of a sentinel node using a handheld gamma counter. The probe has a collimator and is pointed away from the primary tumor. Radioactivity will fall off rapidly until the sentinel node is encountered. Mark the site of an increase in activity.

Figure 18.12 A hot, blue sentinel node identified through a small incision. Frozen section is requested only if the sentinel node is grossly suspicious. Immunohistochemical staining is performed if the routine hematoxylin and eosin staining does not reveal metastatic disease. After a sentinel node is removed, the wound is explored with the gamma counter to assure that there is no other sentinel node in the field.

Based on these pilot study results, two large multi-institutional trials were initiated to determine the utility of SLN

biopsy (SLNB) in women with vulvar cancer. The Groningen International Study on Sentinel Nodes in Vulvar Cancer (GROINSS-V) trial used a prospective, observational design, enrolling 403 evaluable women with tumors ≤4 cm who underwent SLNB alone. Of these, 276 women had a negative SLNB and were closely observed for recurrence during a 2-year follow-up period. Eight patients (2.9%) suffered a groin relapse. When patients with multifocal primary tumors were removed from the analysis, the relapse rate was only 2.3% (94). Long-term results in 377 patients with unifocal disease from this same study were recently reported, detailing 36.4% and 46.4% (p = 0.03) 10-year local recurrence rate for sentinel node-negative and sentinel node-positive patients, respectively. In addition, they found that isolated groin recurrence rate was 2.5% for sentinel node-negative patients and 8% for sentinel node-positive patients at 5 years. The authors concluded that although survival is favorable for sentinel node-negative patients, the high rate of LR in these patients is of concern (95).

The second study, GOG 173, employed a validation design. All women underwent SLNB followed by unilateral or bilateral inguinofemoral lymphadenectomy: 515 women were enrolled, and 418 were evaluable. If the primary tumor was more than 2 cm from the midline, a unilateral SLNB and inguinofemoral lymphadenectomy were performed. If the tumor was within 2 cm of the midline, or involved the midline, bilateral inguinal lymphadenectomies were performed. The false-negative rate was 8.3%, and the false-negative predictive value (FNPV) was 3.7% for the entire cohort. The FNPV is a prediction of the chance of a positive non-SLN when the SLN is free of tumor and a lymphadenectomy has not been performed. In GOG 173, the FNPV by groin was 2.7%; for patients with tumors <4 cm, it was 2%. This means that a patient with a tumor <4 cm, no palpable LNs, and a negative SLNB has a 2% chance of a groin relapse (96). The results of these studies indicate that, for appropriately selected women in the care of a surgeon experienced with this technique, the risk of groin relapse following a negative SLNB is 2% to 3% (Table 18.3). This compares favorably with superficial inguinal lymphadenectomy, as reported by Stehman et al. (97) for the GOG. As with all surgical innovations, individual practitioners must use care when implementing new procedures. Gynecologic oncologists can learn the procedure from peers or from surgical oncologists treating melanoma or breast cancer patients. Prior to adopting this as his or her standard, each gynecologic oncologist should determine his or her own false-negative rate by performing SLNB followed by inguinofemoral lymphadenectomy in approximately 10 cases. Some practices see very few vulvar cancer patients, in which case referral is appropriate. Considered together, the GROINS V and GOG 173 trials strongly support an assertion that, under the appropriate circumstances, SLNB should be offered to eligible women with vulvar cancer.

TABLE 18.3 Sentinel Lymph Node Biopsy Sensitivity Analysis

Analysis	SLNB Result	Present	Absent	Total	Sensitivity	90% CI	NPV (%)	90% CI	FNPV (%)	9 C
By patients	Positive	121	0	121						
	Negative	11	286	297						
	Total	132	286	418	91.7	86.7 - 95.3	96.3	93.9 - 97.9	3.7	2. 6.
By groin	Positive	140	0	140						
	Negative	12	441	453

Source: Reprinted with permission from Levenback CF, Ali S, Coleman RL, et al. Lymphatic mapping and sentinel lymph node biopsy in women with squamous cell carcinoma of the vulva: a Gynecologic Oncology Group study. J Clin Oncol. 2012;30(31):3786–3791.

It is important to note that the largest SLN evaluations to date have all involved pathologic ultrastaging with serial sectioning and immunohistochemical (IHC) staining if routine H & E staining does not reveal metastatic disease. In most studies, including GOG 173 and GROINS V, approximately half of the LN metastases were detected by immunohistochemical staining. SLNB has the promise of reducing the number of unnecessary lymphadenectomies performed in node-negative women, while at the same time identifying additional women who may benefit from adjuvant therapy.

The combination of local vulvar resection and SLNB holds the promise of improved outcomes for many women with vulvar cancer. Preservation of sexual function and body image, a reduction in the risk of lymphedema, and more focused use of adjuvant therapy are all possible.

Patients with Clinical Stage I/II Tumors at Presentation

Tumors demonstrating a DOI ≤1 mm have minimal risk for lymphatic dissemination. Excisional procedures that incorporate a 1 cm normal tissue margin are likely to provide curative results (88,98). Patients in this category represent the only subset for whom surgical evaluation of the inguinal LNs can be omitted. These superficially invasive carcinomas tend to arise in younger patients with HSIL/VIN lesions that are commonly associated with oncogenic HPV infections. Occult invasion in lesions thought to be intraepithelial is common (99,100). Consequently, the entire lower genital tract and vulva should be carefully evaluated before surgical resection of these lesions is attempted. The risk of vulvar recurrence or development of a new lesion at another vulvar site is significant. After primary therapy, these patients should undergo frequent follow-up examinations.

Management of clinical stage I and II vulvar cancer includes wide radical excision of the primary tumor with unilateral or bilateral SLNB, with or without inguinofemoral lymphadenectomy. The operation removes the primary tumor with a wide radial margin of normal skin (2 cm), along with a deep margin to the deep perineal fascia; thus, the vulvar specimen will contain tumor, skin, subcutaneous fat, vascular perforators, and dermal lymphatics. This approach provides excellent long-term survival and local control in approximately 88% of patients (101). Every attempt should be made to preserve structures such as the clitoris and urethral meatus. Deep margins are rarely a problem except on the perineum, where there is little or no subcutaneous fat. In this case, removal of the capsule of the anus or some of the sphincter muscle itself can be performed without loss of anal function.

Vulvar defects for small primary tumors can usually be closed with simple mobilization of the skin and fat surrounding the vulva. In cases where primary closure is not possible, any one of a number of plastic closures is useful (discussed later). Consultation with a plastic surgeon in such cases can be invaluable.

A subanalysis of GOG 173 data also provided guidance regarding when unilateral groin evaluation is safe. GOG 173 required bilateral LN evaluation except when the tumor was more than 2 cm from a midline structure. There were 234 women enrolled on GOG 173 who had a preoperative LSG, and at least one SLN was identified during surgery. There were 105 women with midline primary tumors; 32 of these women had unilateral drainage on preoperative LSG. Four of

these patients had LN metastases on the side that did not have LSG drainage. There were 65 women with tumors located within 2 cm of the midline but not directly involving a midline structure; 27 women (42%) had unilateral drainage on LSG and bilateral surgical groin evaluation. None of these patients had metastases to the side without LSG drainage. These data support the time-honored oncologic surgical experience that midline tumors can have bilateral drainage and a unilateral LSG should not result in omission of one side (102). Conversely, if the tumor is lateralized (>2 cm from midline) and unilateral drainage is confirmed by LSG, unilateral SLNB is appropriate. The authors routinely obtain preoperative LSG, preferably by SPECT/CT (see Fig. 18.16), regardless of the location of the primary, because it helps confirm the location of the SLN in three dimensions as well as the lymphatic drainage pattern.

Overall survival for women following an adequate resection of a primary squamous carcinoma limited to the vulva and with uninvolved inguinal LNs is >90%. Stage II patients who have negative margins and uninvolved nodes but involvement of the lower vagina or urethra should obtain similar results.

Clinical Stage III and IV Cancers at Presentation

Some women have LN metastases detected by preoperative physical examination or diagnostic imaging, or at the time of their primary surgery. If a node is grossly involved at this point, most gynecologic oncologists will proceed with inguinofemoral lymphadenectomy on the assumption that there is a high likelihood of additional positive LNs.

Clinical stage II/III tumors that extend to adjacent mucosal structures often involve inguinal LNs. Many are bulky; however, some are of modest size but are considered high risk because of proximity to critical midline structures. Some primary tumors can be curatively excised by radical vulvectomy or by some variation of PE and vulvectomy. Surgical resection of 1 to 1.5 cm of the distal urethra to achieve a negative surgical margin does not appear to compromise bladder continence (103). Although radical surgery is an option for patients with locally advanced tumors, contemporary therapeutic strategies have centered on sequenced RT or CRT followed by radical surgery as a means to preserve either urinary or fecal continence or both. Vulvar cancers are sufficiently sensitive to therapeutic radiation such that function-sparing operations are feasible in selected patients with advanced disease who receive combined modality treatment (89). For patients with stage IVA tumors, similar experiences have been reported; ultraradical (exenterative) resections may also be considered for selected patients. Although occasional cures have been described with innovative combinations of surgery, radiation, and chemoradiation, treatment of patients with stage IVB vulvar cancer should be considered palliative.

Node-Positive Cancers

An optimal management strategy for clinically apparent node-positive patients is yet to be defined. Two factors impact management of regional disease: radiation can have a significant impact on sterilizing or eradicating small-volume nodal disease; surgical resection of bulky nodal disease improves regional control, and probably enhances the curative potential of RT. In multivariate analysis, Hyde et al. (104) found that, for patients with clinically positive groin nodes who underwent surgery followed by RT, the method of surgical groin node dissection (nodal “debulking” vs. full groin dissection) had no prognostic significance.

Patients who undergo bilateral inguinofemoral lymphadenectomy as initial therapy and are found to have positive nodes—clearly those with more than one positive node—benefit from postoperative irradiation to the groin and lower pelvis. RT is superior to surgery in the management of patients with positive pelvic nodes. The morbidity of combining inguinofemoral lymphadenectomy with radiation may be substantial. The highest incidences of chronic groin and extremity complications, primarily lymphedema, are seen in such cases (105).

The optimal management of patients found with a single involved lymph node has been a matter of controversy since the publication of GOG-37. In the interim, multiple retrospective studies have tried to establish whether or not such patients benefit from adjuvant RT (106,107). Recently, Mahner et al. published a retrospective analysis of 1,618 patients with vulvar cancer, among which 495 patients were noted to have (+) inguinal nodes; 447 of these patients received

surgical groin staging; 244 and 169 did and did not receive adjuvant therapy, respectively; 172 patients were found to have a single (+) LN, and 77 of these received adjuvant therapy. Multivariate regression was unable to identify a significant survival advantage in this population of patients who received adjuvant RT. The authors postulated that this could be attributable to the small number of patients in this subgroup; however, lack of benefit could not be excluded (108). Similarly, several management options are available for patients found to have positive nodes during the course of an inguinal lymphadenectomy when performed as a staging procedure: (a) no further surgical therapy may be performed; (b) the lymphadenectomy can be extended to include the ipsilateral deep nodes, the contralateral groin nodes, or both; or (c) postoperative irradiation can be added to any of these surgical options. Given the heterogeneity of vulvar cancer presentations, treatment individualization is necessary. If postoperative RT to the inguinal nodes is ultimately deemed necessary, it would be reasonable to limit resection to grossly positive nodes. Here the intent would be to minimize the likelihood of lymphedema following combined radical surgery and radiation. Excellent local control and minimal morbidity have been achieved when selective inguinal lymphadenectomy and tailored postoperative adjuvant therapy were administered to carefully selected patients (101).

The ideal management for a patient with a microscopically positive SLN who did not have a full lymphadenectomy at primary surgery is unknown and is being investigated in the GROINS VII/GOG 270 trial. In this trial, women with a negative SLN are observed, women with a metastasis ≤2 mm receive postoperative RT, and women with larger metastases are managed with inguinofemoral lymphadenectomy and RT. Concurrent radiosensitizing cisplatin is optional. Until these results are reported, uncertainty will remain about the management of SLNB-positive patients.

Management of Recurrent Squamous Vulvar Cancers

Vulvar cancer recurrences can be categorized into three clinical groups: local (vulva), groin, and distant. Published experience with a localized vulvar recurrence is surprisingly good. Recurrence-free survival (RFS) can be obtained in up to 75% of cases when the recurrence is limited to the vulva and can be excised with a gross clinical margin (109). The observation that many of these recurrences arise at sites remote from the initial primary tumor or that they occur years after apparently successful primary treatment suggests that some recurrences probably represent new primary tumors rather than the development of new disease. Recurrences in the groin, however, are almost universally fatal. A few patients may be saved by resection of bulky disease and local radiation, perhaps even using intensity-modulated RT (IMRT) in patients who have had prior pelvic radiation. Patients who develop distant metastases are candidates for palliative systemic cytotoxic or targeted CT or transition to comfort care.

Management of Nonsquamous Vulvar Cancers

Malignant Melanoma

Malignant melanoma is the second most common vulvar malignancy, and it is most commonly seen in postmenopausal Caucasian women. Typical presentations include either an asymptomatic pigmented lesion identified during a routine exam or pruritic or painful vulvar mass (Fig. 18.13) (110). A definitive diagnosis is established with a biopsy. IHC staining for melanoma-specific antigen and S100 may be helpful in uncertain cases. Melanomas may arise from existing pigmented vulvar lesions or as new isolated primary tumors. Consequently, any pigmented vulvar lesion should be considered for biopsy. Cutaneous melanoma has evolved significantly over the past 45 years. Because of the rarity of vulvar melanoma, it has not been clear whether extrapolation of prognostic and treatment data from cutaneous nonvulvar disease is appropriate for vulvar melanoma patients. Thus, until recently, multiple authors have described their experience with vulvar melanoma using one or more different staging systems (e.g., Breslow's depth, Clark's levels, AJCC staging), making standardization of prognostic groups and treatment strategies difficult. Moxley et al. reported a multi-institutional retrospective examination

of 77 patients with vulvar melanoma. Patient stages were determined using the AJCC Staging Guidelines (6th edition) (2002), Breslow's thickness, and Clark's levels, and treatments were correlated with outcomes, specifically recurrence and overall survival. Among the three staging methods, only AJCC staging was significantly correlated with OS, although Breslow's thickness was significantly associated with likelihood of recurrence (38). For this reason, the 2009 AJCC Melanoma Staging and Classification revision recommended against continued use of Clark's level and Breslow's thickness for management of T1 invasive melanoma lesions (66).

Figure 18.13 Nodular, darkly pigmented malignant melanoma of the left labium majus.

The primary treatment modality for vulvar melanoma is surgical excision. Radical vulvectomy with bilateral inguinofemoral lymphadenectomy has been the historical treatment of choice (111). Because most failures are distant, radical local resection does not appear to enhance survival. Furthermore, many patients with vulvar melanoma are elderly, with coexisting medical problems, making less radical and morbid surgery compelling. More recent reviews recommend some form of hemi-vulvectomy or wide local excision along with inguinal lymphadenectomy or SLN mapping (38,63). DOI, mitotic activity, and the presence of ulceration are prognostically significant and should be considered in treatment planning. Based on information derived from large series of patients with cutaneous melanomas at nongenital sites, regional lymphadenectomy should probably be considered a prognostic rather than a therapeutic procedure. In a multivariate analysis of 644 patients with vulvar melanoma, Sugiyama et al. (110) reported 5-year disease-specific survival rates of 68%, 29%, and 19% for patients with zero, one, and two or more positive LNs, respectively. Lymphadenectomy can be avoided in patients with superficial melanomas (<1 mm), for whom the risk of metastatic disease is negligible. SLN identification and biopsy have been increasingly applied to the surgical management of cutaneous malignant melanomas, and multiple authors assert that for those surgeons who are competent with the technique, SLN mapping and biopsy should be considered a standard practice, with false-negative rates extrapolated from squamous carcinoma of the vulva

comparable to other disease sites as are typical in breast cancer and cutaneous, nonvulvar melanoma (38,63).

High-Risk Vulva-Localized and Metastatic Melanoma

Until more recently, systemic therapy for high-risk localized or metastatic melanoma was considered strictly palliative; durable responses were rare, and adverse effects were considerable. Interferon α-2b, dacarbazine, temozolomide, and platinum-based cytotoxic therapies have shown activity in patients with small-volume tumor burden; however, toxicities are considerable, with limited improvements in survival (63). More recently, with improved molecular characterization of cutaneous (nonvulvar) melanomas and the development of multiple targeted inhibitors that have dramatically improved survival for this disease, systemic therapies for high-risk localized as well as metastatic and recurrent melanoma follow the evolving treatment paradigms of nonvulvar malignant melanoma. Examples of such targets with associated inhibitors are B-Raf (vemurafenib), c-Kit (imatinib), and CTLA-4 (ipilimumab) (112). A more involved discussion of systemic therapy for melanoma is beyond the scope of this chapter. For those gynecologic oncologists without considerable experience in the treatment of melanoma patients, we recommend early referral for high-risk localized vulvar or metastatic melanoma patients to a medical oncologist or gynecologic oncology center that specializes in the systemic care of malignant melanoma patients.

Patients with superficial lesions have an excellent chance for cure after surgical resection; however, patients with deeper lesions, or metastases at the time of diagnosis, have a worse prognosis. These patients are good candidates for investigational trials.

Basal Cell Carcinoma

BCCs should be removed by excisional biopsy using a minimum surgical margin of 1 cm. Lymphatic or distant spread is exceedingly rare (113). Local recurrence may happen, particularly in tumors removed with suboptimal resection margins.

Adenocarcinoma

Patients presenting with vulvar adenocarcinoma should first undergo a clinical evaluation to determine whether the lesion in question is a vulvar cancer or a metastasis. Despite the paucity of data regarding the evaluation and treatment of vulvar adenocarcinoma, resection of localized disease with a radical margin is recommended by radical wide excision, and hemi-vulvectomy or radical vulvectomy seem appropriate (88). Some form of inguinal lymphadenectomy should be included with primary surgical resection. RT may have a role in enhancing local control for women with large primary tumors or inguinal metastases.

Paget’s Disease

Paget’s disease is associated with a concurrent underlying invasive adenocarcinoma component in approximately 15% of cases (114). As many as 20% to 30% of these patients will have or will later develop an adenocarcinoma at another nonvulvar location (115,116), although more recent series suggest a lower incidence of secondary malignancies (117). Observed sites of nonvulvar malignancies developing in patients with extramammary Paget’s disease include breast, lung, colorectum, gastric area, pancreas, and upper female genital tract. Screening and surveillance for tumors at these sites should be considered in patients with Paget’s disease.

Paget’s disease should be resected with at least a 1 cm margin. If underlying invasion is suspected, the deep margins should be extended to the perineal fascia. Black et al. (118) showed that patients with microscopically positive margins had a significantly higher rate of recurrence; however, with extended follow-up, all patients eventually recurred. Others have shown that despite surgical efforts to the contrary, microscopically positive margins are frequent, and disease recurrence

is common regardless of margin status. Repeat local excision of recurrent disease is usually effective in the absence of invasion (116).

NONSURGICAL THERAPY

Imiquimod is an immune modulator that is believed to affect the function of the Toll-like receptor (Tlr) as a costimulatory molecule for T cell-mediated immune response to malignant cells. It has well-documented activity for treatment of genital warts as well as vulvar dysplasia. Reportedly, it also has activity in extramammary Paget's disease. In several small case series, complete response (CR) rates of as much as 92% have been reported (119,120).

Tumors Metastatic to the Vulva

Treatment of tumors metastatic to the vulva have a uniformly poor prognosis, and treatment should focus on local control. As with bulky, primary site vulvar cancers, a multimodal approach seems to provide some opportunity for long-term survival, as well as enhanced local tumor control and organ preservation.

Cutaneous vulvar lymphatic metastases may occur as in-transit tumor emboli from anorectal tumors, or as retrograde flow metastases when bulky tumors of the cervix or uterus obstruct the normal lymphatic drainage patterns (Fig. 18.14). These metastases are multiple and are often bilateral. Their histology reflects that of the primary tumor. Because this metastatic pattern is associated with advanced tumors, the primary tumor is usually readily detectable by examination.

Figure 18.14 Multiple in-transit lymphatic metastases from a cloacogenic carcinoma of the rectum. A large constricting lesion was evident on rectal examination.

SURGICAL TECHNIQUES

In planning a surgical approach, it is important to take into account the patient's age, medical comorbidities, desire for sexual function preservation, tumor size, and disease stage. In the case of a locoregional vulvar cancer, surgery will remain the first choice of therapy (121).

Wide Radical Excision

Several names have been applied to the procedures used to resect small vulvar cancers: partial deep excision, radical wide excision, radical local excision, wide local excision, modified radical vulvectomy, and hemi-vulvectomy. Regardless of the preferred nomenclature, the surgical procedure should be adequately defined and described. Surgical incisions are devised to allow for at least a 1 to 2 cm resection margin encompassing the primary lesion (Fig. 18.15). Dissection is carried to the

deep perineal fascia. Tumors located close to the anus or anal sphincter can be managed by radical wide excision with sphincter or flap repair, or they can be treated with combined modality therapy, as outlined in the RT section. Most wide radical excision sites can be closed primarily. In some patients, fasciocutaneous pedicle flaps can be used to facilitate coverage of the vulvar defect. Some form of inguinal lymphadenectomy, performed through a separate incision, is generally combined with radical wide excision.

Figure 18.15 An early vulvar cancer identified in a background of VIN III. A planned 2-cm margin is outlined.

Ambulation is begun, if possible, on the day of surgery. Perineal irrigation and air (natural or forced) drying is started within 24 hours of the surgery. The average hospital stay for patients undergoing radical wide excision is usually one to two days. Wound breakdown, usually of minor degree, is reported in at least 15% of cases (122). The incidence and severity of groin complications is proportional to the extent of the lymphadenectomy.

Inguinofemoral Lymphadenectomy

Appropriate surgical management of the groin nodes has been evolving for many years. Original descriptions of radical vulvectomy included en bloc resection of the vulva with inguinal and pelvic lymph nodes. The extent of lymphadenectomy was steadily reduced, first eliminating the pelvic node dissection and then reducing the extent of the groin dissection. The concept of superficial inguinal lymphadenectomy was proposed in the late 1970s; however, this approach was ultimately rejected by gynecologic oncologists owing to an unexpectedly high relapse rate (Table 18.4) (123).

TABLE 18.4 Unanticipated Groin Failure in Patients with Negative Superficial Lymphadenectomy

Investigators	No.	%
Burke et al. (124)	4/76	5.2
Berman et al. (125)	0/50	0
Stehman et al. (126)	6/121	5.0

Gordinier et al. (127)	9/104	8.6
Total	19/351	5.4

The most common current approach starts with an incision parallel to and just above or below the inguinal ligament. The incision is carried through Camper's fascia, and small flaps are elevated to expose the lymph node-bearing fat and preserve blood supply to the skin. There is no need to skeletonize the femoral artery; however, identification of the medial wall of the femoral vein helps ensure removal of the medial fat pad, where the SLN is frequently found. The dissection can usually be performed solely with electrocautery or a small vessel-sealing device. The saphenous vein is encountered at the lower medial margin of the dissection, and whenever possible, should be preserved to reduce the risk for postoperative lymphedema. The dissected specimen is removed for pathologic assessment. The skin incision can be closed with either staples or absorbable sutures. A closed-suction drain is placed and removed when output is <25 mL/day.

Unfortunately, historic nomenclature for performance of inguinofemoral lymphadenectomy has been inconsistent and often confusing. The authors find the terms "deep" and "superficial" especially troubling and, in the SLN era, largely meaningless. A satisfactory groin dissection has been performed when the inguinal ligament, adductor longus, saphenous vein, medial wall of the femoral vein, and the fossa ovalis have been identified, and the LNs and most adipose tissue within these boundaries are removed. Cadaver studies identify 8 to 10 LNs in the femoral triangle defined by the inguinal ligament, sartorius muscle, and adductor longus. Surgical node counts are dependent on the thoroughness of the surgeon and pathologist.

Sentinel Lymph Node Biopsy Technique

As discussed previously, SLNB should be offered as an alternative to inguinofemoral lymphadenectomy as part of primary management in women with tumors ≤4 cm, with no suspicious LNs on physical examination or imaging and no prior groin surgery or radiation that might interfere with lymphatic drainage pathways. There is insufficient evidence to make a recommendation regarding SLNBs in women who have tumors >4 cm, or multifocal disease (128,129).

The authors obtain an LSG in most patients. If possible, the surgeon should perform the injection for vulvar cancer or ensure that the nuclear medicine specialist is comfortable with injecting the vulva. The injection is painful; EMLA cream can be helpful in decreasing the associated discomfort. SLNs can be identified using a dye such as isosulfan blue, blue violet, or methylene blue, or a radioactive tracer called technetium-99m (99mTc) with LSG; the blue dye and radiotracer can be used alone or in combination. If using technetium-99m, 0.1 to 0.5 mCi radiolabeled filtered Tc-99m is generally injected one day prior to surgery, followed by the performance of a preoperative scintigraphy (usually on the morning of surgery) (130).

Various techniques have been described for SLN. de Hullu et al. described their technique involving a combination of technetium-99m as well as blue dye. In their protocol, 0.2 to 0.6 mL of 60 MBq technetium-99m-labeled nanocolloid is injected circumferentially around the tumor and LSG is performed, and skin sites correlating with the findings of the lymphoscintigram SLN location are marked with a pencil. On the morning of surgery, following induction of anesthesia, 2.0 mL of patent blue dye (2.5% in aqueous solution containing 0.6% sodium chloride and 0.05% disodium hydrogen phosphate) is injected in the same locations. SLNs are then identified using a handheld gamma probe. For SLN dissections employing only blue dye, 4 mL of isosulfan blue can be injected adjacent to the primary tumor. Following injection, the tissues can be massaged to aid with dye dispersal. After approximately 5 minutes, a groin incision can be made and LN dissection carried out. In those patients with midline tumors, bilateral injections should be performed (130).

The half-life of the radiocolloid is approximately 6 hours, so a patient can be injected in the morning and operated on the same day. Frequently, this is not possible, and a second injection is necessary. If blue dye is utilized, it is visible in the SLN for only 45 minutes. The authors typically inject the radiocolloid prior to sterile prepping and draping, and inject the blue dye only when the team is prepared to make an incision. All injections are intradermal, 0.5 to 1.0 cm from the tumor itself. Intratumoral or subcutaneous injections will most likely result in a failure to identify the SLN. Transdermal

localization of the SLN using a handheld gamma counter is possible in most patients. The SLN is identified using a tenfold higher measured radiation than the basal count at the primary injection site (130).

There are pros and cons to the various methods and injection materials used in SLN dissection. If using blue dye, the color becomes visible in the nodes and lymphatic channels, quickly allowing for rapid SLN dissection (101). There is a low rate of hypersensitivity reactions to blue dye, and the dye is also inexpensive (131,132). The disadvantage of using blue dye is that it rapidly passes through the lymphatics, and so it is possible to miss the SLN (131). The advantages of LSG include the ability to determine the number and location of the SLNs preoperatively and to detect a SLN outside the nodal basin; however, the cost of equipment associated with the use of a radiotracer, as well as the involvement of nuclear medicine, requires more coordination between the operating room and radiology departments (131).

SPECT/CT is also valuable for locating the SLN in relation to the femoral vessels (Fig. 18.16). A small incision is made over the location of the SLN. Although data are limited, clinical experience indicates that the SLN is commonly medial to the femoral vein and just above the adductor longus muscle. Once the SLN is removed, the wound is scanned for any residual radioactivity. It is imperative that all SLNs in the groin are removed. The gamma counter may detect second echelon nodes in the pelvis just above the inguinal ligament. If blue lymphatic channels lead to a node that is not hot or blue, it is still considered an SLN.

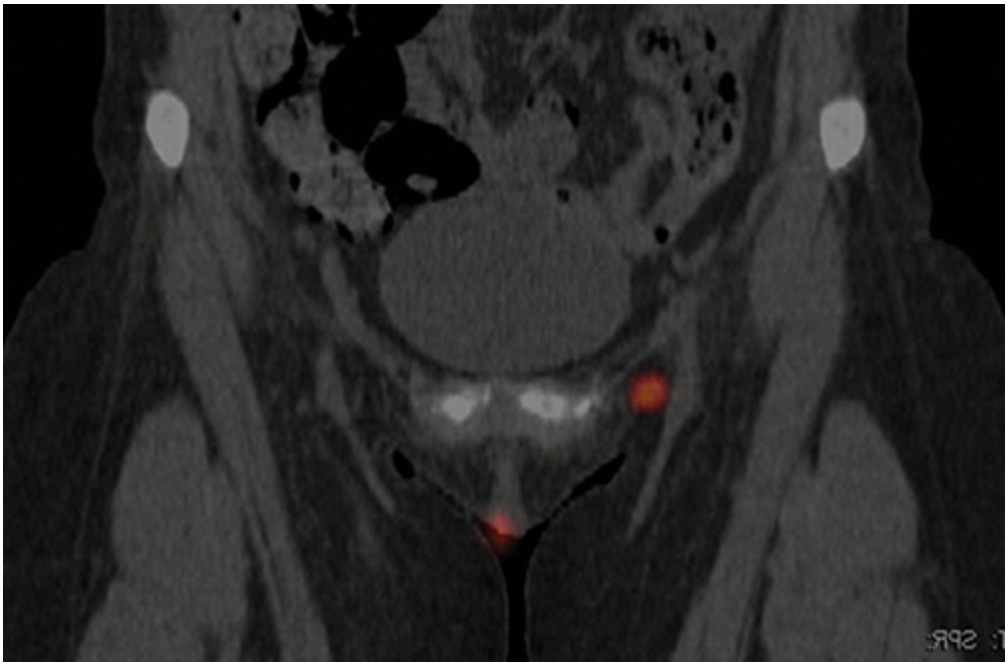

Figure 18.16 SPECT/CT demonstrating left sentinel lymph node just medial to the femoral vein. SPECT/CT provides superior localization of sentinel lymph nodes compared with 2-dimensional lymphoscintigraphy. The number of sentinel nodes identified should correspond to the number removed at surgery.

Studies in vulvar cancer in which SLN dissection was performed, followed by a completion inguinofemoral lymphadenectomy, suggest that the SLN is accurate in identifying LN metastasis with a NPV approaching 100% (132). A meta-analysis undertaken by Mead et al. evaluated SLN detection rates between blue dye, radiotracer, and combination injection. Within this meta-analysis, combined blue dye and 99mTc testing had the highest rate of SLN detection; pooled rates are 94.0% for 99mTc (95% confidence interval [CI], 90.5 to 96.4), 68.7% for blue dye alone (95% CI, 63.1 to 74.0) and 97.7 (95% CI, 96.6 to 98.5) for 99mTc and blue dye combined (133).

Within the pathology laboratory, the evaluation of SLNs requires detailed and systematic evaluation of the submitted specimen. The LN sample submitted requires proper identification of patient name, source, name of the surgeon submitting, node location, date, and number of nodes identified.

In sectioning SLNs, it is recognized that, to achieve close to 100% identification of all metastases, the section spacing must be one-half the diameter of the tumor to be detected (133). The LN or nodes are sliced in 1 to 2 mm slices, cutting the LN at right angles to the long axis of the node. All of the LN tissue (slices) should be submitted for study.

Once the nodal tissue is embedded in the paraffin block, the node slices can be cut at closer intervals to improve tumor detection. Although there are some variations on this sectioning method, our approach is to cut three sections from each block. After facing the block to get a full face of the sectioned nodal tissue, the first 5-µm section is cut. This section is stained with H&E. We then cut 100 microns into the block and cut another 5-µm section. This second slide is held for additional H&E staining, or IHC, if the first and last H&E sections have equivocal findings. We then cut an additional 100 microns into the block and take the third section. This slide is stained with H&E. The pathologist reviews the two H&E slides, and if the findings are equivocal, the held second slide is then studied.

Limited information is available regarding ideal surveillance following SLNB. Our preferred technique is ultrasound, since it is noninvasive and the internal architecture of the LNs can be imaged (Fig. 18.17A, B). Early detection of a groin failure may help improve outcomes with multimodality treatment.

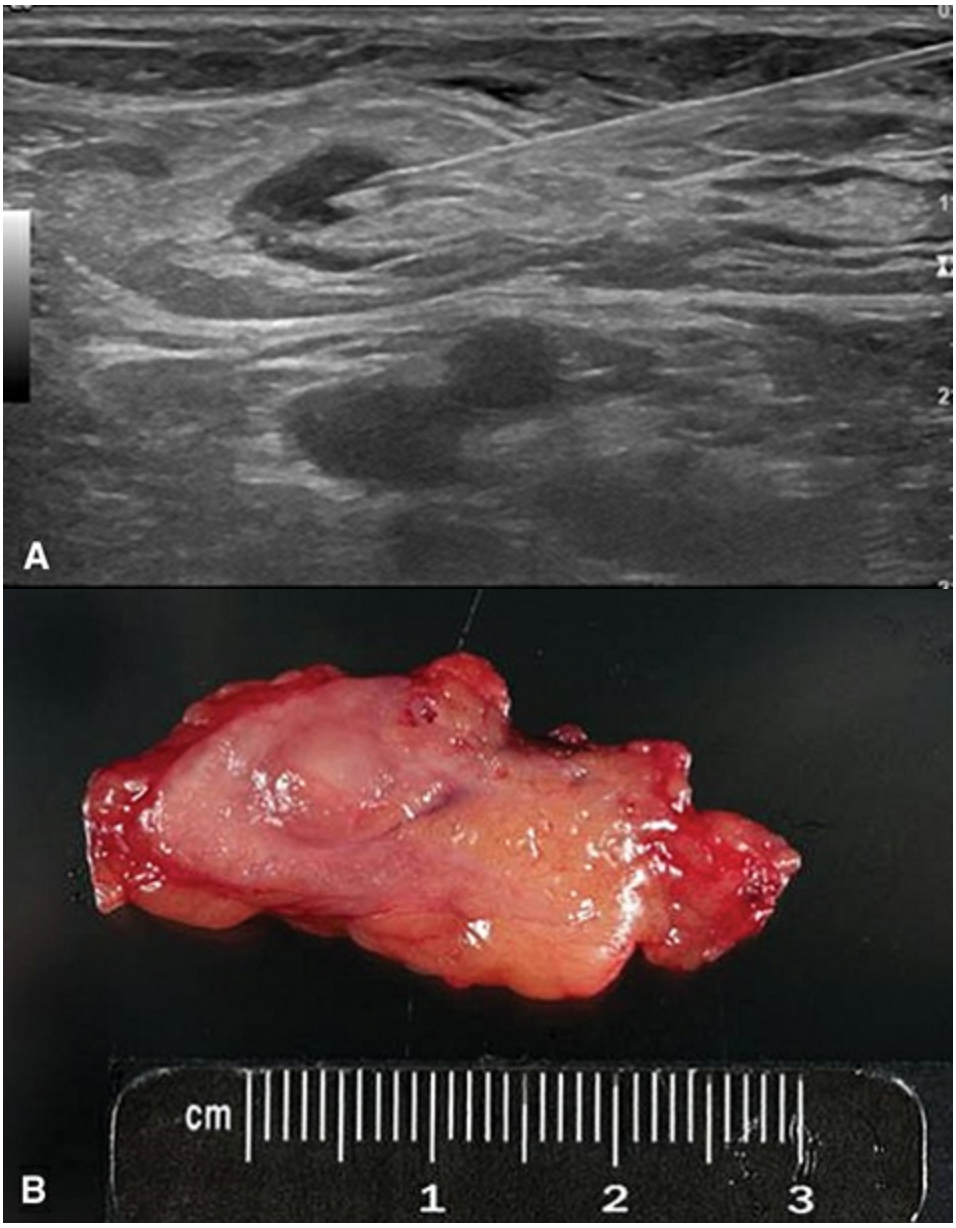

Figure 18.17 Close surveillance following sentinel lymph node biopsy is recommended because groin relapse is difficult to treat. Physical examination is very unreliable.

A: Ultrasound can be very effective, as illustrated here. Six months after negative sentinel lymph node biopsy, ultrasound detected a 5-mm metastasis. Fine needle aspiration confirmed metastatic disease. B: The patient underwent inguinal femoral lymphadenectomy and radiation therapy. She remains disease free at 2 years.

Surgical Resection for Recurrent Disease

The site and volume of recurrent vulvar lesions dictate both resectability and potential for cure. Recurrences can be categorized as local (vulvar), inguinal, or distant (pelvis, lower extremity, or beyond). Surgical therapy plays a curative or palliative role in selected subsets of patients with recurrent disease.

Wide Radical Excision

As many as 75% of patients with recurrent disease limited to the vulva can be salvaged by radical wide excision (partial deep vulvectomy) or reexcision of the tumor (109,134). Surgical principles of recurrent vulvar tumors are identical to those for primary tumors: wide excision with a measured normal tissue margin of at least 1 to 2 cm. Particular attention is also focused on obtaining a clear deep margin. Because most patients have had prior operative therapy, primary closure of the vulvar defect is frequently more difficult. More complex reconstructive efforts may be needed to restore tissue integrity.

Radical Vulvectomy

Rarely, radical vulvectomy may be indicated for recurrent vulvar cancer. The classic description of en bloc radical vulvectomy and bilateral lymphadenectomy can be based on either a “butterfly” or “longhorn” approach. The butterfly incisions use convex “wings” over the groin and around the anus to facilitate closure of the defect (Fig. 18.18). The longhorn incisions were developed to limit skin resection over the groin in an attempt to reduce wound breakdown (135). The arcing superior incision is placed from the lateral margins of the groin dissection across the mons pubis. The lateral vulvar incisions are placed at the labiocrural folds, because these topographical landmarks represent the most lateral location of the superficial vulvar lymphatics. The perianal incision is placed to allow resection of the perineal body. These incisions are taken to the level of the deep inguinal and perineal fascia and permit en bloc removal of both superficial and deep groin nodes, the entire vulva, and an intervening skin bridge.

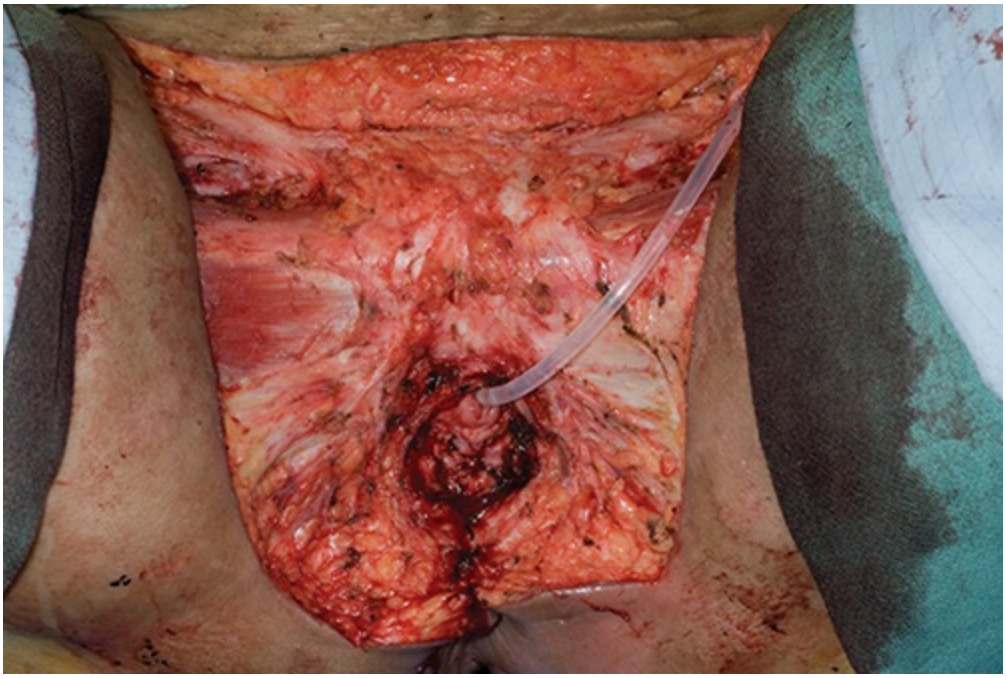

Figure 18.18 Butterfly incision described for a traditional radical vulvectomy with bilateral inguinal lymphadenectomy. Modern indications for radical vulvectomy are exceedingly rare. The patient shown in Figure 18.5 was treated with concurrent chemoradiation and still had bilateral gross tumor. This figure demonstrates the field following resection.

After removal of the specimen, the skin and mucosal edges are undermined to permit mobilization and primary closure with delayed absorbable suture. Some degree of tension at the suture lines is unavoidable, particularly in the perineal body and periurethral areas. Closed-suction drains are usually placed in the groin sites to remove excess lymphatic and serous fluid accumulations, and are usually removed when drain output is minimal (5 to 14 days).

A small degree of wound breakdown is seen in approximately 50% of patients. Local wound care results in satisfactory secondary healing in most of these cases. Lymphocyst formation is relatively common and frequently presents as a tense but nontender groin mass. Percutaneous needle drainage is usually sufficient, but occasionally replacement of a groin drain may be required. Inguinal cellulitis, lower extremity lymphangitis, and lymphedema are uncommon late sequelae. The incidence of these complications is related to the extent of groin therapy, and is highest in patients treated with superficial and deep lymphadenectomy followed by inguinal RT. The 3-incision concept preserves the radicality of the vulvar resection while retaining skin over the groin. Consequently, the incidence of major wound breakdown is significantly reduced to approximately 15% to 20% of cases (136). As with other techniques, the incidence and severity of groin complications such as infection, wound breakdown, or lymphocyst formation remain high (122).

Pelvic Exenteration

Curative resection may still be possible when vulvar recurrence extends to the vagina, proximal urethra, or anus. Selected patients have achieved long-term survival after PE for such recurrences (137,138). The surgical approach in these cases should be individualized to the size and location of the recurrent tumor, prior therapies, and the age and overall health of the patient. Patients considered for PE should have a thorough preoperative evaluation to exclude the presence of regional and/or distant metastases. Frequently, anterior or posterior exenteration with an extended vulvar phase will provide excellent resection margins, while allowing preservation of either urinary or fecal continence. The techniques used to perform the exenteration are identical to those routinely used for the treatment of women with recurrent cervical carcinoma. Multiple vulvar and perineal reconstructive techniques have been described for coverage of large surgical

defects (139–141).

Resection of Groin Recurrence

Patients who develop isolated groin recurrence should be treated with multimodality treatment if radiotherapy is still an option. Surgical resection should be viewed with caution in the previously irradiated patient. A resection with negative margins usually requires the resection of vessels or bone with plastic reconstruction. Ultraradical surgery attempted in young patients with outstanding performance status and a small relapse in an irradiated groin that appears resectable on preoperative imaging is associated with high morbidity. Extended survival is possible for the few patients who achieve control of recurrent disease in the groin and do not later manifest distant metastasis (142). Isolated groin recurrence is a rare event, so the data to support the efficacy of this treatment are anecdotal.

Vulvar Reconstruction

With careful planning and adequate tissue mobilization, most vulvar defects can be closed primarily. When large portions of the vulva have been resected, when tissue mobility is poor, or when RT has been administered previously, primary closure may not be feasible. Alternate tissue sources must be considered for these difficult cases. Categorically, the two types of techniques commonly employed for extensive vulvar reconstruction are fasciocutaneous flaps and myocutaneous flaps. Local advancement flaps can be used for smaller defects, and pedicled flaps harvested from the inner thigh, gluteal fold, and the abdomen are used for larger defects. The techniques referenced in the next section should be employed only by surgeons who are regularly practiced in their use.

Fasciocutaneous Advancement Flaps.

A variety of fasciocutaneous advancement flaps are described for vulvar reconstruction. These flaps include skin, underlying subcutaneous tissue, and underlying fascia. Nearly all of them are based on the rich, redundant blood supply from the internal pudendal artery and subsequent superficial perineal artery perforators that approach the vulva and perineum, primarily from the posterior and lateral directions. This is significant because most vulvar fasciocutaneous flaps are designed to preserve fasciocutaneous perforators from these directions. Studies performed by John et al. have evaluated approaches to perineal reconstruction following resection of large portions of the vulva and perineum. Following a wide local excision, the most common reconstructive method is the local flap. If larger amounts of tissue are removed, the next choice for reconstruction is the V-Y advancement flap, with or without incorporation of the gracilis muscle (143).

Among gynecologic oncologists, the most widely utilized pedicle flap has been the rhomboid flap; however, lotus pedicle flaps are also commonly used by plastic surgeons for closure of large vulvar defects. The lotus petal fasciocutaneous flap, irrespective of the specific design, is supplied primarily by perforating branches of the internal pudendal artery, and also through nonperforating branches of the inferior gluteal artery. The lotus petal flap best respects a natural anatomic fold at the donor site leading to the most cosmetic donor site closure (144). Although a detailed discussion of the techniques employed for these flaps is outside the scope of this chapter, references for multiple fasciocutaneous flaps that have been employed by these authors are referenced here (140,145,146).

Myocutaneous Flaps.

Myocutaneous flaps, in comparison with fasciocutaneous advancement flaps, include a segment of muscle, and usually receive their blood supply and innervation through an identifiable, named neurovascular pedicle. These are usually large, thick tissue sources that are best suited for the reconstruction of substantial defects. Each of the following listed flaps has notable advantages and disadvantages. Several types of myocutaneous flaps, namely the gracilis, gluteus maximus, tensor

fascia lata, vastus lateralis, and vertical rectus abdominus flaps, have been used to repair and reconstruct large vulvar and groin defects (141). Historically, the gracilis flap was used to fill large vulvar and urogenital defects; however, in recent decades, the myocutaneous flap most commonly described for extensive vulvar reconstruction is the transverse rectus abdominis muscle (TRAM) flap based on the robust inferior epigastric pedicle. TRAM flaps are useful for repairing defects in the anterior vulvar regions (147). As with fasciocutaneous flaps, a detailed description of each flap is beyond the scope of this chapter; however, a number of techniques are referenced here (145,148).

Vulvar reconstruction with myocutaneous flaps has numerous disadvantages when compared with fasciocutaneous flaps, namely, increased intraoperative complexity, requirement for meticulous wound care postoperatively, and requirement for larger incisions. Myocutaneous flaps require the sacrifice of functional muscles. Fasciocutaneous flaps, in contrast, do not sacrifice muscle and can be performed with a more modest-sized flap thickness, resulting in less morbidity (147). Regardless of method or type of flap performed, it is important to monitor patients in the postoperative period for wound dehiscence and flap necrosis (143).

RADIATION THERAPY

Early accounts of poor survival rates after primary RT of vulvar carcinomas led some investigators to surmise that radiotherapy had a narrow therapeutic role in the curative management of patients with vulvar cancer (149). The use of high doses of radiation alone, delivered with low-energy ^{60}cobalt photons and en face electron boosts, in patients who were mostly poor surgical candidates, resulted in a suboptimal therapeutic benefit between tumor control probability and normal tissue complications (150). More modern-day practices, such as incorporating consecutive daily fractionation, attention to dosimetric planning detail, and appreciation of vulvar and low pelvic radiation tissue tolerance limits, have undoubtedly shown that relatively high doses of radiation can be delivered safely. RT is now accepted as an important element in the multidisciplinary management of patients with vulvar cancer.

Adjuvant Radiotherapy to the Vulva

Following initial resection of a vulvar primary tumor, various surgico-pathologic features are associated with a higher risk of local recurrence, including tumor margins <8 mm after tissue fixation (deep or at the skin surface), lymph-vascular space invasion, and deep tumor penetration (80,81,151).

Avoidance of local recurrence is critical given poor salvage rates, particularly among those with nodal relapse. Although no prospective trials of postoperative vulvar site RT have been completed, adjuvant radiation of the primary tumor bed in selected patients with close/positive margins or multiple other high-risk features (LVSI, depth >1 cm, or size >4 cm with high-grade histology) does improve vulvar tumor control (152,153). For example, in a retrospective series by Faul et al., (152) patients with positive surgical margins had a significant reduction (33% vs. 69%) in the risk of locoregional recurrence, if receiving adjuvant RT. A similar benefit was seen for patients with close surgical margins (5% vs. 31%). Recent data also highlighted a dose–response relationship for patients with close (≤5 mm) or positive margins, where patients receiving ≥56 Gy had lower rates of vulvar recurrence compared with ≤50.4 Gy (21% vs. 34%, $p = 0.046$) (153). In combination, the data suggest that patients with close/positive margins benefit from adjuvant RT to the vulva to reduce risk of relapse. Nonetheless, after RT, the rates of locoregional relapse remain elevated (16% to 35.7%), suggesting that reexcision, when feasible, may be appropriate (152,153).

Adjuvant Regional Radiotherapy

The requirement for surgical evaluation of the LNs depends largely on the risk of involvement, which is driven

predominantly by DOI and clinical tumor size (88). In general, well-lateralized T1a lesions (<2 cm in size with ≤1 mm stromal invasion) have a low probability of nodal involvement. The application of sentinel node biopsy for T1b lesions (≥2 cm in size or >1 mm stromal invasion) enables avoidance of the morbidity of inguinal dissection, although the role of completion dissection versus adjuvant RT alone in sentinel node-positive disease is the question being addressed in GROINSS-VII.

GROINSS-VII was initially designed to have women with negative SLNs observed, whereas patients with positive SLN(s) were to receive adjuvant RT with or without CT. Interim analysis demonstrated a high rate of recurrences based on the size of LN metastases (2.1% for LN ≤ 2 mm vs. 20% for LN > 2 mm) (94). Based on these findings, the trial protocol was modified to mandate completion dissection and then possible adjuvant RT for patients with macrometastases defined as >2 mm. Although these interim results suggest suboptimal efficacy of RT for macrometastases, some concerns have been raised regarding contouring and target volume delineation described in the protocol, prompting modification of RT contouring details (154). Additional controversy exists regarding the definition of macrometastases, with GROINSS-VII identifying this entity as metastases >2 mm. With most patient accrual completed, the final results of this trial, including detailed analysis of dose and volume, will help guide the treatment of sentinel node-positive patients. With the interim findings, patients with macrometastases in sentinel nodes should be considered for inguinal node dissection followed by assessment for adjuvant RT.

GOG 88 attempted to define the optimal approach to clinically negative inguinal nodes in a trial that randomized patients between inguinal node irradiation and radical lymphadenectomy (followed by inguinopelvic radiation in patients with positive nodes) after resection of the primary tumor (155). This study was closed after the entry of only 58 patients when there appeared to be a higher rate of groin recurrence in the RT arm (0% vs. 18.5%). However, a number of criticisms arose from the treatment protocol because of lack of CT-based planning, underdosing of the inguinal nodes due to technique, and lack of radiographic staging. Review of treatment delivery revealed that all five patients who failed had inadequate tumor doses (<47 Gy), reflecting the unaccounted for depth of inguinal nodes (mean 6.1 vs. 3 cm prescribed depth) (156,157). Appropriate volume-based contouring guidelines have now been established on the basis of patterns of recurrences (158).

Despite GOG 88 findings, a number of retrospective studies have suggested that regional prophylactic RT is an effective method of preventing groin recurrences with minimal morbidity when appropriately delivered (158–161). In a large single-institution retrospective analysis, Katz et al. (158) reported no differences in the inguinal relapse rates for patients treated with prophylactic groin irradiation compared with those undergoing lymph node dissection. Combined across retrospective series, the incidence of groin recurrence following treatment of the undissected nodal region appears to be 0% to 12%, the lowest occurring in a series using three-dimensional treatment planning and intensity-modulated RT. Improved and greater application of pretreatment radiographic staging may further contribute to lower inguinal recurrence rates.

Although the role of prophylactic RT in the undissected but high-risk groin remains controversial, there is strong evidence that adjuvant RT after surgical assessment improves regional tumor control and survival in patients who have documented nodal metastases following inguinal node dissection. Retrospective studies suggested that patients with metastases to multiple nodes or extranodal tumor extension had an increased risk of groin recurrence after radical surgery, and therefore may benefit from RT (162). However, the critical role of RT was not appreciated until 1986, when Homesley et al. (163) published prospective GOG trial results.

In GOG 37, 114 patients with involved inguinal nodes underwent radical vulvectomy and inguinal lymphadenectomy. Patients who had positive inguinal nodes were randomized intraoperatively to receive either pelvic node dissection or postoperative irradiation to the pelvic and inguinal nodes. This trial was closed before the projected accrual goal, based on interim analysis identifying a significant survival benefit with RT (68% vs. 54%, $p = 0.03$). The differences between the 2-year survival rates of patients treated with RT or pelvic dissection were most marked for patients presenting with clinically positive nodes (59% vs. 31%, respectively) and for those with two or more positive groin nodes (63% vs. 37%, respectively). Extended follow-up showed a nonsignificant 6-year overall survival benefit to the radiation arm (51% vs.

41%). Yet the cancer-related death rate was significantly higher for pelvic node resection than for radiation (HR, 0.49 [95% CI, 0.28 to 0.87]; 51% vs. 29%) (105). Coupled with higher rates of inguinal failure for patients treated with surgery alone (24% vs. 5%), these results emphasized the poor salvage rate seen in patients developing groin recurrences. Interestingly, 8% of patients in both treatment arms had recurrences at the primary site, even though the vulva was not included in the radiotherapy field, raising the question of whether selective radiation to the vulva may have further increased the benefit of radiation.

The largest challenge at present is whether RT should be applied to patients with a single node with an adequate dissection and without ulceration or extracapsular extension. On unplanned subset analysis in GOG 37, the survival benefit seen with radiation was maintained for those with N2/3 disease, ≥2 positive lymph nodes, or inadequate nodal dissection (defined as node positivity ≥20% of dissected nodes). On the other hand, no significant difference in survival was seen for patients with one microscopically positive node; the authors later commented that the number of patients in this subset was insufficient for reliable analysis. Retrospective data suggest that patients with even a single positive inguinal nodal metastasis benefit from adjuvant radiation, particularly if the groin dissection was less extensive in scope or if a nodal positive ratio is >20% (105,106,108,164). More recent analyses from SEER and a retrospective multicenter cohort study from Germany suggest a benefit to adjuvant RT even in patients with a single positive node (108,164). Another indication that radiation may be useful in the single positive inguinal lymph node patient is derived from data in the GROINSS-V study (165). Patients with a single sentinel node metastasis larger than 2 mm had a lower DSS (69.5%) than patients with a single sentinel node metastasis ≤2 mm (94.4%, $p = 0.001$). Overall, these findings suggest that patients with N2/3 disease, ≥2 positive LNs, or inadequate nodal dissection should receive adjuvant radiation. In addition, patients with a single positive LN should be strongly considered to receive radiation based on suboptimal outcomes and supportive retrospective data.

Despite nodal dissection and adjuvant radiation, outcomes are poor in node-positive patients, even in the modern era. In GOG 37, the 6-year overall survival was only 51%, while retrospective data show similarly suboptimal survival (105,106,108,164). Other prospective GOG trials have proven high rates of distant relapse among node-positive patients, particularly in those with multiple node involvement (89,105). With this appreciation and the growing application of concurrent CT in the preoperative setting, the role of CT postoperatively has yet to be clearly addressed. Recent registry-based data using the National Cancer Database (NCDB) illustrated a benefit with predominantly concurrent CT (HR, 0.62, $p < 0.001$), providing further suggestion of the potential role of CT.

Preoperative Radiotherapy

In patients who present with more advanced primary tumors, RT may be delivered preoperatively. Advocates of this approach have listed several theoretical advantages for patients with locally advanced vulvar carcinomas:

1. Less radical resection of the vulva may be adequate to achieve local tumor control after preoperative treatment of the vulva with radiation;
2. Tumor regression during radiation may allow the surgeon to obtain adequate tumor-free surgical margins without sacrificing important pelvic structures such as the urethra, anus, and the clitoris;
3. RT alone may be sufficient to sterilize microscopic regional disease when the inguinal nodes are not radiographically determined to be involved and may mobilize fixed and matted nodes, facilitating subsequent surgical excision.

Although the published experiences with preoperative single-modality RT are small, several investigators have reported excellent responses and high local control rates after treatment of advanced tumors with relatively modest doses of radiation followed by local resection (162,166). These early reports provided evidence that radiation could significantly debulk advanced local disease and allow for more conservative, viscera-sparing surgery, while preserving good local

control.

Data has since emerged that support the therapeutic benefit of concurrent CT with radiation, typically followed by limited surgical resection, in managing locally advanced disease (89,167,168). Typical regimens have included combinations of radiation coadministered with 5-fluorouracil (5-FU), and cisplatin or mitomycin C. Most investigators have observed remarkable regressions of bulky lesions with concurrent CT with RT, suggesting that therapeutic responses may be better than would be expected with RT alone. Randomized trials of the role of concurrent CT have not been done and are unlikely to be feasible within this disease, given the small number of patients and heterogeneity of clinical presentation. However, recent single experimental arm trials have demonstrated improved local control and survival when concurrent cisplatin CT was added to radiation in locally advanced vulvar cancers (89,167).

The most compelling data in support of concurrent CRT in the management of locally advanced disease come from two large prospective phase 2 trials performed by the GOG. In the first study (GOG protocol 101), 71 evaluable patients with locally advanced T3 or T4 disease who were deemed not resectable by standard radical vulvectomy underwent preoperative CRT (167). CT consisted of two cycles of 5-FU and cisplatin. Radiation was delivered to a dose of 47.6 Gy, using a planned split-course regimen, with part of the radiation given twice daily during the 5-FU infusion. Patients underwent planned resection of the residual vulvar tumor, or incisional biopsy of the original tumor site in the case of complete clinical response (cCR), 4 to 8 weeks after CRT. A cCR was noted in 33 of 71 patients (47%). Following vulvar excision or biopsy, 22 patients (31%) were found to have no residual tumor in the pathologic specimen. In all, only 2 of 71 patients (3%) had unresectable disease after CRT, and in only 3 patients was it impossible to preserve urinary and/or gastrointestinal continuity following complete resection of the primary tumor. With a median follow-up interval of 50 months, 11 patients (16%) have developed locally recurrent disease in the vulva (167). These results are all the more notable considering the relatively low dose of radiation used in these typically bulky, advanced tumors.

Building on this experience, investigators sought to study weekly cisplatin (40 mg/m^2) coadministered with radiation (GOG protocol 205). Additionally, this study eliminated the break in RT and increased RT dose to 57.6 Gy. On this trial, 58 evaluable patients with untreated locally advanced T3 or T4 disease not amenable to standard radical vulvectomy underwent preoperative radiation with concurrent CT (89). Following preoperative therapy, 64% had a clinical CR and 50% had a pathologic complete response (pCR), a notable improvement compared with the regimen used in GOG 101. In an attempt to further improve on the pCR rate, GOG 279 has been designed with use of concurrent gemcitabine with cisplatin, integration of IMRT, and dose escalation to 64 Gy. This trial is currently accruing patients.

Following preoperative chemoradiation for locally advanced disease, it remains unclear whether surgery is necessary in those who achieve cCR. In GOG 101, approximately 70% of patients who achieved cCR were found to have no pathologic residual in the surgical specimen (167). In GOG 205, 34 of 37 patients (92%) underwent surgical biopsy only to assess treatment response (169). Of these 34 women, 29 (78%) had biopsies showing a CR. Based on this 22% to 30% risk of discordant findings between CR and PR, at minimum, an excisional biopsy of the primary site should be completed to confirm a CR to treatment.

The role of preoperative CRT has been assessed in patients who present with bulky, unresectable inguinal adenopathy. In GOG 101 (study of preoperative CRT for local regionally advanced vulvar cancer), there was a cohort of 42 evaluable patients with N2 or N3 nodal disease who were deemed initially unresectable. Patients received 47.6 Gy of RT in split-course fashion, with two concurrent cycles of 5-FU and cisplatin, as described above. Planned inguinofemoral LN dissection was performed 3 to 8 weeks later. In only 2 patients (5%) did nodal disease remain unresectable. The surgical specimen showed histologic clearance of nodal disease in 15 patients (36%). At a median follow-up of 78 months, only 1 of 37 patients (3%) who completed the fully prescribed regimen of preoperative therapy and bilateral inguinofemoral node dissection relapsed in the groin. This study, while nonrandomized, provides further evidence of the efficacy of combined CRT in the management of local regionally advanced vulvar cancer and of patients with significant regional adenopathy.

Definitive Radiotherapy

Historical data evaluating the use of RT alone for vulvar cancer was generally disappointing, with a significant number of recurrences and considerable toxicity. With integration of more modern, advanced techniques and favorable results from preoperative radiotherapy, some have reexplored the role of definitive radiotherapy using higher cumulative doses. Two of these series have shown that doses exceeding 55 to 56 Gy independently predict for improved local control (170,171). Based on these findings, radiotherapy alone may be an option for patients not suitable for surgery, assuming intent to reach relatively high doses.

In an effort to reach these doses when treating definitively, few studies have assessed the role of interstitial brachytherapy, either alone or after external beam radiotherapy (EBRT) (172,173). When delivering a high dose via EBRT (mean dose, 50.4 Gy) and an interstitial brachytherapy boost (mean dose, 28.7 Gy), Tewari et al. (173) illustrated no local failures among patients with primary advanced vulvar SCC. Hoffman et al. (172) similarly evaluated patients treated with interstitial brachytherapy with or without EBRT, demonstrating disease control in 7 of 10 patients receiving 70 to 90 Gy, albeit with high rates of necrosis. The considerable hot spot at the skin achieved with brachytherapy may account for this high rate of soft tissue necrosis. Brachytherapy boost should therefore be used cautiously and possibly selectively for patients with significant vaginal extension.

Radiation Therapy Technique

Conventional (Two- and Three-dimensional) Radiotherapy

Radiation techniques used for treatment of vulvar carcinoma reflect a need to cover the vulva plus lower pelvic and inguinal nodes, while simultaneously minimizing radiation dose to the femoral heads. Conventional approaches utilized an anterior field that encompasses the inguinal regions, lower pelvic nodes, and vulva, and a narrower posterior field that encompasses the lower pelvic nodes and vulva but excludes most of the femoral heads. The intent here is to cover one nodal echelon proximal to the nodal echelon with metastatic vulvar cancer disease. The inferior-most borders of the fields should extend 2 to 3 cm caudal to the saphenous and femoral vein junction. If the fields are evenly weighted to the midplane of the pelvis using 6 MV photons, the contribution of the anterior field to the groin nodes at a depth of 3 to 5 cm will generally be 60% to 70% of the dose to the mid pelvis. Some choose to use 6 MV from the anterior field and 15 MV from the posterior field to save posterior organs at risk. The difference may be made up by supplementing the dose to the lateral groins with anterior electron fields of appropriate energy.

Currently, CT scans obtained in the process of radiation dose planning are used to detect enlarged nodes that may not be appreciated on clinical exam and to determine the appropriate electron energy. Based on patterns of relapse, institutional contouring guidelines have been established to ensure adequate coverage (174) (Fig 18.19). Gross disease in the groin or vulva may be boosted with en face electron fields or conformal photon RT. If radiation is directed to the regional nodes only, with intentional sparing of the vulva, care must be taken to avoid a large “midline” block, which may lead to higher medial groin and vulvar failures.

Intensity-Modulated Radiotherapy

The complex anatomy of the vulva and its regional lymphatics have led some investigators to propose the use of IMRT in

the management of vulvar cancer (Fig. 18.20) (175,176). To whom IMRT should be offered remains debated, although this modality is now being incorporated in clinical trials (i.e., GOG 279). In modern practice, IMRT may replace conventional external beam approaches used in the treatment of vulvar cancer; however, outcome data remain limited. Most data come from experience extrapolated from the treatment of anal carcinoma in multi-institutional clinical trials or limited single-institution series (169,176,177). IMRT is gradually being used more for radiotherapeutic management of gynecologic malignancies, including vulvar cancer. It is an attractive approach to RT in the pelvis because of its ability to escalate radiation dose while decreasing radiation dose to nearby healthy normal tissue, improving the therapeutic window for radiation.

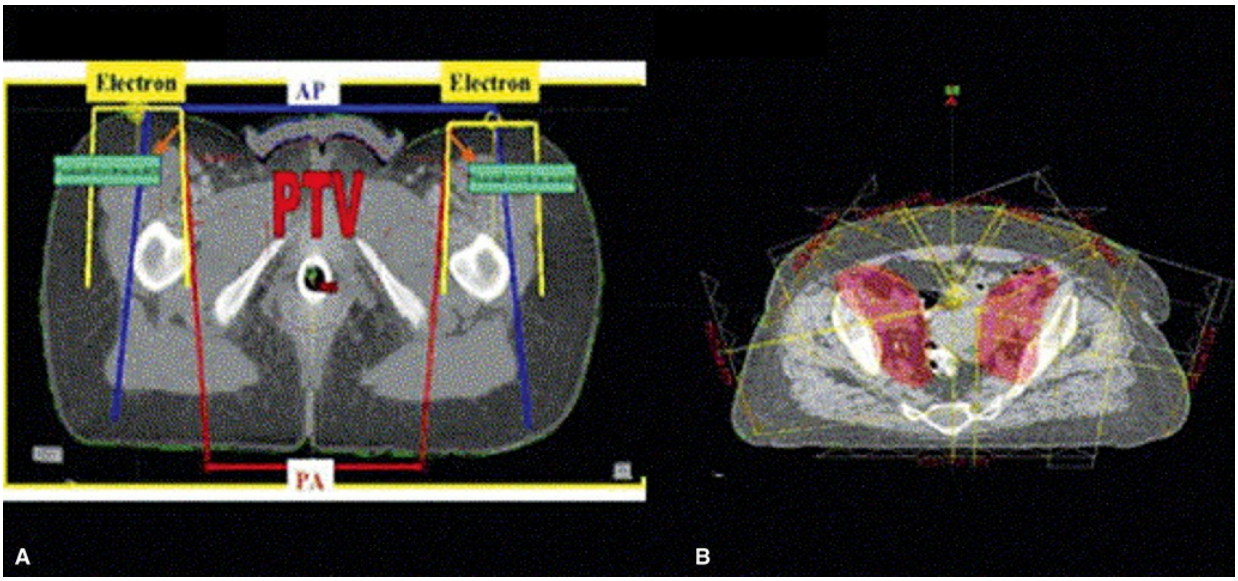

Figure 18.20 A:Conventional radiotherapy. B: Intensity-modulated radiation therapy in the management of vulvar cancer.
Source: Reprinted with permission from Beriwal S, Heron D, Kim H, et al. Intensity-modulated radiotherapy for the treatment of vulvar carcinoma: a comparative dosimetric study with early clinical outcome. Int J Radiat Oncol Biol phys. 2006;64:1395－1400.

Although radiobiologically effective, IMRT has some practical limitations. Uncertainties in patient setup and target volume definition when using IMRT techniques have been raised. Vulvar and groin target motion resulting from quiet breathing during treatment is expected to be minimal, as are shifting bladder and rectal volumes unlikely to substantially modify primary disease position during beam-on time. Again borrowing from overall RT experience, it is not unreasonable to conclude that daily repositioning of women prior to radiation delivery, using such devices as on-board cone beam CT, will adjust for setup inconsistencies. Single-institution data evaluating patterns of inguinal relapse have better clarified challenges with target delineation (174). Presently, consensus group contouring guidelines for volume and dose have been presented in a national meeting in anticipation of a manuscript to be published this year. This manuscript may help enable uniform contouring practices when using IMRT.

Acute Complications of Radiation Therapy

Acute radiation reactions are brisk, and doses of 35 to 45 Gy routinely induce patchy or confluent moist desquamation. However, with adequate local care, this acute reaction usually heals within 3 to 4 weeks. Sitz baths, steroid cream, and treatment of possible superimposed Candida infection all help to minimize the discomfort. If the patient is sufficiently flexible, he or she may be placed in a frog-leg position during treatment to minimize the dose and ensuing skin reaction on the medial thighs; care must then be taken, however, to deliver an adequate dose to the vulvar skin. Although most patients will develop patchy to confluent dermatitis by the fourth week of treatment, this is usually tolerated if the patient is warned

in advance and assured that the discomfort will resolve after treatment is completed. Although a treatment break is occasionally required, delays should be minimized, because they may allow time for repopulation of tumor cells. IMRT helps reduce dose to uninvolved skin, especially in groin regions, which also helps reduce dermatitis (176).

Late Complications of Radiation Therapy

Many factors add to the late morbidity of RT in patients with vulvar carcinoma. Patients with advanced vulvar carcinomas are often treated with RT following radical surgery, which may include extensive dissection of the inguinal and possibly pelvic nodes. Large ulcerative cutaneous lesions frequently have superimposed infection. Patients are often elderly and may have complicating medical conditions, such as diabetes, multiple prior surgeries, and osteoporosis. The contribution of concurrent CT to local morbidity is not yet clearly defined, but may contribute to bowel and bone complications (178). Conversely, the addition of complex treatment planning such as IMRT may further reduce the risk of skin, small bowel, bone and bone marrow toxicities, with a single-institution series showing no severe (grade ≥ 3) late complications for vulvar cancer patients (177,179).

The incidence of lower extremity edema after inguinal irradiation alone appears to be small (155). RT is likely to contribute to the cumulative incidence of peripheral leg edema following radical node dissection, but there was no difference evident in the GOG randomized study of radiation (16%) versus pelvic node dissection (22%) (163). Other complications include the risk of pelvic and femoral head fracture, most notably when delivering RT to the inguinal nodes (180,181). Previous techniques provided substantial dose to the femoral heads, which can be decreased by techniques such as IMRT (175,177).

The effect of RT on the long-term cosmesis and function of the vulva is poorly understood. Although treatment with radiation or CRT and wide excision is becoming a more accepted alternative to extensive surgery for selected patients, and major complication rates appear to be acceptable, very little has been reported regarding subtler late effects of such treatment in the vulva. Possible late effects include atrophy and telangiectasias. Late effects are expected to be dose-related. Better information will become available only as treating physicians record and report the late cosmetic and functional results of treatment (178).

CHEMOTHERAPY

Primary Treatment of Advanced Disease

Most patients diagnosed with vulvar cancer can be cured with surgery with or without postoperative RT; thus, CT monotherapy has traditionally been used solely for salvage. Patients with advanced vulvar cancers tend to be older, with significant medical comorbidities, making them poor candidates for cytotoxic therapy because of concomitant diseases that increase the likelihood of significant adverse effects. Furthermore, recurrent vulvar cancer often occurs in the setting of extensive prior surgery and/or RT, making tolerance to cytotoxic therapy poor.

Cytotoxic Chemotherapy

Neoadjuvant Chemotherapy

Squamous carcinoma is the only histologic type of vulvar cancer for which there are significant data assessing the utility of cytotoxic CT in recurrent or advanced primary vulvar cancer not initially amenable to surgery or RT. In order to reduce morbidity of subsequent curative intent surgical therapy, a number of smaller studies have been performed to assess the

feasibility of this approach. Geisler et al. subjected 13 patients to neoadjuvant CT with cisplatin (50 mg/m^2) and 5-FU (1,000 mg/m^2/24 hours) q3w (n = 10 cisplatin and 5-FU, n = 3 cisplatin only). The combination achieved CRs in 100% of patients (10% CR); 9/10 patients then underwent radical vulvar resection and inguinofemoral lymphadenectomy. In all patients, preservation of anal and urethral sphincter function was achieved; 9/9 patients who completed both neoadjuvant CT and surgery remained alive and free of disease at 49 months (182).

In a more recent prospective study of 10 patients with advanced primary vulvar cancer whose only curative option was PE combined with neoadjuvant CT, patients were offered either paclitaxel (175 mg/m^2, d1 + ifosfamide (5 mg/m^2, d2) + cisplatin (70 mg/m^2, d1) [TIP], or paclitaxel (175 mg/m^2, d1) + cisplatin (70 mg/m^2, d1) [TP] at the discretion of the treating physician (TIP n = 4, TP n = 5). Overall response rate (ORR) was 80% with one CR, two persistent carcinoma *in situ* and 6 patients with PR >50% tumor regression; 9/9 patients underwent radical surgery with inguinofemoral lymphadenectomy, and all were disease-free at completion of primary combined therapy. Ultimately, 6/9 patients recurred with a PFS = 14 months from surgery (multiple different salvage therapies were utilized). After a median follow-up of 40 months, 56% of patients were alive and without evidence of disease (NED) (178).

A prospective multicenter trial compared four cisplatin-based regimens and one bleomycin-based regimen in 35 patients with advanced vulvar cancer; 33 of 35 patients completed CT, with PRs noted in 30 patients and stable disease noted in 3 patients; 27 patients subsequently underwent radical surgery (25 with inguinofemoral lymphadenectomy). Of 16 patients with clinically apparent nodes before treatment, 11 were found with residual nodal disease, and they then underwent CRT. At a median of 49 months of follow-up, 24 of 27 patients remained NED. Because of the overall number of patients treated, as well as the multiple different cytotoxic regimens used, the authors could not establish a clear standard for recommendation; however, the results suggest a possible role for neoadjuvant CT for advanced vulvar cancers initially not amenable to surgery (179).

Before neoadjuvant therapy is considered a standard approach in advanced patients, further study involving larger numbers of patients and more controlled therapy regimens is recommended.

Systemic Treatment of Metastatic and Recurrent Vulvar Cancer

Despite the success of curative intent therapies in advanced vulvar cancer patients, a significant minority of patients will recur (40% to 50%), and 5-year overall survival (OS) in this group of patients is <10% (167,185). Unfortunately, in view of the rarity of this disease and difficulty with a prospective study of an even more infrequently encountered group of patients, there is no clear standard for treatment of patients with metastatic or recurrent disease who are not amenable to surgery or RT. As a result, most patients are treated with regimens extrapolated from study of CT in metastatic SCC of the cervix. Accordingly, most patients are treated with cisplatin-based combination regimens, and there is interest in the use of bevacizumab in vulvar cancer.

Early studies in vulvar cancer with single-agent cytotoxic chemotherapies such as piperazinedione, cisplatin (50 mg/m^2, q21d), and mitoxantrone were disappointing, with no responses noted (186,187).

A prospective phase 2 study evaluated the use of cisplatin (80 mg/m^2, q21d) + vinorelbine (25 mg/m^2, d1, d8) in 16 chemotherapy-naïve patients; 15 patients were evaluable for response, and ORR was 40%, with 4 CRs, 2 PRs, and 5 patients with stable disease. Median PFS was 10 months, with a median OS of 19 months. Toxicity was considered manageable, with nausea/vomiting and leukopenia the primary grade 3 and 4 toxicities (188).

Single-agent therapy with paclitaxel (175 mg/m^2 q21d) was evaluated in 31 heavily pretreated patients with advanced, recurrent, or metastatic vulvar cancer who were not amenable to surgery or RT. In 29 evaluable patients, ORR was 14% (189). Based on this, further study of single-agent paclitaxel in this population has not been attempted.

Receptor Targeted Therapies

Epidermal Growth Factor Receptor (EGFR) Inhibitors

Recognition of the fact that EGFR expression via IHC staining is elevated in malignant vulvar tumors has led to the use of EGFR tyrosine kinase inhibitors (TKIs) as monotherapy and in combination with cytotoxic CT in palliation of advanced and recurrent vulvar cancer patients. Olawaiye et al. (190,191) reported two dramatic PRs to single-agent erlotinib in women with advanced, treatment-refractory disease; Bacha subsequently reported a PR in a woman with advanced disease. A phase 2 prospective GOG trial using erlotinib in 41 patients with advanced or recurrent vulvar cancer described PRs in 28% and SD in 40% of patients. Unfortunately, responses were not durable, and grade 3 and 4 toxicities (diarrhea, dehydration, and renal failure) were notable (191).

Vascular Endothelial Growth Factor Receptor (VEGF) Targeting

Recent advances in the treatment of cervical cancer with antiangiogenic therapies, most notably bevacizumab, have led to significant interest in application of similar antiangiogenic therapies in the treatment of vulvar cancer (192). As approximately 40% of vulvar cancers are believed to be a result of HPV infection, there is hope that similar efficacy for this classically chemo-refractory disease will be possible. To date, though, there are no published reports of activity for antiangiogenic therapies in vulvar cancer.

RESULTS OF THERAPY

The overall results of therapy for women with squamous cancers of the vulva are excellent, largely because approximately two-thirds of patients present with early-stage tumors. Five-year survival rates for vulvar cancer have improved over the past two decades. Landrum et al. used GOG data to perform an historical comparison between patients treated between 1977 and 1984 (n = 577) and patients treated between 1990 and 2005 (n = 175). Stratification into “minimal, low, intermediate, and high-risk” groups was performed to enable comparisons. Patients treated in the era of less radical surgery and modern CRT fared better than historical comparisons, with 5-year survival by risk group (minimal → high) of 100% versus 97.9%, 97% versus 87.4%, 82% versus 74.8%, and 100% versus 29.0% (193).

Several strategies to enhance survival for women with vulvar cancer are evident. High-risk patients can be educated and screened more consistently for the development of early cancer. Women with HPV infections, *in situ* vulvar disease, long smoking history, and other genital neoplasms are at risk for developing vulvar cancer (194). Careful screening targeted at women with these high-risk factors may lead to improvements in early diagnosis (195).

The survival rate for women with nodal spread is one-half that for women without nodal disease who have similarly sized primary tumors. Improvements in the use of molecular markers for metastatic disease and biologic aggressiveness would be helpful for triaging higher-risk patients into more effective adjuvant therapies. And, of course, there is a dire need for better treatment options for node-positive patients.

SEQUELAE OF TREATMENT

Immediate complications such as wound infection and lymphocysts were common in the radical vulvectomy era. These occur much less frequently now because of the use of multimodal primary therapies, less radical surgery, and innovations such as prophylactic antibiotics and closed-suction drains. Breakdown of the vulvar incision is increased in patients who are smokers, as well as those with vasculopathy.

Lymphedema starts to appear within weeks of surgery. The severity is related to the extent of groin surgery, wound complications, postoperative RT, and preexisting conditions of the lower extremities. Lymphedema is not always limited to the lower leg and thigh. It may also include the mons, groins, and hips. The use of SLNB reduces but does not eliminate wound complications and lymphedema. Pressure stockings, sequential compression devices, lymphedema massage, and microvascular surgery have been used to manage lower extremity lymphedema, with limited results. *Prevention* of lymphedema with the use of SLNB is the best strategy for limiting its adverse effects (132).

All gynecologic surgery, especially surgery for vulvar cancer, can have an adverse effect on body image and sexual function. Informed consent obtained for vulvar cancer surgery should include a discussion regarding these risks. No assumptions regarding a woman's sexual activity should be made on the basis of age or marital status. We have found that preoperative consultation with a sexual health expert can be invaluable for many women.

FUTURE DIRECTIONS (RESEARCH, POTENTIAL MANAGEMENT CHANGES)

The incorporation of SLNB into the care of women with vulvar cancer raises many new questions regarding treatment of lymph node-positive patients. Should a woman with a microscopically positive SLN undergo full regional lymphadenectomy? How does the size of a groin metastasis impact survival, and how should it affect decisions regarding adjuvant treatment? Are isolated tumor cells clinically relevant (129,196)?

The GROINSVII/GOG 270 protocol, which is being conducted in Europe and North America, seeks to answer some of these questions. The original study design called for SLN-positive patients to be treated with 50-Gy RT to the groin. Early stopping rules were met because there were an unexpected number of patients with groin relapse following SLNB and RT. On further analysis, there were no groin relapses among patients with metastases <2 mm. The study has been amended to require inguinofemoral lymphadenectomy for women with metastases over 2 mm and postoperative RT of 56 Gy. The role of adjuvant CT is unclear. GROINSVII/GOG 270 allows the use of concurrent cisplatin during RT, albeit at the discretion of the treating physician.

Another area of significant interest will be targeted therapy. Large phase II/III trials in vulvar cancer are unlikely because of population size; however, lessons learned from squamous carcinomas of the anus, head and neck, cervix, and cutaneous melanoma will likely provide significant insights into novel therapies for vulvar cancer patients.

SUMMARY

Most patients with vulvar cancer are potentially curable at the time of presentation for care. The major challenge for providers is how to balance providing curative therapy with preserving quality of life, including organ function, sexual function, and body image.

The preferred therapy for patients with early disease is surgery alone. The morbidity of surgery can be reduced with the use of SLNB as an alternative to regional lymphadenectomy. This approach has proved very successful in the treatment of patients with breast cancer and cutaneous melanoma. There is now enough clinical evidence to support routine use in patients with vulvar cancer. Further investigation is needed to determine the ideal management of patients with a positive SLN.

Women with advanced disease usually benefit from multimodality therapy. The exact combination and order of treatment rely on consultation with a team including a gynecologic oncologist, radiation oncologist, pathologist, and diagnostic imager. Vulvar cancer is sufficiently infrequent for even busy clinicians to consider referral to a high-volume center when considering the care of women with this disease.

Vulvar Cancer in the Developing World

Adriana Bermudez, MD

The incidence of vulvar cancer in the developing world is unknown, because most of these countries have no reliable tumor registries.

Screening programs for gynecologic cancers are not readily available in low-resource settings. Furthermore, cultural and religious reasons make gynecologic cancer diagnoses more difficult, because patients feel ashamed to be attended by a male doctor in many communities. This is especially true for older patients with vulvar lesions.

Because most female cancer patients are managed by general gynecologists, once vulvar cancer is diagnosed, treatment is often not on hand. Radical surgery cannot be performed for want of infrastructure and necessary skill sets, and RT machines are usually saved for younger patients.

Opioids and morphine are also not available in many countries in the developing world. As a result, many women with vulvar cancer in these countries die without treatment or palliative care.

Vulvar Cancer in Chile

Jorge Brañes Yunusic, MD

The incidence of vulvar cancer in Chile, as in other regions of the world, is relatively low, accounting for 3% to 5% of all genital tract malignancies. Mortality rates are also similar, and have been unchanged for the last two decades at approximately 0.5/100,000 women (1).

According to local data, compared with that of international publications, patient characteristics are almost identical in many respects (e.g., mean age at diagnosis, histology, body mass index, etc.), except for stage at diagnosis, because our patients usually present with more advanced disease. In one series of patients, the average size of the primary tumor was 4 cm (personal communication). Along the same lines, 68% of patients from another cohort presented with stage III disease at diagnosis (2). These two issues, along with the disease's relatively low frequency, influence the way we treat our patients.

In most centers, sentinel lymph node (SLN) detection is not routinely performed. The main reasons for this are the following: (a) low number of cases per center, which minimizes a surgeon's chances of getting accustomed to and mastering the technique, and (b) as mentioned above, the high number of patients presenting with advanced disease at diagnosis—a group of patients in whom the method has not been entirely validated.

Besides complete blood tests, the preoperative workup should include a CT scan of the abdomen and pelvis. When involvement of the midline structure is suspected, MRI can help guide treatment between surgery and RT for the primary tumor.

Clinical management of stage IA disease is wide local excision without evaluation of the inguinofemoral LNs. Stage I/II disease, other than IA, is managed with wide local excision or radical vulvectomy for the primary tumor and unilateral or bilateral inguinofemoral lymphadenectomy.

In case of involvement of midline structures, where urinary or fecal continence cannot be assured, CRT followed by resection of residual disease is preferred. Postoperative RT to the pelvis and inguinal nodes is indicated in the case of two or more positive inguinal nodes.

In conclusion, the 5-year overall survival rate reported in a Chilean retrospective cohort study of 86 patients with vulvar cancer was 57%. Among the studied variables, stage was the independent factor in the analysis (2).

INTERNATIONAL PERSPECTIVES

Vulvar Cancer in Latin America

Gustavo Ferraris, MD, PhD

Vulvar cancer is rare in Latin America, representing 3% to 5% of all gynecologic tumors. Characteristic of postmenopausal women, the percentage of patients younger than 50 years is progressively increasing in the region, showing a strong association with HPV infection.

The workup is similar to what is mentioned elsewhere the chapter, with the exception of the use of cystoscopy and sigmoidoscopy, which is reserved for advanced cases. In Latin America, most of the patients present with advanced disease at the time of diagnosis, and the standard treatment is CRT, most commonly a modification of the Nigro protocol for anal cancer (5-FU CI days 1 to 4, and mytomicin C, day 1, two cycles 21 days) plus radiation (50 Gy beginning first cycle; boost 20 to 25 Gy in residual disease). The same treatment scheme is also used for recurrent tumors larger than 5 cm, or tumors in any location where surgical resection may not allow for appropriate margins. For operable disease, a sentinel node biopsy technique is used in cases of squamous histology, tumors smaller than 4 cm, unifocal tumors, and nonpalpable or cytology-negative inguinal nodes.

Single-institution reports (1) of combined modality therapy in advanced disease show an actuarial 5-year survival rate of 60.5%. Analyzing the impact of nodal status on survival, 5-year survival in patients with negative nodes was 80%, and 74.5% for patients with a single node-positive, dropping to less than 7% in the setting of multiple metastatic nodes.

CHAPTER 19 Vaginal Cancer

Josephine Kang, Amanda N. Fader and Akila Viswanathan

ANATOMY

The vagina is a fibromuscular tube that extends from the cervix down to the vestibule, or cleft, between the labia minora. The average length of the vagina is 3 to 4 inches. Superiorly, it joins the uterine cervix at an angle and, as a result, the posterior vaginal wall is longer than the anterior wall. The upper aspect of the posterior vaginal wall is separated from the rectum by a peritoneal reflection known as the pouch of Douglas. Invaginations between the vaginal mucosa and cervix form the anterior, posterior, and lateral fornices. Laterally, the vagina is adjacent to the pelvic fascia and levator ani muscles. Inferiorly, the vagina extends through the urogenital diaphragm to lie dorsal to the urethra and ventral to the rectum. The fibromuscular perineal body separates the vagina from the anal canal. At the introitus, the vagina has a perforated fold of thin connective tissue and mucous membrane known as the hymen (Fig. 19.1).

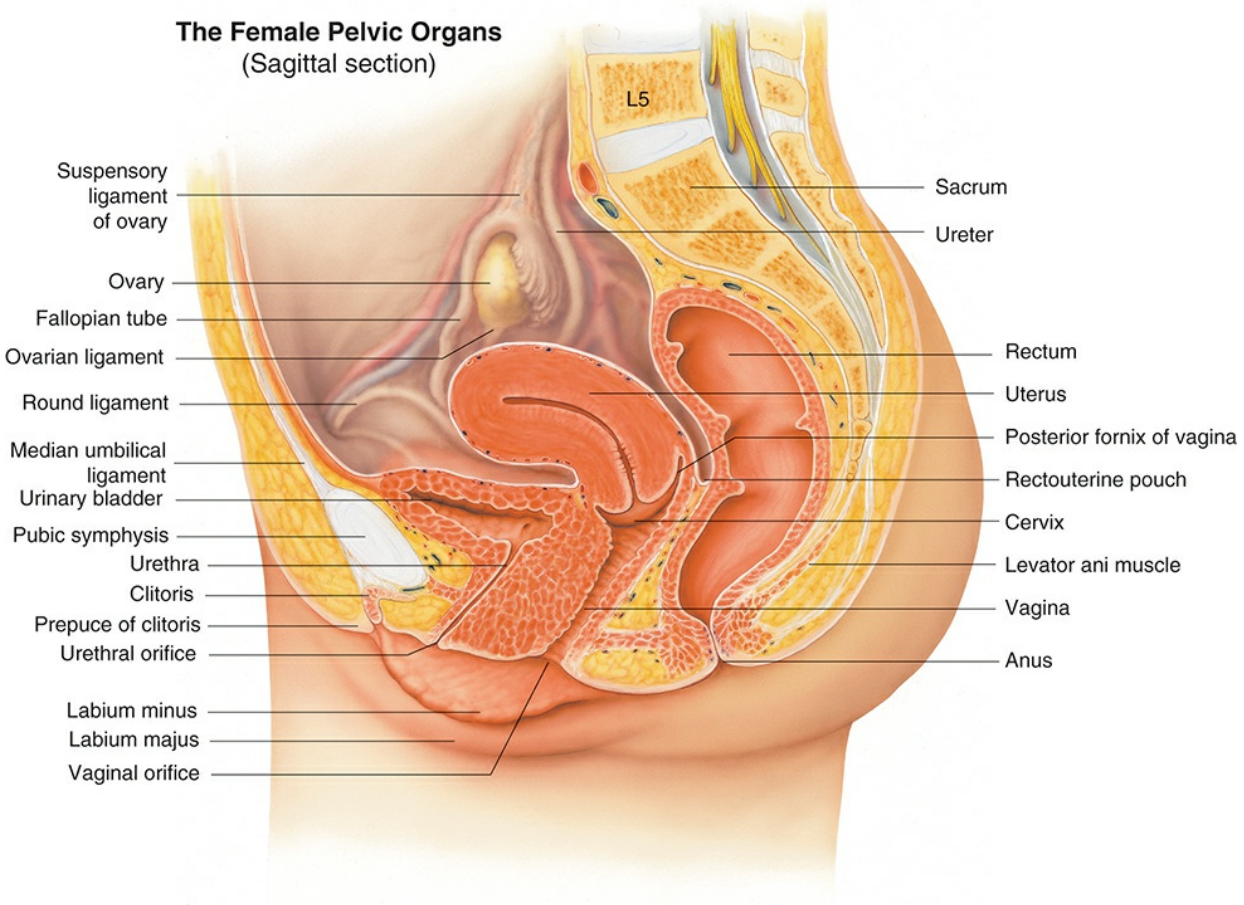

Figure 19.1 The lower female pelvis in sagittal view. The vagina is a fibromuscular

tube situated posterior to the bladder and urethra and anterior to the rectum. The anterior and posterior fornices are formed by protrusion of the cervix into the vaginal canal.
Source: Reproduced from Anatomical Chart Company, Female Reproductive System Anatomical Chart, Philadelphia, PA: Wolters Kluwer Health, 2001.

The vaginal wall comprises the mucosa, muscularis, and adventitia. The innermost lining of the vagina is formed by a nonkeratinizing, stratified squamous epithelium overlying a basement membrane. Underneath the mucosa is connective tissue composed of elastin, and a thick muscularis layer composed of two layers of smooth muscle. The inner layer is arranged circularly, whereas the outer layer is arranged longitudinally. This muscular layer is covered by the third layer, a thin adventitia that merges with neighboring organs. This epithelial mucosa lacks glandular structures, and instead receives lubrication from mucous secretions originating in the cervix.

The vagina has a complex, extensive network of lymphatic drainage, with vessels that course through the submucosal and muscularis layer. The uppermost portion drains primarily via cervical lymphatics. The superior anterior vagina drains along cervical channels to the interiliac and parametrial nodes, and the posterior upper vagina drains into the inferior gluteal, presacral, and anorectal nodes (Fig. 19.2). The inferior aspect of the vagina drains into the inguinal and femoral nodes, and ultimately to the pelvic nodes, following the drainage patterns of the vulva. Lesions in the midvagina have been shown to drain either way (1). Lesions infiltrating the rectovaginal septum may spread to the pararectal and presacral nodes. Because there are multiple interconnections between lymphatic channels, the pattern of drainage cannot be reliably predicted based on location of the primary tumor.

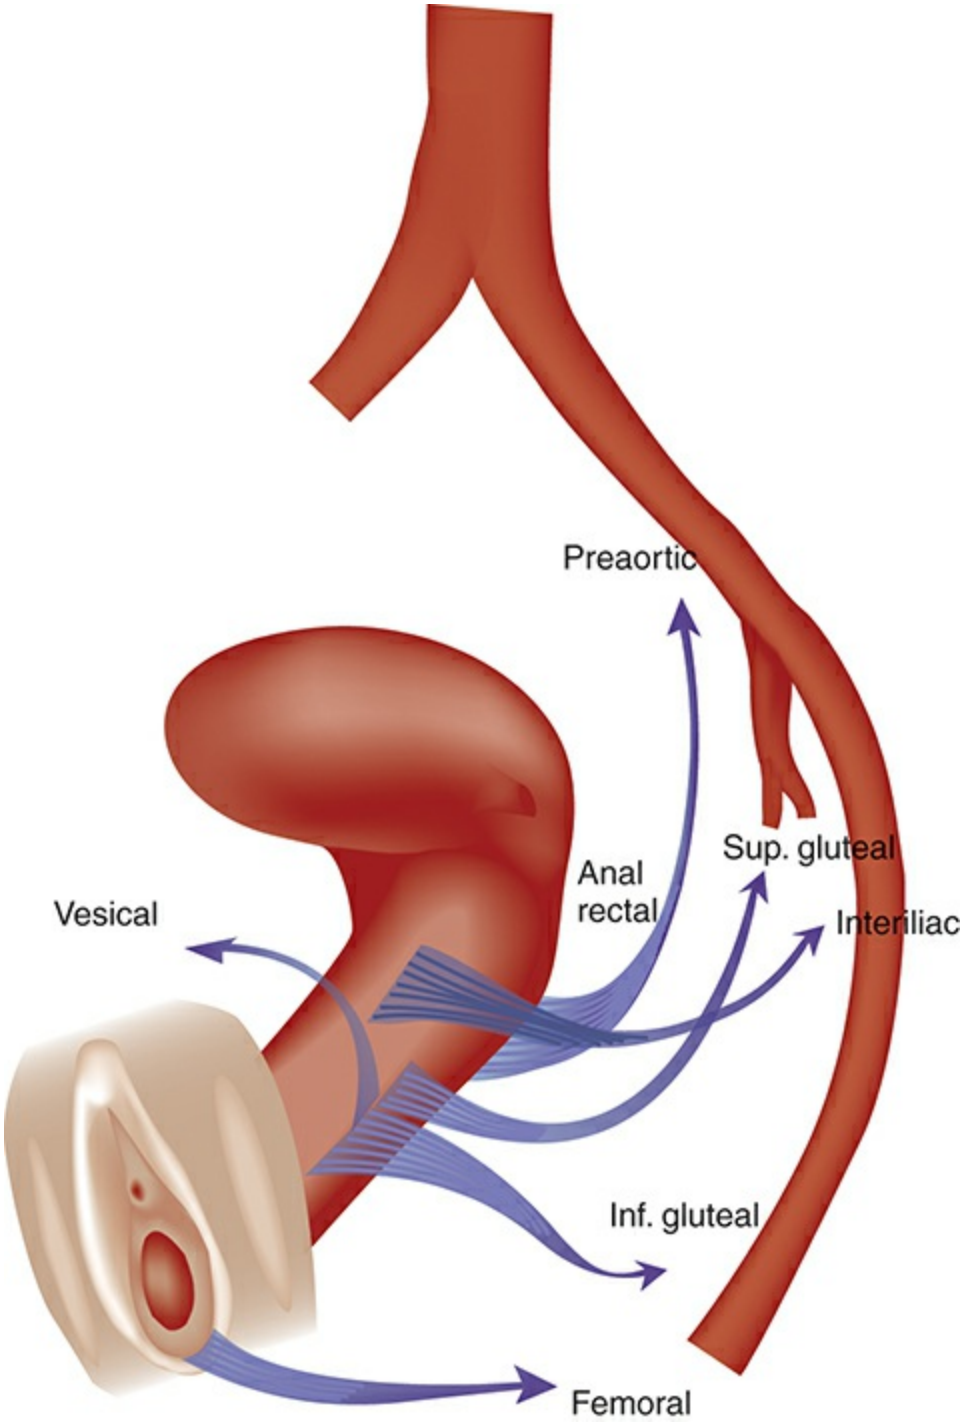

Figure 19.2 Lymphatic drainage of the vagina.

Proximally, the vagina is supplied by the vaginal artery, which arises from the cervical branch of the uterine artery and runs lateral to the vagina until it anastomoses with the inferior vesical and middle rectal arteries. The venous plexus runs parallel to the arteries, draining into the internal iliac vein. The vaginal vault is innervated by the lumbar plexus and pudendal nerve, with branches from sacral roots 2 to 4 (2). Embryologically, the vagina is believed to be of dual origin, with the upper third derived from the uterine canal, while the lower two-thirds are derived from the urogenital sinus (3).

EPIDEMIOLOGY, PRESENTATION, AND MANAGEMENT

According to the American Cancer Society estimates for 2016 (4), there will be approximately 4,600 new cases and 950 deaths from primary vaginal cancer. Primary vaginal cancer is a rare malignancy, constituting 1% to 2% of all gynecologic malignancies (5). According to compiled data from US population–based cancer registries spanning 1998 to 2003, the incidence of all vaginal cancers was 0.18 per 100,000 females for in situ cases and 0.69 per 100,000 females for invasive cases (6).

Most primary vaginal malignancies are squamous cell carcinomas (SCC). According to a National Cancer Data Base (NCDB) report (7), which evaluated 4,885 patients with primary vaginal cancer registered from 1985 to 1994, approximately 92% of patients were diagnosed with in situ or invasive SCC or adenocarcinomas, 4% with melanomas, 3% with sarcomas, and 1% with other/unspecified types of cancer. Sixty-six percent of all vaginal cancers were invasive, with SCC representing 79% of all invasive cases.

The peak incidence of primary vaginal cancer is in the sixth and seventh decades of life. According to data from the Surveillance, Epidemiology and End Results (SEER) Program (8), 2,149 women in the United States were diagnosed with primary vaginal cancer from 1990 to 2004. The mean age at diagnosis was 65 +/– 14 years, and incidence rates increased with age. There has been an overall decrease in the incidence of primary vaginal tumors, possibly secondary to earlier detection and to implementation of strict exclusion criteria in the International Federation of Obstetrics and Gynecology (FIGO) staging system.

At the same time, there has been a steady increase in the diagnosis of vaginal intraepithelial neoplasia (VAIN) over the past several decades, perhaps as a result of expanded cytologic screening and increased awareness (5). It is hypothesized that VAIN is a precursor lesion to SCC of the vagina (9).

Most malignant lesions in the vagina are attributable to direct spread or metastases from other gynecologic malignancies, and are classified accordingly. According to the FIGO staging system, any tumor involving both the vagina and the cervix should be classified as a cervical carcinoma. Similarly, any tumor involving both the vagina and the vulva is to be classified as a vulvar carcinoma (10). A malignant vaginal lesion in a patient with a prior history of invasive cervical carcinoma within the past 5 years also excludes diagnosis as a primary vaginal cancer (11). As a result, only a minority of vaginal carcinomas meet the criteria of a primary vaginal cancer. According to one study of 141 vaginal carcinoma cases, only 26% could be classified as such (12).

Owing to infrequent presentation, treatment recommendations are based on results from relatively small retrospective series comprising heterogeneous patient populations and treatments. Given the low incidence of vaginal cancer, it is unlikely that randomized clinical trials will be undertaken.

Vaginal Intraepithelial Neoplasia

Epidemiology

Hummer and colleagues first reported VAIN in 1933 and defined it as atypical squamous cells without evidence of stromal invasion (9). The incidence of VAIN is estimated to be 0.2 to 0.3 cases per 100,000, with peak incidence found in women who are 40 and 60 years of age (5,9,13,14). VAIN is further characterized according to depth of epithelial involvement from one third, two thirds and greater than two thirds thickness as VAIN 1, 2, and 3, respectively. Several series report that the median age at diagnosis for patients with VAIN 1 or 2 is lower than that for VAIN 3 (15–17), but this has not been corroborated by other series (9,18).

Involvement of the full thickness of the epithelium is known as in situ vaginal cancer and is included as VAIN 3 (Fig. 19.3). The incidence of in situ vaginal cancer is estimated to be 0.1 per 100,000 women, with peak incidence between

ages 70 and 79, according to data from the U.S. Centers for Disease Control and Prevention's National Program of Cancer Registries, and the National Cancer Institute's SEER Program (19). These numbers are similar to data from US population–based cancer registries encompassing the years from 1998 to 2003, which report incidence of in situ vaginal cancer to be 0.18 per 100,000 females (6). The peak age of in situ vaginal cancer is slightly higher than that for primary vaginal cancer.

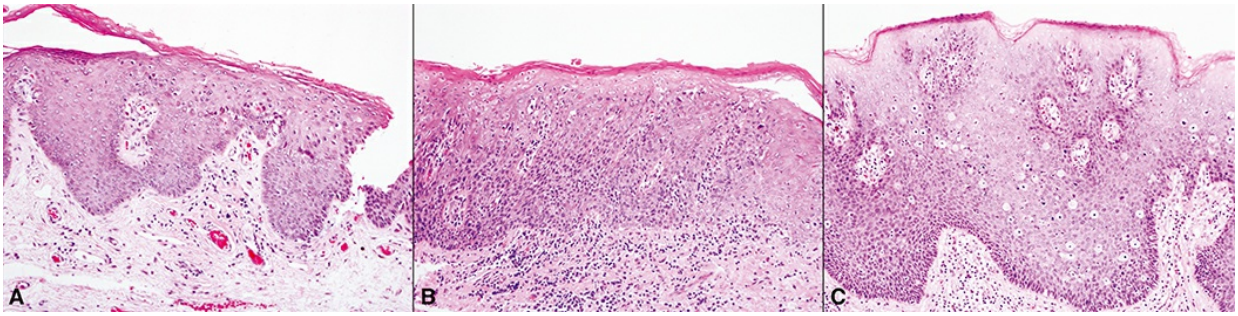

Figure 19.3 Vaginal intraepithelial neoplasia (VAIN) A: Low-grade squamous intraepithelial lesion of the vagina (VAIN 1) is characterized by nuclear enlargement in the upper one-third of the squamous epithelium with nuclear contour irregularities, occasional binucleation or multinucleation, and distinct cytoplasmic halos. B, C: High-grade squamous intraepithelial lesion of the vagina (VAIN 2-3) shows changes in the basal keratinocytes including nuclear pleomorphism with high N:C ratio, crowding, and hyperchromasia. In VAIN 3 lesions (C), these changes involve the full thickness of the epithelium, and frequent mitoses are usually seen. In VAIN 2 lesions (B), these changes involve less than the full thickness of the epithelium, and mitoses, when present, are confined to the lower levels of the epithelium. There are multiple risk factors for VAIN; the most common are low socioeconomic level, history of genital warts, hysterectomy at an early age, history of cervical intraepithelial neoplasia (CIN), immunosuppression, prior pelvic radiation, smoking, exposure to diethylsilbestrol (DES), and history of sexually transmissible diseases (STD) and/or human papillomavirus (HPV) infection (15,20–22). HPV is implicated in the development of VAIN, and the relationship between HPV and development of intraepithelial neoplasia has also been best demonstrated for cervical lesions. HPV 16 and 18 are the most prevalent subtypes associated with VAIN (23). A review of 232 published VAIN cases documented a high prevalence of HPV using identified on PCR or hybrid capture assays for detection, with 98.5% and 92.6% of VAIN 1 and VAIN 2/3 cases positive for HPV (24). A series by Sugase et al. (25) examining 71 biopsy specimens of VAIN found HPV in 100% of samples. Fifteen different known subtypes were identified (HPV 16, 18, 30, 31, 35, 40, 42, 43, 51, 52, 53, 54, 56, 58, 66). It is estimated that HPV 16/18 is identified in 40% of VAIN 1 and 60% of high-grade VAIN 2/3 cases (24).

The diagnosis of VAIN is associated with prior or concurrent neoplasia elsewhere in the lower genital tract. Multiple series suggest approximately 50% to 90% of patients with VAIN have concurrent or prior history of intraepithelial neoplasia or carcinoma of the cervix or vulva (13,15,26). Immunosuppression from human immunodeficiency virus (HIV) is also a risk factor for both VAIN and HPV, though a higher incidence of invasive vaginal cancer in infected women has not been demonstrated (27–29). The role of pelvic radiation in the development of secondary vaginal neoplasia is unclear, with conflicting data suggesting that a history of ionizing radiation may predispose to VAIN or vaginal cancer after a latency period of many years (30–32). In utero exposure to DES may double the risk of VAIN, thought to be due to transformation zone enlargement, increasing the risk of HPV infection (33). With widespread implementation of HPV vaccination, it is anticipated that the incidence of VAIN will start to decline. It is predicted that HPV vaccination will ultimately prevent up to 70% of VAIN cases (34,35).

Although the pathogenesis of both VAIN and CIN is attributable to HPV infection, the incidence of VAIN is notably lower. One study reported a 100-fold difference in incidence (15). It is speculated that the mature, squamous epithelium of the vagina is less vulnerable to persistent dysplasia than the metaplastic transformation zone of the cervix (9,15).

Natural History

Although the likelihood of VAIN progressing to invasive disease is difficult to predict in individual cases, multiple clinical series have demonstrated a significant overall increase in risk of invasive vaginal cancer after a diagnosis of VAIN (26,32,36,37). Similar risk factors for VAIN and invasive vaginal cancer, as well as the younger average age at presentation of VAIN compared with invasive disease, support the theory that VAIN is a precursor lesion to invasive SCC. It is believed that high-grade VAIN, in particular, is a direct precursor to invasive disease (9).

In one series, 23 patients with VAIN, with a mean age of 41 years, were followed for at least 3 years without treatment (26); the cases included multifocal lesions as well as lesions associated with CIN or vulvar dysplasia. Two cases (9%) progressed to invasive cancer; one patient had VAIN 1 and progressed to stage I vaginal carcinoma in 5 years, and the second patient had VAIN 3 and progressed to stage I vaginal carcinoma in 4 years. The overall spontaneous regression rate was 78%, all occurring in patients with VAIN 1 or VAIN 2. Similarly, several additional retrospective studies have demonstrated a range of 2% to 20% of patients with VAIN progressing to invasive vaginal cancer (26,32,36,38–40). The rate of occult invasive disease in patients with VAIN 3 is reportedly as high as 28% (41). The risk of malignant transformation in VAIN 1 and 2 is less clearly elucidated (18,20).

Histopathology

VAIN is defined as the presence of squamous cell atypia without evidence of invasion. Histopathologically, most lesions are epidermoid and exhibit full-thickness alterations with atypical mitoses and hyperchromatism (42). Punctation and mosaic patterns are often noted in high-grade VAIN (18). Most lesions are multifocal and can involve all surfaces of the vagina, although the superior one-third of the vagina is most common (26,32).

VAIN is further classified into low-grade (VAIN 1) and high-grade (VAIN 2-3). VAIN 1 is characterized by cytomorphologic changes limited to the upper one-third of the epithelium. Such changes include nuclear enlargement, nuclear hyperchromasia, cytoplasmic halos, and occasional binucleation. VAIN 2-3 is characterized by cytomorphologic changes in the basal keratinocytes, including nuclear pleomorphism, nuclear hyperchromasia and crowding, and mitotic figures (including atypical forms). VAIN 2 and 3 are distinguished by depth of cytologic change. Cytologic changes confined to the lower two-thirds of the epithelium are designated VAIN 2, whereas changes involving the full thickness of the epithelium are VAIN 3. Carcinoma in situ encompasses the full epithelial thickness and is included under VAIN 3.

Excluded from the diagnosis of VAIN is the presence of glandular intraepithelial dysplasia, or atypical vaginal adenosis; these entities are associated with in utero DES exposure and are deemed to be precursors of DES-associated clear cell adenocarcinoma (43).

Clinical Presentation

VAIN is usually asymptomatic (32) and most commonly detected after cytologic evaluation as part of surveillance in patients with a history of CIN or invasive cervical carcinoma. Vaginal colposcopy with iodine stain is important when patients present with an abnormal pap smear but no gross abnormality. Any colposcopically abnormal area warrants a directed biopsy. Around the vaginal vault, where occult carcinoma may be found, excisional biopsies are recommended (44). According to the 2002 American Cancer Society guidelines, surveillance cytology for VAIN in posthysterectomy patients is recommended if there is a history of cervical pathology, although it is low yield (45). The optimal incorporation of HPV testing into screening is not yet known (46). At present, evidence does not support routine surveillance in patients without a history of CIN or invasive cervical cancer.

Prognostic Factors

A significant association between higher viral load of HPV and likelihood of persistent disease after treatment was demonstrated by So et al. (47). There is also a significant association between risk of relapse in patients positive for high-risk HPV versus those who are negative (48). Of such patients, a retrospective review of 33 patients with VAIN treated at the University of Pennsylvania (38) found patients with a history of radiation therapy (RT) to be more refractory to treatment, with a significantly higher likelihood of recurrence after surgical and ablative therapy. Patients with a history of RT had an odds ratio of 3.6 for recurrent disease (95% CI, 1.5 to 9.0) compared to patients without a history of RT.

Treatment Options

There is currently no consensus on optimal treatment modality, as reported data are generally retrospective and based on decades of experience with various treatments and patient characteristics; thus, it is difficult to compare different therapeutic modalities (Table 19.1). Treatment approaches include local excision, partial or total vaginectomy, laser vaporization, electrocoagulation, topical 5% fluorouracil (5-FU) administration, topical 5% imiquimod, and radiation (15–18,20,52,61,71,75–77). Reported success rates for different approaches range from 48% to 100% for laser vaporization (56,78,79), 52% to 100% for colpectomy (41,52,57), 75% to 100% for topical 5-FU (60–63,80–83), 57% to 86% for topical 5% imiquimod (77), and 83% to 100% for radiation (68,69,72,76,84. Given the breadth of available therapies, an individualized approach to patient management is advised, with consideration given to the patient's overall health, desire to preserve sexual function, candidacy for surgery, disease multifocality, and prior treatment failures.

TABLE 19.1 Local Control of Vaginal Intraepithelial Neoplasia by Treatment Modality

Series	Year	# Patients	% Recurrence	Follow-up	Treatment Notes
Surgery					
Benedet (49)	1984	136	25%	>5 years	WLE, PV, TV
Lenehan (32)	1986	19	16%	5–112 months	PV, TV
Ireland (50)	1988	25	4%	3 months–11 years	PV, TV
Hoffman (41)	1992	32	17%	6–73 months	PV; 28% invasive cancer
Fanning (51)	1999	15	0%	22 months	PV; 6.6% invasive cancer
Cheng (13)	1999	35	34%	1–124 months	WLE
Dodge (20)	2001	13	0%	>7 months	PV
Indermaur (52)	2005	105	12%	2–9 months	PV, 12% invasive cancer
Terzakis (53)	2010	23	25%	24 months	
Gunderson (9)	2013	44	27%	1–194 months	PV, LE
Laser therapy					
Jobson (54)	1983	24	17%	6–27	

				months	
Audet-LaPoint (55)	1990	32	28%	7 – 85 months	3.8% invasive cancer at excision 3 of 11 w/invasive cancer at recurrence
Hoffman (56)	1991	26	42%	2.2 years (mean)	
Diakomanolis (57)	1996	25	32%	35 – 82 months	
Campagnutta (58)	1999	39	23%	13 – 90 months	
Dodge (20)	2001	42	38%	>7 months	
Perotta (59)	2013	21	14%	12 – 78 months	
Gunderson (9)	2013	34	47%	1 – 194 months	
Topical 5-FU					
Woodruff (60)	1975	9	11%	3 – 7 years	1% – 2% 5-FU q month
Petrilli (61)	1980	15	20%	2 – 60 months	BID × 5 d
Kirwan (62)	1985	14	7%	4 – 42 months	q week × 10 weeks
Krebs (63)	1989	37	19%	12 – 84 months	q week × 10 weeks
Audet-Lapointe (55)	1990	12	17%	9 – 42 months	q d × 5 days
Dodge (20)	2001	22	59%	>7 months	
Topical imiquimod					
Diakomonolis (64)	2002	3	See note		3 × weekly × 8 weeks 3 pts with high-grade disease, therapy revealed regression to VAIN1 (n = 2) or cure (n = 1)
Buck (65)	2003	56	14%		0.25 g q week × 3 weeks
Radiation					
Prempree (66)	1977	7	0%		ICB 70 – 80 Gy
Chyle (67)	1996	37	17%		ICB or orthovoltage radiation
MacLeod (68)	1997	14	14%	46 months (mean)	HDR-ICB, 34 – 45 Gy to vaginal surface, 4 – 10 fx
Ogino (69)	1998	6	0%	13 – 153 months	HDR-ICB, mean dose 23.3 Gy
Perez (70)	1999	20	6%		ICB 60 – 70 Gy

Graham (71)	2007	22	14%	77 months	MDR-ICB, 48 Gy to point Z
Blanchard (72)	2011	28	7%	79 months	LDR, 60 Gy to 5 mm below mucosa
Song (73)	2014	34	6%	48 months	HDR-ICB, 40 Gy in 8 fx
Zolciak-Siwinska (74)	2015	20	10%	39 months	HDR-ICB, 6–7.5 Gy x 3–5 fx

Fx, fractions; HDR, high dose rate; ICB, intracavitary brachytherapy; LDR, low dose rate; MDR, medium dose rate; PV, partial vaginectomy; TV, total vaginectomy; WLE, wide local excision.

Most patients with VAIN 1 are offered close surveillance. Lesions often regress spontaneously; in one study by Aho et al. (26), 78% of patients with VAIN 1 or VAIN 2 had spontaneous regression of disease without treatment. However, over time, VAIN 1 can recur or progress. In one study by Gunderson et al. (9) on 37 patients with VAIN 1, 54% of patients who were observed developed recurrent, persistent, or progressive disease, versus 73% of patients who were treated with excision or ablation. Overall, disease recurrence/progression occurred at a median time of 17 months. Appropriate treatment for VAIN 2 should be determined on an individual basis, based on disease extent and associated patient factors. Therapy for VAIN 3 should be more aggressive, as there is a higher likelihood of progression to invasive disease, including occult invasive disease (41,52).

Surgical and Ablative Therapies. Surgical excision for VAIN is an option in select cases, particularly for vaginal vault lesions. Approaches include local excision, partial vaginectomy, and, in rare cases, total vaginectomy for highly extensive disease, which provides the advantage of obtaining a complete pathologic diagnosis. Most resections can be performed through a transvaginal approach. Location of VAIN in the vaginal vault or posthysterectomy suture recesses may require partial vaginectomy for complete resection, because redundancy of the vaginal mucosa makes it difficult to rule out occult disease with biopsy alone.

Excision of smaller lesions can be achieved through a cold-knife approach, electrosurgical loop excision, laser, or ultrasonic surgical aspiration (85–87). The CO_2 laser has been used for ablation of local tissue, with multiple treatments required in approximately one-third of patients (55,56,58,63,79,88,89). Complications include postoperative pain, scarring, and bleeding; however, the treatment is fairly well tolerated overall, with minimum impact on sexual function (90). Diakomanolis et al. (57) reported that of 52 patients who underwent laser treatment or partial vaginectomy, the results favored laser ablation for multifocal disease and partial vaginectomy for unifocal disease. Ultrasonic surgical aspiration is another technique with the same efficacy as that of laser ablation; in one series of 110 patients, 1-year recurrence-free survival rates were 24% and 26%, respectively (52).

Series on surgical treatment of VAIN report recurrence rates in the range of 0% to 50%, with follow-up ranging from 3 months to 18 years (13,15,32,41,49. Overall, series that specifically examine upper vaginectomy report control rates of 68% to 88% (17,36,41,52,57. For example, Hoffman et al. (41) reported that 83% of patients with VAIN 3 remained free of disease at a mean follow-up time of 38 months. Of note, 28% of all patients were found to have occult invasive disease upon upper vaginectomy. A subsequent study by Indermaur et al. (52), which retrospectively reviewed 36 patients treated with upper vaginectomy for VAIN, reported 88% to be free of recurrence at a mean follow-up time of 25 months. Thirteen patients (12%) were found to have invasive cancer: 8 had frank invasive disease, and 5 had microinvasive carcinoma. Complication rates of upper vaginectomy have been variably reported; in the series by Indermaur, there was a 9% complication rate. Potential complications from surgery depend on the extent and method of surgical resection, and range from vaginal shortening and stenosis to standard postoperative morbidity associated with abdominal procedures. It

should be noted that patients with a history of RT are at higher risk of postoperative complications, with a higher rate of fistula formation reported in one study (13).

Topical Treatments. Topical therapies have been utilized in patients with early-stage lesions, multifocal disease, or multiple comorbidities that render them non-ideal surgical candidates. Topical creams are favored in the management of young, HPV-positive women presenting with multifocal lesions (91). Topical applications have also been utilized before surgery to reduce lesion size and improve stripping of neoplastic epithelial cells from underlying stroma (15). Treatments include topical 5-FU and 5% imiquimod cream, with response rates of up to 86% for imiquimod and 41% to 88% for 5-FU (60,62–65,76,81,82,92,93). Imiquimod increases levels of interferon-alpha, interleukin 12, and tumor necrosis factor (64), resulting in immunomodulation of the vaginal mucosa. Side effects of topical treatments include local irritation, with burning and ulceration being the most commonly reported adverse events (60,81).

Radiation Therapy. In general, RT is reserved for patients who relapse after more conservative treatments. RT is an alternate treatment with a long history of efficacy, with several small series over the past 20 to 30 years reporting control rates ranging from 80% to 100% (16,32,55,69,71,72,76,84,94,95). High dose rate (HDR), medium dose rate (MDR), and low dose rate (LDR) techniques have reportedly yielded acceptable results, although it is difficult to compare regimens because of small patient numbers, generally short follow-up times, and overall lack of uniformity among series. Drawbacks to RT include potential undertreatment of occult invasive disease, the risk of secondary malignancy, and long-term morbidity, although there are no prospective data available regarding the impact of treatment on sexual function and quality of life.

Overall, excellent local control and low toxicity have been reported for LDR brachytherapy. LDR treatment is delivered with an intracavitary vaginal cylinder using cesium 137. Typically, a dose of 60 Gy is delivered to the vaginal mucosa, but a wide range of doses, depending on depth of dose prescription, as well as a variety of techniques, have been reported (70,72,76,84,95. Chyle et al. (67) prescribed 70 to 80 Gy to the vaginal surface, and reported a 17% recurrence rate at 10 years in their series of 37 patients. Perez et al. (70) treated patients with a dose of 60 to 70 Gy to the vaginal surface, and reported one recurrence out of 20 patients. The recurrence occurred in the distal vagina and was noted to be marginal. Blanchard et al. (72) published a series on 28 patients with VAIN 3 treated at Institut Gustave Roussy from 1985 to 2008. Patients were treated with LDR brachytherapy, using a vaginal mold technique, to a dose of 60 Gy prescribed 5 mm below the vaginal surface; 18 patients received treatment to the upper half of the vagina, 6 were treated to the upper two-thirds, and 4 were treated to the whole vaginal length. With a median follow-up time of 41 months, the authors report only one in-field recurrence, and a 10-year local control rate of 93%. Treatment with LDR brachytherapy is well tolerated overall; in the Blanchard et al. series, there were no grade 3 or 4 late toxicities, and only one grade 2 gastrointestinal toxicity noted. This is consistent with the Perez series, in which there was only one grade 3 urinary complication among 40 patients with VAIN 3 or stage 1 vaginal cancer treated with LDR (70).

There are limited data on the use of MDR brachytherapy treatment for VAIN. Graham et al. (71) reviewed their experience using MDR intracavitary brachytherapy for VAIN 3 at the Beatson Oncology Center in Glasgow, UK. Using a MDR Selectron, 48 Gy was prescribed 0.5 cm lateral to the ovoid surface (point Z) over two insertions, spaced 1 week

apart. Ovoids were chosen over vaginal cylinder placement in order to adequately cover epithelium sutured into the superolateral vagina at hysterectomy. With a median follow-up of 77 months, recurrent/residual VAIN 3 was documented in three patients, two of whom subsequently developed invasive or microinvasive vaginal carcinoma. One other patient developed late progression 14 years after treatment. There were minimal acute effects during treatment; however, with longer follow-up, all patients were noted to have grade 1–2 mucosal atrophy, dryness, and telangiectasia. Four patients developed grade 3 toxicity with severe vaginal stenosis, and one patient developed a grade 4 vaginal ulcer that presented 2 years after treatment. One other patient developed grade 3 urinary toxicity with urethral stricture, requiring intermittent self-catheterization.

Several series have reported promising results for HDR brachytherapy, with disease-free survival (DFS) rates of 90% or greater. HDR brachytherapy is generally reserved for patients with VAIN 3, particularly if there is an in situ disease component. Ogino et al. (69) reported their experience treating six patients with VAIN 3 at Kanagawa Cancer Center from 1983 to 1993, with a mean dose of 23.3 Gy (range 15–30 Gy); most treatments were delivered in five fractions using two ovoids, with dose calculated to a point 1 cm superior to the vaginal apex. Lesions distal to the vaginal vault had doses calculated 1 cm beyond the plane of the vaginal cylinder in order to deliver adequate dose to the entire vagina. Median follow-up was 90.5 months, and there was no evidence of disease recurrence in the treated patients. Two patients developed moderate to severe vaginal stenosis, and three patients developed rectal bleeding, that resolved. MacLeod et al. (68) reviewed their experience treating 14 patients with VAIN 3 from 1985 to 1995. The total dose was 34 to 45 Gy to the vaginal surface, in 8.5-Gy fractions delivered twice a week, or 4.5-Gy fractions delivered four times a week. One patient developed invasive cancer, and one patient had persistent VAIN 3. There were no major acute toxicities, and two patients developed late grade 3 vaginal atrophy and stenosis. According to one study that evaluated toxicity after use of HDR brachytherapy for VAIN in 20 patients, utilizing the CTCAE scale, a biologically equivalent dose of 70 Gy or greater results in significantly greater toxicity. The most common toxicities were decreased libido, vaginal discharge, dryness, mucositis, stenosis, and vaginitis (74).

Malignant Tumors of the Vagina: Squamous Cell Carcinoma

Epidemiology

The NCDB review by Creasman et al., for the period 1985 to 1994, revealed 3,244 cases of invasive primary vaginal carcinoma, with 24% of patients presenting with American Joint Committee on Cancer (AJCC) stage I disease, 20% AJCC stage II, 24% AJCC stages III–IV, and 32% unknown. Most tumors were moderately (28%) or poorly (28%) differentiated at presentation. Consistent with this data, a review of five series, including a total of 1,375 cases of vaginal cancer, reported the FIGO stage distribution as follows: 26% stage I, 37% stage II, 24% stage III, and 13% stage IV (96).

According to the SEER study by Shah and colleagues (8), most women diagnosed with primary vaginal cancer are non-Hispanic Whites (66%), followed by African Americans (14%), Hispanic Whites (12%), Asian/Pacific Islanders (7%), and others (1%). Incidence rates were highest for African American women (1.24/100,000 person-years) and lowest for Asian/Pacific Islanders (0.64/100,000 person-years). The greatest proportion of women (36%) presented with stage I disease, and 65% had squamous histology, consistent with other reports.

Risk Factors

Risk factors for primary vaginal SCC are similar to those for VAIN and cervical neoplasia. Commonly cited factors include HPV infection and/or history of cervical or vulvar intraepithelial neoplasia, immunosuppression, multiple sexual partners, and early age at first intercourse. It is believed that most cases of vaginal cancer can be attributed to HPV infection.

According to a meta-analyses comprising 14 studies, the overall HPV prevalence was 70% for vaginal carcinomas, with the most common subtypes as follows: HPV 16 (53.7%), HPV 18 (7.6%), and HPV 31 (5.6%). Multiple subtypes of HPV were identified in 3.4% of cases (97).

In a population-based case–control study of 156 women with VAIN or invasive cancer, significant risk factors included early age at intercourse, increased number of lifetime sexual partners, and current smoking. HPV DNA was detectable in 80% of patients with in situ disease and in 60% of those with invasive disease; 30% of patients reported a history of treatment for invasive malignancy, most commonly cervix, or in situ anogenital neoplasia (37). A case–control study of 41 women with in situ disease or invasive carcinoma identified low socioeconomic status, history of genital warts, vaginal discharge or irritation, history of abnormal cytology, prior hysterectomy, and vaginal trauma as potential risk factors (98). A larger case–control study of 36,856 women found an increased risk of vaginal cancer in alcoholics, likely associated with a higher incidence of other lifestyle factors, such as promiscuity and smoking, which are also associated with a higher incidence of HPV infection. Early hysterectomy appears to be a risk factor in some studies, if performed for malignant or premalignant disease (37,99).

Patients with a history of cervical cancer have a significantly higher risk of developing in situ as well as invasive carcinoma of the vagina. Studies suggest that 10% to 50% of patients with a history of VAIN or invasive carcinoma of the vagina have undergone treatment for in situ or invasive cervical carcinoma (32,67,100–106), with the interval from treatment of cervical disease to development of vaginal carcinoma averaging approximately 14 years (102,107). HIV-infected women are also at higher risk of developing vaginal carcinoma, which tends to behave more aggressively in HIV-positive than in HIV-negative patients (108).

The role of ionizing radiation to the pelvis in the development of vaginal carcinoma is unclear, with conflicting reports. According to one study that analyzed 1,200 patients treated over a 20-year period for carcinoma of the cervix, prior RT was not shown to result in increased secondary pelvic neoplasms (31). A second study by Boice et al. (30), however, reported a 14-fold increased risk of vaginal cancer in women with a history of pelvic irradiation before the age of 45, with a significant dose–response relationship.

Another potential risk factor is chronic irritation of the vaginal mucosa, resulting in chronic inflammation, hyperkeratosis, thickening, and acanthosis (108), with subsequent metaplastic and dysplastic changes; however, this is not proven. Although older studies showed that more vaginal cancers arise from the posterior vaginal wall, other studies report approximately equal distribution of invasive carcinomas on the anterior and posterior walls (36,102,109–111); this poses an argument against the theory that pooling of irritating substances in the posterior fornix contributes to the development of vaginal cancers, particularly on the posterior wall. Chronic irritation from the use of vaginal pessaries has also been implicated as a factor in vaginal cancer development (112,113).

Clinical Presentation

Up to 65% of patients with vaginal cancer present with irregular vaginal bleeding as their primary symptom (102,114,115). Vaginal discharge is the second most common symptom, occurring in 10% to 15% of patients. Less frequent symptoms, associated with locally advanced disease, include the presence of a mass; pain; urinary symptoms including frequency, dysuria, or hematuria; or gastrointestinal complaints such as tenesmus, constipation, or melena. Because of the proximity of anterior wall lesions to the urethra and bladder, urinary symptoms can be seen more commonly in vaginal cancer than in cervical cancer. Up to 20% of women are asymptomatic at the time of diagnosis (102,116), with lesions detected via cytologic screening or by speculum examination.

Vaginal cancer most frequently involves the superior one-third of the vaginal canal, with series reporting 50% to 83% of cases occurring in this region (36,110,111,117–120). A high proportion of patients have a history of prior hysterectomy. There is approximately equal involvement of the middle and inferior thirds (36), although some studies suggest that involvement of the lower third is more common than involvement of the middle third (102,111). The lateral walls are less frequently involved. Tumors may exhibit an exophytic or ulcerative, infiltrating growth pattern.

Vaginal tumors can spread along the vaginal walls to involve the cervix or vulva, but involvement of the cervix or vulva at the time of diagnosis excludes classification as a primary vaginal cancer. Lesions can extend radially, either into the lumen to form exophytic masses or through the vaginal wall to invade surrounding musculature and organs. Anterior wall lesions can infiltrate the vesicovaginal septum and/or urethra. Posterior wall lesions can infiltrate the rectovaginal septum and involve the rectal mucosa. Advanced disease can extend laterally toward the parametrium and paracolpal tissues, or into the urogenital diaphragm, levator ani muscles, or pelvic fascia, and eventually to the pelvic sidewall.

Distant metastases can occur with advanced disease at presentation, or on recurrence after primary therapy. The most frequent site of hematogenous metastasis is the lung, whereas less commonly noted sites are the liver and bone (67). In a series by Perez et al. (105), the incidence of distant metastasis was 16% for stage I, 31% for stage II, 46% for stage IIB, 62% for stage III, and 50% for stage IV. Some histologies may have a higher likelihood of distant metastases than others. Chyle et al. (67) noted a higher incidence of distant metastases in patients with adenocarcinoma (48%) than in those with SCC (10%), with correspondingly lower 10-year survival rates (20% vs. 50%).

Histopathology

Grossly, SCC of the vagina can present as nodular, ulcerated, indurated, exophytic or endophytic lesions, and it is difficult to histologically distinguish a primary vaginal SCC from recurrent cervical or vulvar carcinoma. Histologically, tumors are graded as well, moderately, or poorly differentiated, and have been described as keratinizing, nonkeratinizing, basaloid, warty, or verrucous. Most of these lesions are nonkeratinizing and moderately differentiated (121) (Fig. 19.4).

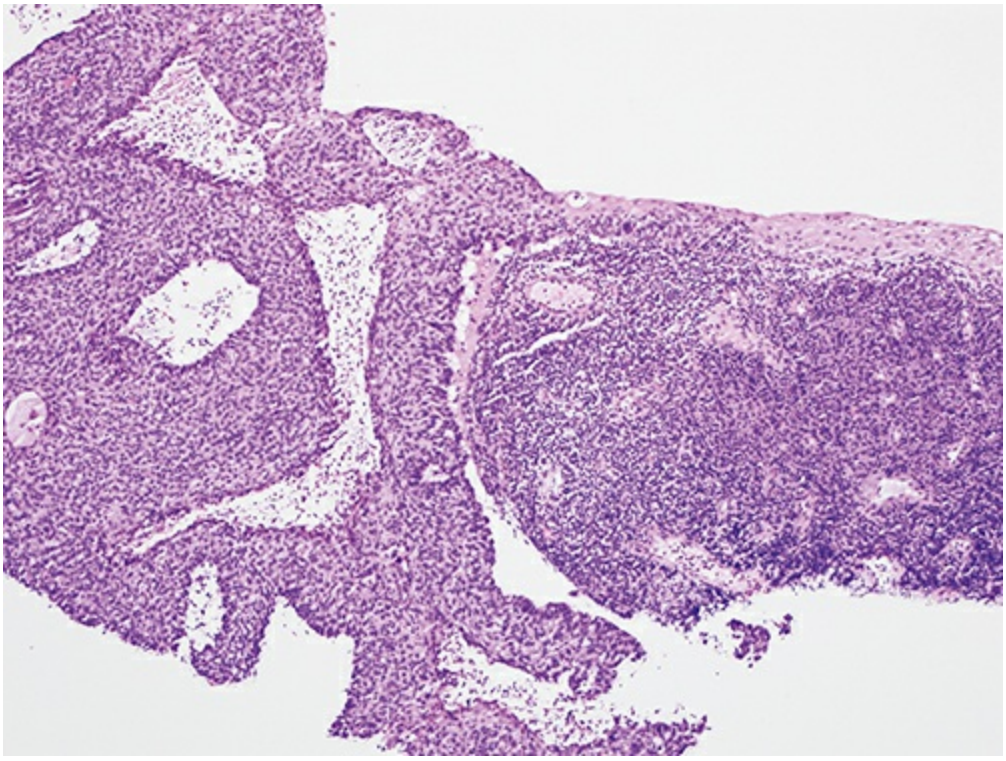

Figure 19.4 Moderately differentiated squamous cell carcinoma of the vagina. Invasive squamous cell carcinoma may appear as nests of atypical keratinocytes, or, alternatively, may appear as complex, redundant strips of neoplastic epithelium. In moderately differentiated squamous cell carcinoma, the keratinocytes show nuclear atypia, nuclear hyperchromasia, and high N:C ratio, often with easily identifiable mitoses, and limited evidence of squamous maturation, as expected in well-differentiated examples. Images courtesy of Emily E.K. Meserve.
Source: Images courtesy of Emily E.K. Meserve.

Verrucous carcinoma is a distinct histologic variant of vaginal SCC (122). It commonly presents as a well-circumscribed, soft, cauliflower-like mass that is microscopically well differentiated, with a papillary growth pattern and acanthotic epithelium (Fig. 19.5). There is surface maturation with parakeratosis or hyperkeratosis without koilocytosis. This variant of SCC exhibits less aggressive behavior, and rarely metastasizes (122–125). Therefore it should be considered an entity distinct from other vaginal SCC.

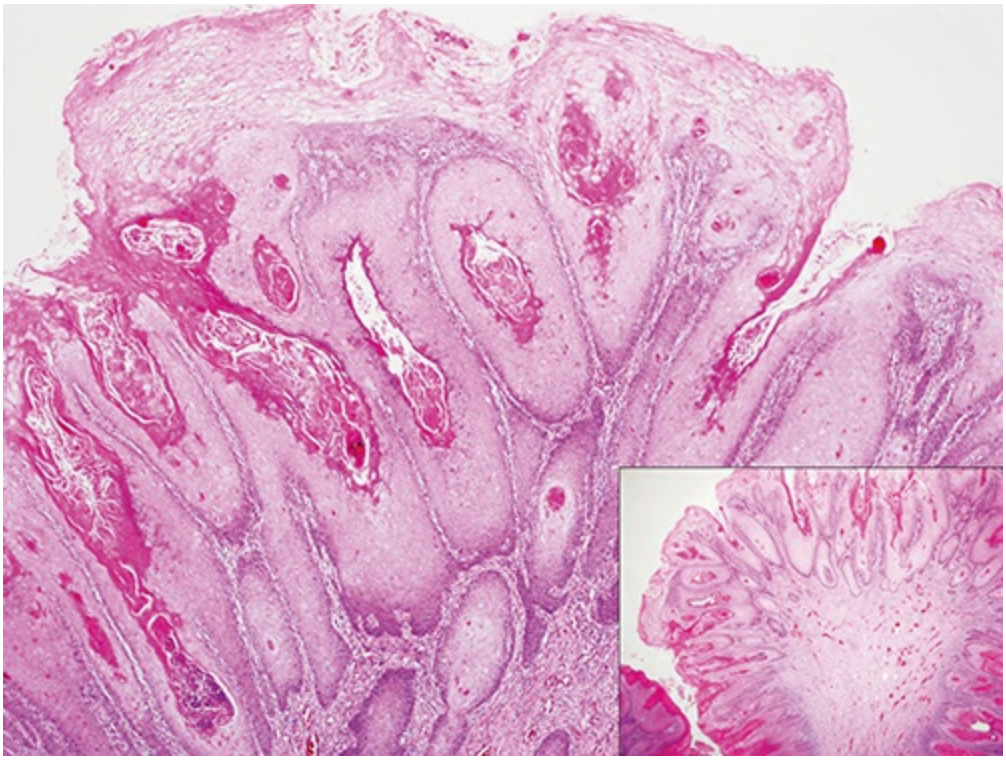

Figure 19.5 Verrucous squamous cell carcinoma. Verrucous squamous cell carcinoma is a rare subtype of extremely well-differentiated squamous cell carcinoma. Tumors are often exophytic (inset) with very bland and uniform cytologic features and often a "pushing" pattern of invasion, rather than invasion by irregular nests or single cells as seen more frequently in conventional SCC. Images courtesy of Emily E.K. Meserve.
Source: Images courtesy of Emily E.K. Meserve.

Sarcomatoid SCC is a rare subset of vaginal SCC, comprising 2% of all cases (Fig. 19.6). It is characterized by spindle-shaped neoplastic cells that may initially be mistaken for sarcoma. However, positive stains for cytokeratin help distinguish sarcomatoid SCC as a poorly differentiated variant of vaginal SCC (126).

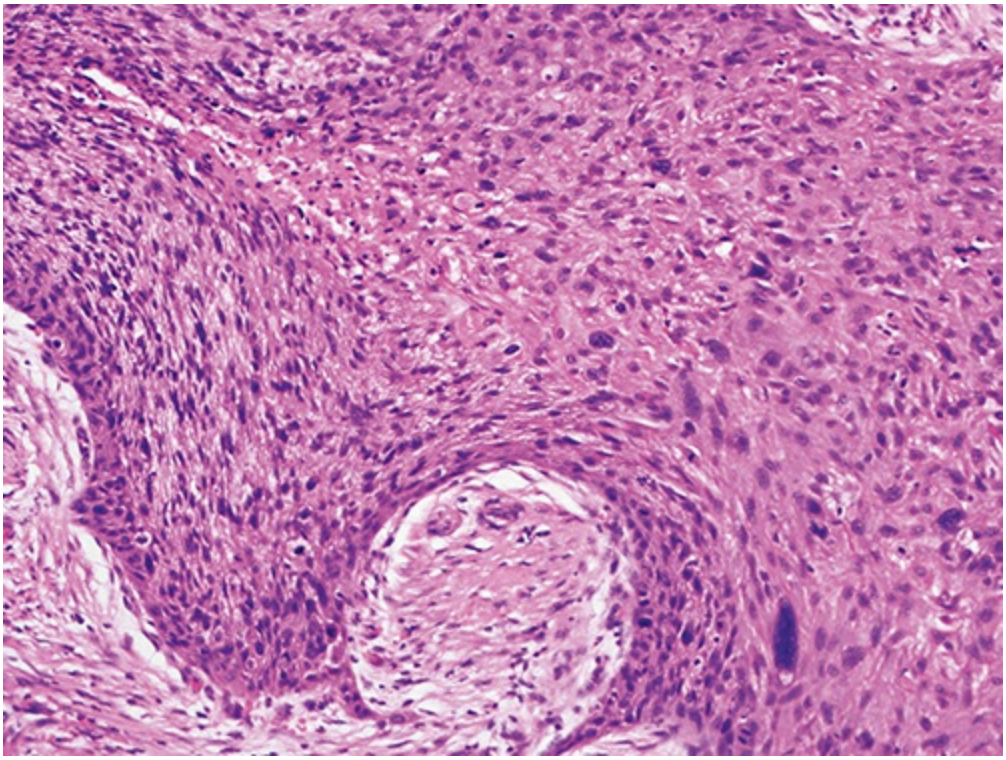

Figure 19.6 Sarcomatoid squamous cell carcinoma. Sarcomatoid squamous cell carcinoma is a type of poorly differentiated squamous cell carcinoma wherein neoplastic squamous epithelial cells exhibit a spindle cell morphology. Keratin expression is less consistent in areas of spindle cell morphology, but continuity with areas of more conventional poorly differentiated SCC, with prominent nuclear pleomorphism and necrosis, helps confirm the diagnosis of carcinoma. Patterns of Lymphatic Drainage

The vagina has a complex pattern of lymphatic drainage, with multiple interconnections. The upper vagina drains to the obturator and hypogastric nodes, similar to the cervix. The lower vagina drains to the inguinal, femoral, and external iliac nodes, and posteriorly situated lesions can drain to the inferior gluteal, presacral, or perirectal nodes. Lymphatic channels in the mucosa run parallel to networks of channels in the submucosa and muscular layer, ultimately converging to form trunks at the vaginal wall periphery, which subsequently drain to major pelvic nodal groups.

In view of considerable crossover drainage, the location of the primary tumor is not a reliable indicator of drainage site. Frumovitz et al. (127) utilized lymphoscintigraphy to determine patterns of lymphatic drainage in 14 women diagnosed with primary vaginal cancers, and found a substantial degree of anomalous drainage, resulting in a change in RT for 33% of patients. For example, among four women with lesions located in the upper third of the vagina, which is predicted to drain along the cervical lymphatic chains to the pelvis, two (50%) were found to have a sentinel node in the inguinal region. Among five women with lesions located at the vaginal introitus, a location predicted to drain along the vulvar lymphatic chains to the inguinal triangle, three (60%) were found to have a sentinel node in the pelvis.

The risk of nodal metastasis appears to increase significantly with stage. Sparse data on nodal metastases are derived from series in which exploratory laparotomies and lymphadenectomies were performed (107). However, the true incidence of positive lymph nodes is difficult to determine because most patients receive treatment with RT and do not undergo surgical lymphadenectomy. The incidence of lymph node involvement has been reported as 0% to 14% in stage I and 21% to 32% in stage II disease (107,128,129). The incidence of nodal involvement in stages III and IV is reportedly as high as 78% and 83%, respectively (111). At diagnosis, up to 20% of patients have clinically positive inguinal nodes, with reported

ranges of 5.3% to 20% (70,105). The risk of nodal failure increases significantly with local recurrence. Chyle et al. (67) reported 10-year inguinal and pelvic failure rates of 16% and 28%, respectively, in patients with local recurrence, in contrast to 2% and 4%, respectively, in patients without local recurrence.

Diagnostic Workup

The diagnostic workup should start with a thorough history and physical examination, giving careful attention to the pelvis. Complete assessment of tumor extent and assessment of vaginal walls is facilitated by examination under anesthesia. During speculum examination, the speculum blades can obscure the anterior and posterior walls, so it is essential to rotate the speculum for visualization of all four walls from the introitus to the apex. Bimanual examination, with careful digital palpation, should be performed, assessing for parametrial and pelvic sidewall involvement and invasion of tumor to the rectal mucosa.

Inguinal nodes should be palpated for disease involvement, particularly if the primary lesion is situated in the lower portion of the vagina, because 5% to 20% of patients reportedly have involved inguinal nodes at presentation (70,105). Suspicious nodes warrant a biopsy. Laboratory tests include a complete blood count with differential and assessment of renal and hepatic function.

A definitive diagnosis is achieved with biopsy of suspected lesions, which can present as an exophytic mass, plaque, or ulcer. If a lesion is not visible in the setting of abnormal cytology, colposcopy with acetic acid, followed by Lugol's iodine stain, is conducted. Biopsies of white epithelium or atypical vascularity should be obtained after application of acetic acid. Iodine will identify Schiller-positive regions, which are nonstaining, and should correspond to areas identified following application of acetic acid. Adequate biopsies should include the cervix, if present, to rule out a cervical primary. Patients can present with multiple regions of abnormality. The differential diagnosis of a vaginal mass includes endometriosis, vaginal polyp, vaginal adenosis, or Gardner's duct cyst.

FIGO staging of vaginal cancer is clinical, and may include chest x-ray, intravenous pyelography (IVP), barium enema, cystoscopy, and proctosigmoidoscopy. Cystoscopy or proctosigmoidoscopy may be necessary in patients with symptoms suggestive of bladder or rectal infiltration. Computed tomographic (CT) imaging and magnetic resonance imaging (MRI) do not affect FIGO stage assignment, but are commonly used. CT of the pelvis is obtained in place of IVP to assess the renal parenchyma, and also to obtain information on the extent of local disease and lymph node status. MRI can provide salient treatment planning information by characterizing extent of invasion and differentiating malignant tumor, which is isointense to muscle on T1 and hyperintense on T2, from normal structures and/or fibrosis (130). Advantages of MRI over other imaging modalities include superior soft tissue contrast resolution, allowing accurate assessment of tumor volume, extent of local invasion, and accurate assessment of pelvic nodal involvement. In general, MRI is regarded as superior to CT for staging of gynecologic malignancies, and should be obtained when available.

Positron emission tomography (PET) has shown efficacy in detecting the extent of primary tumor and abnormal lymph nodes in vaginal cancer with higher sensitivity than CT (Fig. 19.7), as is the case in cervical carcinoma (131). Primary vaginal carcinoma and metastatic lesions demonstrate avid uptake of 2[fluorine 18]-fluoro-2-deoxy-D-glucose (FDG). In one study, 23 patients with primary vaginal carcinoma received both PET and CT during staging. CT identified the primary tumor in only 43% of patients, whereas PET identified the tumor in 100%. PET identified suspicious uptake in groin and pelvic nodes in 8 of 23 patients, compared to 4 of 23 with CT. Treatment planning was modified in 14% of patients because of findings from PET, and the authors concluded that PET detects primary tumor and abnormal lymph nodes more often than CT (131). It is important that the patient have an empty bladder before imaging, as physiologic FDG activity in a filled bladder can potentially interfere with accurate estimation of vaginal involvement. In practice, most patients undergoing planning for RT are assessed with CT as well as MRI and/or PET, based on extrapolation from studies of other gynecologic malignances as well.

Staging

The AJCC (132) and FIGO (10) systems are used to stage vaginal cancer (Tables 19.2 and 19.3). Primary vaginal melanomas and lymphomas are staged according to the AJCC staging systems for melanomas and lymphomas, respectively (132).

TABLE 19.2 International Federation of Gynecology and Obstetrics Staging System for Carcinoma of the Vagina

Stage	Description
Stage I	Carcinoma is limited to vaginal wall
Stage II	Carcinoma has involved the subvaginal tissue but has not extended to the pelvic wall[a]
Stage III	Carcinoma has extended to the pelvic wall
Stage IV	Carcinoma has extended beyond the true pelvis or has involved the mucosa of the bladder or rectum; bullous edema as such does not permit a case to be allotted to Stage IV
Stage IVA	Tumor invades bladder and/or rectal mucosa and/or direct extension beyond the true pelvis

For patients with a prior gynecologic malignancy, a 5-year disease-free period is generally considered adequate to allow for distinction between recurrent disease and a new primary vaginal cancer. FIGO no longer recognizes carcinoma in situ as stage 0.

Stage I disease is defined as limited to the vaginal wall, and stage II disease involves subvaginal tissue without extension to the pelvic wall. Discriminating between stages I and II can be subjective; thin tumors <0.5 cm are generally classified as stage I, whereas thicker infiltrating tumors or those with paravaginal nodularity are classified as stage II. Perez et al. proposed a modification to the FIGO system in 1973, distinguishing tumors with paravaginal submucosal extension only (stage IIA) from tumors with parametrial infiltration (stage IIB) (70). The study reported a 20% 5-year

survival difference (55% vs. 35%) between stages IIA and IIB. This modification has not been adopted into FIGO staging; however, some investigators consider the distinction to be prognostically relevant (66,105).

Prognostic Factors

Stage at time of presentation is the most significant prognostic factor, according to numerous studies (8,70,103,133–136). According to the NCDB study, the largest population-based series on vaginal cancer thus far, 5-year survival rates are as follows: 96% for stage 0, 73% for stage I, 58% for stage II, and 36% for stages III/IV disease (7). The series by Shah et al. (8), based on SEER data for women diagnosed between 1990 and 2004, also reveals the correlation between stage and outcome, with 5-year disease-specific survival (DSS) rates of 84% for stage I, 75% for stage II, and 57% for stages III/IV; the adjusted hazard ratio for mortality, on multivariate analysis, was 4.67. In the Perez et al. (105) series, 165 patients with primary vaginal cancer were treated with definitive RT, and had 10-year actuarial DFS rates of 94% for stage 0, 75% for stage I, 55% for stage IIA, 43% for stage IIB, 32% for stage III, and 0% for stage IV (137).

Size of the initial lesion is a prognostic factor that has shown significance in several series. The SEER database study (8), which included 2,149 women with primary vaginal cancer, noted a significantly lower 5-year survival rate in women with tumors ≥4 cm than in those with tumors <4 cm (65% vs. 84%); however, size information was missing for 52% of women. After multivariate analysis, patients with the larger tumors had an adjusted hazard ratio of 1.71 for mortality. Chyle et al. (67), in their review of 301 patients treated at M.D. Anderson Cancer Center (MDACC) from 1953 to 1991, found that women with lesions larger than 5 cm in maximum diameter had a significantly higher 10-year local recurrence rate than those with smaller lesions (40% vs. 20%). The series by Hellman et al. (135), with 314 patients treated at the Karolinska University Hospital from 1956 to 1996, found that only three factors independently predicted poor survival on multivariate analysis: advanced age, tumor size ≥4 cm, and advanced stage. Tumors comprising two-thirds or more of the vagina and tumors growing circumferentially were associated with an extremely poor prognosis. The series by Tran et al. (138), which reviewed records of 78 patients with SCC treated at Stanford University Medical Center from 1959 to 2005, also found size to be a prognostic factor for DFS on multivariate analysis, along with stage, prior hysterectomy, and pretreatment hemoglobin level. Smaller series by Tjalma et al. (139) and Kirkbride et al. (103) also describe adverse outcomes with larger tumor size. Other series have failed to show significance, but are likely hindered by small numbers, difficulties in accurate assessment of size, and treatment heterogeneity.

Extent of vaginal canal involvement has also been identified as significant, perhaps because it is a surrogate for tumor size. In a series by Stock et al. (110) that examined 100 cases of primary vaginal carcinoma treated at Magee-Women's Hospital from 1962 to 1992, patients with involvement of one-third of the vaginal canal or less had a significantly higher 5-year disease-free survival rate (61%) than patients with more extensive involvement (25%).

Several studies suggest HPV status is an indicator of favorable prognosis. Fuste and colleagues found a trend toward longer survival in women with HPV-positive tumors in their series of 32 patients, with median survival times of 113.9 months versus 19.7 months for women with HPV-positive and HPV-negative tumors, respectively (p = 0.15) (140). Alonso et al. (141) evaluated a total of 57 patients, of whom 70.2% had evidence of high-risk HPV. On multivariate analysis (MVA), HPV-positive status was a favorable prognostic variable for overall survival (OS) (HR 0.35, p = 0.038). Brunner et al. (142) evaluated 35 patients with primary invasive SCC of the vagina. Using in situ hybridization, HPV was detected in 51.4% of cases. There was no significant influence on clinical stage, grade, or tumor size, nor did prognosis differ between HPV-positive and HPV-negative tumors. However, in a subset of patients with FIGO stage III or higher disease, HPV positivity was found to correlate with improved DFS and overall survival (OS), with p values of 0.004 and 0.023, respectively.

There is conflicting evidence concerning the impact of lesion location on prognosis; it has been noted in some (67,117,143–145) but not all (105,120,146) reports. In an analysis of 110 patients by Kucera (147), 5-year survival rates were 60% for lesions of the upper third of the vagina, 37.5% for lesions of the middle third, and 37% for the lower third. Chyle et al. (67) noted a 17% rate of pelvic relapse in patients with tumors in the upper third of the vagina, 36% for

patients with tumors in the middle or lower third, and 42% for patients with whole vaginal involvement. Lesions in the posterior wall were also associated with a worse prognosis than lesions involving the anterior vaginal wall (67), with 10-year recurrence rates of 32% versus 19% on univariate analysis ($p < 0.007$). The Hellman series (135), however, found no difference in prognosis between anterior and posterior tumors. Similarly, histologic grade has been an independent significant predictor of survival in several series (103,117,145), but not others (135). Hellman et al. evaluated the impact of tumor grade and other histopathologic variables (mitotic activity, koilocytosis, growth in vessels, lymphocytic reactions) and found no correlation with survival.

Several series suggest a correlation between older age and decreased survival (9,135,145). For example, age was also noted to be a significant prognostic factor in the Urbanski et al. (145) series, with 5-year survival rates of 83% for patients younger than 60 compared with 25% for those 60 years of age or older ($p < 0.0001$). Age >60 years was negatively associated with survival in the series by Gunderson et al., (9) which examined a total of 110 patients (HR 2.16; $p = 0.0339$). Other series have failed to demonstrate the statistical significance of age (70,148).

Other possible prognostic factors include hemoglobin levels, prior hysterectomy, and smoking status. Tran et al. reviewed records of 78 patients with primary SCC of the vagina treated at Stanford University Hospital, and found a hemoglobin level <12.5 g/dL prior to definitive treatment to be prognostic for worse pelvic control and DSS (128); 5-year DSS rates were 55% for women with Hg levels <12.5 g/dL and 76% for those with levels ≥12.5 g/dL. This remained significant after multivariate analysis, along with prior hysterectomy, stage, and tumor size. The study by Tran et al. (138) is the first to identify prior hysterectomy as a favorable prognostic factor on multivariate analysis. This may reflect more rigorous surveillance in posthysterectomy patients, resulting in tumors discovered at an earlier stage, or may be a reflection of less overall vaginal tissue as a substrate for tumorigenesis. Two subsequent studies have identified hysterectomy as a significant prognostic factor, but only on univariate analysis (67,135).

For patients treated with radiation, treatment time may be a significant factor impacting tumor control (149,150). Lee et al. (150) found overall treatment time of ≤9 weeks to be associated with a pelvic tumor control rate of 97%, compared with 57% for treatment time >9 weeks ($p < 0.01$). Pingley et al. (149) also noted a correlation between treatment time and outcome; patients receiving brachytherapy within 4 weeks of external beam RT (EBRT) had a 5-year DFS rate of 60%, compared with 30% in patients who had an interval greater than 4 weeks.

Treatment: Surgery

For most patients with invasive vaginal cancer, surgery has a limited role, and radiation is the treatment of choice. Owing to the rarity of these lesions, and the required individualization of treatment, it is recommended that patients be referred to a tertiary center with experienced practitioners. In general, surgery is considered useful in the following specific scenarios.

For example, patients with early-stage lesions may have acceptable outcomes if a potentially curative resection can be achieved without extensive functional morbidity. Typically, amenable lesions are small, superficially invasive, and well demarcated, and localized to the upper vagina. A wide local excision can be performed for in situ lesions. For more invasive lesions, a radical upper vaginectomy and pelvic lymphadenectomy can be considered. If the uterus is still present, a radical hysterectomy is also recommended; the goal is to achieve at least 1 cm margins (11).

Surgery can be considered for previously irradiated patients who cannot receive further radiation. Typically, such cases require pelvic exenteration.

Surgery is also a consideration for select patients with stage IVA disease. Extensive lesions in the proximal aspect of the vaginal canal require radical hysterectomy, upper vaginectomy, and bilateral pelvic lymphadenectomy. Older surgical series often required pelvic exenteration in 40% to 50% of cases to obtain negative margins (107,111). Anterior exenteration removes the vagina, urethra, and bladder, and is often necessary to achieve negative margins for invasive anterior wall lesions. Posterior exenteration requires resection of the vagina and rectum. Deeply invasive, circumferential lesions may require a total exenteration in order to achieve clear margins. With positive margins, adjuvant radiation should be offered. Lesions that extend to the inferior vagina require a total vaginectomy with radical hysterectomy, pelvic lymphadenectomy,

and possibly vulvovaginectomy and inguinofemoral lymphadenectomy (101,102,110,111). It is not uncommon for relatively small lesions to invade the rectum or urethra early in the disease course, given the close proximity of the vagina to these structures. Given the potentially devastating functional results associated with radical surgery, definitive radiation is the treatment of choice for most patients with invasive vaginal cancer, and has largely replaced surgery as the primary therapeutic modality.

Reported 5-year OS rates for stage I vaginal cancer treated with surgery range from 75% to 100% (Table 19.4) (7,101,107,110,139,151). The distinction between stage I and II disease is made clinically, based on physical examination, and it can vary. The NCDB review for cancers of the vagina noted superior survival rates in patients treated with surgery (7), though this likely reflects selection of healthier patients with good performance status for radical surgery. A more recent analysis utilizing the SEER database (8) found women with stage I disease treated with surgery only to have a lower risk of mortality than those treated with radiation only, combined modalities, or no treatment; however, this difference did not reach statistical significance. For stage II vaginal cancer patients, there was a similar trend toward increased mortality in women who did not have surgery alone as their primary treatment modality, but values once again did not reach statistical significance in their multivariate adjusted model.

TABLE 19.4 Early-Stage Vaginal Cancer Treated with Primary Surgery

Series	Stage	# of Pts	Outcomes	Column1	Notes
Creasman (1985–1994) (7)	I	76	5y OS 90%		
	II	34	5y OS 70%		
Tjalma (1974–1999) (139)	I	26	5y OS 91%		4 pts received adjuvant RT 5 LE, 19 htx, 2 ext
Rubin (1957–1980) (111)	I/II	9	5y OS 75%

	II	8	5y OS 63%		1 ext

Ext, exenteration; htx, hysterectomy; LE, local excision; pts, patients; PV, partial vaginectomy; RV, radical vaginectomy.

Ling et al., (152) in a small series consisting of four patients with stage I disease, report their experience using laparoscopic radical hysterectomy with vaginectomy and reconstruction of the vagina. With follow-up times ranging from 40 to 54 months, they report that all patients were free of disease, with satisfactory sexual function. The authors suggest that laparoscopic surgery may be an option for select patients with early-stage disease, with good outcomes.

Other series also report excellent results with primary surgical therapy, though authors acknowledge bias resulting from selection of healthier patients with less extensive disease for primary surgery over radiation. In a review of 100 cases by Stock et al. (110), with 85 SCC cases, surgical treatment was noted to be a significantly favorable prognostic factor for DFS, compared with RT alone. For stage I patients, DFS rates were 56% and 80% for patients treated with surgery

versus RT, respectively. For stage II patients, survival rates were 68% and 31% after surgery and RT, respectively, though this likely reflects selection bias, with patients with more extensive involvement offered RT. Overall 5-year survival was 47%. Stock et al. concluded that surgery consisting of radical hysterectomy, pelvic lymphadenectomy, and upper vaginectomy could be reasonable for stage I lesions and select stage II lesions, with RT being the preferred primary modality for patients with stage IIB disease. It should be noted, however, that 23 of 33 stage II patients (70%) treated with surgery required a total vaginectomy or exenterative procedure, which carries significant morbidity and functional impairment.

Smaller series also support use of surgery in select patients with early-stage disease. Tjalma et al. (139) reported on 55 cases of primary vaginal SCC. Of 27 patients with stage I disease, 26 received surgery, with 4 subsequently receiving some form of adjuvant RT. With a median follow-up time of 45 months, 5-year survival was reported to be 91%. Otton et al. (151), in their retrospective review of 70 patients with stage I–II vaginal carcinoma treated at Queensland Center for Gynaecological Cancer between 1982 and 1998, report that patients treated with surgery alone, or a combination of surgery and RT, had significantly longer survival times than patients treated with radiation alone. The authors suggest that surgery may be effective in a select subset of patients with small, localized tumors that permit clear surgical margins. Peters et al. (120) reviewed records of 86 patients with vaginal carcinoma, including 68 SCC cases, treated at the University of Michigan Medical Center. Twelve selected patients had surgery as primary therapy, with a 75% survival rate. Similarly, Rubin et al. (111) reported on eight patients with stage I or II disease who received surgery as primary treatment; 5-year survival was 75%, and the overall local control rate for the stage I patients was 80%, suggesting that highly selected patients can achieve excellent outcomes with surgery. Davis et al. (107) reported on 89 patients with vaginal carcinoma, treated primarily at the Mayo Clinic from 1960 to 1987. A total of 52 patients were treated with surgery as primary therapy, with 5-year survival of 85%, compared with 65% for patients who received RT alone. In the stage II patients, the 5-year survival rates were 49%, 50%, and 69% for surgery, radiation, and combined treatment with surgery and RT, respectively. However, treatment modalities cannot be effectively compared using retrospective series, given selection biases.

Several series report their experience using surgery for advanced-stage III or IV patients, with most cases requiring radical excision, typically pelvic exenteration (101,102,110,111). Control rates, at best, are around 50%, even with highly selected patients. In practice, given the overall poor prognosis and morbidity associated with surgery, advanced-stage patients should receive definitive RT, typically in combination with chemotherapy (CT).

Another approach that has been proposed involves neoadjuvant CT followed by radical surgery (153,154). Benedetti et al. (153) reported 11 patients with stage II SCC of the vagina treated by using three cycles of neoadjuvant paclitaxel and cisplatin followed by surgical resection. Ninety-one percent of patients obtained a partial or complete response to neoadjuvant CT; 27% achieved a complete response. All patients had disease-free resection margins after surgery, and only one patient had positive lymph nodes. At a median follow-up time of 75 months, 10 of 11 patients (91%) were alive, and of those, eight (73%) were free of disease. Postoperative complications were mild.

A case report documented the use of neoadjuvant CT consisting of bleomycin and cisplatin, followed by radical surgery, for one patient with stage II SCC of the vagina. The patient was free of disease, with satisfactory sexual function, at 30 months (153). However, it is necessary to evaluate the feasibility of this treatment in larger series of patients, with longer follow-up.

Treatment: Radiation

For most patients, RT is the treatment of choice given the desire for organ preservation and the significant morbidity that may be incurred by exenterative surgery. It is important to individualize RT techniques based on size, depth, and location of the lesion. The outcomes of retrospective series on use of RT for vaginal cancer are summarized in Table 19.5, and are addressed in detail in the next section.

TABLE 19.5 Outcomes for Vaginal Cancer Treated with Primary Radiation

Series	Outcome	Stage I	Stage II	Stage III	Stage IV	Treatment
Dixit (1985–1989) (147)	2y DSS	100%	70%	19%	0%	EBRT and/or BT
Fine (1963–1991) (155)	5y OS	42%	68%	58%	0%	EBRT and/or BT

Miyamoto (1972–2009) (161)	3y OS	56% (Combined I–IV)				RT ± S

[a]Outcomes for stage IVA, IVB respectively.

[b]Outcomes for stage IIA, IIB respectively.

5-FU, 5-fluorouracil; AWD, alive with disease; BT, brachytherapy; cis, cisplatin; CSS, cause-specific survival; DFS, disease-free survival; DID, died of intercurrent disease; DOD, died of disease; DSS, disease-specific survival; EBRT, external beam radiation; HDR, high dose rate; LC, local control; MMC, mitomycin C; NED, no evidence of disease; OS, overall survival; PC, pelvic control; RT, radiotherapy (any form); S, surgery.

Stage I.

Brachytherapy alone is an option for select patients presenting with small, superficial tumors (see treatment algorithm in Fig. 19.8). Reported local control rates range from 62% to 100% (104,105,109,115,117,145,162–164). Perez et al. (70) reported pelvic tumor control of 88% in patients with stage I disease who received brachytherapy alone, using a dose of 60 to 70 Gy prescribed 5 mm beyond the plane of the implant or vaginal mucosa, with a vaginal surface dose of 80 to 120 Gy. Notably, tumor control in stage I vaginal carcinoma was similar to that of brachytherapy alone, versus brachytherapy plus EBRT. This observation is consistent with reports from some groups (70,147,165), but not others (115,164). Other series suggest high locoregional failure rates with brachytherapy alone. Kanayama et al. report that three of eight (38%) patients with stage I vaginal cancer, treated with brachytherapy alone, developed lymph node recurrence. Frank et al. (115) reported on 21 patients with stage I disease who were treated with local radiation only, without regional node coverage. Nine received brachytherapy alone, 11 received EBRT with or without brachytherapy, and one received local EBRT using a transvaginal orthovoltage cone. Three of nine patients treated with brachytherapy alone developed recurrent disease in the pelvis, resulting in a 10-year pelvic disease control rate of 67%. Patients who received EBRT with or without brachytherapy did not have pelvic recurrences. A pelvic relapse rate of 18% at 10 years was noted by Frank and colleagues (115), with all pelvic failures occurring in patients treated with brachytherapy alone. Overall, these results suggest a need for caution when brachytherapy alone is used without prophylactic lymph node irradiation, given the fairly high rates of lymph node recurrence. Appropriate patient selection is critical, particularly because the distinction between stages I and II is based on clinical exam, and can vary between providers.

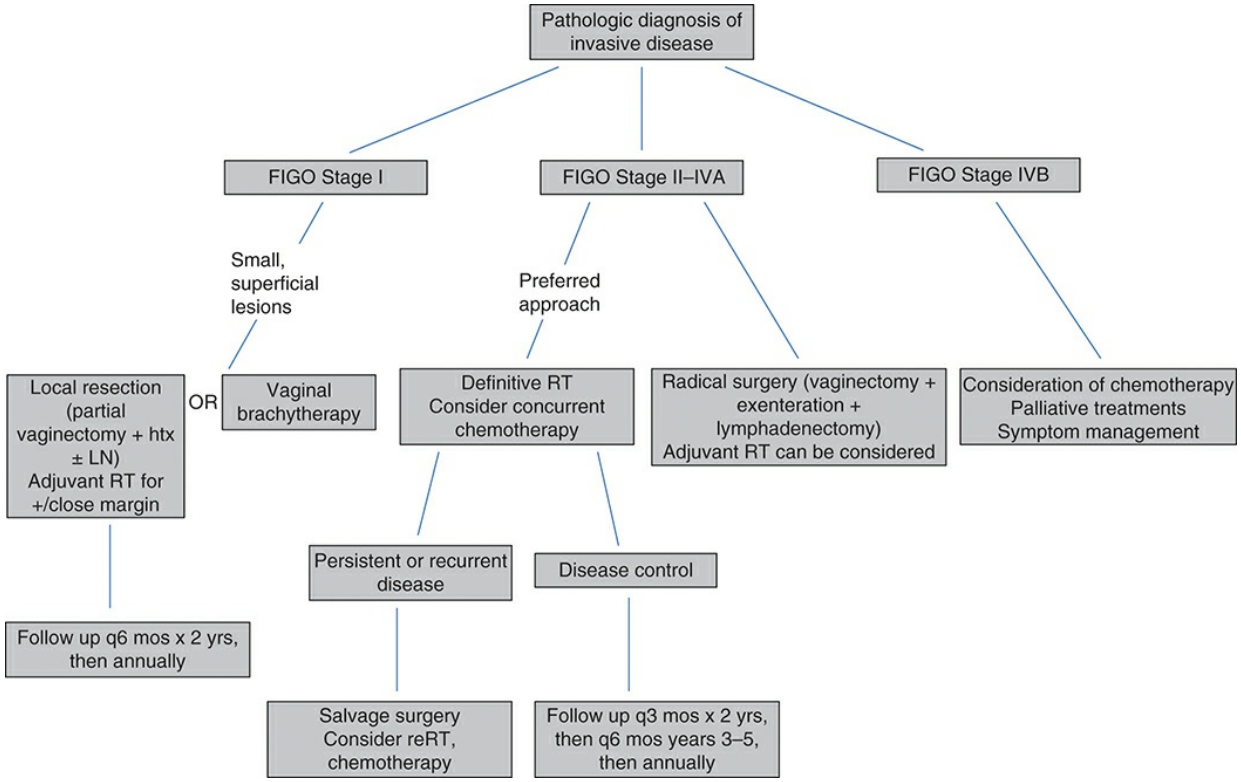

Figure 19.8 Proposed treatment algorithm for invasive squamous cell cancer of the vagina. htx, hysterectomy; LN, lymphadenectomy; RT, radiation treatment.

Poorly differentiated or extensively infiltrating stage I lesions should be treated with a combination of EBRT and brachytherapy. Given possible underestimation of submucosal disease and/or nodal disease, resulting in a potentially high likelihood of recurrence with brachytherapy alone, some groups recommend incorporating EBRT into treatment of all stage I patients, except for those with very small, superficial lesions (115,164). In their series of patients with vaginal cancer treated at MDCC between 1970 and 2000, Frank et al. (115), noted a trend toward increasing use of EBRT for stage I vaginal SCC over time.

Actuarial 5-year survival rates for stage I disease range from 60% to 85% (8,105,115,138). DSS rates for stage I disease, treated with definitive radiation, range from 75% to 95% (67,70,106). The 10-year pelvic relapse rate, comprising local, pelvic nodal, and inguinal nodal failures, was reportedly 16% (115) for stage I patients. Most failures are locoregional. Distant metastases are uncommon and occur in about 5% of patients (70,107,162).

With LDR, treatment can be delivered in two applications, the first designed to treat the entire vaginal wall, and the second to cover the tumor volume. When HDR brachytherapy is the primary treatment, the entire length of the vagina is typically treated to a mucosal dose of 60 to 65 Gy, with an additional mucosal dose of 20 to 30 Gy delivered to the area of tumor involvement (166). Treatment can be delivered with a shielded vaginal cylinder or with a multichannel HDR cylinder to treat the tumor with a 2-cm margin and block uninvolved mucosal surfaces (167). HDR can also be used to treat superficial lesions.

Use of a multichannel HDR cylinder is an alternative technique with favorable local control and low toxicity. The standard multichannel HDR cylinder consists of a central channel with 6 to 12 peripheral channels, allowing preferential dosing to the target but decreasing dose to normal structures. Vargo et al. (168) reported outcomes for 41 patients with vaginal cancer treated with this technique to a median equivalent dose in 2 Gy fractions (EQD2) of 77.1 Gy. Definitive treatment consisted of EBRT followed by brachytherapy. Most (71%) patients had FIGO 1 disease. At 2 years, there was 93% local control, and 4% overall late grade 3 or higher toxicity, demonstrating comparable results to historical treatments. A tumor thickness cutoff of 5 mm for the apex and posterior vagina, and 7 mm for other locations, was utilized.

Guidelines from the American Brachytherapy Society recommend a cumulative D90 (dose to 90% of volume) EQD2 of

70 to 85 Gy to the vaginal tumor (169). Various regimens can be used to achieve this dose, with commonly utilized schedules of 45 Gy in 25 fractions EBRT followed by HDR brachytherapy in five fractions of 4.5 to 5.5 Gy (EQD2 = 71.4 to 79.8 Gy), or 9 to 10 fractions of 3 Gy (EQD2 = 73.5 to 76.8 Gy).

Stage II.

Stage II vaginal carcinoma involves the subvaginal tissue, but does not extend to the pelvic sidewall. The primary treatment for stage II disease is radiation, most commonly as a combination of EBRT followed by vaginal brachytherapy; CT can also be considered. Outcomes with brachytherapy alone have been poor, and thus this approach is not recommended. With brachytherapy alone, Perez et al. (70) noted a 36% pelvic tumor control rate in stage II patients, compared with 67% in patients treated with a combination of EBRT and brachytherapy. The benefit of combining EBRT and brachytherapy, as opposed to using either alone, has been shown in other series as well (67,110).

During EBRT, the pelvis generally receives 45 to 50.4 Gy in 1.8 Gy fractions, with consideration of a parametrial boost if there is extensive primary infiltration or high suspicion of nodal disease. Inguinal lymph nodes are included in a modified whole pelvic field for lesions involving the distal one-third of the vaginal canal.

Brachytherapy should be carefully delivered to ensure adequate coverage of tumor volume. An interstitial technique, ideally with three-dimensional (3D) imaging for treatment planning, is required for tumors >5 mm in depth (104,170). Extensive tumors, or deeply infiltrating tumors with nondistinct margins, may be poor candidates for brachytherapy. In such cases, boosting tumors with conformal techniques or intensity-modulated RT (IMRT) may be preferred, and may yield better outcomes than suboptimal brachytherapy (115). The tumor volume should receive a minimum of 75 to 80 Gy using combined EBRT and brachytherapy. Fleming et al. (171) and Puthawala and colleagues (172) both report improved outcomes with higher doses of 80 to 100 Gy.

The 5-year survival rate for patients with stage II disease treated with RT alone ranges from 35% to 70% for stage IIA, and 35% to 60% for stage IIB (29,151,173). Pelvic relapse at 10 years has been reported at 25% by Frank et al., which is consistent with recent series reporting 5-year pelvic control rates ranging from 76% to 84% (115,138). The likelihood of distant metastasis is higher for stage IIB lesions compared with stage IIA (105,165), with overall reported rates ranging from 22% to 46% (105,107).

Stages III and IVA.

Locally advanced vaginal cancer is treated with a combined modality approach of RT and consideration of CT, extrapolating from favorable outcomes with use of chemoradiation therapy (CRT) in cervical cancer patients (174,175). Radiation is delivered as pelvic EBRT, followed by additional parametrial boost when warranted. If adequate tumor coverage can be achieved without undue toxicity, interstitial brachytherapy is employed to deliver a minimum tumor dose of 75 to 80 Gy. If brachytherapy is not feasible because of extensive tumor infiltration of the rectovaginal septum or bladder, a shrinking-field technique or IMRT have been used to deliver additional dose to the primary lesion (176,177). The overall cure rate for patients with stage III disease ranges from 30% to 50%. Stage IVA carries a worse prognosis. In highly selected patients with small-volume stage IV disease, pelvic exenteration can yield good long-term control; however, in practice, EBRT remains the primary treatment (7,8,70,110,111,115,145,178,179). Five-year actuarial survival rates for women with stage III disease range from 25% to 58% (7,8,180), with local failure rates of 30% to 75% (105,115,138). Outcomes for stage IV disease are worse, with survival rates of 0% to 40% (67,110,155). Despite treatment with EBRT and brachytherapy, only 20% to 30% of patients with stages III-IV disease achieve local control. Pelvic recurrences are more frequent than distant recurrences (115). A combination approach utilizing CT with concurrent RT has shown favorable outcomes. A single-institution retrospective review of patients treated with RT alone, versus CRT, showed that use of concurrent CT to improve DFS on multivariate analysis (HR 0.31; $p = 0.04$) (178).

Role of Chemotherapy and Radiation

CT has been incorporated with radiation for treatment of vaginal cancer, extrapolating from studies in cervical cancer showing improved PFS and OS when cisplatin is added to RT (70,161,174,175,181,182). Given the rarity of vaginal cancer, there are no randomized trials comparing RT alone with RT plus CT. Retrospective series are limited by small numbers or inclusion of other cancers, such as cervical and vulvar carcinomas. Nonetheless, studies suggest that a combined modality approach is feasible and may yield improved outcomes. These studies are summarized in Table 19.6.

TABLE 19.6 Select Series with Outcomes for Combined Chemotherapy and Radiation for Vaginal Cancer

Series	Outcomes	Stage	Notes
Miyamoto (1972–2009) (161)	3y OS 79%	St I, n = 18; St II, n = 19, St III, n = 8, St IVA, n = 6	RT+cis, 5FU or carboplatin
Dalrymple (1986–1996) (183)	NED n = 9 (FU 74–168 months); DOD n = 1 (12 months); DID n = 4 (46–109 months)	St I, n = 1; St II, n = 10, St III, n = 1	RT+5-FU, cis/5FU or MMC
Gunderson (1990–2004) (184)	4y OS 64% (Stage I), 40% (Stage II), 12% (Stage III/IV)	St I, n = 31; St II, n = 30; St III/IV, n = 69	CRT, n = 87; S + CRT, n = 43
Samant (1999–2004) (185)	5y OS 66%	St II, n = 6; St III, n = 4; St IVA, n = 2	RT+cis
Nashiro (2002–2005) (186)	DOD n = 1 (25 months); NED n = 4 (FU 19–54 months); AWD n = 1 (FU 19 months)	St II, n = 2; St III, n = 1; St IVA, n = 3	RT+cis or cis/5FU

AC, adenocarinoma; B, brachytherapy; CRT, chemoradiation; EBRT, external beam radiation; FU, fluorouracil; LR PFS, locoregional progression-free survival; NED, no evidence of disease; OS, overall survival; SCC, squamous cell carcinoma.

Holleboom et al. (187) published a case report documenting the use of cisplatin with EBRT and brachytherapy in a patient with advanced-stage SCC of the vagina. The patient was free of disease at 16 months. Evans et al. (188) reported the use of radiation with 5-fluorouracil (5-FU) and mitomycin C (MMC) in seven patients with vaginal cancer. Four of the seven patients were free of disease, with follow-up times ranging from 19 to 39 months. Roberts and colleagues (189) reported results for seven patients with vaginal cancer treated with concurrent 5-FU, cisplatin, and radiation. Three patients received interstitial brachytherapy after EBRT, and two patients received intracavitary brachytherapy after EBRT. Eighty-five percent of patients achieved a complete response initially. Ultimately, 61% recurred, at a median time to recurrence of 6 months. There were three local recurrences and one distant metastasis and the 5-year OS rate was 22%. Kirkbride et al. (103) reported on the use of concurrent 5-FU, with or without MMC, in 26 of 153 patients with vaginal carcinoma treated at Princess Margaret Hospital. Seventy-seven percent of the patients had stage III/IV disease. Radiation was EBRT followed by interstitial or intracavitary brachytherapy to a total dose of 62 to 74 Gy. The 5-year survival rate was 50%. Dalrymple et al. (183) reported results using 5-FU–based chemotherapy in combination with radiation for treatment of primary SCC of the vagina. Thirteen of 14 patients (93%) had stage I or II disease. The median dose of radiation was 63 Gy, achieved using EBRT alone, or EBRT with intracavitary brachytherapy. The 5-year survival rate was 86% for all patients, and nine patients were free of disease with a median follow-up time of 100 months, suggesting that good local control can be achieved despite the use of lower radiation doses. A 31% rate of severe bowel complications was reported, with two deaths as a result of bowel obstruction.

A retrospective series from MDACC by Frank and colleagues (115) included nine patients with stage II–IVA SCC of the vagina treated with RT and concurrent cisplatin-based CRT. With a mean follow-up time of 129 months, improved local control with the use of chemotherapy was noted, with 44% of patients treated with concurrent CRT remaining free of disease. Samant et al. (185) published a review of 12 vaginal cancer patients, stage II–IVA, treated with concurrent weekly cisplatin at a dose of 40 mg/m^2 for 5 weeks. Patients received concurrent EBRT to a median dose of 45 Gy, with LDR interstitial or HDR intracavitary brachytherapy boost of median dose 30 Gy. Six patients had stage II disease, four had stage III disease, and two had stage IVA disease. Ten of 12 patients (83%) had SCC; the other two had adenocarcinoma. Overall, treatment was well tolerated, with 92% of patients completing therapy as prescribed. Two of 10 patients who received interstitial brachytherapy required surgery for fistula repair. The 5-year OS, progression-free survival, and locoregional progression-free survival rates were 66%, 75%, and 92%, respectively, supporting the use of concurrent weekly cisplatin therapy. A small series of six patients treated with CRT at the University of the Ryukyus was reported by Nashiro et al. (186) All patients received EBRT to 50 Gy, followed by either a boost with shrinking fields (n = 4) or intracavitary brachytherapy (n = 2). Radiation was delivered with two to three cycles of cisplatin. Two patients had stage II, one had stage III, and three had stage IVA disease. All six achieved a complete response, and four of six patients remained free of disease at follow-up times of 18 to 55 months.

In a retrospective analysis of 71 patients with primary vaginal cancer treated at Dana-Farber Cancer Institute/Brigham and Women's Hospital from 1972 to 2009, 51 patients were treated with radiation alone, and 20 were treated with CRT and RT (182). Of the patients treated with chemosensitization during radiation, 85% of patients received weekly cisplatin CT, whereas the remainder received either carboplatin or 5-FU. Three-year actuarial OS and DFS was 56% for the RT-alone group, compared with 79% for the CRT group (p = 0.01). Three-year DFS was 43% for the RT alone group, compared with 73% for the CRT group (p = 0.01). At a median follow-up of 3 years, tumor relapse was seen in 15% of patients treated with CRT compared with 45% of patients treated with radiation alone (p = 0.03). On multivariate analysis, the addition of CT was a significant predictor of DFS (HR 0.31).

A retrospective series by Gunderson et al. (184) examined patients treated with CRT and reported outcomes by stage. Of 110 patients treated between 1990 and 2004, 41 patients received CRT. Of this cohort, 4-year survival was 64% for stage I, 40% for stage II, and 12% for stage III/IV.

Ghia et al. (190) published a retrospective patterns-of-care analysis using the SEER database, analyzing data on women with primary vaginal cancer treated with EBRT and/or brachytherapy between 1991 and 2005. Of the 326 women in the study cohort, 80.4% had SCC. It was noted that CRT was used in 7.5% of patients treated before 1999 compared with 36.1% of those treated afterward (p < 0.001). Cisplatin was the most frequently utilized agent, accounting for 59% of CRT treatments. CT was significantly less likely to be used in conjunction with RT for women older than 80 years of age; otherwise, there was no difference for race, stage, grade, histologic diagnosis, comorbidities, or brachytherapy use. On multivariate analysis, CRT was not found to correlate with improved cause-specific or OS.

Outcomes

According to SEER-based data, outcomes for vaginal cancer may be improving. A recent study by Shah et al. (8) analyzed records from the SEER database of 2,149 women diagnosed with primary vaginal cancer between 1990 and 2004. The risk of mortality was noted to decrease over time, with a 17% decrease in the risk of death for women diagnosed after 2000 relative to those diagnosed between 1990 and 1994. The authors reported 5-year DSS rates of 84% for stage I, 75% for stage II, and 57% for stages III–IV. An older study by Creasman et al. (7) focused on 4,885 women diagnosed with vaginal cancer between 1985 and 1994, and reported 5-year survival rates of 96% for stage 0, 73% for stage I, 58% for stage II, and 36% for stages III–IV, with 85% of invasive cases being SCC.

In general, the rate of locoregional recurrence ranges from 10% to 20% for stage I and 30% to 40% for stage II. Patients with advanced disease often have persistent disease despite treatment. In a series by Dixit et al. (148), 68% of failures in stage III patients were due to persistent disease. Most treatment failures occur within 5 years, with a median

time to recurrence of 6 to 12 months (115,191), and local recurrence is the most common pattern of treatment failure in most published series. Extravaginal recurrences in the pelvic lymph nodes are less common. The reported rates of distant metastasis vary, ranging from 7% to 33% and usually occur later in the course of disease, with approximately half of all distant metastases presenting at the time of local recurrence (104,105,118,148).

Clear Cell Adenocarcinoma

Epidemiology

Clear cell adenocarcinoma of the vagina was first reported in 1971 by Herbst and Scully (192), who documented six cases of primary vaginal clear cell carcinoma in patients 15 to 22 years of age: five of the six had been exposed to the synthetic estrogen DES in utero during the first trimester. This was the first report suggesting that in utero exposure to DES, prescribed during the mid-1940s to 1960s for high-risk pregnancies, could result in an increased risk of clear cell adenocarcinoma. DES-related clear cell adenocarcinoma presents at a young age, with studies documenting median age at presentation to be within the second or third decade of life (192,193). Studies suggest that there is a bimodal distribution for clear cell adenocarcinoma of the vagina, the first peak comprising young women with a mean age of 26, most of whom were exposed to DES in utero, and a second peak comprising women with a mean age of 71 years, not exposed to DES (192,194). Most patients present with stages I–II disease (192,195).

Risk Factors

In 45% to 95% of cases, clear cell adenocarcinoma of the vagina is associated with vaginal adenosis, defined as the abnormal presence of glandular epithelium in the vagina (196,197). Vaginal adenosis has three patterns: endocervical, tuboendometrial, and embryonic (44,197,198). Grossly, vaginal adenosis appears as red, velvety, grapelike clusters in the vagina. Glandular columnar epithelium of Mullerin type either appears beneath the squamous epithelium or replaces it, undergoing progressive squamous metaplasia (199).

Vaginal adenosis is believed to be a precursor lesion to clear cell adenocarcinoma of the vagina. It is a common histologic abnormality in women who have been exposed to DES in utero, presenting in up to 95% of such women (196,197). However, it is not strictly confined to this population (200).

The risk of developing clear cell adenocarcinoma in DES-exposed women is estimated to be 1 in 1,000 (195), suggesting that there are multiple factors contributing to pathogenesis. Additional factors associated with increased risk include DES exposure before the 12th week of pregnancy, a maternal history of prior miscarriage, birth in autumn, and prematurity (170).

Histopathology

Clear cell adenocarcinoma of the vagina is most often located in the upper third of the anterior vagina and may vary greatly in size. These cancers can also arise in the cervix. Grossly, they exhibit exophytic growth and are superficially invasive (201). Microscopically, they are composed of vacuolated, glycogen-rich cells; hence the term clear cell carcinoma (Fig. 19.9). The most common histologic pattern is tubulocystic, although solid, papillary, and mixed cell patterns have also been described (129,202). Cells are cuboidal or columnar in shape, with large, atypical protruding nuclei, rimmed by a small amount of vacuolated cytoplasm.

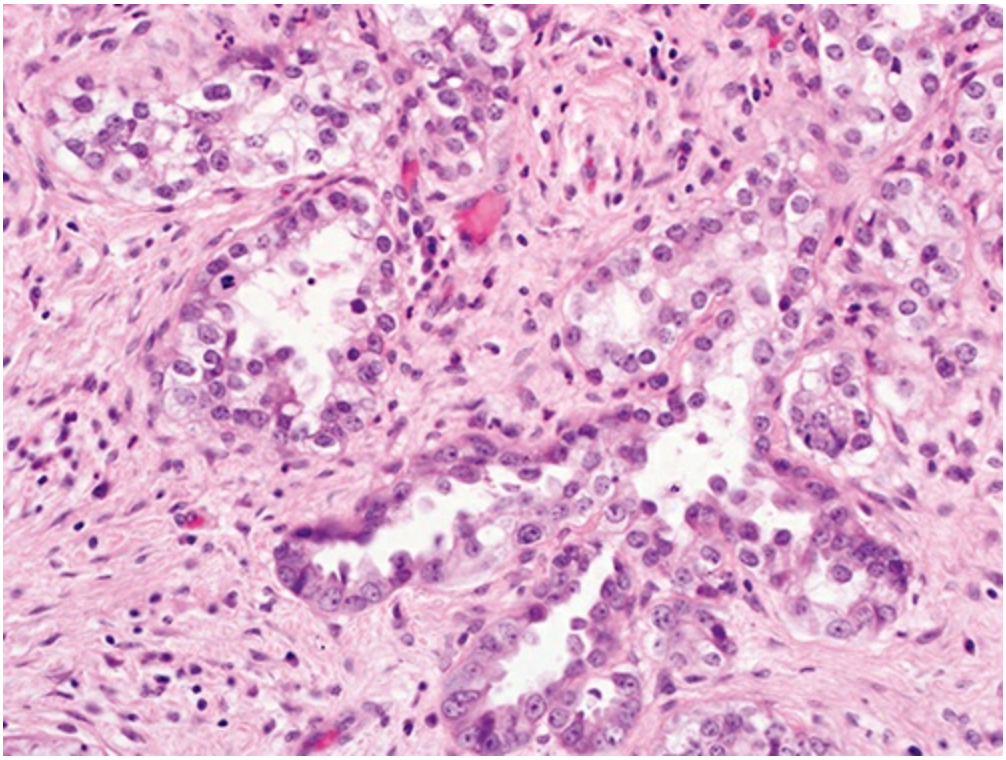

Figure 19.9 Clear cell carcinoma. Clear cell carcinoma (CCC) of the vagina appears as nests and irregular glands lined by cells with characteristic clear to pale eosinophilic cytoplasm. CCC may show a mixture of architectural patterns including papillary, tubulopapillary, and tubulocystic patterns, and cytologic features may be variable from round to oval nuclei with prominent nucleoli (as seen in this example) to more significant nuclear pleomorphism and conspicuous mitoses.

Clinical Presentation

Patients with clear cell adenocarcinoma most often present with abnormal vaginal bleeding (192), which is found in 50% to 75% of cases. Cytology is not reliable, revealing abnormality in only 33% of cases; therefore, careful assessment of the entire vaginal vault to assess for submucosal irregularity is recommended, in addition to four-quadrant cytologic assessment (203). Abnormal discharge, urinary symptoms, and lower gastrointestinal complaints can also be noted, particularly in advanced cases. The differential diagnosis of vaginal adenocarcinoma is often challenging, because it must be distinguished from metastases from distant sites.

Prognostic Factors

For clear cell adenocarcinoma, prognostic variables associated with worse survival include advanced-stage, nontubulocystic pattern of histology, size >3 cm, and depth of invasion >3 mm (201). A study of 21 women with clear cell carcinoma of the vagina and cervix reported that overexpression of wild-type p53 was associated with a more favorable prognosis (204). Primary adenocarcinoma of the vagina not associated with DES exposure is extremely rare. In a review of 26 such cases by Frank et al., (205) 5-year OS was 34%, significantly worse than in patients with SCC. A recent series described five cases of clear cell adenocarcinoma in patients without prior DES exposure, treated between 1990 and 2013 (206). The patients were all older than 40 years of age. There was high incidence of distant spread, especially to the lungs; OS at 5 years was 55%.

Treatment Options

The optimal management of clear cell adenocarcinoma is unclear. There are several published series on DES-related clear cell adenocarcinomas (129,201,207–209) using conventional treatments similar to those used for SCC of the vagina for stage I and II disease, including surgery with radical hysterectomy, vaginectomy and lymphadenectomy with construction of a neovagina, or definitive RT and consideration of radiosensitizing concurrent CT (210,211). In these series, there has been an emphasis on preservation of ovarian and vaginal function, owing to the earlier age at diagnosis in DES-exposed patients. According to data from the United States Registry for Research on Hormonal Transplacental Carcinogenesis, approximately one half of all vaginal clear cell adenocarcinoma cases were treated with radical surgery alone (212).

Wharton et al. (213) report the use of intracavitary or transvaginal irradiation for early-stage disease, with excellent tumor control and preservation of ovarian function. Herbst et al. (214) reported on 142 cases of stage I clear cell adenocarcinoma. For the 117 patients treated with radical surgery, there was an 8% risk of recurrence and 87% OS. For patients treated with radiation, there was a 36% risk of recurrence. The authors acknowledge that it is difficult to compare surgery with radiation, as radiation was most likely used in patients with larger lesions less amenable to resection.

A series by Senekjian et al. (208) reported on 219 cases of stage I clear cell vaginal adenocarcinoma. Forty-three patients received local therapy alone, consisting of vaginectomy, local excision or local irradiation with or without excision, and the remaining patients had conventional radical surgery. At 10 years, the actuarial survival rates were equivalent (88% vs. 90%). However, the actuarial recurrence rate was significantly higher (40% vs. 13%) with local excision alone. Patients who received local irradiation, with or without local excision, had decreased local recurrence compared to those treated with excision alone ($p < 0.03$).

A subsequent series by Senekjian et al. (129) reviewed 76 cases of stage II clear cell adenocarcinoma. The 10-year OS rate was 65%. The 5-year survival rates were 80% for patients treated with surgery, 87% for patients treated with radiation, and 85% for patients treated with both. The authors advocate treatment with combination EBRT and brachytherapy for stage II disease, with surgery reserved for smaller, more easily resectable lesions in the upper vagina. The use of pelvic exenteration for primary and recurrent lesions has been reported by Senekjian and colleagues (209). Survival outcomes were comparable to those of patients treated with other modalities. Thus, to minimize morbidity and preserve quality of life, exenterative approaches are advocated only for patients with disease recurrence after RT. Herbst et al. reported a 5-year survival rate after pelvic relapse was reportedly 40% (207).

Most recurrences occur within 3 years of therapy, although recurrences 10 to 20 years after treatment have been reported (215). Most recurrences are local or locoregional, with approximately one-third detected at distant sites, most commonly in the lungs or extrapelvic lymph nodes, although there have been rare cases of central nervous system (CNS) metastases manifesting years after treatment (216). The 10-year actuarial survival rate for clear cell adenocarcinoma of the vagina is 79%. For stage I and II disease, survival rates are 90% and 80%, respectively.

Other Adenocarcinomas

Most adenocarcinomas that present in the vagina are attributed to metastatic spread from other sites. Vaginal metastases from adenocarcinoma of the breast, kidneys, or other gynecologic primary sites have been described (217–219). Primary non-CCA of the vagina is extremely rare, and occurs predominantly in postmenopausal women. Histologic variants include endometrioid, mucinous, mesonephric, and papillary serous adenocarcinoma (Fig. 19.10). Vaginal endometrioid adenocarcinoma is the most common non-clear cell subtype, and presents most often in women with a history of endometriosis. Only a handful of case reports or series have been published in detail about endometrioid adenocarcinoma of the vagina (220–230). In one series of 18 cases of primary vaginal endometrioid adenocarcinoma (220), 10 cases arose from the apex; 14 of 18 cases had vaginal endometriosis, which is important in indicating a primary vaginal tumor rather than secondary spread from the endothelium. Median age at presentation was 57, with a range from 45 to 81 years. There have been case reports of mucinous adenocarcinoma of the vagina (221–233), with at least one arising from a focus of

endocervicosis (234).

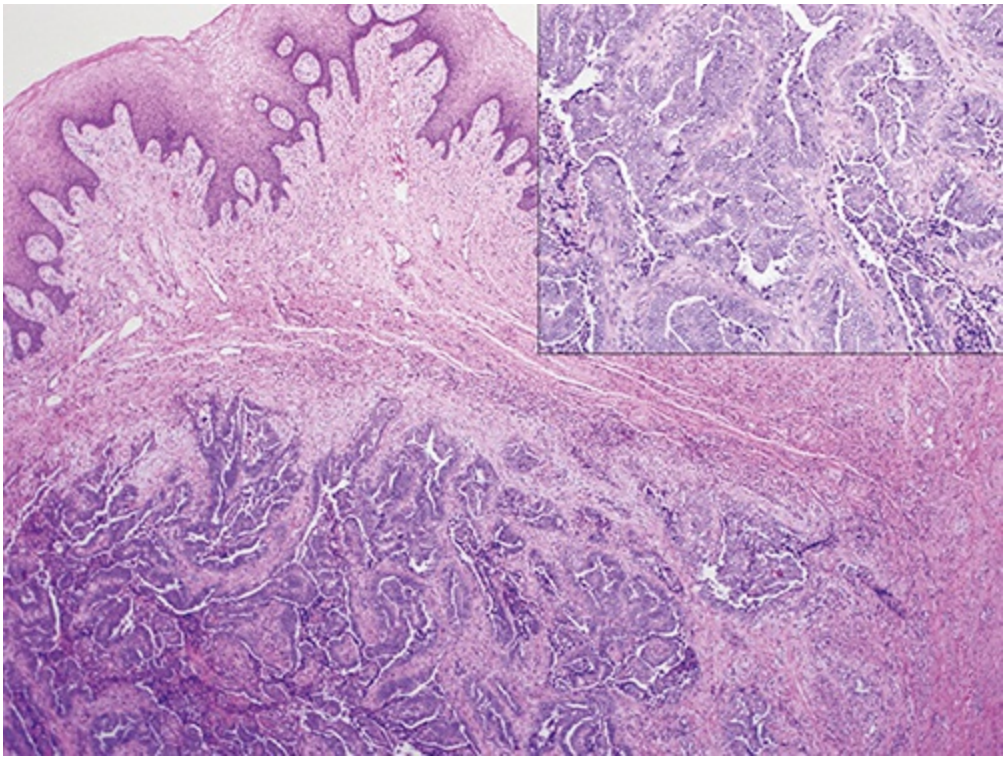

Figure 19.10 Vaginal adenocarcinoma. Vaginal adenocarcinoma appears as irregular glands infiltrating beneath unremarkable squamous mucosa often associated with endometriosis. Cytologically (inset), the cells are oriented around the glandular lumen and show nuclear pleomorphism, coarse to vesicular chromatin, and often frequent mitoses. Images courtesy of Emily E.K. Meserve.
Source: Images courtesy of Emily E.K. Meserve.

On gross exam, endometrioid adenocarcinomas can be polypoid, papillary, rough, granular, fungating, exophytic, or flat, and most arise from the superior aspect of the vagina. Microscopically, tumors display a predominant component of typical endometrioid carcinoma, with tubular glands lined by columnar cells with moderate amounts of eosinophilic cytoplasm, and large elongated nuclei. Only a handful of cases of mucinous adenocarcinoma have been described (218,231–233), including rare cases arising in neovaginas (235) or arising from endocervicosis (234). Mesonephric adenocarcinoma arises from mesonephric duct remnants situated in the lateral vaginal wall (236,237). Primary papillary serous adenocarcinoma of the vagina has rarely been reported (238).

Melanoma

According to the NCDB report by Creasman et al. (7), vaginal melanomas comprise 4% of all primary vaginal cancers. Melanomas arising from the vaginal mucosa are rare, accounting for 2.8% to 5% of all vaginal neoplasms (239–241), with just over 100 new cases reported each year in the United States. Melanomas arising from the vaginal mucosa are thought to originate from mucosal melanocytes in regions of melanosis or from atypical melanocytic hyperplasia.

The incidence of vaginal melanoma has remained stable and is reportedly 0.26 per million (242). Most reported cases are in Caucasian women; one study of 37 women with primary melanoma of the vagina reported that 84% of patients were Caucasian and only 3% African American (239). According to a report by Hu et al. (243) analyzing SEER data from 1992 to 2005 on 125 cases of vaginal melanoma with known race/ethnicity, there is no significant difference in incidence of vaginal melanoma between Caucasian and African American women, with a White/Black ratio of 1.02 after age

adjustment. In the report by Creasman and colleagues, most patients were of advanced age at presentation, with only 23% of patients diagnosed before the age of 60; 28% were diagnosed between the ages of 60 and 69, 28% were diagnosed between the ages of 70 and 79, and 22% were diagnosed at age 80 or older (7).

Grossly, melanoma of the vagina tends to be pigmented, and may present as a dark mass, plaque, or ulceration; multifocal presentation is also common. The most common appearance is polypoid nodular (244). The most common location at presentation is the anterior vaginal wall and lower one-third of the vagina (239,240,245).

In a case series of 37 women with primary vaginal melanoma reported by Frumovitz et al. (239), median tumor size at presentation was 3 cm (range 0.4 to 5 cm), with median depth of invasion of 7 mm (range 1 to 21 mm). Twenty-one percent of patients presented with multifocal disease. Twenty-four patients (65%) presented with lesions in the distal third of the vagina or introitus.

Microscopically, tumors may be composed of epithelioid, spindle or nevus-like cells, and stain frequently positive for S-100 protein, HMB-45, and Melan A (Fig. 19.11). When S-100 is negative or only focally positive, tyrosinase and MART-1 are useful markers. Poorly differentiated tumors may be difficult to distinguish from carcinomas or sarcomas. Tumor thickness correlates with prognosis and may be measured by Breslow's methods (246).

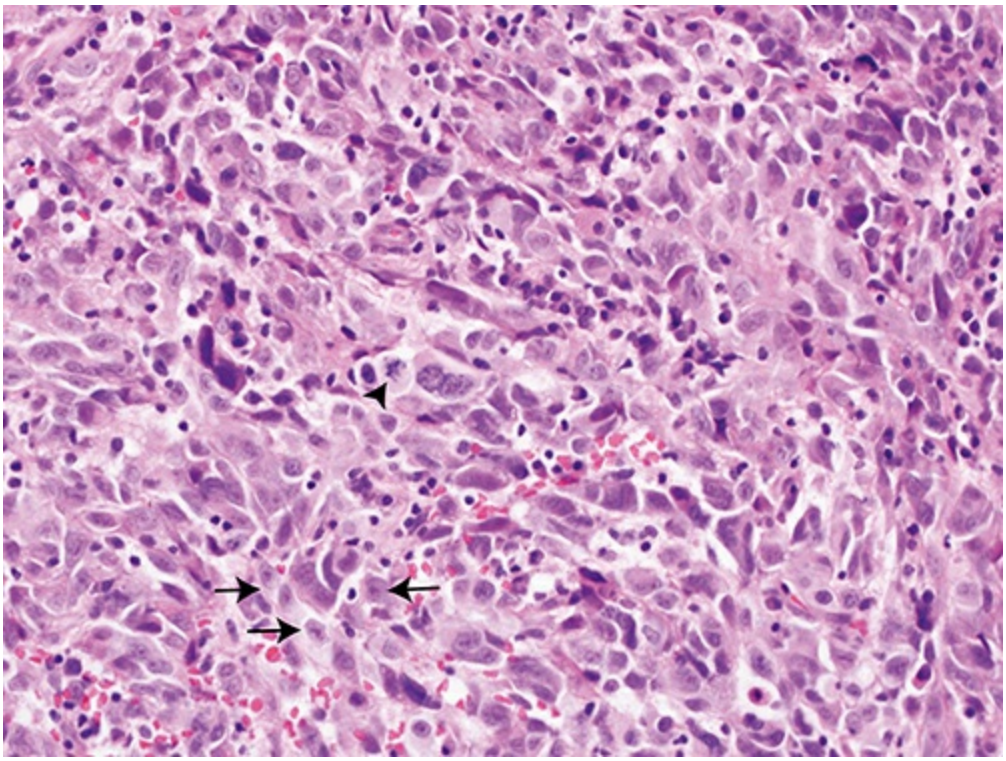

Figure 19.11 Vaginal melanoma. Malignant melanoma exhibits variable morphology. This example shows a vaguely nested to discohesive epithelioid neoplasm with characteristic eosinophilic nucleoli (arrows), significant nuclear pleomorphism, and mitoses (arrowhead). The presence of melanin pigment and immunohistochemistry can be helpful to confirm the diagnosis. Images courtesy of Emily E.K. Meserve.
Source: Images courtesy of Emily E.K. Meserve.

Vaginal melanoma is a highly malignant disease with a propensity for early hematogenous spread. The most common presenting symptoms are slight vaginal bleeding and usually blood-tinged, foul-smelling, or purulent vaginal discharge (247). Reid et al. (248) reviewed 115 patients with primary melanoma of the vagina, and found depth of invasion and lesion size >3 cm to be negative prognostic factors. Stage was not found to be prognostic for outcome, but only 42 of the 115 patients had this information available. Compared to women with SCC, patients with vaginal melanoma have a significant 1.5-fold increased risk of mortality (8).

Treatment Options

Primary vaginal melanoma is uncommon; as a result, treatment outcomes for only a small number of patients have been reported (239,247,248–253), and it is difficult to make definitive treatment recommendations. Treatments used in published series include wide local excision, radical surgery, RT, and CT, or a combination of modalities.

Regardless of primary treatment, outcomes have been disappointing. Overall prognosis is poor, with historic 5-year survival rates ranging from 5% to 30% regardless of treatment modality or extent of surgical resection (248,249,252). There is a high rate of distant metastases, ranging from 66% to 100% (249,254,255).

Some authors advocate incorporation of radical surgical resection into the treatment paradigm, when feasible (256–258). Surgery is favored over RT because melanoma tends to be radioresistant. Geisler et al. (256) recommend primary pelvic exenteration for vaginal melanomas with invasion >3 mm, reporting a 5-year survival rate of 50% if pelvic nodes are free of disease. Morrow and DiSaia (258), in their review of gynecologic melanoma, recommend radical surgery based on a review of the literature that revealed 3 out of 19 long-term survivors after exenteration with wide local excision. Chung and colleagues (249) reviewed 19 cases of primary vaginal melanoma treated between 1934 and 1976. All patients who received wide local excision developed recurrence. Five-year survival was only 21%. Miner and colleagues (259) reported on 35 patients treated at Memorial Sloan Kettering Cancer Center from 1977 to 2001: 69% underwent surgery, which was either en bloc removal of the involved pelvic organs, wide excision, or total vaginectomy, with elective pelvic lymph node dissection in 74% of cases. Thirty-one percent of patients received definitive RT. Primary surgical therapy was significantly associated with a longer OS (25 vs. 13 months). Recurrence-free survival was not found to correlate with surgical extent. A study by Huang et al. (300) found 5-year OS to be 32%, but as high as 47% in patients who underwent surgical treatment.

Several series comparing radical surgery and local excision find equivalent outcomes (247,250,261,262). In general, treatment modality does not appear to significantly affect survival. Bonner et al. (263) reported on nine cases of vaginal melanoma. Three patients were treated with wide local excision, and six underwent radical surgery. All nine patients developed locoregional recurrence. Therefore, the authors suggest adding pelvic RT to improve local control. The use of wide local excision followed by postoperative EBRT and brachytherapy has been proposed. A more recent review by Frumovitz and colleagues (239) reported that RT after wide local excision can reduce local recurrences. However, most patients develop distant metastases, most commonly in the lungs and liver.

Retrospective data suggest that RT may improve local control for vaginal melanoma (247,264). Among the few long-term survivors reported in the literature are a handful of patients who were treated with radiation. Harwood and Cummings (265) described a complete response in four patients with vaginal melanoma treated with radiation, although two subsequently relapsed. Rogo et al. (266), in their series of 22 cases of vulvovaginal melanoma, reported comparable results for surgery and RT, with eight patients (36%) alive 5 years after treatment. Petru et al. (264), in their series documenting 14 patients treated for primary malignant melanoma of the vagina, noted that three of nine patients treated with radiation, either as primary treatment (n= 2) or in the postoperative setting (n = 1), survived longer than 5 years. Median OS for all patients was 10 months, with a 5-year DFS rate of 14% and an OS rate of 21%.

Given the high rates of distant metastases, CT has been used, either alone or in conjunction with RT (239,267). The use of systemic CT and/or immunotherapy has not consistently been shown to improve patient outcomes thus far (267). Frumovitz et al., in their review of 37 women with stage I melanoma of the vagina treated at MDACC between 1980 and 2009, report very poor prognosis even in this group of patients with localized disease, with a 5-year OS rate of 20%. In that study, 10% of patients received nonsurgical treatment with RT, CT, or both. Patients treated surgically had significantly longer survival times compared with those treated nonsurgically. RT delivered after wide local excision reduced local recurrence and demonstrated a trend toward longer survival times, from 16.1 months to 29.4 months. A study by Xia et al. (253) evaluated 44 women, diagnosed and treated for vaginal melanoma between 2002 and 2011. There was no difference in OS between local excision and radical surgery. However, the authors noted increased PFS with the addition of adjuvant CT and RT (8.6 vs. 16.0 months, p = 0.038). Other reports have described the use of immunotherapy

after surgery, and reveal that the best outcomes are achieved with this approach (260).

Based on limited but promising data suggesting an improvement in local control with the addition of adjuvant RT, treatment can be considered. However, there is no general recommendation for the treatment of primary vaginal melanoma. When RT is administered, vaginal melanoma is treated similarly to vaginal carcinoma, with volumes and doses ranging from 50 Gy for subclinical disease to 75 Gy for gross tumor.

Sarcoma

Sarcomas represent 3% of all primary vaginal cancers (7). In a report based on data from the NCDB between 1985 and 1994 (7), there were 135 cases of primary vaginal sarcoma, of heterogeneous histologies and varying age. Twenty-two percent of patients were under 14 years of age, with a median age at presentation of approximately 50 years. Consistent with this, a recent analysis of the SEER database identified 221 patients with primary vaginal sarcoma, diagnosed between 1988 and 2010, with a mean age of 54.9 (268). Compared with other vaginal cancers, sarcomas tend to be larger, with decreased likelihood of lymph node involvement, and are more commonly treated with primary surgery without RT. It was estimated that, after adjusting for other variables, patients vaginal sarcomas had a 69% greater risk of cancer-related mortality when compared with SCC.

Vaginal sarcoma most frequently presents as an asymptomatic vaginal mass (269). In one series, this was the most common system, and was, found in 35% of patients, followed by vaginal, rectal, or bladder pain (26%), bleeding or serosanguinous discharge from the vagina or rectum (18%), leucorrhea (9%), dyspareunia (7%), or difficulty in micturition (7%).

Leiomyosarcoma (LMS) is the most common histology in adults, representing up to 65% of all vaginal sarcoma cases; however, overall numbers are very small, with fewer than 150 published reports in the literature (269). Vaginal leiomyosarcomas originate from the smooth muscle of the vaginal wall, but may also develop from smooth muscle cells in tissues adjacent to the vagina. Grossly, patients present with a palpable submucosal nodule, although advanced tumors may demonstrate palpable necrosis or exophytic polypoid tissue (270). Criteria to distinguish between benign leiomyoma and leiomyosarcoma include greater than five mitoses per 10 high-power fields (HPF), moderate or marked cytologic atypia, and infiltrating margins (271) (Fig. 19.12). In view of considerable variation in smooth muscle tumors from area to area, adequate sampling is recommended to achieve an accurate diagnosis. Microscopically, leiomyosarcomas demonstrate interlacing bundles of spindle-shaped cells, with blunt-ended nuclei and fibrillar cytoplasm (247,271). Leiomyosarcomas have a predilection for the posterior vaginal wall, with published reports suggesting approximately 43% to 45% in the posterior vagina, 17% to 21% anteriorly, and 34% to 39% laterally (269,272). Leiomyosarcomas are also aggressive; they undergo early hematogenous dissemination, frequently recur locally (7,269), and often demonstrate pulmonary metastases (273).

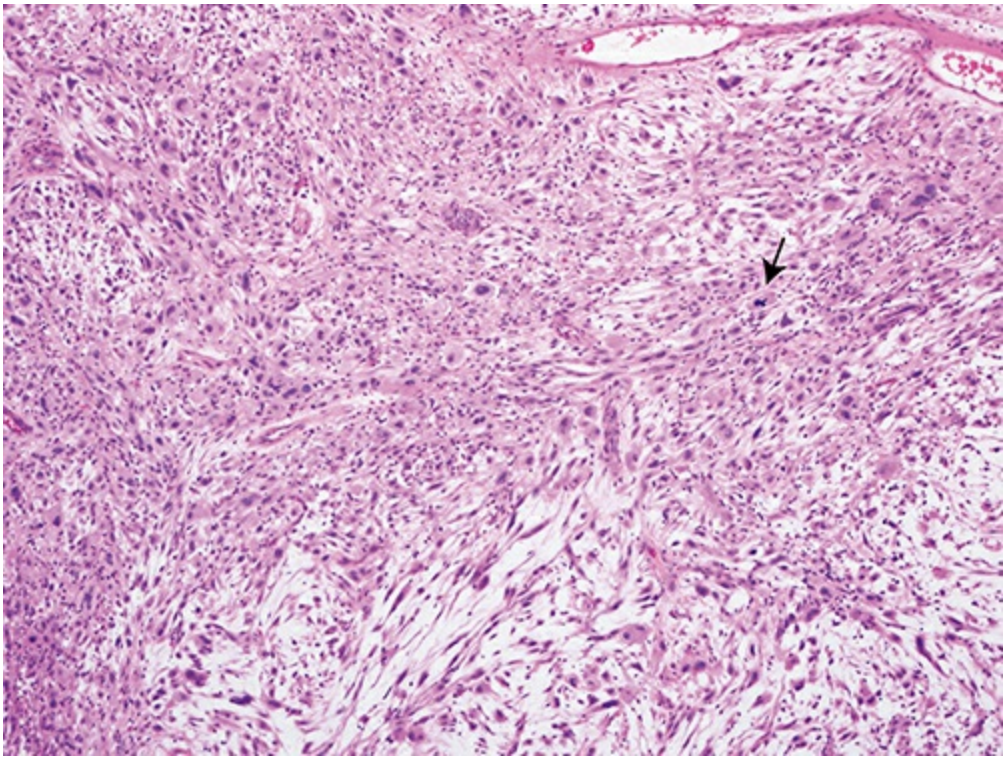

Figure 19.12 Leiomyosarcoma. Leiomyosarcoma of the vagina appears similar to malignant smooth muscle tumors in other anatomic sites and shows spindled to epithelioid (when morphologically higher grade) cells in a fascicular architecture. There is significant nuclear atypia with nuclear hyperchromasia and numerous mitotic figures, including atypical forms (arrow). Images courtesy of Emily E.K. Meserve.
Source: Images courtesy of Emily E.K. Meserve.

Other less common histologies include malignant mixed Mullerian tumor (MMT), endometrial stromal sarcoma, and angiosarcoma (274,275). MMTs, also called carcinosarcomas, are highly aggressive, biphasic neoplasms composed of an epithelial component as well as a sarcomatous component. The epithelial component in vaginal MMT is most often SCC (274). The sarcomatous component may be composed of fibroblasts and smooth muscle, or include cartilage, striated muscle, bone, and other heterologous tissues. The metaplastic carcinoma theory suggests that there is a common cell of origin for MMT, with carcinoma giving rise to the sarcomatous component via metaplasia (276). The most common differential diagnosis is sarcomatoid carcinoma. The spindle and carcinomatous components are positive for cytokeratin in sarcomatous carcinoma, whereas MMT demonstrates a sarcomatous component that is positive for vimentin, with the carcinomatous component positive for cytokeratin (274).

The first case of vaginal MMT was described in 1975 by Davis et al. (277), after which only 11 cases have been reported in the literature, with patients' age ranging from 57 to 74 years (274,278–282). At least one case report of MMT of the vagina detected high-risk HPV in both the carcinomatous and sarcomatous components, suggesting that some vaginal MMTs may be related to HPV (278). Fewer than 10 cases of angiosarcoma of the vagina have been reported in the literature (283,284). A history of pelvic RT is a risk factor for pelvic sarcomas, particularly angiosarcoma (275).

In the pediatric population, embryonal rhabdomyosarcoma/sarcoma botryoides is the most common histology (285), with 90% of cases occurring in children younger than 5 years of age (286).

Prognostic Factors

Review of the literature indicates that vaginal sarcomas undergo early hematogenous dissemination as well as frequent local recurrence. Pulmonary metastases are common (269,272). Adverse prognostic factors for vaginal sarcoma include

high histologic grade, stage, size >3 cm, infiltrative borders, and cytologic atypia (273).

Treatment Options

Despite surgery and the use of adjuvant RT in select cases, sarcoma patients sustain poor outcomes due to a high incidence of local recurrence and distant metastasis. Locoregional control is especially important for vaginal leiomyosarcoma. A series by Peters et al. (287) reported on 17 cases, comprising 10 patients with leiomyosarcoma, 4 with MMT, and three with other types of sarcomas. There were only three patients alive and free of disease with follow-up times of 84 to 161 months. All three patients had undergone pelvic exenteration. Patients who received other forms of primary therapy all died of recurrence, with the pelvis as the first site of recurrence in all cases. In 50% of cases, the pelvis was the only site of failure, stressing the importance of local treatment. OS of 8 and 10 years following wide local excision have been reported (272).

Postoperative RT has been used to manage soft tissue sarcomas in other sites to reduce locoregional recurrence rates (288). Results from adjuvant radiation for high-grade sarcoma in other regions of the body have been extrapolated to vaginal cancer. In patients with involved margins, high doses above 62.5 Gy are generally required to achieve local control (289). Systemic treatment with doxorubicin is standard for leiomyosarcoma (290).

Outcomes

In the SEER analysis, 5-year survival was 89% for stage I, and under 50% for stage II vaginal sarcomas of all types (268). Other series describe similarly poor outcomes. Five-year survival was 36% for patients with leiomyosarcoma in the Peters et al. (287) series. The survival rate for patients with MMT was even lower, at 17%. There are only a few case reports and small series detailing treatment of primary vaginal MMT. Neesham and colleagues (280) published a case report of a 74-year-old patient treated with wide local excision and radiation for a 5.5-cm stage I MMT. She developed distant metastases within 6 months of local therapy. Analysis of patterns of failure suggests that local therapy does not have a significant impact on survival owing to early distant spread. Therefore, CT is typically administered after surgery for MMT in other sites, and should be considered for primary vaginal lesions, along with adjuvant RT as warranted. Platinum-based CT has been used for MMT occurring elsewhere in the pelvis. It has not yet been determined whether platinum agents are best administered alone or in combination with other agents. Combination regimens include a platinum agent and/or paclitaxel and/or ifosfamide (291–294).

Lymphoma

Lymphomas of the female genital tract are rare, accounting for only 1% of all primary extranodal lymphomas (295). Lymphomas of the vagina are exceedingly uncommon, with fewer than 30 cases reported in the literature thus far (296–315). In one review from the Armed Forces Institute of Pathology, only 4 of 9,500 cases of lymphoma were determined to originate from the vagina (316). Diffuse large B cell lymphoma is the most common histology, though there have also been reports of lymphoplasmacytic, Burkitt's, and mucosa-associated lymphoid tissue (MALT) lymphomas (303).

On exam, the tumor is typically palpable, with infiltrative thickening and/or ulceration of the vaginal wall (311). Immunohistochemical analyses are valuable techniques for confirming diagnosis, with tumors typically expressing CD20 (304,314). The most common symptom at presentation is vaginal bleeding. Leukemic infiltrates may be difficult to distinguish from lymphoma; therefore, chloroacetate esterase or myeloperoxidase staining may be useful. Although there is no established treatment protocol for primary lymphoma of the vagina, it seems reasonable to extrapolate from results for extranodal lymphomas elsewhere in the body and to use similar chemotherapeutic and response-based RT regimens. For patients wishing to retain fertility, CT alone may be an option in select cases.

If diagnosed at an early stage, the prognosis for vaginal lymphoma is excellent, with 5-year survival rates of up to 90%. Of 10 cases reported in the literature between 1994 and 2007, all patients except one were cured of disease after treatment with CT or a combination of RT and CT (302,304,308,310,317–320). Follow-up periods for these 10 cases ranged from 6 to 120 months, and one patient died from other causes. Eight patients had Ann Arbor stage IEA disease, one had IIEA, and one did not have stage reported. The most common CT regimen was cyclophosphamide, doxorubicin, vincristine, and prednisone (CHOP). Complete remission was also achieved using methotrexate, doxorubicin, cyclophosphamide, vincristine, prednisone, and bleomycin (MACOP-B) in one patient. Half of the patients did not receive RT because of an excellent response to CT alone.

Small Cell Carcinoma of the Vagina and Other Rare Histologies

Primary small cell carcinoma of the vagina is a rare entity, with fewer than 25 cases reported in the literature (321). Mean age at diagnosis is 59 years, with poor outcome due to early widespread dissemination. Eighty-five percent of patients die within 1 year of diagnosis (322,323). Neuroendocrine differentiation is often manifested by secretory granules, argyrophilia, and expression of neuroendocrine markers (324,325), staining positive for cytokeratin, neuron-specific enolase, chromogranin A, and serotonin (Fig. 19.13). Thyroid transcription factor 1 can also be positive, and should not be used to differentiate primary from metastatic disease (326). Microscopically, it is indistinguishable from that of the lung. These tumors can occur in pure form or be associated with squamous or glandular elements (322,324). Ectopic Cushing's syndrome has been documented in primary small cell carcinoma of the vagina (325). Treatment typically follows general principles for small cell carcinomas of the cervix, with aggressive therapy, including combination cisplatin-based CT, RT, brachytherapy, and surgery if feasible.

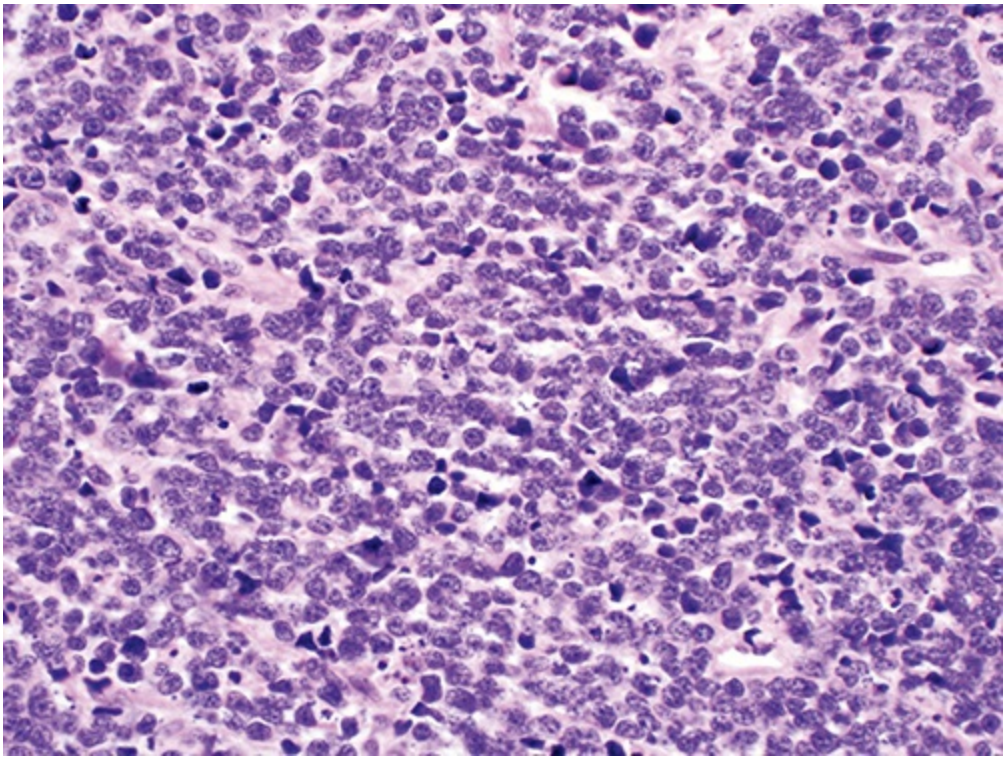

Figure 19.13 Neuroendocrine carcinoma of the vagina. Small cell carcinoma of the vagina is a poorly differentiated neuroendocrine carcinoma showing small blue cells with round to irregularly shaped nuclei with coarse ("salt and pepper") chromatin, very scant cytoplasm, and numerous mitotic and apoptotic figures. Importantly, designation as a primary small cell carcinoma of the vagina is possible only after exclusion of

metastasis from other anatomic sites (i.e., lung). Immunohistochemical markers are generally not helpful in establishing site of origin in neuroendocrine carcinomas. Images courtesy of Emily E.K. Meserve.
Source: Images courtesy of Emily E.K. Meserve.

Vaginal paraganglioma is a rare neuroendocrine tumor, with fewer than 10 cases reported in the literature in younger women, with median age at presentation of 31 years (327–329). It is thought to be an indolent tumor, managed surgically. The tumor can manifest with catecholamine secretion, similarly to paragangliomas elsewhere in the body (327).

Adenosquamous carcinoma of the vagina is also uncommon. Microscopically, tumor cells are composed of glandular and squamous elements. One case report described adenosquamous carcinoma associated with small cell carcinoma of the endometrium in a 64-year-old female (330). Treatment approaches similar to those used for SCC of the vagina, including consideration of combination CRT for patients with gross disease.

CHAPTER 20 Cervix Uteri

Charles A. Kunos, Fadi W. Abdul-Karim, Don S. Dizon and Robert Debernardo

EPIDEMIOLOGY

According to the World Health Organization, uterine cervix cancers were the fourth most common malignancy in women, and the seventh most common overall, with 528,000 new incident cases reported in 2012 (1). An estimated 266,000 women died around the world from uterine cervix cancer in 2012, accounting for almost 8% of all female cancer deaths (1). Nearly 9 out of every 10 women with uterine cervix cancer died in underdeveloped regions of the world (1). In the United States, the American Cancer Society (ACS) projected that 12,900 new cases of uterine cervix cancer would arise in American women in 2015, and an estimated 4,100 (32%) of those women would die (2). Based on these statistics, 1 (0.6%) in 154 American women would develop invasive uterine cervix cancer between birth and death (2). It has been claimed that these statistics likely underestimate a true worldwide uterine cervix cancer disease burden, mostly because inadequate medical resources in rural and economically depressed regions infrequently capture new incident cases of uterine cervix cancer. Indeed, uterine cervix cancer is only one of two cancers (the other, colorectal cancer) that can be effectively screened for as a precancerous lesion. Early detection of uterine cervix cancer is a paramount health care issue, as around 40% of newly diagnosed uterine cervix cancers in American women occur in women with no prior screening, and another 10% of new incident cases occur in women who have not had screening in the preceding 5 years (3).

Two specific American populations deserve mention, Hispanics and African-Americans. The United States Census Bureau recognized nearly 51 million Americans in 2010 as self-identified Hispanics or Latinos, accounting for 16% of the total US population (4). Hispanics are the largest, fastest-growing, and youngest minority group in the United States, with one of every two residents dwelling in the states of California, Florida, or Texas. The ACS estimated in 2012 that 2,100 (4%) new uterine cervix cancers befell Hispanic Americans, for a probability of developing uterine cervix cancer between birth and death of 1 (1.1%) in 95 Hispanic females (4). For the same year, 500 (24% of the 2,100 new cases) Hispanic Americans were anticipated to die from uterine cervix cancer (4). The 2012 incidence rate of uterine cervix cancer among Hispanic American women was 64% higher than among non-Hispanic Whites (4). The highest incidence rates were found among Hispanic women residing in the American Midwest, reportedly due to new immigrant populations (5). Efforts to improve early detection have been successful—the prevalence of Papanicolaou (Pap) testing rose from 64% among 18-year and older Hispanic women in 1987 to 75% in 2010 (4). Across Hispanic subpopulations, up to 80% of Cuban and Puerto Rican women undergo uterine cervix cancer screening (4). However, most US cancer data are reported for Hispanic Americans as an aggregate group, which hides critical differences that exist between subpopulations according to their country of origin.

African-Americans have the highest mortality and shortest cancer-specific survival for most cancers of any racial or ethnic group in the United States. In 2013, 42 million self-identified African-Americans resided in the United States (13% of the total US population), with one of every four residents living in the states of Florida, New York, or Texas (6). The ACS estimated that in 2013, 2,060 (3%) new uterine cervix cancer cases occurred in African-American women (6). In 2013, African-American females had a lifetime uterine cervix cancer diagnosis probability of 1 (0.85%) in 119 (6). Also in

2013, 720 (35% of the 2,060 new cases) uterine cervix cancer deaths were expected among African-Americans (6). This translates into a new uterine cervix cancer incident rate in 2013 that was 34% higher than among white women (6). Racial disparity in this disease has narrowed considerably, as new case rates have fallen precipitously in African-Americans due to more effective programmatic screening efforts (7). Between 2008 and 2010, the prevalence of Pap testing within the previous 3 years was similar among African-American and white American women (78%) (6).

ETIOLOGY AND RISK FACTORS

The etiology of uterine cervix cancer has been connected to sexual activity, although the exact molecular events implicated in its pathogenesis have not been fully known. Risk factors such as young age of coitarche (8), multiple sexual partners or male partners with multiple partners (9), and a history of sexually transmitted disease (10) correlate with a risk for uterine cervix cancer pathogenesis. Uterine cervix cancer is exceedingly uncommon among females not sexually active (11,12). Low income (13), low educational status (14), and a history of human papillomavirus (HPV) infection (15) are surrogate risk factors for uterine cervix cancer. Smoking (current smoker or former smoker or never smoker) has been associated with a risk for a malignant uterine cervix cell phenotype (16).

Molecular and clinical evidence have implicated HPV infection as at least one causative agent for uterine cervix cancer neoplasia. HPV subtypes 16, 18, 31, 33, 35, 45, 52, and 58 (**Table 20.1**) are the most virulent forms associated with cervical intraepithelial neoplasia (CIN) (now coined high-grade squamous intraepithelial lesion on biopsy) or cancer (15). HPV infections (single or multiple infections) account for as much as 86% of worldwide incidence of invasive uterine cervix cancer (15). Certainly, immune competence has a role in HPV-related carcinogenesis (17,18)—in as much as a uterine cervix cancer diagnosis might define an AIDS illness event (19). HPV subtyping screens have become sufficiently discriminating, with sensitivity and specificity of around 95% each (20,21), but HPV subtyping screens are not yet a primary stand-alone diagnostic tool in all women (22). For contrast, exfoliative cytology has a modest 53% sensitivity but high 97% specificity (23). The ATHENA trial of 47,208 women found that 10% of women testing positive for HPV 16 or HPV 18 had grade 3 CIN or worse undetected by cytology alone (24–26). According to 2015 consensus guidelines of the American Society for Colposcopy and Cervical Pathology, women 30 to 65 years should be cotested with exfoliative cytology and HPV testing every 5 years (22). If found to have negative cytology but a positive for high-risk HPV (16, 18, or 16/18), cotesting should be repeated in 12 months or HPV genotyping should be done. If the HPV genotyping assay is positive, women should submit to timely colposcopy (22). As such, HPV pathophysiology provides a context for the clinical management of uterine cervix cancer, and so attention is turned next to the known core molecular processes governing the disease process.

TABLE 20.1 Human Papillomavirus (HPV) Genotypes

Low-Risk Oncogenic HPV	High-Risk Oncogenic HPV
6, 11, 42, 43, 44	16, 18, 31, 33, 35, 39, 45, 51, 52, 56, 58, 59, 68

HPVs are nonenveloped viruses utilizing double-stranded closed circular DNA to replicate in the cutaneous and mucosal epithelia of the female and male anogenital tracts (27). HPV DNA encodes six early proteins (E1, E2, E4–E7) and two late proteins (L1, L2) that hijack host cell molecular pathways first to synthesize DNA and then to package it (27). HPV-E6 binds p53, causes its degradation, and thereby removes a G1/S-phase cell cycle restriction checkpoint (28–30). HPV-E6 also disrupts DNA building block output from the usual rate-limiter ribonucleotide reductase, in that the virus promotes more 2'-deoxyribonucleoside diphosphates (dNDPs) to be supplied freely when demanded (31–33). HPV-E7 degrades hypophosphorylated retinoblastoma protein through a proteosome-dependent pathway (34) that also promotes unchecked activation of a synthesis cell cycle transcription factor (E2F) (35). E2F turns on S-phase proteins critical to DNA replication, like ribonucleotide reductase M2 protein (36). Through an activated telomerase (37), HPV extends host cell life

and thus increases HPV-infected cell numbers. Far-reaching outcomes of HPV overriding cell cycle checkpoints include instability of the host cell genome and susceptibility to neoplasia or to an oncogenic phenotype (27). Such observations suggest that throughout its evolution HPV has targeted at least transcriptional and protein–protein checkpoints in uterine cervix cells to unleash dNDP production by ribonucleotide reductase.

UTERINE CERVIX ANATOMY

The *cervix uteri* (Latin: neck of the uterus) is centered in the pelvis, representing the lower narrowed segment of the uterus. The cervix assumes a conical shape, truncated at its distal apex, and has its long axis directed backward and downward. It projects posteriorly into the vagina, connecting the vaginal vault to the uterine body hollow (*corpus uteri*) by its endocervical canal (*canalis cervicis uteri*). The supravaginal portion of the cervix (*portio supravaginalis*) extends to the lower uterine segment (isthmus) and associates intimately with the bladder peritoneum forming the vesicouterine pouch, an anterior *cul-de-sac* that must be dissected and separated for surgical exposure. The peritoneum covers the supravaginal cervix posteriorly and is reflected upon the rectum, forming the posterior rectouterine cul-de-sac (pouch of Douglas). The vaginal portion of the cervix (*portio vaginalis*) protrudes into the vagina as a round extremity with a circular external aperture between the anterior and posterior vaginal fornices. The vaginal portion of the cervix has two lips, a short anterior and a long posterior. In length, the cervix ranges 2 to 5 cm.

The uterine cervix is fibrous, covered by membranes (*tunica mucosa*) of squamous cells when in contact with the vagina (ectocervix) and by columnar cells when communicating with the uterus (endocervix). A transition from stratified squamous to ciliated columnar cells, coined the transformation zone, occurs in the lower one third of the canal. The length of the transition zone changes throughout life, receding in old age. The preponderance of preneoplastic and neoplastic lesions of the uterine cervix arises from the transformation zone. The ciliated columnar cells secrete viscid alkaline mucus.

The uterine cervix has four cardinal ligaments: one anterior, one posterior, and two transverse (Mackenrodt). The anterior ligament involves the vesicouterine fold of peritoneum, anchoring the supravaginal cervix to the anterior pelvis via the anterior cul-de-sac. The posterior ligament consists of the rectouterine fold of peritoneum, connecting the supravaginal cervix by the rectum to fibrous tissue and nonstriped muscle constituting the uterosacral ligaments. The two transverse ligaments (*ligamentum transversali coli*) span either side of the uterine cervix, and continuously extend into the tissues of the pelvic sidewall surrounding the pelvis iliac blood vessels. The cardinal ligaments anatomically define two surgical spaces, the paravesical space anteriorly and the pararectal space posteriorly. Portions of the cardinal ligament overlie the pelvic ureter (below the uterine artery, above the uterine vein) about 2 cm superior and 2 cm lateral to the external os of the cervix, an anatomic triangle referred to in brachytherapy as prescription point A. For completeness, superior to the supravaginal cervix arise the two lateral or broad ligaments (*ligamentum latum uteri*) enveloping the uterine tubes, round ligament of the uterus, the ovary and its ligaments, the epoophoron and paroophoron. The innervation of the uterine cervix derives from sacral (S2–S4) nerve roots.

Blood supply to the uterine cervix and its return occurs through the uterine artery and vein, tributaries of the anterior branch of the hypogastric blood vessels. Collateral arterial anastomoses arise from the ovarian artery (descending aorta), internal pudendal artery (hypogastric artery tributary), and obturator artery (hypogastric artery tributary). A web of venous blood vessels returns blood to the bilateral gonadal and bilateral iliac veins.

The uterine cervix is considered an immunocompetent organ, capable of mounting an immune response to an external pathogen antigen (38–40). In some respects, the bulk of large uterine cervix cancers might represent normal cells, cancer cells, and tumor-infiltrating lymphocytes. In an orderly fashion, lymph vessel drainage from the uterine cervix flows to paracervical and obturator nodes, internal iliac nodes, external iliac nodes, common iliac nodes, and then paraaortic nodes. First nodal sites of disease include the paracervical and the iliac nodes (41). Left supraclavicular lymph nodes are next echelon extrapelvic distant sites of lymphatic spread. Uterine cervix immunocompetence (42) impacts anticancer proimmune drugs (43), and radiation-induced immune-mediated tumor abscopal response (44).

UTERINE CERVIX DISEASE NATURAL HISTORY

Preinvasive Disease

Uterine cervix cells acquire an oncogenic phenotype through what appears to be a methodical neoplastic process reflected in epithelial cell histology. For uterine cervix squamous cell disease, the histologic terms for preinvasive disease have been consolidated. Terminology describes (a) low-grade squamous intraepithelial lesions (LSIL) indicating microscopic acute HPV infection; (b) high-grade squamous intraepithelial lesions (HSIL) indicating precancerous lesions; and (c) cancer. Histologically, HSIL correlates with CIN grade 3 (CIN 3) and most cases of CIN grade 2 (CIN 2) (45).

Most LSIL cases and half of HSIL cases regress to normal cytology within 2 years of first diagnosis by cytology. Thus, a recommendation for active surveillance has been supported for women with CIN 1 or CIN 2 (22). There is prognostic value in labeling CIN 2 distinct from CIN 3 by histopathologists, and so, follow-up cytology evaluations must undergo greater scrutiny (22).

Invasive Disease

The oncogenic potential of uterine cervix cancers follows a more erratic evolution—disease benchmarks are not well chronicled. Uterine cervix cancers follow an International Federation of Gynecology and Obstetrics (FIGO) clinical staging system (**Table 20.2**) (46). Surgical findings or radiographic-guided biopsies of lymph nodes or lung metastasis must not be used to change or to modify clinical FIGO staging. All uterine cervix cancer histologies are included. If staging disagreements arise, earlier stage is given.

TABLE 20.2 Uterine Cervix Clinical Staging

TNM[a]	FIGO[a]	
Primary tumor (T)		
TX		Primary tumor cannot be assessed.
T0		No evidence of primary tumor
Tis	0	Carcinoma in situ (preinvasive carcinoma)
T1	I	Cervical carcinoma confined to uterus (extension to corpus should be disregarded)
T1a	IA	Invasive carcinoma diagnosed only by microscopy. Stromal invasion with a maximum depth of 5 mm measured from the base of the epithelium and a horizontal spread of ≤7 mm. Vascular space involvement, venous or lymphatic, does not affect classification.
T1a1	IA1	Measured stromal invasion ≤3 mm in depth and ≤7 mm in horizontal spread
T1a2	IA2	Measured stromal invasion >3 mm and ≤5 mm with a horizontal spread ≤7 mm
T1b	IB	Clinically visible lesion confined to the cervix or microscopic lesion >T1a/IA2
T1b1	IB1	Clinically visible lesion ≤4 cm in greatest dimension
T1b2	IB2	Clinically visible lesion >4 cm in greatest dimension
T2	II	Cervical carcinoma invades beyond uterus but not pelvic wall or lower third of vagina
T2a	IIA	Tumor without parametrial invasion

T2a1	IIA1	Clinically visible lesion ⩽4 cm in greatest dimension
T2a2	IIA2	Clinically visible lesion >4 cm in greatest dimension
T2b	IIB	Tumor with parametrial invasion
T3	III	Tumor extends to pelvic wall and/or involves lower third of vagina, and/or causes hydronephrosis or nonfunctioning kidney.
T3a	IIIA	Tumor involves lower third of vagina, no extension to pelvic wall.
T3b	IIIB	Tumor extends to pelvic wall and/or causes hydronephrosis or nonfunctioning kidney.
T4	IVA	Tumor invades mucosa of bladder or rectum, and/or extends beyond true pelvis (bullous edema is not sufficient to classify a tumor as T4).
Regional lymph nodes (N)		
NX		Regional lymph nodes cannot be assessed.
N0		No regional lymph node metastasis
N1	IIIB	Regional lymph node metastasis
Distant metastasis (M)		
M0		No distant metastasis
M1	IVB	Distant metastasis (including peritoneal spread, involvement of supraclavicular, mediastinal, or paraaortic lymph nodes, lung, liver, or bone)

[a]The American Joint Committee on Cancer definitions of the T categories correspond to clinical stages accepted by the International Federation of Gynecology and Obstetrics (FIGO). Both systems are listed.

TNM, tumor-node-metastasis.

Source: AJCC. Cervix uteri. In: Edge SB, Byrd DR, Compton CC, et al, eds. AJCC Cancer Staging Manual. 7th ed. New York, NY: Springer; 2010:395–402.

Metastatic Disease

Patterns of spread of uterine cervix cancers are considered predictable and orderly, as pelvic lymph node metastases are low in the absence of deep stromal invasion of the uterine cervix (47–49) and paraaortic lymph node metastases are low when pelvic lymph nodes are uninvolved (50,51).

For instance, depth of stromal invasion elevates the risk for regional lymph node metastasis. Fifty-one women (1981 to 1984) who had conization of the cervix for cancer with 3 to 5 mm of invasion (width limited to 7 mm) followed by completion radical hysterectomy plus lymphadenectomy were found to have no lymph node metastases, no recurrences, and no cancer-related deaths over a 5-year observation period (47). Inner third, middle third, and outer third depth of invasion were associated with a frequency of pelvic lymph node metastases of 5% (9 of 199), 13% (28 of 210), and 26% (60 of 227) in a surgicopathologic study (1981 to 1984) of uterine cervix cancer patients (48). Invasion into adjoining parametria is associated with a frequency of pelvic lymph node metastases of 43% (19 of 44) (48). Also in this study, histologic grade 2 or grade 3 disease conferred 14% (52 of 373) and 22% (39 of 179) frequencies of pelvic lymph node metastases (48). Lymphovascular invasion was associated with a 25% (70 of 276) chance of pelvic lymph node metastases (48).

Indeed, lymph node metastases are an important clinical consideration even though nodal status is not considered in International FIGO staging of uterine cervical cancer. Take for an example an Italian Group study (1986 to 1991) that

investigated 172 patients who had undergone radical abdominal hysterectomy for uterine cervix cancer stage IB or IIA patients (50). The study found a 25% (28 of 114) rate of pelvic node metastases when the cervical diameter measured ≤4 cm, whereas the rate was 31% (17 of 55) when the cervical diameter measured >4 cm. An American Gynecologic Oncology Group study (1973 to 1981) found paraaortic lymph node metastases associated with initial clinical stage, with rates of 5%, 16%, and 25% for stage IB, II, and III, respectively (51). For 98 patients who had paraaortic lymph node metastases found at staging laparotomy or at definitive operative management, a 15-month median survival and a 25% probability of 3-year survival was reported (51).

Metastasis to scalene lymph node occurs infrequently, unless uterine cervix cancer involves paraaortic lymph nodes (11% prevalence rate, [52]). Distant spread of uterine cervix cancers includes dissemination to the lungs or liver, and less commonly to the brain and axial or appendicular bones. After intervention, there are uterine cervix recurrences within 24 months, with a median of 20 months (50).

CLINICAL PRESENTATION AND DIAGNOSTIC EVALUATION

Preclinical Invasive Disease

Screening Cytology

Screening cytology is of high clinical benefit because of its ease of sample acquisition, test sensitivity, and ability to detect multiple phases of uterine cervix dysplasia. But, a single test may have limited sensitivity for uterine cervix cancer detection (45). Two primary sampling methods are used, the conventional Pap smear or liquid-based cytology.

Following its 2013 final recommendations, the United States Preventive Services Task Force (USPSTF) recommends uterine cervix dysplasia screening in women aged 21 to 65 years with Pap cytology every 3 years, or for women aged 30 to 65 years who desire a longer screening interval, screening by Pap cytology and HPV cotesting done every 5 years (53).

The ACS has addressed age-appropriate screening strategies in its view, including appropriateness of Pap cytology with or without HPV cotesting, follow-up of women after screening, the age at which to exit screening, and screening strategies for women vaccinated against HPV 16 or 18 infections (54). For women aged less than 21 years, no screening is recommended. Women aged 21 to 29 years should consider Pap cytology alone every 3 years. Women aged 30 to 65 years should preferably undergo Pap cytology and HPV cotesting every 5 years. In this category, women with cytology negative and HPV-positive testing undergo 12-month follow-up with cotesting, or if subsequently found positive for HPV 16 or 18 undergo colposcopy. Women aged 65 years or older exit screening if prior screening was negative. Hysterectomy prompts exit from further Pap cytology or HPV cotesting, that is, when the uterine cervix is surgically absent or a personal health history of CIN 2 or more (<20 years) and uterine cervix cancer (ever) are absent. HPV-vaccinated women follow their age-specific recommendations (same as unvaccinated women). The American College of Obstetricians and Gynecologists (ACOG) does not support changing screening intervals (55).

An updated standard terminology, the Bethesda system 2014, describes specimen adequacy and dysplastic cytologic abnormalities. For squamous cell epithelial cell abnormalities, it describes the following: (a) atypical squamous cells of undetermined significance (ASCUS) or atypical squamous cells—cannot rule out high-grade squamous intraepithelial lesion (ASCH); (b) LSIL; (c) HSIL (encompassing CIN 2 or CIN 3 or carcinoma *in situ*), and squamous cell carcinoma (56). For glandular epithelial cell abnormalities, it describes the following abnormalities: (a) atypical glandular cells (AGS, specifying endocervix, endometrial, or not otherwise specified origins); (b) AGS favoring neoplastic; (c) endocervical adenocarcinoma *in situ* (AIS); (d) adenocarcinoma (56).

A large multicenter trial (ASCUS/LSIL Triage Study [ALTS]) of 3,488 women begun in 1997 randomized immediate colposcopy versus triage to colposcopy according to Pap cytology and HPV cotesting (57). Pap cytology reported 86% of

cases with an overall CIN 3 or worse diagnosis. HPV cotesting identified 92% (10 pg/mL cutoff) or 96% (1 pg/mL cutoff) of cases with an overall CIN 3 or worse diagnosis. The ALTS study established high-risk HPV testing as the most cost-effective triage test for ASCUS. After this study, the American Society of Colposcopy and Cervical Pathology (ASCCP) and American Society for Clinical Pathology (ASCP) have endorsed HPV cotesting as the preferred method of triage for ASCUS smears detected by liquid-based cytology for women 30 years or older (54).

HPV Testing

For women ≥30 years undergoing screening in the United States, a recommendation for HPV cotesting as an adjunct to cytology has been made to triage women with ASCUS (24,25). In European nations, HPV tests serve to triage women with ASCUS, to monitor them after CIN treatment, and even to be a stand-alone primary screening test without cytology (58). Australia (59) and the Netherlands (60) have accepted self-sampling HPV tests as primary screens for their national uterine cervix dysplasia and cancer screening programs. Detection of HPV DNA involves either hybrid capture 2 or polymerase chain reaction technologies. HPV cotesting has become more widespread as a diagnostic aid (26,57,61,62). **Table 20.3** catalogs the triage of cytology categories negative for intraepithelial lesion of malignancy (NILM) or ASCUS to CIN 3 or worse by HPV testing.

TABLE 20.3 Cytologic Testing or Cotesting and Intervention According to Test Results

Cytology or Cotesting Result	Proportion (%) of Screening Result	Risk (%) of HSIL or Cancer	Suggested Intervention
Squamous cell carcinoma	<0.01	84	Immediate colposcopy
HPV+/HSIL	0.20	71	Immediate colposcopy
HSIL	0.21	69	Immediate colposcopy
HPV−/HSIL	0.01	49	Immediate colposcopy
HPV+/LSIL	0.81	19	Immediate colposcopy
LSIL	0.97	16	Immediate colposcopy
HPV−/LSIL	0.19	5	Repeat testing in 6–12 months
HPV+/AGC	0.05	45	Immediate colposcopy
AGC	0.21	13	Immediate colposcopy
HPV−/AGC	0.16	2	Immediate colposcopy
HPV+/ASC-H	0.12	45	Immediate colposcopy
ASC-H	0.17	35	Immediate colposcopy

HPV−/ASC-H	0.05	12	Immediate colposcopy
HPV+/ASCUS	1.10	18	Immediate colposcopy
ASCUS	2.80	7	Repeat testing in 6–12 months
HPV−/ASCUS	1.80	1	Repeat testing in 3 years
HPV+/Pap−	3.60	10	Repeat testing in 6–12 months
Pap−	96	0.68	Repeat testing in 3 years
HPV−/Pap−	92	0.27	Repeat testing in 5 years

AGC, atypical glandular cells; ASC-H, atypical squamous cells (cannot rule out high-grade lesion); ASCUS, atypical squamous cells of undetermined significance; HPV, human papillomavirus; HSIL, high-grade squamous intraepithelial lesion; LSIL, low-grade squamous intraepithelial lesion; Pap, Papanicolaou.

The effect of HPV cotesting as an adjunct to liquid-based cytology was evaluated by a large cohort study (ATHENA, 2008 to 2009) involving 47,208 American women (25). In that study, the combination of cytology and HPV cotesting was superior to cytology alone for the detection of CIN 3 or worse over a 3-year observation period. HPV testing alone identified 64% more CIN 3 or worse lesions (294, 95% confidence interval [CI]: 260 to 325) than cytology (179, 95% CI, 152 to 206) and 23% more than cotesting (240, 95% CI, 209 to 270). ATHENA is the first screening study in American women to support HPV primary screening with triage of HPV-positive women using HPV 16 or 18 genotyping and reflex cytology at age 25 years (25).

Reduced uterine cervix squamous intraepithelial lesion prevalence has arisen out of prophylactic HPV vaccination of adolescent women. A randomized trial reporting 42-month follow-up on 17,622 HPV-naive adolescent women (aged 16 to 26 years) has shown that a prophylactic quadrivalent HPV vaccine (types 6, 11, 16, 18) administered day 1, month 2, and month 6 sustains immunocompetence against HPV 16 and HPV 18 CIN in those receiving vaccine versus those receiving placebo (63). Long-term high efficacy, immunogenicity, and acceptable safety in adolescent women have been confirmed in a Nordic region extension of the original studies (64). Moreover, Australia instituted in 2007 a nationally funded vaccination program with the quadrivalent HPV vaccine. The initial program launched vaccination as a continuing component of a 12 to 13-year-old schoolgirl health program, and funded two catch-up programs targeting 13 to 17-year-old school adolescents and 18 to 26-year-old women in general practice and community well-woman evaluations (65). A 0.38% (95% CI, 0.16 to 0.61) decrease in a population-wide prevalence of CIN 2 or worse was noticed in the vaccinated cohort between 2007 and 2009, compared to incidence found in the Victorian Cervical Cytology registry (Australia, 2003 to 2009). In the United Sates, adolescent female vaccination rates are low, with only about 40% of adolescents reporting receiving the vaccine (66,67). HPV vaccination efforts remain aggressive (68,69).

Colposcopy

Colposcopy examines the lower genital tract by a colposcope with binocular magnification (5× to 30×) for visual diagnosis and biopsy of suspicious precancerous or cancerous lesions. Colposcopy is an important diagnostic tool in uterine cervix cancer prevention in women with an abnormal screening test (70). Acetic acid or Lugol solution highlights dysplastic change such as acetowhite plaques or vacuolar abnormalities (including punctations, mosaicism, and abnormal vessel branching) that may signify high-grade lesions. Indications for colposcopy include an abnormal-appearing cervix, persistent postcoital bleeding or discharge, persistent CIN 1, 2, or 3 cytology, *in utero* exposure to diethylstilbestrol (DES,

a synthetic estrogen), and ASCUS cytology with positive high-risk HPV 16, 18, or 45. Adequate colposcopy examinations involve full visualization of the uterine cervix and its transformation zone. Endocervical curettage (ECC) might be helpful, and yet, its routine practice remains debatable (71). Multiquadrant biopsy improves accuracy of colposcopy, especially when a lesion is not readily visualized (71,72).

Conization

Conization of the uterine cervix means surgical extirpation of the squamocolumnar junction (transformation zone). The procedure involves either cold knife conization in the operating room suite, or thermal cautery with loop excision in the outpatient office or in the operating room suite. Indications for conization include inadequate colposcopy, positive ECC, persistent CIN 1 (typically >1 year), CIN 2 or 3, carcinoma *in situ*, and discrepancy among cytology, colposcopy, and pathologic findings. After examination of 447 histopathologic slices from 97 patient conization procedures, small cone height was significantly associated with positive disease margin status: a 20-mm cone height was recommended (73).

Loop Diathermy

Outpatient thermal cautery with loop electrosurgical excision procedure (LEEP or loop diathermy) is an alternative to cold knife conization (74). Studies have demonstrated loop diathermy to be as effective as cold knife conization (75) and laser vaporization (76), with some gynecologists favoring loop diathermy in terms of cost, anesthesia, and ease of use. Thermal artifact obscures margin status. Return patient visits after loop diathermy might be due to incomplete excision complicated by thermal artifact, secondary hemorrhage, and findings of invasive cancer (74).

Clinical Invasive Disease

Symptoms and Complaints

Uterine cervix cancer presents most often with abnormal vaginal discharge, postcoital bleeding, or nonmenstrual vaginal bleeding. Well-woman visits might also discover asymptomatic lesions upon pelvic examination or cytologic evaluation. As a lesion grows in size, it might elicit local pelvic pain or disrupted urination or defecation. If disease were to spread to regional pelvic or paraaortic lymph nodes, back pain or unilateral leg swelling (or even bullous edema) might become evident.

Physical Findings

Abnormal contour of the uterine cervix on physical examination might be the first clue to disease, with necrotic or friable lesions being particularly suspicious. Palpable extension of disease onto the walls of the vagina must be described, if present. Parametrial, sidewall, and uterosacral ligament extension are best felt and described by rectovaginal examination. Nodal disease in the groin, femoral, and scalene lymph node regions should be assessed to guide intervention.

Diagnostic Biopsy

Biopsies should secure sufficient nonnecrotic tissue at depth for diagnosis of uterine cervix cancers. Marginal biopsy rather than central necrotic tissue biopsy yields superior results.

Staging

Clinical Staging Procedures

Pelvic examination with rectovaginal palpation provides the basis for clinical cancer staging. An examination under anesthesia, when needed, provides superior visual and manual examination when patients relay discomfort and pain with routine pelvic examination. Examination under anesthesia affords cystoscopy, proctoscopy, and special instrument biopsy when indicated.

Clinical Laboratory Studies

A complete peripheral blood count is indicated to assess anemia (<10 g/dL), which might need packed red blood cell correction. Thrombocytopenia might be found in up to 30% of patients, which might need replacement prior to therapeutic intervention. Serum blood urea nitrogen and creatinine obtained as part of the chemistry panel assess renal insufficiency and dehydration, which might need stabilization and rehydration prior to cisplatin-based radiochemotherapy. Liver function panels are obtained generally prior to chemotherapy when indicated. A baseline urinalysis including pregnancy test are indicated to assess for pregnancy in potential childbearing patients.

Clinical Serum Tumor Markers

Table 20.4 lists actively investigated serum tumor markers for uterine cervix cancer (78–88). Uterine cervix cancers—represented mostly by HPV-competent squamous cell carcinoma or adenocarcinoma—express unique phenotypic fingerprints, which are possibly indicative of higher rates of nodal or visceral metastases and poorer disease-specific survival. Prospective trials randomizing go or no-go therapeutic decisions based on serum tumor markers remain elusive.

TABLE 20.4 Biologic Markers Predicting Lymph Node Metastasis in Uterine Cervix Cancer

Test	Cutoff (ng/mL)	Sensitivity (%)	Specificity (%)	% Node Metastasis	Test Used in Decision for	Referenc

Uterine cervix circulating tumor cells (CTCs)	E6/E7+	0	78	25 (3 of 12)	CTC	(88)

AR, adjuvant radiation; BR, biochemical response; CTC, E6+ or E7+ circulating tumor cells; ID, initial detection; NR, not reported; PR, predicting response.

Clinical Radiographic Studies

The FIGO system for cancer staging relies only on clinical examination (46). Noninvasive chest radiography, intravenous pyelography (IVP), cystoscopy, sigmoidoscopy, and barium enema radiography may aid in clinical evaluation, but are not mandatory (46). Computed tomography (CT), 2-[^{18}F]fluoro-2-deoxy-d-glucose (FDG), positron emission tomography (PET), dual PET/CT, magnetic resonance imaging (MRI), and dual PET/MRI studies (89) are not yet integrated into formal staging criteria. In the United States and other countries, these studies are considered important in the care of women with uterine cervix cancer as they improve diagnostic accuracy.

When compared to operative staging, FIGO clinical stage for uterine cervix cancer understages 30% of stage IB, 25% of stage IIB, and 40% of stage IIIB patients (90). Abdominopelvic CT or MRI images help sort out cross-sectional anatomy and assist in evaluating prognostic features such as tumor size and lymph node metastasis. A 25-center intergroup trial conducted by the American College of Radiology Imaging Network and by the Gynecologic Oncology Group (ACRIN 6651/GOG 183]) begun in 2000 prospectively evaluated MRI, CT, clinical exam, and histopathologic analysis for their ability to predict lymph node involvement as verified by lymphadenectomy in 208 women with uterine cervix cancer (91–93). MRI correctly identified 20 (37%) of 54 of cases with surgicopathologic-confirmed lymph node metastases; CT correctly labeled 17 (31%) of 55 cases (93). The investigators concluded both modalities had an underperforming, low

sensitivity for detecting lymph node metastases. However, MRI outperformed CT in the ability to measure uterine cervix cancer diameter (92), an important prognostic variable. MRI has therefore been associated with a positive predictive value of 61 (95% CI, 48%–73%) among women surgically confirmed for positive pelvic and paraaortic lymph node metastases, a negative predictive value of 66% (95% CI, 55%–75%) among women surgically confirmed for positive pelvic lymph nodes and negative paraaortic lymph nodes, and a negative predictive value of 86% (95% CI, 76%–92%) in women with surgically confirmed negative pelvic and paraaortic lymph nodes (94). In cases of parametrial extension, MRI provides superior detail of tumor-related anatomic invasion and affords best contour definition in brachytherapy radiation planning (95).

PET studies have shown that the radiotracer FDG associates with all measures of disease burden, including the prevalence of lymph node metastases, rates of objective (complete or partial) treatment response, and progression-free survival, in patients with uterine cervix cancer (96–99). FDG proves useful due to its "look-alike" sugar form, being "trapped" by intracellular hexokinase, and being concentrated in overactive cancer cells. A 32-patient surgicopathologic study (1994 to 1998) of presurgical abdominopelvic PET followed by open surgical lymphadenectomy showed a 75% sensitivity and 92% specificity for uterine cervix cancer metastases in paraaortic lymph nodes (96). A 101-patient radiographic study (1998 to 2000) of whole-body PET found that PET-avid paraaortic lymph nodes predicted progression-free survival (97). A 482 patient retrospective study (1997 to 2008) investigated imaging-only confirmed sites of lymph node metastases (98). It found 205 patients (43%) with no FDG-avid lymph nodes; 186 patients (39%) with FDG-avid pelvic lymph nodes only; 65 patients (13%) with FDG-avid pelvic and paraaortic lymph nodes; and 26 patients (5%) with FDG-avid pelvic, paraaortic, and supraclavicular lymph nodes. Among 51 uterine cervix cancer patients (2004 to 2009) in whom presurgical PET scans were obtained, a ≤0.33 posttherapy: pretherapy standard uptake value maximum ratio of primary cancer metabolic signal was associated in 88% of patients with an at least partial radiochemotherapy treatment response (99). A phase I trial (2006 to 2008) explored PET-assessed metabolic response to novel radiochemotherapy in uterine cervix cancer patients (100). Afterward, a prospective phase II clinical trial (2009 to 2011) in 25 women with advanced-stage uterine cervix or vaginal cancers used a 3-month posttherapy PET-assessed metabolic response as the primary efficacy endpoint (101,102).

Pretreatment Paraaortic Node Operative Staging

Paraaortic lymph node metastases indicate negative prognosis and short survival (96). It is debatable whether there is a therapeutic advantage to operative removal of paraaortic disease. An extraperitoneal approach or transperitoneal approach to paraaortic lymphadenectomy was of similar sensitivity and morbidity in a 288-patient (1977 to 1981) uterine cervix cancer surgical staging study (103). Knowledge of paraaortic lymph node disease has been shown to direct care away from surgery toward extended-field radiation therapy in up to 20% of patients (104). As part of a prospective, multicenter clinical trial (1999 to 2002), patients with histologically confirmed stage IB2, stage IIA ≥4 cm or stage IIB to IVA uterine cervix cancers underwent MRI prior to pelvic and abdominal lymphadenectomy (94). Lymph nodes <1 cm were bisected whereas those >1 cm were serially sectioned into 5-mm sections for microscopy. Thirty-three patients had 94 metastasis-positive and 659 metastasis-negative lymph nodes removed. Mean size of the long axis of the 60 largest positive and the 209 negative lymph nodes removed did not differ (19 ± 9 mm vs. 19 ± 12 mm; $p = 0.47$). The authors suggested that the negative predictive value of MRI for paraaortic lymph nodes among patients reported to have negative pelvic and paraaortic lymph nodes on MRI is high enough that surgical evaluation and extended-field radiation therapy are not necessary. For all others, the positive and negative predictive values of MRI are too low to determine the need for extended-field radiation therapy without first performing surgical evaluation. A phase III international trial evaluating lymphadenectomy in locally advanced uterine cervix cancer study (LiLACS) is underway (105).

Sentinel Lymph Node Mapping in Early Uterine Cervix

Cancer

The feasibility of sentinel lymph node mapping has been explored in 39 patients with invasive uterine cervix cancer undergoing radical hysterectomy and pelvic lymphadenectomy (106). All patients underwent presurgical lymphoscintigraphy and intraoperative mapping with both a blue dye and a handheld gamma probe. Lymphoscintigraphy revealed at least one sentinel lymph node in 33 (85%) patients, including 21 (55%) patients with bilateral sentinel lymph nodes. All 39 patients had at least one sentinel lymph node identified during surgery. The majority (80%) of sentinel lymph nodes were in iliac, obturator, and parametrial nodal basins (in descending order of frequency). The remainder was in either the common iliac or the paraaortic nodal basins. A total of 132 nodes were identified clinically as sentinel lymph nodes; 65 (49%) were both blue and hot, 35 (27%) were blue only, and 32 (24%) were hot only. The sensitivity of the sentinel node was 88% and the negative predictive value was 97%. The German AGO Study Group (1998 to 2006) identified a 93% sentinel lymph node detection rate, 77% sensitivity, and 94% negative predictive value in 590 women of all uterine cervix cancer stage who underwent lymph node detection after labeling with technetium, patent blue, or both (107). Obstacles to widespread adoption include sensitivity of frozen section preparation to detect lymph node metastasis, pathologic expertise, uniformity of surgicopathologic technique, and a determination of whether the clinical impact of presurgical tumor size affects the rate of sentinel lymph node event (41).

PATHOLOGY

Squamous Cell Carcinoma

Squamous cell carcinoma of the uterine cervix includes microinvasive and more deeply invasive squamous cancer cell variants that may differ in biologic behavior, such as verrucous, papillary squamous, transitional, warty, or lymphoepithelioma-like carcinoma.

Preinvasive Disease

High-grade squamous intraepithelial lesion describes full-thickness epithelial neoplasia of the cervix. The normal maturation steps of a squamous epithelium are absent. Cells often have enlarged oval nuclei, increased nuclear: cytoplasm ratios, and mitotic figures (**Fig. 20.1**). Persistent squamous cell carcinoma *in situ* became invasive cancer in 22% of New Zealand women over a five-year period (108).

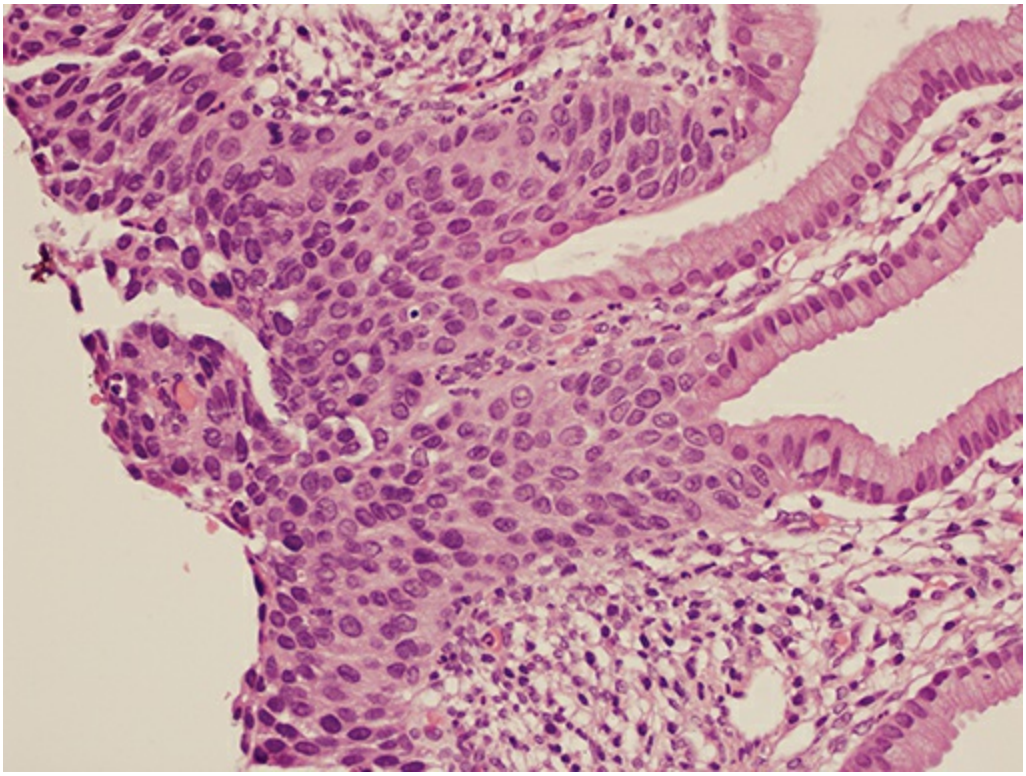

Figure 20.1 Squamous carcinoma in situ. The epithelium displays full-thickness atypia. Cells have enlarged, hyperchromatic nuclei, and there is no evidence of maturation.

Microinvasive Disease

Microinvasive squamous cell carcinoma typically arises from squamous intraepithelial neoplasia, originating from surface epithelium or from endocervical glands. Microinvasive carcinoma describes irregular, haphazardly arranged small nests of squamous cells that have penetrated the basement membrane of the surface or glandular epithelium. Cells are larger, have abundant eosinophilic cytoplasm, and are associated with a desmoplastic stromal reaction (**Fig. 20.2**).

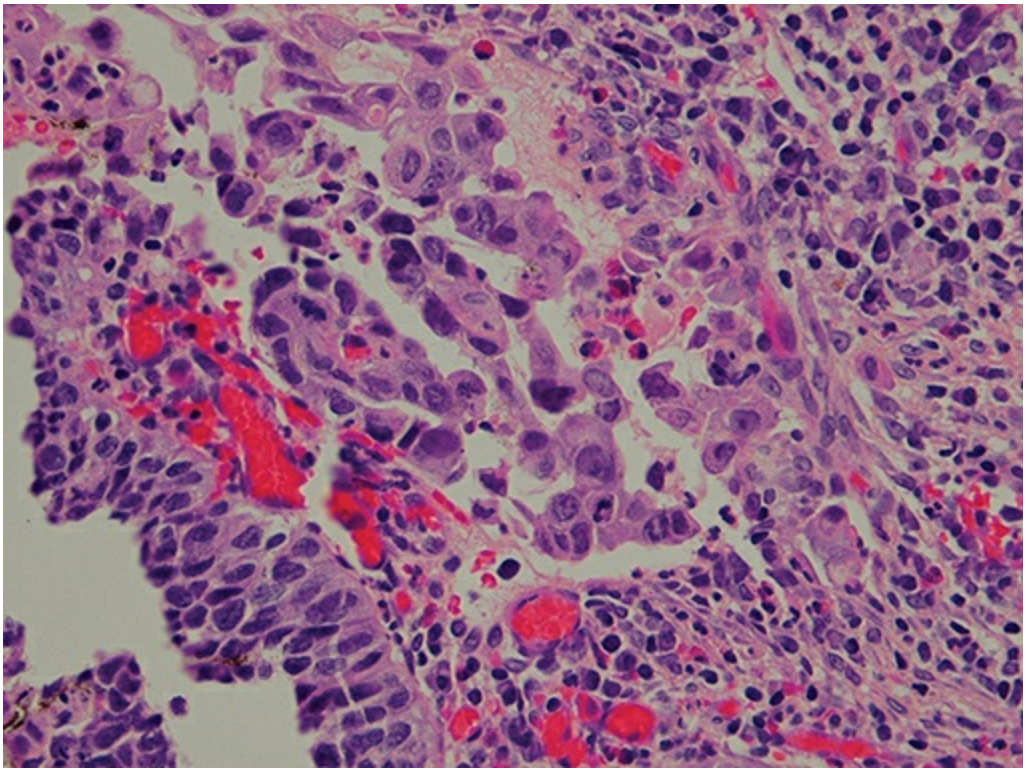

Figure 20.2 Microinvasive squamous carcinoma. There is an area of squamous carcinoma in situ (lower left). A nest of invasive carcinoma cells (center) has broken through the basement membrane. The invasive cells are larger, with more abundant cytoplasm and larger, more pleomorphic nuclei. A desmoplastic stroma response is present (right).

Microinvasive squamous cell depth of invasion should be measured from the originating basement membrane. For instance, if carcinoma arises from the surface epithelium, depth is the distance from the basement membrane of the surface epithelium to the deepest nest of invasive cells. If carcinoma arises from an endocervical gland, depth is measured from the basement membrane of the gland. If the originating site is unclear, depth is measured from the basement membrane of the surface epithelium. Nests of superficially invasive squamous cells observed in small biopsies should be reported along with the dimensions of any invasive tumor. A diagnosis of microinvasive squamous cell carcinoma of the cervix requires a loop diathermy or conization biopsy that encircles the entire lesion with negative margin. In a 133-patient surgicopathologic microinvasive cancer of the uterine cervix study (1965 to 1976), tumor penetration was <1 mm in 38%, 1 to 2 mm in 30%, 2 to 3 mm in 17%, 3 to 4 mm in 12%, and ≥4 mm in 4% (109). No lymph node metastases were detected at the time of radical hysterectomy in 74 patients. Only two (1.5%) patients developed relapse (109).

Invasive Disease

Invasive squamous cell carcinoma of the uterine cervix arises most often from high-grade dysplasia, which initially may have been detected up to 10 years beforehand. It has been shown that CIN 2 progressed eight times more often and CIN 3 progressed 22 times more often to carcinoma *in situ* or invasive cancer than did CIN 1 (110). HPV is associated with invasive disease in more than 86% of incident cases (15). Tumors may be firm indurated masses, polypoid, or ulcerated. Under the microscope, irregular, haphazardly infiltrating nests of cells are apparent. Cells have an eosinophilic cytoplasm, and nuclei that are enlarged, atypical, and hyperchromatic (**Fig. 20.3**). Mitoses may be numerous and atypical. A pronounced desmoplastic stromal reaction occurs around invasive cell nests, perhaps indicative of host immune cell response to virally altered uterine cervix cells and manifesting as bulky tumor (111). Lymphovascular space invasion may be present, especially in more deeply invasive tumors.

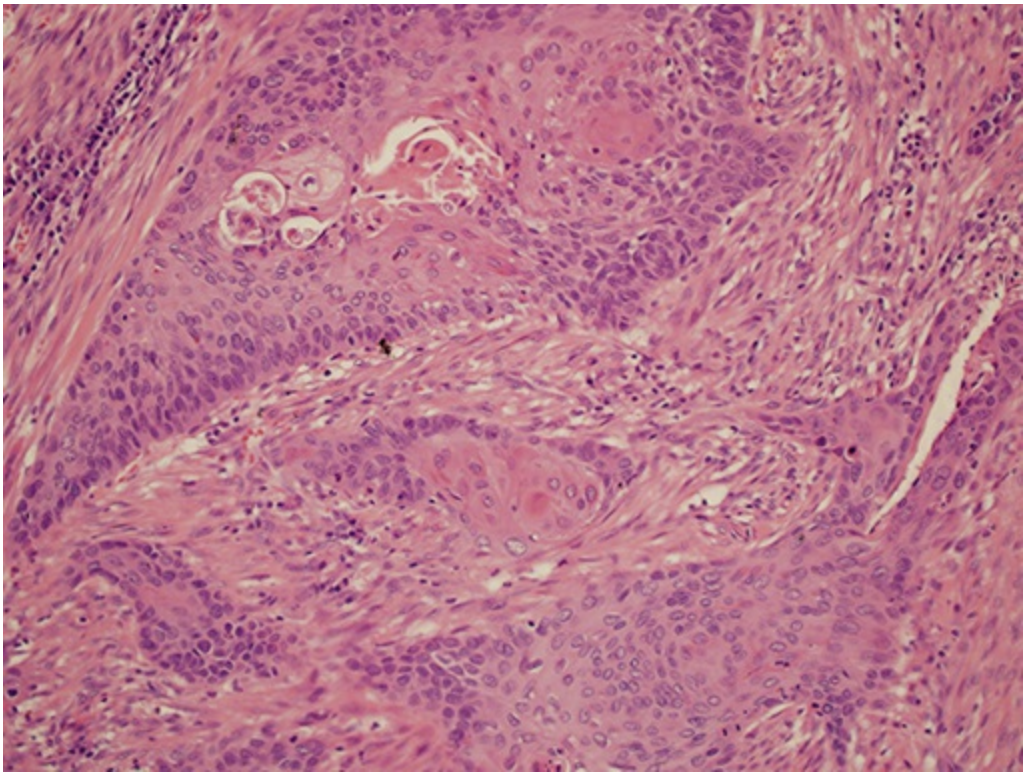

Figure 20.3 Invasive squamous carcinoma. Small, irregular nests of cells with markedly atypical nuclei are present. They are surrounded by desmoplastic stroma containing inflammatory cells.

Invasive squamous cell carcinomas are labeled as keratinizing or nonkeratinizing. Keratinizing squamous cell carcinomas show keratin pearl architecture. Nonkeratinizing squamous cell carcinomas lack keratin pearls, display abundant eosinophilic cytoplasm, and show intercellular bridges. Small cells lacking neuroendocrine differentiation are classified as nonkeratinizing squamous cell carcinomas.

Invasive squamous cell carcinomas are graded. Grade 1 well-differentiated cancers are rare, possess keratin pearls, and comprised of keratinized cells predominantly. Grade 1 cell nuclei show modest atypia and mitoses are uncommon. Grade 2 moderately differentiated cancers represent the majority, are typically nonkeratinizing squamous cell carcinomas, display nuclear pleomorphism and more numerous mitoses, and have an infiltrative pattern. Grade 3 poorly differentiated cancers either have smaller cells without neuroendocrine differentiation, or are pleomorphic with anaplastic nuclei. Grade 3 cancers have a propensity for spindle-shaped cells that must be distinguished from sarcoma by positive cytokeratin stains.

Squamous Cell Carcinoma Variants

Papillary Squamous and Transitional Cell Carcinoma

A papillary superficial architecture with substantial nuclear atypia occurs as one variant of uterine cervix cancer. The most common presenting symptoms are vaginal bleeding and abnormal Pap smears. Papillary, polypoid, or granular lesions are often evident on examination of the cervix.

Papillary squamous and transitional cell carcinomas have thin or thick papillae that contain connective tissue cores covered by highly atypical epithelium displaying keratinization. Occasionally, the epithelium consists of multiple layered cells with oval hyperchromatic nuclei without keratinization and resemble urothelial transitional cell epithelium. Nuclear grooves may be present. Immunohistochemical studies have shown that most of these tumors are cytokeratin 7 positive and cytokeratin 20 negative; these results are consistent with a squamous cell differentiation. HPV-16 DNA has been

detected and these tumors have a shared uroplakin III negative, p63 positive, and $p16^{INK4A}$ positive immunophenotype regardless of light microscopic features (112).

Papillary squamous cell and transitional cell carcinomas of the uterine cervix are associated commonly with an underlying invasive squamous cell carcinoma. Other cases of invasive cancers have been described. Therefore, superficial biopsies displaying only a papillary portion of the neoplasm may be inconclusive. Loop diathermy or conization should be done to exclude an underlying invasive cancer.

Local relapse and systemic metastasis occur with these cancer types. Papillary squamous cell and transitional cell carcinomas must be separated from verrucous carcinomas, which display little cell atypia and have a much more indolent clinical course.

Verrucous Carcinoma

Verrucous carcinoma arises in a papillary excrescence of the cervix resembling condyloma acuminatum (perhaps the "giant condyloma of Buschke and Lowenstein"). Microscopic examination displays pointed "church spire" papillary fronds of squamous epithelium lacking connective tissue cores. Connective tissue beneath these fronds displays bulbous nests of squamous epithelium that invade the stroma with a pushing margin but minor cytologic atypia. Significant nuclear atypia identifies another form of uterine cervix carcinoma. The histopathologic distinction between verrucous carcinoma and squamous cell carcinoma is critical because verrucous carcinoma invades local tissues but does not metastasize elsewhere. A verrucous carcinoma diagnosis necessitates visual inspection of the invasive portion of the tumor; superficial biopsies are inconclusive.

Warty Carcinoma

Warty carcinomas are rare papillary neoplasms marked by condylomatous changes but possess histopathologic features of invasive squamous cell carcinoma at their deep margin (113). HPV-related cellular changes ("koilocytotic atypia") are shown in **Figure 20.4**.

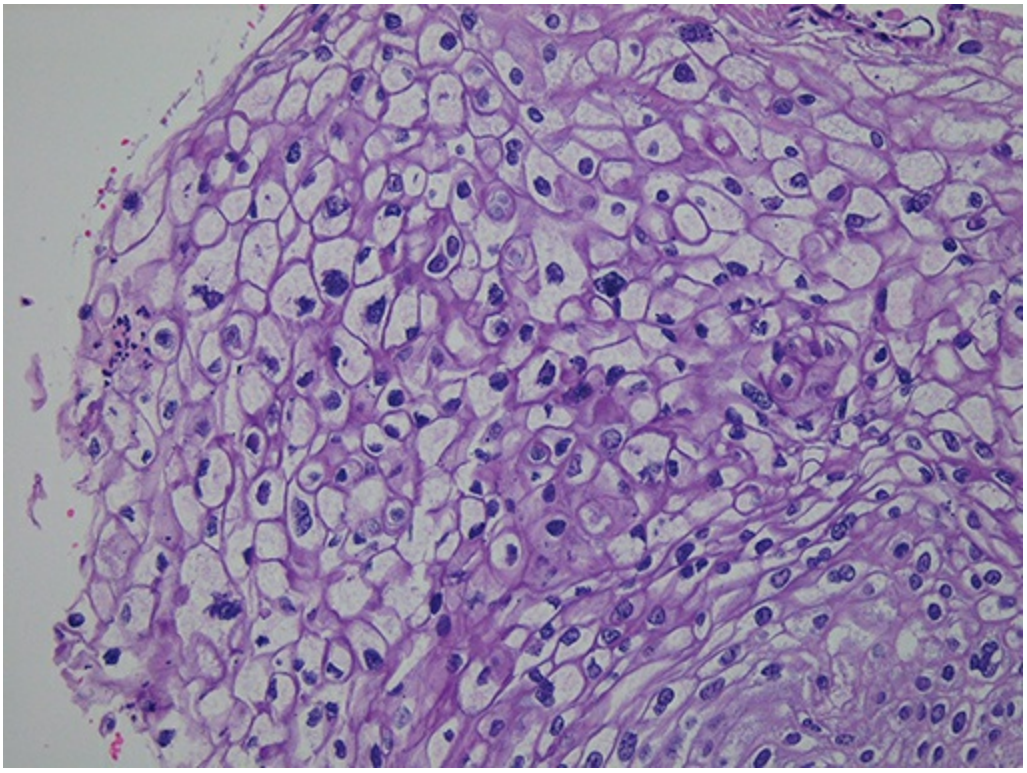

Figure 20.4 Human papillomavirus changes. This squamous epithelium displays cells with large halos surrounding atypical nuclei (“koilocytotic atypia”).

Lymphoepithelioma-Like Carcinoma

Lymphoepithelioma-like carcinoma, most commonly seen in the nasopharynx, represents another variant of uterine cervix cancer. The clinical presentation ranges from a cervical tumor producing modest abnormal vaginal bleeding to nonvisible cervical tumors detected only by cervical cytology smears. Lymphoepithelioma-like carcinoma of the cervix presents most often in Asian women and is associated with Epstein–Barr virus infection in those patients (114). The latter observation remains controversial. Microscopic examination reveals nests of cells with pale eosinophilic cytoplasm and large vesicular nuclei with prominent eosinophilic nucleoli. Cell margins are indistinct, lending to a syncytial phenotype. A prominent inflammatory infiltrate comprising of lymphocytes, plasma cells, and eosinophils occurs. This carcinoma distinguishes itself from glassy cell carcinoma (also accompanied by prominent inflammation) by its indistinct cell margins and granular eosinophilic cytoplasm. The lymphocytic infiltrate contains predominantly CD8+ suppressor/cytotoxic T cells (115).

Adenosquamous Carcinoma

Adenosquamous carcinoma includes an admixture of malignant glandular cell and squamous cell elements. This term is not a basket classification for poorly differentiated squamous carcinomas, in which mucicarmine stains show only scattered mucin vacuoles. Likewise, this term is not descriptive of a true collision tumor, where an adenocarcinoma abuts a squamous cell carcinoma. An adenosquamous carcinoma has high tumor cell grade, presence of vascular invasion, and aggressive malignant potential.

Adenocarcinoma

Adenocarcinoma of the uterine cervix is on the rise, accounting for 25% of incident cancer cases (116). Two are described, endocervical AIS or adenocarcinoma (56). HPV types 18, 33, 35, 45, 51, 58, or 59 confer risk for adenocarcinoma, although HPV 16 occurs as well (117).

Adenocarcinoma In Situ

Under the microscope, AIS preserves overall endocervical gland architecture with varying degrees of cytologic atypia, including nuclear enlargement and stratification, nuclear hyperchromasia, and mitotic figures (**Fig. 20.5**). Most AISs occur near the transformation zone.

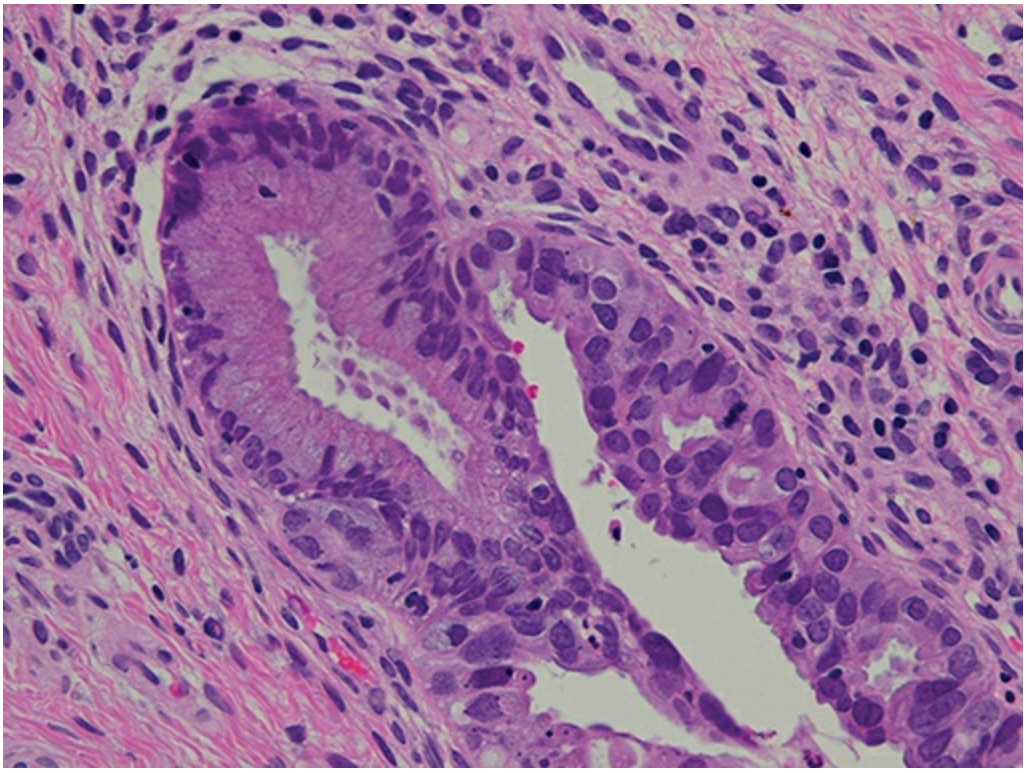

Figure 20.5 Adenocarcinoma in situ. Part of this endocervical gland is normal (upper left corner). Stratified cells with atypical, large nuclei and mitotic figures have replaced the remainder of the gland.

Adenocarcinoma

Adenocarcinoma of the uterine cervix shows altered endocervical gland architecture in the form of solid or cribriform nests of cells, architecturally irregular or incomplete glands lined by malignant cells, or small buds of highly atypical cells arising from glands involved by AIS. A desmoplastic stroma accompanies tumors. The FIGO definition of microinvasive carcinoma generally applies to all types of cancers, but the term has not been generally accepted for adenocarcinoma of the uterine cervix because an increased incidence of metastatic disease corresponds to incremental increases in depth of invasive disease.

Mucinous Adenocarcinoma

Mucinous adenocarcinoma of the uterine cervix includes endocervical, intestinal, signet ring cell, minimal deviation, and villoglandular variants. HPV DNA has been detected in 91% of mucinous adenocarcinomas of the cervix (118).

Mucinous Adenocarcinoma, Endocervical Variant

An endocervical variant of mucinous adenocarcinoma occurs most often. Irregular, haphazardly arranged tubuloracemose glands are lined by cells resembling those seen in normal endocervical glands, but with limited amounts of cytoplasmic mucin. Nuclei are basally located, stratified, and atypical (**Fig. 20.6**). Mitoses are found. Grade 1 well-differentiated cancers have uniform nuclei with minimal stratification and few mitotic figures. Grade 2 moderately differentiated adenocarcinomas have more prominent cytologic atypia with more frequent mitoses. Grade 3 poorly differentiated adenocarcinomas contain prominent solid regions, pleomorphic nuclei, and many mitoses. A desmoplastic stromal response is variable.

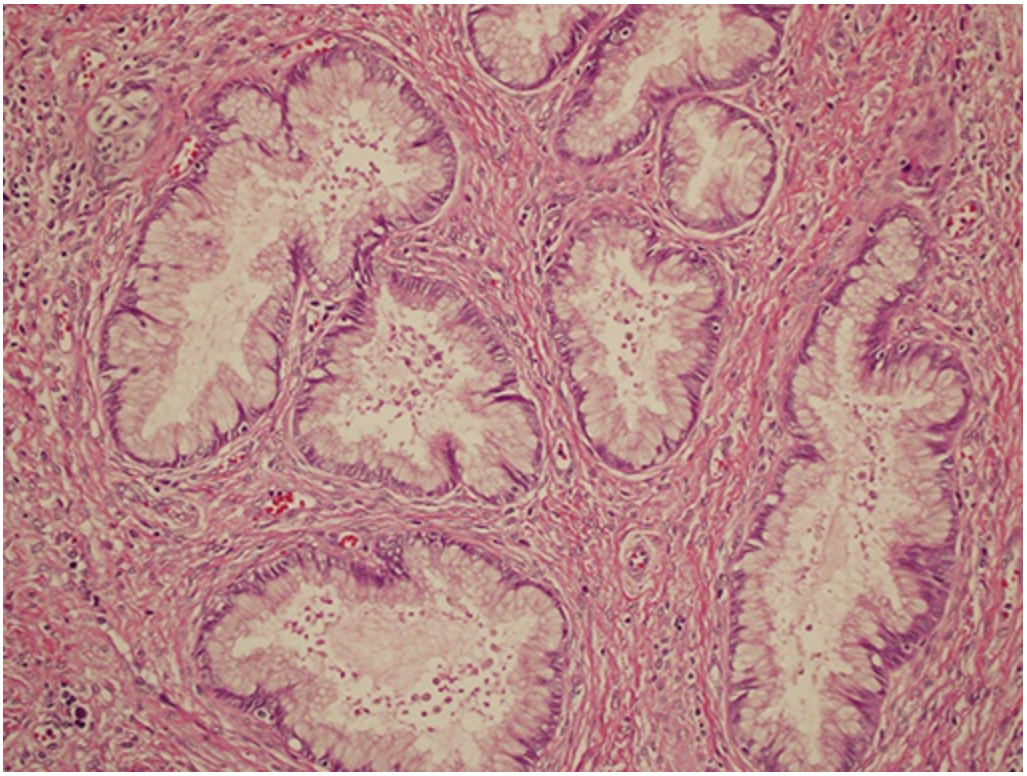

Figure 20.6 Well-differentiated glands infiltrate desmoplastic cervical stroma. The glands display a haphazard pattern. Nuclei are basally located but stratified and atypical.

Mucinous Adenocarcinoma, Intestinal Type, Signet Ring, and Colloid Variants

A rare form of uterine cervix adenocarcinoma has goblet cells in endocervical glands; these tumors possess intestinal differentiation. Malignant signet ring cells and colloid cells are rare in the uterine cervix; these adenocarcinoma variants must be distinguished from metastatic gastrointestinal tract cancers.

Mucinous Adenocarcinoma, Minimal Deviation Variant

The minimal deviation variant of mucinous adenocarcinoma represents only about 1% of uterine cervix adenocarcinomas (119) and is not associated with HPV infection (120). Firm, tan–yellow tumors are found in hysterectomy samples. Microscopic inspection finds disorganized glands infiltrating the cervical stroma, with budding contours or angular peaked outlines. The glands look deceptively benign on low-power magnification. A lack of cytologic atypia must be seen for this diagnosis. On high-power magnification, cells may have some nuclear enlargement, stratification, and rare mitotic figures. The infiltrating glands are devoid of substantial desmoplastic reaction.

Mucinous Adenocarcinoma, Well-Differentiated Villoglandular Variant

Well-differentiated villoglandular adenocarcinomas occur as polypoid or papillary endocervical masses. Microscopy reveals villous, papillary structures assuming long and slender forms or short and broad forms. A connective tissue core with inflammatory cells may be present. The overlying epithelium consists of a single stratified layer of cells with endocervical,

endometrial, or intestinal differentiation. Nuclei are mildly atypical and mitotic figures are infrequent (**Fig. 20.7**). Invasive adenocarcinoma may be seen beneath papillary areas, characterized by branching glands lined by atypical cells and surrounded by desmoplastic stroma. This does not display marked nuclear atypia and epithelial tufting seen in the much more aggressive papillary serous carcinoma of the uterine cervix. This variant may be associated with typical AIS of the uterine cervix. Usually, a villoglandular uterine cervix cancer should not be suggested when only small biopsy specimens are available for review; a definitive diagnosis should be made only when viewing conization or hysterectomy surgical specimens. Villoglandular cancers having a high-grade cytologic component or an underlying obvious invasive adenocarcinoma may be linked to lymphovascular invasion, lymph node metastases, and higher probability of relapse (121).

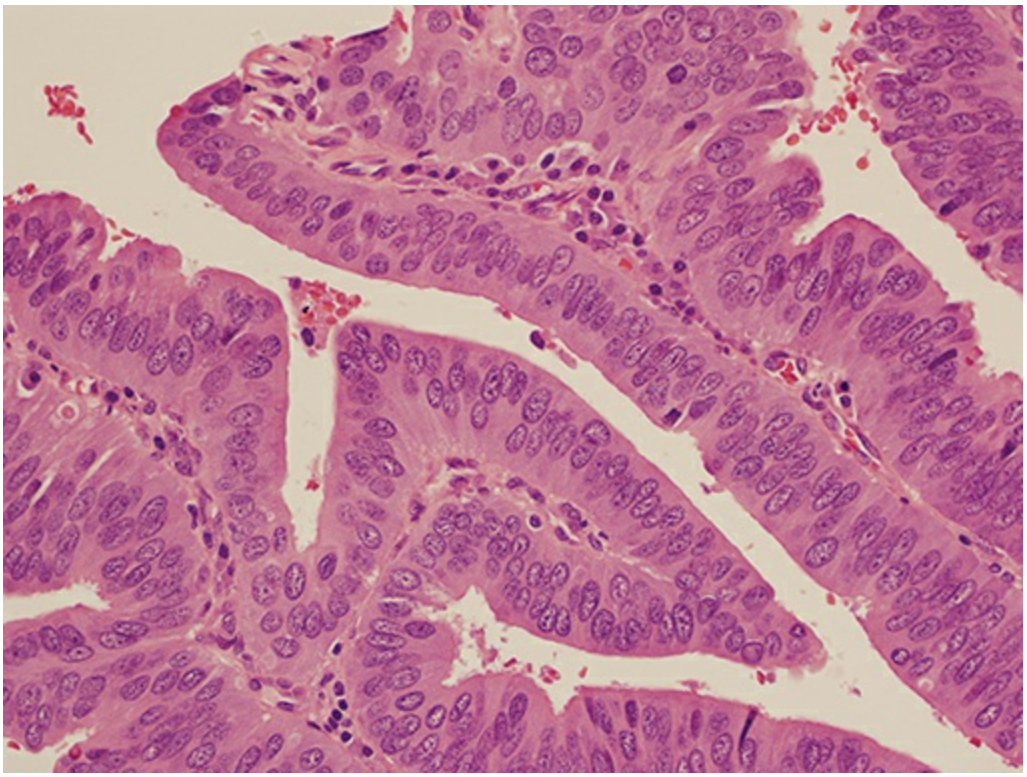

Figure 20.7 Well-differentiated villoglandular adenocarcinoma. Long, slender villous processes are covered with epithelium, displaying mild atypia. Nuclei are crowded, but they retain an oval shape and are uniform in size.

Adenocarcinoma, Endometrioid Variant

Endometrioid carcinomas of the uterine cervix are rare and overdiagnosed, accounting for 7% of all adenocarcinomas of the uterine cervix. These are “look-alike” malignancies sharing histopathologic features with endometrioid cancers of the uterine corpus. Thus, a primary endometrial adenocarcinoma with endocervical extension or drop metastasis masquerading as a uterine cervix cancer must be excluded. Immunohistochemical signature of carcinoembryonic antigen (CEA) positivity, estrogen receptor (ER) negativity, and vimentin negativity marks uterine endocervix primary cancers, while the opposite signature characterizes uterine corpus primary cancers. HPV markers (e.g., p16) also support a uterine endocervix primary cancer.

Adenocarcinoma, Clear Cell Variant

Clear cell cancers of the uterine cervix are linked to intrauterine DES exposure; however, clear cell cancers also occur in

the absence of DES exposure. Histopathologic examination identifies solid sheets of cells containing abundant glycogen-rich clear cytoplasm, atypical nuclei, and numerous mitoses. A tubulocystic pattern involves alternating tubule and cystic spaces lined by oxyphilic, hobnail, or clear cells. A papillary pattern is uncommon and often mixed solid and tubulocystic areas are seen. Clear cell carcinomas of the cervix are not associated with HPV infection (120).

Adenocarcinoma, Papillary Serous Variant

Papillary serous uterine cervix cancers are not associated with HPV infection (120). There is a bimodal age distribution, occurring in patients younger than 40 years and patients older than 65 years. Gross pathologic examination reveals a nodular mass, an indurated cervix, or no visible abnormality. Under the microscope, these cancers appear identical to serous tumors of the ovary, endometrium, and primary peritoneal serous carcinomas. Exclusion of metastasis or extension of disease from another primary site, especially the endometrium, is paramount. Histopathologic examination identifies fibrous papillae lined by atypical epithelial cells; secondary papillae or tufts of malignant-appearing epithelial surface cells are often present (**Fig. 20.8**). Glandular structures have misshapen luminal borders because of cancer cell tufts. Nuclei show high-grade atypia and an abundant number of mitoses are observed. These aggressive cancers often metastasize to pelvic, paraaortic, and groin lymph nodes, and portend a worse prognosis.

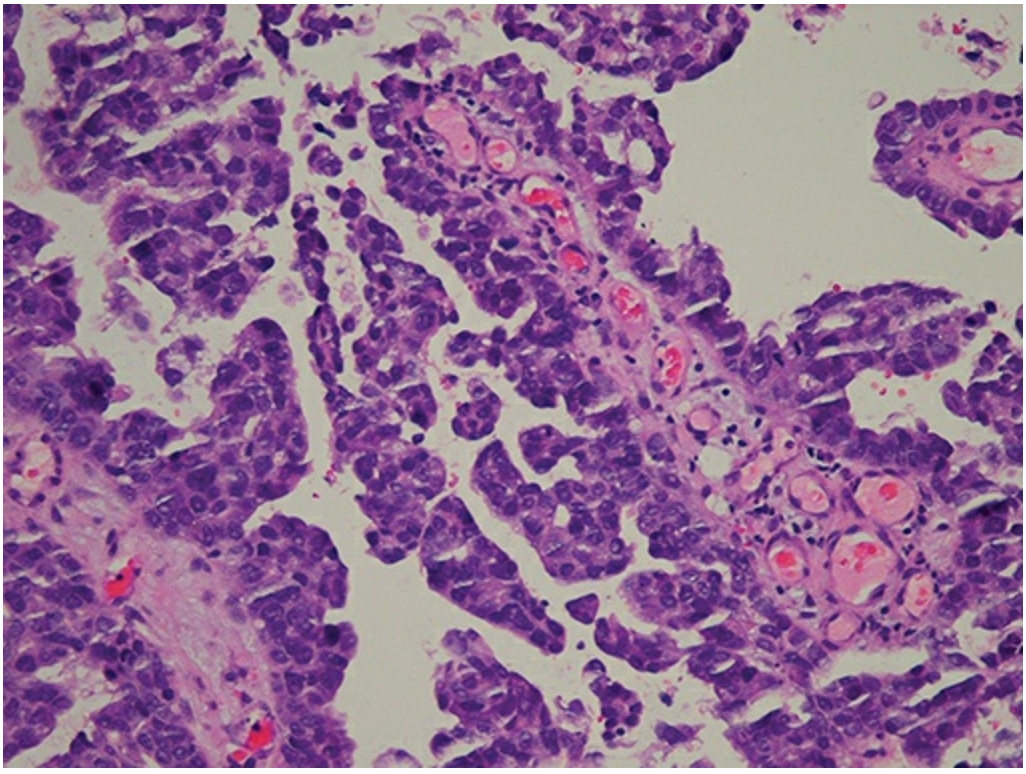

Figure 20.8 Serous adenocarcinoma. The papillary structures have a connective tissue core. There is marked tufting and stratification, and the nuclei are markedly atypical.

Adenocarcinoma, Mesonephric Variant

Mesonephric duct remnants in the lateral aspects of the uterine cervix may be identified as lobules of small, round, glandular structures lined by flattened cuboidal epithelium with intraluminal periodic acid-Schiff stain (PAS)-positive material. These cells do not contain intracytoplasmic mucin, unlike cells lining endocervical glands. Mesonephric-variant adenocarcinomas arise from the lateral mesonephric duct remnants, with few cases reported. These cancers display ductal, tubular, retiform, solid, and sex cord–like patterns and cells that lack intracytoplasmic mucin.

Adenocarcinoma, Microcystic Endocervical Variant

Microcystic endocervical-variant adenocarcinoma is rare, as only eight cases are described (122). The hallmark pattern involves many low-power microscopic cystic and dilated glands. Magnification reveals abundant cytologic atypia and mitoses. Pockets of mucinous or intestinal endocervical adenocarcinoma are found; cells are deeply invasive. Postsurgical local relapses have been recorded.

Glassy Cell Carcinoma

Glassy cell carcinoma represents an uncommon variant of adenosquamous carcinoma, showing cells with eosinophilic cytoplasm, well-defined margins, and prominent nucleoli. A plasma cell infiltrate is often seen. Relapses of adenocarcinomas or adenosquamous carcinomas may assume a glassy cell carcinoma appearance when the original cells have been irradiated (116).

Adenoid Cystic Carcinoma

Adenoid cystic carcinoma of the uterine cervix is both rare and aggressive, presenting most often in elderly patients. Microscopy reveals a cribriform gland pattern, with glands enclosing hyaline or mucinous material. Nuclei are large and pleomorphic, both to a greater extent as compared to adenoid basal epithelioma. Mitoses are present. Necrosis might be seen. Cells stain with cytokeratin; in contrast to the salivary gland variant, this cancer does not exhibit myoepithelial cells, either by immunohistochemistry for S100 protein or by electron microscopy. Relapses and metastases occur.

Adenoid Basal Epithelioma (Carcinoma)

Adenoid basal epitheliomas are rare neoplasms of the uterine cervix. An indolent behavior led to the term “adenoid basal epithelioma.” HPV 16 DNA integration has been observed (120). These lesions may be precursors for a variety of uterine cervix carcinomas. A subclassification as adenoid basal epitheliomas versus carcinomas should be used. Microscopically, adenoid basal epithelioma shows cell nests with a basaloid appearance and peripheral palisading. Gland lumina are found within nests, but the number of glands formed is variable. Squamous metaplasia and mitoses are seen infrequently. Adenoid basal epithelioma, in the absence of a coexisting invasive carcinoma, is benign. The disease must be distinguished from adenoid cystic carcinoma, given the profound difference in oncologic phenotype. Adenoid basal epitheliomas with carcinomatous components should be reported as cancers.

Neuroendocrine Cancers

Consistent labeling for neuroendocrine tumors of the uterine cervix facilitates epidemiology and natural history chronologies of these cancers (123). Immunohistochemical chromogranin or synaptophysin stains provide necessary evidence of neuroendocrine differentiation except in small cell carcinoma of the uterine cervix. Typical carcinoids of the uterine cervix are rare, identified with caution because most uterine cervix neuroendocrine tumors are aggressive, and too few cases describe the histopathology and natural history of this cancer variant. Atypical carcinoids of the uterine cervix are rare, display organoid cell nests, nuclear atypia, and have a mitotic rate of 5 to 10 foci per high powered microscope field of view. Necrosis may be present. Large cell neuroendocrine carcinomas of the uterine cervix (**Fig. 20.9**) possess organoid cell nests with peripheral palisading of nuclei, prominent nucleoli, variable levels of necrosis, eosinophilic cytoplasmic granules, and numerous mitotic figures (>10 foci per high powered microscope field of view). Lymphovascular space involvement may be seen. Coexisting AIS or adenocarcinoma of the cervix is often found, marking these cancers as highly aggressive neoplasms. Evidence of neuroendocrine differentiation is required; chromogranin or

synaptophysin immunoreactivity is used for diagnosis.

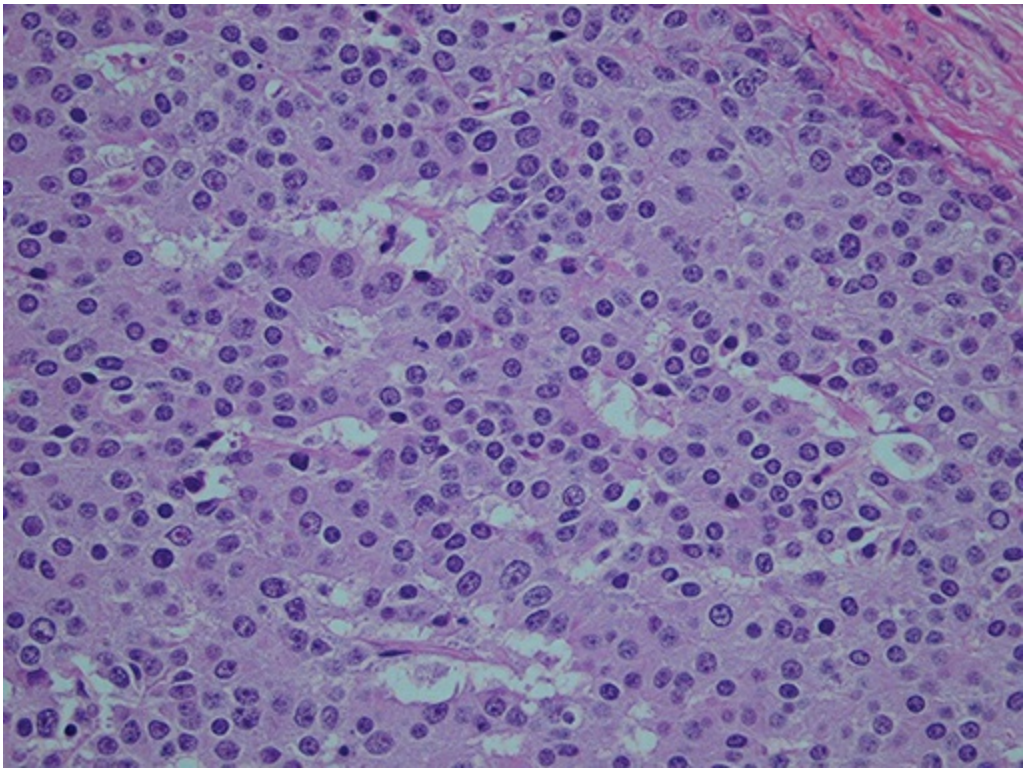

Figure 20.9 Large cell neuroendocrine carcinoma. This tumor displays organoid architecture. The tumor cells are much larger than those seen in small cell carcinoma. They have abundant eosinophilic cytoplasm, and there are numerous mitotic figures. Areas of necrosis were present elsewhere in the tumor.

Small Cell Carcinoma

Most neuroendocrine cancers observed arising from the uterine cervix are small cell carcinomas. Small cell carcinomas have cells with scant cytoplasm, inconspicuous nuclei with finely stippled chromatin, nuclear molding, extensive necrosis, crush artifact, and numerous mitotic figures (**Fig. 20.10**). Single-cell infiltration of the stroma has been observed commonly. Lymphovascular space invasion is seen often. Small cell carcinomas can be difficult to treat and recurrences are common.

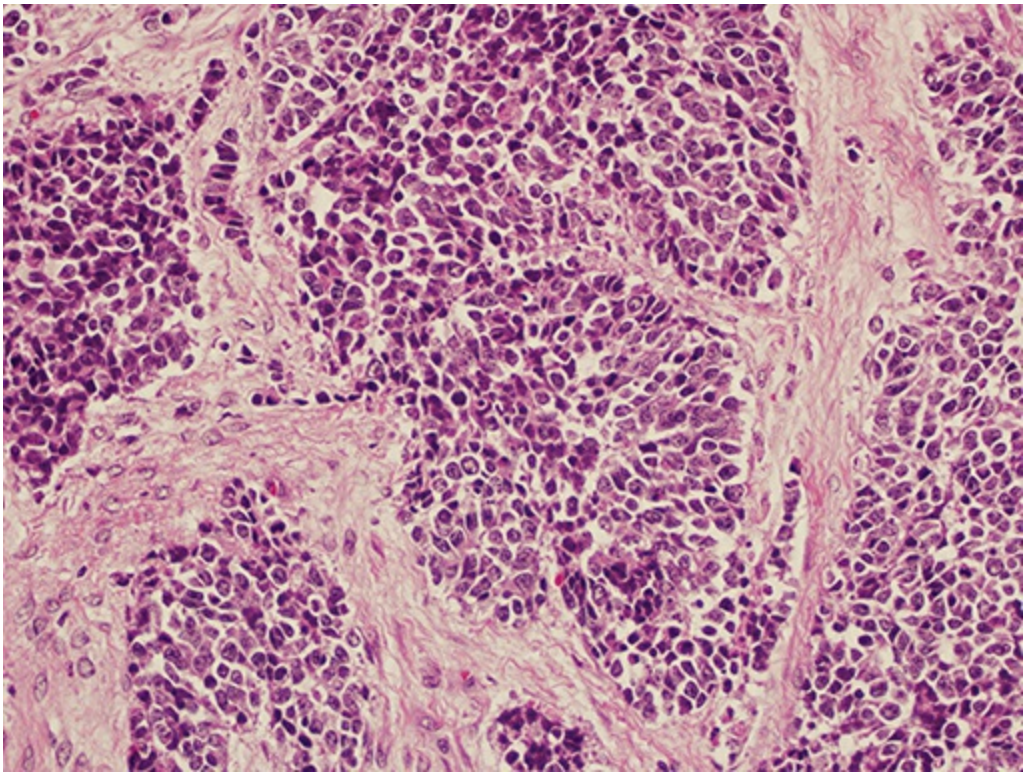

Figure 20.10 Small cell neuroendocrine carcinoma. This tumor displays cells that are smaller than those of squamous carcinoma. Nuclei are large and atypical with molding of adjacent nuclei. There is a very high mitotic rate.

Mixed Epithelial and Mesenchymal Tumors

Mullerian adenosarcomas may arise from the uterine cervix (124). Polypoid or papillary masses often give rise to nonmenstrual bleeding. Cells form benign-appearing glands in a sarcomatous stroma. A periglandular cuff of condensed stroma may be present. The sarcomatous element shows a variable number of mitotic figures, and some instances display heterologous elements such as striated muscle or cartilage. Mullerian adenosarcomas confer a favorable prognosis; deep invasion and sarcomatous overgrowth are adverse prognostic factors. Malignant mixed mullerian tumors may involve the cervix, but only five cases have been reported (125).

Other Malignant Tumors

Sarcomas arising from the uterine cervix are observed but uncommon. A histopathologic review of 1,583 malignancies of the uterine cervix found only 8 (0.5%) sarcomas (126). Five were carcinosarcomas and three were unclassified, leiomyosarcomas, or endometrial stromal sarcomas. Extranodal lymphomas of the uterine cervix are typically of diffuse B-cell origin (127). Primitive neuroectodermal tumors (128) and desmoplastic small round cell tumors (129) also have been described.

Secondary tumors of the uterine cervix might represent neoplasms invading from contiguous organs (such as the uterine corpus, urinary bladder, or rectum) or metastases from other organ sites (such as the ovary, uterus, or other visceral organs).

UTERINE CERVIX CANCER PROGNOSTIC FACTORS

Surgicopathologic Factors

A prospective 732-patient surgicopathologic study (1981 to 1984) of untreated stage I squamous cell uterine cervix cancer evaluated prognostic factors and cancer outcome (48,49). The protocol stipulated radical hysterectomy, pelvic and paraaortic transperitoneal lymphadenectomy, and peritoneal cytology. Gross primary tumors were associated more often (85 [21%] of 477) with pelvic lymph node metastases than occult primary tumors (15 [9%] of 168, $p = 0.009$). Three-year disease-free survival estimates were 95% for occult tumors, 88% for tumors ≤3 cm, and 68% for tumors >3 cm.

In the same study, a risk of pelvic lymph node metastases was associated with the depth of invasion in fractional thirds more so than absolute tumor size in millimeters—5% for inner third (9 of 199), 13% for middle third (28 of 210), and 26% (60 of 227) for outer third ($p = 0.0001$). Three-year disease-free survival estimates were 94% for inner third, 85% for middle third, and 74% for outer third invasion. Lymphovascular space invasion is associated with risk of pelvic lymph node metastasis, as 25% (70 of 276) of positive invasion cases had nodal metastases versus 8% (30 of 366) when invasion was absent. Three-year disease-free survival was 77% in positive lymphovascular space invasion cases and 89% in negative cases. Invasion of the parametria by uterine cervix cancer was associated with risk for pelvic lymph node metastases. When present, 43% (194 of 44) of cases had pelvic lymph nodes with metastases. When absent, 14% (81 of 599) of cases had pelvic lymph nodes with metastases.

Age at diagnosis is the least dramatic significant factor contributing to risk of lymph node metastases (48), and loses more significance when 50 years is used as an arbitrary breakpoint (49). Following an example of a moderately differentiated uterine cervix cancer with middle third invasion and no lymphovascular space or parametrial invasion, the expected probabilities of lymph node metastases in women aged 35, 45, 55, or 65 years are 9%, 8%, 5%, and 3%, respectively (48).

Lymph Node Factors

Lymph node metastasis from uterine cervix cancer has long been identified as a major prognostic factor, with surgical and radiotherapeutic management decisions partially based on the risk for nodal disease. Six (3%) of 177 patients with ≤5 mm invasion had pelvic lymph node metastases, the lowest risk of nodal disease in a surgicopathologic study (48). Sixteen (22%) of 74 patients with uterine extension had pelvic lymph node metastases (48). Well, moderately, and poorly differentiated tumors had risk for pelvic lymph node metastases of 10% (9 of 93), 14% (52 of 373), and 22% (39 of 179), respectively (48); 545 patients with no pelvic node metastases had a 3-year disease-free interval estimate of 86%, while 100 patients with positive pelvic node metastases had a 3-year disease-free interval estimate of 74% (49). A larger number of removed pelvic node metastases did not correlate with a poorer prognosis, as the 3-year disease-free intervals were 72%, 86%, and 65% for one, two, and three or more positive pelvic nodes, respectively (49). Despite the significant impact of nodal status on prognosis, nodal metastasis is not included in the FIGO staging system.

Clinical Stage Factors

Clinical stage has been found to be a weak risk factor in an era where radiographic and pathologic information are more powerful prognostic factors. A multivariate analysis of prognostic variable among 626 women included in therapeutic clinical trials did find correlated clinical stage and progression-free interval (130). This retrospective study involved 150 patients who received radiation therapy alone, 136 patients who received radiation therapy and *Corynebacterium parvum*, 156 patients who received radiation therapy plus misonidazole, and 184 patients who received radiation therapy and hydroxyurea. Paraaortic lymph node metastases were associated with sixfold risk for death and 11-fold risk for short progression-free interval (130). The investigators stated that with increased risk of node positivity, the distinction made by clinical stage falls. The investigators concluded that a combination of the most powerful risk factor (node status) with the most commonly used risk factor (clinical stage) presents a clear separation of patients in regard to uterine cervix cancer

survival (130).

Histopathology Factors

In a study from the United States Military Health Care System, 185 women with adenocarcinoma and 88 women with adenosquamous carcinoma were studied for clinical outcomes. Adenosquamous histopathology was associated with a significantly decreased 5-year survival (65% vs. 83%; $p < 0.002$). In a 243-patient randomized clinical trial of radiation alone versus radiochemotherapy, histopathology lost its prognostic significance when chemotherapy was added (131). Among 182 women with adenocarcinoma or adenosquamous cancer treated by cisplatin radiochemotherapy, survival was not lower than the survival seen for 842 women with squamous cell cancer (132).

Hypoxia and Anemia Factors

Among 494 women treated on two consecutive prospective radiation therapy trials, 278 (56%) had stage II and 216 (44%) had stage III or IV disease. After adjusting patient age, race, performance status, cancer stage, tumor size, cell type, and duration of radiation, mean hemoglobin values during treatment were found to predict disease progression ($p < 0.0001$). Pretreatment values were not predictive of disease progression. When a 6-week treatment course was divided into 2-week periods (early, middle, and late), hemoglobin values during the late period were the most predictive of disease progression ($p = 0.0289$). Review of translational science confirms the same (133).

Anemia affects patterns of relapse and survival in women with uterine cervix cancer (134), and packed red blood cell infusions are recommended. Recombinant human erythropoietin has been used to stimulate red blood cell production and maintain hemoglobin levels above 12 g/dL. In a trial (135), women with stage IIB–IVA uterine cervix cancer and an initial hemoglobin less than 14 g/dL were randomly assigned to radiochemotherapy without or with recombinant human erythropoietin (40,000 units s.c. weekly). Erythropoietin was stopped if hemoglobin was greater than 14 g/dL. The study closed prematurely, with less than 25% of the planned accrual, due to thromboembolic events attributed to erythropoietin. Median follow-up was 37 months. Three-year progression-free and overall survivals were estimated at 65% and 75% after radiochemotherapy and at 58% and 61% after radiochemotherapy plus erythropoietin, respectively. Thromboembolic events occurred in 4 (8%) receiving radiochemotherapy and 11 (19%) receiving radiochemotherapy plus erythropoietin. All thromboembolic events were not treatment related. No deaths occurred from thromboembolic events. A second line of evidence deterring use of erythropoietin is from an 18-patient (1999 to 2002) surgicopathologic study. Erythropoietin receptor expression was found in 16 (89%) of 18 uterine cervix cancers (136), suggesting the possibility that erythropoietin agents might stimulate growth of uterine cervix cancer cells. As such, packed red blood cell infusions, not erythropoietin, are recommended to correct anemia in uterine cervix cancer patients.

Smoking may lead to tissue hypoxia. In a trial that randomized 328 women to cisplatin–radiation or to 5-FU–radiation, 133 (42%) were reported smokers of any kind and 111 (40%) were smokers of nicotine-based products (137). In a multivariate analysis, a significant increase in the risk of death (but not disease progression) was seen for reported smokers (hazard ratio [HR], 1.51; 95% CI, 1.01 to 2.27, $p = 0.04$) and for tobacco-derived smokers (HR, 1.57; 95% CI, 1.03 to 2.38, $p = 0.04$). The biologic mechanism of this phenomenon is still under investigation.

Uterine Cervix Cancer Biomarkers and Imaging Correlates

Uterine cervix cancer biomarkers are under investigation (**Table 20.4**), including ribonucleotide reductase subunit expression (138).

PET scans have been studied as imaging correlates in uterine cervix cancer trials. PET has 75% sensitivity and 92%

specificity (96). Posttherapy FDG-avid uptake (persistent or new) is negatively associated with metabolic treatment response, developing metastatic disease, and death from uterine cervix cancer (139–141). Consensus recommendations for use of PET as an indicator of therapeutic response have been put forward (142)—a >25% increase in FDG standard uptake value indicates progressive metabolic disease, a ≤25% increase or a <15% decrease in FDG standard uptake value indicates stable metabolic response, a >15% reduction in FDG standard uptake value indicates partial metabolic response, and complete absence of FDG standard uptake value indicates complete metabolic response (143). In the modern era of radiotherapy, FDG responses >15% are seen in nearly all cases, and thus, makes use of FDG PET imaging to assess uterine cervix cancer response after radiotherapy challenging (99). A 51-patient radiochemotherapy study evaluated more rigorously a "true" metabolic response if a patient's posttherapy: pretherapy uptake ratio was ≤0.33 and found that this cutoff was more meaningful in assessing treatment response (99). A prospective phase II radiochemotherapy trial found that a posttherapy: pretherapy uptake ratio of ≤0.33 occurred in 96% (23 of 24 [95% CI, 80% to 90%]) of treated radiochemotherapy patients (101) and none has had local relapse.

Dynamic contrast-enhanced MRI (DCE-MRI), diffusion-weighted MRI (DWI-MRI), or MRI may be a useful biomarker for response to therapy, recurrence, and overall survival. Serial MRI scans before, during, and after radiation therapy were obtained in 115 women (144). Residual MRI volumes of 20% or more detected at 4,000 to 5,000 cGy were independently associated with inferior 5-year local control (53% vs. 97%, $p < 0.001$) and disease-specific survival rates (50% vs. 72%, $p = 0.009$). After all radiation delivery, patients having residual MRI volumes of 10% or more had no local control and a 17% disease-specific survival, compared with 91% local control and 72% disease-specific survival when less than 10% of tumor volume remained ($p < 0.001$).

GENERAL MANAGEMENT AND RESULTS OF TREATMENT

Severe Dysplasia and Carcinoma In Situ

Women with CIN 2 or 3 or carcinoma *in situ* have no risk of lymph node metastases, and thus, are often treated by conization, loop diathermy, cryotherapy, simple hysterectomy, or rarely intracavitary brachytherapy. These techniques have similar efficacy.

In a 1,121-patient case series of carcinoma *in situ* (1951 to 1975), therapeutic conization was completed in 795 women, with only 19 (2%) recurrent carcinoma *in situ* cases and only 7 (1%) invasive cancer cases observed in follow-up (145). In this same study, therapeutic hysterectomy was performed in 238 women with only 3 (1%) recurrent carcinoma *in situ* and only 5 (2%) invasive cancers observed during follow-up. Therapeutic outpatient fine loop diathermy under local anesthesia (1988 to 1989) was done in 557 women, with 506 (91%) having normal cytology and 19 (3%) having persistent CIN at 6 months posttherapy (87). For seven low-morbidity surgical techniques used in 23 trials, there has been no obviously superior surgical technique for treating CIN (146). Conization is preferred to ablative procedures when endocervical curettage reveals malignant-appearing cells (147), when adenocarcinoma *in situ* is present (148), or when colposcopy is unsatisfactory. Uterus-sparing low-morbidity procedures might have adverse effects such as cervical stenosis, predisposition to preterm labor in subsequent pregnancies, persistent vaginal discharge, and possible infertility.

Cryotherapy

Cryosurgery involves use of a liquid nitrogen-containing probe fitting in the endocervical canal to cool abnormal cells to below −20°C and destroy abnormal tissues by forming an "ice-ball." In a retrospective study of 37,142 women treated for CIN 1, 2, or 3 (1986 to 2004) from the British Columbia Cancer Agency cytology database (149), cryotherapy was associated with the highest rate of posttherapy persistent or recurrent disease as compared to all other low-morbidity

procedures (adjusted odds ratio for invasive cancer = 2.9, 95% CI = 2.1 to 4.6). For more conservative management of CIN, cryotherapy might be considered reserved for low medical resource practices.

Intracavitary Brachytherapy for the Poor Surgical Candidate

Women with CIN have almost no risk for metastases to pelvic lymph nodes, thus intracavitary brachytherapy is a treatment option when the patient is a poor surgical candidate. In a limited 21-patient case series (1959 to 1986), a disease control rate of 100% was reported with no significant adverse events (150). The average radiation dose to point A was 4,612 cGy and to the surface of the cervix 9,541 cGy.

Clinical Stage IA

Stage IA1 (or microinvasive) uterine cervix cancer has a 5% or lower risk of lymph node metastases or relapse and has been managed by surgical techniques ranging from cold knife conization to radical hysterectomy with a near 100% rate of disease control (109). Postsurgical confirmation of lymphovascular space invasion in a conization specimen may prompt definitive hysterectomy and lymphadenectomy (109). Technetium-99 and blue dye labeling for lymph node mapping was associated with high rates of sentinel lymph node detection, 92% sensitivity, and 98% negative predictive value for metastasis detection (151).

Stage IA2 uterine cervix cancer has a 5% to 13% chance association with pelvic lymph node metastases. Low-morbidity surgeries are not used often, deferring to modified radical hysterectomy and selective pelvic lymphadenectomy as standard. Sentinel node dissection is under investigation (151). Parametrial invasion remains a surgical planning concern in stage IA2 patients (152), as even limited parametrial invasion confers a high 43% risk for nodal metastases (48). Radical vaginal trachelectomy and extrafascial hysterectomy are being explored in those desiring fertility preservation.

Radical Vaginal Trachelectomy

A radical vaginal trachelectomy surgically removes the cervix, the upper part of the vagina, and pelvic lymph nodes. It is a two-step surgery. A pelvic lymphadenectomy is done first to exclude nodal metastases. If no nodal metastases are found, a trachelectomy is done. After completion of the trachelectomy, the uterus and vagina are reunited and a cerclage placed. The radical vaginal trachelectomy may be an option for younger women with small (≤2 cm in size) uterine cervix cancers who want to become pregnant (153,154). In a 137-patient case series (1994 to 2007), uterine cervix cancers had a median depth of invasion of 3 mm, lymphovascular space invasion present in 68%, and most (60%) were well differentiated (grade 1). After a median follow-up of 51 months, 5 (4%) developed a relapse for a 5-year recurrence-free survival estimate of 95% (153).

Intracavitary Brachytherapy for the Stage IA Poor Surgical Candidate

Women with stage IA have a 5% or less risk for metastases to pelvic lymph nodes, and so intracavitary brachytherapy is a treatment option when the patient is a poor surgical candidate. In a limited 34-patient case series (1959 to 1986), a 97% disease control rate was reported with a 6% rate of manageable adverse events (150). The average radiation dose to point A was 5,571 cGy and to the surface of the cervix was 10,430 cGy.

Nonbulky Clinical Stage IB–IIA

Clinical stage IB describes lesions confined to the uterine cervix, and is dichotomized into nonbulky IB1 (≤4 cm) or bulky IB2 (>4 cm) cancers. Nonbulky clinical stage IB1 and IIA uterine cervix cancers can be cured by radical surgery or by radiation therapy with similar effectiveness. Radical surgery offers an opportunity to study histopathologic factors for optimal risk group assignment. The 5-year survivals after surgery range from 83% to 92% (50,155). Radiation therapy is reasonable and effective in nearly all clinical stage IB to IIA patients, as 5-year survival after radiation therapy ranges from 83% to 91% (50,155). Patient health, tumor features, and clinical patterns of care influence treatment of choice.

Radical hysterectomy has been performed by abdominal, vaginal, laparoscopy and robot-assisted approaches. Since salpingo-oophorectomy is not part of a routine radical hysterectomy, surgical removal of the ovaries is based on a woman's age and other clinical factors such as menopausal status and medical illness—the rate of ovarian metastasis from uterine cervix cancer is less than 0.5% (156). A radical trachelectomy may be an option for young women with ≤2 cm uterine cervix cancers who desire future pregnancy (154).

Both radiation therapy and surgery are active against nonbulky uterine cervix cancer, and have been compared in a randomized trial among women with clinical stages IB to IIA cancer (50). In that study (1986 to 1991), radiation therapy involved two-field or more external pelvic radiation to deliver a median total dose of 4,700 cGy (range 4,000 to 5,300 cGy). After 2 weeks, one ^{137}cesium low dose rate (LDR) insertion was done to raise the point A dose to a median 7,600 cGy (range 7,000 to 9,000 cGy). Positive lymph node metastases had boosts of 500 to 1,000 cGy. In the same study, radical surgery involved a class III radical abdominal hysterectomy and lymphadenectomy. Adjuvant radiation therapy was given to surgical patients who had at least one risk factor—that is, surgical stage > pT2a, <3 mm of uninvolved cervical stroma, cut-through positive surgical margins, and presence of lymph node metastases. Adjuvant radiation involved the same multiportal field design and a total dose of 5,040 cGy to the pelvic-only fields. Extended-field paraaortic fields received 4,500 cGy when lymph node metastases were detected at surgery. Sixty-four percent (108 of 169) of the randomized radical hysterectomy group underwent adjuvant radiation; 5-year estimates for overall and disease-free survival were 83% and 74%, respectively, and did not differ significantly between the radiation therapy and radical hysterectomy groups (50). For patients whose tumors were ≤4 cm, the 5-year disease-free survival rate was 82% after radiation and 80% after surgery. For patients whose tumors were >4 cm, the 5-year disease-free survival rate was 57% after radiation and 63% after surgery. Between-group differences by tumor size were not significant. Among all patients, 86 (26%) patients developed relapse: 42 (25%) after surgery and 44 (26%) after radiation. Of the 86 patients with relapse, 50 (58%) patients had local or pelvic relapse—22 (52%) after surgery and 28 (64%) after radiation therapy (p = 0.42). Severe grade 2 or 3 morbidity was significantly higher in the surgery group (28%) as compared to the radiation therapy group (12%, p = 0.0004). The investigators concluded that there was no superior treatment of choice for nonbulky uterine cervix cancer (50).

Postoperative Node-Negative Patients with Intermediate-Risk Factors for Relapse

Postoperative pelvic radiation has been assessed in a randomized trial (1988 to 1995) of 277 women with clinical stage IB uterine cervix cancer with negative lymph nodes but also must have had two or more features including more than one third stromal invasion, lymphovascular space invasion, and tumor diameter ≥4 cm (**Table 20.5**) (157). Radical hysterectomy was required in all patients. For those randomized to radiation, a pelvis-only four-field box delivered 4,600 cGy to 5,040 cGy. No brachytherapy was done. Local and distant relapse rates were 21% and 9% after surgery and 14% and 3% after adjuvant radiation, respectively. A significant 46% reduction in the hazard for relapse (0.54, 95% CI, 0.35 to 0.81, p = 0.007) and 42% reduction in the hazard for progression-free survival (0.58, 95% CI, 0.40 to 0.85, p = 0.009) were observed; 3-year progression-free and overall survival estimates were 85% and 88% after radiation and 70% and 82% after observation, respectively. A 7% rate of grade 3 or above gastrointestinal complications was reported. The

investigators concluded that radiation therapy is an option for women with node-negative stage IB uterine cervix cancer with two or more pathologic risk factors. There is currently an open randomized phase III trial by the Gynecologic Oncology Group trial (GOG 0263) evaluating the role of chemoradiation versus radiation alone in intermediate-risk, stage I/IIA cervical carcinoma with high-risk features as above.

TABLE 20.5 Gynecologic Oncology Group Protocol 092 Eligibility Criteria

Lymphovascular Space Involvement	Cervix Stromal Invasion	Tumor Size
Positive	Deep 1/3	Any
Positive	Middle 1/3	⩾2 cm
Positive	Superficial 1/3	⩾5 cm
Negative	Deep or middle 1/3	⩾4 cm

Postoperative Patients with High-Risk Factors for Relapse

Indications for adding chemotherapy to adjuvant radiation include positive lymph nodes, parametrial invasion, or positive surgical margins (158). In a 243-patient trial (1991 to 1996), women who had IA2, IB, or IIA uterine cervix cancer initially treated with radical hysterectomy and lymphadenectomy and had positive pelvic lymph nodes or positive margins or parametrial invasion randomized to adjuvant radiation or adjuvant radiation plus chemotherapy. Radiation involved a pelvis-only four-field box delivered 4,930 cGy in 29 daily fractions; brachytherapy was not permitted. A paraaortic extended field was allowed for 4,500 cGy if high common iliac nodes were positive for metastases. Four cycles of chemotherapy were given, starting on day 1 of radiation therapy. One cycle included cisplatin (70 mg m^{-2}) by 2-hour infusion on day 1 and 5-fluorouracil (5-FU) (1,000 mg m^{-2}) as a 96-hour infusion over days 1 to 4. The third and fourth cycles began after radiation therapy, on days 43 and 64. Local and distant relapse rates were 9% and 10% after radiochemotherapy versus 22% and 16% after radiation alone, respectively ($p = 0.20$). A significant reduction in the hazard for progression or death (0.50) was observed, favoring radiochemotherapy ($p = 0.003$). A 16% rate of grade 3 or above gastrointestinal complications was reported. It was concluded that radiochemotherapy improved survival among women with early-stage uterine cervix cancer and postsurgical findings of positive pelvic lymph nodes, positive margins, or parametrial invasion. Later analyses suggested that clinical benefit arose most from adding chemotherapy among women with tumors >2 cm in diameter (+19%) or when two or more lymph nodes harbored metastases (+20%) (131).

Bulky Clinical Stage IB

Barrel-shaped bulky uterine cervix cancers were considered best addressed by hysterectomy rather than by intracavitary radiation because of awkward anatomic geometry and inhomogeneous tumor hypoxia from expanded cell bulk (159,160). The increased central pelvis relapse rate in women with bulky tumors was reportedly greatly lowered by hysterectomy, but data for improved survival was lacking. A 256-patient clinical trial (1984 to 1991) in women with bulky, >4 cm, stage IB uterine cervix cancers underwent pelvis-only radiation and were randomized to a radiation-only arm or to a radiation–surgery involving extrafascial hysterectomy (161). Two- or four-field external beam radiation therapy delivered 4,000 cGy in the radiation-only arm and 4,500 cGy in the radiation–surgery arm. Intracavitary brachytherapy prescribed to point A delivered 4,000 cGy in the radiation-only arm and 3,000 cGy in the radiation–surgery arm. Two to six weeks after radiation, extrafascial hysterectomy with removal of the fallopian tubes and ovaries and not contiguous parametrial tissue was done. Local and distant relapse rates were 35% and 15% in the radiation-only arm as compared to 17% and 19% in

the radiation–surgery arm. No survival benefit was observed. Grade 3 or above gastrointestinal adverse events occurred in 6% of radiation-only patients and in 7% of radiation–surgery patients. The investigators concluded that extrafascial hysterectomy was of limited clinical benefit to women with bulky, >4 cm, stage IB uterine cervix cancers.

A second trial (1992 to 1997) studied 369 women with bulky ≥4 cm stage IB uterine cervix cancers randomly partitioned into radiochemotherapy plus hysterectomy versus radiation-only plus hysterectomy treatment arms (162). All patients underwent extrafascial hysterectomy 3 to 6 weeks after completion of radiation. A pelvis-only four-field box delivered 4,500 cGy; LDR brachytherapy delivered 3,000 cGy to point A. Cisplatin was infused once weekly at a 40 mg m^{-2} dose, for a maximum of six doses. Grade 3 or 4 gastrointestinal adverse events were 5% in the radiation–surgery arm and were 14% in the radiochemotherapy–surgery arm (162). Local and distant relapse proportions were 24% and 18% in the radiation–surgery arm and were 11% and 13% in the radiochemotherapy–surgery arm (163). At surgery, there were more radiochemotherapy patients (52%) with no microscopic residual cancer than radiation-only patients (42%). This finding likely confounded the observation of improved 5-year progression-free (76% vs. 60%) and overall (80% vs. 66%) survival estimates favoring radiochemotherapy. There was no significant difference in survival (HR, 0.89). Hysterectomy substituting for additional brachytherapy seemed to obscure results and the investigators suggested that a clinical benefit of adjuvant hysterectomy was doubtful (162,163).

A 288-patient trial randomly allocated women with bulky, ≥4 cm, stage IB uterine cervix cancers to neoadjuvant cisplatin–vincristine chemotherapy followed by radical hysterectomy or to radical hysterectomy alone (164). About half of all patients received postoperative radiation therapy for adverse risk factors persistent at the time of surgery. From this study, there was no evidence that this form of neoadjuvant chemotherapy provided clinical benefit in the bulky, ≥4 cm, stage IB uterine cervix cancer population.

Clinical Stages IIB, IIIB, and IVA

Radiochemotherapy is standard for women who have clinical stage IIB, IIIB, and IVA disease (**Table 20.6**). This is in due part to the observation that radiation therapy alone provides 5-year survival rates of 60%, 45%, and 30% for clinical stage IIB, IIIB, and IVA disease, respectively (165). The role of chemotherapy in the treatment of advanced-stage disease has been established in landmark clinical trials, with clear gains in survival benefit (up to +15% or more) seen over the past 25 years (166 to 176). Regardless of biologic mechanism, radiochemotherapy has been under intense clinical study. Cisplatin protracts repair of radiation-induced DNA damage (177), enhancing radiation-induced cell kill (32). Hydroxyurea, 5-FU, and gemcitabine interfere with DNA precursor supply by ribonucleotide reductase (178), and these drugs successfully have added to cisplatin–radiation effects (168,170,171,175). Tirapazamine undergoes one-electron reduction in hypoxic cells and elicits single-strand and double-strand DNA breaks (179), but was not found to be clinically useful (176).

TABLE 20.6 Randomized Radiochemotherapy Trials for Advanced-Stage Uterine Cervix Cancer

Coadministration of weekly cisplatin during radiation therapy lowers the relative risk of relapse and death from disease by nearly 40% in women with advanced-stage uterine cervix cancer, compared with radiation therapy alone. Most disease progression and cancer-related death events are observed within the first 2 years after therapy, and the hazard falls to near zero after that interval making 3-year endpoints most relevant. Durable evidence from four randomized clinical trials confirms an advantage of cisplatin-based radiochemotherapy (131,163,169,170). All of the trials listed in **Table 20.6** share problems in logistics and in cross comparison. When taken in sum, trials indicate weekly cisplatin is standard for women with uterine cervix cancer who require radiation therapy.

One of two molecular changes relating to ribonucleotide reductase are found in uterine cervix cancers—cells have become addicted to HPV-related dNDP overproduction or mutated *p53* allows workarounds to cell cycle restriction checkpoints (43). All four trials showing reduction in relapse and death are rooted in mitigating ribonucleotide reductase DNA precursor payout (178). Building on this notion, a promising series of triapine radiochemotherapy trials has been reported (100–102). Triapine blocks the M2/M2b subunit of ribonucleotide reductase, protracts cisplatin–radiation DNA damage, and increases uterine cervix cancer cell kill (31,32). For 24 women with clinical stage II or III or with node-positive stage IB2 uterine cervix cancer (2006 to 2009), three times weekly triapine (25 mg m^{-2}) added to once weekly cisplatin (40 mg m^{-2}) and standard daily radiation resulted in a 3-year 96% pelvic disease control rate and 82% overall survival (102). Two (8%) cancer-related deaths occurred among these 24 women. No serious adverse events were encountered. A randomized phase II trial of triapine radiochemotherapy has begun (NCT01835171).

An alternative antiangiogenesis strategy has been studied to improve survival (180). Three-cycle bevacizumab (10 mg kg^{-1}) was added to once weekly cisplatin (25 mg m^{-2}) and standard daily radiation for treatment of 49 women with bulky stage IB or stage II–IIIB uterine cervix cancer. This phase II clinical trial (2006 to 2009) reported no serious adverse events. Three-year overall and disease-free survival estimates were 81% (95% CI, 67%–90%) and 69% (95% CI, 54%–80%), respectively. A 23% local relapse rate was noted, with six patients noted to have persistent disease at 12 months posttherapy. Bevacizumab radiochemotherapy warrants further primary therapy investigation.

Clinical Stage IIIA

Cervical carcinomas extending to the lower third of the vagina without pelvic sidewall extension or hydronephrosis are uncommon, representing only 3% of patients with uterine cervix cancer (181). A 5-year local control rate of 72% but survival rate of 37% was noted (181). Cisplatin-based radiochemotherapy is standard. Inguinal lymph nodes might harbor metastases, and should be irradiated prophylactically (4,500 to 5,040 cGy). Radiation dose can be escalated (>6,500 cGy) if inguinal lymph nodes are confirmed positive. Custom-designed radiation portals and intracavitary or interstitial brachytherapy are common (**Fig. 20.11**).

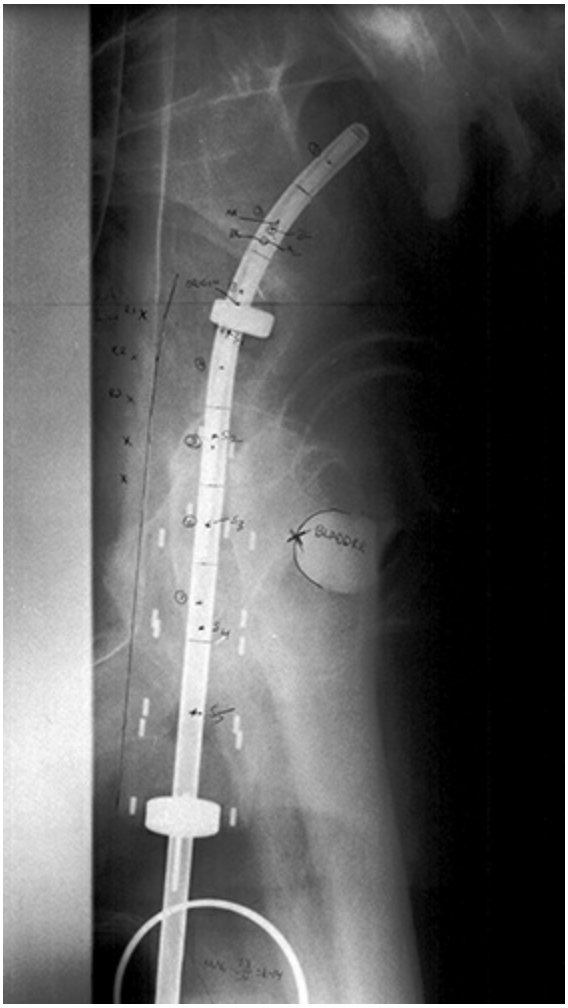

Figure 20.11 Lateral view of an intracavitary implant for a stage IIIA cervical carcinoma with extension to the lower third of the vagina. The tandem extends from the uterine fundus through the vagina. Delclos rings are placed over the tandem throughout its course in the vagina. This controls the distance from the radioactive sources (^{137}cesium in this case) and allows the vaginal radiation doses to be measured and controlled.

Clinical Stage IVB

Women with metastatic clinical stage IVB uterine cervix cancer, or even persistent or recurrent disease, have unmet therapeutic needs and quality of life assessments during chemotherapy. In a 284-patient randomized clinical trial with built-in quality of life study (182), 56% of enrollees died before or during the 9-month observation period. Cisplatin 50 mg m^{-2} is considered the most active drug with an up to 50% response rate (183). Bevacizumab 15 mg kg^{-1} has improved survival (184).

Cisplatin (cis-diamminedichloroplatinum II) as a single agent was evaluated in a 22-patient phase II clinical trial among women with advanced-stage or recurrent uterine cervix cancer (183). Cisplatin was administered as 50 mg m^{-2} over a 1 mg min^{-1} infusion every 3 weeks until adverse events precluded further treatment or disease progressed. Eleven (50%) of 22 women with no prior chemotherapy exposure had an objective response. Two (17%) of 12 women with prior chemotherapy treatment had an objective response. Median duration of response was 6 months. Adverse events included clinically significant leukopenia (3%), thrombocytopenia (3%), nausea or emesis (18%), and nephrotoxicity (10%). Three cisplatin dose schedules were tested in a 497-patient randomized trial (1978 to 1982): regimen 1 gave cisplatin 50 mg m^{-2} every 21 days, regimen 2 gave 100 mg m^{-2} every 21 days, and regimen 3 gave cisplatin 20 mg m^{-2} for five consecutive

days repeated every 21 days (185). The regimens were tolerated, but with regimen 2 especially a 44% leukopenia rate and 14% nephrotoxicity rate was noted. Response rates were 21%, 31%, and 25% for regimens 1, 2, and 3 respectively; the response rate for regimen 2 versus regimen 1 was statistically significant ($p = 0.015$) but less than the magnitude initially considered clinically significant. The median duration of response was 5, 4, and 5 months for regimens 1, 2, and 3, respectively.

A cisplatin-paclitaxel combination has been evaluated in a 264-patient randomized clinical trial (1997 to 1999) of women with clinical stage IVB or persistent or recurrent uterine cervix cancer (186). Cisplatin (50 mg m^{-2}) was given as a 1 mg min^{-1} infusion every 21 days. Paclitaxel (135 mg m^{-2}) as a 24-hour infusion preceded cisplatin (50 mg m^{-2}) on day 1 of an every 21-day cycle. This was done to take advantage of possible G_1/S (cisplatin) and M-phase (paclitaxel) cell cycle–disrupting synergy among the agents. The 19% rate of response in the cisplatin-alone group was similar to the rate described in previous studies of cisplatin for metastatic uterine cervix cancer (range, 17%–31%). The addition of paclitaxel significantly increased the rate of response to 36% ($p = 0.002$), suggesting that paclitaxel introduces additional cytotoxicity in uterine cervix cancer. Grade 3 or 4 anemia (28% vs. 13%), thrombocytopenia (4% vs. 2%), and leukopenia (55% vs. 3%) were more common in the cisplatin–paclitaxel arm. The observation that nearly all patients eventually had disease progression and died within 2 years of treatment suggests an acquired resistance to a cisplatin-paclitaxel combination.

A cisplatin-topotecan combination has been tested in a 293-patient randomized clinical trial (1999 to 2002) of women with clinical stage IVB or persistent or recurrent uterine cervix cancer (187). Cisplatin (50 mg m^{-2}) was given as a 1 mg min^{-1} infusion every 21 days. Topotecan (0.75 mg m^{-2}) was given as a 30-minute infusion on days 1, 2, and 3 followed by cisplatin (50 mg m^{-2}) on day 1, repeated every 21 days. It was hypothesized that disruption of DNA replication forks by topotecan would slow DNA adduct repair and exacerbate cytotoxicity. The 13% response rate in the cisplatin-alone arm was lower than expected. Adding topotecan elevated the response rate significantly to 27% ($p = 0.004$), indicating synergy. Grade 3 or 4 thrombocytopenia (31% vs. 3%) and leukopenia (63% vs. 0.5%) were more common in the cisplatin-topotecan arm. Grade 3 or 4 anemia was similar (31% vs. 38%). All patients had disease progression and died within 3 years of study entry.

A trial of four cisplatin-containing doublets (2003 to 2007) randomized 513 women with clinical stage IVB or persistent or recurrent uterine cervix cancer to cisplatin-paclitaxel, cisplatin-vinorelbine, cisplatin-gemcitabine, or cisplatin-topotecan (188). Paclitaxel (135 mg m^{-2}) over 24 hours on day 1 preceded cisplatin (50 mg m^{-2}) on day 2 of an every 21-day cycle. Vinorelbine (30 mg m^{-2}) was given on days 1 and 8 plus cisplatin (50 mg m^{-2}) on day 1 every 3 weeks. Gemcitabine (1,000 mg m^{-2}) was infused on days 1 and 8 plus cisplatin (50 mg m^{-2}) on day 1 every 3 weeks. Topotecan (0.75 mg m^{-2}) was administered on days 1, 2, and 3 plus cisplatin (50 mg m^{-2}) on day 1 every 3 weeks. The rates of response were 29% for cisplatin-paclitaxel, 26% for cisplatin-vinorelbine, 22% for cisplatin-gemcitabine, and 23% for cisplatin-topotecan. Grade 3 or 4 leukopenia was 63%, 68%, 43%, and 71% and grade 3 or 4 thrombocytopenia was 7%, 8%, 28%, and 35% for the cisplatin-paclitaxel, cisplatin-vinorelbine, cisplatin-gemcitabine, or cisplatin-topotecan regimens, respectively. None of the regimens was superior to cisplatin-paclitaxel, and trends for response, progression-free survival, and overall survival favored cisplatin-paclitaxel (188).

A two-by-two factorial design randomized clinical trial (2009 to 2012) of bevacizumab 15 mg kg^{-1} added to chemotherapy was completed in a 452-patient study (184). Chemotherapy consisted of cisplatin (50 mg m^{-2}) plus paclitaxel (135 mg m^{-2}), or cisplatin (50 mg m^{-2}) plus paclitaxel (135 mg m^{-2}) plus topotecan (0.75 mg m^{-2}). The rate of response was significantly higher for women who received bevacizumab (48%) than among those who did not receive bevacizumab (36%, $p = 0.008$). An added median survival of 3.7 months was observed (17.0 vs. 13.3 months, hazard ratio for death 0.71, 98% CI, 0.54 to 0.95). Gastrointestinal events (52% vs. 44%), fistula (6% vs. <1%), and neutropenia (35% vs. 26%) were observed. The observation that a cytostatic vascular endothelial growth factor-neutralizing antibody had an impact on overall survival in women with metastatic, persistent, or recurrent uterine cervix cancer was the most remarkable finding for this clinical trial.

Persistent or Recurrent Uterine Cervix Cancer

General Considerations

Uterine cervix cancer-related death occurs most often because of uncontrolled disease in the pelvis. Persistent disease after primary treatment or short-interval relapse of disease in the pelvis is often amenable to salvage surgery or radiation therapy; however, patient desire for treatment and selection of therapeutic intervention are often predicated on disease extent, disease-free interval, impact of prior therapy on pelvic anatomy, patient performance status, and patient comorbidities.

If curative salvage treatment is intended, a biopsy of the relapse and restaging radiographic imaging should be acquired. Sciatic pain, leg edema, and hydronephrosis are pathognomonic for pelvic sidewall involvement. PET may be the most accurate restaging test (189).

Radical Surgery for Pelvic Disease after Prior Radiation Therapy

Radical hysterectomy, not planned as part of initial care, has been used as a means of surgical salvage for small (<2 cm) persistent or recurrent uterine cervix cancers (190). But most often total pelvic exenteration has been performed for central pelvic relapses without evidence of extrapelvic disease, with up to one third of the procedures aborted at some point during the procedure. Exenteration operative time ranges up to 8 hours, average blood loss is 3L, and postprocedure hospital stay can be up to 23 days (191). Perioperative mortality rates are as high as 14% (192). Complications arise in up to 45% of patients (193), with bowel obstruction (22%), intestinal fistula (15%), and urogenital fistula (8%) as significant adverse events (191). In a 55-patient retrospective study (1998 to 2004), tumor-free exenteration surgical margin is associated with a 55% survival estimate, as compared to a 10% survival estimate when margins are positive for tumor (194). Overweight and obese women with recurrent disease undergoing exenteration experience longer operative times and higher wound separation rates than otherwise, but overall postsurgical survival appears equal to normal-weight women (195).

Pelvic anatomy reconstruction typically involves urostomy, colostomy, and muscle-flap neovagina. Diversion of urine flow by implanting the ureters into an isolated piece of ileum for a separate urostomy with bag reservoir is preferred over a wet colostomy involving implantation of the ureters into a colostomy diverting fecal flow (196). An ileal urostomy is incontinent. Continent internal reservoirs using bowel wall allow for self-catheterization, but are associated with a 50% to 65% rate of complication from pyelonephritis, ureteral stricture, leak or fistula, renal stone formation, and even rarely, renal failure (197–199). Muscle-flap reconstructions of a neovagina for sexual activity, pelvic tissue fill, and prevention of fistulas have been described (200–203).

Radical Radiation or Radiochemotherapy for Pelvic Disease after Prior Surgery

Small (<2 cm) persistent or recurrent disease, or vagina-only relapses are amenable to radiation therapy, with durable control exceeding 70% (204–206); 10-year survival estimates in radiotherapy-naive patients are as high as 35% (206). Interstitial brachytherapy (3,000 to 5,500 cGy) (207,208) and stereotactic body radiation therapy (2,400 cGy) (209) have been described for disease involving deep pelvic tissues. Use of carboplatin-gemcitabine chemotherapy and stereotactic body radiation therapy has been explored in a phase I trial (210).

For pelvic or paraaortic lymph node relapses after first-line surgery or radiochemotherapy, conventional radiochemotherapy (>4,500 cGy) (211) or stereotactic body radiation therapy (800 cGy × 3 doses) (209) have been used. Low toxicity and durable disease control rates exceeding 95% have been documented with either of these two techniques.

Intraoperative electron radiation therapy has been used during radical salvage surgery for persistent or recurrent uterine

cervix cancer. The technique is attractive due to its direct exposure of at-risk tumor-harboring tissue to limited penetration electrons and because of its low radiation dose scatter to normal tissues retracted away or shielded during dose delivery. A single fraction of 1,500 cGy (range 625 to 2,500 cGy) was used most often in a case series of 86 patients (1983 to 2010) (212). Adverse events include peripheral neuropathy (19%), ureteral stenosis (5%), and bowel fistula or perforation (5%). Eleven (69%) of 16 women experiencing neuropathy after intraoperative radiation required long-term pain medication.

Chemotherapy and Biologic Targeted Agents for Persistent or Recurrent Uterine Cervix Cancer

Currently, chemotherapy and biologic targeted agents for persistent or recurrent uterine cervix cancer falls into a palliative role. These therapies may prolong 6-month progression-free survival in up to 24% of patients (213). However, there are no randomized trials that compare best supportive care against chemotherapy or biologic targeted agents to show that these therapies improve overall survival. Women with relatively good performance status are often presented with chemotherapy or biologic targeted agent treatments. Regimens used are discussed in the chemotherapy section of this chapter.

CHAPTER 21 Corpus: Epithelial Tumors

Susana M. Campos, Larissa J. Lee, Marcela G. Del Carmen and D. Scott Mcmeekin

Endometrial cancer accounts for nearly 50% of all new gynecologic cancers diagnosed in the United States. It is the fourth most common malignancy in women, and the eighth most common cause of cancer death. The American Cancer Society (ACS) estimated that there were 60,050 new cases of endometrial carcinoma and 10,470 deaths from advanced or recurrent disease in 2015 (including both endometrial cancers [EC] and uterine sarcomas) (1). Worldwide, EC is only second to cervical cancer in frequency. The ACS reported that the incidence of EC rose 13% from 1987 to 2012; however, the numbers of deaths rose ~250% in the same time period. Endometrial carcinoma occurs most often in the sixth and seventh decades of life, with an average age at onset of 60 years. It is estimated that 75% to 85% of the cases occur in women aged 50 years and older, and 95% occur in patients over 40 years of age (2,3). The disease, although reported in patients as young as age 16 years, is rare in women younger than 30 years of age.

Endometrial cancer is commonly confined to the uterus at diagnosis. Data from the National Cancer Institute's Surveillance, Epidemiology, and End Results (SEER) program demonstrated that stage I disease was found in 73% of patients, and 10% had stage II disease (4). The 26th Annual Report of the International Federation of Gynecology and Obstetrics (FIGO) on 9,386 EC patients demonstrated that 83% of patients were stage I–II (5). With the favorable disease distribution at presentation, it is not surprising that most patients have a favorable prognosis. Results from FIGO show that 85% to 91% of stage I patients are alive at 5 years, and patients in the SEER database with localized disease have 96% 5-year survival (4,5). As a result, EC has been considered a "good cancer"; that is, most patients present with early-stage, highly curable disease. Despite the favorable characteristics for most patients, those with high-risk factors, including increased age, higher tumor grade, aggressive histology, and advanced-stage face real challenges.

The management of EC continues to evolve. In the past, most patients received some form of pre- or postoperative radiation in combination with a simple hysterectomy. With a better understanding of the relationship between uterine factor and risk of nodal disease and recurrence, selective use of surgical staging was integrated. This was followed by an era during which, increasingly, surgical therapy expanded to include routine use of pelvic and para-aortic lymphadenectomy. Minimally invasive techniques were studied, and have been routinely adopted into the surgical management of women with EC. Today, greater emphasis is being placed on the selection of particular patients for whom lymphadenectomy may offer better outcomes, and whose avoidance may result in less morbidity. Understanding tumor biology as it relates to predicting recurrence and survival, and how genetic changes can be exploited to direct postoperative therapies, represent our current challenges. Over 10 years ago, the National Cancer Institute convened an expert panel to develop a national 5-year plan for research priorities in gynecologic cancers. The resulting report, Priorities of the Gynecologic Cancer Progress Review Group (PRG), specified that an understanding of tumor biology was the central key in controlling gynecologic cancers. For EC, one of the top research priorities defined by the PRG was to identify prognostic and predictive markers for treatment efficacy and toxicity. In a 2006 State of the Science Meeting in Manchester, UK, a series of research questions on prevention, adjuvant treatment, and treatment of advanced or recurrent disease were proposed for setting the stage for a clinical trials agenda over the next 5 years (6). In 2011,the Society of Gynecologic Oncologists convened a panel of experts that produced a report, "Pathway to Progress in Women's Cancers." That report detailed areas of research, by disease site, on which the women's cancer community should focus for the next decade. For EC, the recommended road

map for the future would include research related to obesity, predicting risk of metastatic disease, targeting therapy based on risk factors and molecular characteristics of disease, and cost-effective care (7).

Current clinical controversies center on identifying which patient populations might benefit most from lymphadenectomy, developing alternatives to performing lymphadenectomy, and creating risk models to assist in selection of patients who may benefit most from adjuvant therapies. While we suspect that an increased use of surgical staging has translated to a better understanding of risk, data also suggest that despite negative nodes, uterine factors play a significant role in risk of recurrence. Current trends also suggest a less frequent use of pelvic radiation therapy (RT) or no use of any radiation (8). There have been important developments in chemotherapy (CT) for EC. Combination CT is increasingly used in the primary management of advanced and recurrent disease, and may hold promise in an adjuvant setting. How to best integrate RT, and which specific techniques to consider, are being studied in ongoing clinical trials. Hormonal therapy remains an important option, and our understanding of steroid receptors at a molecular level may help to determine which patients may benefit most (9). Enhanced understanding of biologically relevant targets has fostered the development of new classes of agents that target susceptible pathways in tumor cells, and targeted agents are being integrated into large clinical trials (10,11).

ANATOMY

The uterus is a fibromuscular pelvic organ situated between the bladder and the rectum and enveloped by peritoneal reflections. It is divided into the fundus, isthmus, and cervix. The uterine wall is composed of the outer smooth muscle myometrium and inner cavity lined by glandular endometrial epithelium with supporting stroma (endometrium). Five paired ligaments cover or support the uterus: broad, round, uterosacral, cardinal, and vesicouterine. The uterosacral and cardinal ligaments provide the greatest support within the pelvis and, contrary to cervical cancer, are infrequently involved with tumor spread. Blood is supplied to the uterus by the uterine artery, a branch of the hypogastric artery, which enters the wall of the uterus at the isthmus after it crosses over the ureter. It anastomoses with the ovarian artery in the ovarian ligament.

Malignant transformation of the endometrium is manifest in many fashions, based on the anatomic relationships. Tumor growth may be confined to the endometrium, invade the underlying myometrium, penetrate to the uterine serosal surface or adjacent bladder or rectum, or extend into the cervical canal and invade cervical glands or stroma. Peritoneal disease spread may occur via transmigration from the fallopian tubes or through serosal penetration. Hematogenous spread is not uncommon in EC.

The lymphatics of the myometrium drain into the subserosal network of lymphatics, which coalesce into larger channels before leaving the uterus. Lymph flows from the fundus toward the adnexa and infundibulopelvic ligaments. The lymph flow from the lower and middle thirds of the uterus tends to spread in the base of the broad ligaments toward the lateral pelvic sidewall (12). There are four drainage channels from the uterus: from the fundus, in the folds of the broad ligament, along the mesosalpinx and fallopian tubes, and along the round ligaments. The drainage sites are principally reflected in metastatic potential to pelvic and para-aortic lymph nodes (LN), and occasionally involve inguinal nodes.

EPIDEMIOLOGY AND RISK FACTORS

The most important risk factor for the development of EC is age. Endometrial cancer is primarily a disease of postmenopausal woman, with median age at cancer diagnosis of 60 years (5). Approximately 85% of cases occur after the age of 50; the peak age-specific incidence is from 75 to 79 years (109 per 100,000), and only 5% of cases are reported in women younger than 40 years of age (2,3,13). The ACS has reported that the probability of developing a uterine cancer to

be 1 in 142 from age 40 to 59, 1 in 124 from age 60 to 69, and 1 in 78 from age 70 and older (1). Not unexpectedly, with an aging U.S. population, the total number of cases of EC has increased yearly, whereas the annual age-adjusted incidence rate peaked in the mid-1970s (33.8 per 100,000) and has remained stable at 23 to 25 cases per 100,000 women over the last 10 years (1).

Race also appears to play a role in the development of EC. The rates of EC are highest in North America and northern Europe, lower in Eastern Europe and Latin America, and lowest in Asia and Africa (14). Factors accounting for these findings include differences in rates of obesity, use of hormone replacement therapy (HRT), and reproductive factors. In the U.S., non-Hispanic White women have the highest age-adjusted incidence of EC at 25.4 (per 100,000 women), compared to women of African American (19.5), Asian (15.8), or Hispanic (17) heritage (15). African American women, however, have a much higher mortality rate (7.1 vs. 3.9 per 100,000) and lower 5-year survival (61% vs. 84%) compared to non-Hispanic White women. Relative survival in White women exceeds that for African Americans by at least 7% at every stage of diagnosis (1). In the 2012 ACS report, incidence rates of uterine cancers in White women were noted to have stabilized; however, since 2004, incidence rates have increased by nearly 2% per year for African American women (1). Multiple explanations have been suggested to explain the differences in outcomes between racial groups, including differences in frequency of high-risk tumor types, differences in access to care (reduced use of surgery and radiation), and differences in medical comorbidities among races. Data from SEER demonstrated that African American women were more frequently diagnosed with higher stage, grade, and high-risk histologies than non-Hispanic White women, but there was no difference in the frequency of recommended therapy between races (4). In two analyses of nearly 1,200 patients with advanced or recurrent EC who participated in phase 3 chemotherapy trials conducted by the Gynecologic Oncology Group (GOG), African American race was independently associated with a lower likelihood of response to CT (relative odds of response 0.62) and decreased overall survival (OS; hazard ratio [HR], 1.26) compared to White women (16,17). These results suggest that racial disparity in outcomes exist even though patients were treated in similar fashion. Interestingly, one small study comparing microarray-based expression profiling between stage-, grade-, and histology-matched African American and Caucasian patients found no clear differences in global gene expression profiles, suggesting that environmental or social issues played a greater role in explaining disparity (18).

Most cases of endometrial carcinoma are thought to be sporadic; however, some cases clearly have a hereditary basis. Lynch syndrome (hereditary nonpolyposis colorectal cancer [HNPCC]) is an autosomal-dominant cancer susceptibility syndrome associated with early-onset colon, rectal, ovary, small bowel, ureter/renal pelvis cancers, and EC. Lynch syndrome–related ECs account for 2% to 5% of all ECs, and occur in nearly 10% of women diagnosed with EC at less than 50 years of age (19). The lifetime risk of EC in women with Lynch syndrome is 40% to 60%, a risk similar to that of developing colon cancer. The risk of ovarian cancer is 10% to 12%. In about 50% of cases where patients have both colonic and gynecologic cancers (endometrial or ovarian), the gynecologic cancer precedes the diagnosis of colon cancer (20). The syndrome is most commonly due to germ-line mutations of one of the DNA mismatch repair genes *MSH2*, *MLH1*, *or MSH6*. In one study, 23% of EC patients diagnosed at <50 years of age, with one relative having a Lynch-type cancer, had a mismatch repair gene mutation (21). Prophylactic hysterectomy and bilateral salpingo-oophorectomy has been shown to be an effective strategy for preventing ovarian and ECs in these high-risk patients (22).

Controversy exists regarding the relationship between *BRCA1 and BRCA2* mutations and the risk of EC. Germ-line mutations of *BRCA1 and BRCA2* account for a large proportion of hereditary breast and ovarian/primary peritoneal cancers. In 1999, Hornreich et al. (23) presented a case report of sisters with the same *BRCA1* mutation who were diagnosed with serous carcinomas of the uterus, and suggested a possible association. Several larger studies have attempted to address this hypothesis. In one study of 199 Ashkenazi Jewish patients with EC from a single institution, Levine et al. genotyped all patients for founder *BRCA1 and BRCA2* mutations that existed in that patient population. The frequency of germ-line mutations (3 per 199, 1.5%) in EC patients was comparable to the baseline rate of 2% in the Ashkenazi population, suggesting no increased risk (24). In a large prospective study by Beiner et al., (25) 857 known *BRCA1 and BRCA2* carriers aged 45 to 70 years were followed over time for the development of EC. With an average length of follow-up of 3.3 years, six women developed EC. Four of the six patients had used tamoxifen. Compared to the

expected rate of EC in a general population, *BRCA* carriers who did not receive tamoxifen did not have a significant increase in risk of developing EC, whereas those patients who had received tamoxifen had an 11.6 incidence ratio (p = 0.0004). Barak evaluated 289 Jewish women with EC (80% type I, 20% type II tumors) for predominant mutations in Jewish populations (*BRCA1*, *BRCA2*, *MSH2*, *MSH6* selected mutations). Five women were found with *BRCA1/2* mutations, reflecting a rate similar to that seen in the general Ashkenazi Jewish population, and the authors indicated that the data did not support screening based on an EC diagnosis (26).

The clinical picture in endometrial carcinoma is varied, as are the associated risk factors for its development. One of the paradigms for bridging the gaps between epidemiologic, clinical pathologic, and molecular factors seen in EC types is the relatively simple, yet attractive classification system of ECs suggested by Bokhman in 1983 (27). Endometrial cancers are thought to broadly arise from one of two different pathways: estrogen dependent or estrogen independent (Table 21.1). On the basis of the clinical and histologic features, ECs have been divided into type I and type II tumors. Type I tumors are more common (85%), tend to be found in younger women, and develop via a precursor lesion of atypical hyperplasia. These tumors are associated with a predisposing history of hyperestrogenism. They tend to be well differentiated and have minimal myometrial invasion, and as a result typically have a favorable outcome. Type II tumors account for a small percentage of ECs, occur in an older population, and frequently develop in the setting of an atrophic endometrium. About half of all relapses occur in this group. Serous, clear cell, and perhaps grade 3 tumors fit into the type II category. Despite the broad generalizations of the two categories, translational science data lends support for distinguishing these groups at a molecular level. For example, mutations of *TP53* are common in uterine papillary serous carcinoma (UPSC), and rare in type I tumors (28). In type I tumors, tumor suppressor genes encoding the phosphatase and tensin homologue (*PTEN)* mutations are common, but are rare with UPSC tumors. Global gene expression profiles have also been shown to be different between type I and II tumors (29).

TABLE 21.1 Comparison between Type I and Type II Endometrial Cancers

	Type I	Type II
Clinical features		
Risk factors	Unopposed estrogen	Age
Race	White > Black	White = Black
Differentiation	Well differentiated	Poorly differentiated
Histology	Endometrioid	Non-endometrioid
Stage	I/II	III/IV
Prognosis	Favorable	Not favorable
Molecular features		
Ploidy	Diploid	Aneuploid
K-ras overexpression	Yes	Yes
HER2/neu overexpression	No	Yes
P53 overexpression	No	Yes
PTEN mutations	Yes	No
MSI	Yes	No

MSI, microsatellite instability.

Endogenous or exogenous exposure to estrogen is believed to be an important risk factor for the development of endometrial hyperplasia and type I cancers (30). Estrogens not opposed by progestins lead to increased mitotic activity of endometrial cells, resulting in more frequent errors in DNA replication and somatic mutations (31,32). These genetic changes are manifest clinically in endometrial hyperplasia and cancer. Estrogen excess as an etiology for cancers is

supported by epidemiologic features of the disease. Patients with chronic anovulation, nulliparity, early age of menarche, and late menopause have classically been identified with EC. Occasionally, endometrial hyperplasia or cancer develops in the setting of an estrogen-producing ovarian tumor (granulosa cell tumor) (33). The use of unopposed estrogens as part of hormone replacement strategies was first defined as an important risk factor in 1975, when the age-adjusted rate for EC peaked at nearly 33.8 per 100,000 (34,35). A meta-analysis of 30 studies showed that the relative risk of ever-users of estrogen therapy was 2.3 compared to non-users, and it increased to 9.5 in users of 10 or more years (36).

Obesity is an increasingly common problem in the U.S., and is estimated to account for 17% to 46% of EC in postmenopausal women (36). Studies have shown that plasma concentrations of androstenedione and estrogens are correlated with body weight in postmenopausal women (37,38). Aromatization of androstenedione to estrone in adipose cells is believed to be the principle mechanism of excess estrogen production (39). While much of the data suggests that the relationship is strongest between estrogen exposures and type I cancers, Weiss et al. demonstrated in a case–control study that the risk of more aggressive tumors (higher grade or higher stage) was also seen with unopposed estrogen therapy, obesity, low parity, and history of diabetes. The authors suggested that the risk of EC was influenced by similar risk factors regardless of tumor aggressiveness (40). Diabetes has also been associated classically with type I ECs (41,42). Only noninsulin-dependent diabetes (type 2 diabetes mellitus [DM]), characterized by insulin resistance and elevated insulin levels, appears to be associated with EC (43). Hyperinsulinemia and higher levels of insulin-like growth factor 1 are thought to have neoplastic potential and, coupled with increased estrogen, are responsible for cancer development (44-46).

Tamoxifen and Endometrial Cancer

Tamoxifen is a selective estrogen receptor modulator (SERM) with antiestrogenic properties in the breast and estrogenic effects in tissues such as bone, the cardiovascular system, and the uterus. It has been used in prevention and treatment for all stages of breast cancer. An association with tamoxifen and EC was first reported by Killackey et al. (47) in 1985. The strongest data initially implicating tamoxifen use and the subsequent development of EC were published in 1989 by Fornander et al. (48). The investigators reviewed the frequency of new primary cancers as recorded in the Swedish Cancer Registry for a group of 1,846 postmenopausal women with early breast cancer who were included in a randomized trial of adjuvant tamoxifen. They noted a 6.4-fold increase in the relative risk of EC in 931 tamoxifen-treated patients compared to 915 patients in the control group. The dose of tamoxifen in this study was 40 mg/d, and the greatest cumulative risk of developing EC was after 5 years of tamoxifen use.

Fisher et al. (49) published data regarding the association between tamoxifen use and the development of EC when they reported the findings of the National Surgical Adjuvant Breast and Bowel Project (NSABP) B-14 trial. Data regarding the rates of endometrial and other cancers were analyzed in 2,843 patients with node-negative, estrogen receptor (ER)-positive, invasive breast cancer randomly assigned to placebo or tamoxifen (20 mg/d), and on 1,220 tamoxifen-treated patients registered in NSABP B-14, subsequent to randomization. The average annual hazard rate for EC in the placebo group was 0.2 out of 1,000 and 1.6 out of 1,000 for the randomized tamoxifen-treated group. The relative risk of an EC occurring in the randomized, tamoxifen-treated group was 7.5. Similar results were seen in the 1,220 registered patients who received tamoxifen. The mean duration of tamoxifen therapy was 35 months, with 36% of the ECs developing within 2 years of therapy and six occurring less than 9 months after treatment was initiated, suggesting that some of the cancers may have been present prior to starting tamoxifen therapy.

Any conclusions drawn regarding the risks of tamoxifen treatment in inducing EC must weigh the benefits of tamoxifen in reducing breast cancer recurrence and new contralateral breast cancers. In the B-14 trial, the cumulative rate per 1,000 women with breast cancer relapse was reduced from 227.8 in the placebo group to 123.5 in the randomized tamoxifen-treated group. In addition, the cumulative rate of contralateral breast cancer was reduced from 40.5 to 23.5, respectively, in the two groups. Taking into account the increased cumulative rate of EC, there was a 38% reduction in the 5-year cumulative hazard rate in the tamoxifen-treated group. Thus, the benefit of tamoxifen therapy for breast cancer

outweighs the potential increase in EC.

The suspected mechanism for EC development following tamoxifen exposure is thought to be related to its estrogenic effects on the endometrium. As such, type I, low-grade/early-stage cancers would be expected. A report from the Yale Tumor Registry by Magriples et al. (50) suggested that uterine cancers occurring in breast cancer patients on tamoxifen may behave more aggressively, and carry a worse prognosis. Other studies, however, have not been able to confirm these findings (Table 21.2) (49,51-53). It would appear from the available literature that there is no difference in the stage, grade, or prognosis of ECs associated with tamoxifen use.

TABLE 21.2 Clinicopathologic Data from Series Reporting on Tamoxifen-Associated Uterine Cancer

More commonly, breast cancer patients are being managed with different strategies, which may reduce the impact of tamoxifen on EC risk. Next-generation SERM agents, such as raloxifene, are effective in preventing breast cancer and reducing osteoporosis. In a large case–control study of women with (547 cases) and without (1,410 controls) EC, raloxifene users had a 50% reduction in risk of EC compared to non-users, and tamoxifen users had three times the risk of developing EC compared to those who had used raloxifene (54). Compared to SERMs, aromatase inhibitors prevent estrogen synthesis by inhibiting the conversion of androgens to estrogens. Third-generation aromatase inhibitors (anastrozole, letrozole, exemestane) are replacing tamoxifen for many breast cancer patients, with ~50% of postmenopausal ER-positive patients receiving aromatase inhibitors (53). In clinical trials, compared to tamoxifen, aromatase inhibitors are associated with lower incidences of vaginal bleeding or EC (54,55). In premenopausal patients, aromatase inhibitors have little activity, and tamoxifen will continue to play a role.

Protective Factors

Factors that reduce circulating estrogen levels (weight loss/exercise, cigarette smoking) appear to be protective against

EC. Similarly, progestins antagonize the effects of estrogen on the endometrium and prevent the development of hyperplasia and cancer, when added to estrogens (endogenous or exogenous) (56). Combined estrogen–progestin HRT has been associated with reductions in the risk of EC in most, but not all, studies. Prior use of oral contraceptives also appears to be protective against the development of EC (57,58).

NATURAL HISTORY OF DISEASE

A better understanding of the natural history of EC has developed through evaluation of the patterns of spread. In a landmark study, the GOG performed a surgical pathologic study (GOG 33) in 621 patients with clinical stage I–occult stage II EC who underwent a standardized surgical procedure including exploration of the abdomen with biopsy of suspicious findings, collection of peritoneal fluid for cytologic evaluation, abdominal hysterectomy and BSO, and pelvic and para-aortic nodal dissection (59). The results of this study demonstrated important relationships regarding uterine tumor characteristics and spread of disease, and should be ingrained into the memory of those caring for patients with ECs.

Overall, 22% of patients with seemingly uterine-confined disease were found to have extrauterine spread. Pelvic and/or para-aortic metastases were found in 11% of patients, 12% had positive peritoneal cytology, 5% had adnexal involvement, and 6% had gross intraperitoneal spread. Nodal metastases were related to tumor grade and depth of myometrial invasion, and patients with positive cytology, or adnexal or intraperitoneal spread also had increased frequency of nodal disease.

Patterns of failure in patients with recurrent EC demonstrate, alone or in combination, hematogenous, lymphatic, intraperitoneal, or local/contiguous spread. As attention has increasingly focused on therapies (surgical, radiation, CT) to reduce particular sites of recurrences, several have argued for defining relationships between initial disease spread and subsequent risk of recurrence (60). In GOG 33, treatment was not specified by protocol, but results showed that outcomes could be predicted by extent of disease found at surgery, thus demonstrating the important relationship between what is learned at surgical staging and recurrence risk (61).

DIAGNOSTIC EVALUATION

Screening

Many ECs develop by way of a precursor lesion. Estrogen-related cancers frequently develop secondary to atypical endometrial hyperplasia (AEH) or demonstrate AEH in the uterus at the time of hysterectomy. Serous tumors may also develop through a precursor lesion, endometrial intraepithelial carcinoma (EIC) (62,63). Prompt recognition of precursor lesions, with institution of proper treatment, will prevent cancers and their sequelae. The relatively low prevalence of EC in the population (5 per 1,000 women >45 years) makes standardized screening inefficient. There are a few uncontrolled studies lending some support to the efficacy of screening programs (64,65). No randomized trials have been published. No health economic data have been presented in relation to the published reports. The American College of Obstetrics and Gynecology and the Society of Gynecologic Oncology do not recommend routine screening of patients for uterine cancer (66,67). The ACS does recommend annual endometrial biopsies starting at age 35 for women known to have or to be at risk for HNPCC.

In lieu of routine screening, prompt assessment of symptomatic patients and those at high risk should be considered. Because 95% of ECs occur in women aged 40 years and older, and because endometrial hyperplasia tends to occur in premenopausal and perimenopausal women, it is appropriate to evaluate individuals past their fourth decade of life if they experience abnormal bleeding. Similarly, a higher degree of suspicion should be held for younger patients with high-risk

characteristics including significant obesity, polycystic ovarian syndrome/chronic anovulation, or tamoxifen exposure.

Prevention

Due to the increased risk of EC associated with unopposed estrogens, women with an intact uterus should rarely, if ever, be prescribed estrogen-only replacement therapy. The addition of progestins to the regimens of patients treated with exogenous estrogen may prevent endometrial hyperplasia and protect against the development of carcinoma (56,57). Continuous or sequential progestin regimens may be used, but the most important factor is administration of a progestin for at least 10 to 14 days each month. In patients with chronic endogenous estrogen exposure, such as obese women with polycystic ovarian syndrome or chronic anovulation, and perimenopausal women with menometrorrhagia, periodic treatment with a progestin to create scheduled withdrawal bleeding and prevent hyperplasia may be considered (68,69).

In most cases, patients with hyperplasia with atypia should be treated by vaginal or abdominal hysterectomy to prevent the development of EC (70). Surgery is the definitive therapy as it stops bleeding, prevents cancer, and alleviates the potential for medical failure. Patients with AEH remain at high risk for recurrence of AEH or cancer during their lifetime, even after successful medical therapy (71). Most importantly, despite a preoperative diagnosis of AEH, many patients will be found to have a cancer at the time of hysterectomy (71,72). Older data suggested that if the endometrial sample is obtained by a biopsy or curettage, 15% to 25% of patients with the diagnosis of atypical hyperplasia may have a uterine carcinoma (73,74). Prospective data from a large surgical–pathologic trial conducted by the GOG demonstrated that, of 289 patients with a community diagnosis of AEH, 40% had an EC (72). Neither the type of preoperative endometrial biopsy (office endometrial biopsy [EMB] or dilatation and curettage [D&C]), nor the use of an expert pathology panel, was associated with a better ability to predict who had cancer or not. Patients with significant medical comorbidities, advanced age, or those desiring future fertility may be managed with progestational therapy (75). It has been suggested that a D&C should be performed in patients who will be medically managed with progestins for therapeutic effect (surgical curettage of tissue) and to better define the risk of an unrecognized cancer, while the data to support these practices are limited. When progestins are used to manage AEH, the specific agents, doses, and schedules may mirror those used to manage dysfunctional uterine bleeding or advanced or recurrent cancer. To assess the success of medical therapy, endometrial biopsies should be performed at 3- to 4-month intervals, provided cancer is not identified (76,77).

Screening and prevention strategies for women on tamoxifen are more challenging. Women with intact uteri who are taking tamoxifen for either treatment or prevention of breast cancer should be informed of the increased relative risk of developing EC with the use of tamoxifen. This risk is balanced by the reductions in recurrence or development of a contralateral breast cancer. Women on tamoxifen should be encouraged to report abnormal bleeding or vaginal discharge. Screening of asymptomatic women on tamoxifen therapy with ultrasound or endometrial biopsies is not recommended (78,79).

CLINICAL PRESENTATION

The classic symptom of endometrial carcinoma is abnormal uterine bleeding. A variety of conditions give rise to abnormal bleeding, but particular suspicion should be held for postmenopausal women, and women aged 40 years and over with high-risk factors. Approximately 10% of symptomatic postmenopausal patients are found to have a cancer on biopsy (80). In one series, using age >70 years, diabetes, or nulliparity as risk factors, patients with all three factors had an 87% chance of an AEH/carcinoma diagnosis, whereas only 3% had significant pathology in the absence of all risk factors (81). Additionally, patients with EC may present with vaginal discharge, or have a thickened endometrium that is incidentally noted on ultrasound performed for another reason. Pap smear screening is not designed to identify EC, but occasionally patients will have abnormal cervical cytology (atypical glandular cells of undetermined significance, adenocarcinoma *in situ*). Patients with intraperitoneal disease may present with similar complaints to patients with ovarian cancer, such as

abdominal distention, pelvic pressure, and pain.

Historically, when EC was a clinically staged disease (FIGO 1971), fractional D&C was the procedure of choice to evaluate abnormal bleeding. Fractional D&C permitted assessment of uterine size and allowed for endocervical curettage, important steps in the staging process. The standard procedure starts with curettage of the endocervix prior to cervical dilatation. Careful sounding of the uterus is performed followed by dilatation of the cervix, followed by systematic curetting of the entire endometrial cavity. Cervical and endometrial specimens should be kept separate and forwarded for pathologic interpretation.

Pathologic evaluation of the endometrium provides histologic diagnosis and can identify other etiologies of bleeding such as chronic endometritis, atrophy, polyps, cervical cancer, or unusual histologic variants (carcinosarcoma, serous carcinoma, placental nodule), which may alter management. Tissue evaluation by office EMB or D&C offer similar information when adequately performed. Today EMB has largely replaced D&C as the diagnostic procedure of choice. In the GOG hyperplasia study, 63% of the specimens were from EMB (Vabra, Novak, Pipelle) and 37% were from D&C (72). Results of endometrial biopsies correlate well with endometrial curetting, and the accuracy in detecting cancer is 91% to 99% (82,83). The accuracy of identifying cancers with EMB is higher in postmenopausal patients than in premenopausal, and a positive study showing cancer is more accurate for identifying disease than it is in excluding it. If office biopsy cannot be obtained (cervical stenosis, patient intolerance of procedure) or results are nondiagnostic, it should be followed by D&C. In cases of abnormal bleeding that persists despite negative biopsy, additional investigation is warranted.

Hysteroscopy has been advocated as an adjuvant to D&C to improve detection of pathology in the evaluation of postmenopausal bleeding. Whether it improves the sensitivity to detect hyperplasia and cancers is controversial (84-86). Hysteroscopy is more accurate in postmenopausal patients, and is more accurate in detecting cancer versus other pathology than it is in identifying cancer or hyperplasia versus other pathology. One concern is that hysteroscopy may promote transtubal migration of tumor cells, which can be detected as malignant pelvic washings on cytology. In one retrospective study, an odds ratio (OR) of 3.88 for positive cytology was seen in hysteroscopic D&Cs compared to D&C alone, and the authors cautioned against hysteroscopy for evaluating EC (87). Similarly, a review of literature suggested that water-based hysteroscopy was associated with increased frequency of positive cytology at time of hysterectomy (88). Positive peritoneal cytology as the sole extrauterine factor is now longer recognized as a stage-defining characteristic under the FIGO 2009 system, however (89). No prospective studies have been performed to date, and it remains uncertain what effect positive washing produced by hysteroscopy has, if any, on prognosis.

Ultrasound is commonly used as a less invasive tool to evaluate abnormal bleeding. The measurement of endometrial thickness (ET) has been shown to best predict the absence of carcinoma, with a false-negative rate of 4%, using a threshold value of <5 mm (90,91). The specific ET used for a cutoff value depends on the menopausal status of the patient population evaluated and on the use of HRT. For example, postmenopausal patients on HRT have a median ET 2 to 3 mm more than those not on HRT (92,93). In a meta-analysis of 85 studies, Smith-Bindman et al. (91) reported that a cutoff level of >5 mm would detect 96% of cancers, and would have a 39% false-positive rate. Transvaginal ultrasound measuring the lining thickness of the endometrium has excellent negative predictive value for ruling out ECs or hyperplasia when the thickness is <5 mm, but provides less information when >5 mm. Given a pretest probability of having EC in a postmenopausal patient with vaginal bleeding of 10%, a normal endometrial stripe is associated with a 1% chance of a cancer. A consensus panel, composed of radiologists, pathologists, and gynecologic oncologists, suggested that when ET is <5 mm, the test can be considered negative for EC (94). For patients with ET >5 mm, EMB, D&C with hysteroscopy, or saline infusion sonohysteroscopy should be performed. Saline infusion sonohysteroscopy has been suggested as a more effective way to define findings in the endometrial cavity noted on ultrasound, and provide clearer distinction of polyps, fibroids, and cancers (95). It is more likely to be successful in pre- than postmenopausal patients. The role of vaginal ultrasound in the evaluation of bleeding remains somewhat controversial, due to the importance of histology in defining treatment (for benign and malignant conditions) and the concern about failing to identify cancers. Good clinical judgment would suggest that patients with ET <5 mm who have persistent bleeding undergo tissue biopsy.

DIAGNOSTIC WORKUP

Preoperative Assessment

Following a diagnosis of EC, the surgeon must assess the surgical risks of the patient, evaluate the patient for possible metastatic spread, and determine the most appropriate surgical procedure. EC patients are frequently elderly and suffer from obesity, hypertension, diabetes, or cardiac disease. In a series of 595 consecutive patients, Marziale et al. (96) found an operability rate of 87%. Preoperative assessment must be performed, occasionally requiring consultation with additional specialists. At a minimum, patients require a thorough examination to evaluate for evidence of cardiac or pulmonary disease, and to determine the surgical approach. A chest x-ray and electrocardiogram (EKG), complete blood count, and assessment of electrolytes and renal function are standard in this population. Preoperative counseling includes obtaining permission to remove the uterus, tubes, and ovaries, and permission for thorough intra-abdominal exploration with biopsy and tumor resection as indicated, including removal of the pelvic and para-aortic LN.

Evaluation of Metastatic Spread

A thorough physical examination may discover suspicious supraclavicular, inguinal, and/or occasional pelvic LN as well as suggest the presence of pleural effusions, ascites, or omental caking. The pelvic examination can suggest cervical, vaginal, or adnexal spread. An assessment of uterine size and mobility is important, particularly in patients being considered for vaginal approaches (laparoscopic-assisted vaginal hysterectomy [LAVH], total vaginal hysterectomy [TVH]). A chest radiograph is done to search for metastatic tumor as well as to evaluate the cardiopulmonary status of the patient. For patients without obvious extrauterine disease, surgery is the next step. In cases where intra-abdominal, gross cervical, or distant disease spread is suspected, additional studies such as computed tomography (CT) scans, magnetic resonance imaging (MRI), or cystoscopy and proctoscopy may be needed to assist with surgical planning.

In general, there is very limited need for imaging studies prior to surgery; findings typically do not result in management changes because most patients present with stage I–II disease, and the surgery is essentially the same for stage I–III patients. Imaging studies have significant limitations in detecting nodal disease, which tends to be microscopic in 90% of cases (97,98). In a small series of higher risk patients who underwent preoperative FDG PET/CT, Signrelli and colleagues showed a 78% sensitivity and 93% negative predictive value (99). The GOG is conducting an ongoing prospective assessment of PET/CT in patients with endometrial and cervical cancer (GOG 233). In a prospective blinded comparison of the accuracy of preoperative transvaginal ultrasound versus frozen section assessment of myometrial invasion, intraoperative frozen section outperformed ultrasound. The sensitivity and specificity of predicting invasion (none, <50%, >50%) of the ultrasound was 75% and 89%, respectively (100). Patient review of systems and clinical examination frequently lead to suspicion of gross extrauterine disease. Imaging studies may be of better use in certain situations. Serous and clear cell tumors have a greater frequency of extrauterine disease spread, and imaging studies may offer additional information in some cases. In some settings, imaging studies may help to determine whether to refer the patient to a gynecologic oncologist, or perform surgical staging when it would not otherwise be considered. In addition, imaging studies may be most useful in helping to counsel young patients who are considering fertility preservation options. It has been suggested that MRI has more value than CT scans in assessing myometrial invasion, cervical invasion, and nodal disease, with several reports indicating a 75% to 90% accuracy in determining muscle involvement (101-104). However, limitations do exist, making routine use more difficult to recommend (105,106). At the present time, the only way to accurately diagnose the extent and depth of intrauterine invasion is by histologic examination of the hysterectomy specimen.

Biomarkers that predict the presence of extrauterine disease spread might be useful in triaging patients to referral centers for consideration of surgical staging, or to define risk. A variety of biomarkers have been proposed as possible

candidates, with CA-125 being the most studied (107-109). Attempts have been made to correlate CA-125 levels with extent of extrauterine disease, as serum levels are frequently elevated in patients with advanced or metastatic EC. This observation was first reported by Niloff et al. (110) in 1984. Values exceeding 35 U/mL were found in 14 (78%) of 18 patients with stage IV or recurrent disease, although none of 11 patients with stage I disease had elevated CA-125. Hsieh et al. (111) reviewed preoperative serum CA-125 levels, operative records, and pathologic reports in 141 patients diagnosed with EC to find out if the preoperative level of CA-125 can provide additional information for determining the extent of lymphadenectomy required in the surgical staging, and which cutoff is optimal in this respect. Of 141 patients, 124 were staged surgically and 24 (19%) were found to have LN metastasis. In the node-positive group, median preoperative serum levels were 94 U/mL (range, 17 to 363 U/mL). Multivariate analysis showed LN metastasis had the most significant effect on the elevation of CA-125 levels (>40 U/mL). The sensitivity and specificity for screening LN metastasis were 78% and 84%, respectively. The data of Hsieh et al. give evidence that preoperative CA-125 levels greater than 40 U/mL can be considered an indication for full pelvic and para-aortic lymphadenectomy in the surgical staging of EC. Rose et al. (112) found serial CA-125 measurements to be most useful in patients with high-risk disease whose initial stage was II, III, or IV, or whose tumor was grade 3 or of clear cell or serous histology. Fifteen (94%) of 16 patients with recurrent disease had an elevated CA-125 level. Serial measurements of CA-125 are also used to monitor for recurrence, and to assess response to tumor therapy in patients whose levels were initially elevated at diagnosis. In the LACE trial, which compared laparotomy to laparoscopy in the management of early-staged EC, 657 patients had preoperative CA-125 levels which were correlated with extrauterine disease spread. Using a cutoff of 30 U/mL, 15% were noted to have elevated CA-125 levels, and of these 37% had extrauterine disease (113). Ideally, serum biomarkers or tests which can be performed on diagnostic samples (EMB, D&C specimens) would be most useful.

Determining the Surgical Procedure

Of all the female pelvic malignancies, there are more advocates for different treatment plans for EC than any other. The standard treatment for this disease has been and remains total hysterectomy and concomitant removal of both ovaries and fallopian tubes. However, through the years, preoperative and postoperative irradiation has had an important role in the management of this disease. The first significant report of employing irradiation in the management of patients with EC was the publication of the “Stockholm technique” by Heyman in 1935 (114). The use of intracavitary implants using the Heyman method became increasingly popular in the ensuing years. Subsequently, reports comparing results in patients treated with a single intrauterine tandem versus those treated with multiple intrauterine capsules revealed a lower incidence of residual disease and an improved 5-year survival rate, in the patients treated with capsules (115-117). In cooperative studies in the late 1960s, Lewis et al. (118) showed that 25% of patients had deep myometrial invasion if treated initially by surgery, and only 8% had deep invasion if treated by preoperative irradiation. Patients frequently were managed with preoperative radiation (whole pelvic radiation [WPR], low-dose-rate [LDR] implant with or without WPR) followed within 4 to 6 weeks by a complete hysterectomy. While surgical evaluation of LN in EC was reported in the 1960s, it was not widely embraced (119-122). The GOG undertook the large surgical–pathologic study, GOG 33, of clinical stage I EC to better define patterns of spread, with the hope that defining pathologic relationships would lead to a tailored (rather than a universal) approach to radiation (59,61). The results of this study subsequently led to the incorporation of a surgical staging system (FIGO 1988). In 2009, FIGO updated staging for EC (Tables 21.3 and 21.4) (89)

TABLE 21.3 Corpus Cancer Surgical Staging, FIGO 1988

Stages/Grades	Characteristics
IA G123	Tumor limited to endometrium
IB G123	Invasion to less than half of the myometrium
IC G123	Invasion to less than half of the myometrium
IIA G123	Endocervical glandular involvement only

IIB G123	Cervical stromal invasion
IIIA G123	Tumor invades serosa or adnexa or positive peritoneal cytology
IIIB G123	Vaginal metastases
IIIC G123	Metastases to pelvic or para-aortic lymph nodes
IVA G123	Tumor invades bladder and/or bowel mucosa
IVB	Distant metastases including intra-abdominal and/or inguinal LN

LN, lymph node.

TABLE 21.4 Corpus Cancer Surgical Staging, FIGO 2009

Stages/Grades	Characteristics
IA G123	No or less than half myometrial invasion
IB G123	Invasion equal to or more than half of the myometrium
II G123	Tumor invades the cervical stroma but does not extend beyond the uterus
IIIA G123	Tumor invades serosa of the corpus uteri and/or adnexa
IIIB G123	Vaginal and/or parametrial involvement
IIIC1 G123IIIC2 G123	Metastases to pelvic LNMetastases to para-aortic LN, with or without positive pelvic nodes
IVA G123	Tumor invades bladder and/or bowel mucosa
IVB	Distant metastases including intra-abdominal and/or inguinal LN
Histopathology, degree of differentiation	
Cases should be grouped by the degree of differentiation of the adenocarcinoma:	
G1	5% or less of a nonsquamous or nonmorular solid growth pattern
G2	6% to 50% of a nonsquamous or nonmorular solid growth pattern
G3	More than 50% of a nonsquamous or nonmorular solid growth pattern
Notes on pathologic grading	
Notable nuclear atypia, inappropriate for the architectural grade, raises the grade of a grade 1 or grade 2 tumor by 1.	
In serous adenocarcinomas, clear cell adenocarcinomas, and squamous cell carcinomas, nuclear grading takes precedence.	
Adenocarcinomas with squamous differentiation are graded according to the nuclear grade of the glandular component.	
Rules related to staging	
Because corpus cancer is now surgically staged, procedures previously used for determination of stages are no longer applicable, such as the finding of fractional D&C to differentiate between stages I and II.	
It is appreciated that there may be a small number of patients with corpus cancer who will be treated primarily with radiation therapy. If that is the case, the clinical staging adopted by FIGO in 1971 would still apply, but designation of that staging system would be noted.	
Ideally, width of the myometrium should be measured, along with the width of tumor invasion.	

D&C, dilatation and curettage; FIGO, International Federation of Gynecology and Obstetrics; LN, lymph node.

Contemporary management of most patients with EC remains surgical and includes, at minimum, an initial surgical

exploration with collection of peritoneal fluid for cytologic evaluation (intraperitoneal cell washings), through inspection of the abdominal and pelvic cavities, with biopsy or excision of any extrauterine lesions suspicious for tumor, and total extrafascial hysterectomy with BSO. In 2009, FIGO removed the status of cytology as a stage-defining criteria (IIIA, by FIGO 1988); however, there was no intent to discontinue the practice of cytologic evaluation. Whereas the traditional approach has been to perform this surgery abdominally (typically through a vertical midline incision), minimally invasive techniques have increasingly been integrated into the forefront. The uterus should be particularly observed for tumor breakthrough of the serosal surface. The distal ends of the fallopian tubes are clipped or ligated to prevent possible tumor spill during uterine manipulation. To complete the surgical staging of EC, the removal of bilateral pelvic and para-aortic LN is also required.

When surgical staging is indicated, a bilateral pelvic and para-aortic nodal lymphadenectomy is performed. The anatomic boundaries of the pelvic nodal dissection are comparable to what is used for a pelvic nodal dissection with cervical cancer, and is outlined by the margins of the circumflex iliac vein distally, the bifurcation of the iliac vessels proximally; the lateral margin is the genitofemoral nerve, and the medial margin is the superior vesical artery. The floor of the dissection is the obturator nerve. Nodal/fatty tissue is skeletonized from these structures. In cases of bulky nodal disease, complete resection/debulking, rather than biopsy to solely demonstrate metastatic disease, is favored where possible. The common iliac nodes can be removed as a separate specimen or divided at a midpoint along the vessels, submitting the inferior half with the pelvic nodes, and the superior half with the para-aortic nodes. Particularly on the left side, the common iliac nodes will be quite lateral in location, and sufficient mobilization will be required in order to visualize these nodes. Removal of para-aortic nodes can be performed through a midline peritoneal incision over the common iliac arteries and aorta, or by mobilizing the right and left colon medially (123,124). In each case, LN are resected along the upper common iliac vessels on either side and from the lower portion of the aorta and vena cava. At the present time, the inferior mesenteric artery is used to demark the superior extent of the para-aortic nodal dissection, although some prefer to routinely extend the dissection to the level of the renal vessels (125). If suspicious nodes extending to the renal vessels are identified, they should be removed if possible.

In cases with gross omental or intraperitoneal disease spread, cytoreductive surgery with total omentectomy, radical peritoneal stripping, and occasionally bowel resection are required. The goal of reducing the residual disease to no or small volumes, akin to what is performed for ovarian cancer, is increasingly considered. In cases complicated by medical comorbidity, advanced age, or obesity, or when nodal dissection cannot or will not be performed, TVH with or without laparoscopic/robotic assistance may also be utilized. Following surgical assessment, patients may be classified based on pathologic features as to their risk of recurrence, and those deemed to be at sufficient risk may be offered adjuvant therapies.

Nonsurgical Management

The principle management of most patients with EC is surgical. The decision to use surgery is a function of patient and disease status. Patients with significant medical comorbidities who are not acceptable candidates for surgery (markedly advanced age, diminished performance status, severe cardiac/pulmonary disease, massive obesity) may be managed by alternative means. Primary RT without surgery has been used, and is discussed later in this chapter. Progestational therapy may be used for those who are inoperable or in younger patients who elect for fertility preservation (75,126). Patients not undergoing surgery should be clinically staged according to the clinical staging system proposed by FIGO in 1971 (Table 21.5) (127). Those who do undergo initial hysterectomy are staged by the 2009 FIGO (revised 1988) system (Table 21.4) (89). Patients who are obese, but otherwise surgical candidates may undergo an abdominal panniculectomy to enhance surgical exposure to facilitate hysterectomy and nodal dissection (128,129). For patients presenting with disseminated or nonresectable disease, nonsurgical options including radiation, CT, or hormonal therapy have also been used. Surgery may be required to control vaginal bleeding in some of these cases.

TABLE 21.5 Corpus Cancer Clinical Staging, FIGO 1971

Stage	Characteristics
I	Carcinoma is confined to the corpus
IA	Length of the uterine cavity is 8 cm or less
IB	Length of the uterine cavity is more than 8 cm
Histologic subtypes of adenocarcinoma	
G1	Highly differentiated adenomatous carcinoma
G2	Differentiated adenomatous carcinoma with partly solid areas
G3	Predominantly solid or entirely undifferentiated carcinoma
II	Carcinoma involves the corpus and cervix
III	Carcinoma extends outside the uterus but not outside the true pelvis
IV	Carcinoma extends outside the true pelvis or involves the bladder or rectum

Approximately 5% of women with EC are diagnosed under the age of 40 (4). For some younger women, the standard treatment of hysterectomy is unacceptable due to desires to maintain fertility. EC in younger women is usually associated with early-stage, low-grade disease and carries a favorable prognosis, making medical management an attractive option to some (76,77,126,130,131). Patients without myometrial invasion are thought to be the best candidates, and may undergo pelvic MRI to assess for myometrial involvement. Progestational therapy, most commonly with medroxyprogesterone acetate (MPA) or megestrol acetate, has been successful in reversing malignant changes in up to 76% of cases (126,130). Increasingly, there has been a consideration for progestin-based intrauterine devices, although the data is limited. In a 2012 systematic review of the literature, 74% of AEH and 72% of grade 1 EC patients achieved a pathologic complete response (CR) for 6 months or longer with oral progestins (132). The range of CRs for AEH was 50% to 95%, and for grade 1 cancer was 50% to 100%. The mean time required to achieve the CR was 6 months. Of 22 patients reported with grade 1 cancer treated with IUD, 68% achieved a CR. Because response may be temporary or incomplete, periodic sampling of the endometrium is advised. Penner and colleagues suggested that lack of response to progestin therapy is more common when the first response assessment shows lack of response, despite adjacent stromal decidualization (133).

Vaginal Hysterectomy

Vaginal hysterectomy with or without postoperative radiation may be another option for managing complicated patients. Vaginal hysterectomy has often been cited as the simplest and least morbid approach to hysterectomy, and has produced similar treatment outcomes in patients with clinical stage I EC (134-136). It is often used as an alternative to an abdominal approach in obese and poor-surgical-risk patients (137,138). Limitations include the lack of exploration of the intraperitoneal cavity, inability to procure cytologic washings, greater difficulty in performing a salpingo-oophorectomy, and inability to assess LN status. Given that LN metastasis is related to such high-risk features as poor differentiation, unfavorable histologic subtypes, and deep myometrial invasion, the option of TVH for management of this cancer centers on preoperative uterine pathology and the need for comprehensive surgical staging (59). TVH is not appropriate for the management of EC in patients with concomitant adnexal pathology.

Nodal Dissection

The value of staging any malignancy relates to the ability to describe the extent of disease at diagnosis, and to define comparable patient populations for whom prognosis and therapy are similar. Given the inability to accurately detect disease spread for many gynecologic malignancies, solely based on clinical examination and imaging studies, surgical staging

systems that require pathologic evaluation of sampled sites have been largely incorporated into practice. The value of surgical staging as it relates to ECs has been the subject of increased scrutiny and debate over the last several years. For ECs, the ability of surgical staging to accurately identify spread to draining LN basins and how this information (or lack of it) changes prognosis and alters the use of postoperative therapies are a source of controversy. Proponents of routine surgical staging suggest that the ability to identify otherwise unrecognized disease spread to the nodes changes the postoperative therapies that are given, and is the most accurate way to assess risk. Most controversial is the assertion that surgical staging has a therapeutic benefit independent of the node status (positive or negative for metastatic disease).

Fundamentally, surgeons must determine for themselves whether or not they believe that surgical staging has sufficient value to offer it for all patients or only selectively based on risk factors identified pre- and intraoperatively. If a patient will not be offered surgical staging/nodal dissection, then minimizing surgical morbidity with only total hysterectomy and bilateral salpingo-oophorectomy may be warranted. In this case, lower risk/quicker recovery comes at the cost of less information. In cases where nodal dissection is deemed necessary or potentially will be performed, patients must be adequately counseled regarding the risks and benefits. The principle risks attributable to nodal dissections include increased operative time, potential for blood loss associated with vascular injury, ileus, and genitofemoral nerve injury with resulting numbness and paresthesias over medial thighs, lymphocyst formation, and lymphedema (Table 21.6) (61,139-141). In general, the risks associated with nodal dissections are low and acceptable. Patients who have nodal dissections and receive pelvic RT may be at a greater risk of bowel morbidity and chronic lymphedema than those without dissections (143,144). Nodal dissections also require the involvement of someone trained and skilled to perform the procedure. The principle advantage of comprehensive staging is that the physician and patient are provided with the greatest amount of information which may be critical in making recommendations with regards to the need for adjuvant therapy and prognosis. In the contemporary management of EC, this information results in less use of radiation, and substitution of vaginal cuff brachytherapy (VCB) for pelvic radiation (122,145,146).

TABLE 21.6 Risks Associated with Nodal Dissection: Surgical Complication Rates Associated with Abdominal Hysterectomy + Pelvic and Para-Aortic Lymph Node Dissection

Study	N	Hemorrhage (%)	GU Injury (%)	DVT/PE (%)	Lymphocyst (%)	Other
Morrow 1991(61)	895	2.2	0.4	2	1.2	—
Homesley 1992(140)	196	6% transfused	—	4	—	"Serious" 6%
Orr 1997(139)	396	4.2% transfused	0.6	1.5	1.2	—
Mariani 2006(142)	96 node(+) patients	—	1	1	3.1	—

DVT/PE, deep vein thrombosis/pulmonary embolism; GU, genitourinary.

The importance, extent, and technique of nodal dissection are hotly debated. Questions relate to which patients should be offered and could benefit from surgical staging (all, some, none), and what is the optimal surgical procedure to be performed (biopsy of enlarged/visible nodes, lymphadenectomy). Controversy also exists between those surgeons who perform only pelvic dissections and those who advocate pelvic and para-aortic nodal dissection. If para-aortic nodes are removed, are bilateral nodes required, and to what superior extent (inferior mesenteric artery, renal vessels) should the dissection proceed?

Nodal Dissection—None

In the United States, comprehensive surgical staging of EC is infrequently performed. Only 30% to 40% of patients

undergo nodal assessment, indicating that the majority of U.S. patients are not staged (146,147). Many gynecologists are neither trained in the techniques of lymphadenectomy nor are familiar with the concept of full surgical staging. Full staging is more commonly performed by specialized surgeons, such as gynecologic oncologists (148,149). Philosophically, those opposed to nodal dissections suggest that most patients are at low risk for nodal disease, treatment decisions can be based on final pathologic information, and despite node dissection the majority of patients who are node-negative do not get benefit (150). Most patients with EC do present with low-risk features. In the entire GOG 33 study population of 621 patients, 75% had grade 1 to 2 tumors, 59% had inner one-third or less myometrial invasion, and only 9% of patients had positive LN (59). The Postoperative Radiation Therapy in Endometrial Cancer (PORTEC) trial evaluated patients with stage IC, grade 1; stage IB-C, grade 2; or stage IB, grade 3 who underwent hysterectomy without LN dissection and compared observation to postoperative pelvic radiation (151). Of note, on the basis of grade and depth of invasion, approximately 60% of patients enrolled in GOG 33 would have had disease characteristics required for eligibility in the PORTEC trial. This patient population managed without nodal dissection had favorable outcomes with or without RT (5-year survival rates of 85% observation, 81% with pelvic radiation) in the PORTEC study (151). In a follow-up study including 427 patients with higher risk disease (age >60 years plus either grade 1 to 2 and outer 50% invasion, or grade 3 with inner 50% invasion, or stage IIA (1988 FIGO) disease, the PORTEC 2 study compared pelvic RT to VCB. None of the patients underwent nodal assessment, and 5-year progression-free survival (PFS) (78% to 83%) and survival (80% to 85%) suggested that even intermediate-risk patients may be managed without lymphadenectomy, albeit at the cost of requiring adjuvant therapy, with resulting favorable outcomes (152). Trimble et al. (153) reported on data from stage I EC patients collected by SEER from 1988 to 1993 and showed that 5-year relative survival for patients without nodal dissection was 98% compared to 96% in those undergoing nodal dissection and suggested that nodal dissection did not convey a benefit for the overall population. Unfortunately, data on adjuvant therapy use was not available. It is suspected that increased use of radiation in unstaged patients may produce similar outcomes to patients who are staged and who avoid RT.

In a nonrandomized trial comparing hysterectomy with or without pelvic lymphadenectomy, followed by RT, 14% of patients (n = 207) with negative nodes treated with VCB recurred compared to 16% who did not have a lymphadenectomy (n = 660) (154). While the authors noted similar cancer-free survival between the groups, all patients who did not have nodal dissections received both pelvic radiation and VCB to attain these results.

Two randomized trials comparing hysterectomy with or without lymphadenectomy have been reported. A Study in the Treatment of Endometrial Cancer (ASTEC) randomized patients with 1,369 EC to hysterectomy with (LND group) or without (no-LND group) pelvic lymphadenectomy (155). Following surgery, patients with stage I-IIA disease were then randomized again to observation or pelvic RT if they had grade 3, serous, or clear cell histology; >50% myometrial invasion; or endocervical glandular invasion (stage IIA). Nodal status did not alter the use of RT such that node-positive patients could be assigned to observation. Treatment centers were also permitted to use VCB regardless of pelvic radiation assignment based on institutional preference. As a result, a patient with unknown nodal status could receive VCB and not be considered to have received RT. Of the LND group, 54 patients were found to positive nodes (9%) compared with 9 (1.3%) patients in the no-LND group. The quality of the nodal dissection has been criticized in this study as 8% of patients within the LND group did not get a nodal dissection, 12% had <5 nodes removed (median = 12 nodes), and para-aortic nodal dissection was not performed. There was no difference in PFS (HR, 1.0) or survival (HR, 1.25; $p = 0.14$) between the LND groups. Pelvic lymphadenectomy was associated with a longer operative time, and increased frequency of ileus (3% vs. 1%), deep venous thrombosis (1% vs. 0.1%), lymphocysts (1% vs. 0.3%), and wound complications (1% vs. 0.3%) compared to the no-LND group. The frequency of transfusions and length of hospitalization were comparable between groups. The authors concluded that the results suggest no evidence of benefit for PFS/OS for pelvic lymphadenectomy and that it "could not be recommended as a routine procedure for *therapeutic* purposes" (155).

A similar study was performed by Italian investigators (CONSORT trial). In this trial, 514 patients were assigned to hysterectomy with or without pelvic lymphadenectomy (156). Patients were required to have myometrial invasion, and patients with grade 1 tumors and <50% invasion were excluded. In the no-LND group, 22% of patients had nodal dissections due to clinical suspicion with 14% of these cases, or 3% of the entire no-LND arm, having node-positive

disease. In the LND group, the median number of nodes removed was 26. Para-aortic dissection could be performed at the surgeon's discretion and was done 26% of cases. In the LND group, 13% were found to have positive nodes. Lymphocysts and lymphedema were more common in the LND group but other early and late complications were similar. Postoperative therapy was not protocol prescribed, but the use of RT was more common in the no-LND group (25% vs. 17%). The 5-year disease-free survival (DFS) was 81% in both groups, and 5-year survival was 90% in the no-LND group versus 86% in the LND group (HR 1.2, $p = 0.5$). The authors concluded that pelvic lymphadenectomy could not be recommended as a routine procedure for therapeutic purposes (156).

Both the ASTEC (A) and Italian (I) studies have been heavily criticized (157-159). Weaknesses of the studies relate to the absence of treatment in patients identified with positive nodes (A), lack of prescribed adjuvant therapy (I), limited power to show improvements in outcome if one truly existed (A, I), poor quality of the LND (A), absence of para-aortic nodal dissection (A, I), lack of quality-of-life assessment evaluating effect of both surgery and downstream use of adjuvant therapy (A, I), and the over representation of low-risk patients (A, I). Despite these limitations, these datasets provide the only level 1 evidence on the role of lymphadenectomy. The studies also suggest that the marginal benefit that lymphadenectomy may provide is likely to be modest for most patients. In addition, the data provide a strong argument that removing negative nodes is unlikely to significantly improve outcomes.

Without nodal information, physicians must rely on uterine factors to estimate the probability for nodal disease and pelvic failure to determine the need for postoperative radiation. Risk assessments may be based on nodal positivity estimates from GOG 33 or based on uterine factor–derived risk groups treated with or without RT (PORTEC, GOG 99; 962,146,153,162). Nodal positivity is not infrequent in patients with higher risk uterine factors based on GOG 99 or PORTEC models. Nugent and colleagues classified a series of 352 clinical stage 1, endometrioid adenocarcinoma patients into risk groups based on PORTEC and GOG 99 models. Nodal positivity rates were 20% with PORTEC and 35% with GOG 99 HIR criteria (151). Without specific nodal information, treatments must be based on estimates of risk/probability; this estimation can result in an increase in the use of radiation, particularly if the primary benefit of postoperative radiation is in node-positive patients. Complicating the issue of nodal dissection is that nodal status is only one of several important prognostic factors (160,161). Kwon and colleagues performed a population-based cohort study of 316 EC patients who underwent lymphadenectomy and reported that pelvic node status was not an independent determinant of survival, whereas prognosis was determined more by uterine factors (161).

The absence of nodal dissection may also lead to poorer outcomes. For example, a subset of 99 patients with stage IC, grade 3 EC, who did not have LN dissection, were not eligible, but were treated with pelvic radiation and followed prospectively within the PORTEC trial (162). Five-year survival for this group of patients was 58%, and 12% had vaginal or pelvic failures despite WPR. It is interesting to note that the outcome of this group is poorer than what has been reported in patients with stage IIIC EC managed by lymphadenectomy followed by radiation (163-165). If patients are not to have nodal dissection, then it would seem reasonable to consider minimally invasive or vaginal approaches to reduce morbidity.

Nodal Dissection—Selective

Surgical staging is the most accurate way to determine the extent of disease spread. Palpation of pelvic LN is not sufficiently accurate, with a sensitivity of 72% in a recent prospective study (166,167). The baseline rate of nodal disease in an "all comer" population of EC patients is roughly 9% (Table 21.7). Increasingly, the challenge has been how to identify the smaller portion of patients at high risk from the larger low-risk population. Clearly, subgroups of patients at very high risk (non-endometrioid histology, carcinosarcoma, gross cervical involvement, gross extrauterine disease spread) exist, but these represent a minority of the 400,000 cases of uterine cancer per year in the U.S. Many gynecologic oncologists consider nodal assessment to be a fundamental step in the evaluation and management of most women with EC, and nodal assessment has been incorporated into the surgical staging of EC since 1988.

TABLE 21.7 Frequency of Nodal Disease

Study	N	Frequency of Nodal Disease (%)
GOG 33 (59)ASTEC(+LND)(−) LND (155)	621 686 685	991
CONSORT(+ LND)(−) LND (156)	264 250	133
LAP II (168)	2510	9
PORTEC HIR Criteria (160)	66	20
GOG 99 HIR Criteria (160)	188	35

Increasingly, there has been a discussion in the literature to attempt to describe which populations should be offered lymphadenectomy, and the optimal strategy for defining those at risk (tumor biomarkers, frozen section criteria, sentinel nodal evaluation). Many believe that nodal dissections should be reserved for those with sufficient risk of nodal disease (59,61,169,170). What risk of nodal disease (3%, 5%, 10%, etc.) warrants the procedure is debated—that is, at what level would one be comfortable missing unrecognized nodal spread. Equally important in the discussion is the understanding of whether uterine risk factors, independent of nodal status, should drive risk assessment and use of adjuvant therapy and whether adjuvant therapies given to those with node-positive or node status unknown perform similarly.

Historically, data from GOG 33 demonstrated important relationships between tumor grade and depth of invasion and frequency of nodal disease that can be used to decide whether to perform nodal assessments (Tables 21.8 and 21.9) (59). For example, the risk of pelvic nodal disease was 3% for all patients with grade 1 tumors, but was 11% with deeply invasive (outer one-third myometrial invasion) tumors. Patients with grade 3 tumors had a risk of pelvic nodal metastases of 18%, and 34% with deep invasion. With cervical invasion, the rate of pelvic nodal disease was 16%. Patients with serous or clear cell histology also warrant nodal dissection as ~30% to 50% will have nodal disease, and even in the absence of myometrial invasion, nodal metastases have been reported in up to 36% of patients (171). Some advocate that LN need not be sampled for tumor limited to the endometrium, regardless of grade, because less than 1% of these patients have disease spread to pelvic or para-aortic LN (59,172). A gray zone in deciding about LN sampling is represented by patients whose only risk factor is inner one-half myometrial invasion, particularly if the grade is 2 or 3. This group has 5% or less chance of node positivity (59). In the most recent survey of Society for Gynecologic Oncology (SGO) members, 35% of respondents reported doing lymphadenectomy for grade 1 tumors; however, the use increased to 60% for grade 2 and 90% for grade 3 (125).

TABLE 21.8 Histologic Grade and Depth of Invasion

Depth	Grade, No. of Patients			
	Grade 1 (%)	Grade 2 (%)	Grade 3 (%)	Total (% of Total)
Endometrium only	44 (24)	31 (11)	11 (7)	86 (14)

Increasingly, the debate has focused on appropriate selection of patients at such low risk for nodal metastasis that lymphadenectomy may be safely avoided. While flawed, the ASTEC and Italian studies have suggested that routine nodal dissection may have limited value. If the primary value of lymphadenectomy is to identify patients with positive nodes (as a "diagnostic test") which define patients who need additional/different postoperative therapy, there is value in defining populations at sufficiently low risk for whom no lymphadenectomy is required. In 2000, the Mayo group described a model which could classify a group with a low risk of nodal disease spread and high DFS based on frozen section evaluation of the uterus that showed grade 1 to 2 endometrioid tumor, inner 50% invasion, and tumor size < 2 cm (173).

Mariani subsequently reported on a prospective experience of 422 patients and reported that 33% of patients with endometrioid-type tumors would qualify as low risk in this model. The authors also showed that 22% patients with risk factors outside of their low-risk model had positive nodal spread at time of lymphadenectomy (174). Several other investigators have attempted to validate these findings. Convery and colleagues tried to replicate the conditions of Mayo criteria (which are assessed intraoperatively by frozen section) by retrospectively evaluating 602 patients with grade 1 to 2 endometrioid EC and who had intraoperative assessment of tumor (for depth of invasion +/− tumor size) (175). The authors showed that 2/110 (1.8%) patients meeting the Mayo criteria who underwent a lymphadenectomy removing at least eight nodes were found to have metastatic spread to LN. Milam attempted to validate the Mayo criteria using a 971-patient surgical dataset from patients participating in the GOG Lap 2 trial (randomized trial of laparoscopy vs. open hysterectomy with pelvic and para-aortic lymphadenectomy [176]). Of 971 patients with endometrioid adenocarcinoma and complete data, 65 (7%) were identified with positive LN. Patients were classified into a "low risk" category based on three Mayo criteria; grade 1 to 2 tumor, <50% myometrial invasion, and tumor size < 2 cm. These risk characteristics were assigned based on final pathology report and not frozen section, however, as was used in the Mayo studies. Approximately 40% of patients met the low-risk criteria and of these 3/389 (0.8%) had positive LN.

Kang reporting for the Korean GOG retrospectively evaluated 540 patients with endometrioid-type cancers who had undergone preoperative EMB, CA-125 level, and MRI followed by hysterectomy and pelvic lymphadenectomy to create a risk model for predicting nodal disease (177). The model was developed on a 360-patient training set and validated against a 180-patient cohort. Interestingly, the logistic regression model included only data from the MRI and CA-125 level, grade was not an independently significant variable. The authors suggested that based on preoperative information, they could classify 53% of patients as low-risk (<50%) myometrial invasion and absence of enlarged nodes or extrauterine disease by MRI and CA-125 (<35 IU/mL). Of the low-risk group, only one patient had positive nodal disease (1.7% false-negative rate) suggesting that these patients may avoid an unnecessary lymphadenectomy.

Low-grade tumors appear to represent the most appropriate group for developing criteria to limit lymphadenectomy. Bernardini performed a retrospective comparison between two academic institutions preferences for management of preoperative grade 1 endometrioid EC (178). Of 483 cases with a preoperative grade 1 cancer, final pathology was grade 1 in 357/483 (74%) cases, and 20% were upgraded (grade 2, 18%; grade 3, 2%). In one institution, surgical staging was performed in 50% of cases, and four (3%) patients were identified with nodal disease. At the second institution, LN dissection was performed in only 12% of patients, and three (1.4%) were found to have positive nodal disease. At the second institution, postoperative use of RT was more common (21% vs. 7%), although older patient age, capillary space invasion, and cervical involvement were more common at the second site. Despite the differences in surgical practice, the 3-year survival was 96% at both centers. These data indicate that there is little margin to improve outcomes through strategies directed at all patients in this patient population.

Selective use of nodal dissection highlights the balance between the likelihood of identifying otherwise unrecognized disease against cost, morbidity, and use of adjuvant therapy (with downstream cost, morbidity). The overall surgical complication of lymphadenectomy is approximately 20%. The serious complication rate is ≤6%, and is likely to be lower with surgeons who more frequently perform the procedure (61,139-141). Downstream utilization of adjuvant therapy, which may occur more frequently in the absence of lymphadenectomy, must also be considered into this balance. While the proposed models predicting low-risk disease status appear to be accurate, it is important to understand that the pretest probability of having positive nodes in a large patient population with grade 1 to 2 endometrioid tumors is ~3% to 7%, illustrating the narrow margin in improved outcome (e.g., identify 100% of patients with positive nodes and then use adjuvant therapy which cures 100% of these) that lymphadenectomy may be able to offer in this population of patients. Lymphadenectomy perhaps allows for fine tuning the management of low-risk patients, but does not appear to be the driver of outcomes.

Intraoperative assessment of the uterus in patients with low-grade endometrioid adenocarcinoma of the endometrium has been used to guide the surgeon as to when to perform a nodal dissection. Gross inspection of the uterus immediately following its removal can be used to estimate the degree of myometrial invasion. If the uterus is opened by the operating

surgeon, care should be employed to avoid distortion of the anatomy. Optimally, the unfixed uterus should be opened by the surgical pathologist, who can grossly estimate the depth of invasion, assess involvement of the cervix, and later sample the tumor for histologic assessment. There is no typical gross appearance of an EC. Most are polypoid or ulcerative. Carcinoma usually differs in texture and color from the surrounding normal endometrium. The normal endometrium is irregular and tan, but a carcinoma is usually shaggy, white to gray–white, and focally hemorrhagic. Areas of myometrial invasion may be visible as gray–white to white, with yellow areas disclosing necrosis (Figs.21.1 and 21.2). The texture may be soft, friable, or firm depending on the degree of necrosis.

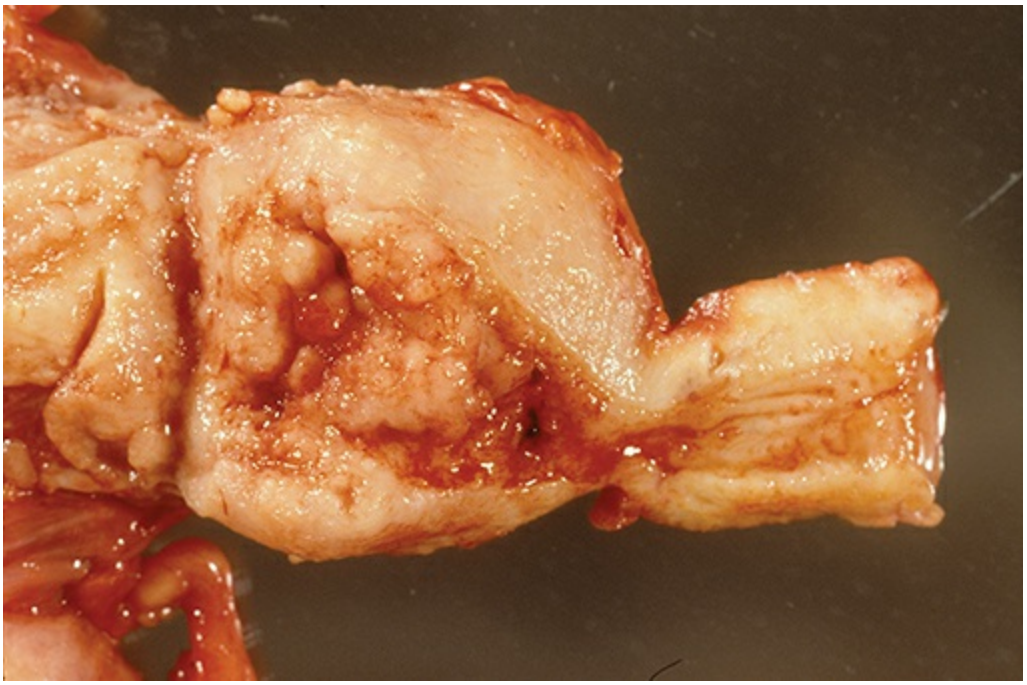

Figure 21.1 Endometrioid adenocarcinoma. A polypoid adenocarcinoma of the endometrium that fills much of the lumen and superficially invades the myometrium.

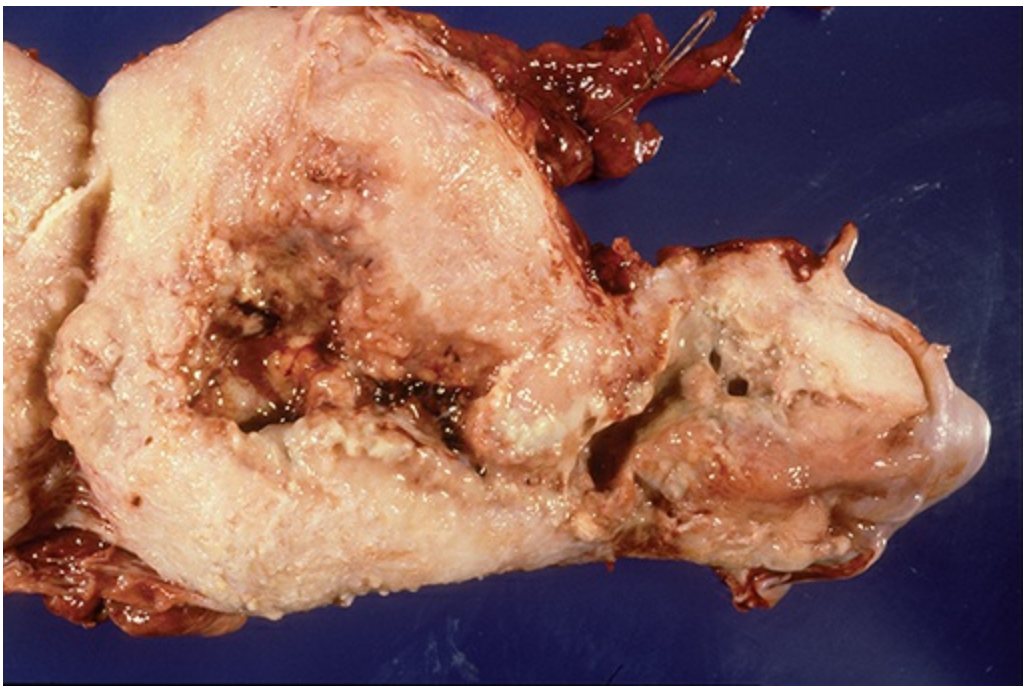

Figure 21.2 Endometrial adenocarcinoma. An ulcerating and deeply invasive adenocarcinoma that extends into the uterine cervix.

Doering et al. (179) reported a 91% accuracy rate for 148 patients for determining the depth of myometrial invasion by gross visual examination of the cut uterine surface. A prospective study indicated that visual inspection of < or >50% correlated with microscopic assessment in 85% cases (167). However, the sensitivity of determining >50% was lower at 72%. Invasion of the myometrium may be more extensive microscopically than is evident visibly because of the characteristic infiltrative growth pattern of the tumor. In a retrospective study by Goff and Riche, the gross estimation by pathologists of myometrial invasion in grades 2 and 3 tumors was poor (180). With invasion, the uterine cavity usually enlarges and the myometrium thickens, but a small uterus may have myometrial penetration to the serosa.

Nodal Dissection—Routine

Data from 1990–2000 provided support for performing uniform comprehensive surgical staging for nearly all patients with EC. The rationale for uniform staging includes the lack of a patient population for whom nodal disease is so low that nodes should be omitted, the inaccuracy of preoperative or intraoperative assessments predicting the risk for nodal disease, the potential for therapeutic benefit in node-positive and node-negative patients, and the lack of significant morbidity associated with the procedure. Postoperative adjuvant decisions are best made with the most complete information. If nodal assessment is the predominant factor by which to categorize patients into risk groups, routine nodal dissection is the best method by which to determine which few patients will require adjuvant therapy.

What constitutes an acceptable rate of nodal disease in EC to warrant the procedure is surgeon dependent. In cervical cancer, routine pelvic lymphadenectomy is advocated for all stage IA2 tumors where nodal positivity rates are 3% to 5% (181). For clinical stage I ovarian cancer, para-aortic dissection is recommended for all, given the 6% risk of para-aortic disease (182). In EC, major complication rates associated with nodal dissection are 2% to 6%, suggesting that this might be an appropriate level of risk to balance against the risk of nodal metastases. Data from GOG 33 show that only patients with tumor limited to the endometrium had a risk of pelvic nodal disease ≤3%, and this group accounted for only 14% of the entire study population.

Frozen section assessment has been the traditional tool to facilitate decisions on selective nodal dissections. Several studies have demonstrated inaccuracies with frozen sections in the interpretation of grade and depth of myometrial invasion compared to final pathology (183-185). In one prospective evaluation, frozen section determination of depth of invasion correlated with final pathology in 67% of cases but resulted in upstaging in 28% of cases (183). Patients with grade 1 EC or AEH were upstaged in 61% of cases. The clinical significance of these errors has been debated (150), but many believe that such unexpected upstaging justifies routine staging even in seemingly low-risk patients (183,184). Data also suggest that the strategy of routine nodal dissection is more cost-effective than either no staging or selective staging based on frozen section results (186,187).

The technique of nodal dissection has undergone evolution. In an era where everyone was to receive RT, there was little value for a complete evaluation of LN. Removal of palpably enlarged nodes, “plucking” of visibly noted nodes, and “sampling” have given way to a more thorough assessment. Only 10% of patients with metastases to LN will have grossly enlarged nodes, and frequently, even in these cases, direct palpation through the overlying peritoneum will fail to identify them (59). Today, adjuvant therapies are based on the extent of disease, and are often only reserved for node-positive patients. Nodal assessments should sufficiently examine sites at risk including external iliac, hypogastric, and obturator nodes in the pelvis, common iliac nodes, and para-aortic nodes. Moving from a sampling technique to a more thorough lymphadenectomy is not associated with increased complication rates (188). Nodal dissection should be bilateral given the frequency of both left and right para-aortic involvement (189,190). It is interesting to note that GOG 33 only specified right-sided para-aortic removal in the surgical protocol. Likewise, the nodal dissection is more apt to be representative when a larger number of nodes are removed.

An assessment of pelvic and para-aortic LN is required to assign stage according to FIGO 2009. The 2009 staging system now separates stage subcategories based on extent of nodal disease (IIIC1, pelvic positive, IIIC2, any para-aortic positive) (89). Two principal nodal basins drain the uterus; the lower and middle portion of the uterus drains laterally to the

pelvic LN, the upper corpus and fundus drain to the para-aortic nodes. When LN are positive, para-aortic nodes are involved in ~50% of the time. Isolated para-aortic nodes with negative pelvic nodes are uncommon, particularly with grade 1 to 2 tumors, and are involved in only ~2% of cases (59,191,192). Para-aortic nodal dissection is more difficult to perform than pelvic dissection, by laparotomy or by laparoscopy, and is associated with greater risk. As such, some advocate for pelvic nodal dissections with only performing para-aortic nodal dissections selectively. In GOG 33, 46% of the positive para-aortic LN were enlarged, and 98% of the cases with aortic node metastases came from patients with positive pelvic nodes, adnexal or intra-abdominal metastases, or outer one-third myometrial invasion (59). These risk factors affected only 25% of the patients, yet they yielded most of the positive para-aortic node patients.

The importance of para-aortic nodal spread in node-positive EC cannot be ignored (Table 21.10). Data from GOG 33 showing that of all patients, isolated para-aortic nodal metastases occurred in 2% is often taken out of context (59). If the goal of nodal dissection is to identify the node-positive patient population and to remove involved nodes, para-aortic disease is seen in 40% to 66% of patients with node-positive/stage IIIC1/2 EC, including isolated positive para-aortic nodes in up to 7% to 21% of cases in certain groups. If only pelvic nodes are removed, when they are positive, para-aortic nodes will be positive in addition in nearly 30% to 40% of cases. It makes less sense to remove only pelvic or only para-aortic nodes given this data. Data would also suggest that when positive, outcomes are improved in patients who have complete surgical resection of para-aortic nodes. Chuang et al. (193) reported on their experience with selective pelvic and or para-aortic dissections and found that failure to systematically remove pelvic and para-aortic nodes resulted in an increased frequency of recurrence in undissected retroperitoneal sites. Similarly, Mariani et al. (188) showed that patients at high risk for para-aortic nodal disease (based on invasion >50%, palpable positive pelvic nodes, positive adnexa) who did not have para-aortic dissection or who had biopsy only and who were managed as though para-aortic nodes were positive had 5-year survival of 71% compared to 85% for those patients with positive para-aortic nodes who did undergo complete resection. Lymph node recurrences were detected in 37% of those not having para-aortic dissection compared to none in patients with positive but resected para-aortic nodes, suggesting a possible therapeutic effect of removing involved para-aortic nodes.

TABLE 21.10 Relationship between Pelvic and Para-Aortic Nodal Involvement in Patients with Node-Positive Endometrial Cancer

Study	N	Surgical Technique	Pelvic (1) Only (%)	Pelvic and Para-aortic (1) (%)	Para-aortic Only (%)	Any Involvement of Para-aortic Nodes (%)
Creasman 1987	70	Routine: sampling	51	31	17	48
Schorge 1996	35	Selective: lymphadenectomy	74	17	9	26

McMeekin 2001	47	Routine: lymphadenectomy	38	41	21	62
Otsuka 2002	23	Selective: systematic lymphadenectomy	66	33	10	43
Havrilesky 2005	96	Selective: lymphadenectomy	52	30	18	48

A provocative study from Japan (SEPAL study) was published in early 2010 that retrospectively compared the practices of two centers with regard to use of pelvic with or without para-aortic lymphadenectomy (194). At one center, systematic pelvic lymphadenectomy was performed in 325 patients. With a median of 34 pelvic nodes removed, the incidence of stage IIIC disease was 12%. At the second institution, 346 patients underwent pelvic and para-aortic lymphadenectomy. With a median of 59 pelvic and 23 para-aortic nodes resected, stage IIIC disease was identified in 16%. The centers were well matched for stage and tumor grade, but the center where para-aortic lymphadenectomy was performed used adjuvant CT more commonly (47% vs. 27%). Patients were classified into low-versus intermediate- to high-risk groups and outcomes were compared based on lymphadenectomy type. In the intermediate–high risk group (but not low risk), recurrence-free, DSS, and OS were significantly better in those women receiving para-aortic dissections. In a multivariate analysis, age, tumor type, nodal spread, and type of lymphadenectomy were independently associated with improved survival. The authors suggested that if future lymphadenectomy trials were to be conducted, both pelvic and para-aortic lymphadenectomy should be performed (194).

At the present time, the superior extent of para-aortic dissection should be at least to the level of the inferior mesenteric artery. Some suggest that dissections should proceed to the level of the renal vessels given the venous and lymphatic drainage following the infundibulopelvic ligament. In one series, 7 out of 11 patients had positive para-aortic nodes identified above the inferior mesenteric artery (195). The Mayo group noted that when para-aortic nodes were positive, 77% of cases had involvement above the IMA (174). This extended para-aortic dissection is feasible laparoscopically as well (196,197). Prospective data describing the frequency of high para-aortic/pararenal nodes are awaited.

The retrospective data suggesting a therapeutic benefit supports, but does not prove, the hypothesis that lymphadenectomy is therapeutic. These studies are largely from single institutions, have short follow-up, suffer from selection biases, and do not clearly account for stage migration. Despite these limitations, the therapeutic value of lymphadenectomy is supported by several reports. Kilgore et al. (198) were among the first to report a therapeutic effect of nodal dissections in a series of 649 clinical stage I–occult II patients who were classified based on the extent of nodal dissection. Patients who underwent multiple site pelvic nodal dissection (defined by nodal dissection of at least four pelvic nodal sites) and had a mean of 11 nodes removed had improved survival over those patients who did not have nodes sampled. The survival advantage for multiple site dissection persisted even when patients were stratified into low-risk (uterine-confined disease) and high-risk (extrauterine disease) groups who received radiation. An explanation for this may be the removal of unrecognized micrometastasis, which goes undetected by standard pathologic processing techniques. Girardi et al. (199) performed pelvic lymphadenectomy in 76 patients with EC (mean 37 nodes removed) and reported a 36% nodal positivity rate. Nodal tissue was processed as step serial sections and 37% of positive nodes were <2 mm in diameter, suggesting that nodal metastases may be missed in a proportion of node-positive patients processed in a less extensive manner. Others have shown improvement in outcomes following a more complete nodal dissection in node-negative populations. Cragan et al. (200) evaluated 509 stage I–IIA patients who underwent selective pelvic+/– para-aortic lymphadenectomy and found a survival advantage for patients with grade 3 tumors who had >11 pelvic nodes removed, compared to those with ≤11 nodes removed (HR 0.25). For patients with high-risk features (grade 3, >50% myometrial invasion, serous/clear cell tumors) 5-year survival was 82% when >11 nodes were removed versus 64% when ≤11 nodes were removed. Chan et al. (201) reported on the effect of a more complete nodal dissection in over 12,000 women with EC tracked in the SEER data system. In patients with high-risk disease (IB/grade 3, IC, II–IV), 5-year survival was proportional to the number of nodes removed, increasing from 75% to 87% when 1 versus >20 nodes were removed. In a multivariate analysis, a more extensive nodal assessment was an independent predictor of survival. Prospective data from the ASTEC and Italian studies suggest that there is no therapeutic benefit to resecting negative LN (155,156). The use of postoperative adjuvant therapy in patients without nodal dissection may obscure potential benefit of lymphadenectomy, making benefit difficult to measure. Likewise, patients with low-risk uterine factors may be identified with nodal disease.

In patients with positive pelvic and/or para-aortic nodes, complete resection followed by adjuvant therapy results in superior outcomes. Havrilesky reported on 91 patients with Stage IIIc disease including 39 with microscopic involvement of the LN and 52 with grossly enlarged nodes. Five-year survival was 58% for patients with microscopic LN, 48% for

those with grossly positive LN completely resected, and only 22% in cases where the nodes were not resected. The authors felt that this data suggested a therapeutic benefit for lymphadenectomy (202). Bristow evaluated 41 patients with bulky adenopathy who underwent complete resection of involved nodes. Compared with patients who had gross residual disease in LN remaining after surgery, those with resected disease had longer PFS (38 months vs. 9 months) (203). Mariani et al. (142) showed that pelvic sidewall failure at 5 years was 57% for patients who had inadequate nodal dissection and/or no adjuvant radiation compared to 10% when patients had adequate (removal >10 nodes) lymphadenectomy and received radiation. The best outcomes reported for node-positive patients follow complete nodal dissection. For example, in one series, of 30 stage IIIC patients managed with systematic pelvic and para-aortic lymphadenectomy (average number nodes removed, 66) followed by RT and CT, 5-year survival was 100% for patients with positive pelvic nodes and 75% for positive para-aortic nodes (163).

The most cogent argument for routine staging is that following thorough nodal assessment, most patients with node-negative disease can accurately be classified as low risk, and may avoid pelvic radiation or receive VCB in lieu of pelvic RT. Three randomized trials comparing radiation to observation have failed to demonstrate a survival advantage for adjuvant pelvic RT in patients with stage I–II disease, suggesting that in the absence of nodal disease no therapy is a reasonable option (144,151,204). Indeed, patients with negative nodes and low-risk uterine factors (which account for two-thirds of stage I–II EC patients) have incredibly low risk of recurrence and death (2% cancer specific death at 48 months, with or without pelvic radiation) (144). Retrospective studies have shown how the incorporation of a strategy using lymphadenectomy changes the use of postoperative radiation (122,139,145,205,206). In a SEER review of 26,043 women with EC, patients with intermediate-risk disease who underwent nodal assessment were less likely to receive external beam pelvic RT and more likely to receive vaginal brachytherapy compared to women who did not undergo nodal assessment (146). In the absence of nodal disease, recurrence risk is low and OS is high, with no radiation or with the substitution of VCB.

Alternatives to Lymphadenectomy

Given the debate as to the value of lymphadenectomy, a variety of alternative strategies have been evaluated. The concept of lymphatic mapping by sentinel LN dissection has been accepted into practice in patients with breast cancer and melanoma, and is increasingly being used in vulvar cancers. The technique uses a preoperative local injection of radioactive colloid 6 to 12 hours preoperatively followed by a lymphoscintigram, with or without an immediately preoperative injection of a colorimetric dye (isosulfan blue). The theory suggests that regional nodal spread first moves to a "sentinel" node(s) for which markers (lymphoscintigram, gamma counter, gross blue appearance of node) make apparent. By selectively resecting the sentinel node, the "at-risk node" is evaluated, but other nodes are retained *in situ*, thus reducing morbidity, length of surgery, blood loss. For sentinel mapping to be effective, reproducible techniques must be developed and validated, standard nodal processing (serial sectioning, immunohistochemical (IHC) evaluations) must be developed, and the false-negative rate must be low. Given that the pretest probability for nodal disease is low (~9%) in an all-comer population, large studies will be required to adequately evaluate sentinel node mapping.

The appropriate site of injection for colloid/blue dye is evident in vulvar cancers and cutaneous melanomas; however, there is debate on where to inject the uterus to delineate nodal drainage of the tumor. Possible sites of injection include the uterine fundus, cervix, or hysteroscopic injection of the tumor (207). As lymphatic drainage of the uterus is complex, it is unclear whether injections of the cervix mirror drainage of the uterus in general or specifically of the tumor. For example, there is discussion in the literature as to whether cervical injections may identify para-aortic sentinel nodal disease. In addition to the surgical technique, controversy exists as to the best way to process sentinel node specimens. Immunohistochemical processing to detect cytokeratin is important in that it increases the identification of micrometastatic implants, although the clinical significance of this type of disease is uncertain (208,209).

Investigators at Memorial Sloan Kettering have performed a series of sentinel node mapping surgeries on 266 patients, followed by pelvic +/− para-aortic lymphadenectomy. Using a cervical injection technique, they reported sentinel detection

was possible in 84% of cases, 12% of cases had positive nodal disease, and metastatic cells were three times more likely in sentinel nodes than in non-sentinel nodes (210). In a meta-analysis of 26 series on sentinel node dissection, Kang estimated that the detection rate for sentinel nodes was 78% and the sensitivity was 93%. In a disease where baseline rates of nodal involvement are roughly 10%, this translates to a ~1% false-negative rate (211). As most of the series in the meta-analysis included small numbers of patients, the authors cautioned against routine substitution of sentinel nodal mapping for lymphadenectomy based on the current data.

Minimally Invasive Surgery for EC

After several years of debate and discussion, minimally invasive techniques have been integrated into the management of EC as a standard of care. Techniques utilized in the initial treatment of EC include LAVH, total laparoscopic hysterectomy (TLH), and robotic hysterectomy with concomitant salpingo-oophorectomy and pelvic and para-aortic nodal dissection to stage patients. Minimally invasive staging techniques include transperitoneal and extraperitoneal assessment of nodes and may be done at the time of hysterectomy or at a later time to restage patients following incomplete surgical staging. The decade of the 1990s advanced the use of minimally invasive surgery and introduced the laparoscopic techniques and tools required for comprehensive surgical staging of EC. As the initial debate on LAVH focused on whether laparoscopic techniques could be substituted for abdominal ones, in EC, debate has focused on whether laparoscopic surgical staging could be substituted for open procedures. Initial case reports and small single institutional series describing technique and demonstrating feasibility were replaced by large series, small randomized trials, and subsequently, multi-institutional randomized controlled trials (168,212-220).

Improvements in laparoscopic equipment facilitated the development of LAVH. Building on that experience, and coupled with the introduction of better optics for visualization, laparoscopic resection of LN became possible. Querleu et al. (221) were the first to report pelvic lymphadenectomy for cervical cancer in 1991, followed by Nezhat et al. (222) who reported in 1992 on the use of laparoscopic pelvic and para-aortic lymphadenectomy with radical hysterectomy in cervical cancer. When first utilized in EC, laparoscopic para-aortic node dissection only evaluated right-sided nodes (212). Techniques have subsequently been developed allowing for dissection to include the left para-aortic nodes, and facilitate extraperitoneal approaches. (196,197,223-225).

Childers et al. (212,213) described the initial experience of LAVH in 59 patients with clinical stage I endometrial carcinoma. Laparoscopic pelvic and right-sided aortic LN samplings were performed in patients with grade 2 or 3 lesions, or with grade 1 lesions, and greater than 50% myometrial invasion on frozen section. For the group, the mean weight was 153 pounds, and in two patients, laparoscopic lymphadenectomy was precluded by obesity. Six patients underwent conversion to an open procedure because of intraperitoneal disease, and two patients required laparotomy to manage complications, including a transected ureter and a cystotomy. The mean hospital stay was 2.9 days. Since that time many retrospective series have appeared in the literature describing techniques and presumed advantages (226-229). In general, mean operating times were longer for laparoscopy, but the overall complication rates, length of stay, and hospital charges were lower. With short follow-ups, there was no significant difference in disease recurrence between the two groups.

Prospective data has also emerged. A small prospective, randomized trial comparing laparoscopic-assisted vaginal versus abdominal surgery in patients with EC was reported by Malur et al. (217). They randomized 70 patients with EC FIGO stage I–III to laparoscopy-assisted simple or radical vaginal hysterectomy or simple or radical abdominal hysterectomy with or without LN resection. Blood loss and transfusion rates were significantly lower in the laparoscopic group. The number of pelvic and para-aortic LN, duration of surgery, and incidence of postoperative complications were similar for both groups. No significant differences in disease recurrence rate and long-term survival were found between the laparoscopic and laparotomy groups (97.3% vs. 93.3% and 83.9% vs. 90.9% for stages I, II, and III, respectively). Malzoni and colleagues reported on a 159-patient trial comparing TLH to TAH with lymphadenectomy. The authors reported less blood loss, shorter hospitalization, and less common ileus with TLH. Operative time was longer (136 minutes vs. 123 minutes) with TLH, but there was no difference in number of nodes removed, frequency of stage IIIC disease,

ability to do para-aortic dissection, or in recurrence. The LACE trial compared TLH (n = 190) to TAH (n = 142) in 332 patients with stage I EC (with or without lymphadenectomy) (168).The preliminary report designed to specifically assess quality-of-life end points showed that 2.4% of laparoscopic cases required conversion to an open approach, operating time for TLH on average was 30 minutes longer, grade 3 to 4 adverse events were more frequent (23% vs. 12%) in the TAH groups, and quality-of-life assessments favored TLH for up to 6 months post surgery. Concurrent LN assessment was more common with TAH versus TLH (68% vs. 41%), and ~20% of patients participating in the study received some form of adjuvant therapy (CT, RT, or both).

The largest and most comprehensive dataset to date comes from the large prospective, randomized trial conducted by the GOG (Lap II trial) (220). The study was designed to compare laparoscopic hysterectomy with comprehensive surgical staging to the traditional laparotomy technique (using a 2:1 randomization favoring the laparoscopic arm) to determine the complete staging rates, safety, short-term surgical outcomes, and long-term cancer recurrence and survival. The study enrolled 920 patients to the open arm and 1,696 patients to laparoscopy. The rate of conversion from laparoscopy to open procedure was 26%, and was most frequently related to poor visibility (15%), extrauterine cancer spread (4%), and bleeding (3%). The conversion rate increased with increasing patient obesity, with the laparoscopic success rate being 90% with a body mass index (BMI) <20, 65% with BMI = 35, and 34% with BMI = 50. Median number of removed nodes was similar between each technique as were the frequencies of patients found to have positive LN. Complication rates (combined rates of vascular, urinary, bowel, nerve, or other complications) for those who had an open procedure were 7.6%, compared to 9.5% of patients randomized to laparoscopy. Of the 1,242 patients randomized to laparoscopy who had the procedure successfully completed laparoscopically, the complication rate was 4.9%. Comparing patients who underwent open surgery versus successful completion of laparoscopy, operative time was longer (median 70 minutes), but hospital time was shorter (2 days vs. 4 days) with laparoscopy. Postoperative arrhythmia, pneumonia, ileus, antibiotic use, and any complications > grade 2 were lower in the laparoscopic group. The authors concluded that laparoscopic surgical staging is an acceptable and possibly a better option, particularly when the surgery can be successfully completed laparoscopically.

Results of long-term survival in laparoscopically treated compared to laparotomy-treated EC patients suggest comparable outcomes. Tozzi reporting on the first prospective trial (n = 122 patients) reported DFS of 91% with LAVH and 94% with laparotomy, with survival of 86% versus 90%, respectively (230). In a subsequent evaluation of recurrence and survival data from the GOG LAP 2 trial published in 2012, 3-year recurrence rates were 11.4% with laparoscopy versus 10.2% with open surgery, and 5-year survival was 90% in each arm (231).

Age and obesity have been suggested as relative contraindications to laparoscopic surgery. In the GOG Lap II trial, the median age was 63 years. Scribner et al. (232) evaluated the surgical experience of uterine cancer patients with age ≥65 years who underwent LAVH with pelvic and para-aortic lymphadenectomy (n = 67) or abdominal hysterectomy with pelvic and para-aortic lymphadenectomy (n = 45). Laparoscopic staging could be completed in 78% of patients. In the laparoscopic group, the BMI was 29.5 kg/m^2 (range, 15.9 to 54.7), and 33% had a history of prior laparotomy. For the 22% of patients who required a conversion to laparotomy, obesity (10%), bleeding (6%), and intraperitoneal disease (5%) were the most frequent reasons. Similar nodal counts (29 laparoscopic, 29 open) were noted, the operative time was longer (236 minutes vs. 148 minutes), and hospital stay was shorter (median 3 days vs. 5.6 days) with laparoscopy. The authors concluded that with the anticipated growth of an aging patient population, laparoscopic management is a viable option.

It has been suggested that obese patients are poor laparoscopic candidates because of difficulties in establishing pneumoperitoneum, poorer visualization, inability to tolerate the steep Trendelenburg positioning needed to facilitate the surgery, and difficulties with ventilation. In the report by Childers et al., (212,213) mean patient weight was only 153 pounds. It is important to recognize that regardless of surgical approach, complete surgical staging is more difficult in an obese patient. Scribner et al. (233) compared 55 obese patients (median weight 96.6 kg, median BMI 40) who underwent LAVH with pelvic and para-aortic lymphadenectomy to 45 patients (median weight 101 kg, median BMI 39) who had abdominal hysterectomy with pelvic and para-aortic lymphadenectomy. Successful completion of laparoscopy was

possible in 64%, with patients with a BMI <35 kg/m^2 having an 82% success rate compared to 44% when the BMI was >35 kg/m^2. Eltabbakh et al. (234) evaluated 40 women with BMI between 28 and 60 years who were treated with LAVH and compared them to 40 similar women treated by abdominal approach. Laparoscopic conversion was only required in 8% of patients. Laparoscopic surgery was associated with a longer operative time (195 minutes vs. 138 minutes), but more pelvic nodes (mean 11 vs. 5), less pain medicine requirement, and shorter hospital stay (2.5 days vs. 5.6 days) were recorded. TLH has also demonstrated feasibility in heavier patients (235). In the prospective GOG series, there was ≥80% success rate with patients with a BMI of 27 or less, but even at a BMI of 35, 65% were able have successful laparoscopic surgery (220).

Robotic surgery may represent the next step forward in minimally invasive surgery. Since FDA approval for hysterectomy and myomectomy procedures in 2005, there has been an increasing utilization of robotic surgery within gynecologic oncology. To date, greater than 15 series ranging in size from 4 to 405 patients have described robotic experience or compared outcomes to laparoscopy and/or open procedures (Table 21.11) (236-242). The proposed advantages of robotic surgery include improved visualization with 3-D optics, "wrist-like" motion of instruments allowing greater dexterity, reduction in tremor, easier learning curve for adoption compared to straight-stick laparoscopy and more comfortable ergonomics. Published data suggest comparable outcomes with respect to blood loss, nodal counts, and operative time compared to laparoscopy. Mean nodal counts and operative complications are comparable to laparoscopy, with several series suggesting lower postoperative complications compared to open surgery. As with new surgical techniques, there is a learning curve through which additional experience leads to quicker operative times and higher nodal retrieval rates. The Ohio State group has suggested that 20 procedures are required for proficiency (243).

TABLE 21.11 Selected Robotic Surgery Series in EC

Study	N (Robot Cases)	Type of Study	Procedure	OR Time (min) (Mean/Median)	# Nodes(Mean/Median)
Boggess-2008	103	Compare to LSC + Open	Hyst + PPALND	191	33

EC, Endometrial Cancer; hyst, hysterectomy; LND, lymph node dissection unspecified; LSC, Laparoscopic; open, laparotomy; PPALND, Pelvic, para-aortic lymph node dissection.

Robotic surgery may offer unique opportunities for obese patients (244,245). Several series suggest that robotics may overcome some of the challenges of laparoscopy and may reduce the morbidity associated with open cases. Seamon and colleagues reported that in a series of 109 obese patients (mean BMI 40) treated by robotic hysterectomy and staging, the conversion rate was 16%. (244) The 92 patients successfully treated by robotic platform were compared to a matched cohort of 162 laparotomy patients. Total nodal counts (~24 nodes each group) and frequency of adequate lymphadenectomy (defined as at least 10 nodes removed) were similar in both groups, but blood transfusion rate, hospital stay, complications, and wound problems were reduced with robotic surgery.

Arguments have been advanced for and against each of the surgical approaches to EC. Vaginal hysterectomy was once a favored operation, but it did not allow for routine removal of the ovaries in some patients. It also did not permit for surgical resection of LN, inspection of the peritoneal cavity or the retroperitoneum for metastatic disease, or collection of peritoneal fluid for cytology (246). Laparoscopic-assisted or total laparoscopic approaches overcome these limitations, however. Compared to open procedures, LAVH/TLH are thought to lead to reduced incisional complications, wound infections, ileus, hospital stay, cost, and improved rate of recovery and quality of life (220,221,247). Data from prospective studies also showed that short-term (6 weeks to 6 months) patient-assessed quality-of-life assessments favor minimally invasive surgery (247). In patients requiring postoperative radiation, laparoscopic surgical staging followed by RT is suggested to result in fewer bowel adhesions and radiation-induced bowel injuries (226). Criticisms of LAVH/TLH with laparoscopic nodal dissection relate to the learning curve required to master new or unfamiliar procedures, the increased length of operative times, and concerns about the adequacy of the nodal dissection. Studies do suggest that with increased experience, operative times decrease and nodal counts increase (223,227). Laparoscopy also introduced different procedure-related complications (228,229). Rarely, the technique has been associated with port-site recurrences or intraperitoneal dissemination of disease by laparoscopic gas and/or uterine manipulation.

Whether a minimally invasive procedure is comparable to an open approach must be judged by the ability to accurately dissect appropriate nodal basins, to remove an adequate/representative number of LN, to identify metastatic disease, and by the rates of recurrence. The technique used to remove the uterus/ovaries is not the source of controversy, although TLH and robotic hysterectomy may facilitate removal of larger uteri or assist in cases with poor descensus compared to LAVH. Comprehensive surgical staging allows for appropriate risk stratification to make appropriate treatment recommendations. Multiple reports demonstrated similar node counts for open, laparoscopic, and robotic techniques in the surgical staging of EC (229,236). In the GOG Lap II trial, median numbers of nodes from pelvic and para-aortic basins, and frequencies of positive nodes were comparable in the surgical arms (220). If laparoscopic nodal dissection cannot be performed, conversion to laparotomy is advised to yield inadequate information for treatment planning.

Minimally invasive surgery must be performed with an acceptable complication rate in order to be considered a viable option. In one series reporting on complication rates with an institution's first 100 pelvic and para-aortic nodal dissections, conversion to manage complications was required in 5 to control bleeding, and 1 to repair a ureteral injury (248). In another group's experience with 150 patients, seven major vascular injuries were reported, but only 4 patients required laparotomy (249). Querleu et al. (250) reported on intraoperative and postoperative complications of laparoscopic node dissection from 1,192 pelvic and para-aortic nodal dissections. Only 13 open procedures were required to complete the nodal dissections, and a laparotomy was required in 7 cases to manage complications. Eleven intraoperative vascular injuries were noted, but none required management by laparotomy. In the GOG Lap 2 study, intraoperative complications were comparable (7.6% open, 9.5% randomized to laparoscopy, 4.9% successful completion of laparoscopy) (220). Postoperative complications and short-term quality-of-life improvements favored laparoscopy. A meta-analysis of robotic studies for gynecologic conditions noted that for endometrial series, robotic surgery was associated with less blood loss and less frequent conversions to open procedure compared to laparoscopy.

Restaging

One of the more useful roles of minimally invasive surgery is in restaging patients who underwent hysterectomy only. Patients who undergo hysterectomy without nodal dissection and who have pathologic risk factors for potential nodal spread face a difficult dilemma. Patients may elect to receive radiation or chemotherapy (presuming nodes are positive), elect observation (presuming nodes are negative), or undergo a second operation. A second laparotomy can be difficult to accept. Laparoscopic staging offers a less invasive option for collecting information. Childers et al. (251) reported the initial experience with restaging in 13 patients, finding disease in 3 patients.

Recommendations for Minimally Invasive Surgery

Standard of care today includes minimally invasive surgery in the management of EC. Additional training and experience are required for successful completion of these procedures, just as they are with open procedures. The demonstration of comparable surgical end points (similar numbers of nodes removed, similar frequency of positive nodes, recurrence rates, and survival) along with shortened hospital stays, quicker recovery, and better quality-of-life indicators compared to open procedures suggest that appropriate patients should be counseled regarding this option. Challenges remain on how to increase the minimally invasive training of gynecologic oncologists in practice and fellows in training programs. As with open procedures, defining populations that should be considered for nodal assessment and for postoperative therapies continues to be an important research focus.

Surgical Management of Intraperitoneal Disease

The management of patients with bulky stage III or stage IV disease depends on the ability to resect disease. In patients with distant metastasis, there may be a limited role for surgery such as to provide control of vaginal bleeding. In patients with intraperitoneal disease, options include resecting easily removable disease (uterus, adnexa, omentum) versus a more extensive cytoreductive effort. The value of extensive cytoreductive surgery in EC has not been as well studied as it has in ovarian cancer. Historically, limitations in postoperative therapies (lack of enthusiasm for whole abdominal radiation, marginally effective CT regimens, reliance on hormonal therapy) perhaps reduced interest. Several retrospective reports suggest that survival correlates with volume of residual disease (252-254). Shih et al. (255) reported on 58 patients with stage IV endometrioid disease treated from 1977 to 2003, of whom 9 had no gross residual, 11 had <1 cm residual, and 32 had residual >1 cm. The median survival for the entire population group was 19 months; however, median survival was 42 months for patients with no gross residual disease. In a multivariate analysis of the data, residual disease and the use of postoperative adjuvant CT were independently associated with survival. Bristow et al. (254) demonstrated that optimal cytoreduction (<1 cm) could be obtained in 55% of stage IV patients and required omentectomy (93%), peritoneal stripping (65%), and bowel resection (29%) to do it. In patients with serous histology, similar survival improvements were seen with optimal debulking of intraperitoneal disease (256).

Surgical Recommendations

The contemporary management of EC has significantly changed. We believe that patients must be appropriately counseled with regard to the presumed benefits of lymphadenectomy as well as the potential risks. Data for the ASTEC and Italian lymphadenectomy trials cast doubt as to the benefit of resecting negative nodes, but both studies clearly demonstrate that nodal disease cannot be found unless one searches for it. The clinician is challenged with finding the “needle in the haystack” in a disease where the baseline rate of nodal metastasis in ～9%. The marginal benefit achieved by lymphadenectomy and the downstream costs associated with or without its use in terms of adjuvant therapy, outcomes, and quality of life need to be better defined so that patients and physicians can make choices based on good information. Clinical pathologic models that define low-risk populations for whom lymphadenectomy may be safely omitted appear promising, but must be validated prospectively in large series. In the future, biomarker-based testing or sentinel nodal assessment may serve as an alternative to lymphadenectomy, but cannot be routinely recommended at this point because the data is immature. Increasing the proportion of patients who undergo minimally invasive surgery to manage EC is an important goal and driven by the data. Patients who *a priori* are deemed not to be candidates for staging should be considered for vaginal or minimally invasive hysterectomies. Surgical therapy for EC removes the disease and defines populations at risk for recurrence and death. Surgical staging, or the lack of it, defines patient groups as surgically staged node-positive or -negative, or unstaged. Comprehensive staging most accurately assigns stage and associated prognosis, although the magnitude of the risk assignment is tempered by the frequency of positive nodes, uterine risk factors, and use of adjuvant therapy. Staging also allows for a more tailored approach to the use of adjuvant therapies. For patients with

resectable intraperitoneal disease, cytoreductive surgery can result in optimal volumes of residual disease, and perhaps improved outcomes.

PATHOLOGY

Hyperplasia

The current classification of endometrial hyperplasia accepted by both the International Society of Gynecologic Pathologists (ISGP) and the World Health Organization (WHO) is based on the schema of Kurman and Norris (257), which divides hyperplasia on the basis of architectural features into simple or complex and on the basis of cytologic features into typical or atypical (Table 21.12). The resulting classification has four categories as follows: *simple hyperplasia* (SH), *complex hyperplasia* (CH), *simple atypical hyperplasia* (SAH), and *complex atypical hyperplasia* (CAH). Simple hyperplasia is defined as an increase in the number of endometrial glands, which may be dilated with little crowding or have an irregular outline and exhibit crowding. Complex hyperplasia is characterized by glands with irregular outlines, marked structural complexity, and back-to-back crowding. The designation "atypical hyperplasia" is used to denote a proliferation of glands exhibiting cytologic atypia, recognized as nuclear enlargement, the presence of nucleoli, or a change from an elongated to a more ovoid or round nucleus. The chromatin may be either evenly or irregularly dispersed. The justification for this classification system rests on three retrospective studies that demonstrate a higher rate of progression of CAH to adenocarcinoma (257-259). It is sometimes difficult to apply this system, which requires one to make a distinction between cytologically atypical nuclei and those without atypical nuclei, because a spectrum of nuclear variability actually exists. As noted by Kendall et al. (260), the definitions of architectural complexity and nuclear atypia potentially rest on a multitude of criteria, and some but not all criteria may be fully developed in any given case.

TABLE 21.12 Classification of Endometrial Hyperplasia

Types of Hyperplasia	Progressing to Cancer (%)
Simple (cystic without atypia)	1
Complex (adenomatous without atypia)	3
Atypical	
Simple (cystic with atypia)	8
Complex (adenomatous with atypia)	29

Several reports have addressed the reproducibility of diagnoses of hyperplasia (260-262). Intra-observer reproducibility was generally found to be moderate to good, whereas interobserver reproducibility was poor to moderate for various diagnostic categories. These studies probably overestimate the interobserver reproducibility because they used expert gynecologic pathologists and specified the classification to be used. In a prospective study by the GOG, neither community-based nor expert panel diagnosis of atypical hyperplasia was highly accurate (72). The current classification of hyperplasia relies on a combination of multiple architectural and cytologic criteria. It is hardly surprising that interobserver reproducibility is relatively low when multiple criteria are used to classify a lesion, because each pathologist must assign a relative value or weight to each potentially conflicting criterion. Other factors contributing to low reproducibility include (a) the fragmentary nature of curettings, (b) the presence of borderline lesions, (c) uncertainty about the significance of focal hyperplasia, (d) the inadequacy of published descriptions and understanding of terms used to define architectural or cytologic atypia, and (e) the difficulty associated with the translation of verbal descriptions into light microscopic interobserver reproducibility for images.

The gross manifestations of endometrial hyperplasia are highly varied. The endometrium is often of diffusely increased

thickness (5 mm to 10 mm or greater), vaguely nodular, tan, and soft without hemorrhage or necrosis. However, hyperplasia may be focal or multifocal in a background of polyps or cycling endometrium, or occasionally associated with a diffusely thin endometrial lining. Part of the variability may reflect a reduction in the ET because of prior endometrial sampling. Coexistent adenocarcinoma is present in 1% to 40% of hysterectomies performed to treat hyperplasia, with the latter number reflecting the frequent co-occurrence of carcinoma with atypical CH.

Endometrial Intraepithelial Neoplasia

On the basis of a combination of morphologic, molecular, and morphometric information, Mutter et al. have proposed an alternative classification scheme to replace the current WHO hyperplasia terminology (263-266). They have presented data that endometrial intraepithelial neoplasia (EIN) is the histopathologic presentation of a monoclonal endometrial preinvasive glandular proliferation that is the immediate pathologic precursor of endometrioid endometrial adenocarcinoma. Monoclonality and forward carryover of EIN mutations into subsequent carcinoma were the original molecular standards used for EIN diagnosis. Computer-assisted morphometric analysis of more than 20 features was carried out initially and the three features seen in molecularly defined precancers enabled an objective delineation of histologic diagnostic criteria (the D-score). The principal components assessed included a reduction in the volume of stroma, an increased variability in nuclear shape gland contour. Several of these features have been translated to characteristics that can be assessed subjectively by the surgical pathologist (Fig. 21.3). These features include the following: (a) the area of the glands exceeds that of stroma; (b) nuclear and cytoplasmic features of the affected glandular cells differ from those of the background glands, and may include loss of nuclear polarity or increased nuclear pleomorphism; in the absence of any background glands, a highly abnormal cytology is sufficient; (c) the maximum diameter exceeds 1 mm; (d) benign conditions including disordered proliferation, polyps, and repair are excluded; and (e) the cribriform or maze-like pattern of carcinoma is excluded. There is a high degree of concordance between EIN diagnoses rendered by computer and those made subjectively by pathologists, and either has superior cancer predictive value when compared to the 14-fold increased cancer risk conferred by the presence of atypia compared to lack thereof in the WHO hyperplasia schema. Clinical outcome studies have shown that almost 40% of women with an EIN diagnosis will be diagnosed with EC within 1 year and, and for those who do not develop cancer within 12 months, a 45-fold increased risk of future EC exists. Correspondingly, absence of an EIN lesion in an initial representative biopsy, including those with only benign hyperplasia, confers very high (99%) negative predictive value for concomitant or future adenocarcinoma.

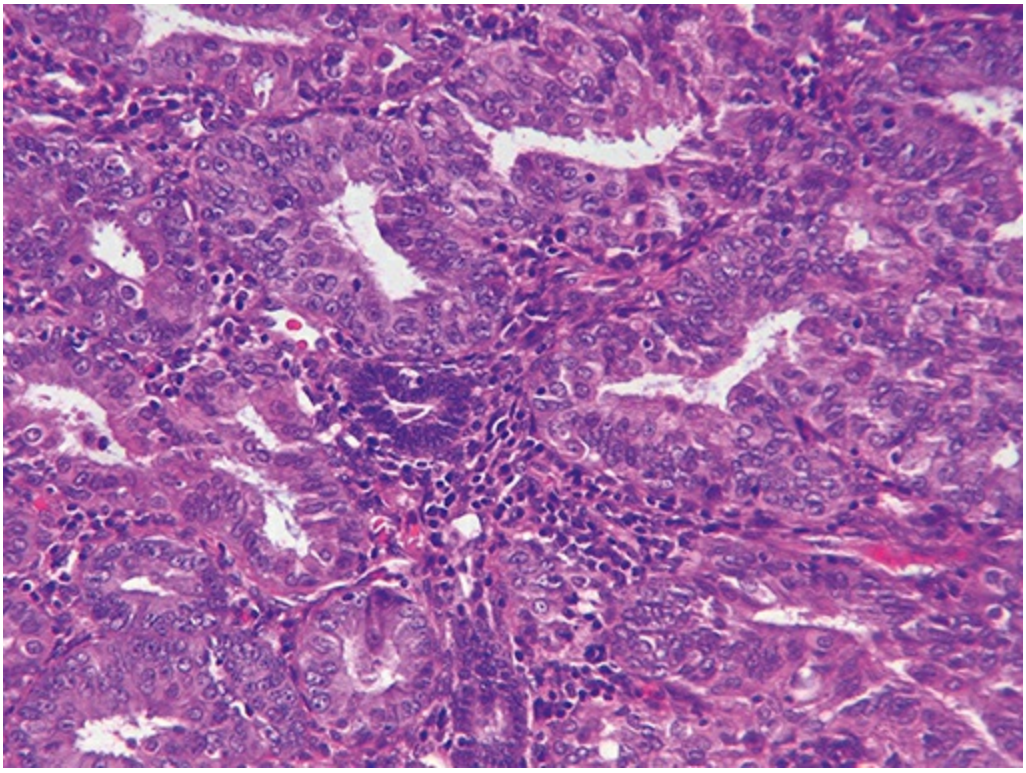

Figure 21.3 A lesion that could be classified in two different systems as either EIN or CAH based on gland crowding and cytologic atypia. Note the presence of a residual inactive endometrial gland that may be used as a reference for estimating cytologic atypia.

Although EIN shares many features with atypical CH, the two entities are not entirely overlapping. The concept of EIN is appealing because there appears to be a strong biologic basis, with EIN representing a clonal process, whereas disordered proliferation and hyperplasia remain as diffuse endometrial physiologic responses to an abnormal stimulus (unopposed estrogen stimulation).

Simple Hyperplasia

In SH, the endometrium is thicker than usual, with dilated glands that have outpouchings and invaginations, producing an irregular outline to the enlarged glands. The glands are crowded, the stroma is more densely cellular than usual, and some foam cells may exist within the stroma. Follow-up of patients with this condition reveals little or no progression to carcinoma.

Complex Hyperplasia

The endometrium is increased in thickness by back-to-back glands in cases of CH. Most glands have irregular outlines. The two main features differentiating this from SH is the high ratio of glands to stroma, with some back-to-back glands that have very little intervening stroma. Epithelial stratification is a frequent finding, producing an appearance of two to four cell layers. Mitotic activity is highly variable, but may range to up to 10 mitotic figures per 10 high-power fields.

Atypical Hyperplasia

Atypical hyperplasia is characterized by cytologic atypia of the glands, which may vary unpredictably according to

vagaries of histologic preparation. The architecture may reflect simple or CH, although it is usually complex. The cells lining the glands display nuclear hyperchromatism and nuclear enlargement, and have an increased nucleus–cytoplasm ratio. Nuclei are irregular in size and shape and have a thickened nuclear membrane, inconspicuous to prominent nucleoli, and a coarse chromatin texture. At times, the nuclei may appear clear with scattered, coarse chromatin clumps.

Progression from Hyperplasia to Cancer

The natural history of endometrial hyperplasia is difficult to define for a variety of reasons, four of which follow: (a) pathologic criteria—criteria and terminology for the various forms of hyperplasia have changed repeatedly; (b) initial sampling—the method of initial diagnosis is often curettage, which removes part or all of the lesion to be studied; (c) coexisting lesions—other lesions such as adenocarcinoma may coexist at the time of diagnosis without our knowledge, since the curettage or biopsy samples only a minority of the endometrium; and (d) subsequent intervention—hormonal or surgical intervention usually interrupts observations of the natural history of the hyperplasia. Nevertheless, there are reasonably good data to support the following assertions: (a) endometrial hyperplasia is commonly a consequence of unopposed prolonged estrogen stimulation; (b) some hyperplasias may regress if the estrogenic stimulus is removed or in response to progestational or antiestrogenic treatment; (c) some hyperplasias coexist with, or progress to, invasive adenocarcinoma; and (d) the probability of progression to adenocarcinoma is related to the degree of architectural or cytologic atypia. Progression from hyperplasia to carcinoma occurs in only 1% of patients with SH and in 3% of patients with CH (71). Progression from atypical hyperplasia is much higher; 8% of patients with SAH and 29% of those with CAH develop carcinoma (Table 21.12) (71,257). Glandular complexity superimposed on atypia probably places the patient at greater risk than does cytologic atypia alone, but the point is unsettled.

Pathologic Diagnosis

The ISGP and the WHO last revised the classification of uterine tumors in 2003 (267), and the portion pertaining to carcinomas of the endometrium is presented in Table 21.13. This relatively simple classification scheme accommodates the vast majority of ECs and distinguishes among neoplasms of significantly different prognosis. Mixed carcinomas with two distinctive cell types are relatively common, and are defined as those carcinomas in which the secondary component constitutes at least 10% of the neoplasm.

Mixed types
Miscellaneous carcinomas

In most endometrial samples, the distinction of adenocarcinoma from hyperplasia is straightforward. However, a small fraction of problematic cases with complex proliferations truly tax the abilities of experts as well as novices to classify them correctly. The diagnosis of a well-differentiated adenocarcinoma is made in the presence of any of the following criteria: (a) irregular infiltration of glands in an altered fibroblastic stroma, (b) a confluent glandular pattern that results in either a cribriform arrangement or confluent interconnected glands, or (c) extensive papillary growth of epithelium and stroma into glandular lumina (257).

Histologic Grade

The differentiation of a carcinoma is expressed as its grade. Grade 1 lesions are well differentiated and are generally associated with a good prognosis. Grade 2 tumors (Fig. 21.4) are moderately well-differentiated and have an intermediate prognosis, and grade 3 reflects poorly differentiated lesions, which frequently have a poor prognosis. Both architectural criteria and nuclear grade are used in the FIGO and ISGP–WHO committee (268) classification of tumors and are applied to endometrioid cell types including variants and mucinous carcinomas (Table 21.13). In contrast, serous, clear cell, and undifferentiated carcinomas are considered high-grade by definition, and are not graded numerically. The architectural grade is determined as follows: grade 1—an adenocarcinoma in which less than 5% of the tumor growth is in solid sheets; grade 2—an adenocarcinoma in which 6% to 50% of the neoplasm is arranged in solid sheets of neoplastic cells; grade 3—an adenocarcinoma in which greater than 50% of the neoplastic cells are in solid masses. Regions of squamous differentiation are excluded from this assessment. The FIGO rules for grading state that notable nuclear atypia, inappropriate for architectural grade, raises the grade of a grade 1 or grade 2 tumor by one. However, FIGO did not define notable nuclear atypia. Justification and clarification for this modification based on extreme nuclear pleomorphism were provided in a recent GOG study. For 715 women with nonserous ECs, three nuclear grades were defined as follows: grade 1—round-to-oval nuclei with even distribution of chromatin and inconspicuous nucleoli; grade 2—irregular, oval nuclei with chromatin clumping and moderate-size nucleoli; and grade 3—large, pleomorphic nuclei with coarse chromatin and large, irregular nucleoli. Patients with tumors of architectural grade 1 or 2, but with a majority of cells having nuclei of grade 3, had a significantly worse behavior, justifying an upgrading by one grade (269).

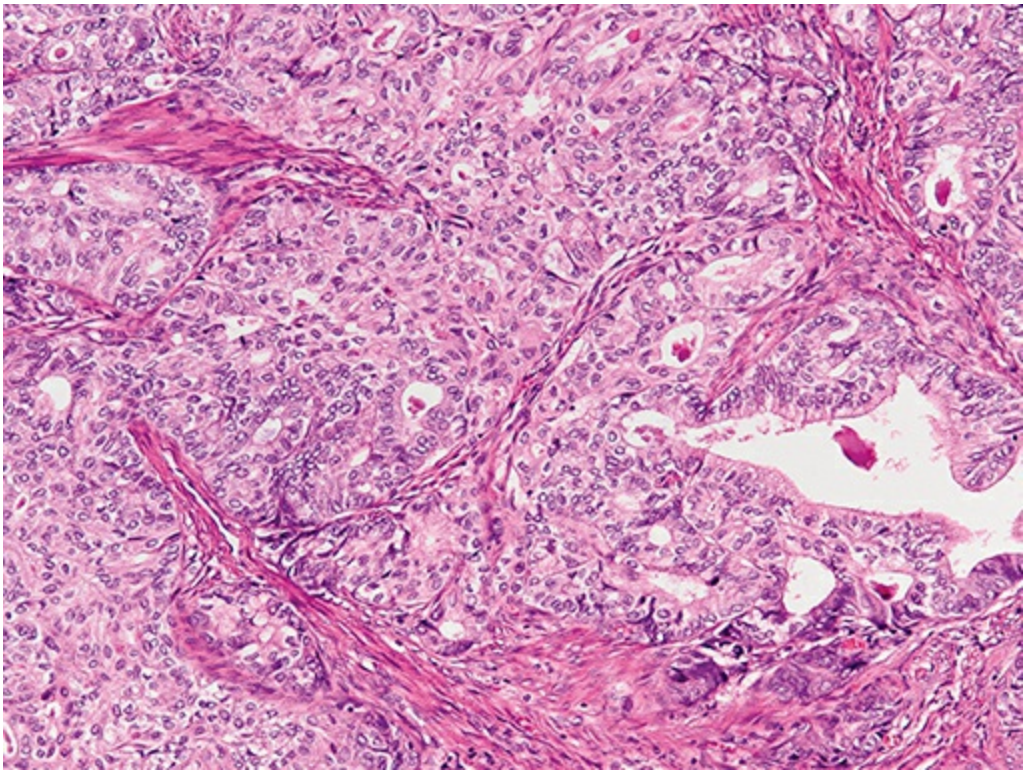

Figure 21.4 Endometrioid adenocarcinoma, grade 2. The glandular component is a caricature of proliferative phase glands, with stratification and a shared luminal border to the neoplastic cells. In grade 2 carcinomas, regions of solid neoplastic growth occupy between 5% and 50% of the surface area of the carcinoma.

Taylor et al. (270) proposed a two-tiered system for grading endometrial carcinoma based on a study of 85 patients with stage I and II EC. They divided tumors at 10% intervals based on the percentage of solid tumor growth, and found that tumor recurrences were confined to the subset with greater than 20% solid tumor. They also found that this binary division yielded a higher degree of interobserver agreement than three architectural grades. Lax et al. (271) have presented preliminary data on a binary architectural grading system based on the presence of greater than 50% solid growth, a diffusely infiltrative growth pattern, and tumor cell necrosis. These methods will have to be replicated in a larger patient population before an assessment of their prognostic utility can be made.

Cell Types

Endometrioid Adenocarcinoma

Endometrioid adenocarcinoma is the most common form of carcinoma of the endometrium, comprising 75% to 80% of the cases (59,272). It varies from well differentiated to undifferentiated. Characteristically, the glands of endometrioid adenocarcinoma are formed of tall columnar cells that share a common apical border, resulting in a smoothly delineated, round or oval luminal contour. With decreasing differentiation, there is a preponderance of solid growth rather than gland formation, and the cells lining glandular lumina become more numerous but not necessarily clearly stratified. Stromal invasion manifested by a desmoplastic host response or vascular invasion is often not evident in the biopsy or curettage specimen.

Villoglandular Carcinoma

There has been considerable confusion about the definition and significance of papillary carcinoma of the endometrium. A

variety of cell types of endometrial adenocarcinoma with differing biologic behavior, including serous, clear cell, mucinous, and villoglandular carcinoma, may grow in a papillary fashion. Thus, the adjective *papillary* does not represent a cell type but rather an architectural pattern (272,273).

Villoglandular carcinoma is a relatively common subtype of endometrioid adenocarcinoma characterized by neoplastic columnar cells covering delicate fibrovascular cores. The apical cytoplasmic borders are straight, the nuclei are usually low-grade, and the tumor cells architecturally resemble those of other endometrioid adenocarcinomas, with which they are often admixed. In the largest study to date, villoglandular carcinomas were better differentiated than ECs, but the age at diagnosis, depth of myometrial invasion, nodal spread, and survival were similar to those of ECs, justifying their classification as a subtype of endometrioid adenocarcinoma (274).

Secretory Carcinoma

Secretory carcinoma is a variant of EC, but it is unusual and represents no more than 2% of the cases (275,276). It is identified by its well-differentiated glandular pattern, consisting of columnar epithelial cells containing intracytoplasmic vacuoles similar to secretory endometrium. It is usually grade 1 architecturally and by nuclear features. There is minimal cellular atypia, stratification, and pleomorphism. The intracellular secretions are not mucin but glycogen. The cellular features of secretory carcinoma differentiate it from clear cell carcinoma, which is more papillary with more pleomorphic nuclei. By its lack of mucin, secretory carcinoma may be differentiated from mucinous carcinoma. Recognition of secretory carcinoma is important because it has a less virulent clinical course (276,277), although the clinical profile of patients is similar to that of patients with adenocarcinoma.

Ciliated Carcinoma

Ciliated carcinoma is rare. Ciliated cells are more commonly identified in endometrial hyperplasia and in benign metaplasia (tubal metaplasia), but they may occur in ECs. Associated with prior exogenous estrogen use, this cell type is reported to have a good prognosis (278).

Adenocarcinoma with Squamous Differentiation

Foci of squamous differentiation are found in about 10% to 25% of endometrial adenocarcinomas (Fig. 21.5). Historically, the tumors were sometimes separated into adenoacanthoma or adenosquamous carcinoma based on whether the squamous component appeared histologically benign or malignant (279-283). However, in about 30% of cases, the squamous component is not clearly benign or malignant. In a GOG study of early-stage disease, it was noted that these tumors with squamous regions behave in a fashion similar to ECs without squamous differentiation (284). The squamous areas usually mirror the degree of differentiation, which, coupled with assessment of histologic grade and other conventional prognostic factors, is thus more useful for prognostication and determination of adjuvant therapy than the historic terms *adenoacanthoma* and *adenosquamous carcinoma*, which are confusing and should be abandoned.

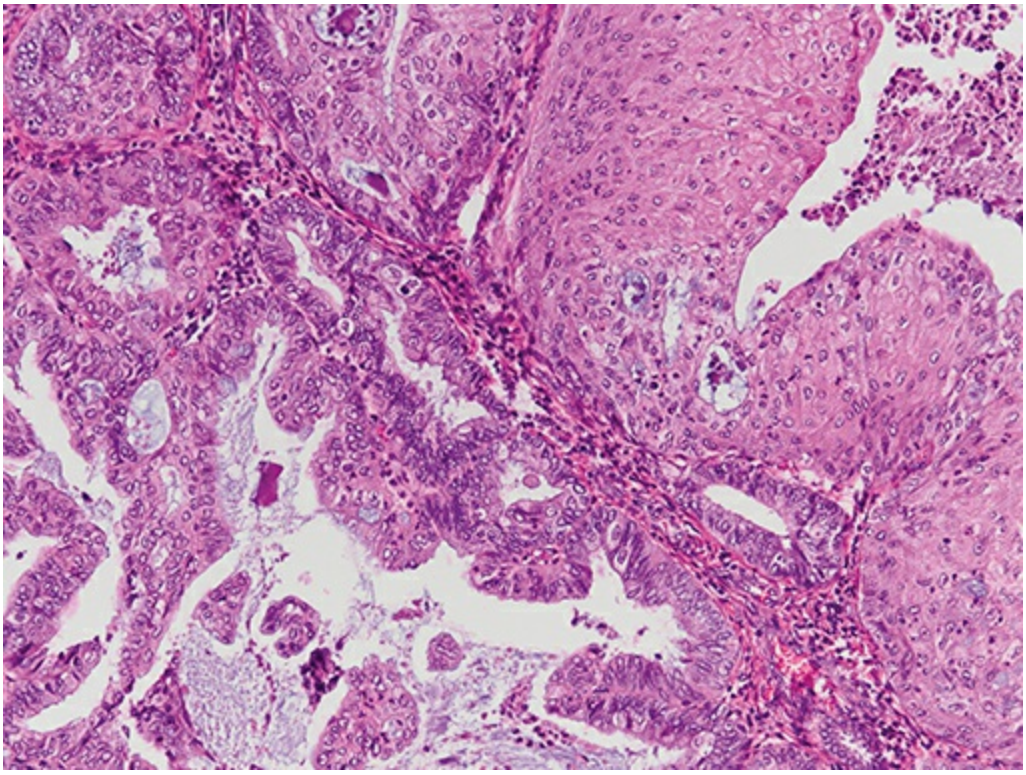

Figure 21.5 Endometrioid adenocarcinoma with squamous differentiation. The squamous component may form keratin pearls, but more often simply is characterized by acquisition of more abundant, deeply eosinophilic cytoplasm and distinct cell borders (upper right of figure). The squamous component may appear histologically benign or malignant.

Mucinous Adenocarcinoma

Mucinous adenocarcinoma is rare in the endometrium, in contrast to its high frequency in the endocervix. It has been reported to represent between 1% and 9% of endometrial adenocarcinomas (285-287), but the former figure is probably more accurate. If present as the major cellular component of an EC, this tumor resembles mucinous carcinoma seen in the ovary and endocervix. Two patterns occur: In one, the cells are columnar with basally oriented nuclei; in the other, the cells are more pseudostratified, as in an adenocarcinoma of the colon or mucinous carcinoma of the ovary (Fig. 21.6). The characteristic cellular pattern should represent over 50% of the entire tumor. Typically, there are either papillary processes or cystically dilated glands lined by columnar or pseudostratified columnar epithelium. The cytoplasm is positive for carcinoembryonic antigen (CEA), mucicarmine, and periodic acid–Schiff stain, but it is diastase resistant (287). This tumor differs from clear cell carcinoma and secretory endometrium by having more mucin and less glycogen. The glandular architecture is usually well maintained, and most are well-differentiated (285). To establish the origin in the endometrium, exclusion of a primary endocervical tumor may be required. If the endocervical sample demonstrates the same neoplasm, the site of origin must be carefully established because this cell type is common in the endocervix (288). Neither the pattern, the type of mucin staining, nor the presence of CEA can reliably distinguish mucinous adenocarcinoma of the endometrium from its more common counterpart in the endocervix (289,290). Mucinous carcinoma of the endometrium has the same prognosis as common EC (286).

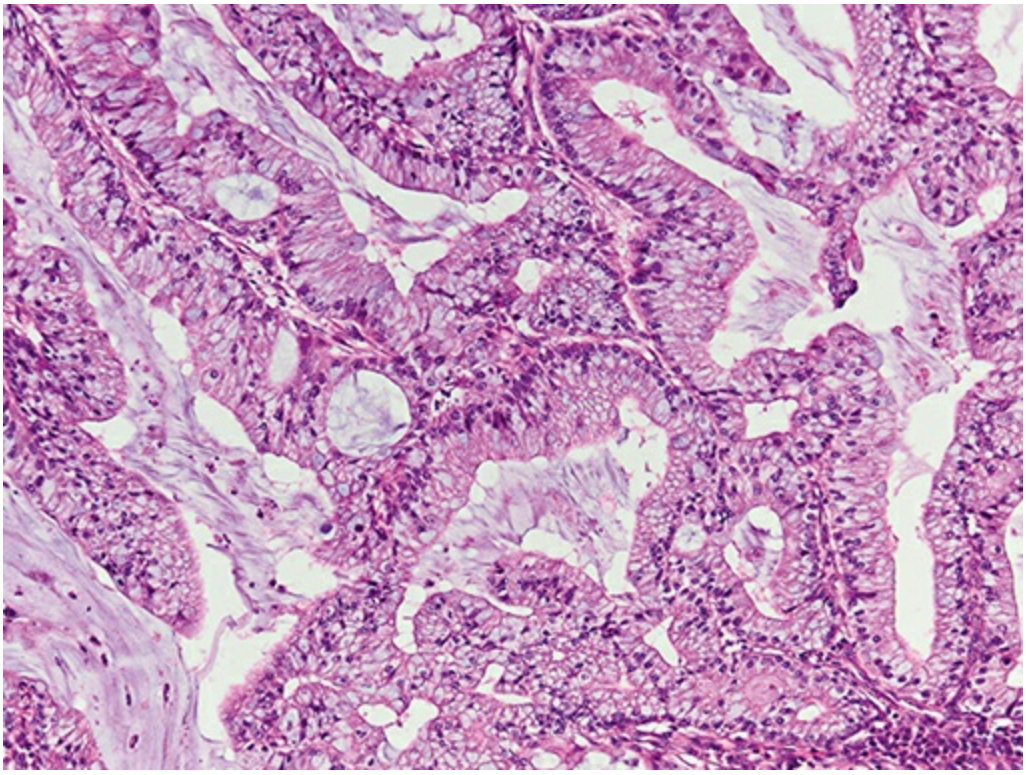

Figure 21.6 Mucinous adenocarcinoma. The apical cytoplasm cells as well as the lumina of glands are filled with a pale basophilic mucoid product.

Serous Carcinoma

Serous carcinoma of the endometrium closely resembles serous carcinoma of the ovary and fallopian tube because its papillary growth and cellular features are similar (Figs. 21.7 and 21.8). It is usually found in an advanced stage in older women (291). Fibrous papillary fronds are lined by epithelial cells, which are almost devoid of cytoplasm, but which manifest stratification, atypism, pleomorphism, mitotic figures, and bizarre forms. These fronds often detach or demonstrate a terminal growth of tiny papillary excrescences and individual cells, which detach easily (Fig. 21.7). A second pattern of irregular gaping glands lined by cuboidal cells with scalloped, apical borders may be present, particularly in the deeper aspect of the tumor (Fig. 21.8). Lymphatic invasion is commonplace in the myometrium. Distinction from clear cell carcinoma may be difficult but can usually be accomplished on the basis of a greater degree of papillary processes, greater nuclear atypia, and less cytoplasm in papillary serous carcinoma. Psammoma bodies are frequently observed in serous carcinoma, but solid growth is more common in clear cell carcinoma.

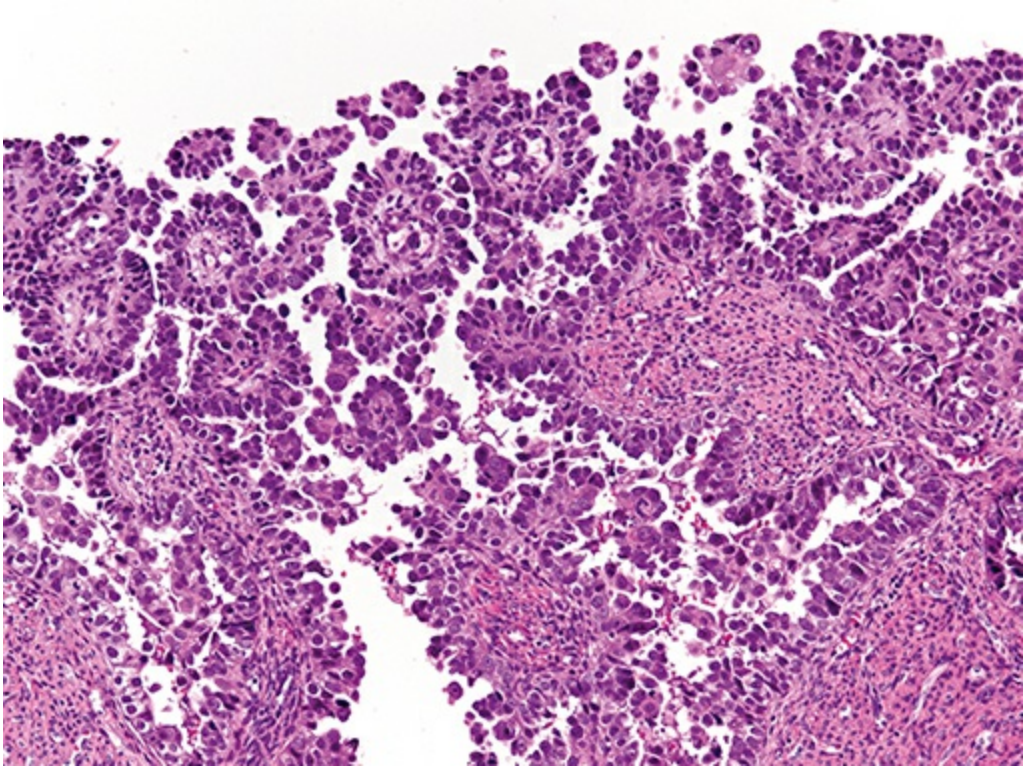

Figure 21.7 Serous carcinoma often arises in endometrium of older women, and superficially, portions usually have a highly papillary architecture.

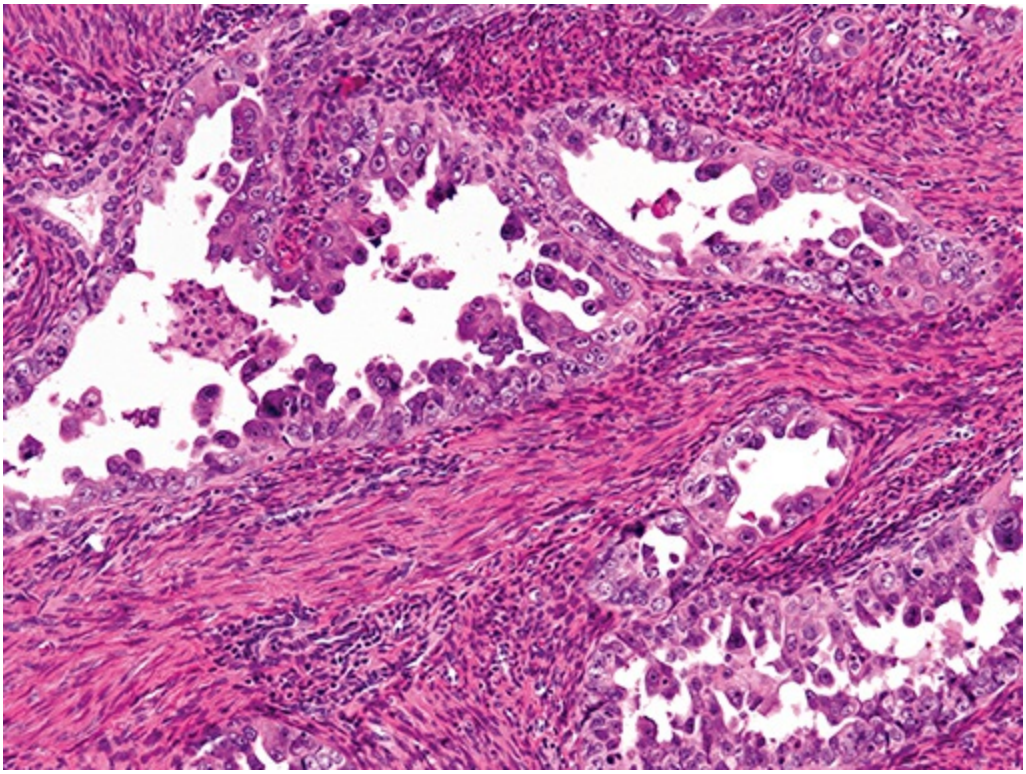

Figure 21.8 Serous carcinoma is characterized by high-grade cytologic atypia in cells that do not share a common apical border. The papillary architecture may be replaced by gaping glands at the interface with the myometrium.

Serous carcinoma represents approximately 10% of ECs, which is fortunate because it is an aggressive tumor. The tumors often deeply invade the myometrium, and unlike typical endometrioid adenocarcinoma, there is a propensity for

peritoneal spread. Unfortunately, advanced-stage disease or recurrence is common even when serous carcinomas are apparently only minimally invasive or when confined to the endometrium in polyps (171,292,293). Because the metastatic disease is often identified only microscopically, about 60% of patients are upstaged following complete surgical staging (171,291,294). A report by Wheeler et al. (295) stressed the prognostic importance of meticulous surgicopathologic staging. They and others found that serous carcinoma truly confined to the uterus had an overall excellent prognosis, whereas patients with extrauterine disease, even if only microscopic in size, almost always suffered recurrence and death from tumor (296,297).

EIC is a histologically distinctive lesion that is specifically associated with serous carcinoma of the endometrium (298-302). Serous carcinomas most often arise from a background of atrophy or polyps rather than hyperplasia (298,299,301), and they are not epidemiologically related to unopposed estrogen stimulation. EIC has been proposed to represent a form of intraepithelial tumor characteristic of serous carcinoma, and it is the precursor to invasive serous carcinoma. Mutations in *p53* that can be detected immunohistochemically as overexpression of the antigen are found in most cases, and the mutation is shared with that found in the invasive serous carcinoma (Fig. 21.9). EIC is usually found in the endometrium harboring a serious carcinoma (299), but occasionally occurs in the absence of any invasive carcinoma. In such cases, it may be associated with synchronous serous carcinoma in the peritoneum (300).

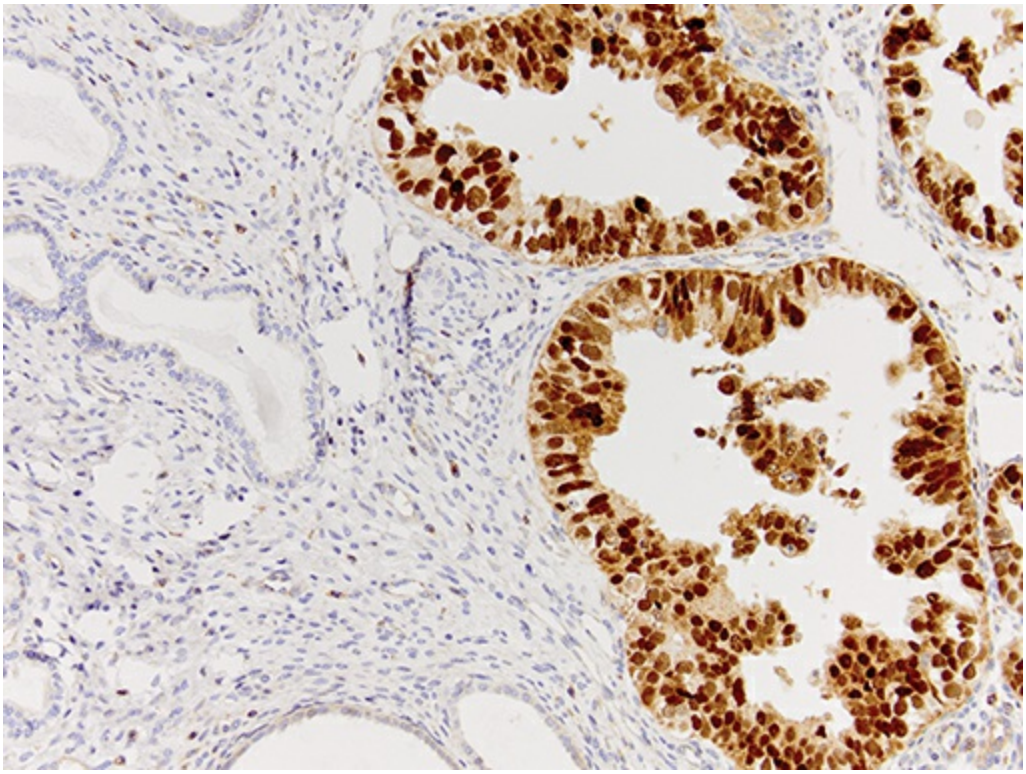

Figure 21.9 Endometrial intraepithelial carcinoma is the precursor lesion of invasive serous carcinoma. It shares histologic and immunohistochemical features with serous carcinoma, including frequent overexpression of p53. In this case, there is nuclear localization of stain in EIC (right), but no staining of the benign glands or stroma of the polyp in which it has arisen (left).

Clear Cell Carcinoma

Clear cell adenocarcinoma of the endometrium is generally recognized and defined on the basis of the distinctive clearing of the cytoplasm of neoplastic cells growing in any combination of solid, glandular, tubulocystic, or papillary configurations. About 4% of endometrial adenocarcinomas are of clear cell type (303-310). In contrast with the diethylstilbestrol (DES)-related clear cell carcinomas of the vagina and cervix, clear cell carcinoma of the endometrium is

almost exclusively a disease of menopausal women. The mean age at diagnosis is about 68 years, which is similar to that of serous adenocarcinoma and about 6 years older than that of typical endometrial adenocarcinoma (303,306,310). It is a biologically aggressive neoplasm, with a 5-year survival rate varying from only about 20% to 65% (5,303,306,308,310).

The hallmark of clear cell carcinoma is the presence of neoplastic cells with optically clear cytoplasm, reflecting an abundance of glycogen. Four basic architectural patterns of clear cell adenocarcinoma exist, including solid, glandular, tubulocystic, and papillary, but most cases display an admixture of patterns. The solid pattern consists of masses of large neoplastic cells of polygonal shape with clear to faintly eosinophilic cytoplasm and distinct cell membranes. The glandular pattern is reminiscent of the tubular glands of endometrioid adenocarcinoma, whereas the tubulocystic pattern is formed of dilated spherical-appearing glands. The papillary pattern is architecturally identical to that of serous carcinoma, with generally short, branching fibrovascular cores, often hyalinized, covered by neoplastic cells. The latter three patterns often have lining cells with a hobnail appearance, resulting from the scalloped apex of individual neoplastic cells that project along the surface (Fig. 21.10).

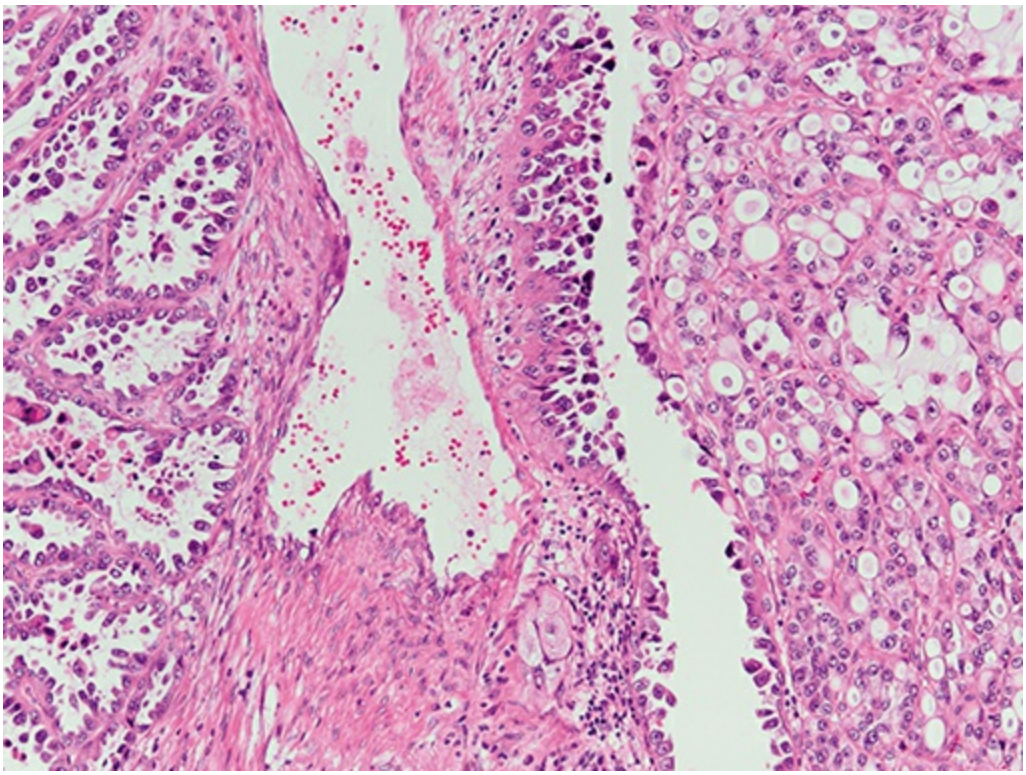

Figure 21.10 Clear cell carcinoma. In this tumor, a tubulocystic pattern with a lining of hobnail cells is present on the left, while a solid pattern is present on the right. Any mixture of solid, tubulocystic, papillary, or glandular architecture may occur.

Squamous Carcinoma

Although focal squamous differentiation is common in endometrial adenocarcinoma, pure squamous carcinoma of the endometrium is extremely rare, representing less than 1% of EC, and with only about 60 reported cases (311-315). Most patients are postmenopausal, and the average age at diagnosis is about 65 years (311,313). Squamous carcinoma of the endometrium is established as primary in the endometrium after a cervical origin is ruled out. There must be no connection with or spread from benign or malignant cervical squamous epithelium. It is often associated with cervical stenosis, pyometra, and chronic inflammation. About 60% of the cases have been confined to the uterus, and the prognosis for these patients has been relatively good (311). In contrast, less than 15% of women with advanced- stage disease have survived 2 years after diagnosis. Histologic grade does not appear to correlate with the probability of survival.

Undifferentiated Carcinoma

Undifferentiated carcinoma of the endometrium has been described as a distinct tumor type. These neoplasms are composed of a monotonous proliferation of medium-sized, round, or polygonal cells growing in sheets with no specific pattern. Mitotic figures are numerous. No glandular, squamous, or sarcomatous differentiation is detected in routinely stained sections. Keratins and epithelial membrane antigen are detected by immunohistochemistry in fewer than 20% of the cells in most cases, in contrast to diffuse staining in most high-grade endometrioid carcinomas. Selected cases may contain neurosecretory granules in a minority of the cells as demonstrated by immunohistochemical stains. Neurosecretory products are apparently not released into the patient's circulation or are not in an active form because no affected women have manifested symptoms. Most patients present with tumors of advanced stage, and the behavior is usually aggressive. A *glassy cell carcinoma* has also been described, which comprises less than 1% of ECs. It is characterized by cytoplasm that has a ground-glass appearance, as in the cervix. Although few cases have been reported, such as serous and clear cell carcinomas, glassy cell carcinoma appears to be aggressive (316,317).

Mixed Cell Type

If an EC manifests two or more different cell types, each representing at least 10% or more of the tumor, the term *mixed cell type* is appropriate.

Metastatic Carcinoma to the Endometrium

Malignancies in other organs may metastasize to the endometrium. The most common extragenital sites are breast, stomach, colon, pancreas, and kidney, although any disseminated tumor could involve the endometrium. The ovaries are the most likely genital sources of metastasis. Metastatic carcinoma presents as abnormal vaginal bleeding, and the initial specimen for evaluation is usually a biopsy or curetting. Although the metastatic disease may appear as a large focus, individual and small groups of malignant cells may subtly intermingle with normal endometrium or myometrium. Lymphatics are usually involved. Special stains for mucin, CEA, or melanin may suggest that the cells are not of endometrial origin. In some instances, unusual cell types, such as signet ring cells, may be present, suggesting a metastasis from the gastrointestinal (GI) tract. It is uncommon but not exceptional for the endometrial sample to be the first indication of an occult primary lesion (318,319).

Simultaneous Tumors

Cancers of an identical cell type may be discovered in the ovary and endometrium simultaneously (320). Usually, the primary site is assigned to the area having the largest tumor mass and most advanced stage. In certain situations, primary malignancies in the endometrium and ovary may coexist. This "field effect" of the "extended Müllerian system" may occur in 15% to 20% of endometrioid carcinomas of the ovary (321,322). In a review of a GOG study of 74 patients with simultaneously detected endometrial and ovarian carcinomas with disease grossly limited to the pelvis, only 16% of women suffered a recurrence of disease, with a median follow-up of 80 months. This group of patients was atypical, with 86% having endometrioid histology in both sites. Recurrence was statistically related to the presence of microscopic metastases or high histologic grade (323).

Carcinomas of more advanced histologic grade and cell type are more difficult to assign to the field effect because of a higher probability of invasion and metastasis at the time of surgery (277). If the endometrial tumor is less than 5 cm in diameter, the ovarian lesion is unilateral, invasion is less than the middle third, vessels are not involved, and the EC is well-differentiated, metastasis to the ovary is unlikely (324).

PATHOLOGIC FACTORS OF PROGNOSTIC SIGNIFICANCE

Pathologic information has been used to estimate risk of nodal metastasis and to define prognosis (recurrence, survival) in EC. Prognostic factors have been identified within each stage of EC, and the discussion of prognostic factors is probably best served by discussing factors within comparably staged groups, more so than as isolated factors. For example, in GOG 99, which compared observation to pelvic RT in patients with stage I–II EC and pathologically negative LN, a model based on combinations of patient age and tumor grade, depth of invasion, and lymphovascular space invasion (LVI) could predict patients at highest risk for recurrence (144). Similarly, PORTEC identified a combination of two of three factors—age >60, grade 3 tumor, and depth of invasion > 50%—that defined patients at high risk for local-regional failure when managed by surgery alone (325). Increasingly, risk models are used to counsel patients as to the marginal benefit of postoperative therapies.

Predicting Nodal Disease

On the basis of pathologic information available at the time of surgery, the risk for nodal metastasis may be estimated. Physicians who selectively perform nodal dissections frequently do so based on the presence of uterine risk factors that suggest the potential for nodal disease. In patients who did not undergo a nodal dissection at the time of hysterectomy, decisions to offer RT are commonly based on the estimation of risk for nodal disease based on uterine risk factors. In the surgical pathologic study GOG 33, pelvic and para-aortic nodal disease was more frequent with increasing grade (percentage of pelvic nodal metastases: 3% grade 1, 9% grade 2, 18% grade 3), depth of invasion (1% endometrium only, 5% inner one-third, 6% middle one-third, 25% outer one-third myometrial invasion), and LVI (27% with LVI, 7% without LVI) (59). Pelvic and para-aortic nodal metastases were also more common with cervical involvement, when peritoneal cytology was positive, and when extra-nodal (adnexal, intraperitoneal sites) disease was found. In a multivariate model, grade, depth of invasion, and intraperitoneal disease were independent predictors of pelvic nodal disease. In a further analysis of patients participating in GOG 33, 47 of 48 patients with para-aortic nodal disease had one or more factors of palpably enlarged para-aortic nodes, grossly positive pelvic nodes, gross adnexal disease, or outer one-third invasion (61). Despite the use of pathology to help predict nodal disease, many believe that LN assessment is superior as it provides actual information on nodal status, as opposed to an estimate, which can then be used to tailor therapy. As previously discussed, patients at very low risk for nodal involvement may also be specified by uterine risk factors (size, grade, depth of invasion) (172-176).

Prognostic Factors

FIGO Stage

Prognostic factors may be used to categorize patients into high- and low-risk groups and to guide the use of adjuvant therapies. Understanding these factors also allows for the development of novel strategies to reduce risk of recurrence or alter patterns of disease failure. Overall, the patients at highest risk for recurrence and death have spread of disease outside of the uterus, which is reflected by FIGO stage (61). The prognostic utility of surgicopathologic stage has been confirmed in multiple studies of large numbers of patients, using both univariate and multivariate analysis (59,303,326-331). FIGO surgical stage is often the single strongest predictor of outcome for women with endometrial adenocarcinoma in studies using multivariate analyses (303). Although the FIGO clinical staging system of 1971 was generally useful, retrospective comparison of the two methods demonstrated the clear superiority of surgicopathologic staging over clinical staging in predicting outcome.

Patients with intraperitoneal or distant metastases (stage IV) have the poorest prognosis with 5-year survival ranging from 20% to 25% (5). In GOG 122, comparing whole abdominal RT to doxorubicin/cisplatin CT as primary therapy for EC patients with <2-cm residual disease stage III–IV, stage IV (compared to stage III) disease was an independent predictor of shorter PFS (HR 2.2.9) and survival (HR 1.9) (332). Gross intraperitoneal spread frequently indicates the presence of larger tumor burden as many patients with intraperitoneal disease also have adnexal and nodal disease. In GOG 33, 51% of patients with gross intraperitoneal spread had positive pelvic nodes, whereas only 7% without spread had positive pelvic nodes (59). Prognosis may be modified by the volume of residual disease after cytoreductive surgery (252-255).

Patients with nodal metastases (stage IIIC disease) also have poorer prognosis compared to node-negative populations. FIGO data shows 5-year survival to be 57% in stage IIIC patients compared to 74% to 91% when nodes are negative (stage I-II) (5). Patients with positive pelvic but negative para-aortic nodes have a better prognosis compared to those with para-aortic disease (61,333,334). For example, Hoekstra and colleagues reported a series of 85 patients with stage IIIC disease who had a 5-year survival of 61% (334). Patients with positive pelvic nodes had a 5-year survival of 70% compared to 49% when para-aortic disease was present. In 2009, FIGO staging was revised for patients with positive pelvic nodes/negative para-aortic nodes who were reclassified as stage IIIC1, and patients with any positive para-aortic node were classified as Stage IIIC2 (89). This change has been validated in two recent reviews (335,336). Two retrospective series have also suggested that patients with nodal disease in addition to positive cytology, adnexa, or serosa have poorer PFS or survival compared to those patients with positive nodes alone (164,333). Lymphadenectomy (142,163,193), complete surgical resection of bulky nodes (337), and use of CT (194,332,335,338) have been suggested to improve outcomes in patients and modify the prognostic effect of nodal disease.

Patients with FIGO 1988 stage IIIA disease represent a heterogeneous population having adnexal, peritoneal cytology, and/or serosal involvement, but with negative LN. Positive peritoneal cytology as the sole upstaging factor was dropped in the 2009 FIGO staging revisions as a stage defining characteristic (89). In the GOG 33 study, 12% of all patients had positive cytology, and of these, 25% had positive pelvic nodes and 19% had metastases to para-aortic LN (59). Six percent of clinical stage I–II patients have spread of tumor to the adnexa, and of these, 32% have pelvic node metastases compared with 8% pelvic node positivity if adnexal involvement is not present (59). Twenty percent have positive para-aortic node metastases, which is four times greater than if adnexal metastases were not present.

For patients who are completely staged and found to have no extrauterine disease, 4% to 6% of patients have positive cytology as an isolated finding (59,216,339). Published opinions are mixed about the significance of this finding (340-345). In a review of the literature, Wethington categorized patients into groups based on low-risk uterine features (grade 1 to 2, <50% depth of invasion, no LVI) with positive peritoneal cytology. In this group, positive cytology occurred in 11% of cases, and had a recurrence rate of 4%. Patients with higher risk features plus positive cytology had a 32% risk of recurrence (346). Saga reported that positive peritoneal cytology alone in staged patients (n = 32) was associated with a 5-year survival of 87%; however, this was worse than the 97% survival seen in cytology-negative patients (347). In a series of 57 patients with FIGO stage IIIA (1988) disease, cytology appears to carry the same significance as adnexal involvement and was an independent predictor of prognosis (348).

Histologic Cell Types

The histologic classification of endometrial adenocarcinoma is important not only because it facilitates the recognition of lesions as carcinoma, but also because the cell type has consistently been recognized as being important in predicting the biologic behavior and probability of survival. Endometrioid adenocarcinoma accounts for the majority of tumors in the uterine corpus and carries a relatively favorable prognosis. Consequently, the virulence of other cell types is usually related to endometrioid adenocarcinoma.

Adenocarcinoma with squamous differentiation is similar to typical endometrioid adenocarcinoma with respect to the distribution by age and frequency of nodal metastasis, and is associated with a slightly increased probability of survival.

Villoglandular carcinoma has a biologic behavior similar to that of endometrioid adenocarcinoma (274,349). *Serous carcinoma* has been considered an aggressive histologic type, with OS rates varying from 40% to 60% at 5 years (5,292,294,350-353). *Clear cell carcinoma* also has a highly aggressive behavior, with 5-year survival rates of 30% to 75% (354-357). One of the problems with using histology as a marker for prognosis is that serous cancers are more likely to have spread at presentation than endometrioid tumors. Patients with serous or clear cell tumors present with stage III–IV disease in 41% and 33%, respectively, compared to 14% with endometrioid type (5). Studies suggest that 40% to 70% of serous tumors will have extrauterine spread at presentation; therefore, complete surgical staging is warranted in this tumor type (171). Given this level of disease spread, it is not surprising that unstaged/clinical stage I serous patients appear to have similar prognosis to stage III–IV endometrioid types. Once patients with serous or clear cell tumors are appropriately allocated into the correct stage, the importance of histology appears to be less (358-361). For example, Creasman et al. evaluated FIGO data and showed that patients with stage I serous tumors had comparable outcomes to those with stage I, grade 3 endometrioid tumors. Five-year survival for stage IB and IC serous tumors was 81% and 55% compared to 84% and 66% for grade 3 tumors (361). In advanced and recurrent EC patients participating in phase 3 GOG CT trials, response rate (RR) to CT was not associated with histologic type, and serous tumor type was not independently associated with PFS (17).

Grade

The degree of histologic differentiation has been considered to be an indicator of tumor spread. The GOG and other studies have confirmed that as grade becomes less differentiated, there is a greater tendency for deep myometrial invasion and, subsequently, higher rates of pelvic and para-aortic LN involvement (59,362-364). Survival has also been consistently related to histologic grade, and in a GOG study of more than 600 women with clinical stage I or occult stage II endometrioid adenocarcinoma, the 5-year relative survival was as follows: grade 1% to 94%; grade 2% to 84%; grade 3% to 72% (61). In patients with early-stage EC participating in the PORTEC trial, the risk of cancer-related death for patients with grade 3 tumors was 4.9 compared to grade 1 to 2 tumors (151).

Myometrial Invasion

Deep myometrial invasion is one of the more important factors correlated with a higher probability of extrauterine tumor spread, treatment failure, and recurrence, and with diminished probability of survival (Fig. 21.11) (144,326,365). In a GOG study of over 400 women with clinical stage I and occult stage II endometrioid adenocarcinoma, the 5-year relative survival was 94% when the tumor was confined to the endometrium, 91% when the tumor involved the inner third of the myometrium, 84% when the tumor extended into the middle third, and 59% when the tumor invaded into the outer third of the myometrium (61). Even in node-negative patients, deep myometrial invasion retains prognostic information. For example, Mariani et al. (366) reported that for stage I (node-negative) patients, deep invasion (>66% myometrial invasion) was an independent predictor for recurrence and distant site of failure.

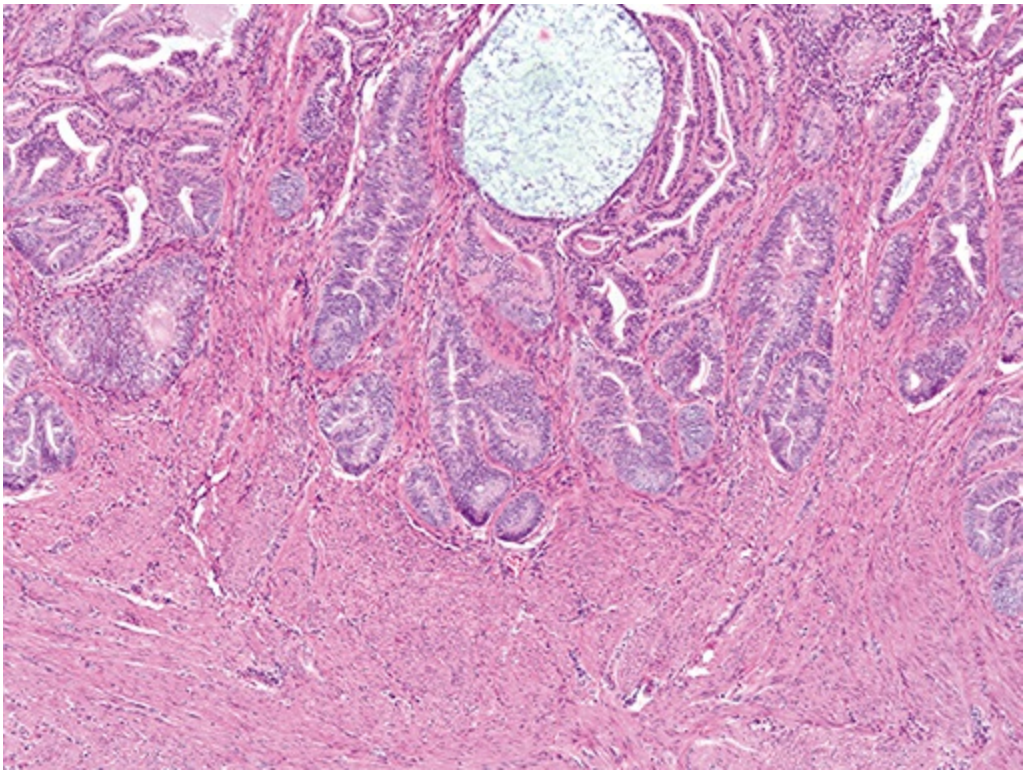

Figure 21.11 Myometrial invasion by endometrial adenocarcinoma may be accompanied by a desmoplastic reaction, but often no such reaction is present, as in this case.

Lymphovascular Space Invasion

Several studies have suggested that LVI is a strong predictor of recurrence and death, and is independent of depth of myometrial invasion or histologic differentiation (Fig. 21.12) (303,367,368). In a retrospective series of 628 surgically staged patients, the presence of high-intermediate risk (HIR) uterine characteristics and LVI were associated with nodal metastases (367). The OR for nodal disease was 4.4 with HIR factors, and 11 for LVI. In this series, the LVI and HIR features were independently associated with PFS and survival. Zaino et al. (331) found that LVI was a statistically significant indicator of death from tumor in early clinical stage but not early surgical stage endometrial adenocarcinoma. This suggests that lymphatic invasion helps to identify patients likely to have spread to LN or distant sites, but that its importance is diminished for those in whom thorough sampling of nodes has failed to identify metastasis. Vascular space invasion or capillary-like space (CLS) involvement with tumor exists in approximately 15% of uteri containing adenocarcinoma (59,368,369). Pelvic LN are positive in 27% of cases, which is four times more often if malignant cells are found in the CLS than if absent. The risk of para-aortic node metastases when LVI was present was 19%, which is a sixfold increase over negative CLS involvement (59). Lymphovascular invasion is identified in 35% to 95% of serous carcinomas of the endometrium, where it has generally been associated with an elevated risk of tumor recurrence or death from disease (294,350,352).

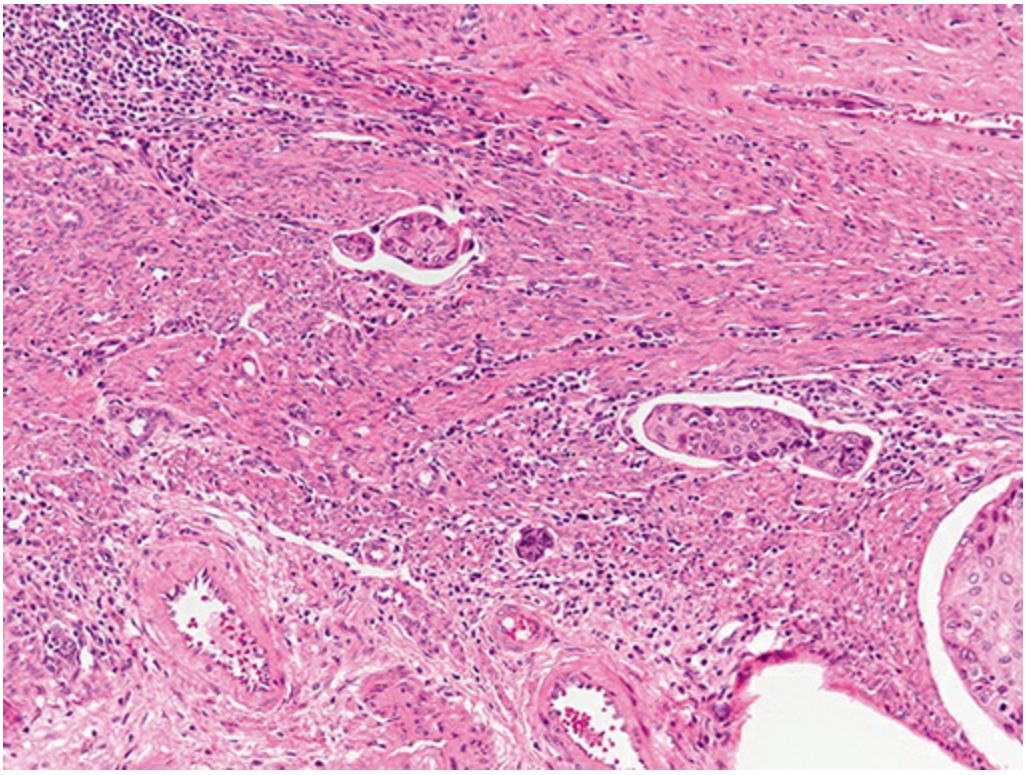

Figure 21.12 Lymphatic invasion by endometrial adenocarcinoma. Nests of neoplastic cells occupy the lumen of an endothelial-lined space. Since artifactual retraction of stroma around tumor may simulate lymphatic spaces, true lymphatic invasion is best assessed in the myometrium adjacent to the tumor.

Patterns of Failure

Another way to approach pathologic information is to understand the pathologic relationships that predict particular patterns of failure. For example, in patients with pathologic negative-node, stage I EC, pelvic sidewall recurrences are rare, and failures occur most frequently at the vaginal cuff or at distant sites (144,370,371). High-risk stage I patients who do not undergo nodal dissections have both pelvic sidewall and distant sites of failure, even with routine use of RT (162). Patients with node-positive disease frequently have recurrences at distant sites, with rare intra-abdominal failures (164,165,334). Patients with stage IV/intraperitoneal disease most commonly fail in the peritoneal cavity. The implications of patterns of failure data are that we may choose our postoperative therapies better by defining patterns of failure for a particular stage distribution or based on the presence of risk factors. The Mayo Clinic group has advocated this approach following a review of patterns of failure data from their group (366,372-375). For example, these investigators suggested that hematogenous, lymphatic, and peritoneal failures could be predicted based on pathologic factors, and that therapy should be directed to reduce failures at these sites depending on pathologic information (60). Whether their finding can be validated in a prospective manner, or if existing therapies effectively control disease at particular sites, needs to be evaluated.

GENERAL MANAGEMENT

Results of Standard Therapy and Their Sequelae

Early uncontrolled trials suggested that progestin therapy after surgery or irradiation was associated with a decreased risk

of recurrence in patients with disease confined to the uterus (376). However, large prospective, randomized trials failed to show a survival advantage (377-379). RT has been and remains the standard adjuvant treatment modality for most patients at risk for recurrence. This standard continues to evolve, however. An older, poorly designed study of adjuvant cytotoxic CT showed no benefit for patients treated with single-agent doxorubicin and arrested interest in adjuvant CT for many years (380). By 2006, two prospective trials comparing RT to CT demonstrated similar outcomes for patients treated with CT or RT (379,380). Adjuvant CT improved PFS and survival in patients with advanced-stage disease compared to whole abdominal RT, suggesting an important role for first-line therapy that includes CT (332). Current research focuses on whether outcomes may be improved by adding CT either sequentially or concomitantly with radiation.

ADJUVANT RADIATION THERAPY

RT continues to play an important role in the management of EC, although its role is evolving. It is used adjuvantly, as definitive treatment for patients who are medically inoperable, for local recurrence, and for palliation. Historically, patients were treated with preoperative intracavitary brachytherapy with or without external beam RT followed by hysterectomy. This approach has not been completely abandoned but is used infrequently and usually only in patients with gross cervical or parametrial involvement. Today, most patients undergo primary surgery; then, depending on final pathologic review, the need for RT is determined. Radiation can be delivered with external beam irradiation, brachytherapy, or a combination of both. Brachytherapy is most frequently delivered by an intracavitary technique, where an applicator is inserted into an anatomic cavity, such as a tandem positioned in the uterus or cylinder in the vagina. Brachytherapy can also be performed by interstitial application, where needles are placed into the tissues at risk under general anesthesia, most commonly in the setting of vaginal recurrence following hysterectomy. Brachytherapy dose may be delivered with low dose rate ^{137}Cs sources (low dose rate [LDR]), an ^{192}Ir source (LDR or pulsed dose rate [PDR]), or a high dose rate ^{192}Ir source (high dose rate [HDR]). With LDR, the patient is admitted to the hospital for the applicator insertion and brachytherapy delivery, and usually requires bed rest for several days. This method exposes other personnel to irradiation, is often costlier, and places the patient at risk for deep venous thrombosis and other medical complications. HDR is typically performed over multiple fractions in the outpatient setting, avoids radiation exposure to personnel, and allows for greater flexibility in the dose distribution by use of a stepping source and remote afterloader. PDR also allows for dose optimization with use of a stepping source and is considered gentler on normal tissues as a low dose of radiation is given every hour over several days. PDR also requires hospital admission but personnel radiation exposure is limited.

Early-Stage Disease

Most of the data on adjuvant radiation in EC pertains to patients with early-stage (I–II) disease, as this is the most common presentation and the focus of several randomized trials. The use of radiation in this group of patients, however, has been undergoing significant changes in practice over the last 10 years. The questions yet to be resolved are clarifying which patients will be best served by adjuvant RT and determining the most appropriate radiation modality, either pelvic radiation, vaginal brachytherapy, or a combination.

Benefit of Adjuvant Radiation

Two prospective, randomized trials compared surgery alone to surgery and postoperative external beam radiation. The first trial was conducted by the GOG (study 99) where 392 patients with stage IB–IIB EC who underwent total abdominal hysterectomy/bilateral salpingo-oophorectomy (TAH/BSO) and pelvic/para-aortic LN sampling were randomized to observation (n = 202) or postoperative pelvic radiation (n = 190) to a total dose of 50.4 Gy in 28 fractions (144). The

study was designed to allow for an 80% chance of detecting a 58% decrease in the recurrence hazard rate and a 56% decrease in the death hazard rate. Recurrence-free interval (RFI) was the primary end point with all-cause survival as well as recurrence-free survival (RFS) as secondary end points. With a median follow-up of 68 months, the 4-year survival rate was 92% in the radiation arm compared with 86% in the observation arm (Relative hazard: 0.86; $p = 0.557$). The estimated 2-year cumulative incidence of recurrence was 3% versus 12% in favor of the irradiation arm (RH: 0.42; $p = 0.007$), indicating that radiation decreased the hazard rate of recurrence by the required 58%. Specifically, the rate of vaginal recurrence, the most frequent area of recurrence, was 6.4% (13 out of 202) in the surgery-alone arm compared to 1.05% (2 out of 190) in the radiation arm. Of interest, the two patients in the surgery arm that recurred were randomized to radiation but refused adjuvant treatment. In addition, the estimated risk of death from any cause was 14% less in the RT arm, but was not statistically significant. More than half of the deaths were from causes other than treatment or EC, and the paper points out that it was therefore not adequately powered to detect an OS difference, a point often not appreciated by many physicians. This GOG study further identified a subgroup of patients termed HIR, who accounted for two-thirds of the cancer-related deaths and recurrences, and has become a population of interest for further study in currently open trials. The definition of HIR by GOG is determined by the combination of age and intrauterine risk factors including grades 2 or 3, outer one-third myometrial invasion, and LVI. Patients are considered to fall into the HIR category if they are age ≥70 years with one risk factor, age ≥50 years with at least two risk factors, or age ≥ 18 years with all three risk factors. In this HIR patient population, the 4-year cumulative recurrence was 27% without irradiation compared to 13% with irradiation, an absolute benefit of 19%. In contrast, for the low-risk population, there was a 6% versus 2% recurrence rate in unirradiated compared to the irradiated enrollees. The GOG trial 0249 was designed to further refine the roles of CT and RT in the HIR population, and randomized women to adjuvant VCB followed by three cycles of carboplatin and paclitaxel versus pelvic irradiation with either 3D conformal therapy or intensity-modulated radiation therapy (IMRT) to 4,500 to 5,040 cGy in 25 to 28 fractions with an optional brachytherapy boost. Publication of GOG 249 is pending, however, there appeared to be no difference in relapse-free or OS between the two adjuvant treatments.

The second trial was the PORTEC study where 714 patients with stage IB grade 2, 3 and IC grade 1, 2 were randomized after TAH/BSO without LN sampling to observation (n = 360) or pelvic radiation (n = 354) to a total dose of 46 Gy in 23 fractions (151). With a median follow-up of 52 months, the 5-year vaginal/pelvic recurrence rate was 4% in the radiation arm compared to 14% in the observation arm ($p < 0.001$). The corresponding 5-year survival rates were 81% and 85%, respectively ($p = 0.37$). In patients with HIR features by the PORTEC definition (where intermediate-risk factors were outer-half invasion, grade 3 or >60 years old, but excluded deeply invasive high-grade tumors; patients were deemed HIR with two of the three factors), the recurrence risk was reduced from 23% to 5% with adjuvant irradiation. It should be noted here that this is different from the GOG HIR definition, and likely a much lower risk population. An update with a median follow-up of 13.3 years has been recently published (381). The actuarial 15-year locoregional recurrence was statistically different at 6% versus 15% for those with adjuvant irradiation compared to observation with no statistical difference in OS or failure-free survival, distant metastases, or secondary cancers. Most recurrences in the observation arm were vaginal (11% of the 15%).

An additional trial, PORTEC II, was completed as a follow-up study (152). The study population was a HIR population based on the PORTEC definition. As in PORTEC I, the patients underwent a TAH/BSO without LN dissection and were randomized to 46 Gy in 23 fractions of external beam irradiation or vaginal brachytherapy alone, with either 21 Gy in three fractions of high-dose rate therapy or 30 Gy in one LDR fraction. Four hundred twenty-seven patients were enrolled in this noninferiority trial designed with the primary end point of vaginal recurrence. The research question was whether vaginal brachytherapy was as effective at controlling vaginal recurrence as external beam radiation, with fewer toxic effects and improved quality of life. Secondary end points were locoregional recurrence, distant metastases, overall and DFS, and quality of life. At a median follow-up of 45 months, the estimated 5-year vaginal recurrence rates were 1.8% for brachytherapy alone and 1.6% for external irradiation. The nodal failure rate was significantly different at 3.8% for the brachytherapy-alone arm and 0.5% for external beam irradiation, although this difference was not felt to be clinically meaningful. Distant metastases, DFS, and OS were similar in both arms. Eighty percent of the patients had deeply invasive

disease, and over 90% had grades 1 or 2 disease. In fact, with central pathologic review, 48% of the patients that were enrolled with grade 1 disease increased to 78.6% of the study population. Final pathology reviewed revealed that 14% of the patients did not fit pathologic eligibility for the trial, although the outcome was unchanged with these patients excluded on reanalysis. It should not be unexpected that pelvic external beam radiation resulted in a similar vaginal recurrence rate to vaginal brachytherapy. In addition, with this lower risk subgroup compared to the GOG 99 HIR population, it should be noted that the pelvic failure rate was quite low, even in the brachytherapy-only arm. Furthermore, GI toxicity and quality of life were significantly improved in the vaginal brachytherapy arm compared to the external beam arm (382,383). The currently enrolling PORTEC 3 trial randomizes high-risk and advanced-stage patients between external irradiation alone and external irradiation with concurrent and adjuvant CT. The patients eligible for PORTEC 3 include those with stage IB if the disease is grade 3 and paired with LVI, IC if grade 3, and Stages IIIA-C or uterine serous or clear cell carcinoma stages IB-III.

The ASTEC/EN.5 trial was actually two trials with separate randomizations combined as one intergroup trial between the United Kingdom Medical Research Council and the National Cancer Institute of Canada (204). This trial examined women with IA grade 3 disease and all grades of IB, and Stages I or II uterine serous or clear cell carcinoma. A LN dissection was not required, and positive cytology was not an exclusion criteria. Positive pelvic nodes were allowed in the ASTEC trial. Patients were randomized to external beam radiation or observation, although vaginal brachytherapy was at the institution's choice, even in the observation arm. The primary outcome measure was OS, and 905 women were enrolled from 112 centers and 7 countries. With a median follow-up of 58 months, no statistical survival difference was noted between the two arms, and the site of the first failure was distant in both arms, that is, approximately 7%. The vaginal and pelvic failure rates were 3.7% versus 1.5% and 2.6% versus 1.1% for observation (with 53% receiving VCB) and pelvic irradiation, respectively (204).

Despite the fact that adjuvant radiation consistently and significantly improved locoregional control in these trials, most of the adjuvant treatment debate focuses on the lack of improvement in OS. The end point of OS is the gold standard for any randomized therapeutic trial in cancer, although when considering early-stage EC, the data should be interpreted with caution. First, in GOG 99, the primary end point was not OS but rather PFS, which was significantly better in the radiation arm (144). Second, because of the relatively high incidence of other comorbidities such as hypertension, DM, and obesity as well as other cancers, the chance of dying from an intercurrent illness is as high if not higher than dying from EC. In the RT arm of the PORTEC trial (151), the 8-year mortality rate from EC was 9.6% compared to 14.4% from other causes and 5.3% from other cancers. In the observation arm, the corresponding rates were 7.5%, 10.6%, and 5.3%. Similar data emerged from GOG 99, which reported that approximately half of the deaths were due to causes other than EC or treatment. This led the authors of GOG 99 to state the following: "With this number of intercurrent deaths in both arms, even if RT reduces the risk of EC-related deaths, the size of this trial is not adequate to reliably detect an OS difference." Thus, it is clear that the competing causes of death in this group of patients having a low cancer-related mortality rate make OS a very elusive end point to attain. Third, even in patients who die from EC, the most common cause is distant rather than local relapse. In the PORTEC trial, the 8-year mortality rate from local versus distant relapse was 1.1% and 7.9%, respectively, in the RT group, and 2% and 5.2%, respectively, in the surgery-alone group (151). Furthermore, women in the observation arm who experienced vaginal relapse received salvage RT with 5-year survival rates of 70%. In the PORTEC 2 trial, vaginal control was the primary end point compared to OS in the ASTEC/EN.5 trial (152,204). In the PORTEC 2 study, 62% and 48% died from intercurrent disease in the external beam and brachytherapy arms, respectively, and 38% versus 52% died of endometrial carcinoma in the irradiation arm and brachytherapy arm, respectively. In the ASTEC/EN.5 trial, 36% of the deaths were observed to be unrelated to disease or treatment. Therefore, it is unrealistic to expect a local treatment modality such as radiation to alter this pattern of relapse. It is also notable that in the GOG 99 and PORTEC I trials, most of the patients did not have poor prognostic features, thus making it difficult to demonstrate any survival advantage to adjuvant radiation. In PORTEC 2, most (80%) of the patients had deeply invasive carcinoma, although those with grade 3 deeply invasive tumors were excluded from the trial. In the ASTEC/EN.5 trial, 75% were deeply invasive but 65% were grades 1 or 2. When the impact of adjuvant radiation in GOG 99 was

assessed in the subset of patients with high-risk features (based on age, grade, depth of myometrial invasion, and presence of lymphovascular invasion), the death rate was nonsignificantly lower in the radiation arm (RH: 0.73; 90% CI, 0.43 to 1.26). The PORTEC 2 study included higher risk patients than PORTEC 1 but was powered as a noninferiority study examining the utility of vaginal brachytherapy to prevent local recurrence. Lee et al. in their analysis of the SEER data showed an OS advantage to pelvic radiation for patients with IC grade 1 and grade 3/4 ($p < 0.001$) EC over those treated with surgery alone in their examination of over 21,000 patients. This survival advantage of adjuvant pelvic radiation was significant even in patients who had surgical LN staging (384). All of these issues need to be considered when assessing the benefit of adjuvant radiation. Such debate is not new in the field of oncology, but it is important to note that other oncologists treating cancers of the breast or rectum, when faced with similar results from prospective, randomized trials, have recognized the importance of a multimodality approach in achieving local-regional control as well as survival.

Type of Radiation

There are two types of radiation (intravaginal brachytherapy or pelvic external beam radiation) that could be used either alone or in combination for early-stage EC. Over the last 3 decades, the debate about the appropriate radiation modality has undergone a full circle. In the 1970s and mid-1980s, there was a shift from intravaginal brachytherapy alone to pelvic radiation plus intravaginal brachytherapy. Then, in the late 1980s and early 1990s, there was a shift toward pelvic radiation alone. More recently, and with the increase in surgical LN staging, there has been resurgence in the use of intravaginal brachytherapy alone. A recent article by Patel et al. (385) documented this by probing the SEER database examining the treatment of FIGO stage I and II EC over the years 1995 to 2005. They examined the treatment of 9,815 patients and found that the proportion of those receiving vaginal brachytherapy alone increased from 12.9% to 32.8% as the use of external beam alone decreased from 56.1% to 45.7% over the same time period. The use of both modalities together also decreased from 31% to 21.4% as well.

Intravaginal Brachytherapy Alone or Combined with Pelvic Radiation

In a historically important trial, Aalders et al. (386) reported on 540 patients with stage IB–IC EC who underwent TAH/BSO without LN sampling and postoperative intravaginal brachytherapy to 60 Gy to the vaginal mucosa. The patients then were randomized to observation (n = 277) or to supplemental pelvic radiation to 40 Gy (n = 263). A significant reduction in local recurrence rates was seen with the addition of pelvic radiation (1.9% vs. 6.9%; $p < 0.01$). With regard to OS, there was no significant difference between the two arms of the study, but in the subset of patients with grade 3 disease and deep myometrial penetration, there was a survival advantage (cause-specific survival) of 18% versus 7% in favor of the pelvic radiation arm (386). The data from this trial contributed to the shift in treatment policy from intravaginal brachytherapy alone to external beam pelvic radiation with or without a brachytherapy boost. As outlined above, in the ASTEC/EN.5 trial, over 50% of the observation arm received vaginal brachytherapy as well. Because the vagina is the most common site of pelvic failure, this paradigm has become more common. Greven et al. (387) reviewed the experience of two institutions to compare the outcome of the two approaches. In that study, there were 270 patients with stage I–II EC: 173 were treated with postoperative pelvic radiation alone, and 97 were treated with a combination of intravaginal and pelvic radiation (387). The corresponding 5-year pelvic control and DFS rates were 96% versus 93% ($p = 0.32$) and 88% versus 83% ($p = 0.41$), respectively. This study as well as others called into question whether the addition of vaginal radiation is needed, particularly when vaginal control rates are excellent with pelvic radiation alone in early-stage disease (388,389). Furthermore, some studies have suggested increased toxicity with the combined approach (388). An examination of the SEER database reviewed 3,395 node-negative EC patients with stages IA, IB, and II disease. Most patients (62.7%) received external beam alone and 37.3% received both external beam and brachytherapy. It was noted that the addition of brachytherapy did not statistically improve survival. A number of other reports (390,391), however,

suggest that vaginal vault radiation can be added to pelvic radiation with minimal morbidity and very low rates of recurrence. Some institutions choose to treat to a lower external beam dose of 45 Gy plus a vaginal brachytherapy boost, whereas others prescribe 50.4 Gy to the pelvis without a boost unless higher risk features are present, such as close or positive vaginal margins, extensive LVI, or cervical involvement. As CT becomes an increasingly common part of the treatment paradigm, the former regimen may spare more bone marrow and bowel. In all randomized studies thus reported (GOG 99, PORTEC 1 and 2, and ASTEC/EN.5), the vaginal recurrence rate following adjuvant pelvic irradiation ranges between 1% to 2%, and therefore, any study to examine whether brachytherapy should be added to external beam RT as a boost would require a very large number of patients and more resources than the question warrants.

Intravaginal Brachytherapy Alone

With the increase in surgical LN staging, the use of postoperative intravaginal brachytherapy alone regained its appeal, the rationale being that full surgical LN staging could potentially eliminate the need for pelvic radiation, whereas vaginal brachytherapy could still address the risk of vaginal cuff recurrence, as demonstrated in PORTEC 2. Several additional reports in the past 10 years also demonstrated a very low rate of recurrence either in the vagina or in the pelvis with such an approach (139,206,392-395).

From the above discussion, it is clear that the options available for patients with early-stage endometrioid EC are numerous. Perhaps it is better to consider different options based on the following factors identified as risk factors for recurrence – age, grade, depth of invasion, LVI, histology, and whether a nodal dissection was accomplished.

Cancer Limited to the Mucosa (Formerly Stage IA, grades 1 and 2).

The risk of pelvic LN positivity (57) is ≤3% and the 5-year PFS rate in this group is of the order of 95% to 98%. It is unlikely that postoperative pelvic external beam radiation would add anything to the final outcome (390,396). The role of intravaginal radiation in these patients is also of questionable benefit because of an almost negligible risk of vaginal recurrence with surgery alone. Straughn et al. (370) reported no vaginal recurrence in 103 patients with stage IA grade 1, 2 treated with surgery alone. This is no longer a discreet stage in the 2010 FIGO staging system.

Cancer Limited to the Mucosa, Grade 3

In GOG 33, there were only eight patients with stage IA grade 3 disease, making it difficult to draw any meaningful conclusion (59). There were no relapses in the three patients receiving postoperative radiation as compared with one failure in the five patients who received no postoperative therapy. The risk of LN metastasis in this group of patients is negligible. Straughn et al. (370) reported on eight patients with stage IA grade 3 disease treated with surgery alone, with two of the patients developing isolated vaginal recurrence. Again this subgroup is not formally staged in the new FIGO staging system.

Low-Risk Stage I A, B Grades 1, 2

Straughn et al. (370) reported on 296 patients with IB grade 1, 2 and found only nine (3%) vaginal recurrences and one (0.3%) pelvic recurrence. Horowitz et al. reported on 62 patients who had surgical LN staging and received adjuvant intravaginal brachytherapy. There was one (1.6%) vaginal recurrence and no pelvic recurrence (392). In comparison, data published by Alektiar et al. (397) reported that 233 patients with IB grade 1, 2 showed a vaginal recurrence rate of only 1% and pelvic recurrence of 2% using postoperative intravaginal brachytherapy alone without routine surgical LN staging. In addition, Sorbe et al. (398) reported on 110 patients without retroperitoneal LN sampling with IB grade 1, 2 who were

part of a prospective, randomized trial evaluating two different intravaginal brachytherapy doses; the rate of vaginal recurrence was 0.9% and pelvic recurrence 1.8%. These patients also often fit the GOG 99, PORTEC 1, and PORTEC 2 trials, with or without lymphadenectomy. Thus, it seems reasonable to suggest that either observation or intravaginal brachytherapy (irrespective of surgical staging) is a reasonable option. But when deciding on whether adjuvant radiation is needed, it is important to address three issues. First, older patients tend to have higher rates of relapse. In the study by Straughn et al., (370) 8 of the 10 vaginal/pelvic recurrences were in patients ≥60 years old, which was confirmed in the randomized trials. Second, patients with lymphovascular invasion (LVI) have a higher chance of vaginal recurrence as demonstrated by Mariani et al. (373) who reported on 508 patients with stage I EC treated with surgery alone (152 out of 508 were stage IA). The presence of LVI increased the vaginal relapse rate from 3% to 7% ($p = 0.02$) as was confirmed by the GOG 99 trial among others. Recent publications of high-intermediate and high-risk stage I–III endometrial carcinoma patients suggest LVI to be an independent prognostic factor for relapse and survival. (367,399). Third, often the indications for adjuvant radiation are rather arbitrarily based on the amount of myometrial invasion defined in thirds and on whether the tumor is grade 1 versus 2. Yet the amount of myometrial invasion in this group of patients and whether an EC is assigned as grade 1 or 2 do not appear to be significant predictors of outcome (400,401). It is reasonable to offer patients younger than 60 years of age with stage IA grades 1 and 2 disease without LVI observation, whereas those patients ≥60 years or those with LVI are offered adjuvant brachytherapy. It is worth noting that the most common site of recurrence is the vaginal vault and adjuvant brachytherapy is a low-morbidity treatment. When undecided whether to offer brachytherapy, it should be considered that it is a far less intensive treatment than salvage radiation for recurrent disease.

Intermediate to High-Intermediate Risk Stage IB Grade 3 to IC Grades 1, 2, 3, Stage II

Up until the last 10 years, most data in the literature on this group of patients were based on pelvic radiation either alone or in combination with intravaginal brachytherapy (389,390,402,403). Since 1988 and with the increase in surgical LN staging in the United States, a shift occurred with regard to the role of radiation for stage IB grade 3 and even in stage IC disease. For some time, the treatment decision between whole pelvis RT and VCB alone was primarily based on whether the patient had surgical LN staging. If the decision is made that nodal assessment is necessary, which has been called into question for all early-stage patients, an adequate LN sampling/dissection should, at a minimum, meet the GOG guidelines of sampling the obturator, external iliacs, internal iliacs, common iliacs, and para-aortic LN stations, and the minimum number of nodes sampled should be ≥10.

Surgically Staged Patients

For patients with IB grade 3 disease, the retrospective data on intravaginal brachytherapy alone after surgical staging was encouraging (Table 21.14). The average rate of vaginal recurrence and pelvic recurrence was reported as 1.3% for both. This compares favorably with the data from the PORTEC I trial where the 5-year rates for vaginal and pelvic recurrence, in the subset of patients with IB grade 3 disease treated with pelvic radiation (n = 35), were 0% and 3%, respectively. A multi-institutional review of 220 patients with stage IC EC by Straughn et al. (371) compared adjuvant radiation to no radiation in patients with negative nodes on surgical staging. The investigators concluded that adjuvant radiation is not needed although the 5-year DFS was 74.5% for those treated with surgery alone compared to 92.5% for those treated with adjuvant radiation ($p = 0.0134$). It is unlikely that observation alone, even in those patients with full surgical staging, will be the best approach when VCB carries low morbidity and can greatly decrease the 18% statistically significant difference in DFS from a retrospective study in which it is inferred that patients with the worst prognostic features were the ones who received radiation.

TABLE 21.14 Outcome for IB Grade 3 EC after Surgical LN Staging and

Intravaginal Radiation Therapy (IVRT) Alone					
Author	Year	No. of Patients	Median F/U	Vaginal Rec	Pelvic Rec
Fanning	2001	21	52 months	0%	0%
Horowitz	2002	31	65 months	0%	0%
Alektiar	2007	21	46 months	4.8% (1/21)	4.8% (1/21)
Total	—	73	—	1.3% (1/73)	1.3% (1/73)

EC, endometrial cancer; F/U, follow-up; LN, lymph node.

Several investigators have shown the feasibility of such an approach with an average vaginal recurrence rate of 1.6% and pelvic control rate of 2.1% (Table 21.15). Thus, intravaginal brachytherapy alone after surgical staging in patients with IB grade 3 and IC EC seems to provide better local/regional control than surgery alone and in a properly selected patient population with very few pelvic failures (144,392,404-407). As described previously, the GOG 0249 trial randomized the HIR population to VCB followed by CT (carboplatin/paclitaxel for three cycles) or pelvic RT (IMRT or 3D conformal) plus an optional cuff brachytherapy boost for high-risk features, and appeared to show equivalence. Note that LN dissection was optional in this trial. In addition, while LN dissection is not allowed, further information may be gained by the PORTEC 3/EN.7 trial that randomizes patients with (1988 FIGO) Stage IB grade 3 with LVI, Stage IC or IIA grade 3, Stage IIB, Stage IIIA or IIIC, or stages IB–III serous or clear cell EC between pelvic RT alone to 48.6 Gy and the same pelvic RT with two cycles of concurrent cisplatin plus four adjuvant cycles of carboplatin/paclitaxel. In the PORTEC 3 trial, the vaginal cuff boost is given in patients with cervical invasion. In the absence of robust evidence, the risk of pelvic failure must be gauged on an individual patient basis to determine whether the risk is sufficient to warrant pelvic radiation versus VCB alone. In the PORTEC trial, 99 patients with Stage IC grade 3 tumors were not randomized but were followed prospectively, and all received pelvic irradiation in the absence of LN evaluation. The locoregional recurrence rate in this high-risk group of patients without a node dissection was 12% (5% vaginal), despite adjuvant irradiation. Note that patients with uterine serous and clear cell carcinoma were not identified separately in this trial, so the percentage of these high-risk pathologies is not known, and given the very high distant failure rate, of 31%, this is noted to be a very high-risk subgroup of patients (162).

TABLE 21.15 Outcome for IC Endometrial Cancer Grade 1–3 after Surgical LN Staging and IVRT Alone					
Author	Year	No. of Patients	Median F/U	Vaginal Rec	Pelvic Rec
Horowitz	2002	50	65 months	2% (1/50)	4% (2/50)
Rittenberg	2003	53	32 months	0%	1.8% (1/53)
Solheim	2005	40	23 months	0%	0%
Alektiar	2007	40	46 months	5% (2/40)	2.5% (1/40)
Total	—	183	—	1.6% (3/183)	2.1% (4/183)

F/U, follow-up; IVRT, Intravaginal Radiation Therapy; LN, lymph node; rec, recurrence.

With the publication of the two randomized trials, ASTEC and CONSORT, questioning the benefit for lymphadenectomy, many gynecologic oncologists in the United States have chosen to evaluate the nodes only in those patients most at risk for metastatic disease—those with deeply invasive tumors, high-grade disease, high-risk histology, older patients, and those with LVI or a combination of factors. Examining the trials where routine lymphadenectomy is performed demonstrates the risk for all Stage I patients to be approximately 10% (59,155,156), but selecting the patients at highest risk for disease, while it may not change survival, can certainly guide further treatment paradigms.

No Surgical Lymph Node Staging

In those patients with a combination of high-risk features such as grade 3 tumor, high-risk histologies, LVI, advanced age, or deep myometrial invasion, intravaginal brachytherapy may not be adequate treatment. In the Aalders et al. (386) randomized trial, the rate of local recurrence in the subset of patients with IB grade 3 to IC was 9.3% (13 of 137) for those treated with brachytherapy alone compared to 1.3% (2 of 146) for those treated with brachytherapy and external radiation. This finding is not unexpected as no LN assessment was performed in that trial. Weiss et al. reported on 61 patients with stage IC EC who were treated with postoperative pelvic radiation alone. With a median follow-up of 69.5 months, there was only one recurrence in the pelvis (1.6%). Their review of the published data from the literature for patients with stage IC disease showed a pelvic recurrence of 1.04% in 240 patients treated with pelvic radiation alone compared to 0.97% in 301 patients treated with pelvic and intravaginal radiation. The authors concluded that pelvic radiation alone is sufficient for local-regional control, and clinical efforts should focus on reducing the risk of distant relapse in this subgroup of patients (408). The results of the PORTEC 3 trial may help further stratify patients who may be appropriate candidates for observation or VCB alone, or those at sufficiently high risk who benefit from intensification of therapy, including a combination of adjuvant irradiation and chemotherapy.

Stage II

It is important to recognize the distinction between gross and occult cervical involvement in EC. Gross cervical involvement increases the risk of parametrial extension as well as spread to pelvic LN in a fashion similar to primary cervical cancer. Patients with gross cervical involvement from EC could undergo radical hysterectomy and pelvic LN dissection or preoperative radiation including pelvic radiation and intracavitary brachytherapy followed by simple hysterectomy. For occult cervical involvement, the treatment often consists of simple hysterectomy with or without LN surgical staging and adjuvant radiation. The type of radiation most often utilized is pelvic radiation and intravaginal brachytherapy. Pitson et al. (409) reported on 120 patients treated with such a combination. The 5-year DFS rate was 68% and the rate of pelvic relapse was 5.8% (7 of 120).

There are also emerging data on the role of intravaginal brachytherapy alone in patients with occult cervical involvement who also had surgical LN staging. The rate of pelvic recurrence in four such series ranged from 0% to 6%, but a larger number of patients and longer follow-ups will be necessary in order to confirm this data. (392,394,410,411). Stage II EC is now defined by cervical stromal invasion. The new staging system now only encompasses the latter with true cervical stromal invasion into Stage II (89). Intravaginal brachytherapy alone could be used for surgically staged patients with mucosal involvement alone (392,412), whereas those with disease invading into the stroma, with close margins or with a significant amount of cervical disease, should be treated with pelvic radiation with or without intravaginal brachytherapy boost until trial results demonstrate a better option.

Advanced-Stage Disease

Radiation

The outcome of patients with isolated adnexal involvement (stage IIIA) treated with pelvic radiation is fairly good, although the studied patient numbers are small. Connell et al. (413) reported on 12 patients treated with postoperative pelvic radiation with a 5-year DFS of 70.9%. The weighted average of 5-year DFS and OS rates from literature review in that study were 78.6% and 67.1%, respectively. Patients with isolated serosal involvement (stage IIIA) have a worse prognosis than those with isolated adnexal involvement. Ashman et al. (414) reported on 15 patients with isolated serosal involvement who were treated with pelvic radiation. The 5-year DFS was only 41.5%. If pelvic node involvement (IIIC1) is the only major risk factor, treatment with postoperative pelvic RT can yield a 60% to 72% long-term survival rate (165,415,416), although distant failure is a problem that new trials evaluating CT will hopefully change. Patients with stage IIIC2 disease, by virtue of para-aortic node involvement, represent a particularly high-risk group. Following surgery, these patients are

generally treated with extended field radiation to encompass the pelvis and the para-aortic regions. With this aggressive approach, several investigators have reported 30% to 40% survival rates in small patient populations (417-419). The question of whether it is safe to omit radiation even after adequate surgical LN staging in patients with IIIC2 EC was addressed in a study from the Mayo Clinic. Mariani et al. reported on 122 patients with node-positive disease; at 5 years, the risk of pelvic recurrence was 57% after inadequate LN dissection and/or no RT compared to 10% with adequate LN dissection (>10 pelvic nodes and ≥5 para-aortic nodes) and radiation. This difference was statistically significant on univariate ($p < 0.001$) and multivariate analysis ($p = 0.03$), indicating the need for postoperative radiation even after adequate surgical staging (142). The recognition that a significant number of patients with stage III disease fail in the abdomen (373,415) has prompted a number of investigators to evaluate whole abdominal RT in these patients (420,421) and after a small GOG trial a randomized trial was undertaken (422).

Chemoradiation

In the GOG 122 trial, 396 patients with stage III and optimally debulked stage IV disease were randomized to whole abdomen radiation (n = 202) or to doxorubicin–cisplatin chemotherapy (n = 194). With a median follow-up of 74 months, there was significant improvement in both PFS (50% vs. 38%; $p = 0.007$) as well as OS (55% vs. 42%; $p = 0.004$), respectively, in favor of CT (332). To elucidate the right approach for these patients, however, a closer look at this data is warranted. First, the overall absolute rate of relapse was 54% in the radiation arm compared to 50% in the CT arm, a small difference if any, yet the corresponding 5-year PFS rates were 38% and 50% ($p = 0.007$), respectively. Why the discrepancy? The answer is that the 5-year PFS rate for the radiation arm was 38%, whereas the CT arm has two separate 5-year rates. The first one, called unadjusted, was 42%, which is not that significantly different from the 38% rate with radiation, and the second, called "adjusted for stage," was 50%, which was significantly different from the radiation arm. This led us to the second issue: Was the adjustment for stage warranted? The answer is no. Numerically, there were more patients with lymph node involvement in the CT than the radiation arm, but having positive LN was not an independent predictor of poor outcome in this study. Therefore, the adjustment was not warranted, and if any adjustment was needed it should have gone to the radiation arm since there were more patients with positive cytology in this arm, a factor with an HR of 1.8 (95% CI, 0.89 to 1.55) in predicting poor outcome. Third, what should be made of the significant difference in OS? There were 15 deaths unrelated to EC or protocol treatment in the radiation arm compared to only 6 in the chemotherapy arm, raising a question about whether the two arms of the study were truly balanced. Finally, the pelvic recurrence rate was lower in the RT arm which indicates that perhaps both modalities could be used for the advantages they provide—locoregional control for irradiation and distant control for chemotherapy. Another randomized trial comparing adjuvant radiation to CT (doxorubicin–cisplatin–cyclophosphamide) in patients with stage I–III was recently reported and showed no difference in outcome between the two arms (423). With a median follow-up of 95.5 months, the 5-year DFS was 63% in both arms ($p = 0.44$), and the 5-year OS rates were 69% in the radiation arm compared to 66% in the CT arm ($p = 0.77$). What these two trials show is that CT at a minimum is equivalent to radiation in this group of patients and ought to be used, not alone, but rather in combination with radiation. Greven et al. reported the results of Radiation Therapy Oncology Group (RTOG) 9708 on 44 patients with stage I–III EC who were treated with pelvic radiation and intravaginal brachytherapy given concurrently with cisplatin 50 mg/m^2 on days 1 and 28 of radiation, followed by four cycles of cisplatin (50 mg/m^2) and paclitaxel (Taxol) (175 mg/m^2). The 4-year DFS and OS rates for those with stage III disease (66% of patients) were 72% and 77%, respectively (424).

As the follow-up study to GOG 122, GOG 184 was launched. The combination of irradiation and CT was used to control disease and was done in a sequential fashion to limit toxicity. Five hundred fifty-two Stage III and IV patients were enrolled (after 66 patients were enrolled, those with upper abdominal disease were excluded) and received tumor volume-directed irradiation (51% received 5,040 cGy pelvis irradiation alone and 49% received 4,320 to 4,350 cGy of extended field for positive para-aortic disease, or undissected para-aortics) and were then randomized to cisplatin/adriamycin or cisplatin/adriamycin/paclitaxel (425). Growth factors were allowed, and 80% of the patients were able to complete the

assigned CT regimen following full-dose RT. The locoregional recurrence rate (any failure in the pelvis, vagina, or para-aortics as first failure) was 10%, which compares favorably with GOG 122 (isolated failures 13% in the whole abdominal irradiation (WAI) arm and 18% in CT arm); Greven's (168) study of 105 irradiated patients with IIIC disease with a pelvic failure rate of 21%; and Mundt's two series, one described 30 patients with stage IIIC treated with postoperative pelvic irradiation with an infield failure rate of 23% and the second, trial of 43 high-risk stage I–IV EC patients treated with CT alone who experienced a 21% actuarial rate of pelvic recurrence as their first or only site of recurrence (426,427). The distant failure rate in these trials was unacceptably high ranging from 26% to 55%. The PORTEC 3 trial described above and the open GOG 0258 address treatment in this advanced population. In the GOG 0258 trial, Stages III or IVA are randomized between volume-directed postoperative irradiation with concurrent cisplatin, followed by four cycles of carboplatin/taxol or six cycles of carboplatin/taxol alone.

CHAPTER 22 Corpus: Mesenchymal Tumors

Mario M. Leitao Jr., Carmen Tornos, Aaron H. Wolfson, and Roisin O'Cearbhaill

INTRODUCTION

Mesenchymal tumors of the uterine corpus are rare, accounting for approximately 7% to 8% of all uterine cancers (1). The outcomes of many of these tumors seem to be less favorable than in many of the more common uterine carcinomas. However, outcomes do vary significantly based on specific histology. These tumors are believed to arise from the mesenchymatous portion of the uterine corpus, and are often considered to be uterine "sarcomas." The World Health Organization (WHO) classification of mesenchymal uterine corpus tumors is summarized in Table 22.1 (2). Uterine carcinosarcomas (CS) may not be best classified as sarcomas or mesenchymal tumors any longer, but rather as metaplastic carcinomas of the uterus (3). Nevertheless, this group of malignancies will be described as "uterine CS" in this chapter. A key concept is that uterine sarcomas are truly heterogeneous tumors with vastly different clinical presentations, responses to therapy, and outcomes. Until recently, much of the available literature has been extremely limited, as most studies have combined all uterine sarcomas into a single cohort.

EPIDEMIOLOGY AND RISK FACTORS

Histologic Distribution

The histopathologic criteria for uterine sarcomas have evolved significantly over the last few years. Therefore, histologic distribution may have shifted. Many series do not include or specify sarcoma subtypes, and many of these studies report on very small patient cohorts. By combining series with at least 100 cases, including CS, we see that the most common uterine sarcomas are leiomyosarcoma (LMS) and CS (4-9) (Fig. 22.1A). LMS accounts for over two-thirds of uterine sarcomas (4-10) (Fig. 22.1B). Endometrial stromal sarcomas (ESS) account for approximately 25% of true uterine sarcomas; all other subtypes are exceedingly rare, comprising <10% (4-10) (Fig. 22.1B). ESS has traditionally been considered a low-grade tumor. Undifferentiated uterine sarcoma is now the preferred terminology for what was previously described as high-grade ESS.

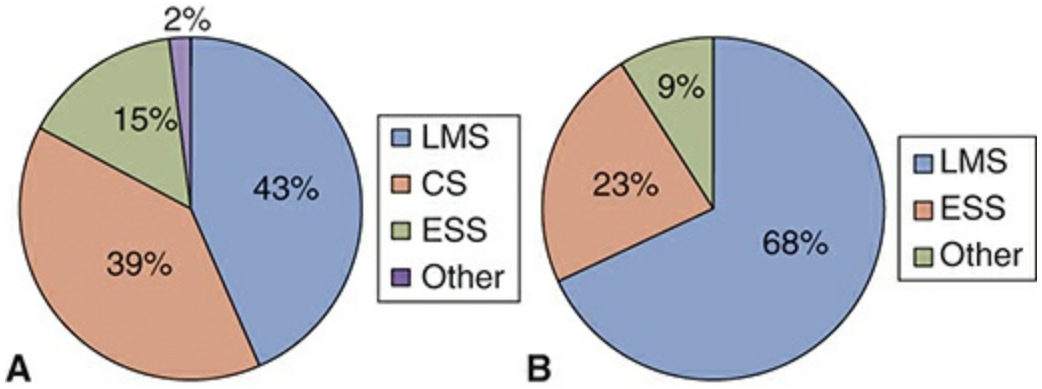

Figure 22.1 Histologic distribution of uterine sarcomas in series with at least 100 cases, (A) including CS and (B) excluding CS. ESS, endometrial stromal sarcoma; CS, carcinosarcoma; LMS, leiomyosarcoma; AS, adenosarcoma.

However, the description of high-grade ESS has been redefined (11). Most recently, Abeler and colleagues (10) reported the largest series of uterine sarcomas (n = 419) from the Norwegian Cancer Registry (which describes histologic subtype distribution). This series excluded CS altogether. Of the 419 included sarcomas, 62% were LMS, 20% were ESS, and 18% were various other subtypes including undifferentiated sarcomas (6%), adenosarcomas (5.5%), sarcoma not otherwise specified (NOS) (4.5%), rhabdomyosarcoma (<1%), giant cell sarcoma (<1%), and perivascular epithelioid cell tumors (PEComa; <1%) (10).

Age Distribution

Patients with CS and adenosarcomas (AS) tend to be older at the time of diagnosis compared to those with LMS and ESS. The mean/median ages reported in the published series range from 42 to 51years for ESS (4,5,9,10-16), 48 to 57 years for LMS (4,5,9,10,17-19), 57 to 67 years for CS (4,5,9,20,21), 58 to 66 years for AS (10,22), and 46 years for undifferentiated sarcomas (12). Thus, many patients with CS are postmenopausal at the time of diagnosis, whereas patients with LMS, ESS, or undifferentiated sarcomas may be pre- or perimenopausal at diagnosis. The mean age for patients diagnosed with smooth muscle tumors of uncertain malignant potential (STUMP) is 43 years, and many of these patients are likely to be premenopausal (23). This has potential implications in terms of patient fertility. The other tumor subtypes are so rare that it is difficult to discern a particular pattern of age distribution among them.

Racial Distribution

Zelmanowicz et al. (24) noted that women with CS are more likely to be of African American descent (among 453 patients and controls, 28% vs. 4% other, p = 0.001) than those with endometrial adenocarcinomas. In reviews by Mortel et al. and Norris et al. (25,26), 33% and 24% of patients with CS were non-Caucasian, respectively. Brooks et al. (27) reported that the age-adjusted incidence of uterine sarcomas in African American women was twice that of controls. The age-adjusted incidences of LMS for Black and White women, respectively, were 1.5 and 0.9 per 100,000. Those for CS in African American and Caucasian women, respectively, were 4.3 and 1.7 per 100,000. Felix and colleagues (28) noted that African American race was more prevalent among 82 LMS cases (20.7%) compared to 98 EMS cases (6.1%).

Risk Factors

Prior Radiation Exposure

Prior exposure to pelvic radiotherapy (RT) is thought to increase the risk of developing a subsequent uterine sarcoma, primarily CS and undifferentiated sarcoma. However, prior pelvic RT is not thought to increase the risk for uterine LMS or STUMP. In a large series from the Mayo Clinic, only 1 (0.6%) of 208 patients with LMS had received prior pelvic RT (29). In a study from MD Anderson Cancer Center, none of 41 patients with STUMP had a history of pelvic RT (23). In a study by Christopherson et al. (30) only 2 of 33 patients with uterine LMS had a history of RT.

In the series of CS reported by Norris et al. in 1966 (26), 9 of 31 (29%) patients had received pelvic RT 7 to 26 years prior to diagnosis. In a 1986 report by Meredith et al. (31) on 1,208 uterine malignancies, only 30 (2.4%) patients had received prior pelvic RT. Interestingly, only 8 patients had received RT for a gynecologic malignancy; others had pelvic RT for a benign diagnosis. Of irradiated patients, 5 (17%) developed CS, with a crude association of 11%. The risk of endometrial adenocarcinoma after radiation was much less than 2%. It has been suggested that postirradiation CS occur at a younger average age than those arising *de novo* (32). Latency to diagnosis of malignancy is generally shorter in older patients (31). Pothuri et al. (33) compared the clinicopathologic characteristics of 23 cases of uterine cancers occurring in patients with prior history of cervical cancer treated with pelvic RT, to 527 cases of uterine cancers in patients with no history of pelvic RT. CS and undifferentiated sarcomas accounted for 9 (39%) of the 23 radiation-associated malignancies, compared to 33 (8%) of the sporadic cases (33). It appears that radiation-associated malignancies tend to have a worse outcome, possibly due to lack of early symptomatology. In the setting of other, very rare uterine sarcoma subtypes, definitive assessment is precluded.

Hormone Exposure and Obesity

It has been suggested that exposure to hormonal medications, including tamoxifen, may increase the risk of uterine sarcomas. The association of estradiol–progestin therapy was assessed by Jaakkola et al. (34) using data from the Finnish Cancer Registry (which captures nearly 100% of all cancers in Finland) and the Reimbursement Registry of the Social Insurance Institution of Finland. Uterine sarcomas occurred in 76 of the 243,857 women identified as having used estradiol–progestin therapy for more than 6 months. Carcinosarcomas were not included in this analysis. Use of estradiol–progestin therapy was associated with a 60% elevation in risk for any uterine sarcoma (standardized incidence ratio [SIR], 1.6; 95% confidence interval [CI], 1.2–1.9). It was mostly associated with LMS (SIR, 1.8; 95% CI, 1.3–2.4); no statistically significant association with ESS was identified (SIR, 1.4; 95% CI, 0.9–2.1). Additionally, the elevated risk was noted only in women who had used estradiol–progestin therapy for 5 years or more.

The Epidemiology of Endometrial Cancer Consortium (E2C2) recently published a pooled analysis of 15 cohort and case–control observational studies (28). This is the largest series to date assessing risk factors for uterine sarcoma (n = 229) and CS (n = 244) versus endometrioid endometrial carcinomas (n = 7,623) and normal controls (n = 28,829). Uterine sarcomas included all sarcomas of the uterus, with 98 ESS and 82 LMS. Oral contraceptive use, postmenopausal estrogen (ER)-alone use, and postmenopausal ER–progesterone (PR) use were not associated with uterine sarcoma or CS. No association was found when LMS and ESS were analyzed separately. Thus, it seems that the association of hormonal use with risk of uterine sarcoma or CS is not strong. As the risk is exceedingly low, these data should not dissuade use of hormones in appropriate cases.

Interestingly, the E2C2 analyses suggested an association of obesity (BMI ≥30 kg/m^2) with uterine sarcoma (OR = 1.73 [95% CI, 1.22–2.46]) and CS (OR = 2.25 [95% CI, 1.60–3.15]). Obesity was also associated with ESS (OR = 1.74 [95% CI, 1.03–2.93]), but not LMS (OR = 1.56 [95% CI, 0.88–2.77]). As ESS is known to be ER-driven, the association with obesity is understandable. However, the association of obesity with CS in this analysis requires further study and validation.

Tamoxifen Use

Tamoxifen use among breast cancer patients may also increase the risk of uterine malignancies, including sarcomas. Using

data from the National Israeli Cancer Registry, Lavie and colleagues (35) reported on 1,507 cases of women with breast cancer diagnosed from 1987 to 1988. They noted that uterine cancers developed in 17 of 886 (1.9%) women treated with tamoxifen, compared to only 4 of 621 (0.6%) women who did not receive tamoxifen (OR, 3.1; 95% CI, 1–9.1). The risk of uterine cancer was associated with increased duration of tamoxifen use. A significant association was seen with more than 4 years of tamoxifen use (OR, 6.6; 95% CI, 2.0–21.1), whereas use of tamoxifen for 2 years or less was not associated with an increased risk (OR, 2.1; 95% CI, 0.4–11.6). Uterine sarcomas developed in only four patients in the entire cohort; these included two CS and two rhabdomyosarcomas. All four occurred in patients who received tamoxifen, suggesting a possible association of tamoxifen use andrisk of uterine sarcoma. Hoogendoorn and colleagues (36) reported that among patients diagnosed with uterine cancer, CS accounted for a much larger proportion of cases in those who had received prior tamoxifen therapy compared to those who had not (15% vs. 4%, respectively).

Hereditary Predisposition

Hereditary predisposition to certain uterine sarcomas has also been suggested, but this remains to be elucidated. Using the Danish Hereditary Nonpolyposis Colorectal Cancer (HNPCC) Registry, Nilbert et al. (37) identified 164 HNPCC families with predisposing mutations; sarcomas of various sites represented only 1% (n = 14) of 1,570 malignant diagnoses. Three sarcomas were uterine: one was a CS in a 44-year-old with loss of MSH2 and MSH6 expression; another CS was seen in a 55-year-old with loss of MSH6 expression; another was an LMS in a 44-year-old with loss of MSH2 and MSH6 expression. Recently, it has been suggested that the prevalence of uterine LMS is increased in women with hereditary retinoblastoma (38). Although the overall risk of uterine sarcoma is low in these hereditary syndromes, it is nevertheless of interest. Because of the high risk of endometrial sarcoma, prophylactic hysterectomy is strongly recommended in women from HNPCC kindreds after childbearing is complete. No such recommendation exists for women with hereditary retinoblastoma, as the potential risk was only recently described. However, we believe that it is reasonable to consider prophylactic total hysterectomy, with retention of ovaries, in women with a history of retinoblastoma who have completed childbearing.

CLINICAL PRESENTATION AND DIAGNOSIS

Presenting Symptoms and Signs

The most common presenting symptom of uterine sarcoma is abnormal vaginal bleeding (4,12,14,22,27,38) (Table 22.2). Patients with LMS often present with an abdominopelvic mass, or a mass that is palpable on physical examination (4,27). LMS and ESS are often incidentally diagnosed after surgery for presumed uterine fibroids. ESS was an incidental finding in 42% of cases reported by Memorial Sloan Kettering Cancer Center (16). Therefore, it is quite likely that the vast majority of patients ultimately diagnosed with LMS or ESS would have some abnormal enlargement of the uterus, discovered after presentation with abnormal vaginal bleeding. Vaginal bleeding in a postmenopausal female should be evaluated appropriately, with endometrial sampling and possibly an intravaginal ultrasound (US). An enlarging pelvic mass in a postmenopausal female is suspicious for a malignant process. Proper assessment of symptoms and signs in premenopausal patients is a challenge, and diagnosis of malignancy is often delayed because multiple benign conditions are likely to cause such symptoms. CS often presents with vaginal bleeding in a postmenopausal female and can often be diagnosed with endometrial assessment, as it is a lesion arising in the endometrium (unlike true uterine sarcoma, which often lacks an endometrial component or endometrial involvement).

TABLE 22.2 Common Presenting Symptoms in Patients with Uterine Sarcomas (Percentage of Cases Describing the Symptoms)

Symptom	ESS (%) (4, 12, 14)	CS (%) (4)	LMS (%) (4, 27)	AS (%) (22, 38)
Asymptomatic	14	7	11	12
Abnormal vaginal bleeding	68	68	53	61
Abdominopelvic mass	14	16	48	—
Abdominopelvic pain	18	9	23	20
Uterine enlargement	64	—	—	—
Uterine cavity lesion	21	—	—	—
Vaginal discharge	4	—	—	—
Abdominal distention	—	—	—	2

AS, adenosarcoma; CS, carcinosarcoma; ESS, endometrial stromal sarcoma; LMS, leiomyosarcoma.

There are no reliable serum tumor markers for uterine sarcoma. Serum CA-125 is elevated in 17% to 33% of LMS, ESS, and CS (4). It should not be routinely used in the evaluation and diagnosis of these tumors. Preoperative endometrial assessment with office pipelle or dilation and curettage under anesthesia are of limited accuracy. However, endometrial assessments should be performed in all women who present with abnormal vaginal bleeding. Bansal et al. (39) reported that invasive tumor was diagnosed in 86% of uterine sarcoma cases through preoperative endometrial sampling. The correct histology was noted in only 64% of the cases ultimately diagnosed as uterine sarcoma (39). However, a majority of sarcomas in this series (32/46; 70%) were correctly diagnosed as CS on final pathology, as well as four LMS, two ESS, and eight other sarcomas (39).

Preoperative Imaging

Preoperative imaging is of limited accuracy in differentiating benign from malignant uterine lesions, especially in the absence of obvious extrauterine disease; nevertheless, it is often utilized as part of the initial evaluation of these patients. While CS are more often diagnosed via endometrial sampling, preoperative imaging may be valuable in determining the presence of extrauterine disease. Small single-institution retrospective series have suggested that pelvic magnetic resonance imaging (MRI) may be of value in identifying uterine sarcomas and distinguishing them from benign uterine lesions. Namimto et al. (40) reported 100% sensitivity and specificity using diffusion-weighted imaging (DWI) and T2-weighted MRI in distinguishing uterine sarcomas from benign lesions, compared to DWI alone. This seems promising, but it is unlikely to be utilized in clinical practice and its accuracy may not be reliably reproducible. For example, Cornfeld and colleagues (41), using various objective MRI criteria, reported that MRI showed very poor accuracy in distinguishing leiomyomas with atypical imaging features from malignant uterine mesenchymal tumors. Using various MRI-specific criteria, the sensitivity of this imaging modality in identifying uterine sarcoma ranged from only 17% to 56%; however, specificity was 80% to 100% (41).

Serum LDH and MRI

Serum lactate dehydrogenase (LDH) may be an interesting additive to imaging in the evaluation of uterine lesions concerning for LMS (Table 22.3). In a prospective trial, Goto and colleagues (42) reported an accuracy of 99.3% in predicting uterine LMS when serum LDH was combined with dynamic MRI. The positive predictive value (PPV) was 91% using the combined assessment, compared to 39% for LDH alone and 71% for MRI (dynamic or not). These results are impressive and require further validation, but it is simple enough to obtain a serum LDH in patients with concerning

lesions of the uterus. Another important point is that the series by Goto et al., as well as other series, report a high specificity and nearly 100% negative predictive value (NPV) for MRI, with or without LDH. This may be useful for patients who do not wish to undergo surgery, especially those desiring fertility. It may also help in deciding upon the surgical approach for patients with presumed benign leiomyomas as well as suspicious lesions.

TABLE 22.3 Test Characteristics Using Dynamic MRI and Serum LDH in Predicting Uterine LMS from Degenerating Leiomyomas

Test	Sensitivity (%)	Specificity (%)	Accuracy (%)	PPV (%)	NPV (%)
Total serum LDH	100	87.7	86.6	38.5	100
MRI	100	96.9	97.1	71.4	100
Dynamic MRI	100	87.5	90.5	71.4	100
LDH ... dynamic MRI	100	99.2	99.3	90.9	100

NPV, negative predictive value; PPV, positive predictive value.

Uterine Morcellation

Laparoscopy has become the standard, preferred approach in the management of women with benign and malignant gynecologic conditions. Morcellation of the uterus, either for removal of the specimen during minimally invasive procedures, for myomectomy for fertility preservation, or for supracervical hysterectomy, has been commonplace for many years. Morcellation is often not done in the setting of CS because these patients tend to be older and the diagnosis of malignancy is known preoperatively. However, it is not unusual that an LMS or ESS is incidentally diagnosed after some form of morcellation, or less-than-total hysterectomy. Morcellation of a uterine LMS is associated with worse outcome. Perri et al. (43) reported a significantly higher rate of recurrence and lower overall survival (OS) in women who had undergone something less than a total abdominal hysterectomy (TAH) and were subsequently diagnosed with uterine LMS. The hazard ratios (HR) for recurrence and survival in TAH compared to other types of resection (myomectomy, morcellation, or supracervical hysterectomy) were 0.39 and 0.36, respectively. Park et al. (44) reported a series in which the 5-year disease-free survival (DFS) was 40% in women who underwent tumor morcellation and were subsequently diagnosed with LMS, compared to 65% in patients with LMS who did not undergo morcellation ($p = 0.04$). Similarly, the 5-year OS was 46% after morcellation, compared to 73% in patients who were not morcellated ($p = 0.04$) (44). Morcellation also appears to have a negative impact on risk of recurrence in ESS, but no adverse impact on OS (45).

The true impact of morcellation of uterine LMS is difficult to fully understand because of the very small cohorts and overall poor quality of published reports. Bogani and colleagues (46) reported the results of an extensive meta-analysis on the impact of morcellation and outcomes in patients with unsuspected uterine LMS. Following an exhaustive review of the available medical literature databases, they identified 60 potential studies. After applying rigorous inclusion material, only four studies remained in the meta-analysis. These included 202 patients (75 morcellated, 127 non-morcellated); all were analyzed retrospectively. The 75 morcellated cases included patients who had undergone open, vaginal, laparoscopic, or hysteroscopic morcellation. Significantly higher rates of overall recurrence, intra-abdominal recurrence, and death were noted in the morcellated cohort. The combined death rate for morcellated versus non-morcellated was 48% and 29%, respectively (OR = 2.42 [95% CI, 1.19–4.92]; $p = 0.01$). The rate of extra-abdominal recurrence was not significantly different. The authors clearly noted a high risk of bias in all four studies.

The higher risk of recurrence and death may be a consequence of disseminated, unrecognized sarcoma during morcellation. The difference in intra-abdominal recurrence rates noted by Bogani and colleagues is very similar to that reported by Oduyebo et al. (47) in a small (but the largest available) series of cases of disseminated disease identified at the time of re-exploration, immediately after morcellation, from an unrecognized LMS. Disseminated sarcomatosis was noted in two out of seven patients (28.6%) with uterine LMS who underwent immediate re-exploration prior to noted recurrence. All seven were presumed to be stage I at the time of initial surgery. Both patients recurred and one died; the other had only 8 months of follow-up. In the five cases without disease at re-exploration, four (80%) have not recurred and are alive without evidence of disease at a median follow-up of 23.4 months (range, 3.5–48.2 months). The true value of re-exploration cannot be definitively stated based on such a small series. Additionally, one cannot comment on whether immediate re-exploration and possible debulking would alter the outcomes. However, immediate re-exploration and possible debulking are reasonable considerations. Re-exploration may provide information to help guide decisions regarding additional therapies. At a minimum, it provides prognostic information and a clearer understanding of the patient's current disease state.

Despite the potential adverse impact of morcellation on outcomes in patients ultimately diagnosed with LMS and ESS, we cannot definitively conclude that morcellation or myomectomy are entirely inappropriate in the management of patients with presumed benign leiomyomas. The risk of LMS and ESS in patients undergoing surgery for presumed benign leiomyoma is quite low. In a combined series of four studies with a total of 4,981 patients, the risk of LMS and ESS after surgery for presumed benign leiomyoma was only 0.24% and 0.06%, respectively (48-51). This risk is no greater in those undergoing surgery for an indication of rapidly enlarging leiomyoma (49).

The risk of unexpected malignancy is associated with age. In two large public database analyses, the risk of any uterine cancer was exceedingly low in women less than 40 years of age, but increased significantly with increasing patient age (52,53). Neither study specifically assessed the prevalence or risk of uterine sarcoma.

In April 2014, the U.S. Food and Drug Administration (FDA) issued a safety communication regarding uterine power morcellation (54). This communication was not an outright ban. It encouraged thoughtful decision-making when considering morcellation, but strongly discouraged it. The FDA communication also specified a need for careful patient counseling regarding the risks of power morcellation before consenting patients for surgery. While the FDA communication comments only on power morcellation, similar concerns remain with respect to myomectomy and supracervical (subtotal) hysterectomy that, as stated previously, are not morcellated. Additionally, little has been mentioned regarding uterine artery embolization of presumed uterine fibroids. In response to the FDA communication, many institutions decided to ban the use of power morcellation altogether. Patient safety is always the prime consideration in surgery. However, when morcellation is completely abandoned, there are many other consequences that must be taken into account. Barron and colleagues (55) reported a decrease in minimally invasive hysterectomies and myomectomies following the FDA announcement. Similarly, Harris et al. (56) reported a decrease in minimally invasive hysterectomy. An increase in surgical complications and readmissions were also noted. It is reasonable to obtain preoperative pelvic MRI when a less-than-total hysterectomy for presumed benign leiomyoma is planned. Appropriate imaging will help localize the tumors, and provides an excellent NPV. Serum LDH may also be useful in determining when morcellation may be less than optimal. However, a patient with a normal serum LDH and/or non-suspicious MRI may reasonably undergo morcellation, with little concern for uterine sarcoma. Morcellation should be avoided in patients with highly suspicious MRI and elevated serum LDH, and in postmenopausal patients with enlarging uterine masses, new uterine masses, or newly symptomatic uterine masses. (As it is unusual for postmenopausal women to experience sudden symptoms from either long-standing benign fibroids or new ones, these cases are highly suspicious for malignancy, and morcellation should be ruled out.) Proper and thoughtful patient selection is likely much more important in surgical decision-making than is the complete abandonment of a particular surgical tool. In December 2013, the Society of Gynecologic Oncology issued a position statement on morcellation, recommending that patients be counseled regarding the risk of occult malignancy prior to undergoing this procedure. They asserted that morcellation is generally contraindicated in the presence of known or suspected malignancy, and may be inadvisable in the treatment of premalignant conditions or risk-reducing surgeries (57).

STAGING AND PROGNOSIS

Staging Systems

The American Joint Committee on Cancer (AJCC) has presented a staging system for soft tissue sarcomas, but there are limitations in applying this to uterine sarcomas. The International Federation of Gynecology and Obstetrics (FIGO) presented a sarcoma-specific system only recently. A modified staging system based on the staging system for endometrial carcinomas was most commonly used (19). In a study at Memorial Sloan Kettering Cancer Center, Zivanovic and colleagues (19) demonstrated that neither the modified FIGO system nor the AJCC staging system was adequate. Figure 22.2 depicts PFS and OS based on staging, using the modified FIGO and AJCC systems (19). The concordance indices for PFS using the FIGO or AJCC systems were 0.6 and 0.596, respectively, and for OS 0.62 and 0.633, respectively. These are not ideal; in more accurate systems they are usually > 0.7. The prognostic inadequacy of both the modified FIGO and AJCC systems was further confirmed by investigators at Brigham and Women's Hospital (58).

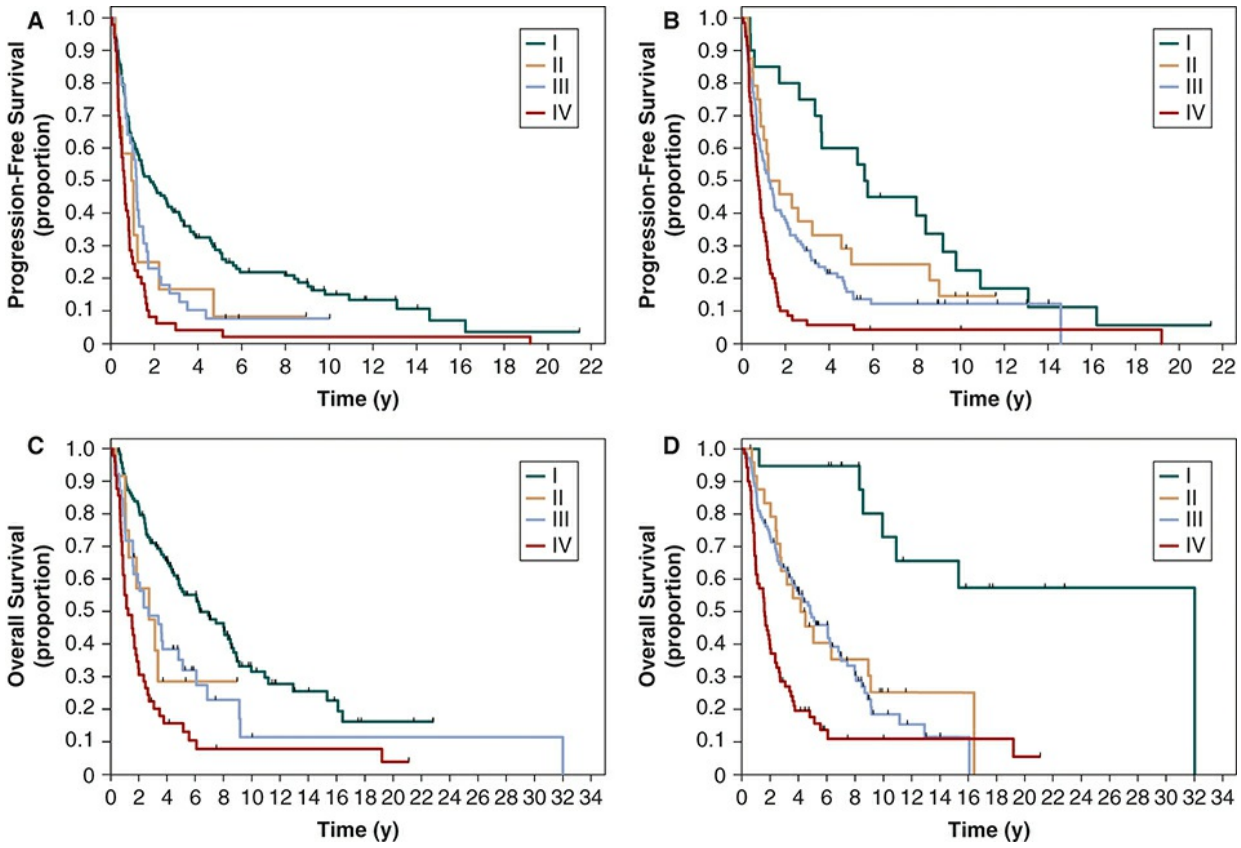

Figure 22.2 Progression-free survival by (A) FIGO stage and (B) AJCC Staging. OS by (C) FIGO stage and (D) AJCC stage.
Source: From Zivanovic O, Leitao MM, Iasonos A, et al. Stage-specific outcomes of patients with uterine leiomyosarcoma: a comparison of the International Federation of Gynecology and Obstetrics and American Joint Committee on Cancer Staging systems. J Clin Oncol. 2009;27:2066–2072, with permission.

In 2009, FIGO devised a uterine sarcoma-specific staging system for LMS, ESS, and adenosarcoma (3) (Tables 22.4 and 22.5). Carcinosarcomas are staged using the system for endometrial carcinomas (3). There are no clear guidelines with respect to staging other less common uterine sarcomas. However, the 2009 FIGO systems have not yet been validated. Garg and colleagues reported that the 2009 FIGO system did not demonstrate a more accurate prognostic

capability compared to the 1988 system for endometrial carcinomas (which was used to stage sarcomas prior to 2009) (21). Figure 22.3 depicts the stage distribution for newly diagnosed uterine sarcomas using older staging criteria—which essentially stages any disease beyond the uterine corpus and/or cervix as stage III or IV. On presentation, the majority of ESS, LMS, and adenosarcomas appear confined to the uterus and/or cervix (59,60). Carcinosarcomas and undifferentiated sarcomas have a much greater propensity for metastatic spread at time of presentation. The value of preoperative imaging to assess for extrauterine spread has been questioned (61). However, it is reasonable to use imaging preoperatively in patients with newly diagnosed uterine sarcomas to assess for extrauterine spread, as there is at minimum an approximately 25% or greater chance of extrauterine disease (Fig. 22.3), (except in the setting of adenosarcoma). On the basis of very small case reports and series, rarer subtypes are usually confined to the uterus on presentation.

	Stage I	Stage II	Stage III	Stage IV
ESS	71%	4%	15%	10%
LMS	68%	3%	7%	22%
AS	81%	8%	6%	5%
UUS	40%	8%	19%	33%
CS	33%	13%	32%	21%

Figure 22.3 Stage distribution of the more common uterine sarcomas. ESS, endometrial stromal sarcoma; LMS, leiomyosarcoma; AS, adenosarcoma; UUS, undifferentiated uterine sarcoma; CS, carcinosarcoma.

TABLE 22.4 2009 FIGO Staging System for Uterine LMS and ESS

Stage	Definition
I	Tumor limited to uterus
IA	Less than or equal to 5 cm
IB	More than 5 cm
II	Tumor extends beyond the uterus, within the pelvis
IIA	Adnexal involvement
IIB	Involvement of other pelvic tissues
III	Tumor invades abdominal tissues (not just protruding into the abdomen)
IIIA	One site

IIIB	More than one site
IIIC	Metastasis to pelvic and/or para-aortic lymph nodes
IV	
IVA	Tumor invades bladder and/or rectum
IVB	Distant metastasis

Uterine sarcomas confined to the uterine body (typically stage I) tend to have a worse prognosis than the more common endometrial carcinomas (except for ESS). The 5-year OS for patients with stage I ESS is approximately 97% (62). OS is excellent for patients with ESS, irrespective of stage; including all stages at presentation, OS is approximately 92% (15). This contrasts sharply with the outcomes seen in other uterine sarcomas. The 5-year OS for adenosarcomas confined to the endometrium is 84% (3); this drops to approximately 65% if there is any myoinvasion (5). The 5-year OS for LMS, CS, and undifferentiated sarcoma confined to the uterine corpus is 57%, 62%, and 52%, respectively (19,59,62). Patients diagnosed with STUMP were previously considered to have low-grade LMS. These patients have an outstanding prognosis, which may have biased previous reports on outcomes in LMS.

Nomograms

Improved prognostic systems and methods are needed for uterine sarcomas. Nomograms to provide prognostic and predictive information are being used more commonly. A nomogram designed to predict 5-year OS in patients with uterine LMS was developed by investigators at Memorial Sloan Kettering Cancer Center (63) (Fig. 22.4). In this nomogram, a total point score is obtained by adding up the various listed clinicopathologic criteria. The score is then plotted against the

5-year OS (line at the bottom) to determine an estimated survival. This nomogram is available online at http://www.mskcc.org/cancer-care/adult/endometrial-other-uterine/leiomyosarcoma/prediction-tools (64). The bootstrap-validated concordance probability (CP) for this nomogram was 0.65. It was externally validated using independent cohorts from two other sarcoma centers (65). The CP in this external validation was 0.67. Although more accurate than the current FIGO or AJCC systems, it is not ideal and requires further development and validation.

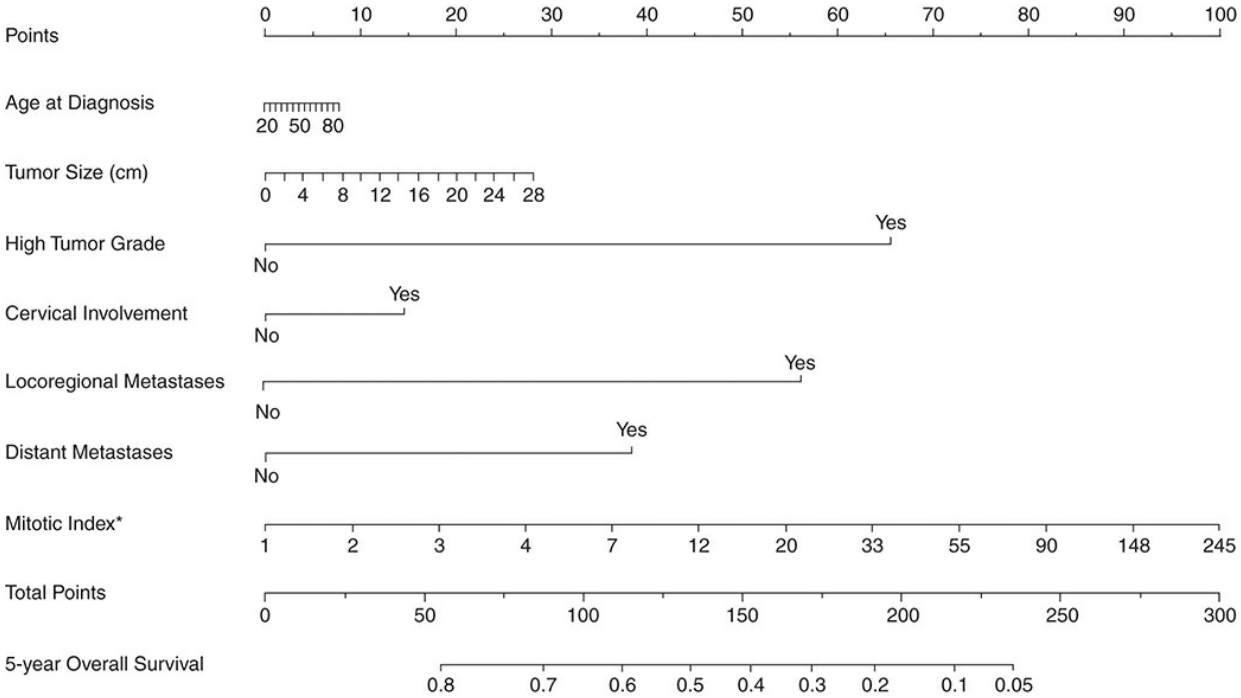

Figure 22.4 Nomogram for 5-year OS for uterine LMS. This is the uterine LMS nomogram for 5-year overall survival. The mitotic index (asterisk) was modeled using log transformation; for display purposes, values were converted back to original scale (exponential; CP, 0.671; bootstrap-validated CP, 0.651).
Source: Zivanovic O, Jacks LM, Iasonos A, et al. A nomogram to predict postresection 5-year overall survival for patients with uterine leiomyosarcoma. Cancer. 2012;118:660-669, with permission.

Molecular Prognostics

A possible reason for the limited prognostic capabilities of current staging systems and nomograms is that they rely on anatomic, clinical, and pathologic criteria that have not been consistently associated with outcome. A better molecular understanding of these tumors is urgently needed, and may possibly provide more accurate prognostication. Leitao and colleagues (66) have reported that ER and PR receptor expression in uterine LMS is associated with outcome. In their evaluation of cases presenting with extrauterine disease, including cervical extension alone, they found that ER/PR expression was not prognostic; however, it *was* prognostic in patients with disease confined to the uterine body. Most notably, of the 10 PR-overexpressing cases, only 1 patient recurred and died, compared to the 10 PR-non-expressing cases in which 9/10 recurred and 5 died (66). Ioffe and colleagues (67) also reported a possible association with hormone receptor expression and outcome in uterine sarcomas. Subtyping hormone receptors may further improve prognostication (68). Koivisto-Korander and colleagues (69) assessed the immunohistochemical association of various proteins (Ki-67, p53, CD10, CD44, desmin, SMA, ERa, and PR-A) with survival outcomes in patients with CS and LMS. They found that none of the expression patterns of any of these proteins was associated with survival in patients with CS (69). However, in patients with LMS, only E-RA and PR-A overexpression was associated with survival (69).

Expression patterns of other proteins have reportedly been associated with outcome. *b*-catenin expression has been

associated with crude survival in patients with LMS, but not in those with ESS, adenosarcoma, or undifferentiated sarcoma (70). Cyclooxygenase-2 (COX-2) expression has been independently associated with outcome in patients with LMS (71). COX-2 was not prognostic in patients with uterine CS (72). In a series reported by D'Angelo and colleagues (73), P53, p16, Ki67, and bcl-2 expression patterns were found to be associated with outcome in patients with LMS, but only bcl-2 was prognostic in undifferentiated LMS and ESS. CD10 and PTEN expression were not found to be prognostic (73). These are all interesting, hypothesis-generating reports. As we begin to unravel the molecular biology of these rare tumors, all of the existing studies will require further validation and investigation before we begin to incorporate them into clinically useful prognostic tools. However, improved prognostication will likely come from molecular-based analyses and possibly from protein and/or gene expression profiling. Unfortunately, uterine LMS appears to be hypermutated, making analysis and understanding of these tumors very challenging (74,75). Microarray analyses have revealed that these tumors harbor nearly 4,000 differentially expressed genes, compared to normal myometrium, at a false discovery rate of 0.0001 (76).

Patterns of Recurrence

Patterns of first recurrence are described in Table 22.6. The median PFS (i.e., time to recurrence) is greater than 100 months (8.3 years) in patients with ESS, based on the current criteria for diagnosis (12,14,77,78). Previous studies reported median PFS of 15 to 23 months for ESS (5,9). However, this probably reflects the inclusion of tumors now considered to be undifferentiated sarcomas, and not truly ESS. Few data exist on patterns of recurrence for undifferentiated sarcomas, but they are likely to reflect the patterns observed in other sarcomas or in those previously reported for ESS. The median time to recurrence for AS is approximately 40 months (22). LMS and CS have a very short median PFS of 12 to 19 months and 11 to 14 months, respectively (5,9,19,21,75,79). Extrapelvic recurrences are common; 82% of CS involve an extrapelvic site. The most common site of extrapelvic recurrence in ESS and LMS is the lung (80). The abdomen is the most common site of extrapelvic recurrence in adenosarcomas and CS. STUMP tumors have an exceedingly low risk of recurrence and nearly 100% OS. In a report from MD Anderson Cancer Center, only 3 of 41 STUMP cases recurred (1 each at 13, 47, and 68 months) (23). All patients were alive and without evidence of disease at the time of publication (23). The rarity of other uterine sarcomas precludes definitive comments on patterns of recurrence, but most tend to recur locally.

TABLE 22.6 Patterns of First Recurrence in Patients with Select Uterine Sarcomas

	ESS (12, 14, 78, 79)	AS (22)	LMS (5, 9, 19, 21, 80, 81)	CS (5, 9, 77, 80)
Median PFS (months)	101 – 130	41	12 – 19	11 – 14
Pelvic-only first recurrence[a]	43%	62%	41%	18%
Extrapelvic first recurrence[b]	57%	38%	59%	82%
Most common extrapelvic site	Lung	Abdomen	Lung	Abdomen

AS, adenosarcoma; CS, carcinosarcoma; ESS, endometrial stromal sarcoma (only includes true "low-grade" cases); LMS, leiomyosarcoma; PFS, progression-free survival.

[a]Includes vaginal ± other pelvic recurrence. [b]Some cases also with concurrent pelvic recurrence.

MOLECULAR BIOLOGY AND GENETICS

The association with expression patterns of certain proteins and outcome is described above. These data are limited and mostly non-validated. The key to improved prognostic and predictive tools, as well as therapeutics, in patients with uterine sarcomas will only be achieved when we attain a significant understanding of the inherent molecular biology of these tumors; at this time, our understanding is limited. Below, we describe some recent molecular studies of particular interest. Many more are in publication, and we expect additional data to be forthcoming. (Further description is provided in the **Pathology** section of this chapter.)

Gene rearrangements have been described and validated in patients with ESS, with at least 75% of tumors demonstrating gene rearrangement (81). The t(7;17) translocation resulting in the *JAZF1-SUZ12* gene fusion is the most common translocation, found in approximately 35% to 50% of ESS (81). Other noted gene fusions are *JAZF1-PHF1, EPC1-PHF1*, *JAZF1* only, and *PHF1* only (81).

Undifferentiated endometrial sarcomas (previously referred to as high-grade ESS) lack these *JAFZ1*-based rearrangements, and instead frequently harbor the *YWHAE-FAM22A/B* genetic fusion (11,82). The *YWHAE-FAM22A/B* fusion has been proposed as a possible oncogene in the development of undifferentiated (i.e., high-grade) ESS, because of the transforming properties of the YWHAE-FAM22 protein expressed by this gene fusion (11,82). Additionally, the *YWHAE-FAM22A/B* fusion appears to be specific to these tumors, as it was not detected in 827 other cases representing 55 tumor types (11).

LMP2 is an important immuno-protease subunit that is induced by IFN-g, and may be involved in various cell events—possibly including the suppression of tumor cell growth (83). Mice lacking LMP2 spontaneously develop uterine LMS, with an incidence of about 40% at 14 months of age (83). LMP2 expression appears to be absent in human LMS, but is retained in human leiomyomata (83). LMP2 may be involved in the sarcoma-genesis of uterine LMS, and this requires continuous investigation. LMS does not appear to harbor somatic mutations in *EGFR*, *CDKN2A*, *MET*, *KIT*, *RAS*, *BRAF*, *PI3KCA*, *HER-2*, or *PDGFR-a*, for which targeted therapies are available (84,85).

Growdon and colleagues (85) analyzed uterine CS for the presence of somatic mutations. The rate of mutations identified for each gene analyzed was *PIK3CA* (56%), *KRAS* (44%), *TP53* (33%), *CTNNB1* (6%), and *NRAS* (6%). *TP53* mutation was the only mutational event that retained an independent association with survival. The Akt/*b*-catenin pathway and alterations in Rb expression may be involved in the development of CS of the uterus (86). This is believed to be modified through transactivation of the *Slug* gene. Cimbaluk et al. (87) assessed immunohistochemical expression of potential therapeutic targets. They found that expression was low in both the epithelial and mesenchymal components for HER-2 (6% and 0%, respectively) and c-Kit (0%, both). EGFR expression in the epithelial and mesenchymal components was 30% and 67%, respectively. COX-2 was expressed in 70% of the epithelial component, but in only 16% of the mesenchymal component. VEGF was highly expressed in both the epithelial and mesenchymal components (100% and 93%, respectively).

PATHOLOGY

Malignant mesenchymal tumors can be classified as either pure mesenchymal tumors or tumors with mixed epithelial and mesenchymal components. In the first group, the most common is LMS, followed by ESS, and (rarely) other tumors including rhabdomyosarcoma, liposarcoma, angiosarcoma, chondrosarcoma, osteosarcoma, and alveolar soft-part sarcoma. Mixed epithelial and mesenchymal tumors include CS and AS. In addition, there are three rare mesenchymal tumors that occur in the uterus: uterine tumors resembling ovarian sex cord tumors (UTROSCTs), perivascular epithelioid cell tumors (PEComas), and inflammatory myofibroblastic tumor (88). These entities are usually benign, but may impede the differential diagnosis of malignant lesions.

LMS and Other Smooth Muscle Tumors

LMS are malignant smooth muscle tumors that usually arise *de novo*. Recent studies have shown that some of these tumors have areas of benign morphology, suggesting progression from leiomyoma to LMS (89,90); however, clonality studies support this progression in only a small percentage of cellular or symplastic leiomyomas (90,91). LMS is usually a solitary, poorly circumscribed mass with a soft and fleshy consistency. The cut surface is variegated, with gray areas intermixed with yellow areas of necrosis, and sometimes hemorrhagic areas. The epicenter of the tumor is the myometrium. Most LMS tumors are intramural. Occasionally, they extend into the cervix or beyond the uterus through the serosa (Figs. 22.5–22.7).

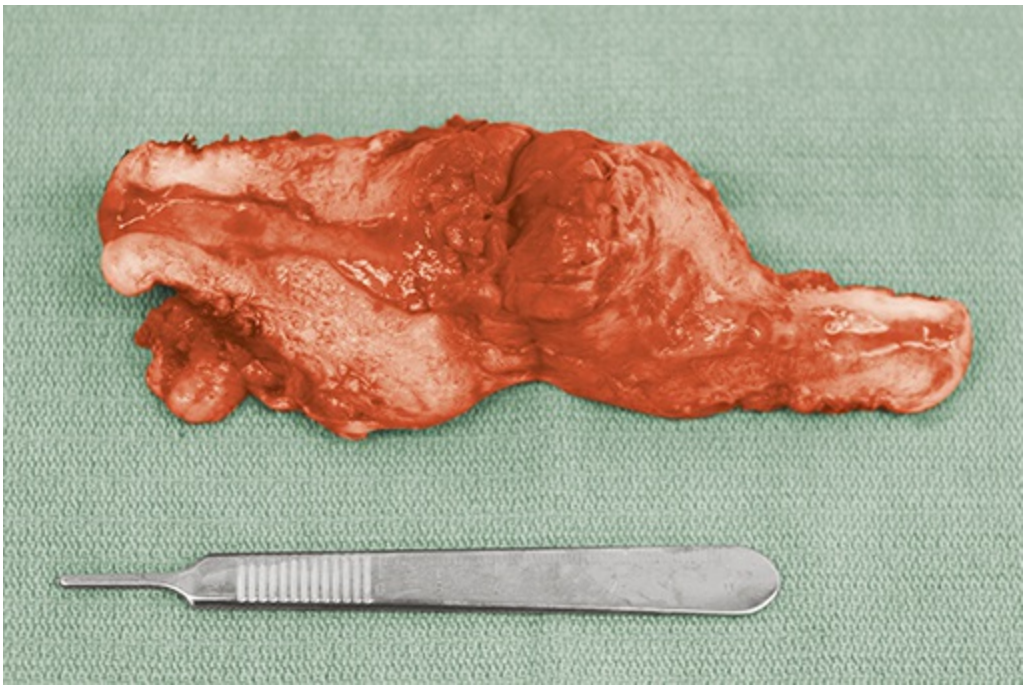

Figure 22.5 LMS, gross.

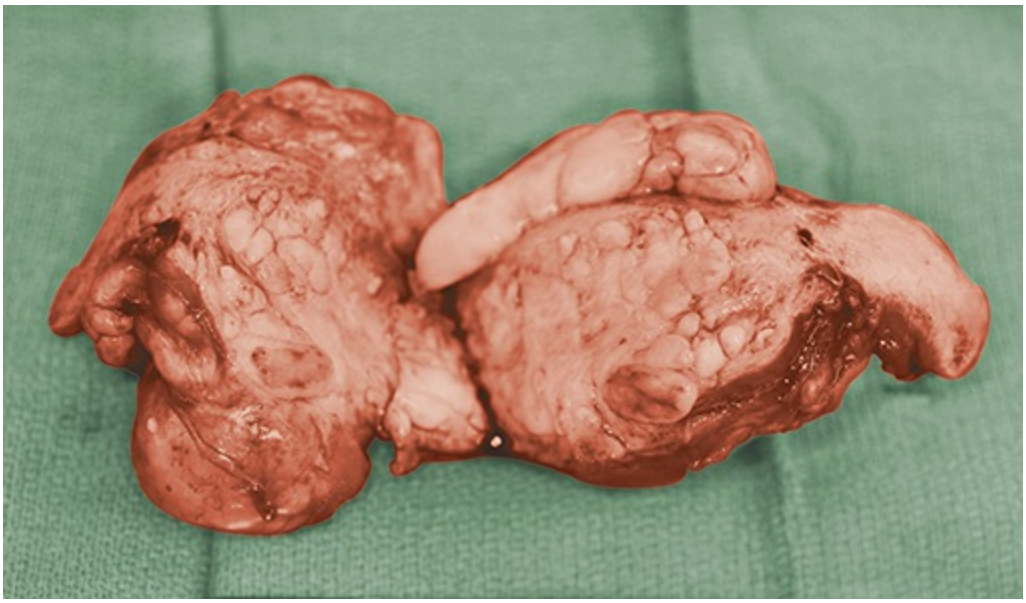

Figure 22.6 LMS, gross, showing heterogenous appearance.

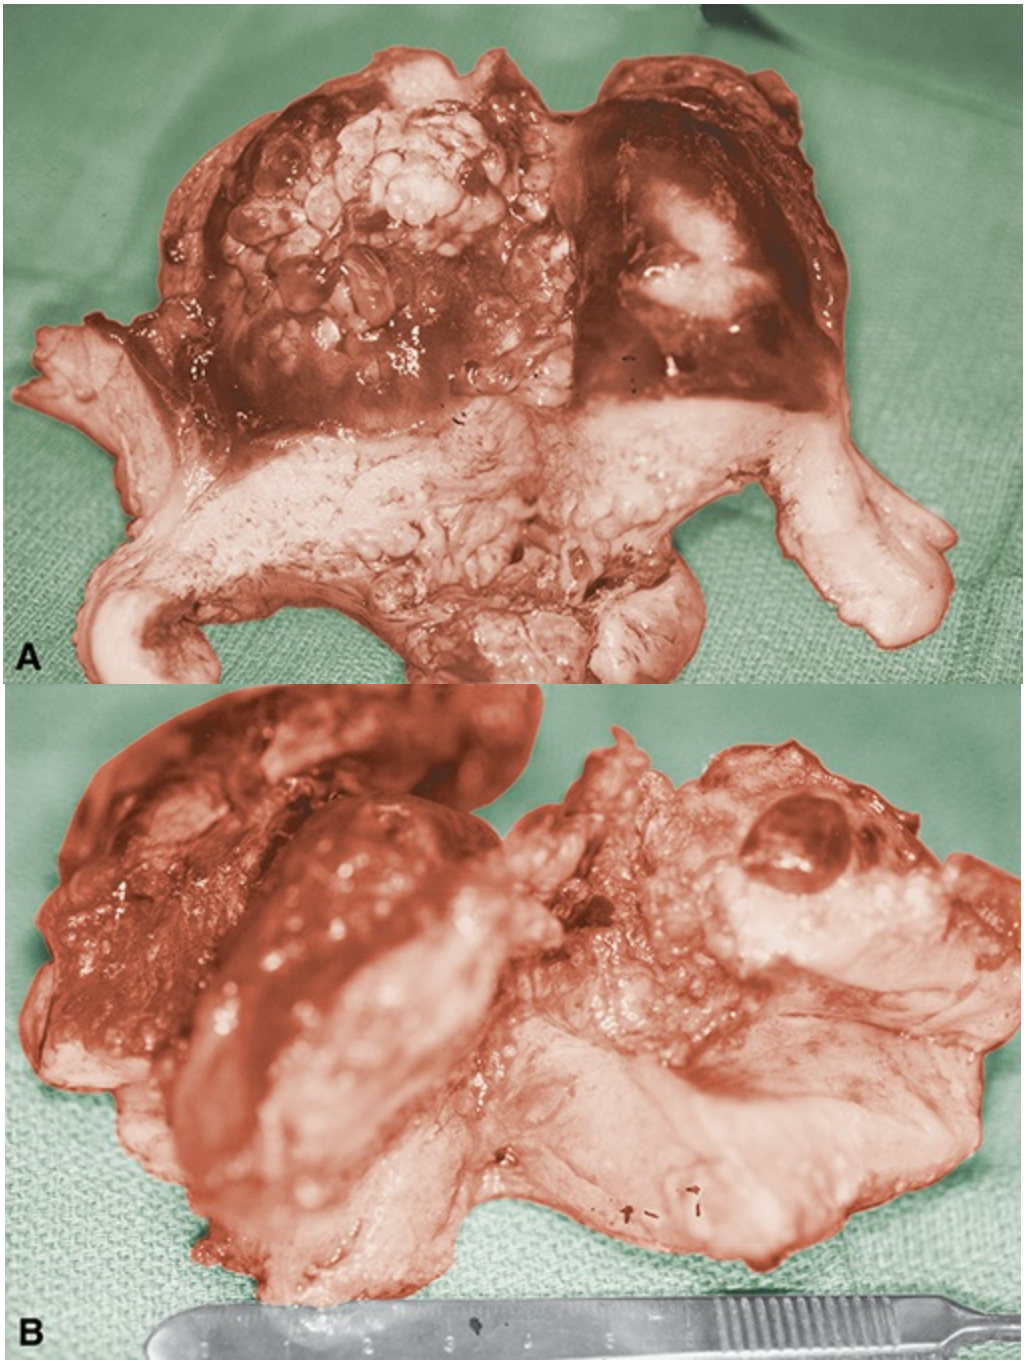

Figure 22.7 Both A and B demonstrate LMS, gross, with extension beyond uterus.

Microscopically, most LMS are overtly malignant with hypercellularity, coagulative tumor cell necrosis (TCN), abundant mitoses, atypical mitoses, marked cytologic atypia, and infiltrative borders (Fig. 22.8). Some lack one or more of these features, and occasionally the differential diagnosis between a benign and a malignant lesion is controversial. The three most important criteria are coagulative TCN, high mitotic rate, and significant cytologic atypia. In conventional LMS (spindle cell type), the diagnosis of malignancy is rendered when any two of the following three criteria are present: TCN, diffuse moderate-to-severe cytologic atypia, and 10 or more mitoses per 10 high-power fields (HPF) (92). TCN is characterized by an abrupt transition from viable to necrotic tissue (Fig. 22.9). In contrast, hyaline necrosis, which is seen in some leiomyomas, has an area of hyalinized tissue between the necrotic and viable tumor.

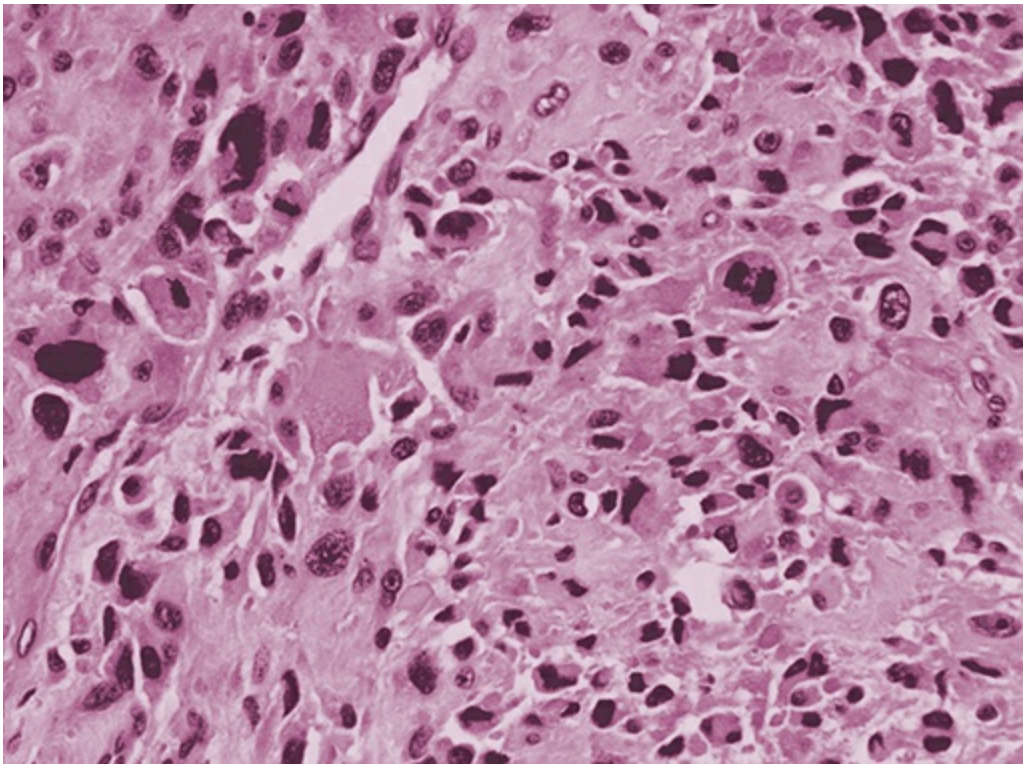

Figure 22.8 LMS, microscopic, with abrupt transition from viable to necrotic tissue.

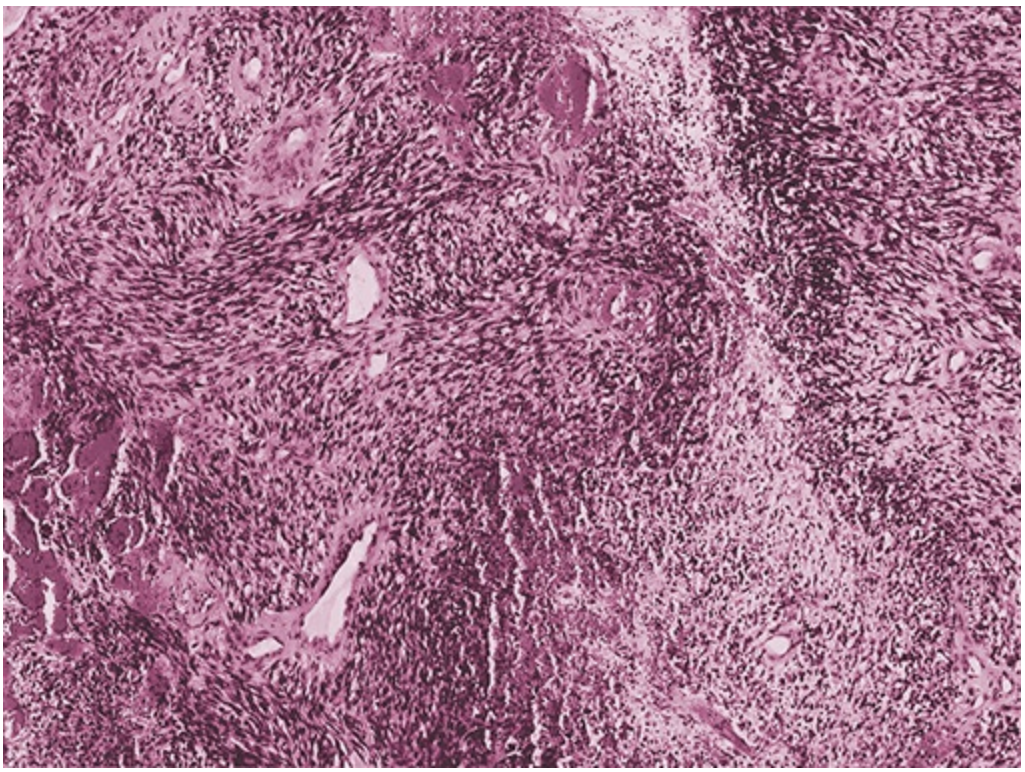

Figure 22.9 LMS, microscopic.

Some smooth muscle tumors demonstrate histologic features that are not worrisome enough to render an unequivocal diagnosis of sarcoma. These lesions can be classified as atypical leiomyomas, smooth muscle tumors with low malignant potential (low probability of an unfavorable outcome), or STUMP, depending on the histologic features. Figure 22.10 summarizes the classification of uterine smooth muscle tumors based on histologic characteristics. This classification is

largely based upon a large retrospective study from Stanford University, published in 1994 (92)—the largest to date. Tumors that clinically and pathologically appear to be leiomyomas, but have up to 15 mitoses per 10 HPF, behave in a benign fashion, and are classified as mitotically active leiomyomas (92,93). Leiomyomas are more likely to have a high mitotic count if they are excised during the secretory phase of the menstrual cycle, during pregnancy, or while patients are receiving exogenous PR therapy.

Five studies in the literature have addressed the diagnosis and clinical behavior of borderline smooth muscle tumors classified as atypical leiomyomas, tumors with low malignant potential, and tumors of uncertain malignant potential (23,94-97). The overall recurrence rate, based on these studies, is 8.6%. Most tumors recurred as STUMP, although one recurred as LMS (23). Most patients were alive and free of disease when these studies were published; one study reported three disease-specific deaths, all occurring more than 6 years after initial diagnosis (94). There are tumors that lack one of the three major diagnostic criteria (mitoses, atypia, necrosis) but show other worrisome features such as infiltrative borders, lymphovascular invasion, or atypical mitoses. Classification of these tumors is always problematic. It is recommended that any unusual cases be reviewed by a gynecologic pathologist. Two recent studies of atypical leiomyomas or leiomyomas with bizarre nuclei have shown a favorable outcome in the majority of cases (110 cases, including both studies). Only one patient (originally treated with hysterectomy) recurred as an atypical leiomyoma in the retroperitoneum at 87.5 months. All other patients were NED, that is, had no evidence of disease, including the 34 patients treated with myomectomy alone.

Infarcted necrosis of benign leiomyomas is sometimes seen during pregnancy, after uterine artery embolization, thermal balloon endometrial ablation, therapy with tranexamic acid, or therapy with high-dose progestins. In addition, pedunculated submucosal leiomyomas may undergo spontaneous torsion and infarction, even protruding through the cervix. Infarcted leiomyomas should not be confused with LMS. As noted before, infarcted necrosis is not TCN. In addition, infarcted leiomyomas are not associated with significant cytologic atypia, high mitotic rate, atypical mitoses, or invasive borders. An accurate clinical history may be useful in many of these cases.

Several recent studies support the use of immunostains for p16, p53, and Ki67 (proliferative activity marker) in the differential diagnosis of problematic smooth muscle tumors. p16 is overexpressed in uterine LMS compared with leiomyomas and STUMP, suggesting that p16 may be implicated in pathogenesis. In addition, LMS is characterized by higher *p53* expression and higher proliferative activity (Ki67) than other uterine smooth muscle tumors. The combination of high p16, p53, and Ki67 expression supports a diagnosis of LMS, if used in combination with H&E features, gross appearance of the tumor, and clinical features (98-103).

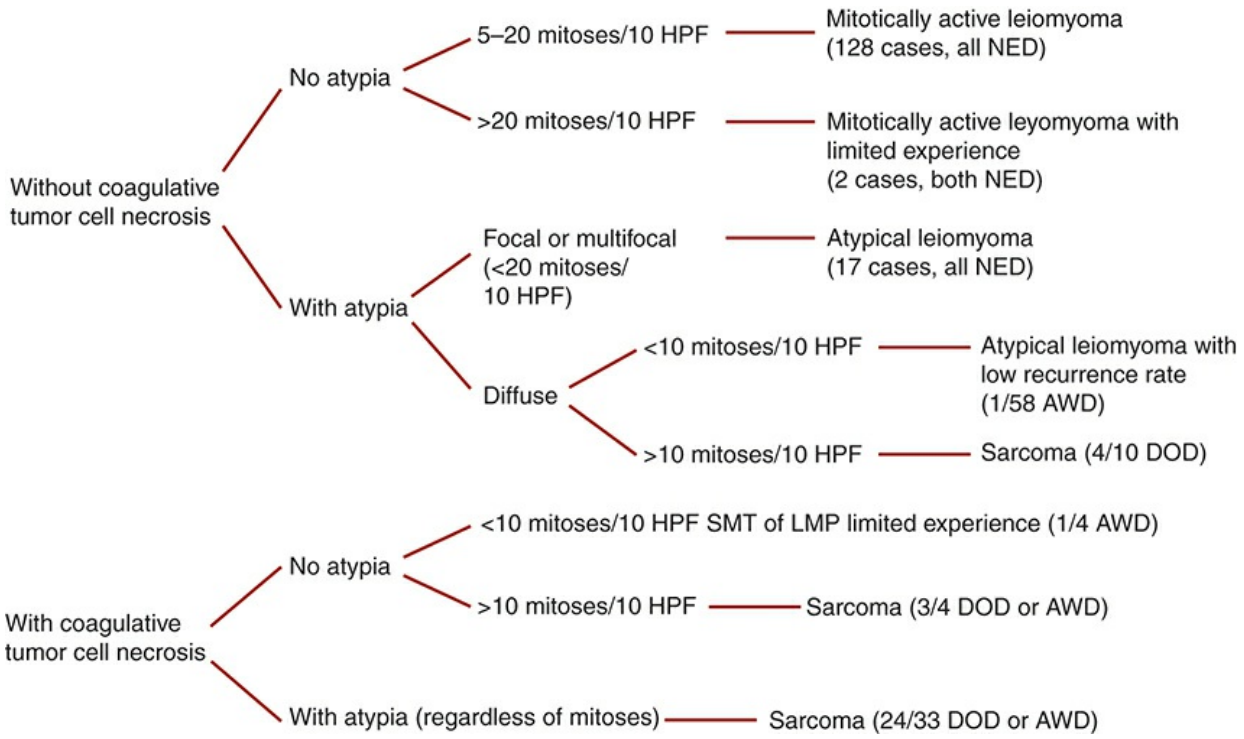

Figure 22.10 Uterine smooth muscle tumors (excluding epithelioid and myxoid types and cervical tumors). AWD, alive with disease; DOD, dead of disease; HPF, high-power fields; LMP, low malignant potential; NED, no evidence of disease; SMT, smooth muscle tumor.

The classification criteria of smooth muscle tumors with either myxoid or epithelioid features differ from the criteria used for spindle cell tumors. Epithelioid tumors have cells that are round rather than spindle-shaped, with round nuclei mimicking epithelial cells (hence the term “epithelioid”) (Fig. 22.11). Epithelioid LMS have significant cytologic atypia of at least 3 mitoses per 10 HPF, and TCN is demonstrated in 50% of cases (104). A previous study suggests that epithelioid tumors may behave more aggressively than spindle cell tumors, with a higher tendency to metastasize (105). Myxoid LMS is rare, and may be histologically deceiving because of the lack of TCN, minimal atypia, and a low mitotic rate. The most reliable histologic criteria of malignancy are infiltrative borders and lymphovascular invasion (106) (Fig. 22.12). Myxoid LMS portends a long-term survival similar to that of other LMS tumors, but at least one study reported better 5-year survival (73%) compared to ordinary LMS (49%) (10).

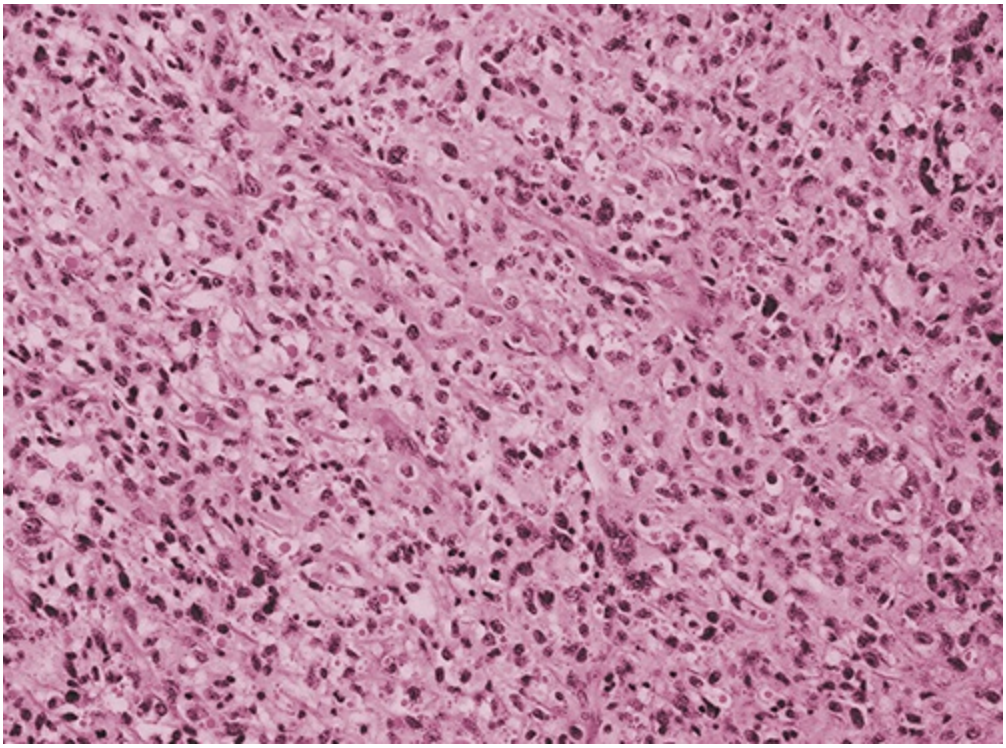

Figure 22.11 Epithelioid LMS, microscopic appearance.

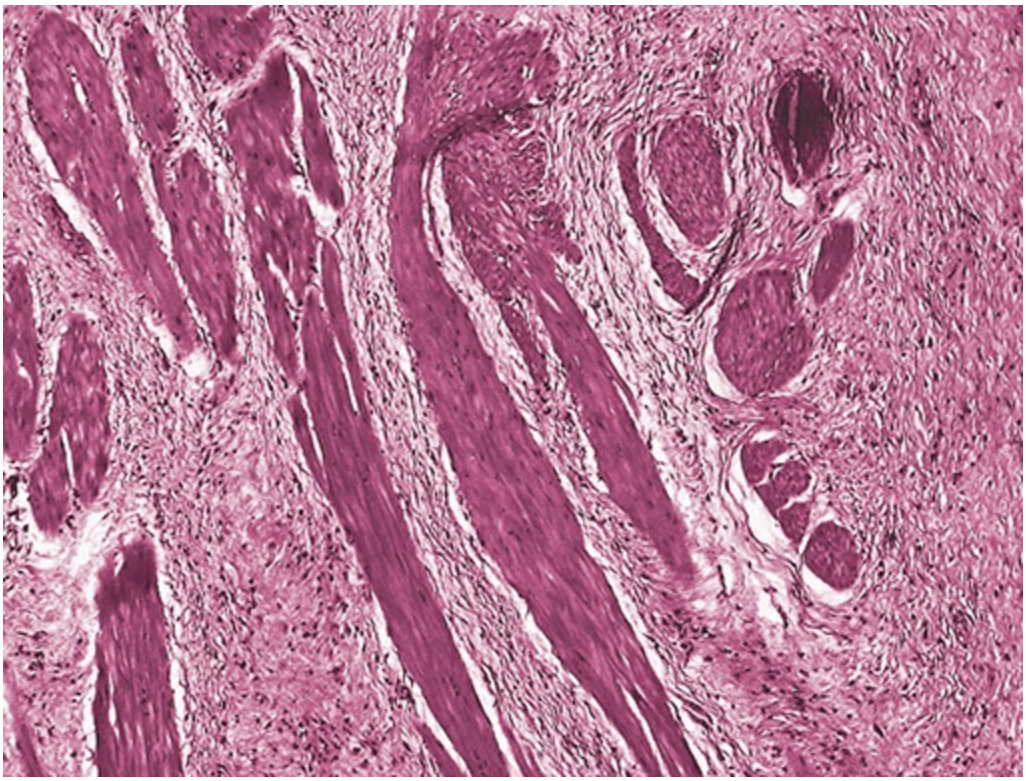

Figure 22.12 Myxoid LMS, microscopic appearance.

The histologic parameters of LMS that have been associated with poor prognosis include mitotic rate (107,108), lymphovascular invasion (107), size (108), diffuse high-grade cytologic atypia (109), and negative ER and PR (66). However, many of these characteristics have not been associated with outcome; therefore, they are not entirely validated.

Benign Metastasizing Leiomyoma

Benign metastasizing leiomyoma (BML) is characterized by the presence of a uterine leiomyoma associated with one or more extrauterine smooth muscle tumors that are histologically benign. The most common site of metastasis is the lung, although metastases have also been described in the retroperitoneum, mediastinal lymph nodes, soft tissue, and bone. Before rendering a diagnosis of BML, the pathologist should sample tissue extensively to rule out any aggressive components. The pathogenesis of these tumors is unclear. Some animal experiments suggest that BML may be secondary to lymphatic and hematologic spread, coelomic metaplasia, and intraperitoneal seeding (a pathogenesis similar to that of endometriosis) (110).

Carcinosarcoma (CS)

Uterine CS, also known as malignant mixed Müllerian tumors, are lesions containing carcinomatous and sarcomatous elements (Fig. 22.13). Numerous studies have shown that these tumors are clonal malignancies derived from a single stem cell, and should be considered metaplastic carcinomas (111,112). One study has identified similar mutation signatures in *PIK3CA*, *KRAS*, and *NRAS* in carcinomatous and sarcomatous elements within a given tumor (85).

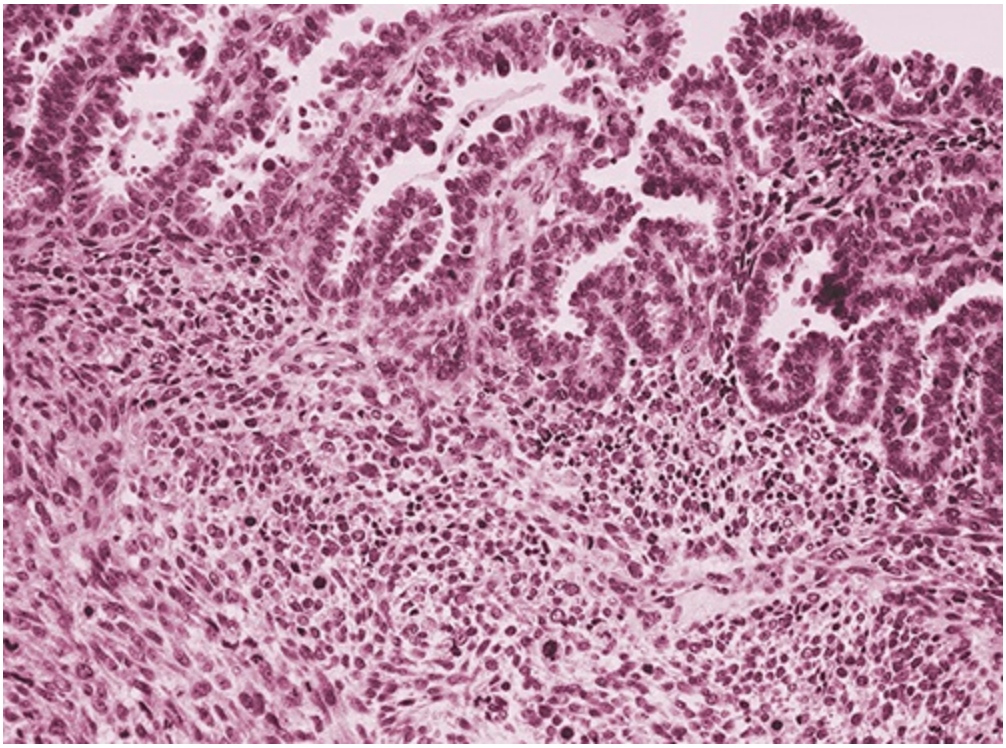

Figure 22.13 CS, microscopic appearance.

Most CS are polypoid tumors that fill the endometrial cavity, and may protrude through the cervical os (Fig. 22.14). These tumors are soft and fleshy, with areas of necrosis and hemorrhage. Occasionally, they show gross myometrial invasion, and may extend into the cervix. The size of the tumor is quite variable, ranging from < 2 cm to > 20 cm in diameter. Microscopically, they demonstrate a typical biphasic pattern with carcinomatous and sarcomatous elements. The carcinoma is usually high-grade and reminiscent of serous carcinoma, although some are undifferentiated, endometrioid, clear cell, or even squamous carcinoma. The sarcomatous component is always high-grade, and may be homologous or heterologous. In homologous tumors, the sarcomatous component is usually high-grade fibrosarcoma, although varieties such as LMS, malignant fibrous histiocytoma, or undifferentiated sarcoma may be found as well. Heterologous elements are seen in half of the cases. The most common heterologous sarcoma is rhabdomyosarcoma, followed by

chondrosarcoma, and, less often, osteosarcoma or liposarcoma (113). Most CS have myometrial invasion, commonly into less than half of the wall (113). Lymphovascular invasion is present in 60%, and the carcinomatous element is usually the component invading the myometrium and lymphovascular spaces (74,113).

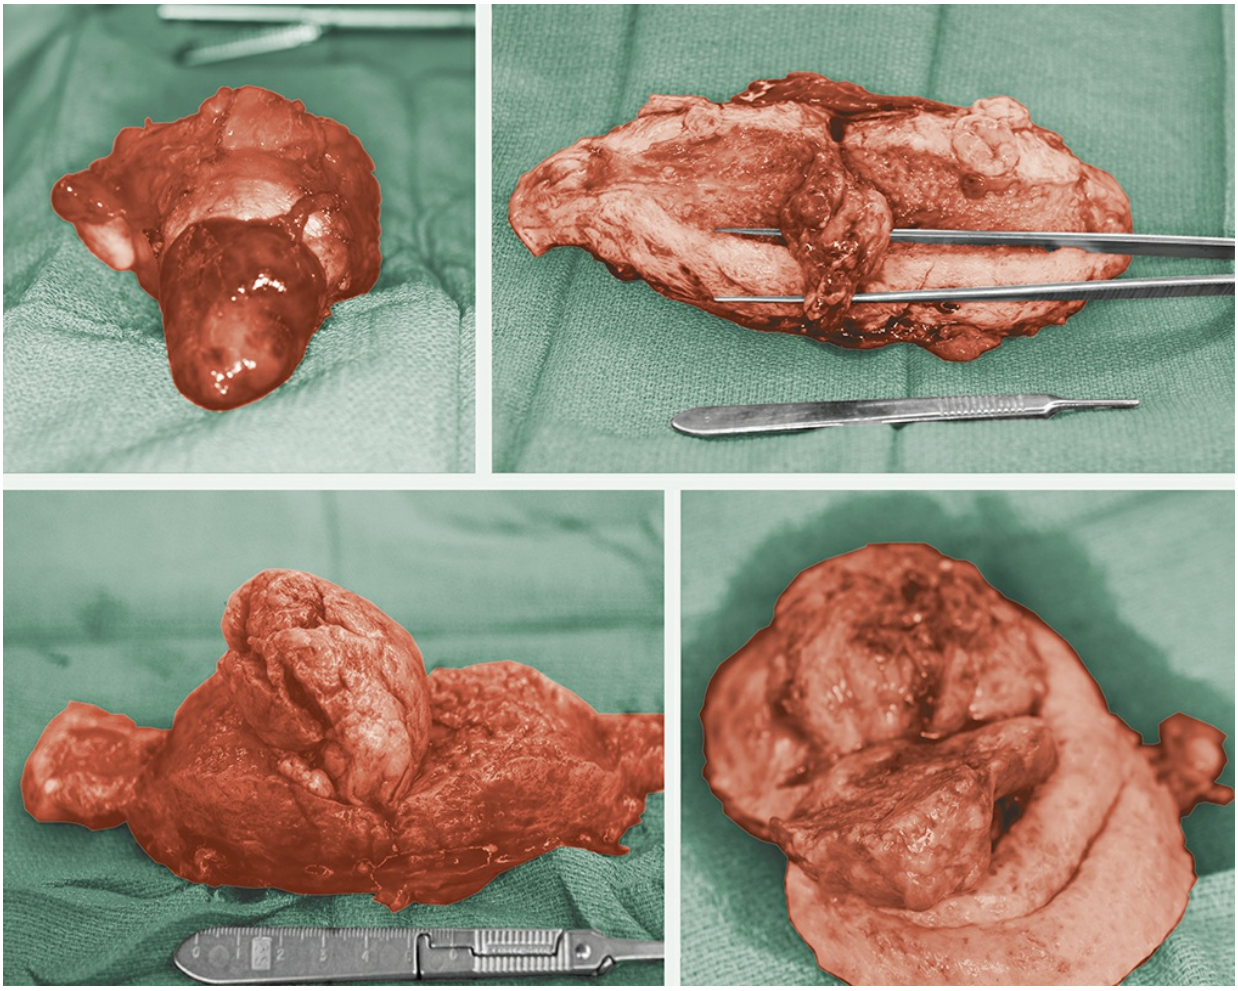

Figure 22.14 CS, gross photographs of four cases demonstrating polypoid nature of lesions.

Most studies suggest that the behavior of CS is predicted by the carcinomatous component. These tumors typically metastasize through lymphatic channels, similar to endometrial carcinomas. Most metastases and recurrences consist of pure carcinoma (29,30). Histopathologic adverse prognostic factors include heterologous elements (in stage I tumors), a high percentage of sarcomatous components in the main tumor and in the recurrences, and deep myometrial invasion (29-31).

Müllerian CS may arise in extrauterine–extraovarian sites. Most have been reported in the peritoneum or retroperitoneum. Some occur at the site of previous RT, and some arise in areas of endometriosis (114-119).

Endometrial Stromal Neoplasms

In the most recent (2014) WHO publication, endometrial stromal tumors are classified as endometrial stromal nodules, low-grade ESS, high-grade ESS, or undifferentiated uterine sarcoma (120). Both endometrial stromal nodules and low-grade ESS are composed of cells identical to those found in the stroma of proliferative endometrium, whereas high-grade ESS and undifferentiated sarcomas are composed of cells with cytologic atypia. The differential diagnosis between an endometrial stromal nodule and an ESS is important, because the nodules are always benign. Differential diagnosis is based

upon the presence of infiltrating margins with or without angioinvasion in ESS. These two features are not seen in stromal nodules, which are always well-circumscribed, with pushing (well-defined) margins (121).

Stromal Nodule

Stromal nodules are the least common of the pure endometrial stromal neoplasms. They are usually solitary masses, with diameters ranging from 1.2 to 22 cm, with an average of 7.1 cm (122). On cut section, endometrial stromal nodules are fleshy and often tan-yellow in color. Microscopically they are composed of uniformly bland, small cells resembling normal endometrial stromal cells, with fusiform nuclei and scant cytoplasm. Abundant arterioles, reminiscent of the spiral arterioles of the normal endometrium, are also present. The mitotic rate is low, with most tumors having fewer than 5 mitoses per 10 HPF. Most endometrial stromal nodules are cellular; some have variable amounts of intercellular collagen, which occasionally forms dense collagen bands or nodules (Fig. 22.15). Another common finding is the presence of clusters of foamy histiocytes within the tumor. The borders between the tumor and the adjacent myometrium are microscopically pushing. Occasionally, they demonstrate more irregular borders with minimal areas of tumor extending into the adjacent myometrium, usually within 3 mm of the main tumor mass (121). Endometrial stromal nodules lack any associated lymphovascular invasion. Other changes seen in endometrial stromal nodules include smooth muscle metaplasia, cystic degeneration, sex cord–like areas, and necrosis.

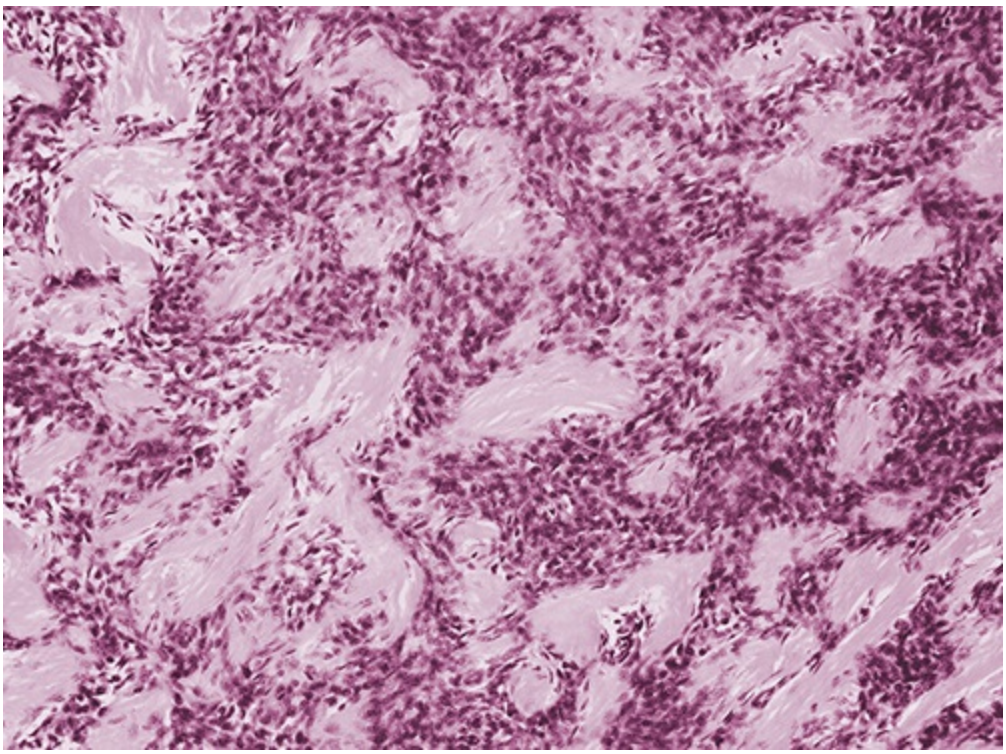

Figure 22.15 Endometrial stromal nodule, microscopic appearance.

Endometrial stromal nodules are sometimes confused with cellular leiomyomas. As both tumors are benign, the misdiagnosis of one for the other is probably of no clinical consequence in a hysterectomy specimen. In a curettage specimen, however, the differential diagnosis is more important. Some histologic features favor a leiomyoma: blood vessels with thick muscular walls, cleft-like spaces, and merging with adjacent myometrium. A battery of IHC stains may be useful. CD10 is usually present in endometrial stromal cells, and smooth muscle tumors stain positively for desmin and h-caldesmon.

Low-Grade ESS

Low-grade ESS is characterized by uniformly bland cells resembling endometrial stromal cells. On gross examination, some comprise a single visible mass, whereas others have multiple masses or diffuse myometrial infiltration by worm-like masses (Fig. 22.16). Typically, these tumors permeate the myometrial wall, in some cases, up to the serosa (Fig. 22.17). Most have fewer than 10 mitoses per 10 HPF. Some ESS tumors have unusual histologic features that may confound the diagnosis. These include myxoid changes, fibroblastic and/or smooth muscle differentiation, epithelioid changes, and extensive endometrioid glandular differentiation (123-126).

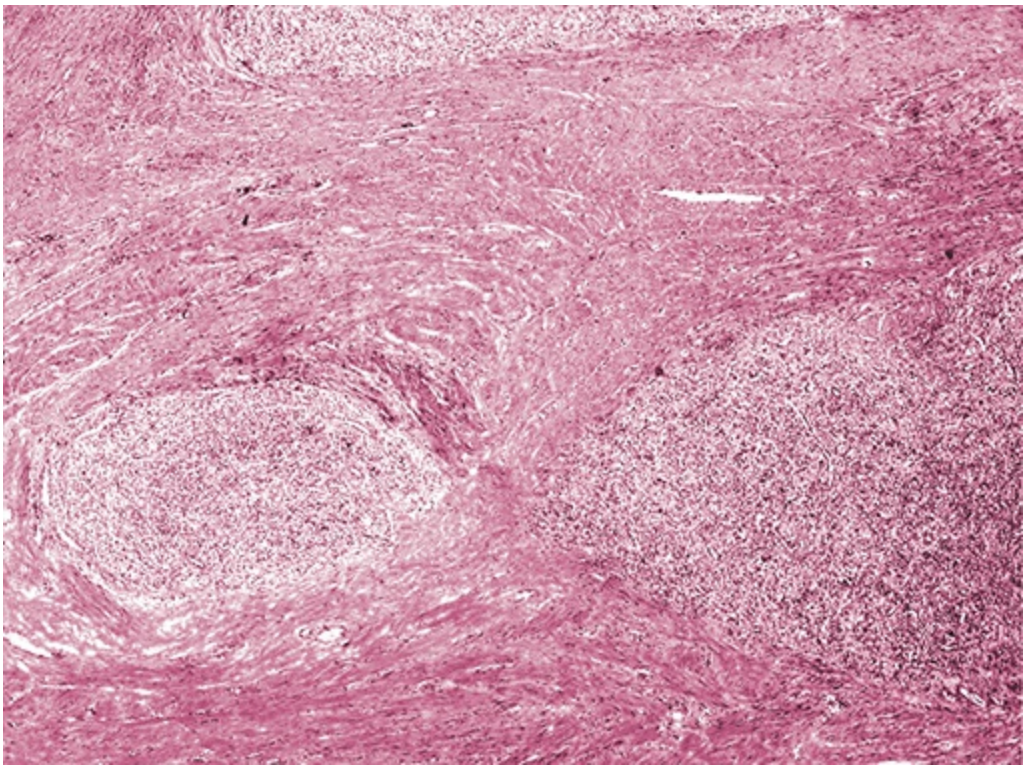

Figure 22.16 Endometrial stromal sarcoma, low-grade, microscopic appearance.

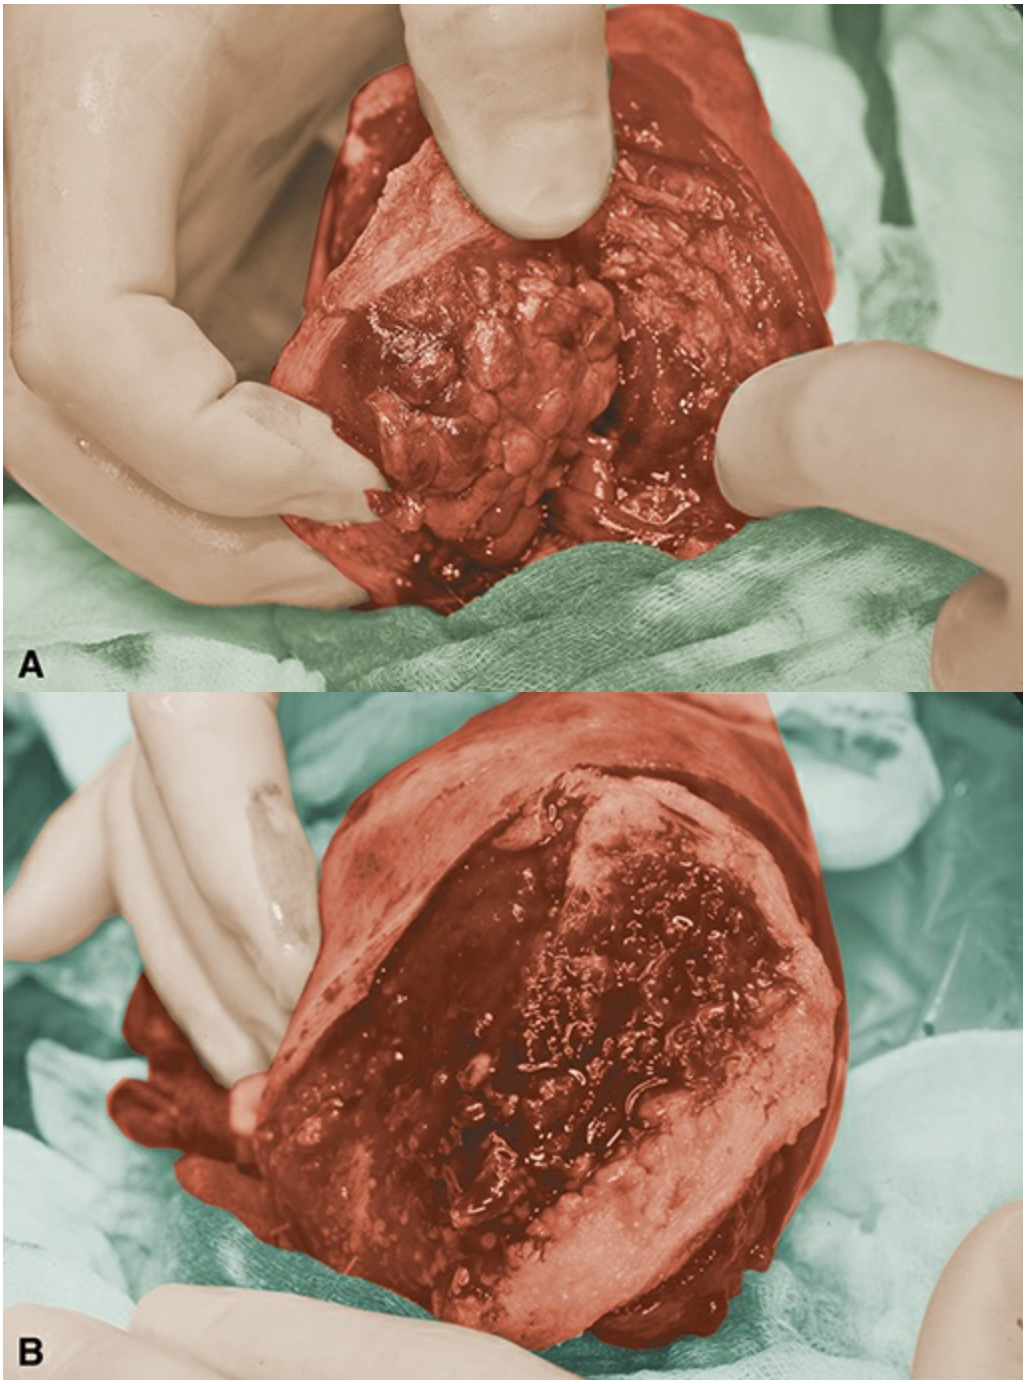

Figure 22.17 Both A and B demonstrate the gross appearance of endometrial stromal sarcoma, low-grade, gross appearance.

Low-grade ESS is usually positive for ER, PR, and CD10, and approximately 50% have cytogenetic abnormalities involving rearrangements of chromosomes 6, 7, and 17. The most characteristic translocation of these tumors, t(T7;17)(Tp15;q21), generates a fusion of the *JAZF1* and *JJAZ1* genes. The presence of this chromosomal abnormality may be useful in diagnosing difficult cases or recurrent tumors (127).

Low-grade ESS may occur in extrauterine sites including ovary, fallopian tube, cervix, vagina, vulva, pelvis, abdomen, retroperitoneum, placenta, sciatic nerve, or round ligament (128-133). Some are associated with endometriosis. Histologically, they are similar to uterine ESS, and a uterine tumor must be excluded before defining the lesion as a primary extrauterine ESS. The relapse rate for extrauterine ESS is 62%, similar to that of advanced low-grade uterine ESS.

High-grade ESS

The newly described entity of "high-grade ESS" is an infiltrative tumor showing confluent destructive growth, often invading deeply into the myometrial wall. These tumors have areas of high-grade cytology with a brisk mitotic count of >10 mitoses per 10 HPF, necrosis, and often lymphovascular invasion. Approximately 50% have an admixed low-grade component, which is usually fibroblastic. These tumors may demonstrate the same histologic variants seen in other endometrial stromal tumors, including rosettes, glandular, and sex cord–like patterns. High-grade ESS typically harbors the TWHAE-FAM22 genetic fusion as a result of t(10;17) (q22;p13). In comparison with low-grade ESS, patients with high-grade ESS have more recurrences and are more likely to die of disease (134). The high-grade component of these tumors is usually negative for CD10, ER, and PR, but positive for cyclin D1 (135). It is usually positive for c-kit, but lacks KIT hotspot mutations (136).

Undifferentiated Uterine Sarcomas

Undifferentiated uterine sarcomas are rare and account for only 6% of all uterine sarcomas (10). They demonstrate cytologic atypia to the extent that they cannot be recognized as arising from endometrial stroma. Morphologically, these high-grade lesions resemble undifferentiated mesenchymal tumors and behave as high-grade sarcomas (10,73,137). It is advisable to describe these entities as "high-grade sarcoma," "undifferentiated sarcoma," or "poorly differentiated uterine sarcoma" (137) rather than as ESS, as this last term may inaccurately suggest an indolent tumor. Undifferentiated uterine sarcomas are usually seen in patients older than 50 years. They have a recurrence rate of over 85%, and are usually fatal (10,73,137). Cheng-Han and Nucci recently authored an excellent review comparing the histology and clinical features of all ESS tumors (138).

Müllerian Adenosarcoma

Müllerian adenosarcomas are mixed Müllerian tumors composed of malignant stroma and benign epithelium. Most adenosarcomas arise in the endometrium; and, rarely, in the endocervix, lower uterine segment, and myometrium (22). Grossly, the majority are solitary polypoid masses with a spongy appearance, secondary to the presence of small cysts. Occasionally, these tumors appear as multiple polyps or masses, and may be multicentric. Their size varies from 1 to 17 cm (mean, 5 cm).

Microscopically, Müllerian AS have a benign epithelial component usually covering the surface of the polyps, and in the form of benign glands uniformly distributed throughout the tumor. The mesenchymal component is usually a low-grade sarcoma that resembles endometrial stroma. The presence of hypercellular stroma around the glands is common, and some tumors have a leaflike papillary growth pattern (Fig. 22.18). It may be difficult to arrive at a diagnosis of adenosarcoma because of the very low-grade nature of this tumor. Minimal criteria were described by Clement and Scully in a review of 100 cases of adenosarcoma published in 1990 (22). They include at least one of the following: two or more stromal mitoses per 10 HPF, marked stromal hypercellularity, and significant stromal cell atypia. Even with these criteria, some cases are deceivingly bland, and several have been seen in which the diagnosis was only possible after the review of multiple recurrences of uterine polyps (139). A minority of cases have sarcomatous overgrowth, in which more than 25% of the tumor is composed of pure sarcoma. In these cases, the sarcoma is typically high-grade and the lesions are aggressive (140) (Fig. 22.19). Recent studies confirm that histologic parameters associated with increased risk of recurrence include stromal overgrowth, lymphovascular invasion, and myometrial invasion (141,142).

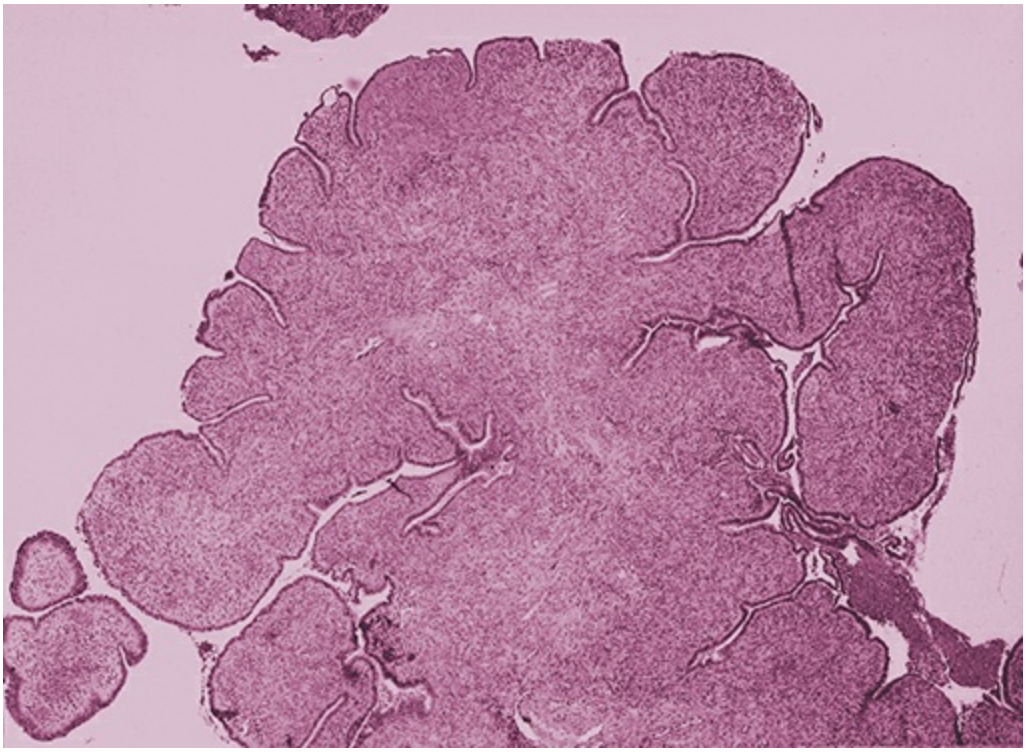

Figure 22.18 Müllerian adenosarcoma, microscopic appearance.

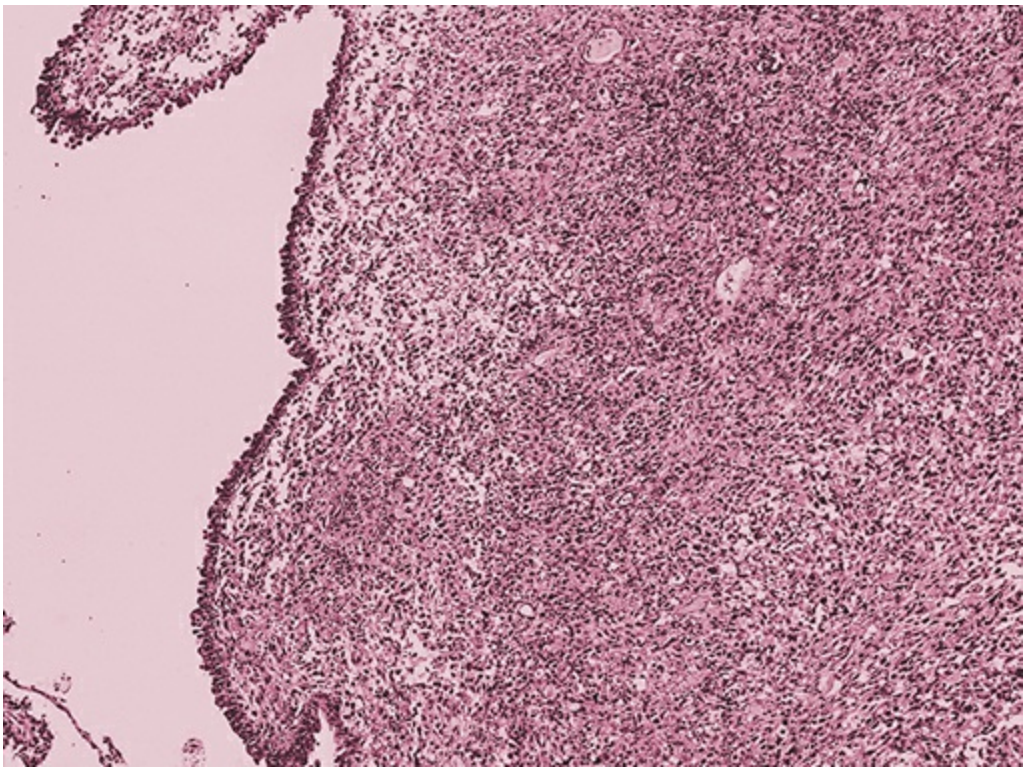

Figure 22.19 Müllerian adenosarcoma with sarcomatous overgrowth, microscopic appearance.

Most AS without stromal overgrowth express ER and PR receptors in the sarcomatous component, which may be used for therapeutic purposes. However, hormonal receptors are negative in AS with stromal overgrowth (139,143). Besides stromal overgrowth, the only other histopathologic features associated with decreased survival are myometrial invasion (22,59,139,140) and the presence of lymphovascular invasion (142). Müllerian AS have been described in

extrauterine sites, including the ovary, and in areas of endometriosis in the vagina, rectovaginal septum, gastrointestinal tract, urinary bladder, pouch of Douglas, peritoneum, and liver (144-152).

Uterine Tumor Resembling Ovarian Sex Cord Tumor

In 1976, Clement and Scully (153) coined the term "uterine tumors resembling ovarian sex cord tumors (UTROSCT)" to describe a series of uterine neoplasms with sex cord–like pattern. Since then, sex cord–like patterns have been demonstrated in endometrial stromal neoplasms, smooth muscle neoplasms, and in cases lacking clear endometrial stroma and smooth muscle differentiation. The term UTROSCT should be reserved for this last category. UTROSCTs are tumors of uncertain histogenesis/lineage. Immunohistochemically, these tumors co-express epithelial, myoid, and sex cord markers (154,155). This immuno-profile can also be seen in ESS with sex cord–like areas. However, UTROSCT lacks the typical *JAZF1-JJAZ1* translocation frequently seen in endometrial stromal tumors (156). UTROSCTs are rare, usually submucosal, and well circumscribed, with a yellow cut surface. Histologically, they are composed of sertoliform tubules with low mitotic activity and little nuclear atypia (153-155) (Fig. 22.20). Most behave in a benign fashion, although there is at least one reported case of a small bowel metastasis (157).

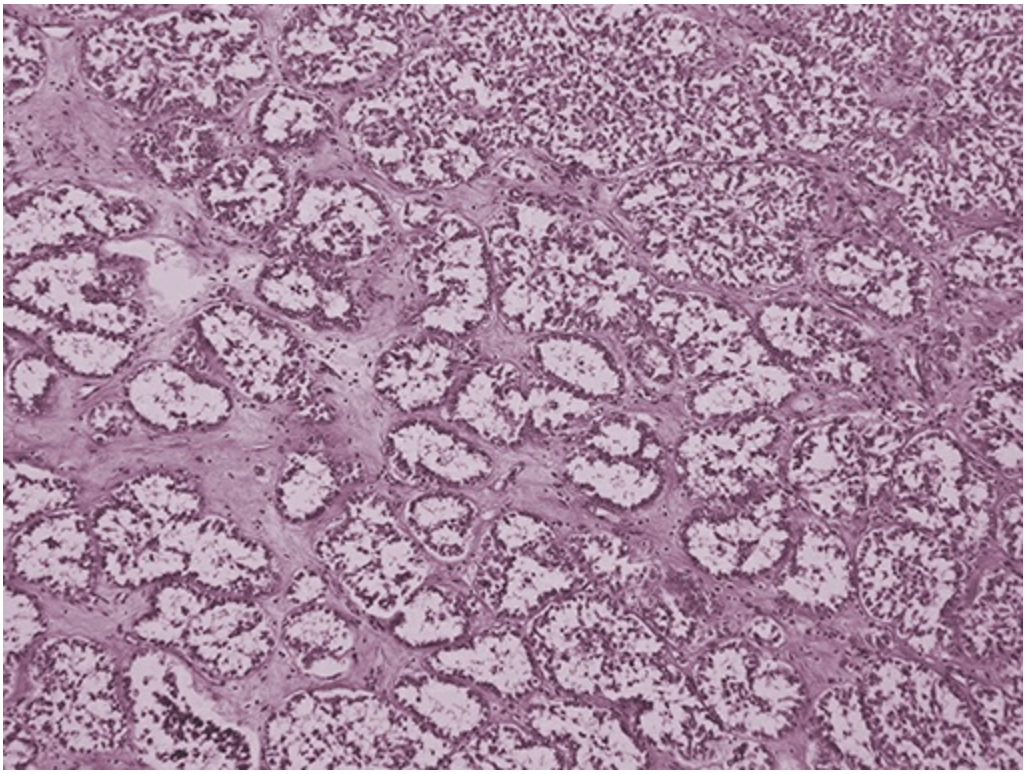

Figure 22.20 UTROSCT, microscopic appearance.

Perivascular Epithelioid Cell Tumors (PEComas)

(PEComas are rare neoplasms presumably derived from perivascular epithelioid cells that co-express melanocytic and smooth muscle markers. Other tumors belonging to the same family include angiomyolipoma, clear cell/sugar tumor of the lung, lymphangioleiomyomatosis, and myomelanocytic tumor of the ligamentum teres/falciform ligament. PEComas have been described in a variety of locations including visceral organs, soft tissues, skin, oral mucosa, orbit, and base of skull (158). The uterus and gastrointestinal tract are the most common locations for visceral PEComas. About 8% of PEComas occur in patients with the tuberous sclerosis complex. Most of these tumors co-express melanocytic (HMB45, Melan-A, microphthalmia transcription factor, S-100 protein) and smooth muscle markers (desmin, SMA, H-caldesmon). Most

uterine PEComas are histologically and clinically benign. They can appear as either grossly well-circumscribed or focally infiltrative masses. Histologically, they are composed of epithelioid cells with abundant clear or eosinophilic cytoplasm, sometimes associated with spindle cells, and a prominent vasculature (158,159). Approximately 25% of reported cases develop metastases and/or recurrences. Most malignant tumors have more than one of these histologic features: size >5 cm, high-grade nuclear features, infiltration of surrounding tissue, necrosis, mitoses >2 per 50 HPF, and lymphovascular invasion. However, there is not a single reliable prognostic indicator other than the presence of lymphovascular invasion (158-161).

A distinct subset including some uterine PEComas harbor *TFE3* gene fusions, and show immunoreactivity for TFE3 protein (162,163). These tumors tend to have distinctive nested/alveolar morphology. In the past, *TFE3* gene fusions were described only in alveolar soft-part sarcomas and in some renal cell carcinomas. PEComas with *TFE3* gene fusions seem to occur in younger people without tuberous sclerosis.

Inflammatory Myofibroblastic Tumor

Inflammatory myofibroblastic tumors (IMT) are rare mesenchymal lesions considered to be of intermediate biologic potential. The most common sites for these tumors include lung, mesentery, omentum, and retroperitoneum. A few cases have been reported in the uterus (164,165), where they present as polypoid masses in the lower uterine segment, or bulky myometrial masses. IMTs range in size from 1 to 12 cm. They are composed of spindle and epithelioid myofibroblastic cells admixed with lymphoplasmacytic infiltrate in variably myxoid stroma cells. IHC expression of ALK is characteristic of all IMTs, and can be used in the differential diagnosis with other uterine spindle cell tumors that are negative (including smooth muscle tumors, ESS, and CS) (164). Most IMTs behave indolently. However, a recent series reported three cases with aggressive behavior including local recurrence, extrauterine spread, or distant metastases. The aggressive tumors were reportedly larger and characterized by a higher percentage of myxoid stroma, higher mitotic count, and necrosis, compared to indolent tumors (166). Given the positive ALK expression, patients with IMT may benefit from targeted therapy.

Other Rare Uterine Sarcomas

Rarely, other sarcomas may be found in the uterine corpus. Rhabdomyosarcomas, although more commonly arising in the cervix of children, have also been encountered in the corpus in adults. These tumors may be of embryonal or pleomorphic histology. They are aggressive, with a 5-year disease-specific survival of only 29%. Patients with pleomorphic rhabdomyosarcoma have a worse prognosis than those with embryonal histology (10,167,168).

Uterine liposarcomas are rare tumors. Some arise in uterine lipoleiomyomas (169), others are associated with smooth muscle tumors, and may represent LMS with cyst-divergent differentiation (168,170).

Other rare sarcomas described in the uterus include angiosarcoma, Ewing sarcoma, alveolar soft-part sarcoma, osteosarcoma, chondrosarcoma, fibrosarcoma, and malignant fibrous histiocytoma (168).

SURGERY

Surgery is a cornerstone in the treatment of a majority of soft tissue sarcomas, including uterine sarcomas. Many women with uterine sarcomas are premenopausal at the time of initial diagnosis; therefore, concerns about fertility and premature menopause should be considered. Surgery to remove the primary tumor—myomectomy, or most often hysterectomy—and inspection of the peritoneal cavity are central to the initial management of these patients. In this section, we will discuss the necessity of performing nodal evaluation, nodal dissection, and removal of the ovaries. The role of

cytoreductive procedures for extrauterine disease at the time of diagnosis, and at recurrence, will also be discussed. Fertility-preserving options are extremely limited, but are possible in a few highly select cases (in the setting of less-aggressive mesenchymal tumors).

Uterine Preservation

Myomectomy, or tumor resection with preservation of the uterus, is an option in younger women diagnosed with STUMP or other atypical leiomyomata of the uterus who wish to preserve fertility. Unfortunately, a total hysterectomy (never supracervical) must be performed in a majority of malignant mesenchymal tumors of the uterus. There is no clear option for preserving the uterus in patients diagnosed with LMS, undifferentiated (or high-grade) ESS, or carcinosarcoma. Uterine preservation has been described in eight women diagnosed with "leiomyosarcoma," and successful pregnancies were reported (171). However, it is unclear from this report whether these were all truly high-grade LMS, or whether some, or all, were STUMPs or other tumors of less malignant histologies (171). Until further conclusive investigation is conducted and reported, TAH must still be recommended.

The management of endometrial stromal tumors is somewhat challenging. A confirmed endometrial stromal nodule does not require completion hysterectomy, as it is a benign lesion. However, it may be difficult to confirm whether such a tumor is an endometrial stromal nodule or an ESS without a significant amount of normal myometrium around it, and to state with confidence that there are no infiltrating margins with or without angioinvasion (120). Therefore, a TAH should be recommended in postmenopausal women and in women who have completed childbearing. However, TAH may also be necessary in women who wish to have children. Uterine preservation in the setting of ESS has been reported in a very young (16-year-old) girl (172) and in a 25-year-old who went on to carry a successful pregnancy (173).

Role of Nodal Evaluation or Lymphadenectomy

Two important questions to ask when deciding whether to perform a procedure—in particular, nodal dissections of non-enlarged lymph nodes and removal of ovaries in premenopausal women—are as follows: (1) What is the risk of microscopic disease in those organs? (2) Is there a benefit to removing those organs? Lymph node metastasis in adult soft tissue sarcomas is <3%, with some variation among histologic subtypes (174). Routine regional lymphadenectomy is not recommended for patients with adult soft tissue sarcomas, but resection of bulky isolated metastases can be considered (174).

The risk of lymph metastasis in LMS overall is approximately 7% (4,5,29,60,175-177) (Table 22.7). However, the rate of occult lymph node metastasis is less than 3% (175-178). There is no clear benefit to routine lymphadenectomy in patients who present with uterine LMS confined to the uterus and/or clinically normal lymph nodes (4,17,29,60,175). Carcinosarcomas have a higher rate of overall (27%) and occult (20%) lymph node metastasis (4,5,20,59,74,176) (Table 22.8).

[a]Occult metastasis means nodal metastasis in clinically normal lymph nodes, and disease clinically confined to the uterine corpus and/or cervix.

Undifferentiated endometrial sarcomas are believed to behave similarly, but clear data are lacking. The role of lymphadenectomy beyond debulking of enlarged lymph nodes is still to be determined. Nemani and colleagues (179) suggested that there is a benefit to lymphadenectomy, irrespective of the use of RT. However, the current standard is that all patients, regardless of stage, receive adjuvant systemic chemotherapy (CT). It is quite possible that the therapeutic benefit of lymphadenectomy, if any, in patients with CS may be tempered by this. Nodal dissection in this setting is reasonable and is considered to be standard treatment. The rate of overall and occult lymph node metastasis in ESS is 16% and 6%, respectively (4,5,14-16,180-182) (Table 22.9). Deep myometrial invasion and extensive lymph–vascular space invasion (LVSI) further increase the risk of occult metastasis (16). These features are often not obvious at the time of hysterectomy. There is no clear known survival advantage to routine lymphadenectomy in these patients (15). Nevertheless, it may be reasonable to consider lymphadenectomy at the time of hysterectomy, recognizing that the therapeutic, prognostic, or predictive value of this in ESS is unknown. Reoperation to complete a lymphadenectomy is not likely to be of any benefit in ESS that does not exhibit deep stromal invasion or extensive LVSI. The rate of lymph node metastasis in adenosarcomas is approximately 3% (59). On the basis of very limited information, lymphadenectomy in patients with disease clinically confined to the uterus may not offer much benefit.

[a]Occult metastasis means nodal metastasis in clinically normal lymph nodes, and disease clinically confined to the uterine corpus and/or cervix.

Role of Oophorectomy

The risk of ovarian metastasis is very low in LMS (176,177) (Table 22.7). Routine oophorectomy, especially in premenopausal patients, provides no benefit. A SEER analysis actually suggested worse survival in patients undergoing bilateral salpingo-oophorectomy (BSO) (17). It is not entirely clear why removal of the ovaries would lead to a worse prognosis, but at the very least these data support retention of the ovaries in premenopausal women who want to retain ovarian function. Occult ovarian metastasis can be seen in approximately 12% of CS (176) (Table 22.8). BSO should be recommended for these patients; fortunately, many are postmenopausal. Occult ovarian metastasis in ESS is rare (16) (Table 22.9). Ovarian preservation appears to be associated with a higher risk of recurrence; however, this has no impact on OS, and these patients do very well in general (12,15,62). BSO is recommended to reduce the risk of recurrence, but this should be carefully discussed with young premenopausal women. The risk of ovarian metastasis and therapeutic benefit is difficult to discern, because of a lack of large series addressing it in this and other rare uterine sarcomas.

Cytoreductive Surgery for Patients with Extrauterine Disease at Initial Diagnosis

Cytoreductive surgery (CRS) in patients presenting with uterine sarcoma has not been well-described. The only information available describes patients presenting with uterine LMS and extrauterine metastasis (183). The median PFS in patients undergoing a complete gross resection was 14.2 months, compared to 6.8 months for those who had surgery and visible residual disease ($p = 0.002$) (183). OS was 31.9 months compared to 20.2 months, respectively ($p = 0.04$) (183). On multivariate analysis, complete CRS maintained an independent association with PFS, but not with OS. The lack of independent statistical association with OS may be explained by the relatively small number of cases studied. CRS may be a reasonable consideration in highly select cases, in which complete resection of tumor is believed to be feasible without the need for extensive procedures such as exenteration. The potential benefit of surgery should be weighed against the potential risks, and these cases must be individually managed.

Surgery for Recurrent Disease

Data are limited with respect to CRS of recurrent uterine sarcomas. However, CRS may be considered in many of these cases, especially if the patient has had a relatively long disease-free interval and the sites of recurrence appear amenable to a complete surgical resection. Surgery is often considered for recurrent ESS because of the relative indolence of these

tumors, long disease-free intervals, and lack of other effective treatments. Currently, the approach to carcinosarcoma is often extrapolated from data for endometrial carcinomas. Resection of recurrent LMS has been described. Surgery for other sarcomas is often considered, but there is no data regarding these very rare uterine sarcomas.

Khoury-Collado et al. (184) described an updated series of 21 patients (from 1997 to 2011) with uterine cancers who developed recurrence in the pelvis after prior RT and underwent pelvic exenteration. The cases included: uterine sarcomas (n = 6), CS (n = 2), adenosarcomas (n = 2), LMS (n = 1), and ESS (n = 1). In the two carcinosarcoma cases, there was a short time between prior therapy and exenteration, and the median survival after exenteration was only 6 months. The median survival after exenteration for the four other sarcomas was not reached, and the 5-year OS was 66%. Pelvic exenteration may also be a reasonable consideration for patients with isolated pelvic recurrences after prior RT. However, it must be recognized that these operations are quite morbid, and the reported outcomes are based on very small numbers of highly selected patients with uterine sarcomas.

Resection of pulmonary metastases at the time of initial diagnosis and the time of recurrence is often considered for patients with soft tissue sarcomas, and is associated with a favorable survival benefit (185). Specifically, in recurrent uterine sarcomas without other extrathoracic disease, resection of pulmonary metastases is associated with a survival benefit (186). Levenback and colleagues (186) reported a 5-year survival rate of 43% after resection of pulmonary metastases in a group of 45 uterine sarcomas including 38 LMS, 4 ESS, and 3 CS. Unilateral pulmonary recurrence was associated with better survival after metastasectomy than bilateral recurrence (mean survival 39 months vs. 27 months, respectively [p = 0.02]). Tumor size, histologic type, use of adjuvant therapy after resection, patient age, and time from hysterectomy to first pulmonary resection were not statistically associated with survival after metastasectomy.

Surgical cytoreduction of recurrent uterine LMS, with or without pulmonary recurrence, has also been reported to provide a possible survival benefit. Leitao and colleagues (80) reported a survival benefit with optimal resection (defined as largest residual tumor mass ≤1 cm in diameter) of pulmonary and extrapulmonary first recurrences of uterine LMS. Median survival was 3.9 years after an optimal resection compared to only 0.7 years after suboptimal resection (p = 0.002). The only other prognostic factor was time to first recurrence. Median survival was 5.1 years in cases with a time to first recurrence >12 months, compared to 1.5 years in cases with a time to recurrence of ≤12 months (p = 0.005). Tumor grade, thoracic versus non-thoracic procedures, sites of first recurrence, and use of adjuvant therapy after resection, were not associated with survival. In a larger series by Giuntoli et al. (187), secondary cytoreduction in patients with recurrent uterine LMS was also associated with a survival benefit. Secondary cytoreduction to no gross residual was independently associated with survival after adjusting for site of recurrence, use of CT, RT, combined surgery and CT, and recurrence time (187). Similar to the findings of Leitao et al., a longer time to recurrence was also prognostic of outcome but with 6 months used for the cutoff (187).

RADIATION THERAPY

As the use of RT for patients with uterine sarcomas has been almost exclusively delivered in the postoperative setting (188), the role of preoperative, primary, or palliative RT will not be presented in this section, nor will we offer a detailed discussion of the techniques and complications of adjuvant RT. This has been more fully discussed in Chapter 21 on Corpus: Epithelial Tumors.

Uterine Sarcomas

There is only one published phase III randomized trial comparing observation versus postoperative radiation therapy (PORT) in surgically staged patients with stages I and II uterine sarcomas. This study opened in July 1988 and closed to patient accrual in July 2001. Eligible patients underwent an initial surgical resection that involved mandatory TAH–BSO. Retroperitoneal lymph node dissection was optional (approximately 25% underwent lymph node sampling). The 1988

FIGO staging classification for endometrial carcinoma was applied to these patients (189). Because of the time period of this trial's inception, there were no recommendations regarding either collection of peritoneal washings or omentectomy. The study enrolled 224 patients for randomization from 36 institutions. Patient histologies included the following: 99 LMS, 92 CS, 30 ESS, 1 myxoid LMS, and 2 unclassified cell types. It must be noted that there was a central pathology review of tumor samples; however, no distinction was made regarding low-grade EES, and high-grade undifferentiated uterine sarcomas (UUS). Eligible study patients were randomized to undergo either observation or PORT, consisting of a total dose of approximately 50.4 Gy in 28 daily 1.8-Gy fractions, over 5 to 6 weeks. Two-dimensional (2-D) treatment planning techniques involving bony landmarks were employed to treat the whole pelvis as follows: (a) cranially, the superior aspect of the 5th lumbar vertebra; (b) caudally, the inferior aspect of the obturator foramen; (c) anteriorly, the upper margin of the symphysis pubis; and (d) posteriorly, the level separating the 2nd and 3rd sacral vertebrae. Treatment field arrangements varied from 3 fields, 4-field box (55%), or parallel opposed pair (40%) beams. CT was not administered to any of the study patients (190).

The primary objective of this European Organisation for Research and Treatment of Cancer (EORTC) Gynecological Cancer Group (GCG) trial was to determine whether patients receiving adjuvant pelvic PORT had reduced rates of local (vaginal) and/or regional (pelvic) relapse versus patients receiving no adjuvant therapy, and to assess whether or not improvement in locoregional (LR) control translated into a significant reduction in distant metastases. Secondary objectives of the EORTC-GCG 55874 focused on the impact of PORT on improved OS and PFS without significant increase in toxicity, compared to the observational group (190).

EORTC-GCG 55874 was originally planned to accrue 75 patients per year for 3 years to obtain the projected 77 LR failures necessary for statistical analyses. However, owing to slow accrual of patients, two unplanned interim analyses—the first in April 1995 and the second in December 2001—were required to assess the feasibility of completing the study objectives. Thus, it required 13 years (median follow-up 6.8 years) for patient accrual to record 68 out of the originally planned 77 LR relapses required for adequate statistical evaluation. Of the 224 enrolled patients, adequate follow-up data was available for analysis in 219 patients (due to insufficient follow-up data in two cases in the observational cohort and three cases in the PORT group) (188).

Crude relapse rates for all cell types in EORTC-GCG 55874 were 47% (52/110) in the PORT cohort and 50% (54/109) in the observational arm. There was a significant reduction in overall LR relapse in the PORT group: 24 (21%) compared to 44 (40%) in the observational arm ($p = 0.004$). Furthermore, there was a reduction in isolated LR relapse of 3% in the PORT group versus 18% in the nonirradiated arm. Distant metastases occurred as a component of failure in 49 (46%) patients in the PORT versus 35 (32%) in the observational cohorts. There was a higher rate of isolated distant metastasis in the adjuvant group versus the nonirradiated cohort (25.5% versus 10%, respectively). The primary cause of death was malignant disease in 81% (39/48) of PORT patients and 93% (43/46) of observational patients. There was no significant difference in OS or PFS and no difference in toxicity identified between the two groups (192) (Figs. 22.21 and 22.22).

Phase III randomized study to evaluate the role of adjuvant pelvic radiotherapy in the treatment of uterine sarcomas stages I and II: an European Organisation for Research and Treatment of Cancer Gynaecological Cancer Group Study (protocol 55874). Eur J Cancer. 2008;44:808–818, with permission (Elsevier).

With respect to patients with uterine CS in EORTC-GCG 55874, PORT did reduce LR failures from 47% (observational cohort) to 24% (PORT cohort) ($p < 0.05$), while not significantly decreasing the overall rate of distant metastasis (29% observational vs. 35% PORT cohort). This improvement in LR control with adjuvant pelvic PORT was further noted in the evaluation of patients with isolated LR failures (24% observational versus 4% PORT). However, there were more isolated distant failures in the adjuvantly irradiated subset of patients with CS (7% observational versus 15% PORT) (190). This latter finding is similar to that shown for patients with endometrial carcinomas randomized to adjuvant pelvic external beam radiation therapy (EBRT) compared to patients not treated with EBRT (191). Nevertheless, the findings of EORTC-GCG 55874 suggest that pelvic PORT should be considered as adjuvant therapy to improve LR control in patients with stage I and II uterine CS. More importantly, PORT was associated with benefit in patient OS, compared to patients receiving no adjuvant RT (HR, 1.58; 95% CI, 0.83, 3.01) (190).

Concerning patients with stage I and II uterine LMS, LR relapse in the observational group (24%) was comparable to that of the adjuvantly irradiated cohort (20%). The overall rate of distant failure in the observational cohort (33%) was less

than that in the PORT cohort (54%). However, isolated LR failures were 14% in the observational cohort and 2% in the PORT cohort. With respect to isolated distant failures, there were 14% in the observational cohort versus 36% in the PORT cohort (190). The findings of EORTC-GCG 55874 may be used to defer adjuvant PORT for patients with stage I and II uterine LMS. Because of the observed impact on improving isolated LR control in this patient subset, one could make an argument for employing pelvic PORT as a salvage or palliative therapy in selected patients with early-stage uterine LMS. Finally, EORTC-GCG 55874 showed a negative impact of PORT on OS in the LMS cohort of early-stage patients (HR, 0.64; 95% CI, 0.36, 1.14) (188).

One reported phase 3 multi-institutional, prospectively randomized clinical trial for stages I, II, and III uterine sarcomas (1988 FIGO criteria) compared experimental adjuvant chemoradiation (arm A) versus standard adjuvant pelvic PORT (arm B) for patients with CS (19 patients), LMS (53 patients), UUS (9 patients) (192). Arm A involved four planned cycles of intravenous (IV) doxorubicin ["A"] (50 mg/m^2) on day 1, cisplatin ["P"] (75 mg/m^2) on day 3, and ifosfamide ["I"] (3 g/m^2/day) with mesna (3 g/m^2/day) on days 1 and 2 every 3 weeks. One month following completion of this "API" CT, arm B patients received pelvic PORT to a total dose of 45 Gy over 5 weeks, with optional vaginal brachytherapy (VBT). The control cohort of patients began pelvic PORT within 8 weeks of surgery, with or without VBT. Of note, this study accrued only 81 of a planned total of 256 subjects (39 and 42 in arms A and B, respectively) from October 2001 through July 2009.

With a median follow-up of 4.3 years, 15/39 (38.5%) in arm A and 26/42 (61.9%) in arm B relapsed; however, patterns of failure were not described. Nevertheless, 30/41 (73.2%) first relapses were described as metastatic, and only 11 (26.8%) as local. The majority of arm A patients (29/39, 74%) received all four cycles. Among the 38 arm A subjects who received at least one cycle of CT, a majority experienced grade 3–4 acute hematologic toxicities, with two grade 5 fatalities occurring from septic shock after the fourth cycle. Only 1 patient in arm B had an acute grade 3 toxic event (gastrointestinal).

With respect to its primary study end point of DFS, this trial would have required 256 patients (128 in each arm) to achieve an 80% power to detect treatment effect of 20% between arms. Nevertheless, the 3-year DFS was statistically better for arm A patients: 55% (95% CI, 40%, 70%) versus 41% (95% CI, 27%, 57%) for arm B ($p = 0.048$). There was no statistical difference in 3-year OS: 81% versus 69% in arms A and B, respectively ($p = 0.41$) (192). Although this novel regimen showed promise in positively impacting outcome for patients with uterine sarcomas, further studies using modified doses of API (to reduce serious toxicities), larger sample size, and longer follow-up will be needed before widespread implementation of this adjuvant combined modality regimen.

Most of the published papers on sarcomas of the uterus have been retrospective in nature, and many years, if not decades, are often required to accumulate enough patients for meaningful statistical analyses. Furthermore, in an attempt to obtain numbers sufficient for evaluation, these studies often combined sarcomas of different cell types. Additionally, there was no central pathology review of the original hysterectomy permanent slides to verify cell type (193-211). These retrospective studies have not achieved statistical power to reach definite conclusions, especially regarding the impact of PORT on OS in uterine sarcomas as a class of female pelvic malignancies.

However, the data from a nonrandomized review of the Surveillance, Epidemiology, and End Results (SEER) analysis of 2,677 cases of uterine sarcoma did demonstrate a statistically significant improvement in survival for adjuvant RT versus observation in stages II, III, and IV (but not stage I) uterine sarcoma (27). The use of adjuvant PORT versus observation to significantly improve outcome, including OS, in advanced cases of uterine sarcoma (stages III and IVA) has been further supported in a retrospective single institutional study of 76 evaluable cases of uterine sarcomas (206). However, another SEER analysis of 1,819 patients with stage I/II uterine CS, and 1,088 with stage I/II uterine LMS, showed improved survival for the subset of patients with CS who did not have any nodal sampling. There was no observed significant survival benefit for CS patients undergoing a node dissection, or for any subset of patients with LMS (212).

Recently, Sampath et al. (213) published a retrospective review—the largest to date—of patients with uterine sarcoma. The investigators conducted a query of the National Oncology Database (Impac Medical Systems, Sunnyvale, CA),

identifying 3,650 evaluable patients with a diagnosis of uterine sarcoma. Of this initial group, 2,206 had definitive surgery; of these, 1,128 had CS, 529 had LMS, and 361 had EES, comprising stages I through IV (with unknown stage, however, in approximately one-third of patients). Statistical analyses showed no significant impact on OS for patients receiving predominantly pelvic PORT (with or without VBT) compared to those receiving no adjuvant therapy. However, a significant reduction in LR relapse was noted in the adjuvantly irradiated cohort compared to the observational cohort: 53% at 5 years ($p < 0.001$). In addition, this LR control benefit conferred by adjuvant RT versus observation was preserved on subset analyses of patients with uterine CS ($p < 0.001$), LMS ($p < 0.01$), and ESS ($p < 0.05$) (213). This latter study may be cited as evidence for future trials to prospectively evaluate the incorporation of adjuvant volume-directed RT into the range of potential therapeutic modalities for uterine sarcomas.

The GOG previously conducted two prospective clinical trials of selected patients with uterine sarcomas. The earliest study (GOG 20) reported on 156 evaluable patients with [surgically staged] stage I or II sarcomas of the uterus (214). Patients were enrolled from 1973 to 1982 and randomized to receive at least one cycle of adjuvant doxorubicin, or no adjuvant CT. Prior to study randomization, patients could receive *optional* adjuvant RT either preoperatively (external pelvic RT of 40 Gy in 4 to 5 weeks with intracavitary VBT of 20 Gy to point A) or postoperative pelvic EBRT alone (to 50 Gy in 5 to 6 weeks) (215).

It should be noted that 11/48 (23%) patients with LMS in GOG 20 underwent adjunctive RT. Forty-nine of 109 (45%) patients with non-LMS (85.3% CS) had adjuvant pelvic EBRT. RT did not appear to affect recurrence in general. Table 22.10 shows a notable decrease in vaginal recurrences in patients with early-stage uterine CS. Table 22.10 also demonstrates an increase in extravaginal failures in the group of CS patients receiving RT (214). Table 22.11 depicts additional data from GOG 20 showing a significant reduction in pelvic relapse (10%) in treated patients compared to untreated patients with [predominantly uterine] CS (23%) (215).

[a]85% of this group (93 patients) with non-leiomyosarcomas of the uterus was stage I/II uterine CS.

Source: Modified from Hornback NB, Omura G, Major FJ. Observations on the uterine sarcomas of adjuvant radiation therapy in patients with stage I and II uterine sarcoma. Int J Radiat Oncol Biol Phys. 1986;12:2127–2130, with permission (Elsevier).

The second major GOG trial (GOG 40) involved a nonrandomized, clinicopathologic evaluation of patients with clinical stage I and II uterine LMS and CS (176). This study opened in February 1979 and closed in October 1988. Of the 453 eligible patients, 430 (95%) underwent the mandated extrafascial hysterectomy, BSO, and selective retroperitoneal

lymphadenectomy. Of this latter group, 301 (70%) had CS, of which 240 (80%) had [surgically staged] stage I/II disease. Table 22.12 shows the locations of first sites of relapse(s) in this subset. Although adjuvant pelvic EBRT was not mandated, it again appears possible that postoperative pelvic PORT plays a role in reducing LR relapses in patients with early-stage uterine CS.

[a]For patients with uterine CS who may have had more than one relapse.

Source: Modified from Major FJ, Blessing JA, Silverberg SG, et al. Prognostic factors in early-stage uterine sarcoma: a Gynecology Oncology Group study. Cancer. 1993;71:1702–1709, with permission (Wiley).

However, in the French pilot study that led to the previously described SARCGYN study (192), 18 patients with optimally debulked surgical stage I, II, and III uterine sarcomas (13/18 with uterine LMS) received three cycles of adjuvant doxorubicin, cisplatin, and ifosfamide, followed by sequential pelvic EBRT to a total dose of approximately 45 Gy in 5 weeks, with or without VBT (209). The investigators then performed a matched case–control study of 18 patients; 16 underwent pelvic RT alone and 2 received no adjuvant treatment. With a median follow-up of 43 months (range, 23 to 56 months), they found that only 5 patients (27.8%) had suffered recurrences. All of these patients failed in extrapelvic sites only. Moreover, neither median survival nor DFS had been reached at the last follow-up. There remains much uncertainty regarding the role of pelvic EBRT for patients with uterine LMS, especially with respect to reserving volume-directed RT in combination with CT as adjunctive treatment, or even as a component of salvage and/or palliative therapeutic intervention (209).

Uterine CS

The most common types of uterine sarcoma histologies currently reported in the literature are referred to as metaplastic carcinoma (111), mixed epithelial and stromal tumors of the uterus (2), historically known as uterine CS, or some variant of mixed Müllerian uterine tumors (195,216-225). There has been one randomized phase 3 prospective trial of adjuvant RT in CS (GOG 150). This study compared whole-abdominal irradiation to three cycles of cisplatin/ifosfamide CT with respect to recurrence rates, DFS, and OS. Also evaluated were therapeutic toxicities. Eligible patients had CS confined to the abdomen and had undergone optimal surgical debulking with no postsurgical residual disease >1 cm. Patients randomized to RT received a total dose of 30 Gy to the whole abdomen using EBRT, followed by a pelvic boost, to a cumulative pelvic dose of approximately 50 Gy.

The first published report on the two treatment cohorts was based on an analysis performed in December 2005 (226). Of the 224 patients enrolled, 206 were evaluable. Of these 206 patients, 105 received adjuvant RT and 101 received CT. The estimated death rate for patients receiving CT was 32.8% lower than those receiving RT ($p = 0.042$). A subsequently published update of GOG 150 based on a May 2006 analysis demonstrated that this reduction in estimated death rate by CT was 31%, relative to RT ($p = 0.046$) (227).

The final analysis of the GOG 150 data was conducted in November 2006 (228). At that time, the median duration of follow-up for patients who were alive at last contact was 63 months. The breakdown of surgical stages for patients in the RT versus CT cohorts is as follows: stage I—35/105 (33.3%) versus 29/101 (28.7%); stage II—11/105 (10.5%) versus

15/101 (14.9%); stage III—45/105 (42.9%) versus 47/101 (46.5%); stage IV—14/105 (13.3%) versus 10/101 (9.9%). The estimated crude probability of relapse within 5 years was nonsignificant: 58% versus 52% for the RT and CT groups, respectively. The sites of first failure are presented in Table 22.13. Although not statistically significant, there were fewer vaginal and more abdominal relapses in the adjuvant RT cohort compared to the CT cohort. Table 22.14 demonstrates an estimated 5-year survival of approximately 35% for patients randomized to adjuvant RT versus 45% in the CT group. After adjusting for stage and age at diagnosis, there was a trend toward reduction of the death rate for those receiving CT (29%) compared to RT (HR, 0.712; 95% CI, 0.484–1.048; $p = 0.085$; 2-tail test). Of interest, patients who received adjuvant RT had more late complications, mainly gastrointestinal, than those undergoing cytotoxic therapy ($p < 0.001$). Two patients undergoing RT died as a direct result of radiation-induced hepatitis (228).

[a]Nonrandomized.

One retrospective single-institutional study from a major academic medical center attempted to further verify the results of GOG 150 by evaluating 49 patients with optimally debulked stage I–IV uterine CS who received either adjuvant RT alone (pelvic or whole abdominal irradiation ± VBT) or predominantly paclitaxel/carboplatin CT (± whole abdominal or pelvic irradiation ± VBT). Although the findings were not statistically significant owing to small sample size, this report did show a reduction in upper abdominal relapses (24% vs. 35%) and extravaginal/pelvic failures in the group receiving combined modality adjuvant therapy compared to the cohort receiving adjuvant RT alone (45% vs. 91%, respectively) (229).

A large single institutional retrospective study of 121 patients with surgically staged I–IV uterine CS (2009 FIGO staging criteria) with central pathologic confirmation of cell type found that the use of any type of adjuvant RT seemed to prevent vaginal failures in all stages. Of note, the use of external beam PORT to the pelvis did impact survival.

A more recent population-based retrospective review of 1,581 patients with [surgically staged] stage I and II uterine CS, using FIGO 1988 criteria, found that the use of VBT rose from 4.5% between 1988 and 1999 to 12.5% between 2005 and 2010. Of the total patient sample, 803 (50.8%) had no RT, 636 (40.2%) had PORT with EBRT, and 142 (9.0%) had adjuvant VBT alone. On multivariable analyses, the type of RT did not impact survival; however, VBT was statistically associated with improved OS compared to no adjuvant RT (HR 0.67, 95% CI, 0.47, 0.95) ($p = 0.024$). This latter report and GOG 150 suggest that there may be a role for adjuvant VBT in patients with uterine CS, especially in the setting of early-stage disease.

Results from other retrospective institutional and population-based series focusing solely on uterine CS are inconsistent concerning the impact of adjuvant therapy on outcome. Some demonstrate no survival benefit for postoperative RT (195,219,221,222,224), whereas others show a significant impact of pelvic PORT on survival (216,218,223,225). One of the above studies involved a review of the nonrandomized SEER database of 2,461 women with CS (1973 to 2003) (225). In this dataset, 890 patients received adjuvant RT. The overall 5-year survival of those receiving RT versus no-RT was 41.5% and 33.2%, respectively ($p < 0.001$); furthermore, a significant improvement in survival was observed in all stages of disease, including stage IV.

Finally, there have been several published retrospective reports suggesting that combined adjuvant CT followed by RT to address the high rate of extrapelvic sites of metastases may impart even longer survival, especially in stage I and II disease (179,217,220,230-233). Nevertheless, the role of adjuvant RT in the management of patients with uterine CS remains inconclusive. As there were more vaginal failures in the CT arm of GOG 150, and other sites of relapse (abdominal recurrences) were similar or less common in frequency than those in the RT arm, it may be reasonable to consider postoperative VBT (either high- or low-dose-rate) with CT (of greater than three cycles) for any patient with optimally debulked CS in future trials.

Uterine LMS

There are no existing randomized phase 3 trials that demonstrate any impact of adjuvant RT on LR relapse or survival in this patient population. Table 22.15 presents data from several retrospective series in which overall pelvic/extrapelvic relapse rates were reportedly 16.6% and 42.0%, respectively, for patients with uterine LMS.

TABLE 22.15 Chemotherapy in LMS of the Uterus

[a]Uterine sarcoma.

[b]Adult soft tissue sarcoma.

[c]Adult Leiomyosarcoma

There is still a paucity of information distinguishing upper-abdominal from extra-abdominal distant sites of tumor involvement. The pelvic and extrapelvic percentages were 18.5% (22/119), and 41.2% (49/119) for the nonirradiated patients, respectively, and 12.9%(8/62), respectively and 43.5% (27/62) for the radiated patients, (176,180,234). It does not appear that postoperative RT has any significant effect on reducing recurrence in patients with uterine LMS. However, two series combined yielded a pelvic relapse rate of 11.1% (4/36) with RT versus 61.1% (22/36) without adjuvant RT (178,181). One recently reported retrospective series of 69 patients with all stages of uterine LMS (staged as per the 2009 staging criteria), of which 46.4% (32/69) underwent PORT with or without adjuvant CT, found, on multivariable analyses, that PORT significantly reduced pelvic failures (HR, 0.28, 95% CI, 0.11, 0.69; p = 0.006) and increased OS (HR, 0.44, 95% CI, 0.23, 0.85; p = 0.014), independent of other clinicopathologic factors (235). The major problem is that, despite achieving local control, the majority of these patients have distant extra-abdominal metastases in organs such as the lung. There is a need to develop more effective systemic therapies to improve patient outcome (176,179,236,237).

A retrospective case–control, single-institution study of patients with uterine LMS demonstrated a trend toward improved survival in 31 patients who received adjuvant pelvic irradiation, compared with 31 controls who did not receive adjuvant RT (29,238,239). A recent retrospective study from a consortium of institutions involving 143 patients with surgical stage I–IV uterine LMS reported on 24 patients (17%) who received pelvic PORT and 63 (44%) who had adjuvant and/or palliative CT. This latter study found that the rate of pelvic relapse was significantly reduced (p = 0.02) for patients who received RT (18%) versus those who did not (49%). Although not maintained at 90 months of follow-up, this study also showed that the 5-year survival of patients receiving adjuvant RT (70%) was greater than the survival of those who did not (35%) (240). A large single-institutional series of 182 patients with uterine sarcomas, of whom 79 (43.4%) had LMS, recently demonstrated that patients receiving PORT had significantly improved 5-year OS compared to those who did not (71.8% vs. 40.2%, respectively; p = 0.018) (241-243). However, the role of adjuvant RT in the management of patients with uterine LMS remains undefined.

Ess

To date, no randomized phase III trials have shown any significant impact of adjuvant RT on outcomes in patients with uterine EES. These tumors can be subdivided into a low-grade category (ESS) or a high-grade category (UUS) of sarcoma. Gadducci and colleagues (244) reported no abdominal or distant recurrences independent of the administration of adjuvant irradiation in all stages of low-grade ESS. Yet, there was a 33.3% (6/18) pelvic recurrence rate, of which the majority did not undergo any RT. This latter finding suggests that postoperative external pelvic RT should at least be considered for the subset of patients with low-grade stage I and II ESS. This has been supported by other retrospective studies (208).

One retrospective report reviewed 28 cases of ESS, of which 19 were low-grade and 9 high-grade (245,246). Fifty percent of the patients in this series underwent adjuvant pelvic RT, with no difference in survival. In addition, almost 30% of patients receiving adjuvant RT relapsed within the treatment field (247). With respect to undifferentiated ESS, another study documented multiple sites of recurrence, including abdominal (34.8% [11/32]), distant (34.8% [11/32]), and pelvic (40.6% [13/32]) sites of relapse (248). However, a more recent small series of 13 patients with all stages of uterine EES reported that the 10 patients who received pelvic PORT (+/− vaginal boost) had an 89% rate of LR control, compared to 50% for the 3 patients who did not (249). Another small retrospective series of 10 patients with stage I/II UUS (as per 2009 FIGO criteria), of whom 8 were treated with PORT, reported that none experienced pelvic failure (250). With the exception of one single-institution, retrospective series (251), no direct survival benefit has been associated with the use of PORT in either EES or UUS (252-254). Thus, the role of RT for patients with uterine EES remains uncertain.

CHAPTER 23 Epithelial Ovarian Cancer

Gini F. Fleming, Jeffrey D. Seidman, Anna Yemelyanova, and Ernst Lengyel

EPIDEMIOLOGY AND RISK FACTORS

In this chapter "ovarian cancer" will generally refer to a Müllerian cancer arising in the peritoneum, fallopian tube, or ovary. Established risk factors for ovarian cancer include genetic factors, including a known genetic predisposition (e.g., BRCA1/2 and hereditary nonpolyposis colorectal cancer [HNPCC]), and a strong family history for breast and ovarian cancer. Hormonal and reproductive factors include parity, breast-feeding, early menarche, late menopause, menopausal hormonal treatment, oral contraceptive (OCP) use, and endometriosis. The relative risks (RRs) associated with endocrinologic factors are small, though important because they are potentially subject to modulation. The most important risk factor, after having a first-degree relative with the disease, is age. Women younger than 40 years without a positive family history rarely have ovarian cancer. Fifty percent of all cases of ovarian cancer in the United States occur in women over the age of 65. A large meta-analysis including more than 1.3 million women showed clearly that most risk factors show heterogeneity across ovarian cancer histologic subtypes. Of 14 established risk factors including the 10 mentioned above, nine risk factors applied only to certain histologies. In general, reproductive and hormonal risk factors are more strongly associated with clear cell and endometrioid ovarian cancers (1). This suggests that there is no unifying etiology for "ovarian cancer" and that the different histologic subtypes must be considered separately to understand the specific risk profile, biology, and clinical behavior.

Epidemiology

Epithelial ovarian cancer is the leading cause of death from gynecologic cancer in the United States and Europe. Surveillance, Epidemiology, and End Results (SEER) data show that 22,280 new cases of ovarian cancer and 14,240 deaths from ovarian cancer are expected in the United States in 2016 (2). It is estimated that in the United States, 1 in 70 women will develop ovarian cancer, and 1 in 100 women will die of the disease. In Europe, the International Agency for Research on Cancer in Lyon estimated that there will be 44,100 new patients with ovarian cancer and 29,800 deaths in the 27 European reporting countries (3). In both the United States and Europe, ovarian cancer is the fifth most common cause of all cancer deaths in women. Estimates for the global ovarian cancer burden, which includes borderline cancers (the US and European numbers exclude them), are that 225,500 patients will develop epithelial ovarian cancer and about 140,200 will succumb to the disease per year.

Ovarian cancer rates vary between different countries and appear to be linked to socioeconomic status and reproductive patterns. North America and most of the industrialized countries of Europe have high incidence rates, whereas the disease is rare in Asia and Africa. The lowest rates of ovarian cancer are in sub-Saharan Africa (Fig. 23.1). Although the reasons for this difference are not well understood, countries with a high incidence rate are generally characterized by smaller family sizes, high-fat diets, higher socioeconomic status, older age, and a predominantly

Caucasian population. Once a woman moves from a country with a low incidence of ovarian cancer to one with a high incidence, her risk for the disease tends to approach that of her adopted country rather than that of her country of origin. The fatality rate of ovarian cancer is high (70%), and 80% of deaths occur within 5 years of diagnosis. The age-adjusted mortality in the United States declined by 23% from 9.8/100,000/year to 7.5/100,000/year from 1975 to 2011. It has been hypothesized that this decline in mortality was largely caused by an earlier decline in ovarian cancer incidence, due, for the most part, to the known protective effect of OCP, which were introduced in the 1960s. Today, 80% to 85% of US women have taken OCP at some point in their life. Paralleling the reduction in mortality, the age-adjusted ovarian cancer incidence fell by 26% from 16.3/100,000 women to 12.1/100,000 women (26%). The decline in incidence was then followed by a decline in mortality supporting the hypothesis that OCP contributed to this effect. Still, despite the widespread use of OCP, it is estimated that, because of the expanding and aging US population, the annual number of ovarian cancer cases will increase from 21,000 to 28,591 in the years from 2010 to 2030 (4).

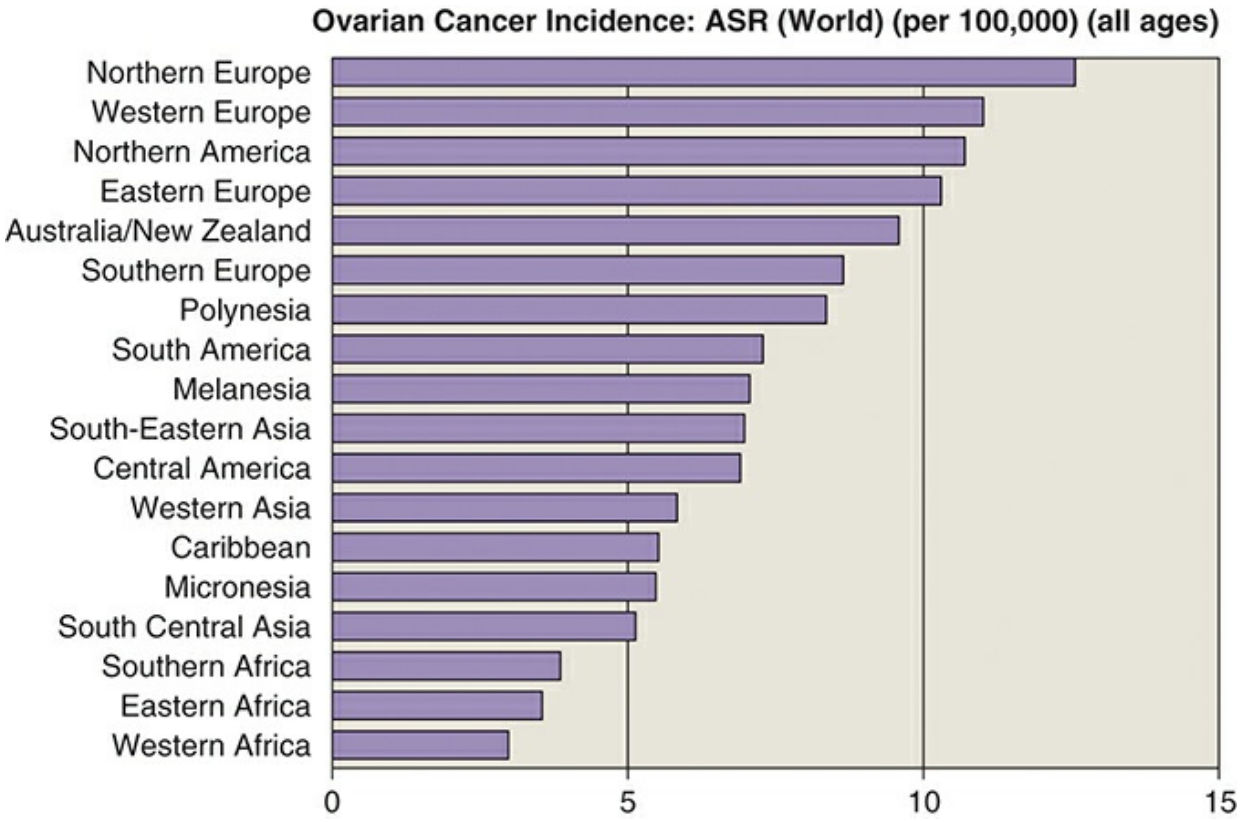

Figure 23.1 Age-standardized incidence rate (ASR) of ovarian cancer in the world. Source: From Ferlay J, Bray F, Pisani P, et al. GLOBOCAN 2000: Cancer Incidence, Mortality and Prevalence Worldwide, Version 1.0. IARC Cancer Base No. 5. Lyon, France: IARC, with permission.

Weight/Body Mass Index

Many epidemiologic studies have reported that height and weight are relevant to the risk of developing ovarian cancer, although the findings of these studies have been inconsistent. In a prospective cohort study that followed 495,477 women for 6 years, body mass index (BMI) and ovarian cancer mortality had a significant association (Fig. 23.2). For women with a BMI of 35 to 39, the RR of developing ovarian cancer was 1.5 (CI, 1.1–2), whereas the RR of developing endometrial cancer was 6.3 (CI, 3.8–10.4). In 2012, a meta-analysis that summarized 47 studies involving 25,157 women with ovarian cancer and 81,311 women without the disease found a small but significant increase in RR (1.07) of ovarian cancer per 5-cm increase in height. The RR for ovarian cancer per 5 kg/m^2 increase in BMI was 1.1 in women who did

not take hormone replacement therapy (HRT) but only 0.95 in women on HRT (5). High BMI was associated with increased risk for borderline serous (recent BMI, OR, 1.24 per 5 kg/m^2; CI, 1.18–1.3), invasive endometrioid (OR, 1.17; CI, 1.11–1.23), and invasive mucinous (OR, 1.19; CI, 1.06–1.32) tumors. Low-grade serous invasive tumors (RR, 1.13; CI, 1.03–1.25), and high-grade serous invasive cancers in premenopausal women (RR, 1.11; CI, 1.04–1.18) were also associated with an increased BMI, but high-grade serous cancers were not (6). However, an analysis from the Ovarian Cancer Cohort Consortium including over 5,000 women with ovarian cancer did not show any significant association of BMI with ovarian cancer or with any subtype (1). Because obesity does not increase the risk of high-grade serous cancers, reducing BMI is unlikely to prevent most ovarian cancers. Given that the association of obesity and ovarian cancer is either weak or absent, it is possible that it can be attributed to confounding factors, such as type 2 diabetes, high-fat diet, or other factors that are currently unknown (7).

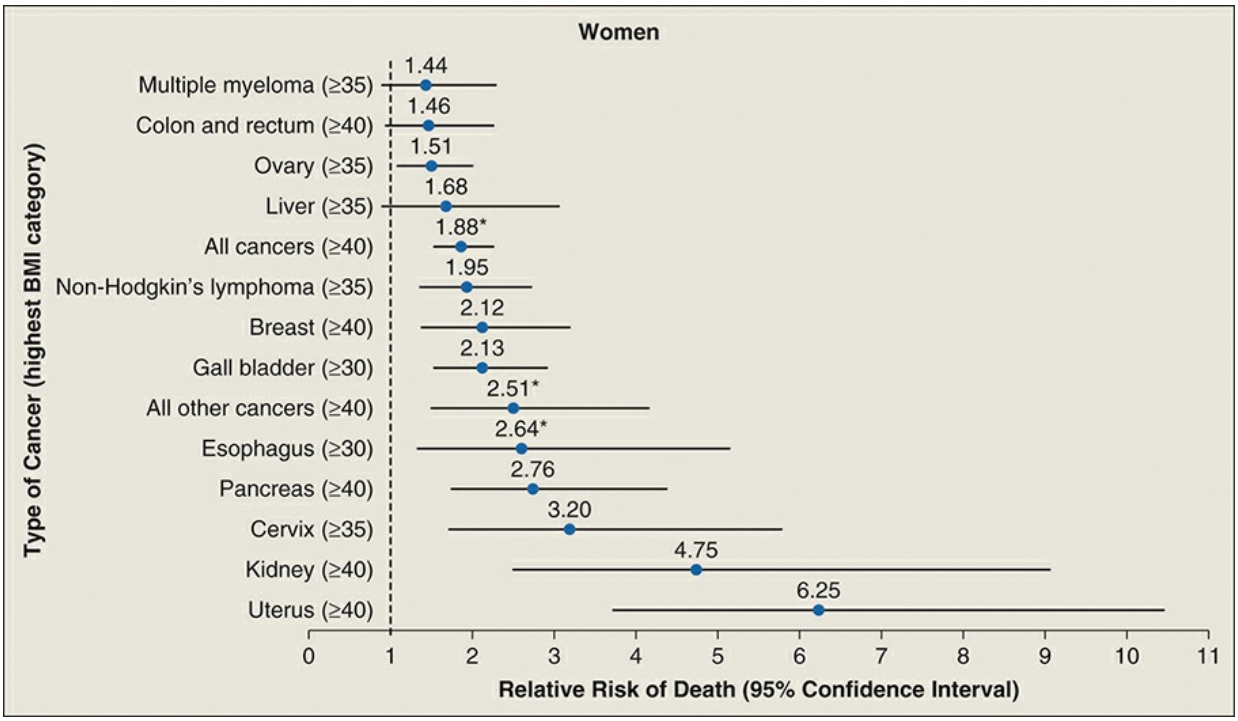

Figure 23.2 Summary of mortality from cancer according to body mass index (BMI) for US women in the Cancer Prevention Study II, 1982 to 1998. For each relative risk, the comparison was between women in the highest body mass index category (indicated in parentheses) and women in the reference category (BMI, 18.5 to 24.9). Asterisks indicate relative risks for women who never smoked. Results of the linear test for trend were significant ($p \leq 0.05$) for all cancer sites.

Reproductive Factors: Pregnancy and Breast-feeding

A number of epidemiologic studies have indicated that early menarche and late menopause increase the risk of ovarian cancer, although increased parity, breast-feeding, and use of OCP reduce that risk. Adding to this evidence are several case–control studies showing that pregnancy lowers ovarian cancer risk and that the risk reduction is greater with each additional pregnancy. The unifying feature of these reproductive factors is an increase or decrease in the number of ovulations that a woman experiences throughout her lifetime. However, a pregnancy after age 35 is more protective against ovarian cancer than a pregnancy in a woman 25 years or younger, regardless of the number of times she has given birth, suggesting that pregnancy at older ages involves mechanisms of risk reduction other than cessation of ovulation (8). There

is no relationship between the timing of the last pregnancy and ovarian cancer survival. Women who breast-feed for longer than 12 months have a substantial reduction in the risk of ovarian cancer in addition to the risk reduction derived from childbirth, and this is likely to be related to suppression of ovulation (9). However, breast-feeding probably reduces ovarian cancer incidence through several additional mechanisms, including reduced serum concentrations of estradiol and luteinizing hormone (LH) and elevated levels of follicle-stimulating hormone (FSH).

Oral Contraceptives

Women who use OCP for at least 5 years reduce their risk of ovarian cancer by an average of 50%, with a concomitant decrease in mortality (10-12) (Fig. 23.3). Protection against ovarian cancer is probably the most important non-contraceptive benefit of OCP. The largest pooled analysis, a meta-analysis reanalyzing data from 45 epidemiologic studies, which included 23,257 women with ovarian cancer and 87,303 controls, showed that the use of OCP in high-income countries reduced ovarian cancer incidence from 1.2 to 0.8 and mortality from 0.7 to 0.5 per 100 users (10). The data also showed a solid duration–response relationship between ovarian cancer incidence and OCP use, because the level of protection conferred clearly increased with duration of use (12) (Fig. 23.4). In addition, the data confirmed that the protective effect continues for decades after OCPs are discontinued and suggested that the earlier a woman begins using OCP, the greater the reduction in her risk for developing ovarian cancer (12). An analysis stratifying the effects of OCP by histologic subtypes showed that a 5-year increase in OCP duration reduced the risk of serous, endometrioid, and clear cell cancer by 14% to 15% (1). However, it is unclear which is more important for a protective effect, the age at which women begin taking OCP or the duration of use. Interestingly, OCP had little effect on risk for mucinous ovarian cancers, which is consistent with the distinct biology of these tumors (13).

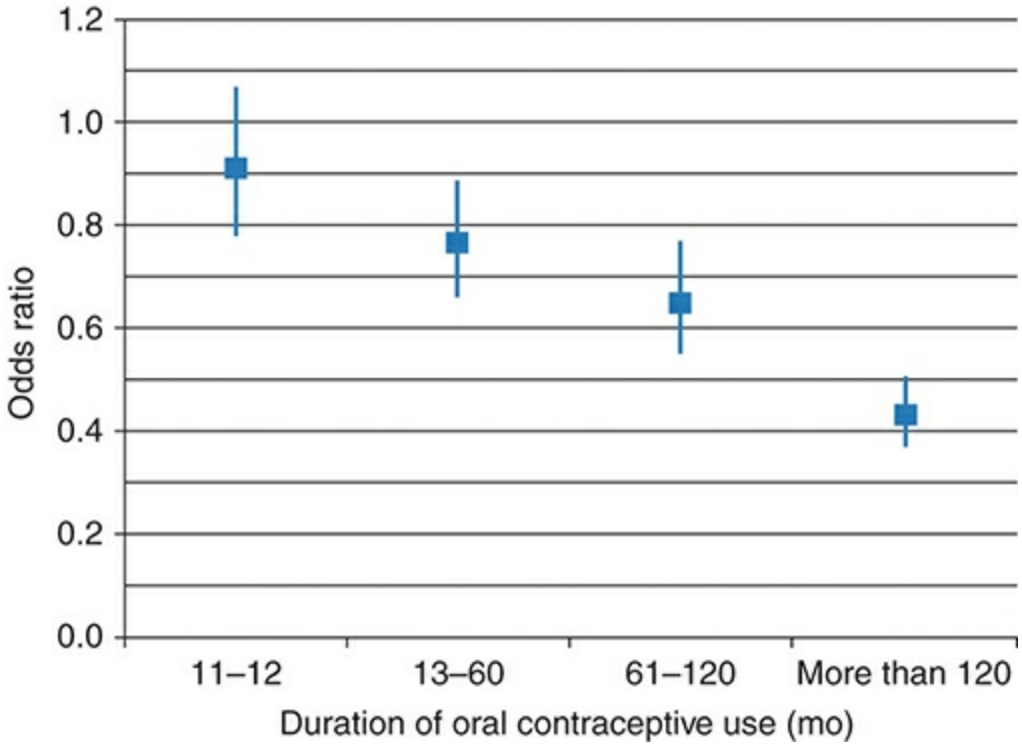

Figure 23.4 Relationship between duration of oral contraceptive pill use and ovarian cancer incidence. There is no evidence of heterogeneity. The estimated value of sigma (σ) is 0.15.
Source: Fig. 3 from Havrilesky LJ, Moorman PG, Lowery WJ, et al. Oral contraceptive pills as primary prevention for ovarian cancer: a systematic review and meta-analysis. Obstet Gynecol. 2013;122:139.

The mechanisms underlying the profound and long-lasting protection against ovarian cancer provided by OCP use are not well understood. The protective effects may be mediated by suppression of ovulation, reduction of gonadotropin levels, and/or induction of apoptosis (11). Moreover, OCPs suppress levels of FSH, LH, and estradiol, all of which can promote tumor cell proliferation. In view of the protective effects of parity and breast-feeding, however, a primary mechanism of protection may well involve suppression of ovulation, which reduces the number of lifetime ovulatory cycles and the associated injury to the epithelial cells on the surface of the ovary. According to an older hypothesis (the "incessant ovulation" hypothesis) (14), ovarian cancer develops from an aberration in the repair process of the surface epithelium, which is ruptured and repaired during each ovulatory cycle. In support of this theory, it is well known that domestic egg-laying hens, which are forced to ovulate incessantly, have a high incidence of lesions believed to be ovarian-derived tumors with peritoneal carcinomatosis (15). Alternative hypotheses center on the ability of OCP to treat endometriosis and reduce the risk of acquiring pelvic inflammatory disease (PID), two conditions known to be associated with ovarian cancer (see below). However, these hypotheses are at odds with an origin of ovarian cancer in the fallopian tube (see Pathology section). A case–control study has shown that progestin-only contraceptive users have a reduced risk (0.39) for developing ovarian cancer (16). Moreover, the increase in progestin levels seen during pregnancy suggests that theprotective effect of pregnancy may involve progestins as well asthe reduction in the number of lifetime ovulations (12). Recent studies in primates indicate that the progestin component of OCPs has a chemopreventive effect by inducing apoptosis of ovarian surface cells that have undergone genetic damage (17). This is supported by the fact that women who use a long-acting progestin-only contraceptive (depot medroxyprogesterone acetate—Depo Provera), which does not completely suppress ovulation, experience a protective effect similar to that observed with OCPs, which completely suppress ovulation (11).

Hormone Replacement Therapy

Currently, the primary indications for the prescription of HRT are severe postmenopausal symptoms and not the prevention of chronic disease. Several prospective cohort studies examined the relationship of postmenopausal estrogen or estrogen/progestin HRT to the risk of developing ovarian cancer. In a prospective, double-blind study, over 8,000 women who had not had a hysterectomy were randomized to either placebo or 0.625 mg conjugated equine estrogen with 2.5 mg medroxyprogesterone acetate (Women's Health Initiative [WHI]) (18). After an average of 5.6 years of follow-up, 20 women in the estrogen/progestin group were diagnosed with an invasive ovarian cancer versus 12 in the placebo group, which was not a significant difference (HR, 1.64; CI, 0.78–3.45). The observational "Million Women Study" (19) showed an increased risk with estrogen-only HRT (RR, 1.49; CI, 1.2–1.81) and, like the Breast Cancer Detection Demonstration Project, showed a lower risk with estrogen/progestin combination therapy (RR, 1.15; CI, 1–1.33). This study also reviewed the cumulative incidence of gynecologic cancers, including ovarian, endometrial, and breast cancer in women taking HRT. The gynecologic cancer incidence per 1,000 women over 5 years increased from 19 per 1,000 in "never-users" to 26 per 1,000 in current users of estrogen-only HRT, and to 35 per 1,000 in current users of estrogen/progestin combinations (Fig. 23.5). The strength of this study, which followed nearly 1 million women, was that the results were adjusted for age at menopause, OCP use, BMI, smoking, and physical activity. HRT was found to be unrelated to the risk of mucinous ovarian cancer. Other data indicate that regular use of vaginal and transdermal estrogen may carry a slightly increased risk of ovarian cancer (19,20).

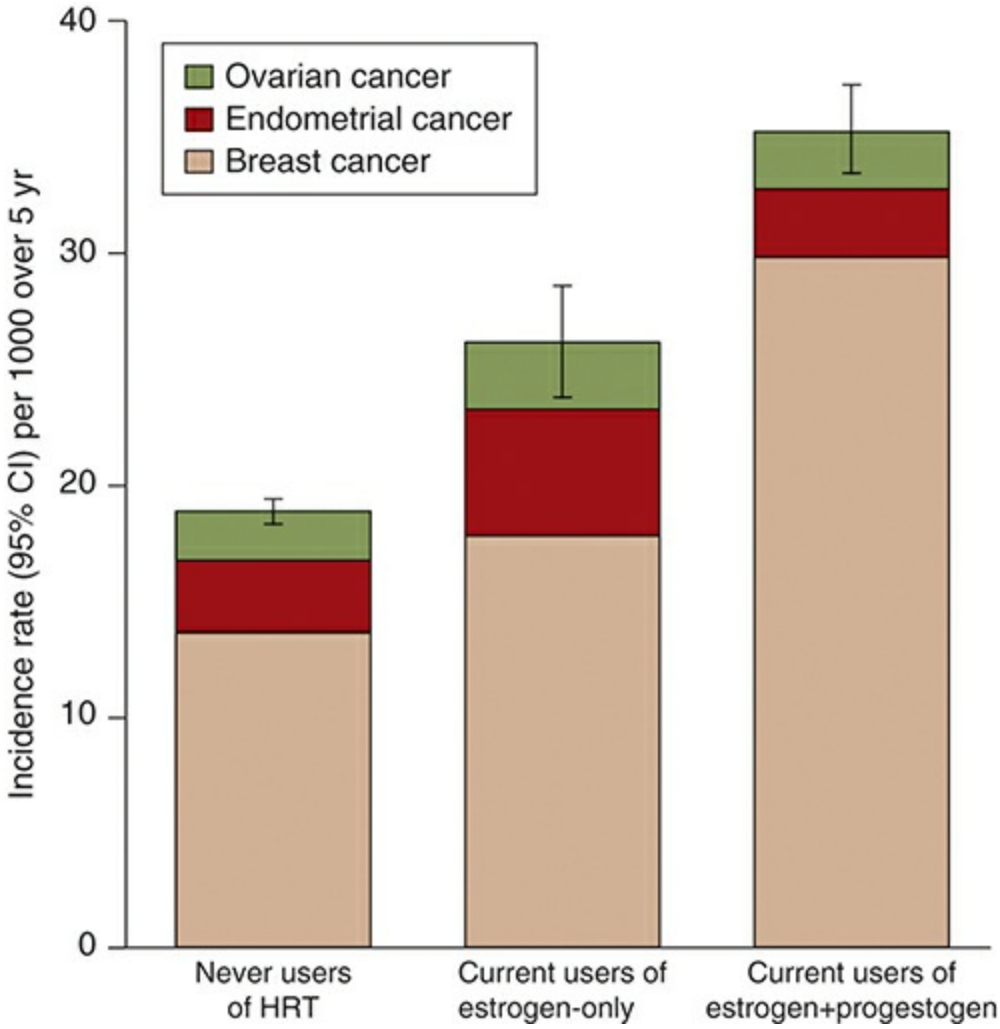

Figure 23.5 Standardized incidence rate (95% CI) for ovarian, endometrial, and breast cancer per 100 women in the study cohort over a 5-year period, for current users of

various types of HRT and for never users. Incidence rates are standardized by age, region of residence, socioeconomic status, time since menopause, parity, use of oral contraceptives, body mass index, and alcohol consumption. Rates apply to women with a uterus and ovaries.

In 2015 a meta-analysis of 52 epidemiologic studies (17 prospective) was published. It included a total of 21,488 postmenopausal women with ovarian cancer and found the RR of ovarian cancer to be increased by 1.14 (CI, 1.10–1.19, $p < 0.0001$) in patients taking HRT (21). The risk was related to the recency of use. The greatest risk was in current HRT users (RR, 1.41; CI, 1.32–1.5), and risk decreased with the length of time since the last use of HRT. In both current and recent users, the ovarian cancer risk was significantly increased with use of both estrogen only (RR, 1.32; CI, 1.23–1.41) and estrogen–progesterone (RR, 1.25; CI, 1.16–1.34) combinations. Interestingly, the RR did not differ between non-epithelial and epithelial tumors and was increased for the two most common tumor histologies, serous (RR, 1.53; 95% CI, 1.40–1.66; $p < 0.0001$) and endometrioid (RR, 1.42; CI, 1.2–1.67; $p < 0.0001$), but not for the less common mucinous and clear cell (RR, 0.75; CI, 0.57–0.98; $p = 0.04$) subtypes. The RR of developing ovarian cancer when taking HRT was independent of age at initiation of HRT. The authors concluded that "5 years of HRT use, starting at age 50, would result in one additional ovarian cancer per 1000 users" (21). However, this meta-analysis did not evaluate dosage and only included patients that were on standard or high doses of HRT. It does not offer information on whether lower doses confer a lower risk, which is particularly relevant now, because most of the women taking HRT in the United States are currently on low-dose regimens. The study did indicate, however, that short-term use of HRT confers less risk. Although an increased risk for ovarian cancer was found in all current users, it did not persist in those who had used HRT less than 5 years and stopped. Therefore, the judicious use of HRT is not necessarily contraindicated by these data. Current clinical practice is to prescribe HRT to patients with severe postmenopausal symptoms and to administer it at the lowest effective dose for less than 5 years.

Interestingly, a meta-analysis (22) of HRT use by women with a history of epithelial ovarian cancer did not show a significant association with increased risk of death or recurrence. In addition, a small (150 patients) prospective randomized study with long follow-up (19 years) suggested that OS was improved in patients with ovarian cancer who took HRT (HR, 0.63; CI, 0.44–0.9; $p = 0.011$) (23). Given the positive effects of HRT on quality of life and the possibility that it may have a positive effect on survival, the benefits of low-dose HRT for menopausal symptom management in patients with ovarian cancer may outweigh concerns about risk for recurrence.

Surgery: Tubal Interruption and Hysterectomy

In general, studies have confirmed that both tubal interruption and hysterectomy without salpingectomy partially protect against the development of ovarian cancer. The four most common surgical sterilization methods, tubal ligation, thermal injury, rings, and clips, are probably equally effective in reducing risk. A large prospective cohort study, the Nurses' Health Study (24), confirmed the findings of smaller case–control studies, showing a RR of 0.33 (CI, 0.16–0.64) of developing ovarian cancer in women who had a tubal ligation. Tubal ligation was shown to almost halve the risk of clear cell cancers and endometrioid tumors (RR, 0.54; CI, 0.43–0.69) and reduce the risk of grade III (RR, 0.77; CI, 0.67–0.89) but not grade 1 serous tumors. It had no impact on the development of mucinous ovarian cancer (25). The same study also reported a weak inverse relationship between hysterectomy and ovarian cancer (RR, 0.67; CI, 0.45–1) and found that the effect of hysterectomy was greater when the surgery was performed at an earlier age (24), a finding that was not confirmed in a later study (25). In the recent analysis by the Ovarian Cancer Cohort Consortium, tubal ligation was associated with reduced risk of endometrioid (RR, 0.6; CI, 0.41–0.88) and clear cell (RR, 0.35; CI, 0.18–0.69) cancers but not with a reduced risk of serous tumors, and hysterectomy was associated with a reduced risk only for clear cell cancers (1).

A retrospective case–control study evaluated the effect of tubal ligation in patients with *BRCA1* mutations (26). Like women unselected for genetic risk, BRCA1 mutation carriers who had undergone a tubal ligation had a considerably reduced risk of developing ovarian cancer (OR, 0.39; CI, 0.22—0.7). Those who both had a tubal ligation and had used OCP in the past had an even lower odds ratio of developing ovarian cancer (OR, 0.28; CI, 0.15–0.52). Possible explanations for the protective effect of tubal interruption against ovarian cancer include (a) an impaired blood supply to the ovaries/distal fallopian tube through the superior branch of the uterine artery, which causes most women to enter menopause earlier and experience fewer lifetime ovulations; (b) an occlusion of the tube that blocks the upward flow of carcinogens and endometrial tissue from the uterus and reduces pelvic infection rates; and (c) the reduced presence and decreased proliferation of progenitor cells in the fimbriated end of the fallopian tube (27).

Inflammation: PID and Endometriosis

PID is a generalized infection of the female genital tract. Several small case–control studies have suggested that PID is associated with ovarian cancer. However, this association only gained wide acceptance with the publication of a large study (28) comparing the ovarian cancer incidence of 68,000 women who had experienced PID versus 136,000 who had not. In this well-designed study, the hazard ratio for ovarian cancer in patients with a history of PID (adjusted appropriately for confounding factors) was twice as high (HR, 1.92) as that of controls and was even higher (HR, 2.46) in women who had at least five episodes of PID. Such indications of a dose–response effect add credibility to epidemiologic findings.

Endometriosis, characterized by the ectopic growth of endometrial glands in the ovary and the abdominal cavity, affects 10% of women of reproductive age. In smaller case–control studies and one large meta-analysis (1), a history of endometriosis has been consistently shown to be associated with clear cell and endometrioid ovarian carcinoma, with an odds ratio of approximately 2. In many endometrioid and clear cell ovarian cancers, endometriosis is detected histologically adjacent to the carcinoma. Combining data from 13 ovarian cancer case–control studies (7,900 patients with ovarian cancer), the Ovarian Cancer Association Consortium (OCAC) published a definitive report that self-reported endometriosis increased the risk of clear cell (OR, 3.05; CI, 2.4–3.8) and endometrioid ovarian cancer (OR, 2.04; CI, 1.7–2.5) (29). In this report endometriosis was also associated, for the first time, with low-grade serous cancers (OR, 2.11; CI, 1.4–3.2), suggesting that these cancers, which are generally believed to arise from serous borderline tumors (SBTs), can also arise from endometriotic implants. Adjusted for histology and International Federation of Gynecology and Obstetrics (FIGO) stage, women with endometriosis-associated ovarian cancer have similar survival to women with non-endometriosis-associated ovarian cancer (30).

There are two pathologic subtypes of endometriosis: displaced benign ectopic endometrial glands and atypical endometriosis. Endometriosis with cytologic atypia and complex hyperplasia (“atypical endometriosis”), present in 2% to 3% of all patients who undergo surgery for endometriosis, is most likely a direct precursor for type I/low-grade ovarian cancers (31). This hypothesis was supported by a study in which *ARID1A* gene mutations were detected in 30% of endometrioid and 46% of clear cell cancers, as well as in areas of atypical endometriosis that were adjacent to the cancers (32). Many genes expressed in endometriosis are also detected in endometrioid ovarian cancer, but do not overlap with genes expressed in high-grade serous cancers (33). In summary, endometriosis is associated with three histologic subtypes of ovarian cancer: endometrioid, clear cell, and low-grade serous (30). The risk of low-grade serous cancers is 3.77 times higher (CI, 1.24–11.48) in patients with endometriosis, but the risk of high-grade serous cancer is not increased (see also Pathology section) (1).

A common mechanism linking endometriosis and PID to ovarian cancer risk may involve the intensive release of cytokines and the infiltration of immune cells (macrophages) that accompanies inflammation. Some (34), but not all (35), epidemiologic data suggest that the use of anti-inflammatory agents, including aspirin and nonsteroidal anti-inflammatory drugs, protects against ovarian cancer. In the largest meta-analysis to date, aspirin was associated with a 20% reduction in ovarian cancer risk (OR, 0.91; CI, 0.84–0.99), which was most consistent for serous histologies. This beneficial effect

was observed with low-dose aspirin (100 mg/d), the dose used for cardiovascular protection. Interestingly, nonaspirin NSAIDs were not significantly associated with a reduction of ovarian cancer risk (36).

Other Risk Factors: Diet, Smoking, Exercise

For the most part, studies that have investigated whether diet affects ovarian cancer risk have had inconsistent and conflicting results. Any association between diet and cancer risk is likely to be difficult to decipher given the inaccuracy of food frequency questionnaires and seasonal differences in the supply of fresh food. Several studies have tried to determine whether vitamin A and β-carotene consumption affects ovarian cancer risk; but although some studies suggested a risk reduction, others could not confirm it. The prospective California Teachers Study, which had almost 100,000 participants, concluded that dietary factors are unlikely to play a major role in ovarian cancer development. In this cohort study, a RR reduction was only found with increased intake of isoflavones, the phytoestrogens found in soy-based foods, some of which have antiestrogenic effects (RR, 0.6; CI, 0.33–1) (37,38). The Women's Health Initiative Dietary Modification Trial was a randomized controlled trial in 48,835 postmenopausal women that prospectively evaluated the effects of reducing fat intake by at least 20% and increasing consumption of vegetables, fruits, and grains on ovarian cancer incidence (39). The overall ovarian cancer HR was not statistically different between the two groups; however, it decreased with the increasing duration of the intervention: for the first 4 years, the risk for ovarian cancer was similar in the intervention and control groups; but over the next 4 years, the risk was lower in the intervention group [0.38 cases per 1,000 person-years in the intervention group vs. 0.64 per 1,000 person-years in the comparison group (HR, 0.6; CI, 0.38–0.96)]. A meta-analysis analyzing 20 epidemiologic studies showed no association between dietary fat intake and epithelial ovarian cancer risk (40). Indirect evidence for the effect of diet on the risk of ovarian cancer is provided by the observations that women from geographic areas with a low incidence of ovarian cancer who relocate to a high-incidence region (North America, Europe) acquire the same risk as women who were born in that region and that ovarian cancer incidence has increased over time in Japan, which is transitioning to a more Westernized eating pattern (41).

Smoking is not generally considered a risk factor for ovarian cancer (42). However, current smoking seems to be associated with an increased risk of developing a mucinous ovarian cancer (OR, 1.78; CI, 1.01–3.15) (43). Smoking cessation reduces this risk back to baseline over 20 years. A large meta-analysis encompassing 28,114 patients concluded that current smoking was associated with a small albeit clinically insignificant increase in ovarian cancer (RR, 1.06; CI, 1.01–1.11). The increased risk was driven by mucinous cancers that are more common in smokers (RR, 1.79; CI, 1.6–2). Interestingly smoking reduced the risk of endometrioid (RR, 0.81; CI, 0.72–0.92) and clear cell (RR, 0.8; CI, 0.65–0.97) and had no association with serous ovarian cancer (44).

Currently, there is no convincing association between physical exercise and ovarian cancer risk and survival (45). A Gynecologic Oncology Group (GOG) trial that recently completed accrual is testing the effect of regular exercise, a low-fat diet, and high intake of vegetables after primary treatment for ovarian cancer on progression-free survival (PFS) (GOG#225: "Can diet and exercise modulate ovarian, fallopian tube, and peritoneal cancer progression-free survival?").

In summary, factors that decrease the number of lifetime ovulations reduce the risk of developing ovarian cancer, whereas hereditary factors increase the risk. From a practical, clinical standpoint, only a positive family history will raise the suspicion of a predisposition to ovarian cancer in an asymptomatic woman.

HEREDITARY OVARIAN CANCER: BRCA AND HNPCC

The study of familial breast and ovarian cancer began in 1866 when the French physician and pathologist Paul Broca noted a much larger than expected incidence of cancer in his wife's family. Over four generations, 10 out of the 24 women in her family died from breast cancer, whereas several more individuals of both sexes developed other malignancies. He concluded that this excess of cancers could not reasonably be attributed to chance. We now estimate that approximately

18% to 24% of invasive epithelial ovarian cancers have an autosomal dominant germ line mutation. *BRCA1* or *BRCA2* is the most common identified genetic mutation in ovarian cancer patients (14% to 18%) followed by mutations in genes linked to Lynch syndrome (*MLH1*, *MSH2*, *MSH6*, *PMS2*); however, of this writing (April 2016), 12 suspected hereditary ovarian cancer genes have been identified (Table 23.1) (46-49). These hereditary mutations are the strongest known risk factors for the development of ovarian cancer. They may also provide targets for therapy, as is the case with *BRCA1/2* mutations and poly-ADP-ribose polymerase (PARP) inhibitors.

TABLE 23.1 Multiplex Testing of Hereditary Ovarian Cancer

Mismatch repair/Lynch-HNPCC	MLH1, MSH2, MSH6, PMS2, EPCAM
Tumor suppressor	TP53, PTEN
Double-strand DNA break repair genes	BRCA1, BRCA2, ATM, CHEK2, NBN
Fanconi anemia pathway	BRIP1, BARD1, PALB2, MRE11A, RAD50, RAD51C, RAD51D, FANCP

Currently there are 12 genes (italicized) associated with hereditary breast/ovarian cancer syndromes (46-49).

Biology of BRCA-Associated Ovarian Cancer

The *BRCA* genes are inherited in an autosomal dominant fashion, which means that every first-degree relative of a mutation carrier has a 50% chance of carrying a mutation. The *BRCA* genes function as classic tumor suppressors, with loss of function of both alleles required for cancer formation. Carriers are initially heterozygous for the *BRCA* gene mutation(s) in all cells and then the sporadic loss of the wild-type allele in epithelial breast or fallopian/ovarian cells results in a predisposition to cancer. The BRCA 1/2 proteins regulate cell cycle checkpoints and gene expression. Their most important function is participation in a specific DNA repair pathway, homologous recombination, which is used for the high-fidelity repair of double-strand DNA breaks. Because cells with *BRCA1/2* mutations lack the ability to repair double-strand breaks, they have increased genomic instability and a predisposition to malignant transformation. The ability of cells with *BRCA* mutations to repair DNA cross-links induced by platinum salts is impaired, which is hypothesized to explain the increased platinum sensitivity of patients with *BRCA* mutations (see below). BRCA1 and 2 are components of the Fanconi anemia DNA repair pathway. Several other genes identified to be mutated in ovarian cancer (*BRIP1*, *PALB2*, *RAD51C*) are also part of this pathway. The *PALB2* gene, which is part of this pathway, binds *BRCA1/2* at sites of DNA damage.

The prevalence of *BRCA1* or *BRCA2* mutations (over 1,000 have been identified) in the general population is about 1:300 to 1:800. However, specific ethnic populations founded by small ancestral groups, such as French Canadians, Icelanders, Mexicans, and Ashkenazi Jews, have a higher mutation rate arising from spontaneous “founder mutations.” For example, 2% to 3% of all Jewish women of Eastern European descent have one of three founder mutations (two in *BRCA1* 187delAG and 5382insC; one in *BRCA2* 6174 delT). The cumulative lifetime risk of developing ovarian cancer for women with a *BRCA1* mutation has been estimated at up to 40% by age 70 and for women with a *BRCA2* mutation up to 18%. The number of *BRCA2*-associated ovarian cancers is smaller overall and the age of onset is later than with *BRCA1*. In comparison, the lifetime risk for ovarian cancer for women in the general population is 1.4% (50). Of note, borderline tumors are not associated with *BRCA1/2* mutations. The age of a *BRCA1/2* mutation carrier, however, is very relevant to her absolute risk of ovarian or breast cancer. The highest incidence of ovarian cancer is between ages 50 and 59 for *BRCA1* mutation carriers and between 60 and 69 years for *BRCA2* mutation carriers and then the risks lower with age but always significantly exceed the risk in the general population (51). There are several online tools for calculating the probability of a *BRCA1/2* mutation and for calculating cancer risk regardless of gene status. One is the Breast and Ovarian Analysis of Disease Incidence and Carrier Estimation Algorithm (BOADICEA), which is used to calculate the risk of breast and ovarian cancer based on family history (52).

Clinical Features of BRCA-Associated Ovarian Cancer

In general, *BRCA* mutation carriers who develop ovarian cancer have a younger age at diagnosis, are more likely to have cancers of high-grade serous histology originating in the fallopian tube, are less likely to have borderline or mucinous tumors, and have, in the short term, a better prognosis than matched controls with sporadic ovarian cancer (46,53). A breast cancer precedes the ovarian cancer diagnosis in 37% of *BRCA1*-associated cases and 37% of *BRCA2*-associated cases (54).

In 1996, Rubin and colleagues reported results of a retrospective analysis suggesting that there are distinct clinical and pathologic features of *BRCA1*-associated ovarian cancer (52). Among 53 patients with germ line *BRCA1* mutations, the average age at diagnosis was only 48, and the vast majority of cancers were serous adenocarcinomas. Cancers associated with *BRCA1* mutations had a relatively favorable prognosis, with an actuarial median survival of 77 months compared with 29 months for matched controls (Fig. 23.6). However, larger studies have shown that although *BRCA1*-related cancers have a better initial prognosis, this advantage decreases over time and eventually reverses at 8 years (47,55). The 5- and 10-year survival rates for noncarriers are 42/30%, for *BRCA1* mutation carriers 45/25%, and for *BRCA2* carriers 54/35%, respectively (55).

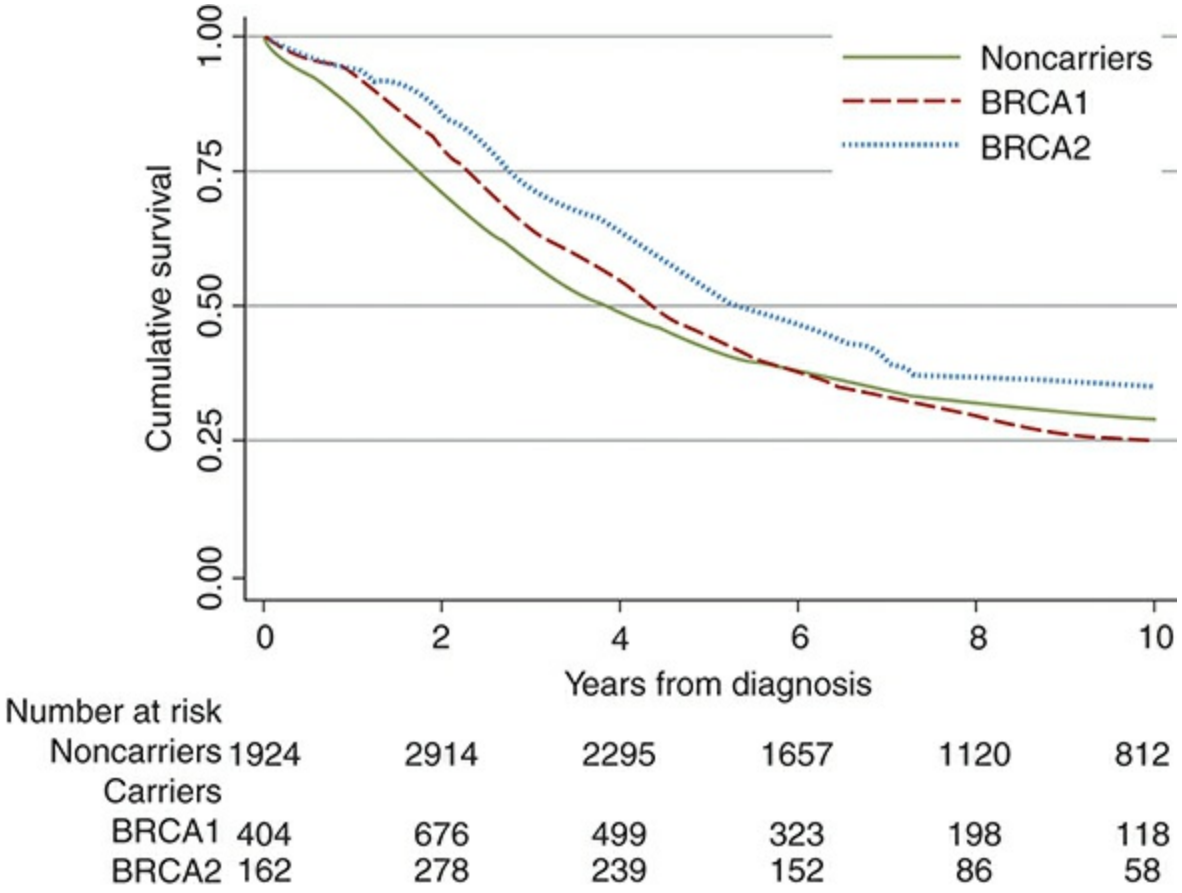

Figure 23.6 Kaplan-Meier estimates of cumulative survival according to BRCA1/2 mutation status.
Source: Fig. 1 from Candido-dos-Reis FJ, Song H, Goode EL, et al. Germline mutation in BRCA1 or BRCA2 and ten-year survival for women diagnosed with epithelial ovarian cancer. Clin Cancer Res. 2015;21:652-657.

Historically, series have reported that *BRCA*-associated cancers are usually of high-grade serous histology; however, recent studies show that *BRCA1*- and *BRCA2*-associated tumors are similar in histology and grade to sporadic cancers (47). In one study of 1,119 *BRCA1/2*-associated ovarian cancers (53), the subtypes included 67% serous, 12%

endometrioid, 2% clear cell, and 1% mucinous cancers. The important clinical implication of these findings is that women with endometrioid and clear cell carcinomas should still be considered for *BRCA* mutation testing. In another series of *BRCA*-associated ovarian cancers with centralized pathology review (56), cancers in *BRCA* carriers were compared with those in noncarriers. Mutation-associated tumors were of significantly higher grade and stage and less often mucinous than non-mutation-associated tumors. No mucinous and no borderline tumors were found in the mutation-associated group. Primary peritoneal carcinoma occurred rarely in both groups. Restricting genetic testing to women with ovarian cancer who have a family history of hereditary cancers, as ascertained by risk factors, will miss half of the patients with a mutation. Therefore, genetic testing solely based on family history alone can no longer be recommended and all ovarian cancer patients with non-mucinous histology should consider testing to evaluate if they have a hereditary ovarian cancer. A large study, which screened 1,342 unselected patients from the province of Ontario diagnosed with epithelial ovarian cancer, reported a *BRCA1/2* mutation frequency of 13.4% (57). Although this study used multiplex ligation-dependent probe amplification and therefore detected the large deletions that normally elude general sequencing, the current standard method to detect genomic abnormalities is next-generation sequencing. Women with ovarian cancer in their fourth life decade had the highest mutation rate (24%), as did women of Italian (43%), Jewish (30%), or Indo-Pakistani (29%) origin. Importantly, 8% of the mutation carriers detected by the screening had no first-degree relative with ovarian or breast cancer. Among Ashkenazi Jewish women with ovarian cancer, there is an estimated 29% to 40% chance that the disease is related to a *BRCA1* or *BRCA2* mutation (58).

Ovarian cancer in a *BRCA1/2* mutation carrier has specific clinical characteristics when compared with sporadic ovarian cancer. It is probable that the improved 5-year survival of women with *BRCA*-associated ovarian cancers is related to the fact that loss of function of *BRCA* proteins, which participate in DNA damage repair, initially results in a more favorable response to platinum-based chemotherapy. Women with *BRCA1/2*-associated ovarian cancers are less likely to have platinum-resistant disease (14.9%) than those with sporadic ovarian cancer (31.7%), and when these patients recur, they tend to have a higher response to second-line platinum-based chemotherapy, even in the setting of initially platinum-resistant disease (4). Platinum salts induce DNA cross-links, which are recognized by DNA damage repair pathways and are repaired by nucleotide excision repair and homologous recombination (59). It may be because *BRCA1/2*-associated high-grade serous cancers harbor defects in homologous recombination that platinum compounds are more efficient in these cancers. A decrease in *BRCA1* mRNA levels (PCR-based measurement) was associated with a significantly longer survival in 57 unselected ovarian cancer patients (60).

Gene Panel–Testing/Counseling

During the 1990s, clinical testing for hereditary ovarian cancer was limited to *BRCA1/2*; however, with the advent of inexpensive next-generation sequencing, we can now test for a wide variety of genes. While *BRCA* and Lynch syndrome are most commonly associated with ovarian cancer, recent findings suggest that 12 other genes confer an increased risk of ovarian cancer, although their biologic role in tumorigenesis is still being investigated (Table 23.1).

Based on three pivotal studies (47-49), most centers perform multiplex testing. Although the specific panels used may vary slightly, most commercial and academic panels include around 20 to 30 genes associated with germ line mutations/insertions/deletions in ovarian cancer. In a cohort of 1,915 ovarian cancer patients identified from GOG protocols 218 and 262 and the Washington University gynecologic tissue bank, 18% were found to have a pathogenic germ line mutation. Approximately 15% had mutations in *BRCA1* (9.5%) or *BRCA2* (5.1%), whereas 3% had mutations in the Fanconi anemia pathway. DNA MMR genes were altered in 0.4% of cases (47). *BRIP1*, a Fanconi anemia pathway gene, is the third most frequent germ line mutation in ovarian cancer patients (0.9–1.6%), conferring a RR of ovarian cancer of about 3.4 (lifetime risk 5.8%) (47). Although *PALB2* increases breast cancer risk, its contribution to ovarian cancer risk is still under investigation. In all these studies, if patients had been selected based solely on clinical criteria (young age, family history, and serous tumor type) a significant proportion of patients with mutations would have been missed. It is estimated that about one-third of patients found to have a non-*BRCA1/2* mutation will experience a change in

clinical management (e.g., risk-reducing salpingo-oophorectomy [RRSO], colorectal screening, additional family testing) (48). However, some controversy over the use of panel-testing remains. It should be realized that we do not understand the significance of germ line variants, including copy number variations or mosaicism, for most of the genes in Table 23.1, and at this point the presence of variants not clearly associated with increased risk should not guide medical decision making.

It is particularly important to offer genetic testing to patients who have already developed ovarian cancer. The identification of a *BRCA* mutation may impact their treatment, because it might indicate an increased sensitivity to PARP inhibitors as well as to platinum compounds both in the first- and second-line setting (46). Although the up-front treatment (carboplatin/paclitaxel) for *BRCA* mutation-associated ovarian cancers is currently the same as treatment for sporadic ovarian cancers, the treatment of recurrent cancer may include PARP inhibitors in *BRCA1/2* mutation carriers. Also, the unaffected first-degree female relatives of *BRCA* mutation carriers have a 50% probability of carrying the same mutation and can be specifically tested for it. Those first-degree relatives who are found to be *BRCA* negative can be informed that they are not at a significantly greater risk of developing ovarian cancer than the general population, whereas those who carry the mutation can be counseled on risk-reducing strategies. Given that a salpingo-oophorectomy reduces the risk of developing ovarian and fallopian tube cancer by about 80%, it is clinically meaningful to be aware that a woman carries a *BRCA* mutation. Negative findings in multigene testing in a patient with ovarian cancer may reassure the unaffected relatives that there is not a known cancer gene in the family; however, the unaffected first-degree relative's ovarian cancer risk would still be slightly elevated (3–7%) compared to the population risk of 1.4%.

Therefore, a negative test provides useful clinical information that will assist with her care and inform screening recommendations. We believe genetic testing should therefore be routinely offered to all women with non-mucinous high-grade epithelial ovarian cancer, regardless of family history.

Considerable expertise and time is needed to counsel women at risk for hereditary cancer. This is of particular importance when testing using cancer gene panels where interpretation of results and management decisions can be complicated. Specifically, although cancer risk estimates are highly reliable for patients with *BRCA1* and *2* mutations, the level of risk associated with other genes is less clear as are recommendations for cancer risk management (61). A genetic counselor or physician with expertise in treating hereditary cancers in women can provide the patient not only appropriate medical information, but also skilled consideration for her concerns and emotional support. *BRCA*- and Lynch syndrome–directed genetic counseling is important for the effective assessment of risk for the patient and her family and for decision making regarding preventive strategies and therapies. However, most women who undergo genetic testing do not receive in-person genetic counseling (62), and at this time there may not be sufficient genetic counseling resources to allow in-person counseling of all patients. Newer genetic counseling models, including phone counseling and the guided use of Internet resources, are currently being explored.

Until a woman with a *BRCA1/2* mutation chooses to have prophylactic surgery, most practitioners will follow her with pelvic exams, CA-125 testing, and pelvic ultrasound, but there is no evidence that these screening strategies improve ovarian cancer survival. Patients should also have regular breast examinations as well as annual mammograms and breast magnetic resonance imaging (MRI). The evidence for use of tamoxifen for primary prevention of breast cancer in BRCA1 and 2 carriers is very limited. In contrast, several studies have shown that removal of the ovaries before menopause reduces breast cancer risk by about 50% (63). Prophylactic bilateral mastectomy should also be discussed with *BRCA* mutation carriers, and patients should be informed of the techniques available for removing and reconstructing the breast, and the expected psychosocial and sexual effects. Counseling about RRSO should balance the risks and symptoms associated with surgical menopause with the morbidity and high mortality of advanced serous ovarian cancer (51).

Most studies have shown that the reproductive and hormonal factors that affect ovarian cancer risk in the general population also affect risk for women who carry *BRCA1* and *BRCA2* mutations. Narod et al., from Toronto, reported results from a large database, which included 670 women with a history of *BRCA1*-associated ovarian cancer, 124 with a history of *BRCA2*-associated ovarian cancer, and 2,424 mutation carriers with no history of ovarian cancer (64). Use of OCPs reduced the risk of ovarian cancer in women with *BRCA1* mutations (OR 0.56) and *BRCA2* mutations (OR 0.39).

The six studies that addressed this question were analyzed together in a meta-analysis (65), showing that the odds ratio (OR) for developing ovarian cancer was 0.65 (CI, 0.47–0.66) in *BRCA1* mutation carriers using OCPs, 0.65 (CI, 0.34–1.24) for *BRCA2* mutation carriers, and 0.58 (CI, 0.46–0.73) for the combined BRCA1/2 group. In summary, OCP use is inversely associated with ovarian cancer risk, whereas a modest but not statistically significant increased risk was observed for breast cancer (65).

Breast-feeding was also found to be protective for carriers of a *BRCA1* mutation (OR 0.74). An effect of similar magnitude was seen for breast-feeding in *BRCA2* mutation carriers, but it was not statistically significant (OR 0.72). Although the Toronto group had previously reported that tubal ligation was protective against ovarian cancer in mutation carriers as well as noncarriers, the association in this expanded cohort was not significant for carriers of either a *BRCA1* (OR 0.8) or a *BRCA2* mutation (OR 0.63). Pregnancy, which had previously been reported to be protective for women carrying a *BRCA* mutation (58), was found to be protective for carriers of *BRCA1* mutations (OR 0.67), but was associated with increased risk for carriers of *BRCA2* mutations (OR 2.74). The reasons for this are not clear.

Finally, it is important to be aware of legislation that addresses issues of discrimination and privacy that are raised by the prospect of increasingly comprehensive genetic information on each patient. The Genetic Information Nondiscrimination Act (GINA) (2008) prohibits health insurers and employers from discriminating on the basis of genetic information (66). Rules governing patient privacy and confidentiality prevent a physician from disclosing genetic test results to a relative without permission from the patient. The American Society of Clinical Oncology (ASCO) guidelines suggest that the ethical duty to warn a relative of genetic risk is satisfied if the doctor explains to the patient that a hereditary cancer syndrome has implications for other family members, advises the patient to share information with them, and offers genetic counseling for those family members who are interested and at risk.

Prophylactic Salpingo-oophorectomy for Prevention of BRCA-Associated Ovarian Cancer

Indications for Surgery

There is, at this time, no scientific evidence that the current methods of screening can detect ovarian cancer early. The current widely used screening procedures (clinical exam, CA-125, pelvic ultrasound) have such low specificity and sensitivity that their utility in detecting ovarian cancer at a curable stage is highly questionable (67,68). Preliminary results from studies of the use of a screening strategy that includes transvaginal ultrasound and the risk of ovarian cancer algorithm (ROCA), which detects a significant change in CA-125, have not been promising even in postmenopausal women (68). Such screening is even less efficient in young premenopausal women because ovulating women may have functional cysts, endometriosis, or a hemorrhagic corpus luteum, which can be mistaken for a suspicious mass (Table 23.4). The ovarian cancer screening studies have not focused exclusively on high-risk women; however, the US Preventative Task Force indicates that there is no reason to believe that high-risk women will benefit from screening (69). The National Comprehensive Cancer Network (NCCN) guidelines do not support ovarian cancer screening, but state that it can be considered at the clinician's discretion starting at age 30 to 35 years.

In contrast, the evidence does strongly support the efficacy of RRSO in reducing mortality through early detection of ovarian cancer and prevention in unaffected women (Table 23.2). In 2002, two large prospective series clearly demonstrated that RRSO reduced the risk of developing Müllerian carcinoma (ovarian, fallopian tube, and peritoneal cancer) in patients with *BRCA1/2* mutations (70,71). Kauff and colleagues from Memorial Sloan-Kettering prospectively studied 170 women with either *BRCA1* or *BRCA2* mutations for 6 years (Fig. 23.7). Ninety-eight women who underwent RRSO were compared with 72 women who elected surveillance. Three large prospective studies showed that the RRSO group had significantly fewer *BRCA*-related gynecologic and breast cancers than the surveillance group (51,71,72).

		cancer at RRSO

RRM, risk-reducing mastectomy; RRSO, risk-reducing salpingo-oophorectomy.

Another larger prospective study reported on the effects of RRSO in *BRCA1* and *BRCA2* germ line mutation carriers separately. Among 1,079 patients, RRSO reduced ovarian cancer risk in women with *BRCA1* mutations by 85% and reduced breast cancer risk in women with *BRCA2* mutations by 72%. There was also a 39% reduction in breast cancer risk in women with *BRCA1* mutations and a reduction in ovarian cancers in women with *BRCA2* mutations, but these were not statistically significant. The absence of a significant reduction in ovarian cancer in *BRCA2* mutation carriers may have been partially attributable to the fact that most women with *BRCA2*-associated ovarian cancer are over 60 years old, whereas the median age of the women in the study was 46 years (57). In another large study coordinated by the Toronto group, 5,783 known carriers of a *BRCA1* or *BRCA2* mutation were identified from an international registry of 32 centers. The overall reduction in risk of Müllerian cancers with RRSO was 80%; the estimated cumulative incidence of peritoneal cancer at 20 years after RRSO was 3.9% for BRCA1 and 1.9% for BRCA2, with most cases occurring less than 5 years after RRSO (73).

Given the strong evidence that RRSO reduces all-cause, breast cancer-specific, and ovarian cancer-specific mortality, the NCCN, the American College of Obstetrics and Gynecology (ACOG), and the Society of Gynecologic Oncology (SGO) (74) have all recommended that prophylactic salpingo-oophorectomy be considered in women with hereditary ovarian cancer syndromes between age 35 and 40 years or after childbearing is completed. Because *BRCA2* mutation carriers will develop ovarian cancer at an average age of 58, and only 2% to 3% of them will develop ovarian cancer by age 50 as compared with 10% to 21% of women with *BRCA1* mutations, delaying RRSO in *BRCA2* mutation carriers until age 50 could be considered (72). However, women with *BRCA2* mutations have a 26% to 34% risk of developing breast cancer by the age of 50, and the evidence suggests that the breast cancer risk reduction conferred by RRSO is greater when the ovaries are removed earlier (47). In one study, RRSO *after* a primary diagnosis of breast cancer significantly reduced breast cancer-specific mortality in *BRCA1* mutation carriers (HR, 0.38; CI, 0.19–0.77) (75). The number of BRCA2 carriers was much smaller and a benefit of RRSO not seen. RRSO mostly benefited patients with ER-negative breast cancer. The data also suggest that oophorectomy is most beneficial during the first year of treatment.

Surgery

Because RRSO substantially decreases ovarian cancer risk by about 80% and reduces breast cancer risk by 48% (51,72), the benefits of prophylactic surgery clearly outweigh the associated risks. Some risk (up to 3.9%) of primary peritoneal cancer remains after RRSO, and that risk could arise from an ovarian remnant, an incompletely removed fallopian tube, or a microscopically metastasized occult cancer that could not be recognized at the time of surgery.

The informed consent discussion for RRSO surgery should include not only information about the general risks of surgery and the risk of occult or subsequent cancer, but also information about the likely side effects of surgical menopause. Permission to perform a full staging or debulking procedure if cancer is found may also be obtained. The rate of occult cancer detected with RRSO (which requires an additional surgical procedure) can be up to 10% in a tertiary referral center (76), although in a population-based study of *BRCA1/2* mutation carriers (5,782 patients) undergoing RRSO it was only 4.2% (51). Hysterectomies are not performed routinely, because there are no reports indicating that the intrauterine portion of the fallopian tube gives rise to a fallopian tube cancer and the data associating mutations in *BRCA* and uterine cancer are very limited (77). However, hysterectomy may be indicated to reduce endometrial cancer risk for patients with Lynch syndrome who are also at risk for endometrial cancer (see below), if there is other uterine pathology (e.g., fibroids, incontinence, menorrhagia), or to simplify HRT.

It is usually possible to perform RRSO laparoscopically as an outpatient procedure. Occasionally a laparotomy will be necessary because of extensive intra-abdominal/pelvic adhesions. After a thorough surveillance of the entire abdominal cavity, including the upper abdomen, peritoneal washings are performed and abnormal areas biopsied. The ureter is

visualized and the infundibulopelvic vessels are transected about 2 cm superior to the ovary to assure that the entire ovary has been removed. The tube and the superior branch of the uterine artery are transected very close to the uterine cornua. A frozen section is only prepared if there is a gross abnormality of the ovary or any other suspicious tumor. Random biopsies of the omentum and peritoneum have not been found to lead to improved detection of occult cancers (76). Some patients presenting for RRSO will have had a previous reconstruction of their breast using some variation of a rectus abdominis myocutaneous flap. Because these procedures can lead to umbilical translocation in relation to the aortic bifurcation, higher camera port placement or a single-site approach may be required. In general, RRSO is associated with a very low risk of operative complications. In a Memorial Sloan-Kettering study, 4 out of 80 RRSOs performed laparoscopically had complications caused by adhesions and trocar injuries, which are known complications associated with operative laparoscopy (71). With improved optical equipment and direct visualization trocars, the current rate may be lower.

Because many experts believe that high-grade serous "ovarian cancer" arises in the fallopian tube (78), the option of removing the fallopian tube and leaving the ovary *in situ* is being debated. Bilateral salpingectomy with ovarian retention (BSOR) has the advantage of avoiding the long-term sequelae of removing the ovaries and inducing surgical menopause. However, given that we lack convincing biologic data that the fallopian tube is the sole origin of ovarian cancer, BSOR remains investigational. A trial studying BSOR with delayed oophorectomy (NCT01907789) is currently underway but results will not be available before 2018. Still, many gynecologists have decided not to wait for the outcome of randomized trials and have begun to remove the fallopian tube at the time of hysterectomy for noncancer indications, as the surgical risk is small. Since 2010, investigators in British Columbia have educated gynecologists about the potential benefits of salpingectomy, suggesting that they remove the tubes at the time of hysterectomy for benign disease and for sterilization in lieu of a tubal ligation (79).

Postoperative Results

Women who have chosen to undergo RRSO generally report a good overall quality of life. The operation is often accompanied by a significant decrease in perceived risk and therefore a decrease in anxiety. Acute surgical menopause, however, can have a significant negative effect on quality of life (80). Menopause affects bone health and can cause a decrease in sexual desire along with vaginal atrophy and dyspareunia, which affect sexual functioning, leading to a further decrease in sexual desire, discomfort, and avoidance of intimacy. Many patients suffer from vasomotor symptoms, such as hot flashes and night sweats, which lead to sleep disturbances. These symptoms can be alleviated, but not completely eliminated, by HRT. Eisen et al. reported that HRT after RRSO is not associated with an increase in breast cancer risk in *BRCA* mutation carriers and those who received short-term HRT (approximately 3 years duration) after RRSO preserved the reduction in breast cancer risk offered by the surgery (HR, 0.38 vs. 0.37) (81). Still, decision making regarding menopausal therapies in women with *BRCA* mutations who are at increased risk of breast cancer is challenging because of the theoretical risk that HRT will promote growth of occult breast tumors. In addition, results from the WHI have influenced women and physicians to avoid use of cyclic estrogen/progestin HRT. Alternative treatments for vasomotor symptoms, such as venlafaxine and gabapentin, which are less effective than HRT, should be discussed in counseling. None of the "natural" treatments for hot flashes have been shown to be more effective than placebo.

The Pathologic Examination of Risk-Reducing Salpingo-oophorectomy Specimens

A family history of ovarian cancer and/or *BRCA* or other cancer gene mutation should be shared with the pathologist, as only one slide from the fallopian tube and ovary of patients with benign gynecologic disease is normally reviewed (4). In the setting of a known history of genetic predisposition to breast and ovarian cancer, most pathologists will submit the entirety of the fallopian tubes and ovaries for microscopic examination. The SEE-FIM (sectioning and extensively examining the fimbriated ends) protocol is now widely used for RRSO specimens. This involves serially sectioning the

tube meticulously, stopping before the fimbriae. The fimbria is amputated and sectioned longitudinally, thereby maximizing exposure. Deeper sections need to be obtained if foci of atypia are to be identified histologically. Foci of *in situ* or invasive occult carcinoma may be very subtle and are often less than 1 mm in maximum diameter (see also Pathology section).

Microscopic occult carcinomas have been identified in RRSO specimens in about 2% to 9% of *BRCA* mutation carriers, generally involving the tubal fimbriae. In one prospective series, 7 ovarian and 3 tubal carcinomas (and 1 case in which washings showed malignant cells but no primary cancer was identified) were found among 490 women who underwent RRSO. Powell and colleagues report that of 111 consecutive BRCA-positive patients treated at a single institution, 9% had occult neoplasia (76). Suspicious epithelial cells, clearly distinct from mesothelial cells, are occasionally identified in cytology specimens. Colgan et al. found malignant cells in 3 of 35 pelvic washings. One microscopic ovarian surface carcinoma and 1 *in situ* tubal carcinoma were found; no carcinoma could be identified in the third patient. Twenty-two percent of specimens showed endosalpingiosis. Positive cytology specimens only rarely lead to the discovery of early-stage tubal carcinomas (81) although sometimes, as mentioned, malignant cells are present in washings at RRSO and there is no identifiable carcinoma by histology (73). Identification of a STIC but no other evidence of disseminated disease generally does not require additional surgery.

Lynch Syndrome—Hereditary Nonpolyposis Colorectal Cancer Syndrome

Epithelial ovarian cancer is also a component of HNPCC syndrome, which refers to patients who fulfill the Amsterdam criteria for Lynch syndrome II. Dr. Henry Lynch, who gave his name to the syndrome, characterized it as autosomal dominant cancer susceptibility syndrome. In addition to a predisposition to develop colorectal and endometrial cancer, women with this syndrome have a 10% to 13% lifetime risk for developing ovarian cancer (82,83) (27% to 71% risk of developing endometrial cancer). These patients develop ovarian cancer at a younger age and present at an earlier stage (83). They also have a higher percentage of low-grade tumors than the general population (84). In a cohort of women with HNPCC and at least two primary cancers, more than half were initially diagnosed with a gynecologic cancer, which preceded the development of a colorectal cancer. Fourteen percent of these women had synchronous cancers; a colorectal and a gynecologic cancer were found simultaneously (82). Women at risk for Lynch syndrome are identified using either the Amsterdam II or the revised Bethesda criteria, which have been enriched for patients who are likely to have a hereditary origin of their cancer. However, even though the Bethesda criteria have been revised to improve identification, they may still miss as many as 28% of patients with Lynch syndrome.

Lynch syndrome describes patients and families with a germ line mutation in *MLH1*, *MSH2*, *MSH6*, *PMS2*, or *EPCAM*. Lynch syndrome-related tumors exhibit a lengthening or shortening of DNA repeat sequences, which leads to microsatellite instability (MSI), caused by an inability to repair DNA replication errors. The germ line mutations that characterize the syndrome are in genes involved in the DNA mismatch repair pathway, especially *MSH2* and *MLH1*, which account for about 90% of the mutations detected in families with Lynch syndrome. *MSH2* is particularly associated with an excess of endometrial and ovarian carcinomas. Other genes in the MMR family, including *MSH6*, *PMS1*, and *PMS2*, account for 10% of HNPCC-related cancers (83). To identify patients with HNPCC using tissue specimens, two approaches are used: for MSI analysis, DNA is extracted from macrodissected tumors using paraffin sections and short tandem repeats are amplified. Immunohistochemical stains are performed for *MSH2*, *MSH6*, *MLH1*, and *PMS2*. If a MMR protein is absent, despite appropriate controls, confirmatory germ line testing is performed. MSI can be owing to epigenetic changes as well as to Lynch syndrome. If tissue analysis is suggestive of HNPCC the diagnosis should be confirmed through germ line testing for Lynch syndrome-related genes.

A French multicenter study reviewed the cancer incidence in 537 families with Lynch syndrome (85). For women in the study, the cumulative risk for Lynch syndrome-associated cancers was 19% by age 50 and 54% by age 70. The age-specific cumulative risk for ovarian cancer by age 70 was 20% for *MLH1* mutation carriers, 24% for *MSH2* mutation carriers, and 1% for those with *MSH6* mutations (Fig. 23.8). The authors found that *MSH6* mutation carriers have much

lower cancer risks than those with *MLH1* and *MSH2* mutations. These findings raise the question of whether women with a *MSH6* mutation really need prophylactic surgery, especially if no other family member has been affected by cancer. However, a smaller cohort study did not confirm this low ovarian cancer risk in women affected by *MSH6* mutations (86). This study from the combined Swedish/Danish cancer registry found that the distribution of ovarian cancer histologic subtypes in patients with Lynch syndrome differed considerably from the sporadic ovarian cancer population. They reported that 35% of the ovarian cancers associated with Lynch syndrome were endometrioid and 17% were clear cell, both much higher percentages than are seen in sporadic cases. *PMS2* mutations are associated with a small increased risk of ovarian cancer.

[a]See eTable 3 (available at http:www.jama.com) for the number of affected individuals and the number of family members contributing to the likelihood for risk estimation.

Figure 23.8 Age-specific cumulative risks of colorectal cancer, endometrial cancer, and ovarian cancer according to gene for mismatch repair mutation carriers.
Source: From Bonadona V, Bonaiti B, Olschwang S, et al. Cancer risk associated with germline mutations in MLH1, MSH2, and MSH6 genes in Lynch syndrome. JAMA. 2011;305:2304–2310, with permission.

As with *BRCA1/2* patients, RRSO is a very effective method for the prevention of ovarian cancer in patients with a Lynch syndrome mutation. Preoperatively, patients should have a colonoscopy to search for polyps and colon cancer, an endometrial biopsy to exclude an occult endometrial cancer, and a vaginal ultrasound to detect any ovarian masses that will affect the surgical approach (minimally invasive vs. open surgery). In a large study combining all Lynch syndrome patients followed at MD Anderson, UCSF, and Creighton University, none of 61 patients who underwent RRSO and a hysterectomy developed ovarian or uterine cancer. However, 12 (5.5%) of the 223 patients who chose surveillance developed ovarian cancer and 33% developed endometrial cancer (87). Consistent with the French study (85), half of the patients who developed ovarian cancer had a *MLH1* mutation and the other half a *MSH2* mutation, whereas none had a *MSH6* mutation. Clearly RRSO and hysterectomy are effective in preventing gynecologic cancers in women affected by HNPCC. Women with Lynch syndrome and ovarian cancer have a better prognosis with a 5-year survival of 88%.

A critical question for patients with Lynch syndrome is at what age a hysterectomy/BSO should be performed. Two studies reported that the median age for endometrial and ovarian cancer in these patients is 46 to 48 years and 42 to 48 years, respectively. Moreover, a significant number of the women in one study (21% to 42%) developed ovarian cancer before age 40 (86,87). However, the French study found that the risk of developing ovarian cancer for all Lynch syndrome mutation carriers by age 40 does not exceed 2% to 3%. Still, a prudent approach is to perform the hysterectomy and RRSO after the age of 35, or once childbearing is completed. Obviously, such an early intervention requires extensive counseling, balancing the consequences of surgical menopause treated with HRT with the benefits of avoiding ovarian and endometrial cancer.

For patients with Lynch syndrome who prefer not to undergo prophylactic surgery there is no scientifically proven ovarian cancer screening option. According to the NCCN guidelines and most experts, transvaginal ultrasound and CA-125 are acceptable exams in patients with mutations, if the patient is fully aware that these interventions will not necessarily diagnose ovarian cancer early and might even be harmful, because of possible complications of surgical follow-up for a false-positive result (67). However, given that two-thirds of HNPCC-associated ovarian cancers are diagnosed during

stages I and II because of their endometrioid and clear cell histology (86,87), a vaginal ultrasound is a reasonable choice for surveillance in a woman who declines prophylactic surgery. Although it has not been thoroughly studied, chemoprevention with OCP together with screening for ovarian and endometrial cancer is currently used in women who want to delay surgery.

NAURAL HISTORY OF THE DISEASE: PATTERNS OF SPREAD

Mucinous and Endometrioid Ovarian Cancer

Mucinous neoplasms are the largest of all known ovarian tumors. They can reach diameters of 30 to 40 cm, often compressing adjacent organs (Fig. 23.9). Intact removal of these tumors may be challenging because of their weight, the large veins that drain from them, and difficulties visualizing the ureter during the procedure. However, mucinous tumors, especially the largest, tend to be benign. Indeed, 80% of these tumors are benign mucinous cystadenomas, and when malignant, most mucinous tumors are low grade. Although high-grade invasive mucinous cancers are very aggressive and resistant to chemotherapy, they are rare. Only 0.5% to 1.5% of advanced ovarian cancers have a mucinous histology. One large study found that 71% of invasive mucinous tumors found in the ovary were metastases from the gastrointestinal tract (colon, pancreas, and appendix), and only 29% were truly primary mucinous ovarian cancers (88,89). These primary invasive mucinous tumors are often confined to the ovary without surface involvement and are unilateral (metastases are more often bilateral) and of a significant size (≥13 cm) (88). Often patients with mucinous tumors have an elevated level of one of two tumor markers, CEA or CA19-9.

Figure 23.9 A 42-year-old patient with a multicystic adnexal mass originating from the left ovary. The specimen was 20 × 15 cm and weighed 5 pounds. The frozen section returned as a mucinous borderline tumor.

Pseudomyxoma peritonei (PMP) is a condition caused by the production of mucin by glandular cells in the peritoneal cavity. These cells have a benign glandular histology, but their behavior is biologically malignant, as the mucin-producing cells implant diffusely on the abdominal and pelvic peritoneum. The cells then produce thick mucin that encases the bowel and pelvic organs, leading to tumor cachexia and bowel obstruction. The most common origins of PMP are currently thought to be appendiceal neoplasms or ruptured benign mucoceles of the appendix with secondary involvement of the ovary. Patients with PMP can progress for months or years without symptoms. Although their disease often has an indolent course, it cannot be cured (10-year survival is 50% to 60%) (90,91). Currently, it is generally recommended that patients receive aggressive cytoreductive surgery with complete peritonectomy and hyperthermic intraperitoneal chemotherapy (HIPEC) in a specialized center, although there are no randomized data to support this strategy (91).

Invasive endometrioid ovarian cancer accounts for about 10% of all ovarian carcinomas and occurs most often in perimenopausal patients. These cancers are often associated with endometriosis (29). Up to 25% of patients of reproductive age with an endometrioid endometrial cancer have a synchronous early-stage endometrioid ovarian cancer (92). Molecularly, these tumors are often clonally related, representing metastatic disease from either the uterus or the ovary (93).

Because of the large size of the primary tumor, both mucinous and endometrioid ovarian cancers are likely to be discovered at an early stage (FIGO I/II). They do not have the pattern of transcoelomic spread along peritoneal surfaces seen with serous cancers and, unlike high-grade serous ovarian cancer, they do not respect anatomic intraperitoneal planes. Locally, they are characterized by thick adhesions to the pelvis and can invade adjacent pelvic organs including the muscularis of the colon and the pelvic sidewall. Advanced metastatic endometrioid and mucinous tumors (FIGO III/IV) implant into the abdominal wall and metastasize to the parenchyma of intra-abdominal organs such as the liver and spleen

(88).

Serous Ovarian Cancer

Serous carcinomas originating from Müllerian epithelium, which include ovarian, peritoneal, and fallopian tube cancers, are characterized by transcoelomic spread (13,94). Recently, there have been new insights into the origin of serous "ovarian" cancer, and a putative precursor lesion in the fallopian tube, serous tubal intraepithelial carcinoma (STIC), has been identified. It is now believed that most serous "ovarian" cancer originates in the fallopian tube as STIC (76,95). A small tumor can be easily assigned to a particular anatomic site, but if the tumor is widely disseminated, it is not possible to clearly identify where a serous tumor originated. In the absence of a STIC, serous tumors will default to ovarian. However, this is not very important from a clinical standpoint, because the dissemination patterns of serous ovarian, fallopian tube, and peritoneal cancer are clinically indistinguishable by virtue of their propensity to exfoliate malignant cells into the peritoneal cavity, and patient survival is very similar. A study (96), as well as clinical experience, suggests that all three tumor subtypes grow quickly and disseminate on mesothelial cell-covered body cavities, including the peritoneal cavity or pleural space. Once the cancer cells detach from the ovarian or fallopian tube tumor, they float in the ascites as single cells or as multicellular spheroids (13). The cells follow the normal clockwise circulation of peritoneal fluid up the right paracolic gutter and to the undersurface of the right hemi-diaphragm, where they may implant and grow as surface nodules. All intraperitoneal mesothelium-covered surfaces are at risk, with frequent involvement of the peritoneum, diaphragm, omentum, to a lesser degree the hepatic flexure and splenic hilum, bowel and bowel mesentery, and appendix (94,97).

The most common sites involved in locoregional metastasis are the contralateral ovary, the peritoneum of the cul-de-sac, and the rectosigmoid colon serosa and its mesentery. Colonization of the cul-de-sac with cancer cells often results in obliteration of the rectouterine space. In patients with extensive pelvic disease (Fig. 23.10), the uterus, bladder dome, side wall peritoneum overlying the ureter, sigmoid colon, ovarian tumor masses, and appendix become a conglomerate pelvic tumor, and it is very difficult to identify the individual organs or any anatomic borders (98,99). If the tumor is predominantly on the patient's right side, a large tumor mass develops in the right lower quadrant involving the ileocecum, appendix, and right ovary. If the tumor is predominantly on the left side, the conglomerate tumor includes the left ovary, the rectosigmoid and its mesentery, and the left side of the uterus.

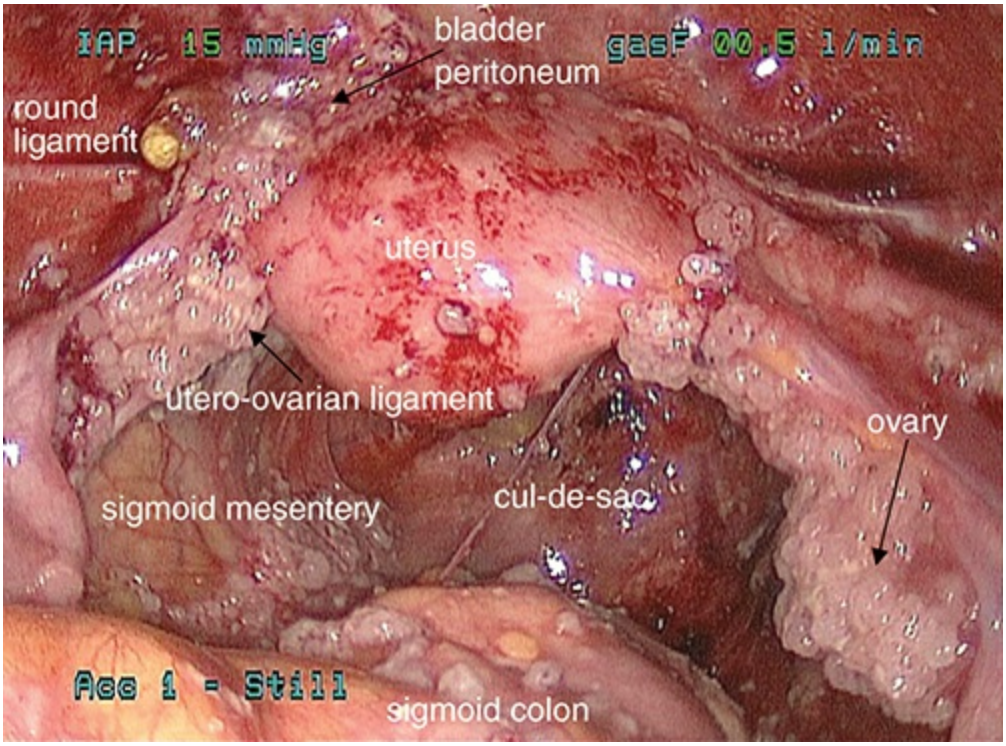

Figure 23.10 Laparoscopic intraoperative image of the pelvis of a patient with disseminated high-volume disease suggestive of ovarian cancer on CT scan. Tumor implants on the sigmoid colon, sigmoid mesentery, pelvic sidewall, ovary, utero-ovarian ligament, and bladder peritoneum.

The most frequent site of distant metastasis is the omentum. Other than metastases to the contralateral ovary, an omental metastasis is often the largest tumor in the abdominal cavity. Serous cancers initially transform the infracolic omentum, but as the cancer progresses the entire omentum is replaced by tumors (94), reaching from the hepatic to the splenic flexure (Fig. 23.11). Because the omentum reaches the spleen in the left upper quadrant, there is often a solid tumor at the lower pole of the spleen and at the splenic hilum directly adjacent to the distal pancreas, sometimes requiring an en bloc resection of the distal pancreas and the spleen in order to completely clear the left upper abdomen (100,101). In patients affected by extensive disease, the lesser omentum, which is attached to the lesser curvature of the stomach, is also involved. Despite extensive involvement of the omentum by a serous carcinoma, there is almost never invasion of the gastric or transverse colon muscularis as the tumor is only invading the serosa. It is almost always possible to develop a plane between the tumor and the muscularis and remove the tumor nodules and plaques without a colon or gastric resection. Also, there is rarely tumor in the retroperitoneal, lesser sac, because serous tumors metastasize on mesothelial cell-covered surfaces. Extensive surface involvement of the abdominal or pleural cavity will cause ascites and a pleural effusion, respectively. Patients with extensive intra-abdominal tumor involvement sometimes have extensive involvement of the small bowel mesentery. A condition described owing to its appearance as “rose budding” will occur when tumor constricts the blood supply to the bowel and limits bowel mobility because of the short mesenteric root. Often these tumors are unresectable because they compromise all blood supply to the small bowel from the superior mesenteric artery and impair venous return through the superior mesenteric vein. In very advanced disease, serous cancers tend to agglutinate the loops of small bowel and cause a high-grade bowel obstruction at many levels (jejunum, ileum).

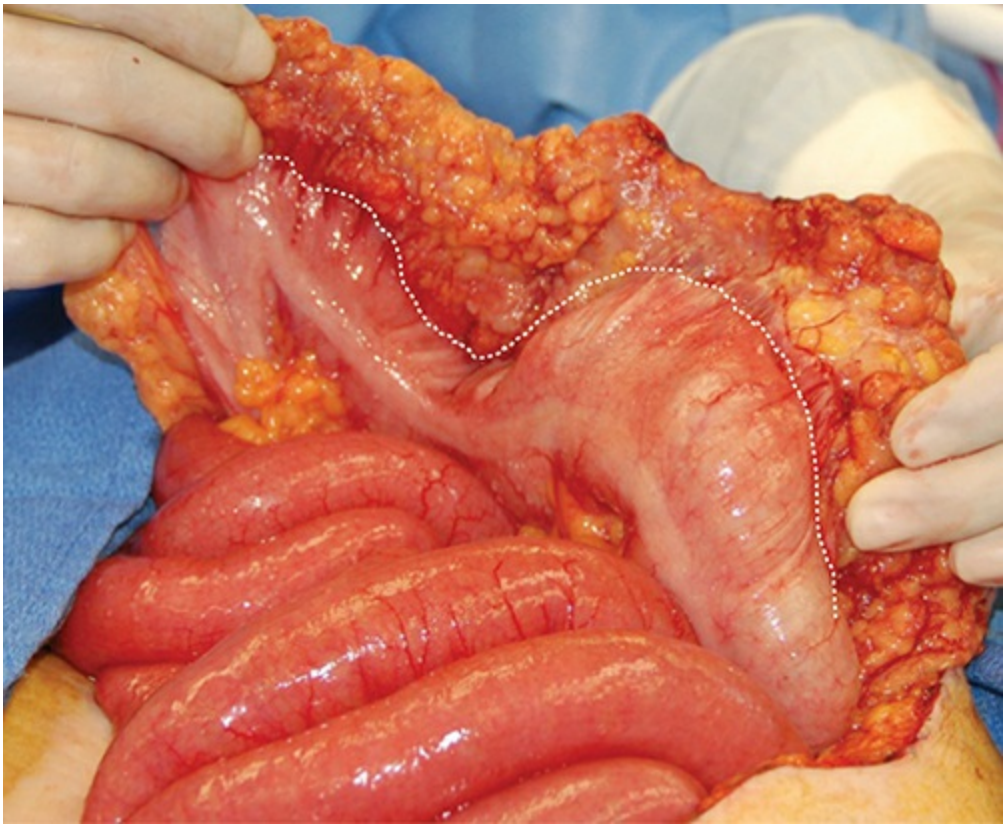

Figure 23.11 Patient with FIGO stage IIIC ovarian cancer with an omental cake. The omentum is completely transformed by tumor nodules. The omentum is lifted superiorly, toward the patient's head. The omental tumor can almost always be dissected off the transverse colon along an avascular plane (white dotted line), allowing entry into the lesser sac.

Women with advanced serous ovarian cancer, who have disseminated miliary disease covering the entire peritoneal surface, including the diaphragms, often have large-volume ascites (102). The ascitic fluid generally contains mesothelial, inflammatory, and tumor cells (13). Rarely, serous tumors will metastasize to the mesothelial cell-covered pericardium, causing a pericardial effusion.

Because FIGO stage IV serous ovarian cancer is defined by several anatomic locations in the upper abdomen and/or a malignant pleural effusion, patients with stage IV disease are a very heterogeneous group. Peritoneal–pleural lymphatic communication through the diaphragm allows trans-diaphragmatic spread of tumor into the mesothelium-covered pleural space, causing a malignant pleural effusion. Because serous cancers have a preference for implantation on the right diaphragm, most patients with FIGO 2013 stage IV disease have a right-sided malignant pleural effusion (37% to 48%) (103,104). Other metastasis patterns that define FIGO stage IVB disease include parenchymal liver metastases, supraclavicular/axillary lymphadenopathy, parenchymal lung metastases, mediastinal adenopathy, and distal vaginal or perineal metastases (103,104). Although serous ovarian cancer disseminates extensively within the abdominal cavity, intra-pulmonary metastasis, or other intra-parenchymal involvement, for example, intrahepatic, spleen, or kidney tumors, are rare. If these are found, the differential diagnosis should be expanded to include a different ovarian cancer histotype (clear cell, mucinous, or carcinosarcoma) or a different tumor origin (gastrointestinal, breast cancer).

Advanced invasive low-grade serous cancers, which represent about 9% of all epithelial ovarian cancers (105,106), have a tumor distribution pattern that is very similar to that of high-grade serous cancers, with metastasis to the omentum (83%), fallopian tube (63%), pelvic peritoneum (49%), and uterine serosa (46%) (107).

Lymph Node Metastasis

Exfoliation followed by implantation is one of two primary modes of ovarian cancer dissemination. The other is via the retroperitoneal lymphatics draining the ovary. This path follows the superior ovarian blood supply in the infundibulopelvic ligament, which contains the ovarian artery and vein as well as extensive lymphatics which terminate in lymph nodes lining the aorta and vena cava up to the level of the renal vessels. The next lymph node stations are at the celiac trunk, from which tumor cells may continue up to the mediastinal and supraclavicular lymph nodes. Lymph channels also pass laterally through the broad ligament and parametrial channels to terminate in the pelvic sidewall lymphatics, including the external iliac, obturator, and hypogastric chains (108). Spread may also occur along the course of the round ligament, resulting in involvement of the inguinal lymphatics (the disease of these patients is now categorized as FIGO IVB). The principal lymphatic drainage of the ovary and fallopian tube appears to be via the para-aortic lymph nodes. Lymph node metastases are correlated with the extent of intra-abdominal disease involvement. Retroperitoneal node involvement has been found in the majority of advanced ovarian cancer cases (109-111).

The initial spread of ovarian cancer, by both the intraperitoneal and lymphatic routes, is clinically occult. As many as 20% of women with the appearance of FIGO stage I/II ovarian cancer have widespread disease (112). Histologic type (serous), grade (III), and CA-125 (high) at diagnosis are risk factors for lymph node metastasis. The true extent of disease can be detected only by histologic examination of visually normal tissues sampled during careful surgical staging (113). Approximately 10% of patients with cancer that appears to be confined to the ovaries will have metastases to the para-aortic nodes. Many patients with apparently localized disease will also have occult disease found in peritoneal washings or in biopsies of the diaphragm and omentum (Table 23.3). However, it should be noted that the data in Table 23.3 predate advanced imaging modalities (e.g., high-resolution computed tomography (CT) scans).

TABLE 23.3 Subclinical Metastases in Apparent EarlyOvarian Cancer

Site	No. of Patients with Involvement	Total Patients	% Involved
Diaphragm	17	223	7.6
Omentum	21	294	7.1
Cytology	13	69	18.8
Peritoneal	6	61	9.8
Pelvic modes	18	202	8.9
Para-aortic modes	35	285	12.3

Recurrent Ovarian Cancer

The majority (80%) of patients with advanced ovarian cancer who undergo a combination of platinum- and taxane-based chemotherapy will have a recurrence, although many will have initial complete response to primary treatment (103,114). Of all patients with ovarian cancer, 75% have an intra-abdominal recurrence; the remainder have extra-peritoneal/intrahepatic or distant metastasis with or without intra-abdominal recurrence (115). Twenty-two percent of recurrences occur outside the peritoneal cavity. The locations of intra-abdominal recurrences include the remnants of the omentum, especially at the splenic flexures, the small and large bowel mesentery, and the epiploic appendices, which are peritoneal pouches filled with fat and located along the colon and intraperitoneal rectum. The majority of deaths occur in the first 2 years (53%) and only 46.2% of all patients survive 5 years (SEER data, accessed April 2016).

Following the increased use of intraperitoneal chemotherapy with the publication of GOG#172 (116), several retrospective studies reported a change in the pattern of recurrence. Women treated with intraperitoneal, rather than

intravenous, chemotherapy were found to have a higher rate of extra-abdominal recurrences, including brain metastasis, pleural effusions, and mediastinal disease. Robinson et al. found that women with recurrent ovarian cancer treated with intraperitoneal chemotherapy had a 26% risk of extra-abdominal metastasis, whereas women treated with only intravenous chemotherapy had a 7% risk (117). Two other retrospective studies reported even higher extra-peritoneal recurrence rates of 41% to 45% after intraperitoneal chemotherapy (118). It has also been reported that when intraperitoneal chemotherapy is combined with bevacizumab, more patients present with recurrent disease in the central nervous system or the skin (117). Regardless of its combination with intraperitoneal therapy, more pleural and parenchymal metastases are observed after bevacizumab treatment (119).

CLINICAL PRESENTATION AND DIAGNOSTIC WORK-UP

The diagnosis and treatment of patients with ovarian masses is difficult because of the diversity of clinical presentation, the plethora of differential diagnoses, and the wide range of therapeutic options (Table 23.4).

TABLE 23.4 Differential Diagnosis of an Adnexal Mass

Definition	Description	Mean Age	Clinical Presentation	Imaging	T
Ectopic pregnancy	Tubal pregnancy, most common in the fimbriated end	Reproductive age women	Positive pregnancy test. History of PID, tubal surgery, fertility treatment, or previous ectopic pregnancies. Pelvic pain, anemia	Pelvic ultrasound	M l s s l h u
Physiologic, functional cysts	Follicular cyst—preovulatory cystCorpus luteum cyst—postovulatory cyst caused by hemorrhage or cyst formation. Theca lutein cysts are caused by hCG stimulation of the ovary. “Other”: paratubal cysts, hydrosalpinx	Reproductive age women	Depending on size, lower abdominal pain, dyspareunia, signs of latent torsion. On exam freely mobile and unilateral. May present as an acute abdomen when ruptured, torsed, or infarcted: unilateral intermittent, acutely worsening pelvic pain	Pelvic ultrasound. Often > 7cm	F C m i a c c w l c
Polycystic ovaries	Endocrine disorder. Multiple follicle cysts enlarging the ovaries to 2–5 times their normal size	Reproductive age women	Irregular menstrual cycles, anovulation, amenorrhea, acne, hirsutism, subfertility,	Pelvic ultrasound, hormonal tests (DHEAS, androstenedione, testosterone, FSH). Glucose tolerance test	C m g l s

			metabolic syndrome		
Serous and mucinous cystadenomas	Serous—cystic: thin walled, unilocular. Mucinous—cystic thin walled but may be multicystic		Serous 5–20 cm, mucinous up to 40 cm	Pelvic/abdominal ultrasound	I a l c
Germ cell tumors	Benign: teratomas/dermoids. Malignant: immature teratoma/dysgerminoma	Young reproductive age patients	Bilateral in 20%. Elevated β-hCG, AFP, LDH, (CA-125)	Ultrasound. Might show calcifications on X-ray or CT. Solid, partially cystic	I c t l s c
Sex cord stromal cell tumors	Benign: fibromas, thecomas, Brenner cell tumorsMalignant: granulosa cell tumor, Sertoli–Leydig cell tumor	30-menopause, but also postmenopausal patients	Solid, firm tumors resembling fibroids. May produce hormones: estradiol, inhibin. May cause irregular bleeding, uterine hyperplasia	Ultrasound/CT. Solid homogeneous tumors. Granulosa cell tumors are heterogeneous and often rupture	I l c c c
Peritoneal inclusion cysts	Cystic	Any age	History of multiple pelvic/abdominal surgeries or recurrent pelvic infections or peritoneal dialysis	Ultrasound: multiple thin walled cysts, CT, MRI can often help to establish a diagnosis	C a f p
Fibroids	Benign. Broad ligament or pedunculated fibroids misdiagnosed	30–55 yr	Often asymptomatic. Degeneration or infarction can occur and cause acute pain	Ultrasound, rarely CT or MRI	C s w h
Endometriosis	1–10 cm endometriotic cysts filled with blood, adherent to surrounding organs. Often bilateral. Endometriotic implants occur in the pelvic peritoneum including the cul-de-sac and bladder peritoneum. Nodularity of the uterosacral ligaments	30–45 yr	Pelvic pain. Dyspareunia. May have cyclical pain with menses, infertility, and dyspareunia. May present with acute pain from rupture, rarely torsion. CA-125 100–300 U/mL	Pelvic/abdominal ultrasound. Diagnostic laparoscopy	C t i C I r e c e r s s f
PID/salpingitis	Tubo-ovarian abscess complicates PID in 15% of all women	Young sexually active patients	History of PID, pelvic pain, malaise, vaginal discharge (GO,	Ultrasound showing one or more masses that are homogenous, cystic, possibly with air fluid	C a C c

			chlamydia), cervical motion tenderness. Fever, chills, leukocytosis, CRP ↑, Platelets ↑. CA-125: 100 – 500 U/mL. Coagulopathy if septic	levels and septations	c a c p s
Appendicitis and appendiceal abscess	Appendicitis, right-sided tenderness, rebound	Younger patients	Fever, guarding, rebound tenderness. Malaise, RLQ pain, nausea, vomiting, absence of vaginal discharge. Pain migration, leukocytosis, CRP ↑, Platelets ↑, CA-125～100-200 U/mL	Ultrasound and CT imaging with contrast. No distinct mass. Features consistent with abscess: enhancement, irregular borders	I
Diverticulitis and diverticular abscess	Diverticulitis mostly in the sigmoid colon causing left-sided pain	Elderly patients	Fever, guarding, rebound tenderness. Malaise, LLQ pain, nausea, vomiting. Pain, leukocytosis, CRP ↑, Platelets ↑, CA-125～100 – 200 U/mL	Ultrasound and CT imaging with contrast. No distinct mass. Features consistent with abscess: enhancement, irregular borders	C a C c p s a t
Colon cancer			Anemia, irregular stools. Induration and irregularity. Family history	Sigmoidoscopy/colonoscopy	
Early invasive epithelial ovarian cancer	Early serous ovarian cancer, endometrioid or clear cell ovarian cancer		CA-125 ↑ only in 50%	Papillary surface excrescences, areas of necrosis, internal solid elements	S i C w e c t c s
Advanced invasive epithelial ovarian cancer	Serous carcinoma with ascites and metastasis to upper abdomen	Postmenopausal women	Persistent bloating, general abdominal pain, early satiety. Vaginal bleeding. CA-125 ↑ in 80%. Platelets ↑	Suspicious adnexal mass and ascites, upper abdominal disease	E l t F g c
Metastasis	Gastric, colon,		CA-125 can be	Bilateral solid complex	E

	breast, and uterine cancer	elevated. Other tumor markers might be helpful (CEA, CA19-9, CA15-3)	masses in patients with prior cancer history	c s i s c
Rare differential diagnoses	- Pelvic kidney - Disseminated abdominal tuberculosis: Young women unlikely to hav at risk, ascites, CA-125 ↑, absence of a dominant adnexal mass			

AFP, alpha-fetoprotein; CA-125, cancer antigen 125; CRP, C-reactive protein; DHEAS, dehydroepiandrosterone sulfate; FSH, follicle-stimulating hormone; GnRH, gonadotropin-releasing hormone; GO, gonorrhea; hCG, human chorionic gonadotropin; LDH, lactic dehydrogenase; LLQ, left lower quadrant; OCP, oral contraceptive pill; PID, pelvic inflammatory disease; RLQ, right lower quadrant.

Clinical Presentation of Patients with a Benign Adnexal Mass or Early-Stage Ovarian Cancer

Almost all patients with small adnexal tumors are asymptomatic; the mass is usually discovered incidentally during a work-up for other conditions (Fig. 23.12). With increasing size, adnexal masses cause pelvic pressure and pain by compressing surrounding structures. A larger pelvic tumor can cause genitourinary symptoms, including urinary urgency, urinary frequency, and dyspareunia. Posteriorly, a fixed pelvic tumor can compress the sigmoid colon, causing severe constipation and pain. These symptoms can occur in both benign disease and early ovarian cancer. It is impossible to differentiate a benign from a malignant ovarian mass by clinical examination alone. Borderline ovarian tumors, nonserous malignant epithelial ovarian cancer (endometrioid, clear cell, mucinous), and non-epithelial (germ cell, stromal cell) malignant tumors frequently present as large adnexal masses at an early stage without any further abdominal dissemination.

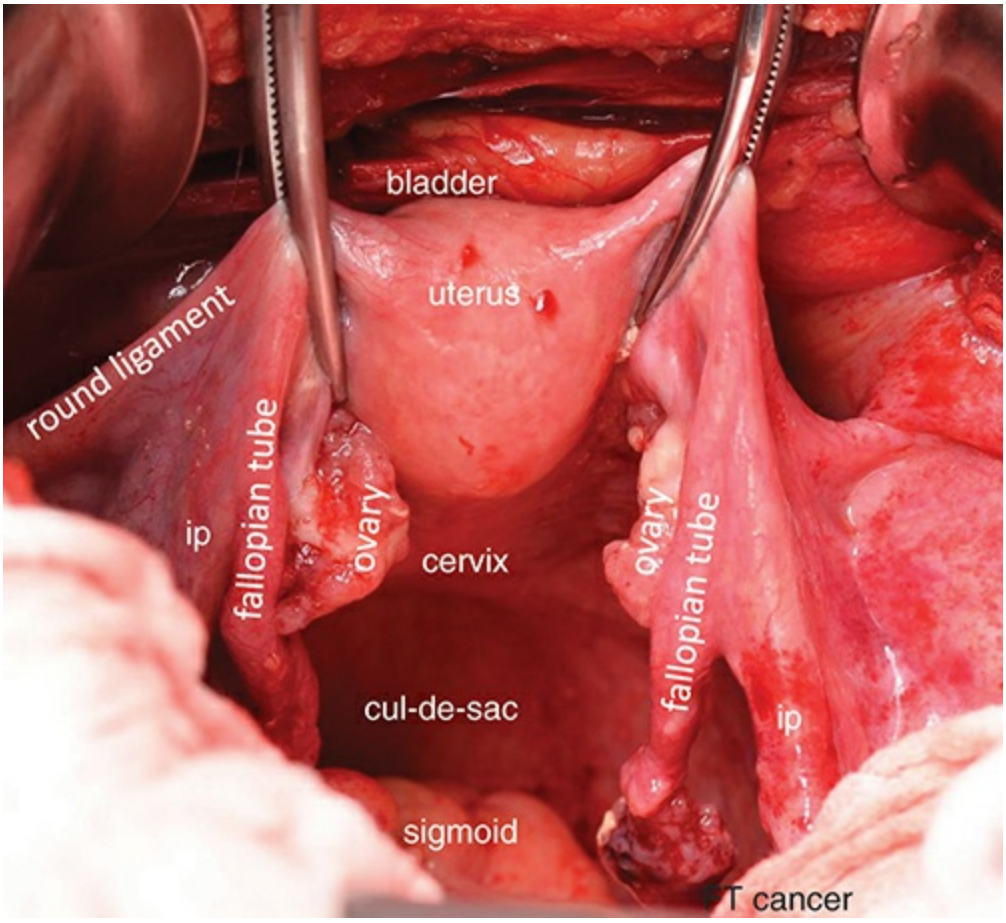

Figure 23.12 Patient with left fallopian tube cancer hanging off the left tubal fimbriae. Fallopian tube (FT), infundibulopelvic (ip) artery and vein.

An ovarian mass becomes a surgical emergency if a patient has a sudden onset of abdominal pain. The differential diagnosis in this situation includes rupture, torsion, and possible infarction of the ovarian mass. In addition, severe abdominal pain can also be caused by a hemorrhage inside a cyst, which distends it, or by the rupture of a blood-filled cyst, causing hemoperitoneum. Sudden abdominal pain associated with an adnexal mass is often accompanied by malaise, nausea and vomiting, low-grade fever, an elevated white blood cell count, and elevated C-reactive protein levels, which are all caused by peritoneal irritation. In the presence of acute pain, peritoneal signs, rigidity, and rebound tenderness, urgent expert surgical evaluation should be considered. Evaluation is most often performed laparoscopically. Delaying surgery can result in infarction, hemorrhage, peritonitis, and sepsis. Vaginal bleeding in a patient with an adnexal mass could be an indication of synchronous endometrial and ovarian cancers (92) or a granulosa cell tumor that produces estrogen, causing abnormal bleeding. Sertoli–Leydig cell tumors, which can cause bleeding, can also lead to virilization.

Clinical Presentation of Patients with Advanced Ovarian Cancer

The clinical presentation of advanced ovarian cancer is varied. Treating physicians are often surprised by how few symptoms women with advanced ovarian cancer may experience. Nonspecific symptoms associated with advanced ovarian cancer include anorexia, fatigue, early satiety, and loss of appetite. Although weight loss is unusual in ovarian cancer because of diffuse ascites production, tumor cachexia can be a presenting sign in patients with high-volume disease and long-standing partial bowel obstruction.

Often patients have nonspecific pelvic and abdominal symptoms, including bloating and diffuse, dull, constant abdominal pain caused by the infiltration of the peritoneum and the bowel mesentery or by extensive ascites. Involvement of the small bowel can cause changes in the frequency of bowel movements, with alternating constipation and diarrhea. If the tumor has metastasized to the omentum, there may be upper abdominal discomfort with nausea, belching, early satiety, and fullness. The abdominal cavity may also be distended by several liters of ascites, which can cause a significant increase in abdominal circumference leading to marked discomfort. Extensive ascites can cause significant fatigue, anorexia, pain, nausea/vomiting, and incontinence. In addition, ascites can cause dyspnea, because the lower lung lobes are compressed by the abdominal distension (102). Signs of bowel obstruction, severe urinary symptoms, intense pelvic pain, and ascites are likely to indicate miliary dissemination on the peritoneal surfaces and large-volume advanced disease. Moreover, patients with advanced ovarian cancer sometimes present with deep venous thrombosis (DVT) from large tumors pressing on pelvic veins or as part of the hypercoagulopathy associated with advanced-stage cancer (120).

Because symptoms often develop late, when the cancer is already advanced, ovarian cancer has been called the “silent killer” or “the cancer that whispers.” There are no specific symptoms that assist in diagnosing ovarian cancer early. However, a careful review of symptoms in women with ovarian cancer has shown that many have abdominal symptoms, urinary frequency, and pain for 3 months or longer before diagnosis (121). One study suggested that ovarian cancer patients tend to have a combination of symptoms (e.g., increased abdominal size/bloating, early satiety, pelvic/abdominal pain, urinary urge, incontinence), which are more severe, more frequent, and of more recent onset than those symptoms reported by patients without cancer who present to a primary care clinic (121). These symptoms are nonspecific and overlap with several common disorders like irritable bowel syndrome, dyspepsia, and menopause. There is no evidence that screening for any of these symptom clusters can aid in recognizing ovarian cancer earlier or improve on the use of CA-125 and ultrasound (122). Several studies have concluded that the appraisal of symptoms alone is not likely to lead to an earlier diagnosis (123,124).

American College of Obstetrics and Gynecology (ACOG) and SGO (125) consensus guidelines recommend referral to a gynecologic oncologist for postmenopausal women with elevated CA-125, ascites, a nodular/fixed pelvic mass, or

evidence of abdominal/distant metastasis. In premenopausal women, a very elevated CA-125, ascites, or evidence of abdominal or distant metastasis should also trigger a referral. These guidelines have a positive predictive value of 39.6% for premenopausal women and 64.6% for postmenopausal women. A benign condition that can closely mimic the constellation of symptoms described in the consensus guidelines is Meigs syndrome (126). This syndrome is characterized by a cytologically benign pleural effusion and ascites, which resolve upon removal of a concomitant ovarian tumor, usually an ovarian fibroma or thecoma.

Diagnosis of Ovarian Cancer

The correct clinical diagnosis of an ovarian mass is difficult and requires considerable experience and clinical judgment (Table 23.4). Age is a very important factor in assessing an adnexal mass, as many ovarian tumors have a predilection for a particular age group. In premenarchal girls, an adnexal mass is often germ cell in origin, whereas young women in their reproductive years are most likely to have benign disease. In postmenopausal patients, a complex adnexal mass is particularly concerning for an epithelial cancer, as a normal postmenopausal ovary is atrophic and small (1.5 × 1 × 0.5 cm) (Table 23.5). On average, the volume of a normal ovary is 10 cm^3 in postmenopausal and 20 cm^3 in premenopausal women (127).

TABLE 23.5 Differential Diagnosis of an Adnexal Mass by Age

History	Age	Differential Diagnosis
Age Pregnancy Menopausal status Family history	Premenarchal	Germ cell tumors, mature teratomas, rhabdomyosarcomas
	Young reproductive age (15–25 years)	Functional cysts, ectopic pregnancy, pelvic inflammatory disease (PID)/salpingitis/tuboovarian abscess (TOA), mature teratomas (dermoid), appendicitis/appendiceal abscess, polycystic ovaries, juvenile granulosa cell tumor, dysgerminoma, endodermal sinus tumor, tuberculosis
	Middle reproductive age (25–35 years)	Endometriosis, functional cysts, polycystic ovaries, serous/mucinous cystadenomas, PID/salpingitis/TOA, mature teratomas (dermoid), Sertoli–Leydig cell tumor
	Advanced reproductive age (35–45 years)	Stromal cell tumors (fibroma/fibrothecoma/cystadenofibroma), pedunculated fibroids, peritoneal cysts, adult granulosa cell tumor
	Perimenopausal (46–52 years)	Functional cysts, fibroids, ovarian cancer, endometrial cancer
	Postmenopausal (<52 years)	Serous/mucinous cystadenomas, ovarian cancer, colon cancer, benign stromal cell tumors, diverticulitis/diverticular abscess, fibroids

An adnexal mass in a woman of reproductive age is a significant diagnostic challenge, because most of these tumors in premenopausal women are benign. However, it is critical that no malignant tumors are missed. The differential diagnosis of an adnexal mass/cyst is described in Table 23.4. There are several categories of benign masses, including functional cysts, adenomas, nonmalignant germ cell tumors (mature teratomas/dermoids), nonmalignant sex cord stromal tumors (fibromas), and endometriosis. The most common benign solid ovarian tumors are ovarian fibromas (fibroma/fibrothecoma/cystadenofibroma). Another common solid tumor is a pedunculated fibroid, which may be

interpreted on imaging as an adnexal mass. Infectious conditions that may present with similar signs and symptoms include PID, appendicitis, and diverticulitis. For women in their reproductive years, the decision to pursue surgery will depend on the degree of clinical suspicion based on the factors detailed above and their desire for future fertility.

In some patients there is no distinct adnexal mass but a conglomerate tumor in the lower abdomen. The differential diagnosis for this includes an advanced ovarian cancer, an advanced endometrial cancer/sarcoma, colon or appendiceal cancer, and retroperitoneal tumors. A metastatic breast, colon, or lung cancer tumor should be considered in the presence of an atypical pattern of metastasis or abnormal mammogram or chest X-ray (Table 23.4) (128,129). It should be remembered, however, that although ovarian cancer is much more prevalent in postmenopausal women than premenopausal women, the most common cause of an adnexal mass in a postmenopausal patient is still a benign cyst. Either this is caused by hormonal imbalances that can exist during perimenopause or this develops postmenopausally, driven by hormones secreted by the postmenopausal ovary. In postmenopausal women, simple unilocular cysts can be monitored, but women with solid or complex masses should be offered surgery. Depending on the level of suspicion for cancer, surgery may begin with a minimally invasive approach that can be converted to an open procedure if the frozen section suggests a borderline tumor or malignancy.

When formulating a diagnosis, the most important factors to consider are the patient's age, menopausal status, family history, clinical exam, and the results of serum (CA-125, HE-4), and imaging studies (ultrasound/CT/MRI) (Tables 23.4 and 23.5). Because of the lethality of ovarian cancer, it is considered advisable to "err on the side of caution." The fear of not detecting a malignancy, which could delay diagnosis or lead to inadequate surgery, has shaped the clinical response to adnexal masses for decades. The current treatment paradigm is that every postmenopausal woman with a solid adnexal mass should have a surgical exploration to determine histology. Given that early-stage ovarian cancer has a much better prognosis than advanced-stage disease, many operations are performed with the goal of "catching" a cancer early. Because only histology can exclude the presence of an ovarian cancer, about 5% to 10% of all women will, at some point, undergo surgery to rule out an ovarian cancer, despite the fact that most adnexal masses are benign (130).

Clinical Exam

A focused clinical exam should begin with an assessment of supraclavicular lymph nodes, a breast exam, and percussion of the lungs to detect a pleural effusion. The abdomen should also be evaluated for the presence of an umbilical hernia. The involvement of the umbilicus by an ovarian cancer is colloquially called "*Sister Mary Joseph nodule*," named after an assistant to Dr. William Mayo, who identified the lesion as a sign of advanced malignancy. The abdomen should also be inspected for surgical scars and visible veins ("*caput medusae*") caused by impaired central venous return from extensive intra-abdominal disease. The size and mobility of the adnexal mass should be assessed and the abdomen examined for the presence of ascites, costovertebral angle tenderness from hydronephrosis, and enlarged inguinal lymph nodes. In a patient with extensive ascites, the bowel floats on top of the ascites leading to central tympany on exam, whereas in patients with a large tumor, the tympany is lateral.

On gynecologic exam, a prominent cystocele can be indicative of ascites. The bimanual and rectovaginal exam should attempt to evaluate and characterize the adnexal mass in respect to size, borders (smooth/irregular), mobility (fixed/mobile), and location. Invasive ovarian cancers often have irregular borders and are often fixed to the pelvic sidewall and fill the cul-de-sac. Pelvic examination findings may also include involvement of the parametrium by tumor, or nodularity of the rectovaginal septum. It may not be possible to differentiate the uterus from the tumor and the cervix is sometimes dislocated anteriorly behind the pubic symphysis. Some ovarian tumors are behind the uterus and can be best palpated with a rectovaginal exam after the bladder is emptied. Still, despite best efforts and experience, the pelvic examination is less accurate than ultrasound and CT in detecting and characterizing an adnexal mass, especially if the patient is obese or if the uterus is significantly enlarged.

Laboratory Tests

The laboratory work-up for patients with suspected ovarian cancer generally includes a complete blood count. Patients with ovarian cancer are often hemoconcentrated, whereas patients with gastrointestinal malignancies are frequently anemic. Patients with ovarian cancer often have thrombocytosis (a poor prognostic marker) (120) and may have a low albumin level, which is indicative of tumor cachexia and malnutrition and is associated with higher peri- and postoperative morbidity. A pregnancy test should be part of the work-up for all premenopausal women, as uterine/adnexal enlargement can be because of pregnancy. The current biomarkers used clinically to asses if an adnexal mass is malignant are CA-125, HE-4, and OVA1.

The CA-125 tumor marker (normal <35 U/mL), initially described by Dr. Robert Bast (131), is the most thoroughly investigated serum marker. It is expressed both on Müllerian (tubal, endometrial, endocervical) and coelemic (pericardium, pleura, peritoneum, ovarian surface) epithelium. Only 50% of stage I disease is associated with an elevated serum CA-125, which is one reason that CA-125 is not a good screening method for early-stage ovarian cancer (132) and even in advanced-stage cancers the marker has a 20% to 25% false-negative rate (133). However, 80% of patients with ovarian cancer of any stage who are over 50 years have an elevated CA-125 (133). A meta-analysis by Myers et al. studied the performance of CA-125 as a serum marker to distinguish between benign and malignant adnexal masses (134). In premenopausal women with an adnexal mass, an increased CA-125 predicts a malignancy with the following statistical performance: sensitivity, 50% to 74%; specificity, 26% to 92%; and positive predictive value, 5% to 67%. For postmenopausal women the performance is much better: sensitivity, 69% to 87%; specificity, 81% to 100%; and positive predictive value, 73% to 100%. The CA-125 is highest in serous and lowest in mucinous ovarian cancers. Clear cell and endometrioid ovarian cancer often have lower CA-125 values, around 200 U/mL or normal values (127,133).

A number of gynecologic conditions can falsely elevate CA-125 levels: In premenopausal women, the differential of an elevated CA-125 includes many diseases associated with acute or chronic inflammation, to the extent that CA-125 can be regarded as an acute phase reactant. CA-125 can be elevated in patients with PID, peritoneal tuberculosis, endometriosis, fibroids, pregnancy, cirrhosis of the liver, systemic lupus erythematosus, and inflammatory bowel disease. Moreover, CA-125 is not specific to ovarian cancer, as it is increased, albeit modestly, in most metastatic solid tumors, including gastrointestinal, breast, and endometrial cancer. Patients with mucinous ovarian cancer often have elevated CEA values, but this tumor marker is also nonspecific and is increased in patients with gastrointestinal malignancies, especially colon and gastric cancer. A ratio of CA-125/CEA > 25 is used clinically to exclude a gastrointestinal malignancy (135).

In summary, CA-125 is most useful in distinguishing between a benign and malignant mass when used in conjunction with clinical history (age, menopausal status, imaging). Accompanied by other factors, it may help triage women with an adnexal mass for surgery or observation. Moreover, although a single-threshold CA-125 should not be used for screening an asymptomatic woman, serial measurements can have utility (see below). CA-125 is also helpful in the evaluation of response to therapy in patients with an established diagnosis of ovarian cancer and can assist in the diagnosis of recurrence. However, the early treatment of relapse based on an increase in serum CA-125 levels has not been found to influence patient survival when compared with treatment based on clinical evidence or the appearance of symptoms (136).

Human epididymis (HE) 4 is a secreted glycoprotein expressed on human ovarian cancer cells (137). A meta-analysis by Lin showed that HE4 assays had a pooled sensitivity of 74% (CI, 0.72–0.76) and specificity of 87% (0.85–0.89) in the differentiation of benign and malignant adnexal masses. When the authors compared HE4 with CA-125, the HE4 serum levels demonstrated higher specificity, probably because CA-125 is overexpressed in many common nonmalignant disorders (see above). A combination of HE4 and CA-125 enhances both sensitivity (90% CI, 0.87–0.92) and specificity (85% CI, 0.82–0.87) compared with either test used alone (138).

OVA1 is a test combining five different serum proteins, including CA-125, pre-albumin, apolipoprotein A1, β2-microglobulin, and transferrin. This test was approved by the FDA to aid in the triage of patients with an adnexal mass. It uses an algorithm to generate a score between 0 and 10; patients stratified as high risk have OVA1 scores ≥ 4.4 (postmenopausal) or ≥ 5 (premenopausal). In a summary analysis of two studies with 1,016 patients, OVA1 had a sensitivity of 92.2% (CI, 88.2–94.9) and a specificity of 49.4% (CI, 45.9–53). In contrast, CA-125 had a sensitivity of 70.6% (CI, 64.7–75.8) and a specificity of 89.6% (CI, 87.2–91.6). OVA1 had a negative predictive value of 94.9% (CI,

92.3–96.7) and a positive predictive value of 37.9% (CI34.2–41.8), whereas CA-125 had a negative predictive value of 90.1% (CI, 87.8–92) and a positive predictive value of 69.5% (CI, 63.6–74.8) (139). The study was criticized because of the high prevalence of cancer (9.1%) in the study population, making it difficult to generalize the findings to practices where ovarian cancer is less prevalent. Use in a different clinical setting reduces the test's positive predictive value and increases its negative predictive value. Until the OVA1 test is studied in nonacademic clinical environments, it is difficult to assess its future use in the evaluation of ovarian masses.

Imaging of Adnexal Masses and Early Ovarian Cancer: Ultrasound and MRI

In patients with adnexal masses, a pelvic ultrasound, as well as a complete history, physical examination, and a CA-125, is generally needed to provide the information necessary to determine if surgery is required. Because the patient history and the clinical exam alone cannot reliably differentiate between benign and malignant masses, imaging is commonly performed to help establish a diagnosis and treatment plan.

Ultrasound can detect and characterize ovarian size and morphology. Although vaginal ultrasound provides high-resolution imaging of the ovary, for large ovarian masses, an abdominal ultrasound will complement the vaginal scan. Defined ultrasound criteria help diagnose functional cysts, dermoids, and endometriomas with a high degree of certainty, allowing the choice of conservative, nonoperative treatment. Benign tumors often appear on ultrasound as unilateral with smooth walls, a few smooth cysts, no solid elements or papillary projections, and an absence of ascites. Functional cysts have thin walls and are fluid filled. In general, most benign tumors are cystic and mobile. The risk of malignancy in unilocular cystic tumors (even if they are >10 cm) and septated cystic ovarian tumors is extremely low. In the absence of solid areas or papillary projections, these cysts are never malignant and 38% to 80% resolve within 1 year (130). Dermoids are often cystic with hyper-echoic areas (teeth, hair). Endometriomas have low-level, layered echos (blood) and thick walls. In contrast, malignant tumors are partially solid and cystic, often bilateral, irregular, fixed, and often accompanied by ascites. Patients with tumors that display these features require surgical exploration. Homogenous solid tumors also require surgical exploration, but the most common finding is an ovarian fibroma or a pedunculated fibroid (Table 23.4). In summary, ultrasound is excellent for predicting a benign ovarian mass, but is less accurate in the prediction of malignancy or the detection of early-stage ovarian cancer (140).

Several sonography-based predictive models have been developed to differentiate between benign and malignant tumors. Sassone developed a model that integrates inner wall structure, wall thickness, septa, and echogenicity as sonographic markers of malignancy and determined that, in premenopausal women, cysts greater than 6 cm should be further investigated for malignancy (141). Indeed, malignant tumors often present as complex masses with partially solid and partially cystic components. In a pooled estimate of 18 cohort studies of the Sassone model, it was calculated that its sensitivity and specificity in differentiating between a benign and malignant ovarian mass are 84% and 80%, respectively (142). Ueland published the most accurate morphology index based on ovarian volume and morphologic complexity (Fig. 23.13) (133,143). The risk of malignancy was related to structural complexity, tumor volume, and a total morphology index score. There was only one malignancy found in 315 tumors with a morphology index <5, indicating that the score is very useful in identifying low-risk tumors. Among 127 patients with a morphology index >5 there were 52 invasive or borderline tumors. A group of investigators from Kentucky expanded this finding by adding serial exams to determine if a change in the morphology index over time could aid in deciding if a patient with an adnexal mass needed surgery (144). Adnexal masses that were found to be malignant showed an increase of 1.6 points per month in the morphology index, whereas the scores of benign ovarian tumors only increased 0.3 per month.

Size	>4–6 cm
Ovarian volume	Length x width x height x 0.523. Premenopausal > 20 cm^3. Postmenopausal > 10 cm^3.
Morphology	Thick septations > 3 mm (differentiate from a papillary projection) Complex solid and cystic (multi–locular) Solid enhancing nodules Papillary projections
Vascularization	Pulsatility index (PI) > 1. Resistive Index (RI) >0.4. Central intramural blood flow
Other findings	Ascites (60 mL or greater) Uterine invasion Peritoneal thickening, carcinomatosis

Risk of malignancy in sonographically confirmed ovarian tumors. Clin Obstet Gynecol. 2012;55:52–64. (B) From Elder JW, Pavlik EJ, Long A, et al. Serial ultrasonographic evaluation of ovarian abnormalities with a morphology index. Gynecol Oncol. 2014;135:8–12.

The studies described above considered ultrasound in a binary model to differentiate benign from malignant adnexal masses. The International Ovarian Tumour Analysis (IOTA) group expanded this approach using the Assessment of Different Neoplasias in the adneXa (ADNEX) model to differentiate between benign, borderline, primary ovarian cancer, and metastatic cancer (145). This large prospective study of 5,909 patients evaluated in 24 primarily European centers used four clinical variables (age, CA-125, family history, referral center) and six ultrasound variables (lesion diameter, proportion of solid tissue, <10 cysts, number of papillary projections, acoustic shadow, ascites). The area under the receiver operating curve (AUC), differentiating between benign and malignant masses, was 0.94, indicating that the model discriminated very well between the two. The model also differentiated well between benign, borderline, primary ovarian cancer, and metastatic cancer with an AUC of 0.85 to 0.99 (145).

Sometimes color flow Doppler is used to aid in distinguishing benign from malignant tumors. The neovascularization of malignant tumors is characterized by an absence of tunica media in tumor blood vessels, leading to reduced flow resistance which can be detected by Doppler. Resistance to blood flow is measured by calculating the pulsatility index (PI) and resistive index (RI). However, these indices, as independent variables, are unreliable for predicting ovarian cancer because the location of tumor vessels is variable (130).

Often ovarian masses are indeterminate on gray-scale ultrasound and, although they provide an insufficient rationale to proceed to surgery, are sufficiently concerning that a second imaging test is ordered for further characterization. Contrast-enhanced MRI is the preferred advanced modality for an ultrasound-indeterminate adnexal lesion because of its high specificity. MRI can differentiate between simple fluid, atypical fluid (mucinous), fresh blood, old hematoma, solid tissue, stromal tissue, and fat (146,147). As with ultrasound, several criteria have been established to differentiate a benign from a malignant mass, including the presence of septations, solid elements, and papillary projections, and solid tissue intensity on T2-weighted MRI. Injection of gadolinium contrast agents adds further information, because solid malignant components within a mass take up the contrast. This also allows a better differentiation of cystic from solid lesions, especially endometriomas, stromal cell tumors, and teratomas. The pretest probability of detecting a borderline or malignant tumor increased from 32% to 77% (95% CI, 69%–85%), with a positive result for malignancy with MRI, and decreased to 4.8% (95% CI, 3%–6%), with a negative result (148). Given this sensitivity and specificity, MRI is a very good (if expensive) test for predicting whether a mass is benign or malignant. However, it is not able to differentiate between borderline and invasive tumors. A meta-analysis found that the average sensitivity and specificity of MRI in distinguishing a borderline or

malignant tumor from a benign tumor were 92% (95% CI, 89%–94%) and 85% (95% CI, 82%–87%), respectively. Although this sensitivity is similar to that reported by ultrasound, the specificity of MRI is superior. A comparison of color Doppler, CT scans, and MRI showed that of all three modalities, contrast-enhanced MRI is most helpful in further characterizing an adnexal mass that is indeterminate on ultrasound (146). In a premenopausal woman with an indeterminate ultrasound and a negative contrast-enhanced MRI, the risk of malignancy is 2%, whereas a positive MRI increases the risk of malignancy in the same patient to 80%. Given the high *a priori* probability that a mass in a premenopausal patient is benign, a reasonable approach is to further characterize an ultrasound-indeterminate adnexal lesion by MRI (146-148). If the MRI is reassuring, the patient can be followed with a combination of clinical exam, serial ultrasounds, and CA-125 every 3 to 6 months to capture a malignant adnexal tumor not detected during the initial work-up (140,147). If the mass is stable, the follow-up interval can be extended.

Computed tomography allows the detection and characterization of an adnexal mass, but performs less well than MRI as a secondary imaging modality following gray-scale ultrasound. Even when intravenous contrast is given, CT offers lower soft tissue contrast than MRI (146). CT has a sensitivity of 87% but a low specificity of 16% in differentiating a benign from a malignant ovarian mass (149).

Although the approaches described above are extremely useful in the evaluation of an adnexal mass, other factors will affect the final decision to perform surgery, including the patient's age, clinical symptoms, fertility preferences, medical comorbidities, and the number and extent of previous surgeries. It is important to stress to the patient that although imaging and clinical judgment can be used to characterize many ovarian masses, only histologic examination can confirm the diagnosis. If a patient has a strong family history of cancer, an elevated CA-125, free fluid/ascites, as well as a large mass (>10 cm), there is sufficient reason to perform surgery.

Imaging of Advanced Ovarian Cancer: Computed Tomography, Positron Emission Tomography Scan, and MRI

Because of its reasonable cost and wide availability, CT scanning is currently the preoperative imaging modality most often used in patients with a high clinical suspicion for ovarian cancer. Frequently, patients are found to have an adnexal mass or advanced disease after a CT scan of the abdomen and pelvis ordered for nonspecific clinical symptoms. A CT scan of the pelvis is able to characterize the adnexal mass and discern any involvement of the surrounding organs (bladder, sigmoid, ureter, and pelvic sidewall). In the upper abdomen, retroperitoneal adenopathy, omental and mesenteric involvement, and intrahepatic liver involvement can be detected reliably by CT scans with intravenous contrast (150). Often the CT scan of the abdomen and pelvis is extended to the chest, which allows detection of intra-pulmonary metastasis, pleural effusion, and pleural disease. These findings predict a lower chance of optimal cytoreduction (151).

Preoperative CT scans can identify the presence of disease in anatomic regions that are difficult or technically impossible to resect (e.g., stomach, lesser sac, liver, small bowel mesentery, and adenopathy above the renal vessels). Bristow and colleagues identified 13 diagnostic features and devised a score to predict the chances of optimal cytoreduction in patients with advanced ovarian cancer (152). The 13 factors included in the score were peritoneal thickening; peritoneal implants greater than 2 cm; small and large bowel mesenteric disease greater than 2 cm; omental extension to stomach, spleen, or lesser sac; extension of the tumor to the pelvic sidewall/parametria/hydroureter; large-volume ascites; supra- and infrarenal lymphadenopathy; diaphragm involvement; inguinal canal disease; liver lesions greater than 2 cm; and porta hepatis/gall bladder disease. Using this model, the authors were able to predict surgical outcomes at their own institution with 93% accuracy (152). However, a multi-institutional validation study showed an accuracy of only 34% to 46% (153). This validation study identified disease on the diaphragm and large bowel mesentery implants as the only statistically significant predictors of suboptimal cytoreduction, and even when the score was limited to these two factors there was a 33% false-positive rate (153).

In a joint prospective study at Memorial Sloan-Kettering and MD Anderson Cancer Center involving 350 patients, Suidan and colleagues sought to determine if a CT of the abdomen and pelvis could predict the likelihood of suboptimal debulking. Three clinical (age≥60 years, CA-125≥500 U/mL, ASA 3/4) and six radiologic criteria were significantly associated with suboptimal debulking to more than 1 cm residual tumor size (154). The radiologic criteria included supra-renal retroperitoneal lymph nodes>1cm, diffuse small bowel adhesions/thickening, tumors>1cm in the small bowel mesentery, root of the SMA, perisplenic area, and lesser sac. Forty-eight patients receiving neo-adjuvant chemotherapy (NACT) during the study period were excluded. This prognostic model was found to have a predictive accuracy of 0.758 (154).

Because surgical outcome depends on so many factors other than anatomical disease distribution (comorbidities, surgeon philosophy, advanced surgical techniques), preoperative CT scanning poorly predicts surgical resectability. Therefore, for most patients surgical evaluation of the peritoneal cavity, which often includes a diagnostic laparoscopy, is required to evaluate the resectability of disease (155-157). Still, a patient whose CT scan clearly indicates high-volume ovarian disease should be evaluated carefully before a decision is made to proceed with primary debulking and serious consideration should be given to NACT (135,158).

Positron emission tomography (PET) has been integrated with CT scan for the diagnosis of ovarian cancer and the evaluation of disease recurrence (150,159). CT/PET combines the high anatomic resolution afforded by CT scan with a functional study of tumor fluoro-deoxy glucose (FDG) uptake. Although PET scans have very high sensitivity, they have low specificity because of increased FDG uptake in benign metabolically active tissues and inflammatory changes. In a single-institution prospective study of 101 patients, the combined CT/PET scan had a sensitivity of 100% and specificity of 92% in the correct diagnosis of tumors that were suspicious on ultrasound (160). CT/PET scans seem to be especially useful in further characterizing a suspected recurrence. In a retrospective study, PET/CT showed a sensitivity of 82% and a specificity of 87% in correctly identifying recurrent disease, which was superior to CA-125 or CT/MRI scans used alone (159). CT/PET scans were also found to be particularly effective in the diagnosis of retroperitoneal lymph nodes (161).

Although CT provides good spatial resolution, MRI is a nonradioactive imaging modality that provides excellent soft tissue contrast resolution. In addition to its utility in the diagnosis of an indeterminate ovarian mass (140,146,147) as described above, MRI is also an excellent modality for the characterization of nonadnexal pelvic pathology (e.g., diverticulitis) and for the further characterization of the extent of ovarian cancer in the upper abdomen. The T1-weighted MRI images, after administration of contrast (gadolinium), allow the detection of peritoneal metastases and bowel implants. They also can determine whether the bowel mesentery or diaphragm is involved by cancer and whether a liver tumor is benign or malignant, or is on the surface of the liver or intrahepatic. MRI is better than CT or ultrasound in the diagnosis of small peritoneal metastases, but CT imaging is superior in identifying the involvement of the omentum by ovarian cancer (149).

In recurrent cancer, MRI is especially useful for differentiating postsurgical changes from a recurrence on the vaginal dome, small bowel mesentery, splenic hilum, liver surface, or diaphragm. The reported sensitivity of MRI for recurrent ovarian cancer ranges from 62% to 91% and the specificity from 40% to 100%, depending primarily on tumor size (150).

Screening

No current screening modalities (CA-125, pelvic ultrasound, pelvic examinations), either individually or in combination, have been shown to decrease the risk of death from ovarian cancer. Because ovarian cancer has such a low prevalence (1 case/2,500 women per year), screening low-risk asymptomatic women requires a test or combination of tests with very high sensitivity and specificity, and high positive and negative predictive values. Several studies have shown that, if asymptomatic women were screened for ovarian cancer, between 5 and 33 operations would be required to find one invasive ovarian cancer (65,122,162). This situation is primarily caused by the high false-positive rates of ultrasound and CA-125 in benign disease.

Three large prospective randomized studies from Japan (162), the United States (65), and the United Kingdom (66)

have compared women screened for ovarian cancer with CA-125 and/or ultrasound with women who were not screened.

The Shizuoka Cohort Study of Ovarian Cancer Screening ran between 1985 and 1999 and screened 82,487 postmenopausal women using fixed cutoff CA-125 values (<35 U/mL) and pelvic ultrasound (162). Ovarian cancer was detected in 32 patients in the control group and 27 patients in the screening group, suggesting that screening does not detect more ovarian cancers. Among these women, the proportion of stage I cancers was 63% in the screened group and 38% in the observation group ($p = 0.22$) indicating that screening did not lead to a significant stage-shift, which signifies earlier detection. However, the group only reported on ovarian cancer detection and no survival data have been published.

The Prostate, Lung, Colorectal, and Ovarian (PLCO) Cancer Screening Trial (1993-2001) randomized 78,216 postmenopausal women to either annual screening with a fixed cutoff value for CA-125 (<35 U/mL) and ultrasound or to usual medical care (65). Ultrasounds were done yearly for three consecutive years and CA-125 yearly for 5 years. Borderline tumors were considered false positive and were not considered malignant neoplasms. The results showed that screening does not improve mortality from ovarian cancer. False-positive screening results were returned in 3,285 patients, 1,080 (32.9%) underwent surgery and of these 15% (163 women) experienced 222 major complications (20.6 complication rate/100 surgeries). The number of patients diagnosed in late stage ovarian cancer was similar in the screening and observation groups, suggesting that screening does not detect ovarian cancer at an earlier stage.

The UK Collaborative Trial of Ovarian Cancer Screening (UKCTOCS), which ran between 2001 and 2005, assessed the effect of screening on disease mortality in more than 200,000 postmenopausal women (66). Two screening strategies were tested: primary ultrasound screening versus multimodality screening (CA-125 followed by ultrasound). They then annually measured CA-125 and used the ROCA for an interpretation of rises in CA-125 over time (163). ROCA is a computer-based algorithm devised to increase the sensitivity and specificity of CA-125 by looking at the changes in levels of CA-125 over time for an individual, instead of using a single cutoff value as the basis for deciding whether additional tests are needed. Using ROCA, the investigators triaged women to annual screening versus repeat CA-125 versus repeat CA-125 and transvaginal ultrasound. The primary outcome was ovarian cancer death; however, the group did not find a significant reduction in mortality. The mortality reduction with multimodality screening, CA-125, and ultrasound was 15% (CI: 3–30%, $p = 0.21$), and the reduction with ultrasound alone was 11% (CI –7–27, $p = 0.21$). The results suggest that most of the disease detected with multimodality screening was low volume (FIGO I, II, IIIA made up 39% of cancers vs. 26% in patients who did not undergo screening). In a *post hoc* analysis there was evidence of a significant mortality reduction (28%) in the patients who had multimodality screening after 7 years, but given the primary analysis did not identify a significant reduction in mortality, this finding is essentially hypothesis-generating. No stage-shift was observed in patients screened with ultrasound alone; 641 patients needed to be screened to prevent one cancer death. Criticisms of the study included the exclusion of primary peritoneal cancers from the main analysis, the exclusion of prevalent cancers, the persistence of high mortality from ovarian cancer despite screening (53% of patients died within 2.3 years of diagnosis), and the potential of lead-time bias associated with early detection. The study results will be reanalyzed in 3 years, which should give us data that could help us assess the value of the screening approaches.

Even women who are at high risk of developing ovarian cancer because of a *BRCA1* or *BRCA2* mutation have not been shown to significantly benefit from annual pelvic exams, CA-125, and ultrasound (73) because of low sensitivities and very low positive predictive values of the three different screening modalities (164). The inability to detect early ovarian cancer using a yearly screening approach is probably because of the very fast growth rate of high-grade serous carcinoma (HGSC) once it is fully transformed, which reduces the time during which screening can detect preinvasive or early invasive ovarian cancer (96). Another reason that screening tends to be ineffective may be the extent of ovarian cancer disease heterogeneity. In summary, pelvic exams, CA-125, and ultrasound have not been conclusively shown to significantly decrease mortality from ovarian cancer in either low- or high-risk populations. If a woman wants to reduce her risk, tubal ligation/removal, OCP, or a prophylactic salpingo-oophorectomy may currently be the best strategy for primary prevention.

Differential Diagnosis of Ovarian Cancer

The most common cause of malignant ascites in women is ovarian cancer, but patients with metastatic breast, pancreatic, and gastric cancer, which usually has concomitant intrahepatic metastasis, can also present with ascites. Therefore, other cancers should be considered in patients with extensive ascites and CA-125 values around 200 U/mL. Reviewing patients with ascites who presented to an oncology clinic, Ayantunde (102) found diagnoses to be ovarian cancer (37%), pancreaticobiliary cancer (21%), gastric cancer (18%), colon cancer (4%), and breast cancer (3%). Nonmalignant causes of ascites include pancreatitis, tuberculosis, hepatitis, systemic lupus erythematosus, cirrhosis, ovarian torsion, and Meigs syndrome. Tuberculotic granulomas on the peritoneum combined with ascites are clinically indistinguishable from serous ovarian cancer. A paracentesis will both establish a diagnosis of malignancy and improve the dyspnea, pain, nausea, and vomiting that the patient may be experiencing as a result of large-volume ascites.

Although serous ovarian cancer disseminates extensively within the abdominal cavity or to retroperitoneal lymph nodes, it will only rarely have metastasized elsewhere at the time of initial presentation. Imaging studies that suggest intra-pulmonary metastasis or intra-parenchymal metastases in the liver, spleen, or kidney, especially in the absence of significant intraperitoneal disease or the absence of a significant ovarian tumor, should broaden the differential diagnosis to include a less common ovarian cancer histotype (clear cell, mucinous, or carcinosarcoma) or a different tumor origin (gastrointestinal: colon/gastric/appendiceal or breast cancer). Younger age and bilateral ovarian tumors may also be a sign that the ovarian tumors are of metastatic origin.

Gastric cancers tend to cause drop metastases to the ovary, referred to as Krukenberg tumors, after Friedrich Krukenberg, a German gynecologist and pathologist. Because gastrointestinal malignancies are apt to metastasize to the ovary because of its extensive blood supply, these cancers are important differential diagnoses for women presenting with disseminated intra-abdominal disease on imaging. Indeed, 9% of all patients with colon cancers have metastases to the ovary, and the ovarian tumor is often bigger than the primary colonic tumor; 1% to 3% of all patients operated on for a presumed ovarian cancer are found to have an extragenital cancer (128). Patients who present with predominantly gastrointestinal symptoms, anemia, a high CEA, low CA-125, and a positive hemoccult test should undergo an esophagogastroduodenoscopy (EGD) and a colonoscopy with biopsies. A CA-125/CEA serum ratio greater than 25 has high discriminative power to differentiate between ovarian and colon cancer, but might not be able to exclude a mucinous tumor (135). The median survival for patients who present with peritoneal and ovarian metastasis from colon cancer is only 10 months.

Breast cancer can also metastasize to the ovary and is the most frequent (84%) primary cause of ovarian metastasis of non-GI origin. Metastasis of breast cancer to the ovary was found at autopsy in 23% to 39% patients who died of breast cancer. The median survival after diagnosis of breast cancer metastasized to the ovary is 26 to 54 months (128,129,165). To determine if an ovarian mass is a breast cancer metastasis or a new ovarian cancer in patient with a history of breast cancer, the stage and histology and other prognostic factors (ER/PR, HER2/neu, proliferation) of the previous breast disease should be considered. Patients with stage IV breast disease are much more likely to have distant metastasis than patients with early-stage tumors, and lobular breast cancer metastasizes more often to the ovary than invasive ductal cancer. Most patients with ovarian metastasis from breast cancer are premenopausal (77%) and present with abdominal distension in the absence of ascites. Often these patients have bilateral ovarian involvement (64%), a high CA15-3, and a low CA-125. However, patients with breast cancer and abdominal carcinomatosis can have a high CA-125, which makes the differentiation from ovarian cancer challenging. On pelvic ultrasound, breast cancer metastases to the ovary tend to be more solid appearing than a primary ovarian cancer, which is often multicystic. The benefit of surgery in the treatment of breast cancer metastatic to the ovaries has not been proven and may be limited to the palliation of symptoms by removing a single mass. Retrospective studies have suggested a possible survival benefit for surgery in patients with no residual disease after the operation, but found no benefit in the setting of widely metastatic disease (129). The 5-year survival for women with ovarian metastasis from breast cancer is 26%, which is much higher than that for those with ovarian metastasis from colorectal and gastric cancer (8% and 1%, respectively), but lower than the median survival for primary ovarian cancer (128). Ovarian cancer is the most common non-breast secondary malignancy after treatment for breast cancer. Indeed, a history of breast cancer is associated with a two- to fourfold increase in the risk of developing ovarian

cancer and this rate is higher in patients with hereditary breast and ovarian cancer syndrome.

SURGERY

Introduction and Definitions

Surgery plays an important role at every phase of ovarian cancer treatment. Patients newly diagnosed with ovarian cancer usually undergo surgery for the purpose of pathologic diagnosis, cytoreduction, symptom relief, and staging. Indeed, both the old and new FIGO staging systems (Table 23.6) require that surgery be performed to confirm the histologic diagnosis and to determine the true extent of the disease. In the recurrent disease setting, surgical biopsy can confirm a diagnosis and also provide therapeutic benefit, as the removal of an isolated mass may render a patient macroscopically tumor-free. In patients with recurrent disease involving extensive tumor dissemination, removal of tumor masses ("debulking" or "cytoreduction") accomplishes significant symptom relief and, in select patients, limited surgery may result in the palliation of bowel obstruction. Clinically there is a distinction between "low-volume advanced-stage disease" and "high-volume advanced disease" because the lower the volume at presentation, the greater the possibility that surgery will result in an absence of residual disease.

TABLE 23.6 FIGO Ovarian Cancer Staging

Surgical FIGO - Ovarian Cancer Staging1988		Surgical FIGO - Ovarian Cancer Staging 2014	
I	Tumors limited to one or both ovaries	I	Tumor confined to ovaries or fallopian tubes
IA	Tumor limited to one ovary; capsule intact; no tumor on ovarian surface; no malignant cells in ascites/peritoneal washings	IA	Tumor limited to one ovary, capsule intact or fallopian tube, no tumor on ovarian or fallopian tube surface, no malignant cells in ascites or peritoneal washings
IB	Tumor limited to both ovaries; capsule intact; no tumor on ovarian surface; no malignant cells in ascites/ peritoneal washings	IB	Tumor involves both ovaries; capsule intact or fallopian tubes, no malignant cells in ascites or peritoneal washings
IC	Tumor limited to ovaries with any of the following: capsule ruptured, tumor on ovarian surface, positive washings/ascites	IC1-3	Tumor limited to one or both ovaries/fallopian tubes IC1: Surgical spill intraoperatively IC2: Capsule rupture before surgery or tumor on ovarian or fallopian tube surface IC3: Malignant cells in the ascites or peritoneal washings
II	Tumor involves one or both ovaries with pelvic extension or implants	II	Tumor involves one or both ovaries or fallopian tube with pelvic extension (below the pelvic brim) or primary peritoneal cancer
IIA	Extension and/or implants on uterus or fallopian tube; negative washings/ascites	IIA	Extension and/or implants on uterus and/or fallopian tubes
IIB	Extension or implants onto other pelvic structures; negative washings/ascites	IIB	Extension to other pelvic intraperitoneal tissues

IIC	Pelvic extension (IIA or IIB) or implants with positive peritoneal washings/ascites		
III	Microscopic peritoneal implants outside of the pelvis; or limited to the pelvis with extension to the small bowel or omentum	III	Tumor involves one or both ovaries or fallopian tubes, or primary peritoneal cancer, with cytologically or histologically confirmed spread to the peritoneum outside the pelvis and/or metastasis to the retroperitoneal lymph nodes
IIIA	Microscopic peritoneal metastases beyond pelvis	IIIA	IIIA1: Positive retroperitoneal lymph nodes only IIIA1(i): Metastasis ⩽ 10 mm IIIA1(ii): Metastasis > 10 mm IIIA2: Microscopic, extrapelvic (above the pelvic brim) peritoneal involvement ± positive retroperitoneal lymph nodes
IIIB	Macroscopic peritoneal metastases beyond pelvis < 2 cm in size	IIIB	Macroscopic, extrapelvic, peritoneal metastasis ⩽ 2 cm ± positive retroperitoneal lymph nodes. Includes extension to capsule of liver/spleen.
IIIC	Macroscopic peritoneal metastases beyond pelvis > 2 cm and/or positive retroperitoneal or inguinal lymph nodes (pT3B N1 or pT3C)	IIIC	Macroscopic, extrapelvic, peritoneal metastasis > 2 cm ± positive retroperitoneal lymph nodes. Includes extension to capsule of liver/spleen (no parenchymal involvement).
IV	Distant metastasis including pleural effusion with positive cytology. Distant metastases outside the peritoneal cavity. Parenchymal liver/splenic metastasis.	IV	Distant metastasis excluding peritoneal metastasis
		IVA	Pleural effusion with positive cytology/biopsy
		IVB	Hepatic and/or splenic parenchymal metastasis, metastasis to extra-abdominal organs (including inguinal lymph nodes and lymph nodes outside of the abdominal cavity)Bowel infiltration - transmural with mucosal involvement and umbilical deposit

Comments on FIGO 2014 (166): There is no stage I primary peritoneal cancer. Dense adhesions containing tumor cells justify upgrading apparent stage I tumors to stage II. Rectum invasion is stage IIB. Positive para-aortic lymph node metastases are considered regional lymph nodes (FIGO 2014 IIIA1(ii)). Involvement of retroperitoneal lymph nodes must be proven cytologically or histologically. Examples of metastatic sites which upstage tumors to FIGO 2014 IVB: Transmural bowel infiltration, subcutaneous/umbilicus/abdominal wall, extra-abdominal lymph nodes (inguinal, axillary), and umbilical metastasis.

The most important prognostic factors predicting long-term survival from ovarian cancer are the FIGO stage and the amount of disease remaining after debulking surgery. Patients with ovarian cancer will benefit from treatment by a gynecologic oncologist or physicians familiar with the disease and skilled in its surgical management.

The widely used 1988 FIGO staging system for ovarian cancer was replaced in 2014 by a new staging system approved by FIGO and published in 2014 which is (166) presented in Table 23.6.

The terms for common surgical procedures, as they are used in this chapter, are defined in Table 23.7.

TABLE 23.7 Terms for Common Surgical Procedures as Used in This Chapter

Procedure	Definition
Paracentesis	Drainage of presumed malignant fluid/ascites in a patient with intra-abdominal tumor masses to establish a diagnosis before initiation of chemotherapy with cytology or to provide symptomatic relief
Biopsy	Biopsy of disseminated disease or an adnexal mass to establish a pathologic diagnosis before initiation of chemotherapy

Primary cytoreductive surgery	Initial laparotomy to establish a diagnosis, stage, and attempt maximal tumor debulking to microscopic disease before the initiation of first-line chemotherapy. Also called by some physicians as “primary debulking”
Interval cytoreduction or interval debulking	Cytoreductive surgery after a biopsy only or a primary suboptimal debulking or a limited surgery (e.g., hysterectomy/BSO) followed by induction chemotherapy
Second look surgery	Surgery performed at the completion of primary chemotherapy in patients who do not have evidence of disease by CT scan or CA-125 to determine if there is residual disease in order to plan for additional chemotherapy. Currently rarely performed
Secondary cytoreductive surgery	Surgery in a patient with recurrent disease who has completed primary treatment, including primary debulking and/or chemotherapy and had been without evidence of disease for 6 months. The procedure is most commonly performed for platinum-sensitive patients with oligometastatic disease. Also called “secondary debulking” by some physicians
Palliative surgery	Surgery performed to relieve symptoms, most commonly performed for a malignant bowel obstruction with the goal to remove the obstruction or perform a diversion. Not primarily intended to remove tumors
Staging surgery	Surgery to evaluate extent of disease guiding treatment decisions (chemotherapy: yes/no) for early stage disease
Posterior pelvic exenteration	En bloc resection of bladder serosa, uterus, sigmoid colon, and proximal rectum, as well as ovarian/fallopian tube masses, cul-de-sac tumors with complete parietal pelvic peritonectomy to encompass all pan-pelvic disease (98)
Surgery: complete debulking	
Result: no macroscopic disease	Complete resection (541): cytoreduction of all tumors independent of preoperative tumor load to microscopic residual disease at the completion of surgery—no gross residual tumors left. R0 resection
Surgery: optimal debulking	
Result: macroscopic disease up to 1 cm	Minimal residual (541): macroscopic disease up to 1 cm in diameter after primary surgery. Also called by some physicians as “optimal cytoreduction.” R1 resection
Surgery: suboptimal debulking.	
Result: macroscopic disease > 1 cm	Gross residual (541): primary cytoreduction resulting in macroscopic disease larger than 1 cm in size at the end of surgery. R2 resection

Early-Stage Ovarian Cancer

Optimal staging in early ovarian cancer includes careful inspection, palpation, and biopsies of peritoneal surfaces (diaphragm, paracolic gutters, bladder, and cul-de-sac peritoneum), pelvic and diaphragmatic washings, removal of the affected ovary, an infracolic or infragastric omentectomy, and a systematic pelvic and para-aortic lymph node dissection

(167). An appendectomy can, though rarely, change the final staging. Preserving the contralateral ovary and the uterus in young patients desiring fertility is considered acceptable in appropriately selected cases of early-stage epithelial invasive and borderline ovarian cancer. Every effort should be made to remove an ovarian mass intact, although it is not clear whether intraoperative rupture affects prognosis. Rupture of an ovarian mass is associated with thick/dense adhesions. If these adhesions contain tumor cells, tumors which otherwise appear to be FIGO stage I should be upstaged to stage II (Table 23.6).

Thorough surgical staging of early ovarian cancer is important for establishing the correct FIGO stage in order to determine prognosis and choice of therapy (chemotherapy vs. observation). In a study of 86 patients with ovarian cancer grossly confined to the ovary, approximately 30% of the patients who underwent completion surgery were upstaged. Sixty percent of these patients were upstaged because of microscopic disease in biopsy specimens from adhesions or omentum, whereas the others had either uterine or fallopian tube metastases or positive lymph nodes. Occult metastases were associated with increasing tumor grade and the presence of ascites (168). Other predictors of unappreciated residual disease after primary surgery include a high preoperative CA-125 level and positive cytology from pelvic or diaphragmatic washings (165).

Complete staging in early disease may obviate the need for cytotoxic chemotherapy. A retrospective subset analysis of patients with FIGO stage I–IIA disease enrolled in the ACTION trial (112,169) found that complete surgical staging was statistically significantly associated with better outcomes, presumably because the unstaged group included patients with occult stage III disease. In this trial, patients were randomly assigned to adjuvant chemotherapy or observation after they had undergone either complete or incomplete staging surgery. Although the trial was not designed to compare different surgical staging procedures (and extent of surgical staging was not randomized), a subgroup analysis of patients with a poorly differentiated tumor found that the optimally surgically staged group ($n = 78$) had a significantly longer ($p < 0.009$) 10-year cancer-specific survival of 85% compared with 56% in patients who were not completely staged ($n = 78$). This improved outcome was independent of age, presumed stage, histology, and whether or not chemotherapy was given (169,170). Moreover, the benefit of adjuvant chemotherapy was seen only in patients with incomplete surgical staging. Incompletely staged patients with a poorly differentiated grade III tumor were found to derive the greatest benefit from adjuvant chemotherapy. However, the role of chemotherapy in relation to staging remains uncertain. The ICON1 trial suggested that both incompletely and completely staged patients with early-stage disease may benefit from adjuvant chemotherapy (171,172).

The surgical approach to the staging of presumed early-stage ovarian cancer will depend on patient comorbidities and number of previous abdominal operations, as well as on how skilled the surgeon is at minimally invasive surgery. Retrospective studies suggest that both a minimally invasive approach and an open laparotomy allow for comprehensive surgical staging. Concerns regarding the minimally invasive approaches include limited visibility of both diaphragms, the inability to palpate tissue, and the longer operating time. Lymph node counts and the size of the omental specimen obtained are similar for both procedures. Given that bulky disease is only rarely detected in early-stage ovarian cancer patients, a minimally invasive surgical approach may be preferable, as it involves less blood loss, a shorter hospital stay, and faster recovery with less pain and allows patients to start chemotherapy earlier. However, specialized surgical training is necessary (173). Another concern with the laparoscopic approach is the possibility of port site metastasis, although this risk seems to be small (1.18%) and such metastases are often a sign of disseminated intra-abdominal disease (174). In early ovarian cancer, restaging involves multiple biopsies of the diaphragmatic, abdominal, gutter, and pelvic/bladder peritoneum, as well as, at the least, a unilateral salpingo-oophorectomy, omentectomy, pelvic and para-aortic lymph node dissection, and pelvic and diaphragmatic washings for cytology. Patients who do not want to preserve fertility will also have a hysterectomy and removal of the contralateral ovary and tubes.

In most cases, unstaged patients with presumed early-stage invasive ovarian cancer should be staged or given adjuvant chemotherapy if staging is not feasible.

Role of Lymph Node Dissection in Early Ovarian Cancer

When treating both early and advanced ovarian cancer, a surgeon should make two decisions: (a) whether to perform a lymph node sampling, and (b) whether to remove only enlarged or palpably suspicious lymph nodes or to perform a systematic lymph node dissection, removing all visible pelvic and para-aortic lymph nodes within defined anatomic borders. Dye studies have shown that the lymphatic drainage of the ovaries originates under the ovarian surface. Lymph fluid predominantly drains superiorly, along both ovarian vascular pedicles (175). On the left side, the lymphatics follow the infundibulopelvic vein until it drains into the left renal vein. The high left infrarenal, para-aortic lymph nodes often harbor lymph node metastasis and are a known site of (isolated) recurrence. The right infundibulopelvic vein and its accompanying lymphatics reach the inferior vena cava about 1 cm below the right renal vein. Cancer cells are then able to continue traveling along a net of lymphatic vessels covering the inferior vena cava and the interaortocaval space to lymph nodes at the base of the celiac axis, and then through the caval opening in the diaphragm into the chest, reaching thoracic, mediastinal, or prescalene lymph nodes. Secondary lymph drainage routes are along lymphatics draining inferiorly through the utero-ovarian ligament to lymph nodes in the broad ligament and along the external iliac artery to the round ligament and then to inguinal lymph nodes. This spread pattern explains why inguinal lymph node metastasis is sometimes detected in patients with ovarian cancer. There is also minor lymph drainage to lymphatics along the internal iliac artery or lymph nodes in the obturator fossa (176). Ovarian lymph drainage does not reach the uterus, explaining why intrauterine or cervical metastases are rare in serous ovarian cancer.

It is recommended that both the pelvic and high, infrarenal para-aortic lymph nodes should be removed when a systematic lymph node dissection is performed in patients with early ovarian cancer (171,172) (Fig. 23.14). However, given the lymphatic drainage of the ovaries, the removal of high para-aortic lymph nodes is the most important (110). The anatomic borders of a pelvic lymph node dissection are laterally, the external iliac artery and the genitofemoral nerve that travels on the psoas muscle; superiorly, the bifurcation of the external and internal iliac artery to the inguinal ligament; and medially, the anterior division of the hypogastric artery and the ureter (Fig. 23.15). By slightly elevating and lateralizing the external iliac vein, the surgeon exposes the obturator fossa and the obturator nerve and then clears the lymph nodes superior to the nerve. To enable right para-aortic lymph node dissection, the descending colon and terminal ileum are mobilized by incising the peritoneum around the cecum to expose the inferior vena cava and interaortocaval space. The cecum is reflected medially and the dissection is begun on the right common iliac artery. The precaval fatty tissue containing lymph nodes is removed from the common iliac artery up to the right renal vein, with care taken not to injure the ureter, renal vessels, or the third/horizontal part of the duodenum. Of note, the superior mesenteric artery/vein is anterior to the third part of the duodenum. To remove the left para-aortic lymph nodes, the fat/lymph node containing tissue lateral to the aorta between the bifurcation of the left common iliac artery and the left renal vein is removed. Although it is rarely necessary, the inferior mesenteric artery can be ligated to accomplish a high para-aortic dissection. Because the lymph nodes rest on top of the lumbar vertebral bodies, great care must be taken not to injure the lumbar veins. A systematic lymph node dissection is associated with increased operating time, blood loss, and blood transfusions. Acute complications of the surgery include, rarely, bowel injury (duodenum), venous vascular injuries (IVC, external iliac, hypogastric vein), and ureteral injuries. Long-term complications include lower extremity lymphedema, adhesive disease, and formation of lymphoceles which can become chronic and sometimes infected, requiring drainage, obliteration, or surgery. The rate of positive lymph nodes is very low in mucinous ovarian cancer, and lymph node dissection probably can be omitted in this histologic subtype (109,177).

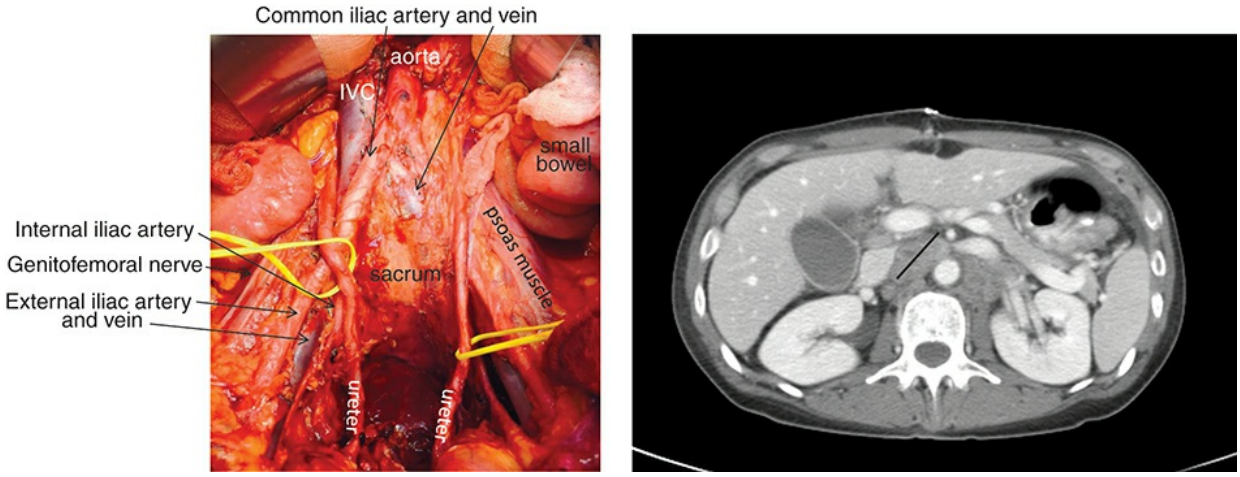

Figure 23.14 Pelvic and high para-aortic lymph node dissection in a patient with FIGO IIIC serous ovarian cancer and bulky para-aortic (see CT scan) and pelvic lymph node metastasis which were surgically removed. Before the lymph node dissection, a posterior exenteration was performed—the next step was to perform an end-to-end anastomosis of the descending colon with the rectum (not shown). The patient was optimally debulked (microscopic disease).

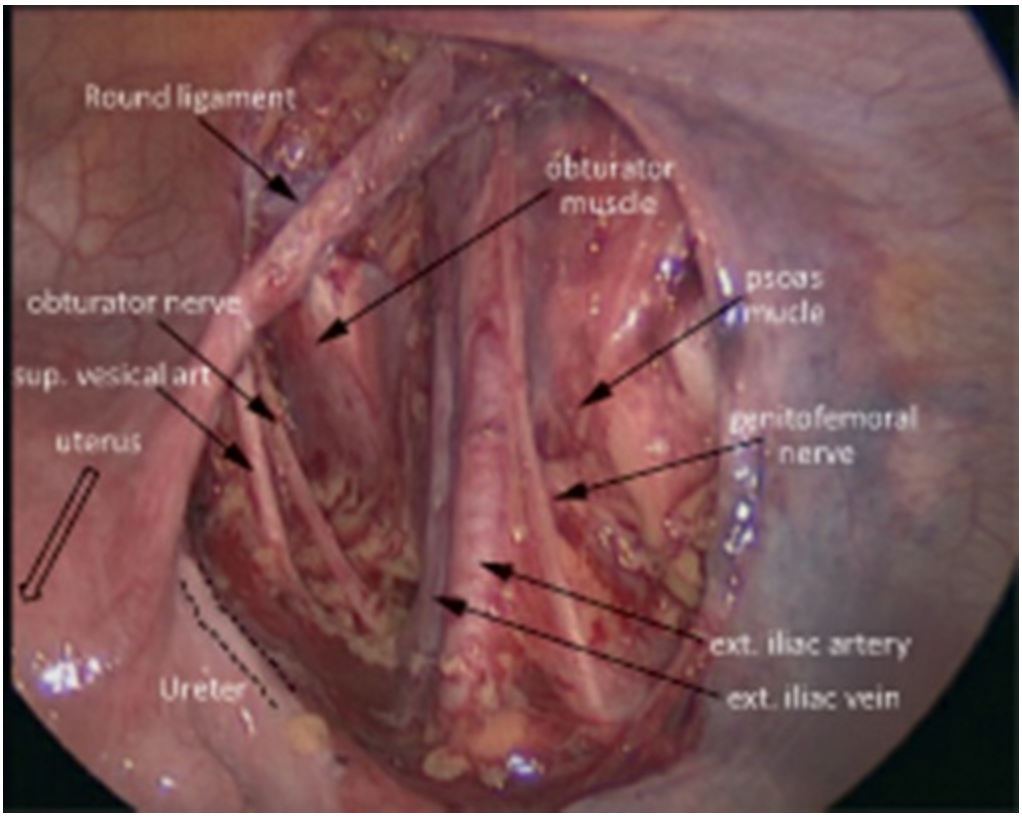

Figure 23.15 Right laparoscopic lymph node dissection in a patient with early ovarian cancer.

Several retrospective studies have indicated that the rate of positive lymph nodes in patients of all FIGO stages who undergo a systematic pelvic and para-aortic lymph node dissection is 25% to 53%, with most of the positive lymph nodes found in the high para-aortic and interaortocaval regions (109-111). Because imaging and intraoperative palpation of lymph node beds have a low sensitivity and specificity for the detection of lymph node metastasis, several studies have investigated the role of a systematic pelvic and para-aortic lymph node dissection. In a prospective trial, Maggioni and colleagues randomized 310 patients diagnosed with early FIGO stage I and II ovarian cancer, who had undergone optimal

surgical debulking, to receive either a systematic lymph node dissection or lymph node sampling (113). Patients with all major histologic subtypes were represented in the study: serous (39%), endometrioid (21%), mucinous (13%), and clear cell tumors (13%). Positive lymph nodes (which upstage a patient to FIGO 1988 stage IIIC or FIGO 2013 stage IIIA1) were found in 9% of patients in the sampling group and in 22% of the systematic lymph node dissection group ($p < 0.05$), suggesting that 13% were upstaged because of the lymph node dissection. Of those with negative lymph nodes, 66% of the patients in the control arm and 51% in the systematic lymphadenectomy arm received chemotherapy ($p < 0.03$), suggesting that, in an unstaged patient, physicians tend to err on the side of overtreatment. The patients in the systematic lymph node dissection arm spent an average of 90 minutes longer in surgery, lost 300 mL more blood, and significantly received more blood transfusions (22% vs. 36%, $p < 0.05$). Both groups had similar rates of postoperative complications. There was no difference in PFS or overall survival (OS) between the two groups, but the study was underpowered for the detection of a small benefit.

The FIGO 1988 staging categorized patients with lymph node metastasis or intraperitoneal metastasis as FIGO IIIC. Patients with an ovarian cancer limited to the pelvis with positive retroperitoneal lymph nodes have a much better 5-year PFS and OS than patients with a pelvic tumor and intraperitoneal disease. Therefore, the new FIGO staging subclassified patients with "only" retroperitoneal lymph node metastasis as stage IIIA1. A review of the large GOG#182 trial analyzed patients who underwent cytoreduction to microscopic residual disease. The median PFS was 21 months for patients with positive lymph nodes and intraperitoneal disease greater than 2 cm before surgery, 29 months with negative lymph nodes and disease greater than 2 cm, and 48 months for patients who had positive lymph nodes but preoperative intraperitoneal disease less than 2 cm (178).

In summary, systematic lymph node dissection provides important prognostic and staging information for patients with suspected early-stage ovarian cancer, which assists with assigning the correct pathologic stage and enables informed decisions concerning the need for adjuvant chemotherapy.

Advanced Epithelial Ovarian Cancer

Rationale for Surgical Debulking

Surgical debulking is central to the initial management of advanced FIGO stage III/IV ovarian cancer, and the extent of residual disease after surgery is the only prognostic factor under the control of the operating surgeon. The concept of removing widely disseminated tumors within the abdominal cavity is specific to epithelial ovarian/fallopian/peritoneal, and appendiceal cancers. It is unusual to attempt primary tumor debulking in patients with widely metastatic colon, breast, or gastric cancer. One reason surgical debulking of ovarian cancer is technically feasible is that serous ovarian cancer is usually confined within the peritoneal borders of the abdominal cavity. It spreads along the peritoneal, diaphragmatic surfaces without deep invasion (13) into abdominal organs, and this allows dissection along a surgical plane between an organ and the attached tumor. For example, although the omental tumor is very large and often densely attached to the transverse colon, it is rarely necessary to perform a transverse colon resection and it is almost always possible to sharply dissect the tumor off without injuring the colon muscularis (Fig. 23.11). The omental tumor often reaches the splenic hilum and distal pancreas, but rarely invades the parenchyma of these organs. Although ovarian tumors can occlude the pelvis completely and transform the pelvic peritoneum into thick tumor plaques, the pelvis can usually be completely cleared of tumors with a modified posterior exenteration (98). Serous ovarian cancer tumors never extend via direct invasion beyond the lining of the peritoneal surfaces, and a retroperitoneal dissection allows the entire tumor-covered peritoneal reflection to be removed (Fig. 23.16) (98). In contrast, uterine sarcomas and colon and breast cancers often grow retroperitoneally, making a complete resection much more challenging.

Several theories have been put forward to explain the strong association of surgical debulking to a state of no visible residual disease with patient survival ("microscopic disease"). One factor could be that the ability to surgically remove all disease correlates with other biologic factors that predispose to better outcomes. However, large bulky tumors may contain necrotic or hypoxic areas that have a low growth fraction and are resistant to chemotherapy. Optimal debulking could then, theoretically, drive remaining microscopic tumor cells into the cell cycle, rendering them more susceptible to cytotoxic chemotherapy.

In advanced "high tumor volume" ovarian cancer, staging traditionally takes place as part of the initial debulking surgery, with the goal of removing all visible disease and, possibly, implanting a port for intraperitoneal chemotherapy (116). In patients with extensive tumor dissemination combined with a chronic bowel obstruction, the cancer leads to tumor-associated cachexia with a catabolic metabolic status, limiting the patient's ability to maintain reasonable nutritional status. Removal of tumor masses ("debulking") produces significant symptom relief from tumors externally pressing on organs in the pelvis or the upper abdomen. Surgical tumor debulking can also reduce ascites production and improve the nutritional and functional status of the patient, resulting in a higher quality of life.

Overall, there is no uniform surgical approach to the treatment of advanced ovarian cancer. Patient (age, nutritional status, comorbidities) and intraoperative factors (disease location, adhesions from previous surgeries, intraoperative stability/anesthesia, blood loss) and the surgical skills of the physician will determine the extent of surgical resection in the individual patient. It requires significant surgical training and experience to successfully remove pelvic and upper abdominal disease with a low complication rate. In Europe, a gynecologist generally collaborates closely with a general surgeon, who usually performs the bowel resections and upper abdominal debulking (e.g., diaphragm stripping, splenectomy). In North America, the majority of debulking, including gastro-intestinal procedures, is performed by a gynecologic oncologist with the consultation of a hepatobiliary surgeon should extensive mobilization of the liver or a liver resection be necessary. Although the comparative efficacy of these two approaches has never been studied, studies on both sides of the Atlantic have shown that high-volume centers have a higher rate of optimal surgical debulking in advanced ovarian cancer. The resectability of extensive disease with acceptable morbidity is likely to reflect a combination of surgical experience, technique, anesthesia care, critical and postoperative care, and nursing. Optimal debulking rates of up to 70% to 80% have been reported in various centers (101,179), but 50% is an accepted quality measure (167). Several centers have shown that a dedicated surgical team and a multidisciplinary effort can improve complete and optimal cytoreduction rates over time. Size and tumor distribution at the beginning and end of surgery should be carefully documented in the operative report in order to define the two most important prognostic factors (stage and residual disease).

The characterization of surgical outcome based on the amount of residual disease at the end of surgery is an accepted measure of surgical success, with the caveat that tumor measurements have a high degree of interobserver variability.

Although many surgeons had previously recommended a maximal debulking effort for patients with advanced ovarian cancer (e.g., Joe V. Meigs 1934), it was not until a retrospective study by the American Gynecologic Oncologist C. Tom Griffiths in 1975 (180) that an inverse relationship between residual tumor size and survival was established. Since that time, a number of retrospective studies and meta-analyses have reported the prognostic value of residual disease for both PFS and OS (89,103,104,179,181-183). In 1992, Hoskins and colleagues (184,185) reviewed survival and surgical results in two GOG studies that enrolled patients with FIGO stage III and IV disease (GOG#52, 97). Defining three different groups (microscopic vs. <2 cm vs. >2 cm residual disease), the authors found that survival is inversely related to the volume of residual disease at the end of surgery. Notably, they also found that, in patients with residual disease greater than 2 cm, increments in the size of residual disease did not appreciably affect survival. Later, Chi and colleagues from Memorial Sloan-Kettering showed that the introduction of radical pelvic dissection and upper abdominal debulking surgery increased the number of patients who could be optimally debulked (101).

In the largest (4,312 women) phase III ovarian cancer trial performed to date (GOG#182), the Gynecological Cancer InterGroup studied the addition of a third chemotherapy group to the standard carboplatin and paclitaxel regimen in women with stage III/IV ovarian cancer (89). Although the addition of a third drug did not show any benefit, the extent of cytoreductive surgery was shown to be significantly correlated with PFS and OS. Patients with FIGO stage III and IV who had no macroscopic disease at the end of surgery, minimal residual disease (<1 cm), or gross residual disease had a median PFS of 29, 16, and 13 months, respectively, and a median OS of 68, 44, and 30 months, respectively. Breakdown by stage is shown in Figure 23.17. A meta-analysis of 81 studies by Bristow and colleagues (179) also showed that survival is associated with the amount of residual disease, with a median OS of 22.7 months for patient cohorts in which 25% or fewer were maximally cytoreduced (≤ 3cm residual tumor) and a median OS of 33.9 months for patient cohorts with 75% or greater rates of maximal cytoreduction. Each 10% increase in the proportion of patients who were maximally cytoreduced was associated with a 5.5% increase in median cohort survival time.

Improved survival with complete tumor resection is also seen in patients with FIGO stage IV disease. Winter et al., reviewing the experience of GOG#111, #132, #152, and #162, showed that patients with residual disease greater than 5 cm, multiple stage IV defining sites of metastasis (parenchymal liver disease, pleural effusion), and clear cell/mucinous ovarian cancer had a significantly worse survival (103). The median PFS and OS for stage IV patients whose tumor was reduced to microscopic disease were better than those for patients with any amount of visible residual cancer. Patients with residual disease where the single largest lesion is 0.1 to 1.0 cm and 1.1 to 5.0 cm had comparable survival and patients with residual tumor bigger than 5 cm had the worst prognosis. These data have been interpreted to suggest that, even in patients with FIGO stage IV disease, cytoreduction to microscopic disease should be the primary goal at initial surgery. A positive association of stage IV disease optimally debulked to microscopic residual disease with longer survival was also confirmed by review of three prospective phase III Arbeitsgemeinschaft Gynäkologische Onkologie (AGO) trials

(AGO-OVAR #3, #5, #7) (104).

Pre-surgical high metastatic tumor load plays an important role in prognosis (184). An important question is whether every patient benefits from surgical debulking, independent of the extent of disease at the beginning of surgery. In GOG#52, patients with large-volume disease at the beginning of surgery, who were optimally debulked using an aggressive upper abdominal procedure, still had shorter survival than patients who initially had low-volume disease, even if the surgical outcome was similar (184). Du Bois and colleagues, summarizing the AGO experience from three prospective phase III trials (3,126 patients from AGO-OVAR #3, #5, #7) with identical inclusion criteria, concluded that complete surgical debulking is associated with improved prognosis in any FIGO substage, but cannot completely overcome the prognostic impact of preoperative disease load (182). Resection to microscopic disease was associated with a longer median OS (microscopic disease: 99.1 months CI, 83.5–not reached; residual <1 cm: 29.6 months CI, 27.4–32.2; residual > 1 cm: 29.6 months CI, 27.4–32). Extending these studies, Horowitz analyzed the impact of preoperative disease burden on survival by studying the impact of aggressive surgery on patients with high- and low-volume disease from GOG#182. Of 1,636 patients with large volume disease preoperatively (upper abdominal disease—diaphragm/spleen/liver/pancreas), 199 (12%) were reduced to microscopic disease, but these patients still had a worse PFS and OS compared with patients with preoperative low-volume disease (186) (Fig. 23.18). Therefore, both the preoperative tumor burden, including the extent of upper abdominal disease, and the extent of surgical resection (postoperative tumor burden) influence the PFS and OS of patients with advanced ovarian cancer.

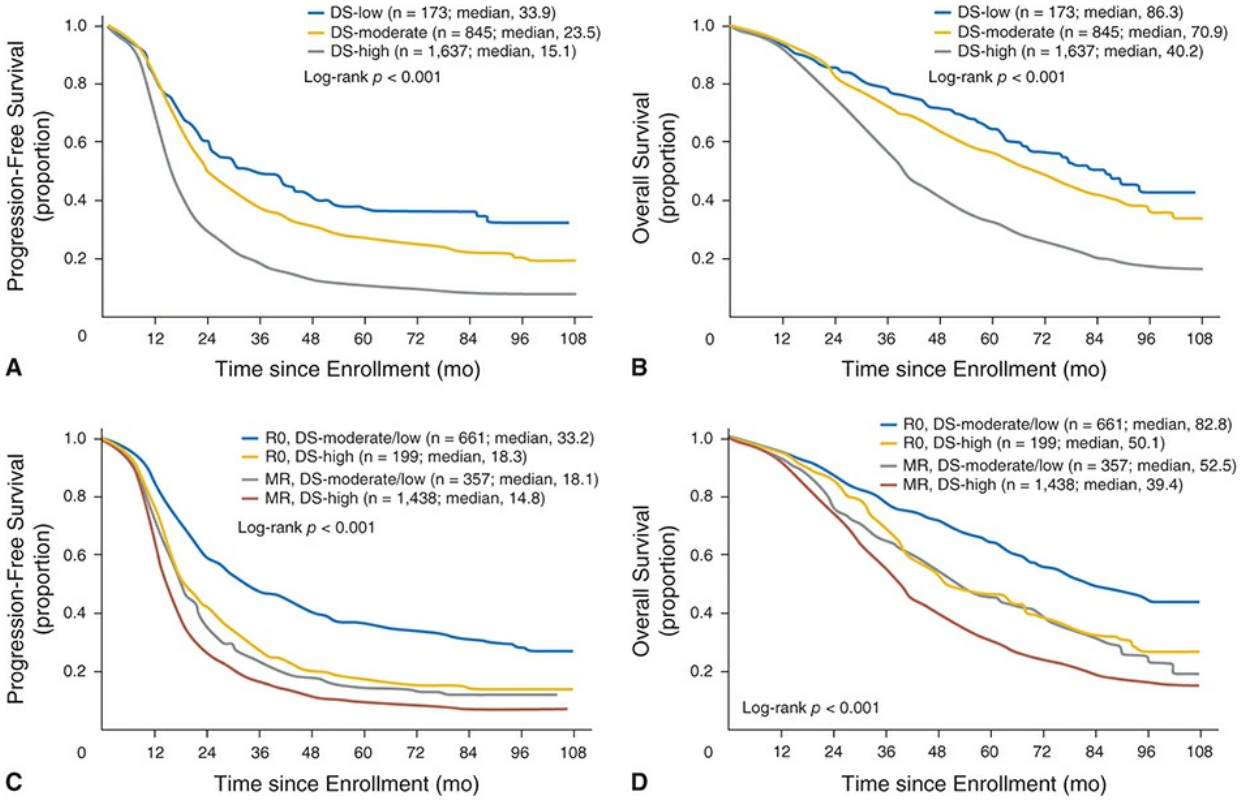

Figure 23.18 (A) Progression-free and (B) overall survival, (C) stratified by preoperative disease burden and (D) further characterized by residual disease for those with high, moderate, and low disease scores. MR, <1 cm of residual disease; R0, complete surgical resection; DS, preoperative disease status.

In summary, surgical debulking plays a very important role in the management of advanced ovarian cancer. However,

patients with very extensive carcinomatosis and extensive upper abdominal disease and/or mesenteric involvement tend to obtain limited benefit from primary debulking procedures, as many will be suboptimally debulked (186). Surgery alone is never curative in advanced disease and therefore should only be attempted as part of a treatment plan including postoperative chemotherapy. As discussed below, it is not possible to predict with accuracy which patients can be optimally debulked, because neither CT nor PET has sufficient specificity (153,154,187). Sometimes only the direct visualization of tumor distribution by laparoscopy provides the necessary information. The overall goal of cytoreductive surgery for patients with advanced-stage FIGO III/IV ovarian cancer should be, whenever feasible, the complete cytoreduction of all visible disease. The reports of improved outcomes with radical debulking suggest that patients should be counseled about this option. However, it is important to remember that, although we justify surgical debulking because it provides symptom relief and it has been shown, in numerous retrospective reviews, to be associated with improved survival, the clinical benefits of radical surgery in ovarian cancer have never been studied in a prospective randomized trial. Heroic attempts to remove unresectable tumors will not benefit patients. In general, complex surgical procedures should be judiciously used in patients with resectable disease, when removal of all visible tumors can be achieved.

Surgical Debulking—Pelvic and Upper Abdominal Procedures

Surgery for patients with advanced ovarian cancer should start with a vertical midline incision extending from the pubic symphysis to above the umbilicus. This allows visualization of the entire abdominal cavity, including the diaphragms, and permits the safe evaluation and resection of upper abdominal disease. Pelvic and diaphragmatic washings and biopsies of suspicious peritoneal surfaces (e.g., paracolic gutters) should be performed. With a careful exploration of the abdominal cavity, the surgeon will be able to evaluate the extent of the disease and plan the surgical approach. Particular attention should be paid to the upper abdomen, as the disease distribution in that region will often determine whether a patient can be optimally debulked. It is helpful to stratify patients with advanced cancer as having either low- and high-volume disease intraoperatively because different surgical strategies are associated with each classification (186,188,189).

Patients with advanced ovarian cancer but low-volume disease should have comprehensive staging, including a total abdominal hysterectomy, bilateral salpingo-oophorectomy, and infragastric omentectomy between the hepatic flexure and the splenic hilum. If the patient can be rendered macroscopically disease free, a pelvic and high para-aortic lymph node dissection is reasonable (110).

Patients with advanced ovarian cancer and high-volume disease usually have extensive tumor burden in the pelvis with encasement of the reproductive organs and sigmoid colon (Fig. 23.10). However, it is almost always possible to completely remove pelvic disease. This requires a modified posterior exenteration, an en bloc resection of the tumor-studded bladder, peritoneum, uterus, sigmoid colon, and proximal rectum, as well as ovarian/fallopian tube masses, cul-de-sac tumors, and possibly the appendix (Fig. 23.16). A low colorectal anastomosis (98,99) should follow; a colostomy is rarely required in patients with serous cancers because serous cancers grow above the peritoneal reflection. Bristow and colleagues have published an excellent step-by-step description of this procedure (98). Performing a rectosigmoid colectomy as part of the pelvic debulking is often the only option if complete cytoreduction is to be achieved and is a superior alternative to peritoneal stripping of disease on sigmoid, sidewall peritoneum, and sigmoid mesentery (99). The possible complications of an extensive radical pelvic dissection include hemorrhage from injury to hypogastric veins, ureteral injury, pelvic abscess, sepsis, and an anastomotic leak. The most important feature of the anastomosis is that it be tension free, which might require mobilization of the splenic flexure of the transverse colon.

Patients with serous ovarian cancer who require a modified posterior exenteration often need one or more upper abdominal procedures as well if complete surgical debulking is to be accomplished (100,101). The decision to perform extensive upper abdominal surgery often depends on the surgeon's opinions regarding the value of upper abdominal surgery and the value of debulking surgery for ovarian cancer in general. Centers that are very aggressive surgically report performing at least one extensive upper abdominal procedure in about 50% of their FIGO stage IIIC ovarian cancer cases

as part of their attempt to render as many patients as possible tumor free. This may include one or two bowel resections, peritonectomy, splenectomy with or without a distal pancreatectomy, diaphragm peritonectomy or full thickness resection, liver resection, and dissection of the porta hepatis (100,101). The most common upper abdominal procedure is diaphragm stripping or resection. Two excellent descriptions of liver mobilization and diaphragm stripping and resection were published by Grimm et al. (190) and Eisenhauer et al. (191). A review (183) of GOG#182 (89), limited to patients with FIGO stage III or IV disease who were optimally debulked (<1 cm), showed that 18% (482 of 2,655 patients) had undergone upper abdominal procedures. The most common procedure was diaphragm surgery (13%), followed by splenectomy and liver surgery (4% each), pancreatectomy (0.5%), and porta hepatis surgery (0.2%) (183). An excellent description of en bloc resection of extensive left upper quadrant disease has been published by Hoffman et al. (192). By using upper abdominal procedures, the authors were able to achieve complete cytoreduction in a high percentage of patients, and OS of patients with upper abdominal disease who were completely cytoreduced was superior to OS of patients with upper abdominal disease who were not completely cytoreduced. However, the preoperative tumor load continues to largely define PFS and OS. Even when aggressive upper abdominal surgery is used to reduce the tumor to microscopic disease, the survival of patients who present with high-volume disease is worse than that of patients who present with low-volume disease (186). As a word of caution, extensive involvement of the upper abdomen with disease may preclude an optimal debulking; aggressive upper abdominal surgery should be performed only when the entire disease can be removed with acceptable morbidity.

Magtibay and colleagues reported on 112 patients at the Mayo Clinic who underwent a splenectomy as part of ovarian cancer debulking (193). The most common indications were metastatic parenchymal involvement (46%), perisplenic involvement from an omental tumor that reached the splenic hilum (42%), and intraoperative trauma (13%). Complications included wound infections (6%), postoperative pneumonitis (4.5%), thromboembolic events (8%), and sepsis (4.5%). The overall perioperative mortality was 5%. A similar complication rate was reported recently; out of 121 patients, 38% had a complication, but severe complications were observed only in 19% (188). Complications were most often observed when ovarian debulking surgery was paired with pancreatectomy or biliary surgery, causing abscess formation, pancreatic fistulas, and/or leakage. The 90-day postoperative mortality rate in this retrospective study was 0.9%.

Long abdominal surgery also increases the risk of hernia formation, as does obesity, wound infection, and diabetes. Patients undergoing elective splenectomy should be vaccinated 2 to 3 weeks before or after surgery to reduce the risk of overwhelming postsplenectomy infection because of organisms like *Streptococcus pneumoniae*, *Haemophilus influenzae* type B, and *Neisseria meningitidis*. Polyvalent pneumococcal, hemophilus influenzae b, and meningococcal vaccinations are recommended.

Role of Lymph Node Dissection in Surgery for Advanced Ovarian Cancer

A prospective randomized Italian trial of 427 patients with advanced ovarian cancer (stages IIIB–IV) compared extensive systematic lymph node dissection with resection only of enlarged (“bulky”) lymph nodes and concluded that, although positive lymph nodes are a negative prognostic marker, systematic lymph node dissection did not contribute to the benefit of optimal tumor debulking. Systematic lymph node dissection improved PFS (median PFS 22 vs. 29 months), but not OS (median OS 59 vs. 56 months) (110). The addition of systematic lymph node dissection resulted in greater blood loss, more transfusions, and added operative time. The perioperative and late morbidity of a systematic lymph node dissection was 28%, whereas morbidity for the resection of only enlarged lymph nodes was 18%. Most of this excess morbidity was caused by lymphocyst formation and lymphedema. Therefore, even in experienced hands, a systematic lymph node dissection carries significant morbidity, which should be factored into decision making. The study took over 12 years to recruit patients from 13 centers. However, it is worth noting that 63% of the patients in this study had residual tumor after debulking surgery, which might obviate any benefit of lymph node dissection. The German AGO retrospectively reviewed data from three large phase III trials (AGO-OVAR# 3, 5, 7) of chemotherapy in advanced epithelial ovarian cancer. They

found that in the subgroup of patients with no residual disease and no enlarged lymph nodes, a systematic lymph node dissection was associated with a small statistically significant survival benefit (median OS, 108 vs. 83 months) (111).

In summary, the current practice in advanced ovarian cancer is to remove enlarged/suspicious lymph nodes as part of tumor debulking, and one retrospective review suggests systematic pelvic and para-aortic lymph node dissection might therapeutically benefit patients who have been optimally debulked to microscopic residual disease. A large international phase III trial that randomizes patients with advanced ovarian cancer who are debulked to microscopic disease to either systematic lymph node dissection or nodal sampling only is now underway (LION trial: lymphadenectomy in ovarian neoplasms).

Neo-adjuvant Chemotherapy

The European Organization for Research and Treatment of Cancer (EORTC)-GCG and NCIC performed a phase III trial (EORTC#55971) randomizing 718 patients with FIGO (1988) stage IIIC or IV ovarian cancer to either neo-adjuvant platinum-containing chemotherapy followed by interval debulking or to primary debulking surgery followed by platinum-based chemotherapy (135). The largest residual tumor after surgery was less than 1 cm in 80% of patients treated with the neo-adjuvant approach, whereas this was only accomplished in 42% of all patients who underwent up-front debulking. There was a trend toward less blood loss, fewer postoperative infections, and fewer thromboembolic complications in the neo-adjuvant treatment group, as well as a shorter operative time. Most importantly, there was no significant difference in PFS (12 months in both groups) or OS (29/30 months) between the two groups, and this was independent of the rate of optimal debulking accomplished in a specific center (Fig. 23.19). The study was criticized for its low PFS and OS results, but most patients had adverse prognostic factors to begin with: 74% had tumors larger than 5 cm (61% >10 cm) in size at baseline, indicating that study participants had very advanced disease. Another, related, criticism of the study was the low rate of optimal debulking. In the primary debulking group 19.4% of all patients were reduced to microscopic disease, whereas the rate was 51.2% for the neo-adjuvant group. In the United States the optimal debulking rate is 40% to 80%.

	No. of Events		No. of Patients at Risk			
Primary Debulking Surgery (PDS)	253	336	189	62	14	2
Neoadjuvant Chemo-therapy (NACT)	245	334	195	46	13	2

Figure 23.19 Neo-adjuvant chemotherapy versus upfront debulking.

A second phase III trial (CHORUS) (158), which randomly assigned 552 women to either primary surgery or NACT (three cycles pre- and three cycles postoperatively) also found no significant difference in OS between the two groups (PFS 10.7 vs. 12 months, OS 22.6 vs. 24.1 months). There were fewer complications in the neo-adjuvant group, and more patients in the neo-adjuvant group had an improvement in global quality of life.

Fourteen patients (6%) died in the primary surgery group, which is a much higher mortality rate than has been previously reported in phase III trials of advanced ovarian cancer and may be related to the advanced stage or poor performance status of the patients entered on the study. The median operative time in both groups was short, at 120 minutes, and debulking to microscopic disease was accomplished in only 17% of the women who had primary surgery compared with 39% of those who had primary chemotherapy (p = 0.0001). In the primary surgery group 27% did not have a BSO, 24% did not have a hysterectomy, and only 20% had upper abdominal surgery.

Results of these studies started a heated discussion on the role of NACT and the best timing of radical debulking in the front-line treatment of ovarian cancer. This discussion is still ongoing. There are no preoperative factors or imaging studies (153) that can be used to predict the success of interval cytoreduction surgery. For patients with FIGO (1988/2013), stage I–IIIB disease, primary surgery is currently the standard treatment. An exploratory analysis of the EORTC study (194)

showed that women with less extensive metastatic disease did better with primary surgery whereas patients with metastatic tumors that are larger than 4.5 cm and patients with FIGO (1988) stage IV did better with NACT. Physicians who feel a primary surgical approach is preferable even in women with large tumor volume note results such as those from a retrospective analysis of patients treated at Memorial Sloan-Kettering Cancer Center during the time of EORTC trial who underwent very aggressive surgery (including upper abdominal surgery), with high rates of optimal debulking, and reported that these patients experienced results that appear superior to those seen in the CHORUS and EORTC trials, with a PFS and OS of 17 months and 50 months, respectively (195).

In patients with extensive tumor burden (ascites, poor performance status and several comorbidities, obesity, and older age), NACT is a very reasonable choice. The current standard for a healthier, younger patient with disease that appears resectable is initial aggressive surgery with the goal of accomplishing a complete tumor debulking with no visible residual disease.

Summary of Primary Debulking Surgery for Ovarian Cancer

Many factors contribute to how long a patient with advanced ovarian cancer survives. Inherent genetic characteristics of the tumor may play a more important role in OS than stage or cytoreductive surgical debulking. However, the study of genetic factors in relation to surgical treatment is in its infancy. At present, the degree of surgical debulking is the only prognostic factor that can be influenced by the surgeon. We know that among patients with advanced-stage III/V ovarian cancer, those who undergo a complete debulking have the most favorable prognosis. Whether a complete resection is performed is, at least in part, determined by the surgeon's skill and willingness to engage in a maximal surgical effort. Once the decision has been made to proceed, the goal of every operation in patients with advanced-stage III/IV ovarian cancer should be a complete resection of all visible tumors to microscopic disease (157).

However, ultraradical surgery, involving the addition of upper abdominal procedures to pelvic tumor debulking, will increase morbidity and not every patient is a good candidate for such an aggressive approach (196). Large-volume involvement of the upper abdomen, extended small and large bowel surface and mesentery involvement or multiple liver metastases, may preclude an optimal debulking. Wright and colleagues, reviewing a large administrative database with over 28,000 patients, showed that the complication rate of extensive ovarian cancer debulking (e.g., surgical site, medical, infectious complications) increases with age. Women younger than 50 years, 70 to 80 years, and those older than 80 years have a 17.1%, 29.7%, and 31.5% complication rate, respectively (196).

Two groups of factors should contribute to the decision whether to take a patient to surgery and perform a radical debulking procedure (155): (a) A careful preoperative evaluation of patient-related risk factors: Patients with significant comorbidities and low performance status (American Society of Anesthesiology [ASA] preoperative scores 3 or 4, poor nutritional status, low albumin <3 g/dL) have a low likelihood of optimal debulking to microscopic disease and are at risk of significant peri- and postoperative morbidity; (b) A critical evaluation of the extent of disease with particular attention to upper abdominal tumor burden, ascites, and upper abdominal tumor distribution. Patients with one or more of these risk factors often have a prolonged postoperative recovery, as they have limited ability to withstand a long operation. Furthermore, once a complication occurs, the patient may not receive chemotherapy and is more likely to succumb to disease within 3 months (155). For these patients, NACT is a well-studied alternative to a debulking surgery and has been shown to produce similar outcomes (Fig. 23.19) and less morbidity in randomized trials (135,158).

Sometimes it is not possible to preoperatively decide whether radical debulking surgery is feasible because of the limited ability of CT scans to predict success (153). Several scoring systems have been developed to select patients who can be completely cytoreduced. All agree that mesenteric retraction and miliary dissemination of tumor nodules on the serosa of the small bowel predict unresectability to microscopic disease. Staging laparoscopy offers an opportunity to evaluate disease extent with a minimal complication rate using a laparoscopy-based scoring system (Fagotti score or predictive index (PI) (156). Other predictive scoring systems including serum markers (albumin, preoperative CA-125)

and radiographic features have performed well in single-institution studies, but were not reproducible (153). However, there is generally good concordance between findings at laparoscopy and findings at laparotomy. The Fagotti score includes the evaluation of peritoneal and diaphragmatic carcinomatosis, omental caking, need for a large/small bowel resection (excluding sigmoid resection), involvement of the stomach, lesser sac, or spleen, and liver surface lesions, assigning a score of 2 for each feature present. A score >10 predicts that it will be impossible to completely cytoreduce a tumor to microscopic disease. At MD Anderson the Fagotti score is used to standardize care. Patients with scores < 8 receive initial cytoreductive surgery, whereas those with scores > 8 receive NACT (157). A prospective trial "SCORPION" conducted at MD Anderson is now testing primary debulking surgery versus NACT in patients with scores from 8 to 12 (157).

Second-look laparotomy was often performed in the 1980s after primary surgery and adjuvant cisplatin-based therapy for prognostic information and to determine the need for further treatment. Chemotherapy was generally continued for those found to have residual small volume disease. Second-look surgery is no longer generally performed, because no therapy instituted as a result of disease found during these procedures altered prognosis. Reoperation following chemotherapy also introduces unnecessary morbidity. About one-third of patients with advanced ovarian cancer were found to be free of disease at a second-look laparotomy, yet over half of these patients eventually experienced a recurrence.

In summary, the extent of primary surgical cytoreduction in patients with advanced ovarian cancer and multiple comorbidities should be determined for every patient individually. If there is doubt, until more data become available, it is reasonable to treat these patients with NACT followed by debulking surgery.

Interval Debulking for Suboptimally Debulked Patients

In this section, the term *interval debulking surgery* refers to a surgical procedure in a patient with persistent abdominal disease after an initial surgical debulking effort and three to four cycles of chemotherapy (Table 23.7).

There is conflicting evidence from two large prospective, randomized trials regarding whether interval debulking surgery can improve survival in patients for whom an initial surgical effort did not achieve optimal results (197,198). In a multicenter trial conducted by the EORTC (197), patients with suboptimal (>1 cm) disease remaining after primary cytoreduction were treated with three cycles of cyclophosphamide and cisplatin. Those without progression were randomized to interval debulking surgery and additional chemotherapy versus additional chemotherapy alone. With approximately 140 patients randomized to each arm, patients undergoing interval debulking showed a statistically significant improvement in both progression-free interval and median survival (Fig. 23.20). The survival of patients with residual lesions of more than 1 cm after the interval debulking surgery was similar to that of patients who did not undergo the surgery. None of the patients in the interval debulking group died and morbidity was minimal. The long-term results from this study showed that after 5 years PFS and OS were still significantly better for the patients in the interval debulking group and that being randomized to interval debulking remained an independent prognostic factor for improved survival (199).

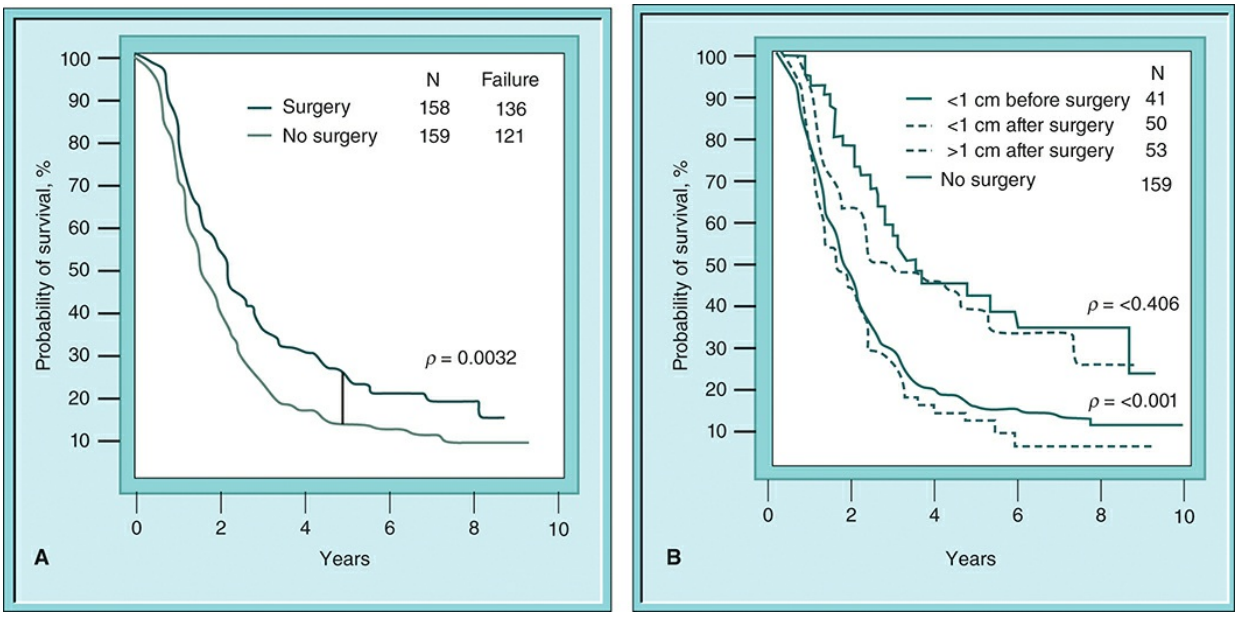

Figure 23.20 . A:Survival of patients who underwent interval cytoreductive surgery and no interval surgery. B: Survival of patients who underwent interval cytoreductive surgery according to size of tumor lesions versus patients without interval surgery. Source: From van der Burg ME. Advanced ovarian cancer. Curr Treat Options Oncol. 2001;2(2):109－118.

The GOG prospective, randomized trial of interval secondary cytoreduction in patients with advanced FIGO stage III/IV ovarian cancer with suboptimal (> 1 cm) residual disease, however, had different results (GOG#152) (198). Five hundred fifty patients were enrolled in GOG#152 within 6 weeks of initial surgery. After three cycles of paclitaxel and cisplatin, patients without evidence of tumor progression were randomized to receive either secondary cytoreduction and three additional cycles of chemotherapy or chemotherapy alone. At the time of the report (2004), median PFS and OS (Fig. 23.21) for the interval cytoreduction group were 10.5 months and 33.9 months, respectively, compared with 10.7 months and 33.7 months for the chemotherapy-alone group. A consistent lack of effect was seen in all patients regardless of the residual tumor size at the end of the interval debulking surgery.

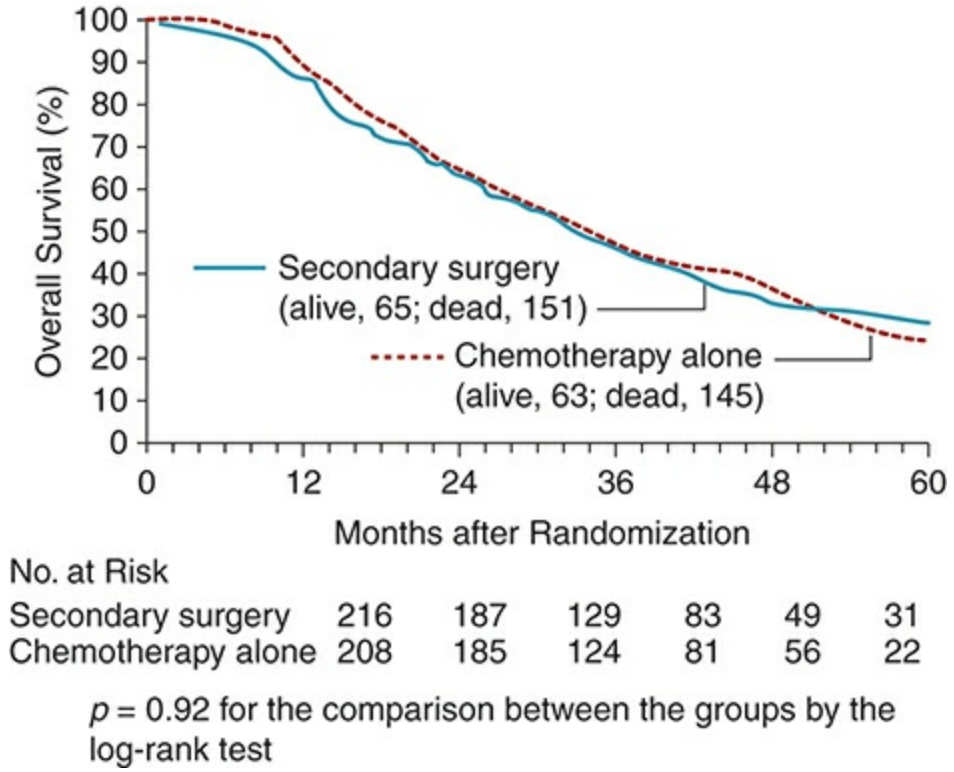

Figure 23.21 Overall survival of patients with advanced ovarian cancer who underwent interval debulking surgery compared with treatment with chemotherapy-only GOG trial. Source: Rose PG, Nerenstone S, Brady M, et al. A phase III randomized study of interval secondary cytoreduction in patients with advanced-stage ovarian carcinoma with suboptimal residual disease: a Gynecologic Oncology Group study. Proc Am Soc Clin Oncol. 2002;21;201A, with permission.

Several theories have been advanced to explain the difference in outcomes between the GOG and European studies. One point raised is that there were differences in the extent of the initial cytoreduction surgery. In the GOG trial, both the initial and interval cytoreductive operations were clearly defined and were performed almost exclusively by trained gynecologic oncologists, whereas in the EORTC trial the extent of the initial surgery was not clearly defined and surgery was most often performed by general gynecologists. As a result, residual disease following primary surgery measured less than 5 cm in about two-thirds of the GOG patients, compared with one-third of the patients in the EORTC trial. Following chemotherapy, residual disease greater than 1 cm was found in 56% of the GOG patients versus 65% of the European patients. In addition, the chemotherapeutic regimen used in the GOG trial, paclitaxel and platinum, may have been more effective than the platinum and cyclophosphamide combination used by the EORTC. Less effective chemotherapy would increase the benefit of interval cytoreduction in the EORTC trial, which found conversion from suboptimal to optimal residual tumor in 45% of patients as compared with 36% in the GOG trial. Differences in outcomes may also be related to different posttreatment surveillance and to the availability of more effective second-line therapies, because the EORTC trial completed accrual in May 1993 before paclitaxel was introduced into clinical care. It is of interest to note that the similar median and OS in both arms of the GOG trial were substantially longer than those reported in the best (interval cytoreduction) arm of the EORTC trial. We can conclude that patients who had an initial maximal effort at cytoreduction resulting in suboptimal debulking are unlikely to benefit from interval cytoreduction (198). However, patients with advanced ovarian cancer who previously only had a biopsy, removal of the ovary, partial removal of ovarian tumors, or, in general, a limited surgical attempt, may benefit from a second surgery that involves maximal debulking (197).

Secondary Cytoreductive Surgery for Recurrent Disease

Despite modest improvements in adjuvant chemotherapy for ovarian cancer (intraperitoneal chemotherapy (116), dose-intense chemotherapy [200,201], and aggressive primary debulking surgery including upper abdominal procedures) (155,183,186,188-190,192,193,202), the majority (70%) of patients with advanced epithelial ovarian cancer will have a recurrence (89). As there is currently no chemotherapy that can cure recurrent ovarian cancer, surgical resection of recurrent disease is an option for a select group of patients.

In 1992 a retrospective study of secondary cytoreduction for recurrent disease from investigators in Munich showed an OS of 29 months for patients cytoreduced to microscopic residual disease, whereas patients with any visible disease after surgery had a median survival of only 9 months (202). Later, Chi and colleagues reviewed outcomes of 157 patients who had undergone secondary cytoreduction at Memorial Sloan-Kettering from 1987 to 2001 (203). For patients with a disease-free interval from completion of their primary adjuvant chemotherapy of 6 to 12 months, 13 to 30 months, and longer than 30 months, the median survival durations were 30, 39, and 51 months, respectively ($p = 0.005$). Median survival was 60 months for patients with a single site of recurrence, whereas patients with carcinomatosis had a median survival of 28 months ($p < 0.001$). In patients whose residual disease at the completion of surgery was larger than 0.5 cm, the median survival was 27 months, compared with 56 months in patients with residual disease less than 0.5 cm.

These results were supported by other studies. Eisenkop and colleagues prospectively followed patients who underwent secondary cytoreductive surgery and showed that patients with microscopic residual disease had a median survival of 44.4 months compared with 19.3 months if any visible disease was left (204). Therefore, as is the case with primary cytoreductive surgery, the disease burden at the end of surgery seems to be the most important prognostic factor. The German/Swiss DESKTOP I trial (205) enrolled 267 patients with recurrent ovarian cancer who had secondary cytoreductive surgery and found that patients with carcinomatosis had a 19.9 months median survival versus 45.3 months for patients without disseminated disease ($p < 0.0001$). In this trial, a score (the "AGO score") was developed to predict optimal operability in this recurrent patient group, using criteria for a positive score that included good performance status (ECOG ≤ 1), complete debulking at first surgery, and less than 500 cc of ascites. The score was then tested in the DESKTOP II prospectively: 76% of the patients who fulfilled all three criteria had an optimal debulking to no residual disease (206). One-third of the patients that had surgery suffered at least one minor or major complication. However, the AGO score was found to have no independent prognostic value. A retrospective study from the Mayo Clinic that applied the AGO score to 192 women who had secondary cytoreductive surgery between 1998 and 2013 found that a positive AGO score predicted a R0 resection in 84.3% of cases. Thus, a positive AGO score does indicate that secondary debulking surgery for recurrent ovarian cancer is likely to be successful. However, 64.4% patients with a negative score also achieved a R0 resection. The median disease-free interval for the entire group was 1.9 years (207). Overall survival was longer for patients with complete (5.4 years) than with optimal (2.4 years) or suboptimal cytoreduction (1.3 years).

A small subset of patients (4% to 5%) will present with isolated recurrences in retroperitoneal lymph nodes. Several small retrospective studies found that complete resection of lymph nodes limited to one anatomic region (60% are high para-aortic) is associated with significantly improved survival (178). This finding is consistent with the better prognosis of patients who present with localized disease in the pelvis and retroperitoneal lymph node metastasis.

All studies reporting on secondary cytoreductive surgery are retrospective or prospective nonrandomized studies, which have an inherent selection bias for patients in a prognostic group judged suitable for surgical interventions. However, based on the consistent findings of these studies, the following selection criteria for secondary debulking seem reasonable: Patients with (a) a disease-free interval longer than 12 months, (b) platinum-sensitive disease with additional chemotherapy options, (c) oligometastatic or localized intra- or retroperitoneal disease with the absence of ascites and carcinomatosis, and (d) a good performance status (208). For all other patients, the potential morbidity and limited benefit associated with suboptimal secondary cytoreduction should be carefully weighed against the possible benefit of surgery. In cases where radiologic studies do not provide a clear preoperative picture of disease extent, a diagnostic laparoscopy to assess resectability may assist with the decision. In appropriately selected patients secondary cytoreduction is associated with an improved patient outcome, with the largest benefit in patients from whom all visible disease is removed (206). Very rarely is surgery indicated in platinum-resistant recurrences. It should be performed only if a PET/CT shows only one or

two lesions and there is no ascites (209).

Three prospective randomized trials will hopefully clarify the impact of secondary cytoreductive surgery on survival. The DESKTOP III trial, the GOG#213 trial, and the SOCceR trial randomize patients with potentially resectable platinum-sensitive disease to secondary cytoreduction or no surgery. Postoperative chemotherapy is required in the GOG trial and recommended in the DESKTOP III trial.

Palliative Surgery Including Surgery for Malignant Bowel Obstruction

The primary goal of palliative surgery is to relieve symptoms and improve the quality of life, rather than prolong survival. Bowel obstruction is one of the main causes of both distress and death from ovarian cancer. Others are extensive ascites, intractable pleural effusions, sepsis from a bowel perforation, and tumor cachexia (210,211). A malignant bowel obstruction is the most common reason for a hospital admission for patients with ovarian cancer during the last year of life. The median survival of patients admitted with a bowel obstruction is around 3 months. The tumor, although it does not deeply invade the bowel, connects and then kinks bowel loops and/or encases the bowel mesentery, limiting bowel mobility and blood supply and causing a combination of mechanical bowel obstruction and adynamic ileus. Other etiologies can be extrinsic compression of the bowel lumen by intra-abdominal tumors or retroperitoneal lymph nodes pushing on the pyloric antrum or the duodenum. In patients without a recurrence, who underwent an extensive debulking procedure or received previous i.p. chemotherapy, adhesions, an old hematoma, or a new incisional hernia may also be the cause of a bowel obstruction.

Patients with advanced disease tend to present to the emergency room with one or more of the following signs and symptoms: tachypnea/dyspnea because of cranial displacement of the diaphragm/atelectasis of lower lung lobes or a pleural effusion, tachycardia from dehydration and pain, or a low-grade fever from the dehydration and chronic inflammation associated with a long-standing obstruction. Symptoms of a bowel obstruction include nausea and vomiting, absence of gas or bowel movements, periumbilical cramping and a combination of dull and sharp abdominal pain, and abdominal distension. Sometimes patients complain of colicky pain from peristaltic waves of bowel against a focal point of obstruction. Changing bowel habits and loose stools are typical of a partial obstruction. Often patients also have a deep vein thrombosis because of active, advanced disease affecting coagulation and prolonged immobility.

Instant nausea and vomiting after oral intake or projectile vomiting is an indication of a very proximal obstruction of the stomach or duodenum which cannot be relieved by surgery. If the patient has an adynamic ileus from peritoneal carcinomatosis, auscultation will show an absence of bowel sounds, but if there is a complete bowel obstruction bowel sounds will be high pitched. Proximal bowel obstruction may be caused either by an extensive upper abdominal tumor load or by enlarged high para-aortic lymph nodes causing extrinsic compression of the duodenum or jejunum. The abdomen of patients with a proximal bowel obstruction is often not distended, which can give the mistaken impression that the problem is limited, although the patients suffer from severe nausea and bilious emesis. Laboratory analysis often shows hemoconcentration, thrombocytosis, low albumin, and hypokalemic, hypochloremic metabolic alkalosis, which is a sign of repeated vomiting and/or long-standing nasogastric tube drainage. Patients with a volvulus or chronic bowel ischemia may have metabolic acidosis, leukocytosis, and an increase in lactate. Although bowel obstruction is a clinical diagnosis, a supine and upright abdominal X-ray ("GI obstruction series") will show air-fluid levels. A chest X-ray may reveal free air. A CT scan of the abdomen and pelvis with oral and intravenous contrast or a small bowel follow-through will permit the evaluation of the small/large bowel over its entire length and will help determine whether there is partial or complete bowel obstruction and whether there are multiple sites of obstruction or a single transition point. The bowel is often dilated proximal to the transition point and collapsed distally.

Treatment options at this point include palliative care with symptom control, a percutaneous endoscopic gastrostomy (PEG) tube, parenteral nutrition, palliative chemotherapy, stents for gastric outlet obstruction or single-site colonic obstruction, and as last resort palliative surgery. Initial treatment for a malignant bowel obstruction should be conservative

and may include bowel rest and hydration to correct metabolic abnormalities, which are signs of a long-standing obstruction. Additional supportive measures include treatment with octreotide to reduce secretions, anti-emetics, corticosteroids to reduce inflammation and act as anti-emetics, and narcotics for adequate pain management. In selected patients it is possible to accomplish a temporary surgical correction and relieve the blockage by either removing the tumors obstructing the bowel or by performing a diversion that may involve a colostomy, ileostomy, or a limited bowel resection with intestinal bypass. Preoperative contraindications to an attempted surgical correction of a malignant bowel obstruction include an adynamic ileus caused by carcinomatosis or extensive ascites, diffusely metastatic cancer with bowel obstructions on multiple levels, and involvement of the proximal ileum, duodenum, or stomach. Relative contraindications to palliative surgery for a malignant bowel obstruction are a long-standing obstruction, significant deconditioning and tumor cachexia (low serum albumin), multiple previous abdominal surgeries, and rapidly progressing, chemotherapy-resistant disease (212). Before surgery, consideration should be given to a large bowel stent if the obstruction is in the distal colon.

Because the purpose of palliative surgery is to improve the quality of life, the procedure must be short and limited, with the lowest possible complication rate. A review of patients with ovarian cancer at a single institution who underwent palliative surgery for bowel obstruction found that, in experienced hands and with appropriately selected patients, a surgical correction was possible in 84% of all patients and successful palliation, defined as the ability to tolerate oral intake for at least 60 days after surgery, was achieved in 71% of patients (213). In 16% of patients, a gastrostomy tube was placed and most of the other patients received an ileostomy, a colostomy, or the obstructed area was bypassed. The rate of major surgical complications was 22% and included enterocutaneous fistula formation, abscess formation, bacterial peritonitis, thromboembolic events, and death. The median survival for patients who were able to receive chemotherapy (70%) was 9.7 months, whereas it was 2.4 months for those not treated with chemotherapy (213). A low preoperative albumin (<2.5 mg/dL), ascites (<2 L), and carcinomatosis were found to be relative contraindications (212). Other studies have shown similar results. Palliative surgery for bowel obstruction in ovarian cancer patients is associated with significant mortality (15% to 25%), whether it is an elective or an emergency procedure. Successful palliation (adequate oral intake > 60 days) is achieved in 53% to 71% of patients and the inoperability rate is around 20% (212-214). These results highlight the importance of discussing possible outcomes with patients, fostering realistic expectations, and learning how the patient defines successful palliation.

Excessive ascites production is also often encountered in patients with progressive disease. Ultrasound-guided intraperitoneal catheter placement is safe and can be performed intermittently as an outpatient procedure. Visceral injury followed by peritonitis is very rare with this procedure, but with repeated paracentesis the ascites may become loculated and drainage incomplete. Often repeated paracenteses are necessary, and in this case, a permanent indwelling abdominal catheter can be placed and the patient or her family instructed on how to drain the ascites. Antiangiogenic therapy may also reduce ascites production.

CHAPTER 24 Ovarian Germ Cell Tumors

Daniela Matei, Robert E. Emerson, and Jubilee Brown

INTRODUCTION

Significant improvement in the management of ovarian germ cell tumors (OGCTs) has been achieved during the past three decades. The development of more effective chemotherapy (CT) regimens is the leading cause for improved outcome in this rare group of patients. Other advancements in the field include the development of a more precise surgical staging system, improved radiographic imaging, more sophisticated pathology techniques, and improved supportive care and symptom control that has enabled safe delivery of treatment. A substantial number of patients with OGCT are long-term survivors and suffer minimal morbidity from treatment. Fertility-sparing surgical procedures enable young women with OGCT to preserve their reproductive potential. These positive results in clinical outcome reflect the ability to build on the treatment success in testicular cancer, as well as a collaborative effort among multiple specialties (gynecologic oncology, medical oncology, pathology, and radiology).

PATHOLOGY

The 2014 World Health Organization classification of OGCTs includes dysgerminoma, yolk sac tumor, embryonal carcinoma, nongestational choriocarcinoma, mixed germ cell tumors, and teratomas (immature teratoma (IT), mature teratoma, and various types of monodermal teratoma) (1,2). Although mature teratomas are relatively common, representing approximately 20% of ovarian tumors, the malignant germ cell tumors are less common and account for 2% to 3% of all ovarian cancers. Both mature teratomas and malignant germ cell tumors usually occur in young women, with a peak age of incidence in the late teens to early twenties. The age range is, however, broad, with rare cases of OGCTs being diagnosed in postmenopausal women.

Dysgerminoma

Dysgerminoma is the most common malignant OGCT, but it represents only 1% to 2% of ovarian malignant tumors overall (1). The mean patient age at presentation is approximately 22 years (1). A small percentage of these tumors are associated with disorders of sexual development with a Y chromosome–containing karyotype, and in this situation the tumor may be associated with gonadoblastoma. Most dysgerminomas, however, occur in normal females who present with abdominal enlargement, a growing mass, or pain. About 10% of dysgerminomas are bilateral on gross examination and another 10% have microscopic involvement of the contralateral ovary. Association with gonadoblastoma increases the risk of bilateral involvement by dysgerminoma.

On gross examination, dysgerminomas are usually large, white to gray, lobulated masses that have no more than very focal hemorrhage or necrosis. Prominent hemorrhage, necrosis, or cystic changes are not expected and, if present,

suggest a mixed germ cell tumor. Microscopically, dysgerminomas are composed of nests and cords of primitive germ cells, with clear to pale eosinophilic cytoplasm and prominent cytoplasmic borders (Fig. 24.1). Nuclei are enlarged but are relatively uniform in size. The nuclei may be rounded or have flat sides. The nests of tumor cells are separated by bands of fibrous tissue with lymphocytes. Occasionally, noncaseating granulomas may be present. Small cysts or pseudoglandular spaces may sometimes be seen, often representing inadequate specimen fixation. Syncytiotrophoblast cells are present in about 3% of dysgerminomas and do not, in the absence of cytotrophoblast cells, indicate a mixed germ cell tumor. These tumors have been designated dysgerminoma with syncytiotrophoblastic giant cells, but have the same prognosis as dysgerminomas (2).

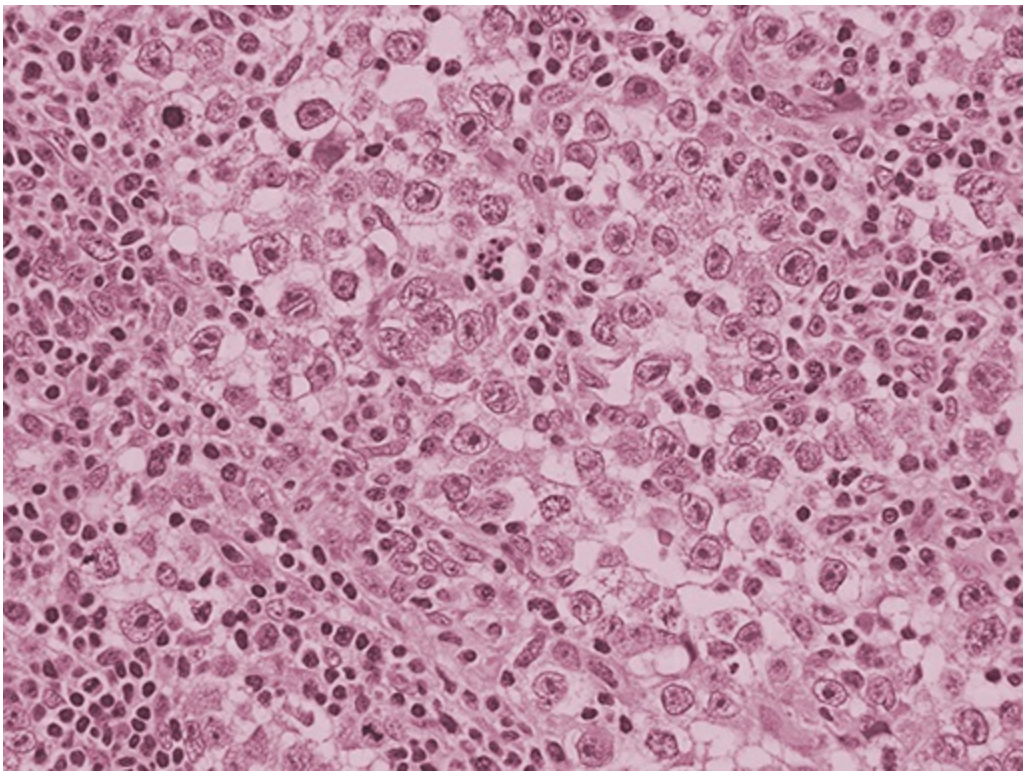

Figure 24.1 Dysgerminoma. This neoplasm has nests of cells with clear cytoplasm and enlarged hyperchromatic nuclei. Fibrous septae containing lymphocytes separate nests of tumor.

Dysgerminomas contain cytoplasmic glycogen that can be visualized using the periodic acid Schiff (PAS) stain. Membranous immunoreactivity for placenta-like alkaline phosphatase (PLAP), c-kit (CD117), and podoplanin (D2-40) is also commonly observed. The most helpful immunohistochemical stain is probably the nuclear transcription factor OCT 3/4, which is highly sensitive and specific for dysgerminoma and embryonal carcinoma as a group (3). Dysgerminomas stain negatively for CD30, whereas embryonal carcinomas are positive for CD30. In contrast to yolk sac tumor, dysgerminoma is negative for α-fetoprotein (AFP). Syncytiotrophoblast cells, if present, will display human chorionic gonadotropin (hCG) staining.

Dysgerminoma is the only OGCT that commonly displays c-kit staining. Approximately 25% to 50% of dysgerminomas harbor c-kit mutations, but the mutations do not necessarily indicate imatinib sensitivity (4-6).

Yolk Sac Tumor

Yolk sac tumors (formerly also known as endodermal sinus tumors) are the second most common malignant OGCTs, accounting for about 20% of cases. Recently, a proposal to rename the tumor as “primitive endodermal tumor” has been

made (2), but although this may more accurately represent the range of differentiation seen in these tumors, this name has not yet gained significant usage. The peak incidence of this tumor is at approximately 19 years of age, and they occur very rarely beyond age 40.

Ovarian yolk sac tumors are typically large and unilateral, although metastasis to the opposite ovary may occur. These tumors have a smooth external surface unless rupture or invasion into surrounding structures has occurred. On sectioning, these neoplasms are solid and cystic and tan to gray in color, commonly with hemorrhage and necrosis. The cut surface may appear mucoid or gelatinous. Yolk sac tumors may have many different histologic patterns. The most common microscopic pattern in primary ovarian tumors is the reticular or microcystic pattern (Fig. 24.2). The tumor has a mesh-like pattern, and it displays a network of flattened or cuboidal epithelial cells with varying degrees of atypia. The endodermal sinus (festoon) pattern contains Schiller–Duval bodies (Fig. 24.3) that have a central capillary surrounded by connective tissue and a peripheral layer of columnar cells. These structures are situated in cavities lined by yolk sac tumor cells. When present, Schiller–Duval bodies may be a helpful diagnostic feature, but they are not present in all yolk sac tumors (7).

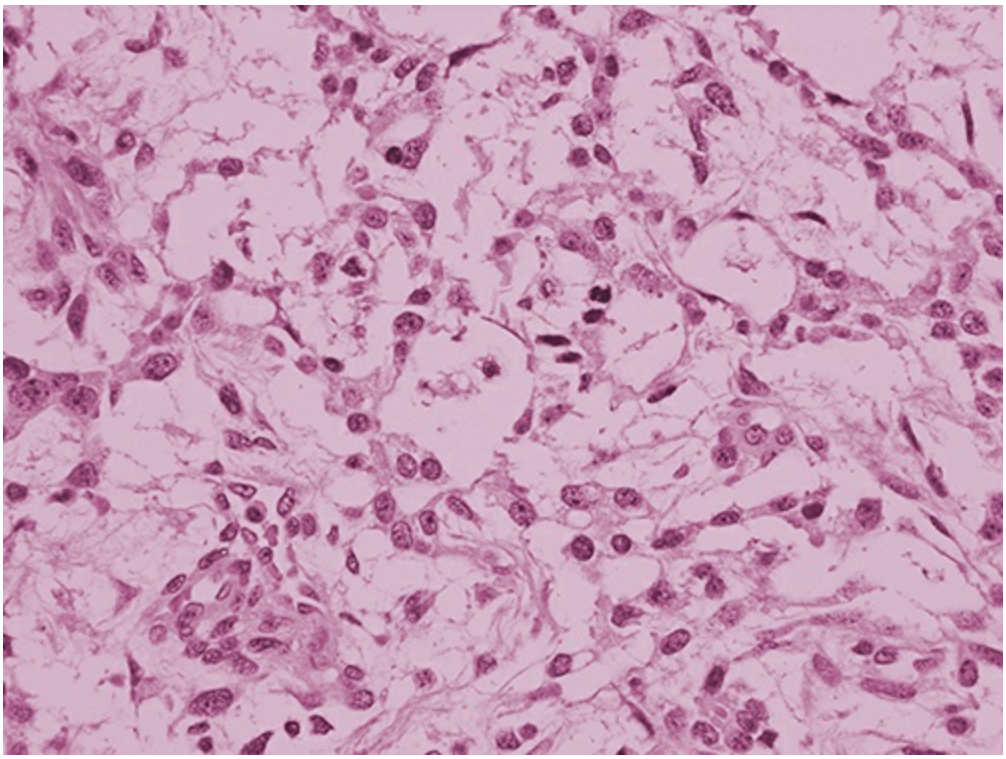

Figure 24.2 Reticular pattern of yolk sac tumor. There is a mesh-like arrangement of cuboidal tumor cells.

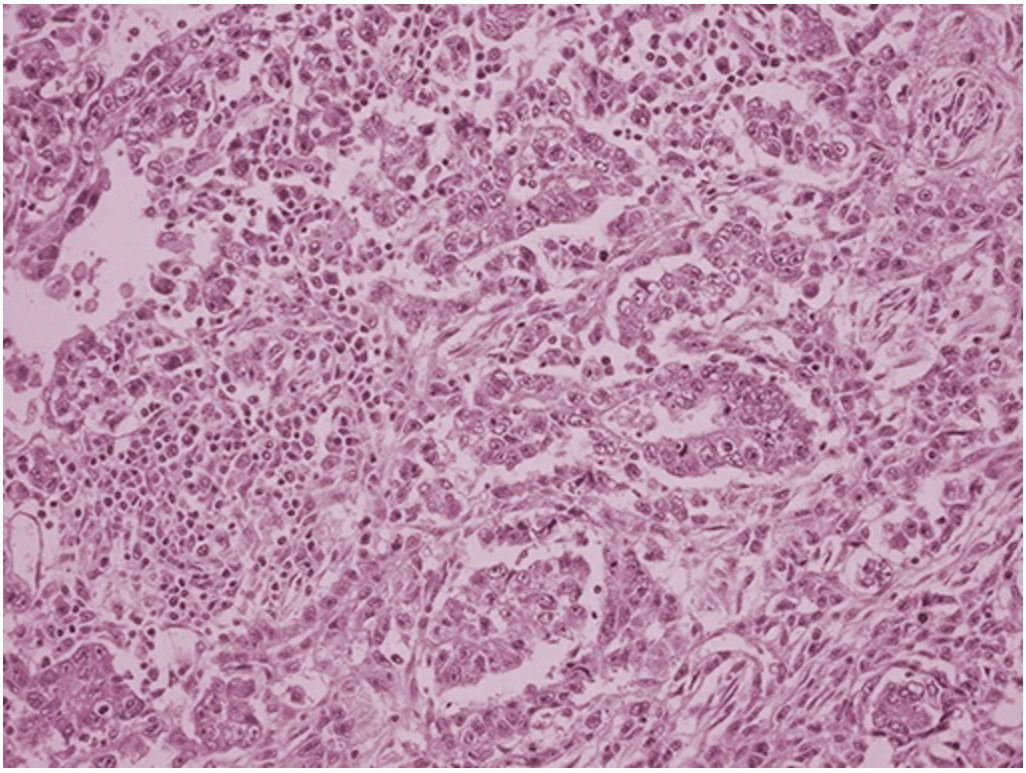

Figure 24.3 Schiller-Duval bodies, papillary structures with central blood vessels, are seen in the endodermal sinus pattern of yolk sac tumor.

Other less common patterns of yolk sac tumor include polyvesicular vitelline, enteric, solid, parietal, glandular, endometrioid-like, hepatoid, and mesenchymal patterns (8). Most patterns of yolk sac tumor may contain eosinophilic hyaline globules that are PAS positive and diastase resistant. These globules may be seen in non–germ cell tumors, and they are not specific for yolk sac tumor. They do not contain AFP. Yolk sac tumors usually show cytoplasmic staining for keratin and AFP, although the parietal pattern of yolk sac tumor typically does not contain AFP. AFP-negative parietal pattern yolk sac tumor may be seen following CT (9). Some types of yolk sac tumor, particularly glandular pattern yolk sac tumor, may closely resemble endometrioid, clear cell, or other adenocarcinomas. Age is an important and distinctive factor, because OGCTs usually occur in younger patients than epithelial ovarian tumors. Lack of staining for keratin 7 and epithelial membrane antigen supports a diagnosis of yolk sac tumor. Glypican-3 is more sensitive as a yolk sac tumor marker, but it is not entirely specific as staining is seen in embryonal carcinoma, hepatocellular carcinoma, and some other tumors. The pluripotency marker SALL4 may, because of the limited sensitivity of the AFP immunohistochemical stain, be useful in some cases, but is also expressed in other germ cell tumors and, rarely, in other tumors. Clear cell carcinoma is, perhaps, the tumor most likely to be mistaken for yolk sac tumor; these tumors were combined as “mesonephroma ovarii” prior to the 1940s (10). Very rarely, yolk sac tumor components have been seen in association with other tumors, usually ovarian endometrioid carcinomas, in older adult women, and these tumors may be less responsive to CT (10).

Embryonal Carcinoma

Embryonal carcinoma is rare in the ovary, either as pure embryonal carcinoma or as a component of a mixed germ cell tumor, in contrast to its frequent presence in testicular mixed germ cell tumors (11). When it is present, ovarian embryonal carcinoma is usually associated with yolk sac tumor in a mixed germ cell tumor. The diagnosis of ovarian embryonal carcinoma can prompt consideration of performing chromosomal analysis, because some tumors may be associated with Y chromosome–containing gonadal dysgenesis (2). On gross examination, embryonal carcinoma characteristically displays areas of hemorrhage and necrosis. Microscopically, this tumor is composed of very crowded, high nucleus-to-cytoplasm

ratio cells with enlarged, pleomorphic nuclei and with prominent nucleoli. Glandular, solid, and papillary patterns may be seen. Vascular invasion is common. Embryonal carcinoma stains for PLAP, keratin AE1/AE3, CD30, and OCT3/4 (11). In contrast to dysgerminoma, embryonal carcinoma seldom stains for c-kit. Syncytiotrophoblast cells may be present, but, if not accompanied by cytotrophoblast cells, do not indicate the presence of a choriocarcinoma component.

Choriocarcinoma

Primary nongestational ovarian choriocarcinoma is rare, either as pure choriocarcinoma or as a component of a mixed OGCT. Choriocarcinomas display abundant hemorrhage and necrosis on gross examination (Fig. 24.4). Microscopically, these neoplasms show a plexiform pattern composed of an admixture of syncytiotrophoblast and cytotrophoblast cells (Fig. 24.5). Syncytiotrophoblastic giant cells have abundant eosinophilic to amphophilic cytoplasm that contains multiple atypical, hyperchromatic nuclei. Cytotrophoblast cells are round and often have well-defined cell borders, clear to lightly eosinophilic cytoplasm, and single nuclei that are usually less darkly staining than the syncytiotrophoblast cells. Blood vessel invasion is commonly seen. Cytotrophoblast cells do not produce hCG. Syncytiotrophoblast cells are formed from cytotrophoblast cells and do produce hCG. Choriocarcinoma may also stain for cytokeratin, α-inhibin, and glypican-3. Intermediate trophoblast cells within the tumor will stain for human placental lactogen (12,13). Nongestational choriocarcinoma must be distinguished from gestational choriocarcinoma because the former has a worse prognosis and requires more aggressive therapy.

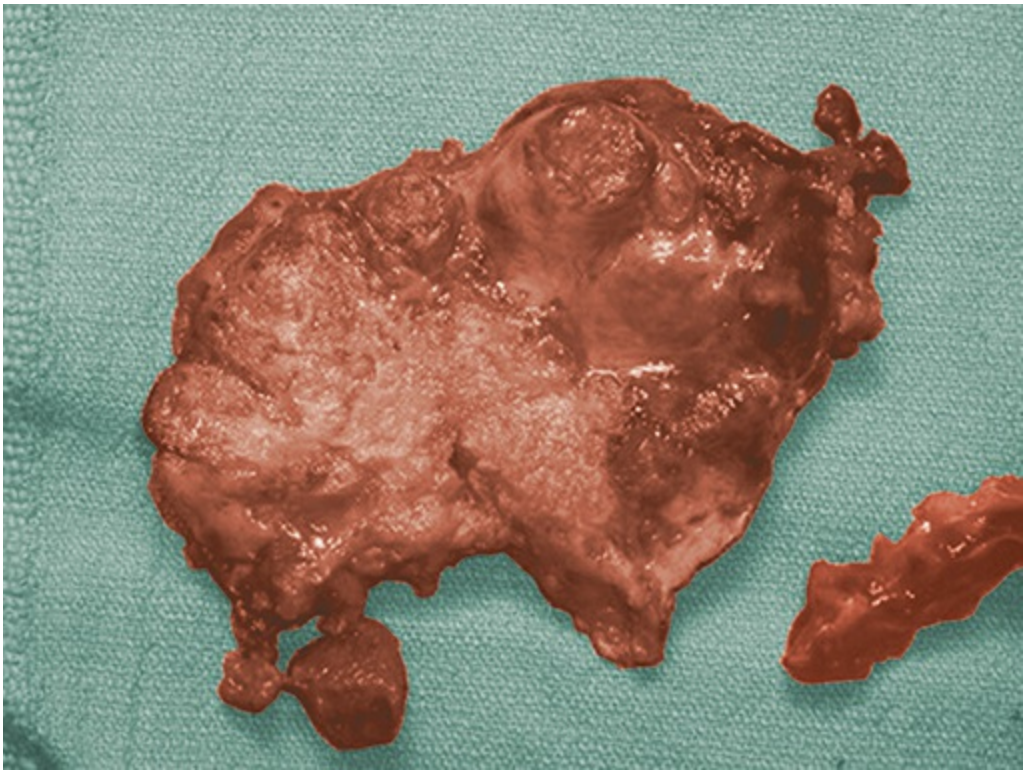

Figure 24.4 Choriocarcinoma. This ovarian neoplasm is extremely hemorrhagic.

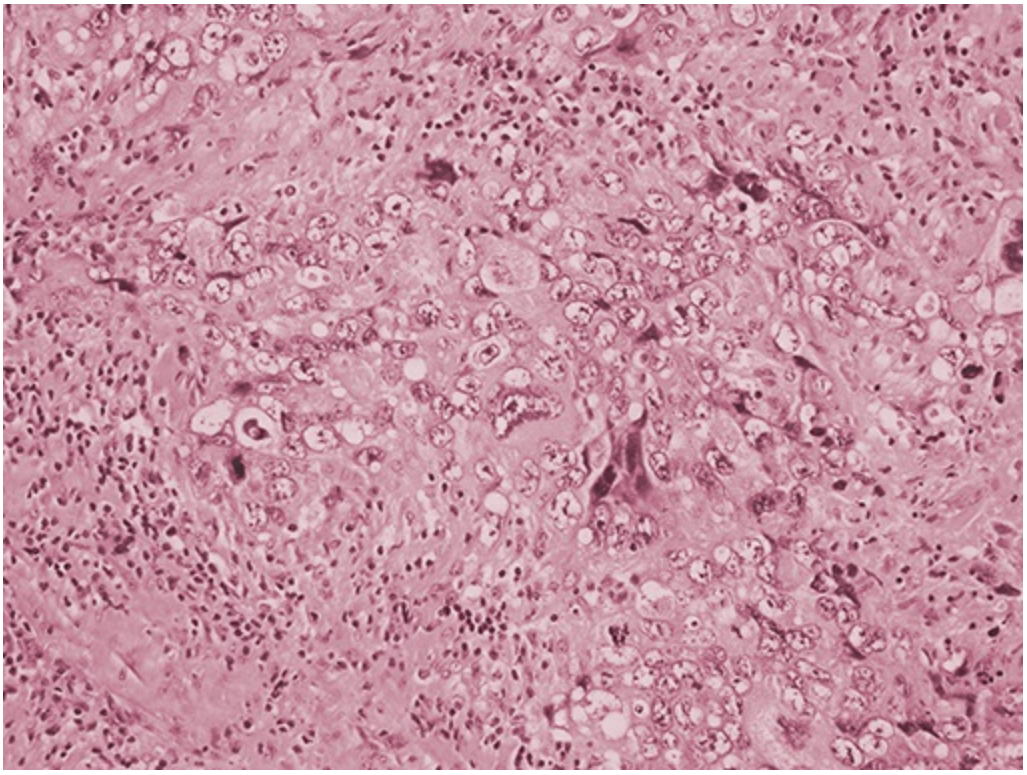

Figure 24.5 Choriocarcinoma. Syncytiotrophoblast cells have dark cytoplasm and multiple atypical nuclei. Cytotrophoblast cells have lighter cytoplasm and single atypical nuclei. Both cell types are admixed in choriocarcinoma. Areas of hemorrhage and necrosis are common.

Mixed Germ Cell Tumors

Mixed germ cell tumors of the ovary contain two or more different types of germ cell neoplasm. They are much less common in the ovary than in the testis. Malignant mixed germ cell tumors are large, unilateral neoplasms, but the gross appearance on the cut surface depends on the types of germ cell tumors present. The most common germ cell tumor element in the Armed Forces Institute of Pathology series was dysgerminoma (80%), followed by yolk sac tumor (70%), teratoma (53%), choriocarcinoma (20%), and embryonal carcinoma (13%) (2). The most frequent combination has been dysgerminoma and yolk sac tumor. Syncytiotrophoblast may occur either as a component of choriocarcinoma or as isolated cells in other germ cell tumor elements. The diagnosis and determination of prognosis of malignant mixed germ cell tumors depend on adequate tumor sampling to detect small areas of different types of germ cell tumor.

Polyembryoma was formerly considered a distinct category of germ cell tumor, but may also be considered a variant of mixed germ cell tumor in which layers of embryonal carcinoma and yolk sac tumor are closely arranged in a pattern that mimics early embryonic development. The microscopic appearance of the resulting embryoid bodies includes an embryonic disc separating a ventral space resembling yolk sac cavity and a dorsal space resembling amniotic cavity. Teratoma is also present in most cases.

Teratomas

Ovarian teratomas are germ cell tumors that typically contain tissue derived from two or three embryonic layers; however, monodermal teratomas with tissue of only one type, such as thyroid (struma ovarii), carcinoid tumor, or primitive neuroectodermal tumor, also exist. Teratomas represent approximately 95% of OGCT. Teratomas are subclassified according to whether immature neuroectodermal tissue is present (IT) or absent (mature teratoma). In contrast to other

OGCT types, ovarian pure teratomas (both mature and immature) do not contain 12p amplification (14). Ovarian teratomas that are part of a mixed germ cell tumor do, in contrast, have 12p amplification and may have isochromosome 12p, suggesting that these tumors have a different pathogenesis than pure ovarian teratomas (14,15). The pure ovarian teratomas may arise from a benign germ cell tumor in a parthenogenetic-like process (similar to pediatric testicular teratoma), whereas teratomas coexisting with a malignant OGCT component derive from malignant germ cells (similar to postpubertal testicular teratoma).

Most teratomas are mature cystic teratomas that contain differentiated tissue components such as skin, glandular epithelium, glial tissue, cartilage, and bone. Any tissue type present in adults may be represented in teratomas. The widest variety of tissue types is characteristically identified in a nodule in the wall of the cystic neoplasms. Mature cystic teratomas are benign neoplasms; however, rare examples may contain a somatic malignancy such as squamous cell carcinoma, papillary thyroid carcinoma, sarcoma, or other non–germ cell tumor. Such malignant transformation is seen in 0.2% to 1.4% of mature teratomas. A rare, recently described unusual clinical manifestation of ovarian mature teratomas is autoimmune encephalitis associated with antibodies to the *N*-methyl-d-aspartate receptor (16). The encephalitis may present with psychiatric symptoms and is typically responsive to surgical removal of the teratoma.

ITs in adult women, in contrast to mature cystic teratomas, are uncommon tumors. They represent about 3% of all ovarian teratomas, but ITs are the third most common form of malignant OGCTs. Most immature ovarian teratomas are unilateral neoplasms. ITs are predominantly solid tumors, but they may contain some cystic areas. The cut surface of ITs is soft and fleshy or encephaloid in appearance (Fig. 24.6). Areas of hemorrhage and necrosis are common. Microscopically, these tumors contain a variety of mature and immature tissue components. The immature elements almost always consist of immature neural tissue in the form of small round blue cells focally organized into rosettes and tubules (Fig. 24.7).

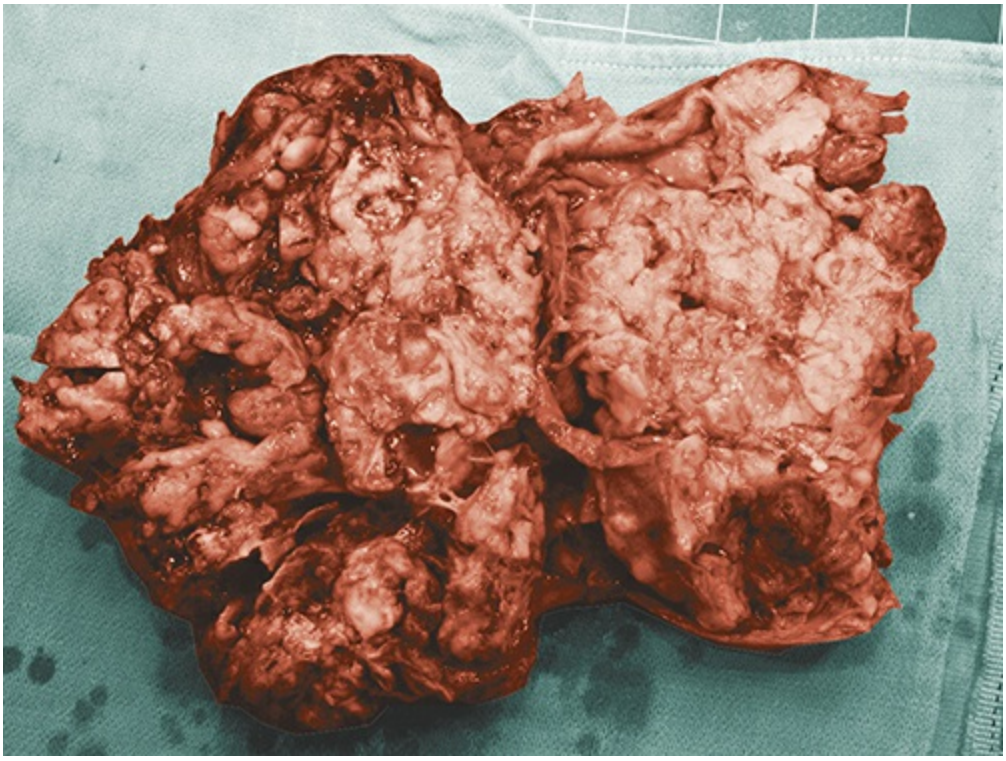

Figure 24.6 Ovarian immature teratoma. The neoplasm is predominantly solid and has a soft, encephaloid appearance.

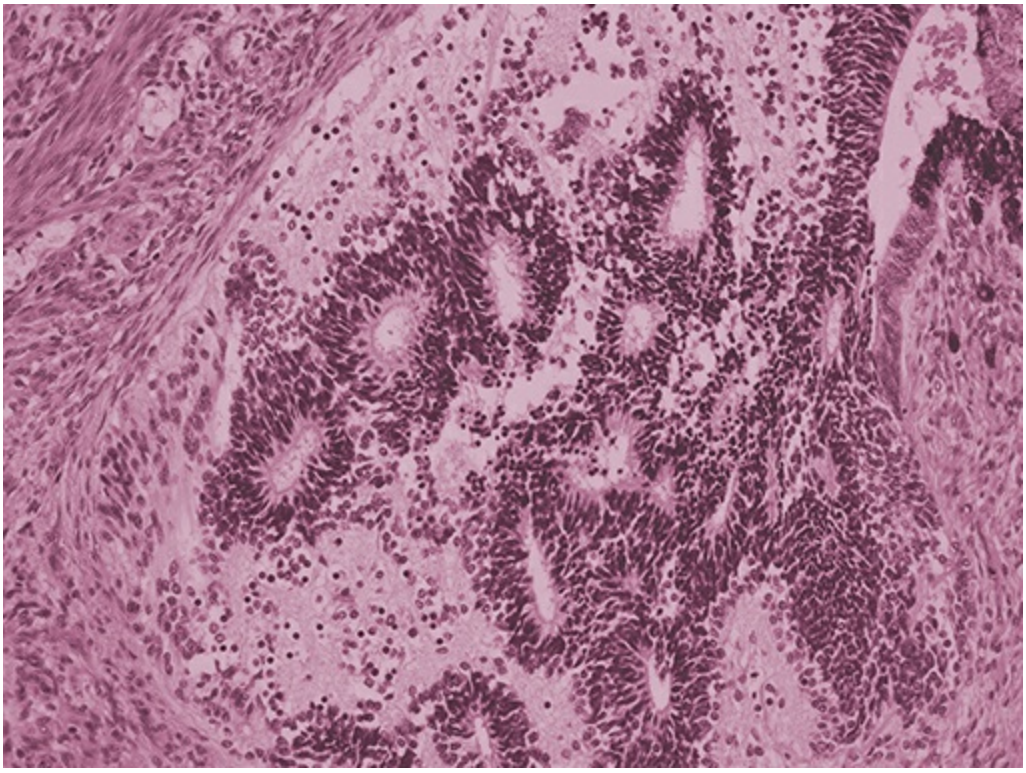

Figure 24.7 Ovarian immature teratoma. Immature neural tissue forms tubules.

There is a correlation between disease prognosis and the degree of immaturity in the teratoma. The three-tiered grading system is still most often used (1). Grade 1 ITs display some immaturity, but the immature neural tissue does not exceed, in aggregate, the area of one low-power field (40× total magnification) in any slide. Grade 2 ITs contain immature neural tissue in one to three low-power fields in any slide. Grade 3 ITs contain immature neural tissue in greater than three low-power fields in at least one slide. Some authors prefer classifying ITs as either low (grade 1)- or high (grades 2 and 3)-grade teratomas. Overgrowth of immature neuroectodermal tissue in an extensive, confluent mass represents primitive neuroectodermal tumor that has a poor prognosis. In patients whose neoplasm has disseminated beyond the ovary, the grade of the tumor metastasis is important in predicting survival and determining treatment.

Occasionally, patients may have peritoneal implants that contain only mature glial tissue (gliomatosis peritonei), but genetic data suggest that these mature glial implants may represent a metaplastic phenomenon rather than actual tumor implants (2). The behavior of gliomatosis peritonei is typically benign, although they may rarely progress to a high-grade glioma. It is extremely important to sample peritoneal disease thoroughly in order to identify foci of IT.

Molecular Characteristics

Biologically, OGCTs, like testis cancer, are derived from primordial germ cells, which undergo defective meiosis. Karyotypic abnormalities are common and include aneuploidy or chromosomal rearrangements (17). In contrast, benign teratomas commonly have a normal karyotype. One report notes chromosomal abnormalities in 7% of mature teratomas (14,15). Analysis of centromeric heteromorphism suggests that 65% to 70% of benign teratomas result from a post–meiosis I type error (homozygotes), whereas the remaining 30% to 35% are caused by defective meiosis I, as demonstrated by heterozygosity of centromeric markers (14). Among malignant OGCTs, aneuploidy and chromosomal translocations or truncations similar to those encountered in testicular carcinoma have been widely reported (17,18). The presence of an isochromosome 12p (i12p) has been noted in ovarian tumors (19), albeit less commonly than in testis cancer. Gains of 12p material may be present in 77% of dysgerminomas and lower percentages of other malignant OGCTs. Other chromosomal aberrations such as loss or gain in chromosomes 1, 11, 12, 16, and X can be identified (20).

The association between dysgerminoma and dysgenetic gonads is well recognized and should be managed accordingly, as will be discussed. MicroRNAs from the *miR-371-373* and *miR-302* clusters are overexpressed in all germ cell tumors, anecdotally correlate with disease burden, and are promising candidate biomarkers for disease monitoring and diagnosis (21). Additionally, *KIT* gene mutations appear to be amplified in dysgerminomas and may represent a potential therapeutic target (6). Other mutations in dysgerminomas have been occasionally identified including *DICER1*, *TP53*, and *KRAS* (4). Protein expression and gene mutation studies of OGCT have recently been reviewed, and overexpression of *POU5F1*, *KIT*, *NANOG*, *PDPN*, and *SOX2* is notable among the frequently overexpressed genes (4).

CLINICAL FEATURES

Malignant germ cell tumors of the ovary occur mainly in girls and young women. In the clinical series reported from the M.D. Anderson Cancer Center (MDACC), the age of the patients ranged from 6 to 40 years, with a median age of 16 to 20 years, depending on the histologic type (22). A recent evaluation of the National Cancer Institute's Surveillance, Epidemiology, and End Results (SEER) database shows a median age at diagnosis of 22 years (range: 0 to 93 years), with 91% of patients being less than 40 years at diagnosis (23). There are ethnic and racial differences in the incidence of germ cell tumors, with increased incidence of OGCTs among pediatric black females compared with black males and among Hispanic girls aged 10 to 19 years, as compared with non-Hispanics (24). Interestingly, a case–cohort study from the Children Oncology Group, including 274 cases (195 OGCTs and 79 testicular cancers), showed that a family history of cancer was inversely correlated with the risk of developing germ cell tumors (25).

Signs and symptoms in these patients are rather consistent. The combination of abdominal pain associated with a palpable pelvic-abdominal mass is present in approximately 85% of patients (26-28). Ten percent of patients present with acute abdominal pain, usually caused by cyst/tumor rupture, hemorrhage, or ovarian torsion. This finding is somewhat more common in patients with endodermal sinus tumor or mixed germ cell tumors and is frequently misdiagnosed as acute appendicitis. Less common signs and symptoms include abdominal distention (35%), fever (10%), and vaginal bleeding (10%). A few patients exhibit isosexual precocity, because of hCG production by tumor cells.

In a small percentage of cases, OGCTs occur during pregnancy or in the immediate postpartum period (27). In the series reported by Gordon (29), 20 of 158 patients with dysgerminoma were diagnosed during pregnancy or after delivery. Nondysgerminomatous ovarian tumors occur less frequently during pregnancy, but rare cases have been reported (30-33). Marked increase in AFP heralds the presence of a germ cell tumor with yolk sac component. By and large, patients with OGCTs diagnosed during pregnancy can be treated successfully, without compromising the health of the fetus. Surgical resection of tumors and CT have been performed safely in mid- and third trimesters. However, rapid disease progression and/or pregnancy termination/miscarriage have been recorded, especially for nondysgerminomatous tumors (34).

Many germ cell tumors possess the unique property of producing biologic markers that are detectable in serum. The development of specific and sensitive radioimmunoassay techniques to measure hCG and AFP led to dramatic improvements in patient monitoring. Serial measurements of serum markers aid the diagnosis and, more importantly, are useful for monitoring response to treatment and detection of subclinical recurrences. Table 24.1 illustrates typical findings in the sera of patients with various tumor histologic types. Endodermal sinus tumor and choriocarcinoma are prototypes for AFP and hCG production, respectively. Embryonal carcinoma can secrete both hCG and AFP, but most commonly produces hCG. Mixed tumors may produce either, both, or none of the markers, depending on the type and quantity of elements present. Dysgerminoma is commonly devoid of hormonal production, although a small percentage of tumors produce low levels of hCG, if multinucleated syncytiotrophoblastic giant cells are present. An elevated level of AFP or high level of hCG (>100 units/mL) denotes the presence of tumor elements other than dysgerminoma. Therapy should be adjusted accordingly (see Dysgerminoma section). Although ITs are associated with negative markers, a few tumors can produce AFP. A third tumor marker is lactic dehydrogenase (LDH), which is frequently and nonspecifically elevated in patients with OGCTs. Unfortunately, it is less specific than hCG or AFP, which limits its usefulness. CA-125 also can be

nonspecifically elevated in patients with OGCTs (35). Age over 40 to 45 years, stage greater than I, yolk sac tumor histology, and treatment outside a referral center have been identified as prognostic factors that affect survival (23,36).

TABLE 24.1 Serum Tumor Markers in Malignant Germ Cell Tumors of the Ovary

Histology	AFP	hCG
Dysgerminoma	−	±
Endodermal sinus tumor	+	−
Immature teratoma	±	−
Mixed germ cell tumor	±	±
Choriocarcinoma	−	+
Embryonal carcinoma	±	+

AFP, α-fetoprotein; hCG, human chorionic gonadotropin.

SURGERY

Operative Findings

Malignant germ cell tumors of the ovary tend to be quite large. In the MDACC series, these tumors ranged in size from 7 to 40 cm, with a median size of 16 cm (26). Predominance of right-sided over left-sided involvement was noted. Bilaterality of tumor involvement (especially true stage IB disease) is exceedingly rare, except for dysgerminoma. Bilateral involvement occurs in 10% to 15% of dysgerminoma patients (29,37-40). For nondysgerminomatous tumors, bilateral involvement signifies either advanced disease with metastatic spread to the contralateral ovary or the presence of a mixed germ cell tumor with prominent dysgerminoma component. Ascites may be noted in approximately 20% of cases. Rupture of tumors, either preoperatively or intraoperatively, occurs in approximately 20% of cases. Torsion of the ovarian pedicle was documented in 5% of patients in the MDACC series.

Benign cystic teratoma is associated with malignant germ cell tumors in 5% to 10% of cases. These coexistent teratomas may occur in the ipsilateral ovary, in the contralateral ovary, or bilaterally. Likewise, a preexisting gonadoblastoma may be noted in association with dysgerminoma and dysgenetic gonads related to a 46XY karyotype (20,41-43). Malignant germ cell tumors generally spread along the peritoneal surface or through lymphatic dissemination. Although the relative frequency of these two principal mechanisms of dissemination is difficult to discern, it is generally accepted that these neoplasms more commonly metastasize to lymph nodes than epithelial tumors. The high prevalence of inadequate staging procedures makes the true incidence of lymph node involvement uncertain. It is our impression that although still uncommon, malignant OGCTs have a somewhat greater predilection than epithelial tumors to metastasize hematogenously to the parenchyma of the liver or lung. The stage distribution is also very different from that of epithelial tumors. In most large series, approximately 60% to 70% of tumors will be stage I (29). The next most common stage is stage III, accounting for 25% to 30% of tumors. Stages II and IV are relatively uncommon.

Extent of Primary Surgery

The initial treatment approach for a patient suspected of having a malignant OGCT is surgery, both for diagnosis and for therapy. The route of surgery, whether through a vertical midline incision or through a minimally invasive approach, should

be determined based on surgical experience with the intent to avoid tumor rupture (NCCN guidelines). A thorough determination of the disease extent by inspection and palpation should be made. If the disease appears confined to one or both ovaries, comprehensive staging biopsies should be performed in adult patients.

The type of primary operative procedure depends on the surgical findings. Because many of these patients are young women, for whom preservation of fertility is a priority, minimizing the surgical resection while ensuring removal of tumor bulk must be thoughtfully balanced. As noted previously, bilateral ovarian involvement is rare, except for the case of pure dysgerminoma. Bilateral involvement may be found in cases of advanced disease (stages II to IV), in which there is metastasis from one ovary to the opposite gonad, or in cases of mixed germ cell tumors with a dysgerminoma component. Therefore, fertility-sparing unilateral salpingo-oophorectomy with preservation of the contralateral ovary and of the uterus can be performed in most patients. Ovarian cystectomy as the sole treatment is not recommended (44-46). If the contralateral ovary appears grossly normal on careful inspection, it should be left undisturbed. However, in the case of pure dysgerminoma, biopsy may be considered, because occult or microscopic tumor involvement occurs in a small percentage of patients. Unnecessary biopsy, however, may result in future infertility because of peritoneal adhesions or ovarian failure. If the contralateral ovary appears abnormally enlarged, a biopsy or ovarian cystectomy should be performed. If frozen examination reveals a dysgenetic gonad or if there are clinical indications suggesting a hermaphrodite phenotype, then bilateral salpingo-oophorectomy is indicated. However, it is difficult to establish this diagnosis on frozen section. This determination should preferably be made by finding the karyotype preoperatively. If benign cystic teratoma is found in the contralateral ovary, an event that can occur in 5% to 10% of patients, then contralateral ovarian cystectomy with preservation of remaining normal ovarian tissue is recommended.

An important problem, albeit rare, is bilateral gonadal involvement in a patient who desires to preserve fertility and who is a candidate for postoperative CT. There are no data regarding the ability of CT to eradicate a primary ovarian tumor. In testis cancer, there are presumptive data suggesting that tumor may persist after CT in the gonad and that the testis may be a drug sanctuary. In exceptional situations, it may be reasonable to preserve an involved ovary in a patient who will be receiving CT. However, it is conceivable that ovarian preservation could increase the risk for recurrence in these selected cases. The decision to preserve an involved ovary is difficult and must be made carefully considering patients' wishes.

The advent of *in vitro* fertilization technology also has an impact on operative management (47). Convention has dictated that if a bilateral salpingo-oophorectomy is necessary, a hysterectomy should also be performed. However, with current assisted reproduction technologies (ARTs) involving donor oocyte and hormonal support, a woman without ovaries could potentially sustain a normal intrauterine pregnancy. Similarly, if the uterus and one ovary are resected because of tumor involvement, current techniques provide the opportunity for oocyte retrieval from the remaining ovary, *in vitro* fertilization with sperm from her male partner, and embryo implantation into a surrogate's uterus. As the field of ART is evolving, traditional guidelines concerning surgical treatment in young patients with gynecologic tumors have to be thoughtfully adapted to individual circumstances.

Surgical Staging

Surgical staging remains the standard of care in adult patients to determine the extent of disease, provide prognostic information, and guide postoperative management. A meticulous approach is important for every patient, but it is of critical importance for those patients with early clinical disease to detect the presence of occult or microscopic metastases and provide CT in those situations. Staging of OGCTs follows the same principles applicable to epithelial ovarian tumors, as described by the International Federation of Gynecologists and Obstetricians (see Table 24.2). Proper staging procedures consist of the following:

TABLE 24.2 FIGO Staging of Ovarian Germ Cell Tumors

Stage	Description
I	Tumor limited to ovaries

IA	Tumor limited to one ovary, no ascites, intact capsule
IB	Tumor limited to both ovaries, no ascites, intact capsule
IC	Tumor either stage IA or IB, but with ascites present containing malignant cells or with ovarian capsule involvement or rupture or with positive peritoneal washings
II	Tumor involving one or both ovaries with extension to the pelvis
IIA	Extension to uterus or tubes
IIB	Involvement of both ovaries with pelvic extension
IIC	Tumor either stage IIA or IIB, but with ascites present containing malignant cells or with ovarian capsule involvement or rupture or with positive peritoneal washings
III	Tumor involving one or both ovaries with tumor implants outside the pelvis or with positive retroperitoneal or inguinal lymph nodes. Superficial liver metastases qualify as stage III
IIIA	Tumor limited to the pelvis with negative nodes but with microscopic seeding of the abdominal peritoneal surface
IIIB	Negative nodes, tumor implants in the abdominal cavity <2 cm
IIIC	Positive nodes or tumor implants in the abdominal cavity >2 cm
IV	Distant metastases present

FIGO, International Federation of Gynecologists and Obstetricians.

1. Although a transverse incision is cosmetically superior, a vertical midline incision is usually necessary for adequate exposure, appropriate staging biopsies, and resection of large pelvic tumors or metastatic disease in the upper abdomen. Minimally invasive surgical approaches for gynecologic cancer staging have become widely accepted, and although trials specific to this approach for malignant OGCTs have not been performed, this approach is considered preferable to open surgery when the same surgical outcomes can be obtained.
2. Ascites, if present, should be evacuated and submitted for cytologic analysis. If no peritoneal fluid is noted, cytologic washings of the pelvis and bilateral paracolic gutters should be performed prior to manipulation of the intraperitoneal contents.
3. The entire peritoneal cavity and its structures should be carefully inspected and palpated in a methodical manner. We generally prefer to start with the subphrenic spaces and move caudad toward the pelvis. The subdiaphragmatic areas, omentum, colon, all peritoneal surfaces, the entire retroperitoneum, and small intestinal serosa and mesentery should be evaluated. Any suspicious areas should be submitted for biopsy or excised.
4. Next, the primary ovarian tumor and pelvis should be examined. Both ovaries should be carefully assessed for size, presence of obvious tumor involvement, capsular rupture, external excrescences, or adherence to surrounding structures.
5. If the disease seems to be limited to the ovary or localized to the pelvis, then random staging biopsies of structures at risk should be performed. These sites should include the omentum (with generous biopsies from multiple areas) and the peritoneal surfaces of the following sites: bilateral paracolic gutters, cul-de-sac, lateral pelvic walls, vesicouterine reflection, and subdiaphragmatic areas. Any adhesions should also be generously sampled.
6. The paraaortic and bilateral pelvic lymph node–bearing areas should be carefully palpated. Any suspicious nodes should be excised or sampled. If no suspicious areas are detected,

these areas should be sampled. There is no evidence that a complete paraaortic and/or pelvic lymphadenectomy is advantageous.

7. If obvious gross metastatic disease is present, it should be excised if feasible, or at least sampled to document disease extent. The concept of cytoreductive surgery is discussed below. There are insufficient data at present to support the use of minimally invasive surgery in the setting of metastatic disease.

Most patients receive initial surgery without the care of a gynecologic oncologist and do not undergo comprehensive staging. On referral of such a patient to a university or a tertiary care center, the oncologist is faced with the dilemma of inadequate staging information. In such cases, postoperative studies including CT scan of the abdomen are recommended. If histopathologic and available information from the first surgery clearly indicates the use of systemic CT, reexploration for obtaining staging information is inadvisable. Reoperation for comprehensive staging may be appropriate for patients who would undergo surveillance and forego CT in the event of negative comprehensive staging. This is an area of current debate, because some patients may be candidates for surveillance, using salvage CT in the event of recurrent disease.

Cytoreductive Surgery

If widely spread tumor is encountered at initial surgery, it is recommended that the same principles concerning cytoreductive surgery applied in the surgical management of advanced epithelial ovarian cancer be followed. Specifically, as much tumor as is technically feasible and safe should be resected. However, because of their rarity, there is scant information in the literature on the impact of cytoreductive surgery of malignant germ cell tumors. In a study of the Gynecologic Oncology Group (GOG), Slayton et al. (48) found that 15 of 54 (28%) patients with completely resected disease at primary surgery failed CT with a combination of vincristine, dactinomycin, and cyclophosphamide (VAC), as opposed to 15 of 22 (68%) patients with incompletely resected disease treated with the same regimen. Furthermore, a higher percentage of patients with bulky postoperative residual disease (82%) failed CT compared with those with minimal residual disease (55%). In a subsequent GOG study reported by Williams, patients received the combination regimen of cisplatin, vinblastine, and bleomycin (PVB). In this study, patients with nondysgerminomatous tumors and clinically nonmeasurable disease after surgery had a greater likelihood of remaining progression free than those with measurable disease (65% vs. 34%) (49). In addition, patients who had been surgically debulked to optimal disease had an outcome intermediate between patients with suboptimal disease and those with optimal disease without debulking.

Even with epithelial tumors, the relative influence of tumor biology, surgical skill, and aggressiveness remains uncertain. Germ cell tumors, especially dysgerminomas, are generally much more chemosensitive than epithelial ovarian tumors. Therefore, aggressive resection of metastatic disease in these cases, especially resection of bulky retroperitoneal nodes, is questionable. The surgeon must exercise thoughtful and mature intraoperative judgment when encountering such situations, carefully weighing the risks of cytoreductive maneuvers in the setting of chemosensitive tumors. There is no substitute for surgical experience and a clear understanding of the biologic behavior of these neoplasms. Even in the face of extensive metastatic disease, it is possible to perform a fertility-sparing procedure with preservation of a normal contralateral ovary, though outcomes data are lacking.

The value of secondary cytoreductive surgery in the management of OGCTs is even less clear than that of primary cytoreductive surgery. Although secondary cytoreduction is of questionable benefit for patients with refractory epithelial ovarian cancer (50,51), germ cell tumors are relatively more chemosensitive than epithelial tumors and are more likely to respond to second-line therapy. Therefore, if a patient has an isolated focus of persistent tumor after first-line CT in an area such as the lung, liver, retroperitoneum, or brain, then surgical extirpation should be considered before changing CT regimens. Although this clinical situation is extremely rare, it has been encountered in other situations involving chemosensitive tumors, such as gestational trophoblastic disease and testicular cancer.

Unlike testicular cancer, the finding of a residual mass after completion of CT is less common in patients with OGCTs

because these women are likely to have considerable tumor debulking at the time of the diagnostic surgical procedure and thus enter CT with significantly less tumor burden. At completion of CT, men with nonseminomatous tumors or seminoma may have persistent mature teratoma or desmoplastic fibrosis. In patients with bulky dysgerminoma, residual masses after CT are very likely to represent desmoplastic fibrosis. Although a number of patients with pure ovarian ITs or mixed germ cell tumors have persistent mature teratoma at the completion of CT, as documented by second-look laparotomy (52), the majority is left with multiple small peritoneal implants rather than with a dominant mass. However, it is now recognized that occasional patients who have received CT for ITs or mixed germ cell tumors containing teratoma will have bulky residual teratoma after CT. The natural history or biologic implications of these findings are not clear. In testicular cancer, patients with bulky residual teratoma may experience slow progression of tumor (53) or may develop overtly malignant tumors over time (54-57). There are similar anecdotal reports of progressive mature teratoma in OGCT patients after CT (58-60). Considering this information, it seems appropriate to resect persistent masses in patients with negative markers after CT for germ cell tumors containing IT. If viable neoplasm is found, additional CT should be considered. However, if only mature teratoma is resected, observation is generally recommended.

Second-Look Laparotomy

Since 1960, second-look laparotomy was included in the routine management of patients with epithelial ovarian cancer to assess disease status after a fixed interval of CT. This approach was extrapolated to the management of patients with OGCTs. In a review of the MDACC experience with second-look laparotomy, findings were negative in 52 of 53 patients (61). The one patient with positive findings at second-look laparotomy had an elevated AFP level prior to surgery, which accurately predicted residual disease. This patient received subsequent CT with PVB, entering prolonged remission. Of the patients with negative findings, one woman relapsed 9 months after the negative second-look surgery and subsequently died. Thirteen patients in this series had biopsy-proven evidence of residual mature teratoma (so-called “chemotherapeutic retroconversion”) at second-look laparotomy; treatment was discontinued in all patients and none developed recurrence. Thus, in this series, second-look surgery did not add prognostic information or alter the therapeutic management of patients. The role of second-look surgery is further obscured in the setting of advancement in imaging techniques (CT scanning, positron emission tomography (PET), and MRI) and in an era where tumor marker measurements are part of routine care of patients with germ cell tumors.

The GOG experience with second-look laparotomy in OGCTs has been reviewed (52). One hundred and seventeen patients who were enrolled prospectively on GOG protocols using cisplatin-based CT after initial surgical staging and cytoreduction (GOG protocols #45, 78, and 90) underwent second-look surgical procedures. Of these, 45 surgical procedures were performed in patients who received three courses of cisplatin, etoposide, and bleomycin (BEP) after complete tumor resection. In this subgroup, 38 patients had negative findings, 2 patients had IT, and 5 patients had mature teratoma. One of the patients with residual IT received further CT and one did not. Both women with residual IT and the rest of the patients remained disease free. One patient with negative second-look surgery findings subsequently relapsed and succumbed to disease. Hence, in the subgroup of patients with completely resected primary OGCTs, the benefit of second-look surgery is nil. In contrast, 72 patients inthis series treated with similar CT had advanced incompletely resected tumors before beginning adjuvant treatment. In this subgroup, 48 patients did not have teratoma elements in their primary tumor. At second-look surgery, 45 patients had no residual tumor and 3 patients displayed persistent endodermal sinus tumor or embryonal carcinoma. All three of the latter patients died despite further treatment. Five patients with negative second laparotomies recurred, of which only one was salvaged with CT. Thus, the value of second-look surgery in patients with incompletely resected germ cell tumors, not containing teratoma, is arguably minimal. However, in the subgroup of patients with incompletely resected tumors containing teratoma elements (total of 24 patients), second-look surgery had an impact on subsequent management. Of these patients, 16 were found to have mature teratoma at second look, which was bulky or progressive in 7 cases. Four additional patients were found to have residual IT. Fourteen of the total 16 patients with teratoma and 6 of the 7 women with bulky residual tumor remained disease free after surgical

resection. Therefore, although second-look laparotomy is not necessary in patients with tumor completely resected primarily or in those patients with initially incompletely resected tumor not containing teratoma, clinical benefit can be derived in those patients with incompletely resected primary tumor that contains elements of teratoma (see Table 24.3).

TABLE 24.3 Results of Second-Look Surgery in Patients Enrolled on GOG Protocols

Primary Surgery	Total Number	Positive Second Look: Progression-Free/Total Number	Negative Second Look: Progression-Free/Total Number
Completely resected tumor	45	7/7[a]	37/38
Incompletely resected tumor	24	16/20[b]	4/4
Teratoma present/teratoma absent	48	0/3[c]	41/45

[a]Five mature teratomas and two immature teratomas.

[b]Sixteen mature teratomas and four immature teratomas.

[c]Three embryonal carcinoma and yolk sac tumors.

Advances in imaging technology, including the advent of positron emission tomography (PET) scanning, may further obviate the need for surgical reexploration. Although PET scan is sensitive for detecting active (malignant) tumor, its usefulness in evaluating residual mature teratoma is more limited (62-65). A positive PET scan in the setting of a residual mass after treatment is highly indicative of viable tumor and, when used in conjunction with traditional radiographic techniques (CT scan, MRI) and tumor marker determinations, can predict relapses with accuracy (66). A recent series demonstrates that in patients with residual masses after treatment for seminoma, a positive PET scan represents strong evidence that the residual mass contains persistent tumor. In contrast, if the PET scan is negative, residual masses are unlikely to contain active tumor. The specificity of the PET scan in this situation was 100%, the sensitivity was 80%, and the positive and negative predictive values were 100% and 95%, respectively (67). Although studies using PET scanning in OGCT are scant (68,69), the concepts are very similar and can be extrapolated from the testis cancer literature.

CHEMOTHERAPY FOR OGCTS

Chemotherapy: From VAC to PEB

One of the great triumphs of cancer treatment in the 1970s and 1980s has been the development of effective CT for testicular cancer (70,71). The lessons learned from prospective, randomized trials in testicular cancer were subsequently applied to OGCTs. Presently, the overwhelming majority of patients with OGCTs survive their disease with the judicious use of surgery and cisplatin-based combination CT. There are many similarities, but a few important differences between testicular cancer and OGCTs.

Historically, the first regimens used successfully for women with OGCTs were *VAC* or VAC-type regimens. Such treatments had curative potential, especially for early-stage disease. However, among patients with advanced disease, the number of long-term survivors after VAC therapy remained under 50%. In the series reported from the MDACC, although

86% of patients with stage I tumors were cured with VAC, the efficacy of the regimen was significantly lower for patients with advanced disease (22). Only 57% of stage II patients and 50% of stage III patients achieved long-term control. The two patients with stage IV tumors in this series succumbed to the disease. Similarly, in a GOG study, only 7 out of 22 patients with incompletely resected OGCTs achieved long-term disease control after VAC, as compared with 39 of 54 patients with completely resected tumors (72). In that report, 11 of 15 patients with stage III and both patients with stage IV disease progressed within 12 months. These data suggest that VAC CT was insufficient for the treatment of advanced stage and/or incompletely resected OGCTs.

Because of the experience gained from the treatment of testicular tumors demonstrating the superiority of cisplatin-based regimens, new platinum-based regimens were tested in patients with OGCTs. Gershenson reported the efficacy of PVB in a small series of patients treated at the MDACC (73). Among 15 patients, 7 received PVB in the adjuvant setting and 8 received the combination at the time of recurrence. Six of seven patients treated with PVB upfront became long-term survivors. Among them, three women had optimally debulked stage III disease.

Subsequently, the PVB combination was evaluated prospectively in GOG protocol #45 (49). In this study, 47 of 89 patients with nondysgerminomatous ovarian tumors (53%) were disease free, with a median follow-up of 52 months. The latest treatment failure occurred at 28 months. Eight other patients had durable remissions with second-line therapy and a few other patients had nonprogressive or slowly progressive IT. Thus, the 4-year overall survival (OS) was approximately 70%. Of note, 29% of patients enrolled in this trial had received prior radiation or CT, which might have negatively affected the overall outcome. As discussed previously, patients who were debulked to optimal disease fared better than those who were not. Histologic type and marker elevation before treatment were not associated with adverse outcome. However, even among patients with nonmeasurable and presumably small volume disease, and without prior treatment, 8 of 30 patients treated with PVB ultimately failed.

In testicular cancer, subsequent experience has documented that etoposide is at least equivalent to vinblastine and produces improved survival in patients with high tumor volume (71). Furthermore, the use of etoposide in place of vinblastine led to reduced neurologic toxicity, abdominal pain, and constipation. The latter two adverse effects are particularly important for patients with OGCTs, because many would have had recent abdominal surgery. These observations led to the evaluation of the combination of BEP (Table 24.4) in patients with OGCTs. In a series from the MDACC, long-term remissions were recorded in 25 of 26 patients treated with BEP (74). The only patient who succumbed to disease had been noncompliant with treatment, monitoring, and follow-up. In this series, four patients with measurable disease after surgery had complete remissions after BEP treatment. This led to a prospective GOG study evaluating BEP in patients with OGCTs (75). The regimen was highly effective, 91 of 93 enrolled patients being free of disease at follow-up. On the basis of these data, although BEP and VAC have not been prospectively compared, BEP emerged as the preferred regimen for patients with OGCTs. The inclusion of cisplatin in the treatment of ovarian tumors resulted indisputably in an improvement in survival and disease control, as shown by the results of GOG studies, as well as by other clinical series (76-78). These results of therapy are summarized in Table 24.5.

TABLE 24.4 The BEP Regimen[a]

Cisplatin	20 mg/m^2 days 1 - 5
Etoposide (VP-16)	100 mg/m^2 days 1 - 5
Bleomycin	30 units IV weekly

BEP, bleomycin, etoposide, and cisplatin.

TABLE 24.5 Adjuvant Chemotherapy

Institution	Regimen	Progression Free/Total (%)
GOG (75)	BEP	89/93 (94)
Australia (77)	Multiple	9/10 (88)

Hospital 12 de Octubre (76)	PVB or BEP	9/9 (98)
M.D. Anderson (73)	PVB	4/4 (98)
M.D. Anderson (74)	BEP	20/20 (98)

BEP, cisplatin, etoposide, bleomycin; GOG, Gynecologic Oncology Group; PVB, cisplatin, vinblastine, bleomycin.

Differences in Outcome for Patients with Completely Resected Tumors versus Advanced Stage Disease

It is clear that several prognostic factors impact the outcome of patients with OGCTs and that there are important differences between testicular cancer and OGCTs. Debulking surgery plays a central role in the management of ovarian tumors, but has a less important role in testicular cancer. In the hands of an experienced surgeon, the majority of women with ovarian tumors are debulked to minimal and often clinically undetectable disease before starting CT. Therefore, unlike patients with testicular cancer, most women who are candidates for CT have minimal or no residual disease. However, even in this circumstance, there seems to be little doubt that adjuvant therapy is appropriate in the majority of cases. The anticipated risk of relapse with surgery alone in patients with advanced disease is as high as 75% to 80%. Particularly, patients with embryonal carcinoma, endodermal sinus tumors, and mixed tumors containing these elements are considered to be at very high risk of recurrence without postoperative therapy. This risk can be minimized by the use of adjuvant CT. In GOG protocol #78, 50 of 51 patients with completely resected OGCTs remained free of disease when three cycles of BEP were given adjuvantly. Other studies using cisplatin-based therapy have given similar results (Table 24.6). The recommended treatment for most patients (with the exception of patients with grade 1 IT, or stage IA dysgerminoma) is adjuvant CT with three courses of BEP. Virtually all patients with early-stage or completely resected disease will survive after careful surgical staging and cisplatin-based adjuvant CT. More recently, clinical series and observations are beginning to suggest that surveillance with careful follow-up after surgery may be an acceptable alternative for carefully selected patients, as discussed below. Given the fact that surgery followed by CT is curative for most patients, this course of action should be taken only after very careful consideration. Further studies are needed in this area.

TABLE 24.6 Chemotherapy of Advanced Disease

Institution	Regimen	Progression Free/Total (%)
GOG (49)	PVB	47/89 (52)
Australia (77)	Multiple	42/46 (89)
Hospital 12 de Octubre (76)	PVB or BEP	15/19 (78)
M.D. Anderson (73)	PVB	7/11 (63)
M.D. Anderson (74)	BEP	5/6 (82)

BEP, bleomycin, etoposide, and cisplatin; GOG, Gynecologic Oncology Group; PVB, cisplatin, vinblastine, bleomycin.

In contrast, most clinical series have shown worse clinical outcome for patients with metastatic disease or with incompletely resected tumors (see Table 24.7). Current clinical trials in testicular cancer separate patients with small tumor volume and a resultant excellent prognosis from those with bulky tumor or liver and brain involvement (79). Patients in the former group are usually complete responders to CT and long-term survivors, whereas only about 50% to 60% of the latter patients are cured. Hence, clinical trials for patients with good prognostic factors investigate shorter or less toxic CT aimed at minimizing toxicity (80), while preserving efficacy. In contrast, clinical trials for patients with high-risk disease have evaluated more intensive CT regimens with the goal of improving the likelihood of cure (81,82). For instance, high-dose chemotherapy (HDCT) with stem cell rescue was tested for patients with high-risk testicular cancer in a multi-institutional clinical protocol (ECOG protocol 3894). Patients considered to have high risk for relapse were randomized to

receive four cycles of BEP (control arm) versus two cycles of BEP followed by HDCT with autologous stem cell rescue in the form of two (tandem) courses using carboplatin, etoposide, and cyclophosphamide as a conditioning regimen (experimental arm). The 1-year durable complete response rate was 52% after BEP + HDCT and 48% after BEP alone (p = 0.53) (83). The results of the trial disproved the concept that more aggressive CT in the first-line setting improves outcome of high-risk testicular cancer patients when compared with standard-dose BEP (84).

TABLE 24.7 A Typical Antiemetic Regimen

Granisetron 1 mg IV 30 minutes prior to cisplatin daily for 5 days
Or
Ondansetron 0.15 mg/kg IV 30 minutes prior and 4 hours after cisplatin daily for 5 days
Plus
Dexamethasone 20 mg IV 30 minutes prior to cisplatin on days 1 and 2
Plus
Aprepitant 125 mg PO on day 1 and 80 mg PO on days 2 and 3, prior to cisplatin infusion

PO, by mouth.

Dependable risk stratification, similar to the one used for testicular tumors, is not currently in use for OGCTs. The only clinical prognosticators for outcome of OGCTs remain stage at diagnosis and increase in tumor marker levels (85). Whether this reflects an inherent biologic difference between OGCTs and testis cancer or merely an underestimation of tumor volume because of intraperitoneal spread is not clear. In summary, with the exception of patients with grade 1 IT or stage IA dysgerminoma, the available evidence supports that women with OGCT should receive three to four cycles of BEP CT after cytoreductive surgery. Therapy courses longer than four cycles are not supported, regardless of tumor volume.

Management of Residual or Recurrent Disease

The large majority of patients with OGCTs are cured with surgery and platinum-based CT. However, a small percentage of patients have persistent or progressive disease during treatment or recur after completion of treatment. Like in testicular cancer, these treatment failures are categorized as platinum resistant (progression during or within 4 to 6 weeks of completing treatment) or platinum sensitive (recurrence beyond 6 weeks from platinum-based therapy).

Most recurrences occur within 24 months from primary treatment, and nearly all cause specific deaths within 5 years of diagnosis (23). In a series from the MDACC, 42 treatment failures were identified among 160 patients with OGCTs treated between 1970 and 1990 (86). Treatment failure in these patients was attributed to inadequate surgery in 14 patients, inadequate radiation in 5 patients, inadequate CT in 16 patients (underdosing and noncompliance), treatment-related toxicity in 1 patient, and unidentifiable causes in 6 patients. A significant number of patients included in this series had received VAC-based CT, which accounted for the higher than expected rate of recurrence.

Given the high curability rate of OGCTs with primary treatment, the management of recurrent disease represents a complex and often difficult issue, and preferably should be performed in a specialized center. Data to guide the management of patients with recurrent OGCTs are scant and largely extrapolated from the clinical experience with testicular cancer. The single most important prognostic factor in patients with testicular cancer is whether or not they are refractory to cisplatin. The likelihood of cure with high-dose salvage therapy in patients who relapse from a complete remission after initial therapy is as high as 60% or more. On the other hand, in patients who are truly cisplatin refractory, the likelihood of long-term survival and cure is significantly less. However, up to 30% to 40% of these patients can become long-term survivors. Approximately 30% of patients with recurrent platinum-sensitive testicular cancer can be salvaged with second-line CT (vinblastine, ifosfamide, platinum) (81). High-dose therapy with carboplatin, etoposide with

or without cyclophosphamide or ifosfamide, and stem cell rescue has been shown to be highly active in this setting (87,88). Generally, in patients who are not cisplatin refractory, one course of standard-dose therapy, usually cisplatin, vinblastine, and ifosfamide, is given. If an initial response is seen, then two subsequent courses of HDCT (carboplatin and etoposide) with stem cell rescue are undertaken (89). A report from the Indiana University describes this approach among 184 patients with recurrent testicular cancer. At a median follow-up of 48 months, 116 patients were in complete remission. Remarkably, of the subgroup of 40 patients who were platinum refractory, 18 became disease free after HDCT (90). Although this approach has not been prospectively tested in women with recurrent platinum-sensitive OGCTs, because of the rarity of such patients, the concepts are very similar and support the use of high-dose therapy in this setting. A recent retrospective analysis on the use of HDCT for recurrent OGCTs at Indiana University revealed that patients with recurrent OGCTs tend to be referred late and have worse outcomes compared with their male counterparts (91). Of 13 women treated with HDCT for recurrent OGCTs, 11 had yolk sac tumors and 8 were platinum refractory. In this series, four achieved long-term survival; however, only five received HDCT as second-line therapy, the rest being referred late in the course of their disease (91). It is, therefore, important to consider early referral to a specialized center for management of recurrent disease to maximize chances of cure. An ongoing Alliance phase III clinical trial (NCT02375204) is comparing standard-dose salvage CT with paclitaxel, ifosfamide, and cisplatin versus a high-dose regimen with paclitaxel and ifosfamide followed by high-dose carboplatin and etoposide, with stem cell rescue as first salvage regimen for relapsed germ cell tumors. The results of the study will set the definitive approach for the management of recurrent germ cell tumors.

Active agents in the setting of recurrence after HDCT include ifosfamide, taxanes, gemcitabine, and oxaliplatin (92-94). In a phase II trial from the Indiana University, the combination of gemcitabine and paclitaxel induced objective responses in 10 of 31 patients who had recurred after HDCT. Of those, five patients were free of disease 2 years after treatment (94). The combination of gemcitabine and oxaliplatin induced a 46% response rate in a group of 31 patients with recurrent germ cell tumors. Over 60% of these patients were platinum resistant or refractory (95). A new class of agents with promising clinical activity includes the cyclin-dependent kinase (CDK) inhibitors. In a clinical trial including 29 patients with recurrent germ cell tumors treated with the CDK4/6 inhibitor palbociclib, the 6-month progression-free survival (PFS) was 28%, suggesting promising activity (96). Referral for treatment with investigational agents for recurrent, refractory OGCTs is appropriate.

Immediate Toxicity of Chemotherapy

Acute adverse effects of CT can be substantial, and these patients should be treated by physicians experienced in their management. About 25% of patients develop febrile neutropenic episodes during CT and require hospitalization and broad-spectrum antibiotics. Cisplatin can be associated with nephrotoxicity. This can be avoided by ensuring adequate hydration during and immediately after CT and by avoidance of aminoglycoside antibiotics. Bleomycin can cause pulmonary fibrosis. Pulmonary function testing is frequently used to follow these patients. However, the value of carbon monoxide diffusion capacity to predict early lung disease has been challenged (97). The most effective method for monitoring patients with germ cell tumors is careful physical examination of the chest. Findings of early bleomycin lung disease are a lag or diminished expansion of one hemithorax or fine bibasilar rales that do not clear with cough. These findings can be very subtle, but if present immediate discontinuation of bleomycin should be mandated. It is important to note that randomized trials in good prognosis testicular cancer have suggested that bleomycin is an important component of the treatment regimen, particularly if only three courses of therapy are given (98,99). Other randomized trials have shown that carboplatin is inferior to cisplatin and cannot be substituted for cisplatin without worsening therapeutic outcome (100,101).

Patients with advanced OGCTs should receive three to four courses of treatment given in full dose and on schedule. There is presumptive evidence in testicular cancer that the timeliness of CT may be associated with outcome. Thus, treatment is given regardless of hematologic parameters on the scheduled day of treatment. Because most patients will not

develop neutropenic fever or infection, hematopoietic growth factors are not routinely necessary (102). It is reasonable to use hematopoietic growth factors to avoid dose reductions for patients with previous episodes of neutropenic fever or in unusually ill patients who are at a higher risk of myelosuppressive complications or those who received prior radiotherapy. Modern antiemetic therapy, an example of which is shown in Table 24.7, has greatly lessened CT-induced emesis. By following these guidelines and providing supportive care as indicated, virtually all patients can be treated on schedule, in full or nearly full dose. CT-related mortality should be less than 1%. In GOG protocol #78, there were no toxic deaths among 93 patients treated. Late effects of CT are discussed below.

Immature Teratoma

The situation of patients with IT is more complex. ITs are categorized as grade 1, 2, or 3 depending on the amount of immature neuroepithelium in the tumor, based on Thurlbeck and Scully's system, which was modified by Norris (2). Our current treatment strategy for adults with ITs is based on a retrospective analysis of 58 patients, in which higher grade correlated with prognosis. Specifically, only 1 of 14 patients with grade 1 IT recurred, but there was an 18% recurrence rate for grade 2 tumors and a 70% recurrence rate for grade 3 tumors (3). These data were further informed by a report of 41 patientswith IT by Gershenson et al. (103) in which 94% of patients treated with surgery only recurred, compared with 14% of patients treated withsurgery and CT. These studies set the current standard of care for women with IT, which is surveillance for stage I grade 1 IT and adjuvant CT with three courses of BEP for all other patients (4). This recommendation has come into question based on the probable underestimation of tumor stage in the Norris report and multiple studies in the pediatric and adult population that suggest observation may be a viable approach in a subset of these patients. Although surgery followed by adjuvant therapy cures virtually all patients with localized high-grade teratoma, it is possible that the risk of relapse is sufficiently low in a defined population of well-staged patients, to warrant clinical observation with careful follow-up, such that relapsing patients would be diagnosed with small volume tumor and cured with subsequent salvage CT.

Studies supporting surgery without CT in the pediatric population include the Pediatric Oncology Group/Children's Cancer Group Intergroup Study (INT) 0106, which reported on 44 girls with completely resected ovarian IT who were observed closely without adjuvant CT. In this series, 26 patients had grade 2 or 3 IT, and 13 patients had microscopic foci of yolk sac tumor. At 4 years, the event-free survival (EFS) was 97.7% with only one recurrence, which was salvaged with BEP; the OS rate was thus 100%. The authors concluded that surgery alone is curative for children with completely resected ovarian IT (104,105). Additionally, investigators at Mount Vernon and Charing Cross Hospitals in England have observed 15 patients with stage IA tumors after initial surgical treatment (106). Of these, nine patients had grade 2 or 3 IT and six had elements of endodermal sinus tumor. There were three recurrences in this series, one of nine in the pure IT group and two of six in the mixed histology group. Two of these patients were salvaged with CT, and one patient died of pulmonary embolus. Of note is that the patient who died became pregnant 4 months after diagnosis and could not be followed adequately because of her pregnancy. Investigators at the University of Milan have also reported the clinical outcomes of 32 patients with pure ovarian IT followed prospectively (107). In this group, nine patients had grade 2 and 3 stage IA ITs and were treated with surgery and intensive surveillance. Only two recurrences were noted in this group. They consisted of one case of mature teratoma and one case of gliosis. The mature teratoma was resected, and the patient with gliosis was followed without treatment. Both patients are alive and well, and never received CT. Furthermore, among four patients with stage IC tumors treated with surgical resection and surveillance, there was one case of gliosis and one recurrence with mature tissue, which was resected (no CT). All patients are currently free of disease. Subsequently, Mann et al. (108) reported on the outcomes of 54 pediatric patients in the United Kingdom with ovarian IT after complete surgical resection and no adjuvant CT. The EFS and OS rates were 85.9% and 95.1%, respectively, also supporting primary surgical treatment for completely resected ovarian ITs in pediatric patients.

Most recently, the Malignant Germ Cell International Collaborative and the GOG published outcomes on pediatric and adult patients with ovarian ITs to establish a uniform treatment approach across all age groups (109). Of 179 patients

included (98 pediatric, 81 adult), 90 pediatric patients had surgery alone, whereas all adult patients had adjuvant CT. The 5-year EFS and OS rates were 91% and 99% among pediatric patients, and were 87% and 93% among adults, respectively. Grade was the most important risk factor for relapse, suggesting that surgery alone was sufficient for patients with grade 1 tumors across all ages and all stages. Because postoperative CT did not decrease relapses in the pediatric cohort, the authors suggest that high-grade recurrent disease in the pediatric patient is not chemosensitive. Adult patients with higher grade tumors may do well with observation alone, using CT or second surgery in the event of relapse. Although this concept is supported by evidence derived from the pediatric literature and limited information in adults, this hypothesis has not been tested prospectively and should be approached with caution until future trials inform best practice for adults.

DYSGERMINOMA

Dysgerminoma is the female equivalent of seminoma. This disease differs from its nondysgerminomatous counterparts in several respects. First, it is more likely to be localized to the ovary at the time of diagnosis (stage I). Bilateral involvement is more common, as is its spread to retroperitoneal lymph nodes. Although less relevant now than before the era of modern CT, dysgerminoma is very sensitive to radiation (29,39,110).

Observation for Stage I Tumors

Approximately 75% to 80% of dysgerminoma patients are stage I at diagnosis (38,111). In a previous era, clinical observation was deemed appropriate for women with tumors less than 10 cm and without contralateral ovarian involvement, whereas adjuvant radiotherapy (RT) was recommended for larger tumors (112). The size-based distinction was subsequently called into question (111,113), and currently observation is considered appropriate for the majority of patients with stage IA disease. In a series reported by LaPolla et al. (111), seven of nine patients with stage IA dysgerminoma followed without postoperative RT remained disease free. All but one patient had tumors greater than 10 cm. In another report, among 14 patients with stage IA dysgerminoma treated with surveillance, 5 recurred. Of those, four patients were salvaged with radiation and one was salvaged with radiation followed by CT. All stage IA patients are alive, free of disease (110). Similarly, Gordon (29) reported that the 5-year survival among 72 patients with stage IA pure dysgerminoma treated conservatively was 95%. The recurrence rate in this case series was 17%, with four deaths attributable to disease. However, in this series, salvage CT was offered to only one patient, which may explain the unfavorable outcomes. A report from Mount Vernon and the Charing Cross Hospitals quoted two relapses among nine patients with stage IA dysgerminoma treated with observation. Both were cured with salvage CT (114). A partial summary of reports' observation after surgery in stage I dysgerminoma is presented in Table 24.8.

AFIP, Armed Forces Institute of Pathology.

Currently, patients with stage IA dysgerminoma are observed after unilateral salpingo-oophorectomy, regardless of the size of the primary tumor. Careful follow-up is required, because as many as 15% to 25% of patients will experience a recurrence. However, because of the tumor's chemosensitivity, virtually all patients can be salvaged successfully at the time of recurrence, if adequate early detection of recurrent tumors is achieved.

Radiation Therapy

In the past, many stage I patients and all patients with higher stage tumors received RT (38). Radiation was delivered to the ipsilateral hemipelvis (with shielding of the contralateral ovary and the head of the femur) and to the paraaortic nodes. A single field with the upper limit at T10–T11 and the lower limit at L4–L5 level was used. For stage III retroperitoneal disease, curative RT used an additional field for mediastinum and supraclavicular nodes. In the presence of peritoneal involvement, the whole abdomen and pelvis, mediastinum, and supraclavicular nodes were irradiated. Typically, 30 Gy (7.5 to 9 Gy/week) was given as prophylactic irradiation for stage I tumors. For curative irradiation of stage III disease, 35 to 40 Gy total dose was given to the pelvis, and a boost (10 Gy) was delivered to the involved nodes. When irradiating above the diaphragm, DePalo gave 30 additional Gy 3 to 6 weeks after completion of irradiation below the diaphragm. When irradiating the entire abdominal cavity, the fields were similar to those used for epithelial tumors (112,115-117). The results of RT were excellent. DePalo et al. (38) reported that all 13 stage I patients (12 stage IA and 1 with stage IB) treated with RT were alive and free of disease, with a median follow-up of 77 months. The 5-year relapse-free survival (RFS) for 12 stage III patients was 61.4%, and the OS was 89.5%. Lawson and Adler (115) reported that 10 of 14 stage I–III patients were alive, with a median follow-up of 54 months. In this small series, there was no correlation between survival and the stage of disease or the size of the primary tumor. Others reported similar results, with overall progression-free rates varying between 70% and 90% (see Table 24.9) (39,40). However, despite the remarkable radiosensitivity of dysgerminoma, RT is rarely performed nowadays, because CT is equally or more effective, less toxic, and less likely to compromise gonadal function. Given that most patients are cured with surgery alone or surgery and CT, and the young age at the time of diagnosis, consideration should also be given to the delayed carcinogenic effects of intermediate dose radiation. Review of the SEER database shows that 10 of 70 patients (13%) who received RT for a malignant OGCT developed a second cancer, significantly higher than patients who did not receive RT (23).

Chemotherapy

Dysgerminoma is very responsive to cisplatin-based CT (74,118). Since 1984, patients with advanced dysgerminoma were eligible for GOG protocols. Patients enrolled on these studies received three to four courses of PVB or BEP. In a combined analysis, 20 patients were evaluated (119). All had stage III or IV disease and most of them had suboptimal (greater than 2 cm) residual tumor. With a median follow-up of 26 months, 19 of the 20 women were disease free. Among 11 patients with clinically measurable tumor, 10 had complete responses to CT. Fourteen patients who underwent second-look laparotomy had completely negative results. Thus, it appears that nearly all patients with advanced dysgerminoma treated with chemotherapy will be durable complete responders.

Considering that patients with stage III dysgerminoma would require extensive radiation and still carry a risk of failure and that such patients probably fare worse with subsequent CT, it is clear that these patients should be treated primarily with CT. For most, the preferred adjuvant therapy is BEP. This regimen almost invariably prevents recurrence in nondysgerminomatous tumors and certainly will do so in dysgerminoma. Most patients treated with BEP will retain fertility. An alternative regimen tested by the GOG consists of a 3-day regimen with carboplatin and etoposide. On this protocol, all 39 patients with pure dysgerminoma remained free of disease at a median follow-up of 7.8 years (120). Although highly active, this regimen is not recommended for routine use because of significantly less experience accumulated with its use and the concern that this regimen is not as effective in tumors containing nondysgerminomatous elements.

The implications of elevated hCG or AFP levels in patients with dysgerminoma should be emphasized. These tumor markers are usually increased in patients with nondysgerminomatous tumors. Therefore, AFP elevation denotes the presence of elements other than dysgerminoma, and treatment should be tailored accordingly. An elevated hCG level can be occasionally seen in pure dysgerminoma. This finding should not alter therapy, but it should prompt reexamination of the tumor specimen to determine whether syncytiotrophoblastic cells are present or if the tumor contains nondysgerminomatous elements.

In summary, the majority of dysgerminoma patients have stage I disease at diagnosis. These patients can be treated with unilateral salpingo-oophorectomy and can be observed carefully with regular pelvic examinations, abdominopelvic CT, and tumor markers including LDH. Fifteen to 25% of patients observed will experience recurrence and will require CT. In patients with more advanced disease, the risk of recurrence is significant enough to warrant adjuvant treatment. The majority of patients receive three cycles of BEP CT. Radiation might be considered as initial treatment only in unusual circumstances, such as in older patients or in those with serious concomitant illness that preclude the use of systemic CT.

LATE EFFECTS OF TREATMENT

As the prognosis of patients with OGCTs has dramatically improved with the evolution of modern combination CT, attention is focused on the late effects of therapy. There is a considerable body of literature on the late effects of treatment in testicular cancer patients, yet the information available for women with OGCTs remains limited. However, many analogies can be drawn.

Sequelae of Surgery

Fertility-sparing surgery is the accepted standard for most patients with malignant OGCT, because most patients are of reproductive age or younger when diagnosed (NCCN guidelines [121]). Young patients with OGCTs undergo at least one, if not multiple, surgical procedures. Although there is no available information on the long-term effects of surgery on these patients, future infertility related to pelvic surgery with subsequent peritoneal and tubal adhesions is well described. Therefore, meticulous surgical technique and avoidance of unnecessary operative maneuvers (e.g., biopsy of a normal contralateral ovary) are required for preventing future complications (44,122,123). Another cause of infertility in this population is unnecessary bilateral salpingo-oophorectomy and hysterectomy, because fertility-sparing surgery is possible in nearly all patients with malignant OGCT, and long-term outcomes including pregnancy are excellent. In a series from Milan, among 55 patients treated with fertility-sparing surgery, without further CT, 12 out of 12 patients who attempted conception became pregnant and 12 normal deliveries were recorded (124). Two additional pregnancies occurred in this group and resulted in termination, one of which was because of in-uterus detection of fetal malformation. Recently, Gershenson reported the findings of GOG protocol 9901 (124). Among 132 survivors of OGCTs treated with surgery and platinum-based CT, 71 patients had fertility-sparing procedures. Of those fertile survivors, 62 (87.3%) maintained menstrual periods and 24 survivors reported 37 successful pregnancies. Although the survivors reported increased incidence of gynecologic problems and diminished sexual pleasure, they also tended to have stronger, more positive relationships with their significant others (125).

The extent of upfront surgical staging required for optimal outcomes is under scrutiny. Pediatric patients with malignant OGCTs typically undergo collection of ascites or cytologic washings and examination of the peritoneal surfaces and retroperitoneal lymph nodes with sampling or excision of abnormal areas, without lymphadenectomy, peritoneal biopsies, or omentectomy (126). Because surveillance may be an acceptable strategy for a growing number of patients, and treatment with CT may be successful in the small percentage of patients who relapse, future investigations may support limiting surgical staging, but this remains the standard of care in adult patients at present. When a patient presents to the gynecologic oncologist after initial surgery with incomplete staging, restaging may not be uniformly indicated, and surveillance may instead be considered (127).

As with any group of patients with a history of pelvic surgery, patients with OGCTs may develop functional cysts in the residual ovary. Muram et al. (127) reported his experience with 27 patients with OGCTs who underwent unilateral salpingo-oophorectomy and were followed for 12 to 215 months after completion of therapy. Of the 18 patients who maintained ovarian function, 13 (72%) developed functional cysts during follow-up. A trial of oral contraceptives and serial ovarian surveillance with sonography is helpful is distinguishing functional cysts from tumor recurrence.

Sequelae of Radiation Therapy

There is limited information about the late effects of RT in dysgerminoma patients. In a review of the late effects of RT in patients receiving abdominal therapy for ovarian dysgerminoma at the MDACC, there was a small increase in reported dyspareunia and the number of bowel movements (128). Somewhat surprisingly, at a median follow-up of 12 years, none of the 43 patients treated with RT developed small bowel obstruction. No other significant intestinal or bladder problems were recorded. As expected, none of the patients treated with radiation conceived (129). A recent review of the SEER database indicates an increased risk of secondary malignancy in patients who received radiation for a malignant OGCT. In this study, 10 of 70 patients (10%) who received RT for a malignant OGCT developed a second cancer, significantly

higher than in patients who did not receive RT (23). In practice, RT is rarely administered, because CT is effective and preservation of ovarian function is preferred (37,130).

Sequelae of Chemotherapy

The evolutionary development and refinement of combination CT have resulted in the cure of a high percentage of patients with chemosensitive tumors, such as lymphomas, testicular cancer, gestational trophoblastic disease, and malignant OGCTs. Within the last few years, several reports have described the long-term effects of CT in cancer survivors. As expected, most reports refer to the more common lymphomas and testicular cancers.

A recently recognized effect of CT used for the treatment of germ cell tumors is the risk of secondary malignancies. The epipodophyllotoxins teniposide and etoposide are associated with the development of acute myelogenous leukemia (AML) with certain morphologic and cytogenetic features (131-135). This treatment complication appears to be dose- (131,132) and schedule-dependent (134). Of 348 male germ cell tumor patients receiving three to four courses of BEP as first-line therapy at Indiana University, two developed etoposide-related leukemia. None of the 67 patients who received only three courses developed AML (131). Similarly, in the study reported by Pedersen-Bjergaard et al. (131) 5 out of 212 patients developed acute leukemia or myelodysplastic syndrome after etoposide therapy. However, all patients who developed AML received more than 2,000 mg/m^2 of etoposide. None of the 130 patients who received less than this dose developed AML. Morphologically, these leukemias are monocytic or myelomonocytic (M4 or M5). Characteristic chromosomal translocations (mostly involving the 11q23 region) are frequently, but not always, present. Leukemia after etoposide treatment occurs within 2 to 3 years compared with alkylating agent–induced AML, which has a longer latency period. Late occurrence of chronic myelogenous leukemia after treatment of testicular cancer was reported (136). In the GOG protocol testing the efficacy of BEP in women with OGCTs, 1 case of AML was recorded among 91 patients treated (75). An additional case of lymphoma was diagnosed during follow-up in this series, yet a correlation between CT and lymphoproliferative disorders has not been reported to date. Taking these issues into account, most clinicians consider BEP as the CT regimen of choice. The incidence of second neoplasms is quite low, particularly in patients receiving low cumulative etoposide doses. The continued use of etoposide over vinblastine is based on its superior efficacy demonstrated in testis cancer (71). Furthermore, vinblastine-induced abdominal pain and ileus are troublesome for some patients, particularly for those who underwent abdominal surgery, such as women with OGCTs. The risk/benefit ratio continues to favor etoposide over vinblastine.

There also continues to be considerable focus on the long-term effects of CT on gonadal function. Studies of patients with a variety of cancers suggest that, although ovarian dysfunction or failure is a risk of CT, the majority of survivors can anticipate normal menstrual and reproductive function (137-139). Factors such as old age at initiation of therapy, greater cumulative drug dose (140), and longer duration of therapy (139) have an adverse effect on future gonadal function. Successful pregnancies after treatment with combination CT have been well documented in other types of malignancies, including Hodgkin's disease, non-Hodgkin's lymphomas, and leukemia. There are similar reports in patients with malignant OGCTs (124,141-143). In a review of the MDACC series (141), 27 (68%) of 40 patients who had retained a normal contralateral ovary and uterus maintained regular menses consistently after completion of CT, and 33 (83%) were having regular menses at the time of follow-up. Of 16 patients who had attempted to become pregnant, 12 were successful. One patient underwent an elective first-trimester abortion, and the other 11 patients bore 22 healthy infants over time, none of which had a major birth defect. In a series from Milan, among 169 patients with OGCTs, 138 underwent fertility-sparing surgery, and of those, 81 underwent adjuvant CT (123). After treatment, all but one woman recovered menstrual function, and 55 conceptions were recorded. Forty normal full-term babies were delivered. There were four babies with congenital malformations, one in a patient who did not receive CT and three in women who had received CT (the difference was not statistically significant).

The GOG evaluated the quality of life and psychosocial characteristics of survivors of OGCTs compared with matched controls. In this analysis, the survivors appeared to be well adjusted, were able to develop strong relationships, and were

free of significant depression (144). The impact on fertility was modest or none in patients undergoing fertility-sparing surgeries (125). OGCT survivors appeared to be free of any major physical illnesses at a median follow-up of 10 years, as compared with matched controls. The only differences were higher rates of reported hypertension (17% vs. 8%, p = 0.02), hypercholesterolemia (9.8% vs. 4.4%, p = 0.09), and hearing loss (5.3% vs. 1.5%, p = 0.09) compared with controls (145). Among chronic functional problems, numbness, tinnitus, nausea elicited by reminders of CT (vs. general nausea triggers for controls), and Raynaud's symptoms were reported more frequently by survivors. Interestingly, late effects of treatment are more pronounced among children receiving treatment for germ cell tumors (146). Specifically, neurotoxicity, growth abnormalities, pulmonary toxicity, and gastrointestinal toxicity have been reported in a higher proportion than in adult patients. Despite persistence of a few sequelae of treatment, in general, OGCT survivors enjoy a healthy life comparable to that of controls, justifying administration of curative treatment in full and timely dosing.

SUMMARY

Virtually all patients with early-stage, completely resected OGCTs survive after careful surgical staging and three courses of adjuvant BEP. Furthermore, up to 80% of patients with incompletely resected or advanced tumors are expected to be long-term survivors. Acute toxicity of treatment is relatively modest. An important, but fortunately unusual late complication of treatment is etoposide-induced leukemia. However, patients receiving the usually administered cumulative dose of etoposide are at low risk for developing AML. Otherwise, late consequences of CT are limited. Efforts should concentrate on fertility preservation for patients who desire subsequent pregnancies.

The majority of dysgerminoma patients have stage I disease at diagnosis. These patients usually can be treated with unilateral salpingo-oophorectomy and careful postoperative observation without adjuvant treatment. CT is offered at the time of recurrence. In patients with more advanced but resected disease, the risk of recurrence is significant enough to warrant upfront adjuvant treatment, which for most patients is CT because of its near universal effectiveness and limited impact on fertility. In patients with incompletely resected tumor or for patients who recur after previous radiation, CT similar to that given for tumors other than dysgerminoma is appropriate.

Surgery continues to have a pivotal role in the management of all patients with OGCTs. Initial careful surgical staging is important in selecting appropriate subsequent therapy (although this is currently a matter of some debate). Second-look laparotomy is not necessary in patients who have no residual tumor after their initial surgical procedure and who receive adjuvant CT. This procedure also does not seem warranted in patients with advanced tumors without elements of teratoma. The judicious use of surgery followed by CT will cure the majority of patients with OGCTs at the expense of minimal and predictable immediate and late toxicities. The role of surveillance in low-risk patients is expanding. In most circumstances, fertility can be preserved.

INTERNATIONAL PERSPECTIVES

Ovarian Germ Cell Tumors: The Spanish View

Luis M. Chiva, MD, PhD

Germ cell tumors of the ovary, which are relatively uncommon, exemplify a special group of female tumors that are associated with an excellent prognosis after adequate surgical and adjuvant therapy. This excellent prognosis has been attributed to the tumors' biologic characteristics, as well as improvements in treatment over the last few decades.

Specific features of these tumors make their management unique. For example, early age at onset calls for a physician/patient shared decision-making process for the consideration of fertility-sparing options. Even adjuvant therapy with platinum-based CT does not preclude future pregnancies. Furthermore, the elevation of specific tumor-associated markers at the time of diagnosis and relapse gives us the opportunity to offer timely therapeutic interventions.

In Spain, germ cell tumors are rare, and patients who develop these tumors are typically managed as in the United States. In many cases, the diagnosis is made after an unexpected finding during a laparoscopic procedure undertaken to assess a pelvic mass in a young woman. After referral to a gynecologic oncologist, laparotomy and comprehensive surgical staging are usually performed. A fertility-sparing procedure can be offered to young patients. Adjuvant therapy (usually BEP) is given in most cases, except to patients with stage IA or IB pure dysgerminoma or stage IA pure IT, grade 1.

Follow-up is carried out similar to that of patients with epithelial tumors, including the assessment of specific tumor markers. CT scan is the basic imaging tool for ruling out recurrence and subsequently PET/CT scan if any suspicious findings are identified.

Unfortunately in Spain, as in other countries, there are still unanswered questions in the management of these tumors, such as whether thorough surgical staging is needed, the definitive indications for adjuvant CT, the best chemotherapeutic combinations in recurrent disease, and the most efficient surveillance schedule. Furthermore, there are poorly understood differences in treatment approaches between pediatric oncologists and gynecologic oncologists that should be explored and clarified. International collaborative trials among specialties investigating these rare tumors, even though challenging, are one of the safest ways to address some of the unknown aspects of this disease.

INTERNATIONAL PERSPECTIVES

Ovarian Germ Cell Tumors (Korea)

Sang-Yoon Park, MD, PhD

In South Korea, the incidence of OGCTs has not changed significantly over the past decade, with 127 cases reported in 1999 and 122 cases reported in 2011. In contrast, there has been a slightly increased incidence of epithelial ovarian cancer of 1.5% annually.

As in other parts of the world, OGCTs, compared with epithelial ovarian cancer, are typically diagnosed at a young age. Issues of concern in the management of these tumors include fertility preservation and the late effects of cancer and its treatment. Fortunately, high cure rates can be expected. In general, we consider fertility preservation even in cases involving the ovaries, uterus, and brain. Therefore, multidisciplinary team care is strongly advocated in our institution and in our country. Because OGCTs are chemosensitive in most cases, cure is our primary treatment endpoint. Therefore, timely initiation of CT without delay is stressed.

With the exception of stage IA dysgerminoma or grade I IT, in which surveillance is appropriate, we recommend adjuvant CT for all patients. Our standard regimen consists of four cycles of combination BEP, and we expect greater than 90% of patients to be rendered disease-free. Alternative regimens include PVB or carboplatin and etoposide. For patients with recurrent germ cell tumors, we generally use taxanes and gemcitabine.

For posttreatment surveillance, we follow appropriate tumor markers, such as AFP and/or hCG. If tumor markers are not useful in a particular patient's germ cell tumor type, sonography and MRI scans are preferred over CT scans to decrease radiation exposure. Our patients are educated on the long-term morbidities of specific CT regimens, and they are followed accordingly.

CHAPTER 25 Ovarian Sex Cord-Stromal Tumors

David M. Gershenson, Sean C. Dowdy, and Robert H. Young

INTRODUCTION

The intraovarian matrix that supports the germ cells and is covered by the surface epithelium consists of cells originating from the sex cords and mesenchyme of the embryonic gonad. Granulosa cells and Sertoli cells, generally considered to be homologous, are derived from the sex cord cells, whereas the pluripotent mesenchymal cells are the precursors of theca cells, Leydig cells, and fibroblasts. Neoplastic transformation of these cellular constituents, either singly or in various combinations collectively, results in neoplasms that are termed sex cord–stromal tumors (SCSTs). The classification of the SCSTs provides the template from which this chapter endeavors to stratify and define these tumor entities according to their morphologic characteristics (Table 25.1).

TABLE 25.1 Classification of Sex Cord-Stromal Tumors

Granulosa stromal cell tumors
Granulosa cell tumor
Adult type
Juvenile type
Tumors in the thecoma-fibroma group
Thecoma (including subset associated with sclerosing peritonitis)
Fibroma (including cellular form)-fibrosarcoma
Sclerosing stromal tumor
Microcystic stromal tumor
Sertoli stromal cell tumors
Sertoli cell tumor
Sertoli-Leydig cell tumor
Well differentiated
Of intermediate differentiation
Poorly differentiated
With heterologous elements
Retiform

Sex cord tumor with annular tubules
Unclassified sex cord-stromal tumors
Gynandroblastoma
Steroid cell tumors
Leydig cell tumors
Steroid cell tumor not otherwise specified

The SCSTs are estimated to account for approximately 7% of all malignant ovarian neoplasms (1). Although SCSTs account for a decreasing proportion of all ovarian malignancies with advancing age, the annual age-related incidence continues to increase through the seventh decade of life (2). Overall, the majority of these tumors are benign or of low malignant potential and are associated with a favorable long-term prognosis. In addition, a significant proportion of SCSTs are diagnosed in patients younger than age 40 years and have the potential to produce a variety of steroid hormones. Hence, adequate knowledge of the natural history of each of these tumors is imperative in diagnosing and individualizing definitive surgical and adjuvant therapy.

SCSTs account for nearly 90% of all functioning ovarian neoplasms (3). With the exception of fibromas, the clinical presentation of patients with SCSTs is frequently governed by the clinical manifestations resulting from the endocrinologic abnormalities. Excessive estrogen production, whether from increased tumor synthesis or peripheral conversion of androgens, influences end-organ responses, which are usually age dependent and can range from isosexual precocious puberty to menometrorrhagia to postmenopausal bleeding. In addition, the associated risks for endometrial cancer and possibly breast cancer must be recognized (4-6). Conversely, the rapid onset of signs ranging from early defeminization to frank virilization heralds a hyperandrogenic state. Elevated circulating levels of testosterone and/or androstenedione provide strong evidence for the presence of an SCST. Although granulosa cell, theca cell, and Sertoli cell tumors are generally considered to be estrogenic, and Sertoli–Leydig cell tumors (SLCTs) and steroid cell tumors (SCTs) are predominantly androgenic, the functional endocrinologic capacities of these tumors are impossible to predict based on their morphologic features. It should also be noted that miscellaneous ovarian tumors, both primary and metastatic, that are not in the SCST family may be androgenic or estrogenic if their stroma is stimulated to undergo luteinization.

GRANULOSA CELL TUMORS

Although granulosa cell tumors (GCTs) of the ovary were initially described by Rokitansky (7) in 1859, the pathogenesis of these neoplasms remains ill defined. At least in part, this is a reflection of the low incidence of GCTs, and hence the limited number of cases managed at any single institution. Although molecular aberrations crucial to the pathogenesis of GCTs have been elucidated recently, to our knowledge there are no recognized risk factors for their development (4,8). Reproductive factors, including the use of fertility-promoting agents and oral contraceptives, do not appear to increase the risk of disease. Unkila-Kallio et al. (9) studied a possible link between fertility-promoting agents and GCTs using the nationwide Finnish Cancer Registry. They analyzed the occurrence of GCTs in Finland from 1965 to 1994 against sales statistics for ovulation inducers. The incidence of GCTs declined by nearly 40% from 1965–1969 to 1985–1994 despite a 13-fold increase in the use of clomiphene citrate and a 200-fold increase in human menopausal gonadotropin use; oral contraceptive use increased fivefold. In another series of 240 GCTs, prior use of oral contraceptives and a history of infertility were associated with improved survival on univariable, but not multivariable analysis (10). No hereditary predisposition for any of the SCSTs has been identified (11), although a case report described the occurrence of adult GCTs in two first-degree relatives (12).

GCTs comprise 5% of all ovarian malignancies, but account for approximately 70% of malignant SCSTs (4-6,13-20). The annual incidence of GCTs in the United States and other developed countries varies from 0.4 to 1.7 cases per 100,000

women (5,6,8,19,21,22). Quirk and Natarajan reported histology-specific age-adjusted ovarian cancer incidence rates that were standardized to the recently adopted year 2000 U.S. standard population utilizing data from the Surveillance, Epidemiology, and End Results (SEER) program (23). Out of a total of 23,484 microscopically confirmed cases of primary ovarian cancer, 293 (1.2%) were of sex cord–stromal origin. Although GCTs have been diagnosed from infancy through the tenth decade of life, the average age at the time of diagnosis in over 750 cases was 52 years (4-6,14,16-19). Considering that GCTs occurring after the third decade of life appear to be histologically distinct, in most instances, from those occurring in children and younger adults, the clinical and pathologic characteristics for the juvenile and adult GCTs will be addressed separately.

GCTs: Adult Type

Adult-type granulosa cell tumors (AGCTs), histologically described below, account for 95% of all GCTs. The majority of patients will present with one or a combination of the following clinical symptoms: abnormal vaginal bleeding, abdominal distention, and abdominal pain (5,6,16-19,24). The latter symptoms are most frequently attributable to the gross size of the tumor at the time of diagnosis, with the majority exceeding 10 cm in diameter and many exceeding 15 cm (5,17,19). In one series, 12% had ascites at diagnosis (24). In many series, menometrorrhagia, oligomenorrhea, or amenorrhea in premenopausal women or bleeding in postmenopausal women are the most common reasons for seeking medical assistance. These and other clinical manifestations such as breast tenderness, uterine myohypertrophy, and endometrial hyperplasia are caused by hyperestrogenism associated with GCT.

The endocrine function of AGCTs, specifically the production of estrogens, has been repeatedly demonstrated. In a detailed retrospective analysis of endometrial specimens from 69 patients with GCTs, Gusberg and Kardon (25) observed histologic features consistent with unopposed estrogen, including atypical adenomatous hyperplasia in 42% of the evaluated cohort, adenocarcinoma *in situ* (4) in 5%, and invasive adenocarcinoma in 22%. Similarly, Evans et al. (4) noted endometrial hyperplasia in 55% and adenocarcinoma in 13% of their GCT study population. Other investigators have corroborated the high prevalence of glandular hyperplasia and have reported adenocarcinoma frequencies ranging from 3% to 27% (5,6,14,16-19,26,27). Selective ovarian venous catheterizations during surgery have documented hormonal production, including the secretion of large quantities of estrogen from the ovary harboring the GCT. The return of serum estrogen to physiologic levels after surgical resection has also been demonstrated. Occasionally, patients with GCTs present with endometrial changes (decidual reaction of the stroma or secretory characteristics of the glands) consistent with tumor production of progesterone (28). Rarely, virilizing changes such as oligomenorrhea, hirsutism, and other masculinizing signs may accompany GCTs (29-31).

Pathology

AGCTs have an average diameter of approximately 12 cm, but a subset, 10% to 15% of the cases, are small and not appreciated on pelvic examination (32). Most characteristically, they are predominantly cystic, with numerous locules filled with fluid or clotted blood and separated by solid tissue (Fig. 25.1), or they are solid, with large areas of hemorrhage. The solid tissue may be gray-white or yellow and soft or firm. A rare tumor is cystic, usually thin walled, but occasionally thick walled, and multilocular or unilocular (30).

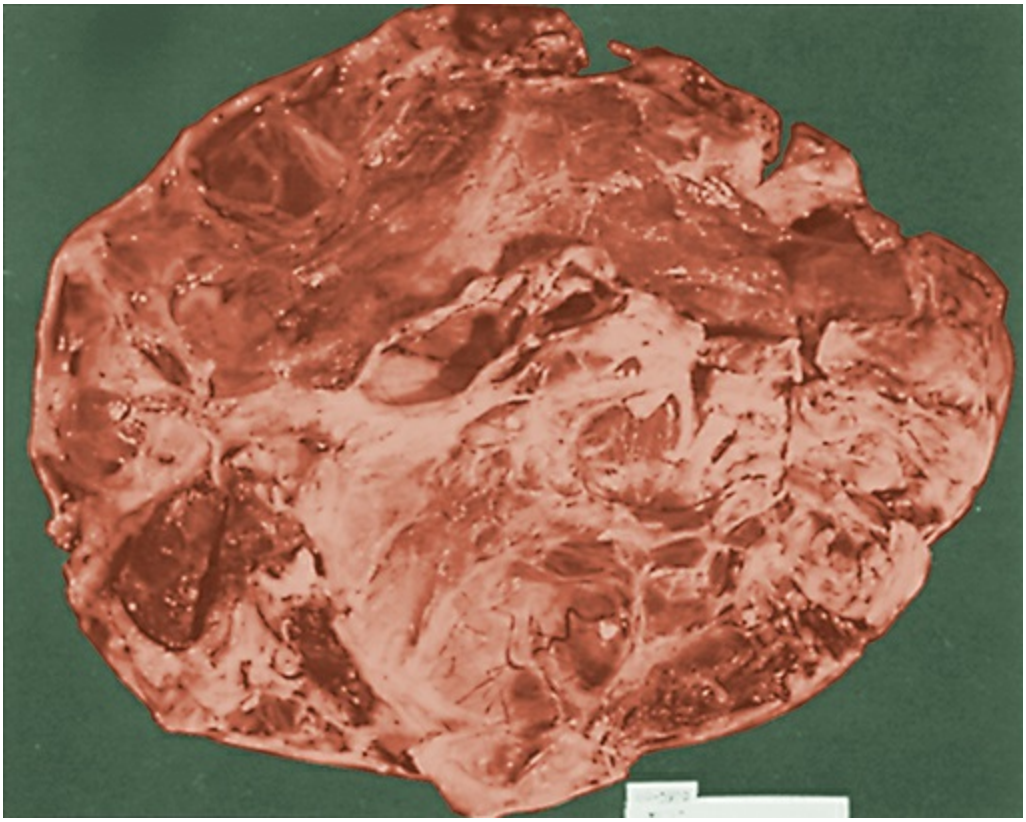

Figure 25.1 Granulosa cell tumor. The sectioned surface is composed predominantly of multiple cysts filled with blood.

Microscopic examination reveals an almost exclusive population of granulosa cells or, more often, an additional component of theca cells, fibroblasts, or both. The granulosa cells grow in a wide variety of patterns. The better differentiated tumors usually have microfollicular, macrofollicular, insular, or trabecular patterns. The microfollicular pattern is characterized by numerous small cavities (Call–Exner bodies) (Fig. 25.2) that may contain eosinophilic fluid, one or a few degenerating nuclei, hyalinized basement membrane material, or, rarely, basophilic fluid. The microfollicles are typically separated by well-differentiated granulosa cells that contain scanty cytoplasm and pale, angular, or oval, often grooved nuclei arranged haphazardly in relation to one another and to the follicles. The uncommon macrofollicular pattern is characterized by cysts lined by well-differentiated granulosa cells beneath which theca cells are present. The trabecular and insular forms of GCTs are characterized by bands and islands of granulosa cells separated by fibromatous or thecomatous stroma. The less well-differentiated forms of the AGCT typically have a water silk (moire silk), gyriform, or diffuse (sarcomatoid) pattern alone or in combination. The first two patterns are manifested by parallel undulating or zigzag rows of granulosa cells, generally in single file, whereas the diffuse form is characterized by a monotonous, patternless cellular growth. In some AGCTs, the neoplastic cells have moderate to abundant quantities of dense or vacuolated cytoplasms; the term *luteinized granulosa cell tumor* is appropriate when such cells predominate (28). The cells in GCTs usually have round to oval, pale, and often grooved nuclei (Fig. 25.2), but rarely the cells are spindle-shaped, resembling a cellular fibroma or low-grade fibrosarcoma; mitotic figures (MFs) may be numerous, but are rarely atypical. There is usually only mild nuclear atypia, but approximately 2% of tumors contain mononucleate and multinucleate cells with large, bizarre, hyperchromatic nuclei, the presence of which does not appear to worsen the prognosis (33).

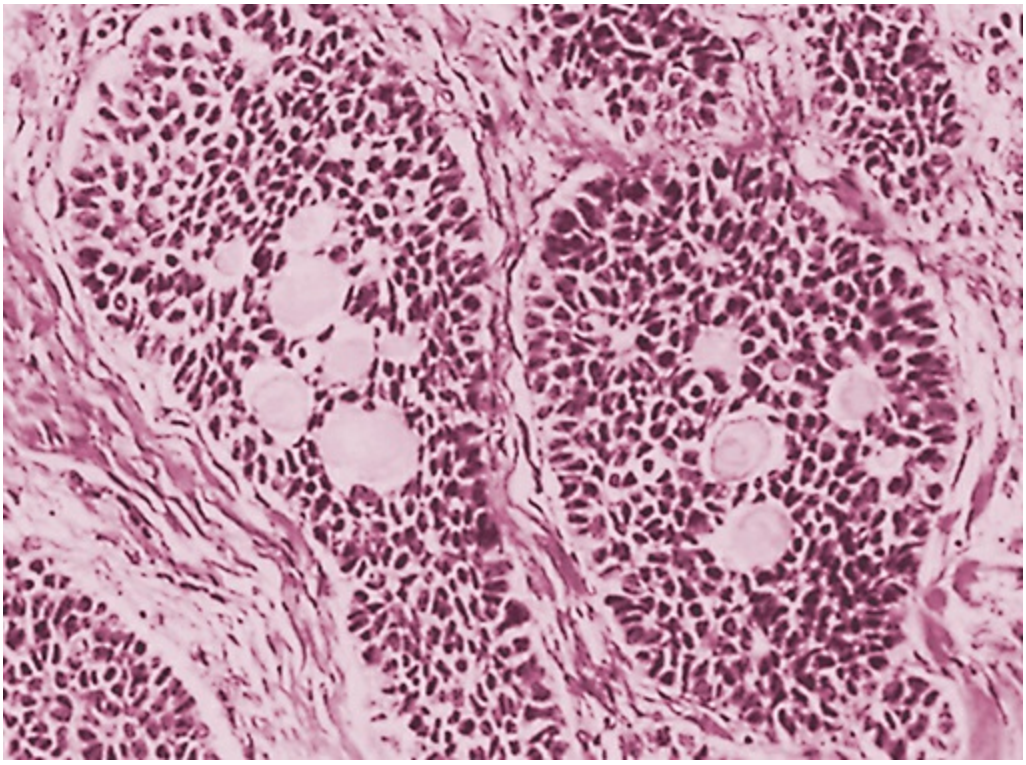

Figure 25.2 Granulosa cell tumor, adult type, microfollicular pattern. Several nests of granulosa cells with small oval and angular nuclei enclose multiple Call-Exner bodies.

Natural History

AGCTs are low-grade malignancies with a propensity to remain localized and indolent. Ninety percent are stage I at diagnosis (27). The 10-year survival rate for stage I disease ranges from 86% to 96%; for disease that is more advanced at diagnosis, the 10-year survival rate ranges from 26% to 49% (27). Bilaterality occurs in less than 10% (24). Tumor rupture occurred in 22% of a series of 97 cases (24). A unique feature of GCTs is that they recur at extended time intervals from primary therapy, suggesting the presence of persistent occult disease with a very indolent growth rate. For patients who recur, the median time to recurrence is 6 years and median survival after recurrence is 5.6 years (4,14). In a series of 160 stage I GCTs, median time to recurrence was 12 years and median overall survival (OS) was similar between patients with and without recurrence (34).

Prognostic Factors

The staging system for GCTs is the same as that used for epithelial ovarian cancer. It was revised in 2014 (International Federation of Gynecology and Obstetrics [FIGO]). Whereas surgical stage has been recognized as the most important prognostic factor for GCTs, the impact of tumor size, rupture, histologic subtype, nuclear atypia, and mitotic activity on outcome is less clear; larger, well-characterized series are necessary to clarify existing discrepancies (8,35,36). As noted above, GCTs are large and therefore prone to rupture. Rupture appears to adversely impact survival in stage I patients, justifying stratification as stage IC (14,34). In a series of 240 patients, treatment prior to 1984, age greater than 60 years, tumor size greater than 10 cm, advanced stage, residual tumor, and use of hormonal therapy were associated with GCT-related death. However, only stage was associated with recurrence on multivariate analysis (10). Tumor size has been variably associated with risk of death (5,15,19,21,37). Increasing degrees of nuclear atypia and increasing mitotic frequency per 10 high-power fields (HPFs) have been correlated inversely with prognosis. Specimens from patients with

more advanced disease tend to demonstrate higher grade of atypia and/or more MFs (5,14,15,19). Despite its somewhat subjective assessment, nuclear grade has reportedly been a reliable prognostic indicator in stage I cases (14,19). The significance of histologic subtypes has been debated, and they appear to be of minimal value. Several investigative groups (4,5,13-15,19) have failed to confirm Kottmeier's (38) report of the prognostic importance of histologic patterns alone in GCTs. Similarly, the results of investigations utilizing flow cytometric analysis of DNA content have been inconsistent. Klemi et al. (39) reported a significant survival advantage for patients with tumors demonstrating normal ploidy and/or an S-phase fraction (SPF) of less than 6%. However, other investigators have suggested that nondiploid GCTs are infrequently encountered (40,41). Another investigation of 20 GCTs found that the degree of nuclear atypia, mitotic count, Ki-67 index, and DNA aneuploidy were not predictive of tumor recurrence (34). Chadha et al. (40) reported that three of five aneuploid tumors from a total population of 43 pathologically diagnosed GCTs were vimentin-negative but positive for cytokeratin and epithelial membrane antigen, and therefore cautioned that such highly aneuploid tumors may represent undifferentiated carcinomas. Indeed, it is clear that some series of GCTs in the literature include undifferentiated carcinomas not otherwise specified, or recently recognized entities such as the large-cell carcinoma of hypercalcemic type. Therefore, series with unusually large numbers of late-stage or poor-prognosis cases should be evaluated cautiously.

Investigators have analyzed several potential molecular markers, including p53 status, telomerase, Ki-67, c-myc, HER2/neu, and vascular endothelial growth factor (VEGF) in GCTs (42-48). To date, no molecular marker provides prognostic information for GCTs beyond what is known from stage and histopathologic parameters.

Ala-Fossi et al. (49) stained 30 GCTs for the inhibin subunit. All 24 stage I and II tumors were positive, whereas four of six stage II–IV tumors were negative. Those that were negative were poorly differentiated and exhibited rapid disease progression. Whether other observers would have accepted these tumors as valid GCTs is a concern. Stage was the sole independent prognostic factor.

Serum Markers

The majority of patients presenting with advanced GCTs will recur. Therefore, the identification of a specific serum tumor marker(s) would facilitate early detection of recurrent disease and monitoring of treatment effectiveness (4,5,17,19). As noted above, serum estrogens are generally produced by GCTs and have been utilized as an indicator of disease status (50). Unfortunately, serum estradiol levels are occasionally normal, and more frequently are only marginally increased, making them less than ideal for monitoring in a significant number of patients. Several proteins derived from granulosa cells, including inhibin, follicle-regulating protein, and Müllerian-inhibiting substance (MIS), are useful markers (51-59). In a prospective evaluation of 27 patients with GCTs, Jobling et al. (53) demonstrated that serum inhibin levels are typically elevated sevenfold above normal follicular phase levels prior to primary surgical management. In a comparative investigation of serum inhibin B and anti-Müllerian hormone, elevations in both were noted in 123 patients with primary and recurrent GCTs. The area under the curve of each was >0.90, and somewhat higher when used in combination (59a). Mom et al. (60) showed that inhibin B was the predominant form of inhibin secreted by these tumors, with a sensitivity and specificity of 89% and 100%, respectively, compared with 67% and 100% for inhibin A. Elevations in inhibin B were present in 85% of recurrences, and predated clinical evidence of recurrence by a median of 11 months. Both inhibin and calretinin have become useful immunohistochemical markers to assist in the diagnosis of GCTs and other SCSTs (61).

GCTs: Juvenile Type

Ovarian neoplasms are relatively rare in childhood and adolescence. When encountered, the majority are of germ cell origin, with only 5% to 7% being SCSTs. The latter are predominantly of the granulosa cell type in this age group, and demonstrate a distinct tumor morphology and to a degree biology from the typical AGCT considered above (62). Approximately 90% of the GCTs diagnosed in prepubertal girls and in most women less than 30 years of age will be of the juvenile type (JGCT). In a clinicopathologic analysis of 125 cases of JGCT, 44% occurred prior to age 10 and only 3%

after the third decade of life (63). The majority of prepubertal patients present with clinical evidence of isosexual precocious pseudopuberty, which may include breast enlargement, development of pubic hair, increased vaginal secretions, advanced somatic development, and other secondary sex characteristics (63-67). Serum estradiol levels were reported as elevated in 17 of 17 cases of JGCTs with pseudopuberty (65). In addition, elevated levels of serum progesterone (6 of 10) and testosterone (6 of 8) were likewise observed, as well as suppressed levels of luteinizing hormone and follicle-stimulating hormone (FSH). The occasional patient will harbor an androgen-secreting JGCT accompanied by virilization (63,65,66). Although the signs of either precocious pseudopuberty or virilization are dramatic, the most consistent clinical sign at presentation in patients with JGCTs is increasing abdominal girth. Young et al. (63) indicated that in only 2 of 113 nonpregnant patients with JGCTs was the treating physician unable to palpate a mass on abdominal, pelvic, and/or rectal examination. Abdominal pain, dysuria, and constipation may coexist. Infrequently, a surgical emergency is encountered following spontaneous rupture or torsion of the enlarged ovary. JGCTs may occur in infants, who appear to have a more favorable prognosis than older individuals (68). Hasiakos et al. (69) described a case of JGCT associated with pregnancy, and reviewed the literature.

The frequency of bilaterality for JGCTs is estimated to be 5%, similar to that for AGCTs (70). When stage was assigned based on surgical and histologic parameters, 88% were stage IA, 2% stage IB, 8% stage IC, and 3% stage II. As noted, extraovarian spread is infrequently encountered at exploration, whereas rupture of the tumor is noted in approximately 10% of cases. Ascites contributes to the abdominal distention in 10% to 36% of cases (63,65).

JGCTs have been reported in association with enchondromatosis alone (Ollier's disease) or concomitantly with hemangiomas (Maffucci's syndrome) (65,71-73). Individuals with these relatively uncommon mesodermal dysplasias generally present prior to puberty and frequently develop secondary neoplasms, most commonly sarcomas, after the second decade of life. JGCTs are the next most frequent tumor associated with these disorders and become evident during the first and second decades of life. These observations appear to imply more than coincidental occurrences and suggest a generalized mesodermal dysplasia, perhaps contributing to the pathogenesis of these neoplastic processes. In addition, congenital bilateral JGCTs of the ovary have been reported in leprechaunism, a disease characterized by insulin resistance resulting from an insulin receptor defect (74).

Pathology

The appearances of JGCTs are similar to the adult form; a solid and cystic neoplasm, in which the cysts contain hemorrhagic fluid, is common (63,64,67). Uniformly solid and uniformly cystic neoplasms are also encountered; the latter may be multilocular or, in rare instances, unilocular. The solid component is typically yellow-tan or gray and occasionally exhibits extensive necrosis, hemorrhage, or both.

Microscopic examination typically reveals a predominantly solid cellular tumor with focal follicle formation, but occasionally, a uniformly solid or a uniformly follicular pattern is seen. In the solid areas, the neoplastic cells may be arranged diffusely or as multiple nodules of various sizes. The follicles typically vary in size and shape; Call–Exner bodies are rarely encountered, and the follicles rarely reach the large size of those in the macrofollicular AGCT. The follicular lumens in the juvenile tumor contain eosinophilic or basophilic fluid, which stains with mucicarmine in approximately two of three cases.

The two characteristic cytologic features of the neoplastic juvenile granulosa cells that distinguish them from those of AGCT are their generally rounded, hyperchromatic nuclei, which almost always lack grooves, and their almost invariable moderate to abundant eosinophilic or vacuolated (luteinized) cytoplasm (Fig. 25.3). Nuclear atypia in JGCTs varies from minimal to marked; in approximately 13% of the cases, severe degrees are present. The mitotic rate also varies greatly, but is generally higher than that seen in AGCTs, often being five or more per 10 HPF (63,64).

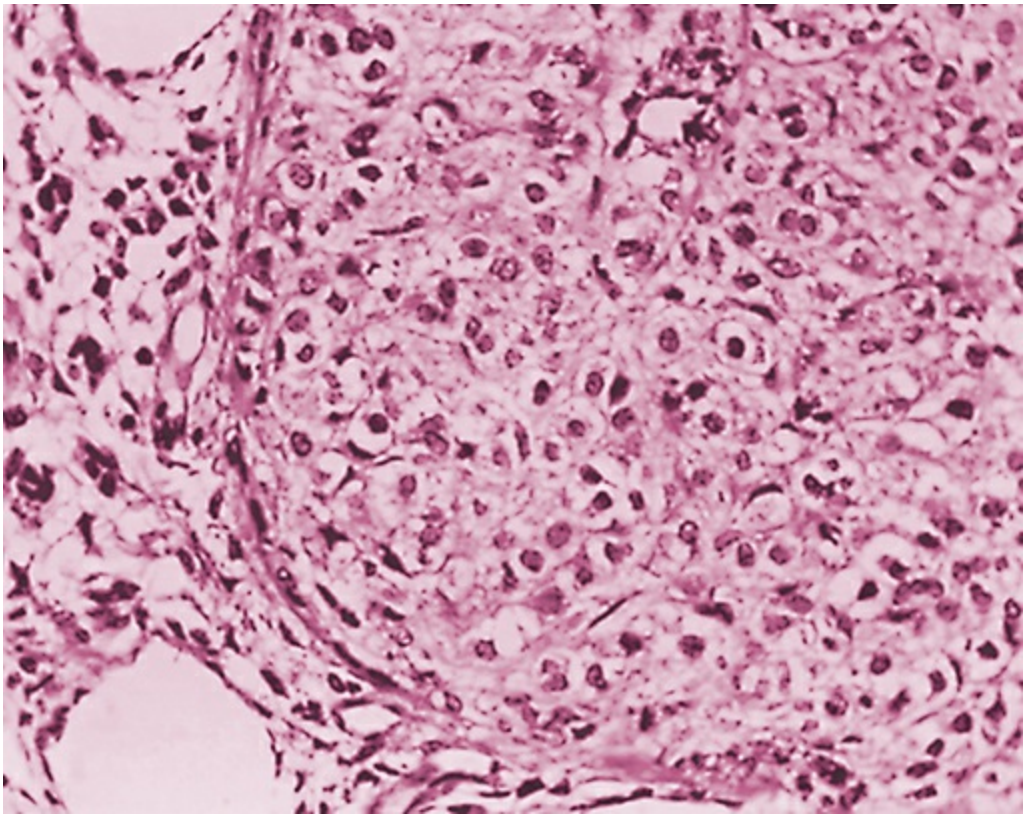

Figure 25.3 Granulosa cell tumor, juvenile type. A nodule of tumor is composed of large cells with abundant cytoplasm and slightly pleomorphic, hyperchromatic nuclei.

Natural History

In the initial series by Young et al. (63), 98% of 125 patients with JGCTs were less than 35 years of age, and 78% were 20 years or less. Notwithstanding the customary presenting complaint of increased abdominal girth and the clinical documentation of a large mass (64% >10 cm), 90% of the JGCTs analyzed by Young et al. (63) were stage IA or IB. The corresponding survival rate for these patients, with an average follow-up of 3.5 years, was 97%. Included were nine stage IA2 patients with rupture of the tumor, all of whom were alive and free of disease. Patients presenting with associated isosexual pseudoprecocious puberty may have a more favorable prognosis. Assessing 80 such cases from 212 reported JGCTs, only two cancer-related deaths (2.5%) were observed. Presumably, the clinical manifestations lead to early diagnosis and excellent outcomes (63,65-67).

Although the presentation of early symptoms and localized disease is similar to that of AGCTs, the natural history of JGCTs differs notably in several respects. Although the adult form frequently includes a latency period with recurrences remote from initial diagnosis, the juvenile counterpart is characteristically aggressive in advanced stages, and the time to relapse is generally within 3 years of the initial diagnosis (63,65,67). Thirteen cases of stage II, III, or IV disease were abstracted from three analyses, with a combined sample size of 180 patients (63,65,66). Of these 13 patients, only three (23%) were alive when reported; notably, the recurrences and deaths occurred within a relatively brief interval.

Prognostic Factors

Young et al. (63) noted that surgical stage represented the most reliable prognostic indicator. Tumor size, mitotic activity, and nuclear atypia were significant predictors only when analyzed without regard to stage. In that series, rupture did not correlate with outcome. Schneider et al. (75) reported on a group of 54 SCSTs in children and adolescents from Germany (45 JGCTs and 9 others). They addressed the outcome of patients with “accidental” stage IC disease, defined as violation

of the tumor capsule during surgery, versus "natural" stage IC tumors, with preoperative rupture or malignant ascites. Among 12 patients with accidental stage IC disease, there were no recurrences. In contrast, five of the nine patients with natural stage IC disease recurred (p = 0.001). Assessment of DNA content via flow cytometry in JGCTs demonstrated nondiploid patterns in nearly half (76,77). However, Jacoby et al. (76) were unable to correlate DNA ploidy or SPF with either stage of disease or prognosis in patients with localized disease. In the series by Schneider et al. (75), mitotic activity correlated with prognosis. There were no relapses in 35 patients whose tumors exhibited low or moderate mitotic activity. Among those with high mitotic activity (>19 mitoses per 10 HPFs), approximately half recurred.

Serum Markers

Although information specific to JGCTs is limited, the various tumor markers discussed above for AGCTs would appear to be applicable to JGCTs for monitoring of recurrent disease.

TUMORS IN THE THECOMA–FIBROMA GROUP

As the ovarian stromal cell is the precursor of both fibroblasts and theca cells, pure thecomas and pure fibromas represent extremes along a continuum, with a significant percentage of the tumors having admixtures of theca cells and collagen-producing spindle cells. Nonetheless, the majority of tumors in the thecoma–fibroma group are readily subcategorized based on relatively distinct histologic characteristics. The major subcategories include thecoma, fibroma–fibrosarcoma, sclerosing stromal cell tumor (SST) and microcystic stromal tumor. The latter neoplasm is currently placed in the stromal category, although it has differing features from other pure stromal neoplasms, and in time may lead to a separate categorization. Another recently described entity is the so-called "luteinized thecoma associated with sclerosing peritonitis," which is also placed in this grouping tentatively (see below, section on Thecoma). Finally, the literature contains the designation "luteinized thecoma." This has been used in the past for any stromal tumor, usually a fibroma, containing lutein cells. However, recognizing that lutein cells may be seen in many neoplasms, the category "luteinized thecoma" as such does not merit its own designation. The presence of many luteinized stromal cells in a stromal tumor may merit notice, as it may explain the presence of androgenic clinical manifestations.

Thecoma

Thecomas (Fig. 25.4) are almost invariably clinically benign (4,78,79). They account for less than 1% of ovarian neoplasms and occur at an older age than other SCSTs. The majority of patients are in their sixth and seventh decades at the time of diagnosis (4,78). Combining two large series totaling over 140 patients, less than 10% presented prior to age 30. Based on a compendium of nearly 300 cases, bilaterality occurs with a frequency of approximately 2% and extraovarian spread occurs rarely, if at all (4,78-,80).

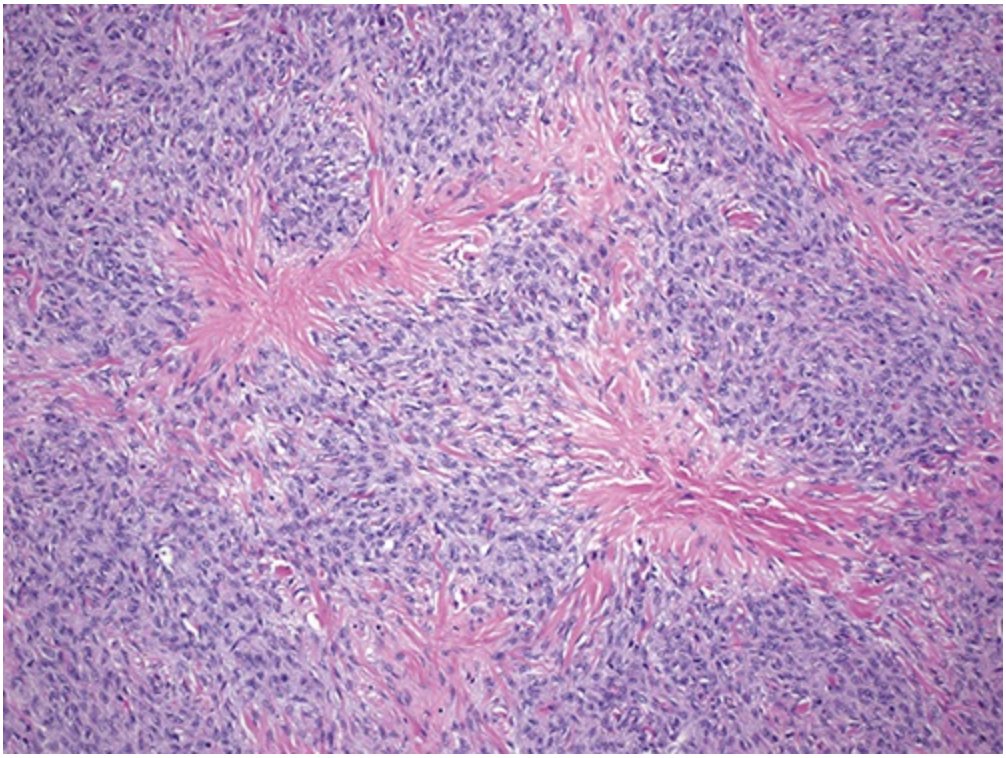

Figure 25.4 Thecoma. The tumor is composed of cells with appreciable pale gray cytoplasm intersected by hyaline plaques.

The primary presenting signs and symptoms in patients with thecomas are abnormal vaginal bleeding and/or an abdominal/pelvic mass (78-80). The former promotes initiation of medical intervention in the majority of postmenopausal patients, whereas increasing abdominal girth or a palpable mass is more frequently the main presenting complaint in premenopausal patients. Lesion size has been reported to vary from less than 1 to 40 cm in diameter (78,79,80). They are, on average, smaller than GCTs.

Thecomas are considered to be among the most hormonally active of the SCSTs. The abnormal bleeding encountered in 60% of patients is presumably attributable to excess estrogen production (78,79). In the series reported by Evans et al. (4), endometrial hyperplasia was observed in 37% of the evaluable patients, and adenocarcinoma consistent with an unopposed estrogen effect was documented in an additional 27%. All the uterine cancers were well-differentiated and minimally invasive, but two patients subsequently died of endometrial carcinoma. Other coexisting uterine pathologic findings potentially influenced by elevated circulating estrogen levels included leiomyomata, myohypertrophy, and endometrial polyps.

An enigmatic tumor that has been considered a variant of luteinized thecoma has been associated with sclerosing peritonitis (81). These tumors are often bilateral and frequently have a brisk mitotic rate, but have not demonstrated metastatic potential. Sclerosing peritonitis has, however, been fatal owing to pursuant complications. Schonman et al. (82) presented a case of luteinized thecoma associated with sclerosing peritonitis treated with ovarian wedge resection. Despite recurrent bowel obstruction, the was successfully treated with high-dose steroids. She achieved pregnancy and was free of symptoms 18 months following treatment.

Fibroma - Fibrosarcoma

Fibromas are the most commonly encountered SCST, accounting for approximately 4% of all ovarian neoplasms. These typically endocrine-inert tumors are seldom bilateral, and vary in size from microscopic to extremely large masses. Although infrequently diagnosed prior to age 30, fibromas can occur at any age; the average age of diagnosis is the latter half of the fifth decade of life (83). As their size increases, fibromas tend to become more edematous, leading to the

escape of increasing quantities of fluid from the tumor surfaces. Ascites is detected in association with 10% to 15% of ovarian fibromas that exceed a diameter of 10 cm (84). Furthermore, 1% of patients develop a hydrothorax in addition to the hydroperitoneum (Meigs syndrome) (85). Gorlin's syndrome is associated with an inherited predisposition to the development of ovarian fibromas along with several other abnormalities, the most frequent of which is the appearance of basal cell nevi at an early age (86).

Approximately 10% of ovarian fibromatous tumors demonstrate increased cellularity and varying degrees of mitotic activity. These tumors are designated cellular fibromas and are considered to be tumors of low malignant potential, particularly if ruptured or associated with adhesions (87). Fibrosarcomas are distinguished by their greater cellular density and, most notably, moderate to marked pleomorphism and even greater mitotic activity (88). Few cases have been reported, but their diagnosis may be facilitated by the presence of elevated inhibin levels, supporting a sex cord origin (89).

Sclerosing Stromal Cell Tumors

SSTs were initially described by Chalvardjian and Scully (90) in 1973 as a distinct subgroup within the thecoma–fibroma family of ovarian tumors. This relatively rare tumor characteristically differentiates itself histologically and clinically from both thecomas and fibromas (91,92). The tumors are on average the same size as fibromas and thecomas, but have a more variegated sectioned surface, which is often at least focally edematous. Histologically, the presence of pseudolobulation of cellular areas separated by edematous to sclerotic connective tissue and prominent vascularity are distinguishing features. Clinically, SSTs commonly manifest during the second and third decades of life, with 80% being diagnosed prior to age 30. This is unique among ovarian stromal tumors (93). They are often associated with other stromal tumors, including thecomas (94). The signs and symptoms that most commonly prompt medical evaluation include menstrual irregularities and/or pelvic pain (95). Ascites is seldom encountered; this further distinguishes SSTs from fibromas (95). In contrast to thecomas, SSTs are usually inactive endocrinologically (90). However, in a limited number of cases steroidogenic activity has been demonstrated, even including androgenic manifestations, particularly if the patient is pregnant (95-99). To date, all SSTs have been clinically benign, and with one exception (100), all have been unilateral. One report noted an elevated CA-125 level (101), but this is unusual.

Microcystic Stromal Tumor

This rare neoplasm (102) typically is unassociated with endocrine manifestations. There are no distinctive gross features. The tumors are often initially believed to be thecomas until the peculiar microcystic formations, which result in the entity being named as it is, are observed. Relatively frequent cytologic atypia may lead to an erroneous diagnosis of a neoplasm with an aggressive nature, but the follow-up information to date indicates a benign outcome in the vast majority of cases. Although these tumors, as noted earlier, are tentatively placed in the stromal category, they differ from most stromal tumors in that they fail to stain for inhibin and calretinin. They also typically show nuclear beta-catenin positivity (103). According to the prominence of the microcysts, a variety of erroneous diagnoses may result, some of them significant, such as potential misclassification as yolk sac tumor, especially if the tumor occurs in the younger female as they sometimes do.

Natural History

Stromal tumors with rare exceptions are benign neoplasms, and any associated morbidity or mortality is generally attributable to side effects of treatment or concurrent disease (4,78,80,83,104). Examples of the latter include deaths from endometrial carcinoma resulting from the unopposed estrogen produced by the thecomas (4). Although cases of "malignant thecomas" have been reported, critical reappraisal of such tumors invariably results in histologic reassignment to sarcomas or diffuse GCTs (105). DNA ploidy analyses of thecomas and fibromas demonstrate aneuploid patterns in the

majority, most commonly trisomy and/or tetrasomy 12, which offer a clue to their pathogenesis (106,107).

Prognostic Factors

The prognosis for patients diagnosed with cellular fibromas is generally favorable. Recurrences of these tumors of low malignant potential are generally correlated with adherent disease, rupture, or incomplete removal at the time of primary cytoreduction (87). In contrast, fibrosarcomas have a higher likelihood of recurrence, but fortunately are rare.

SERTOLI STROMAL CELL TUMORS

This category includes pure Sertoli cell tumors and SLCTs. Nomenclature-wise, it could also include Leydig cell tumors; however, Leydig cell tumors have been traditionally been classified in the steroid cell category because they share with those tumors a uniform population of cells of endocrine secreting type (with either eosinophilic or pale lipid-rich cytoplasm) and lack an epithelial element.

Neoplasms arising in the ovary, exhibiting morphologic characteristics similar to those of the testes during various stages of gonadogenesis, were recognized and elegantly described by Meyer (108,109). He reasoned that the origin of these tumors was the male blastema and coined the term *arrhenoblastoma*. Considering the functional nature of these male homologs and the varying degrees of associated defeminization and/or masculinization, the term *androblastoma* was also adopted. However, Morris and Scully (110), in 1958, contended that both designations implied masculinization, which is frequently absent; furthermore, a variety of unrelated androgen-producing ovarian tumors exist. Therefore, they recommended the adoption of the morphologic designation SLCT, a nomenclature based on morphology rather than clinical manifestations.

Sertoli Cell Tumors

Sertoli cell tumors are rare, accounting for less than 5% of all Sertoli stromal cell tumors (93). The average age at presentation is about 30 years, but this lesion can occur at any age. Evidence of estrogen production has been observed in approximately two-thirds of the reported cases. Consistent with excess estrogen production, isosexual precocious puberty has been witnessed during the first decade of life, menstrual disorders during the reproductive decades, and postmenopausal bleeding in the decades after the climacteric. Reflecting tumor size (average 9 cm), capsular distention, and/or adnexal torsion, and abdominal distention and/or pain are frequent complaints. Pelvic examination generally confirms the presence of tumor under these circumstances. The frequency of excessive renin production in association with Sertoli cells appears to exceed mere chance (111-113). Evaluation of refractory hypertension and hypokalemia has, rarely, resulted in the discovery of a Sertoli cell tumor as the origin of the excess renin. An occasional Sertoli cell tumor has arisen in a patient with Peutz–Jeghers syndrome (PJS) (114,115).

Pathology

On gross examination, these rare tumors are typically solid, lobulated, and yellow (93,116). Microscopic examination shows hollow or solid tubules lined by cells that usually exhibit relatively bland cytologic features, but rare tumors exhibit moderate to severe nuclear atypia. In most of these tumors, a tubular pattern predominates, but occasionally a diffuse pattern is conspicuous.

Prognosis

The great majority of these rare tumors have been unilateral stage I lesions. The greater majority of Sertoli cell tumors are well differentiated, and are rarely malignant (93). Excision of the tumor results in prompt resolution of the hyperestrogenic state.

Sertoli-Leydig Cell Tumors

SLCTs are extremely uncommon, accounting for less than 0.2% of all ovarian tumors. As implied by their designation, the tumors contain both Sertoli and Leydig cell elements. The clinical characteristics, specifically endocrine, are related to the degree of histologic differentiation and the presence of a retiform pattern and/or heterologous elements ((described below, in section on Pathology of Sertoli-Leydig Cell Tumors), the latter two variants being less often androgenic. The average patient age at diagnosis is approximately 25 years, with the majority (70% to 75%) of the tumors becoming clinically manifest during the second and third decades of life. Less than 10% occur either prior to menarche or after the climacterium. Patients harboring well-differentiated tumors present at an average age of 35 years, or 10 years later than patients with intermediate or poorly differentiated lesions. Conversely, tumors with retiform patterns are generally detected 10 years earlier than the intermediate and poorly differentiated tumors (117-119). Based on the compiled data from three reported series totaling over 300 patients, the frequency of extraovarian spread of disease at the time of diagnosis is approximately 2.5%. The likelihood of encountering bilateral tumors is even less (117-119).

The most frequent complaints at the time of presentation of, in these generally healthy adolescents and young adults, are menstrual disorders, virilization, and nonspecific symptoms resulting from an abdominal mass. Nearly one-half of the patients experience sufficient abdominal pain or discomfort or note abdominal distention, or palpate a mass on self-examination, prompting them to seek professional assessment. Whereas capsular distention and/or intralesional hemorrhage or necrosis of the tumor and/or adjacent visceral compression by the tumor account for the associated chronic or intermittent pain, acute abdominal pain necessitating emergency intervention invariably reflects vascular compromise from torsion. Although lesion size varies according to histologic differentiation (approximately 5 cm for well-differentiated tumors to >15 cm for poorly differentiated tumors), abdominal, vaginal, and/or rectal examination readily identifies an adnexal mass in approximately 95% of symptomatic patients. The most common premonitory symptoms, namely, menstrual disorders and subtle androgenic manifestations, predate by several months, and sometimes years, the recognition of the overt clinical signs or symptoms. Irregular bleeding, oligomenorrhea, and postmenopausal bleeding, retrospectively, have been attributed to either excess androgens or estrogens. The etiology of the latter is presumably the peripheral conversion of androgens to estrogens or, rarely, from an estrogen-secreting SLCT. Frank virilization occurs in 35% of the patients with SLCTs, and another 10% to 15% have some clinical manifestations consistent with androgen excess. The most frequent androgenic symptom complex encountered includes amenorrhea, voice deepening, and hirsutism. In addition, breast atrophy, clitorimegaly, loss of female contour, and temporal hair recession, for example, are signs of masculinization witnessed in patients with SLCTs (117-119). The prevalence of androgenic manifestations appears to be independent of the degree of histologic differentiation, but is observed less frequently in heterologous SLCTs and only occasionally in patients harboring retiform lesions (118,120-123). Although the preoperative diagnosis of SLCT in the absence of androgenic excess may be impossible, this neoplastic entity should constitute the primary preoperative diagnosis in patients with androgenic manifestations presenting during the second through the fourth decades of life with a unilaterally palpable adnexal mass.

Uncommonly, estrogen manifestations are witnessed in the context of presumed end-organ estrogenic responses, including postmenopausal bleeding and endometrial polyp formation, hyperplasia, and adenocarcinoma. Cautious interpretation of such observations is required, realizing that peripheral conversion of androgens to estrogens may be as plausible as a primary estrogen-secreting SLCT. As expected from the clinical findings, most patients demonstrating signs of defeminization or virilization have elevated plasma testosterone levels (117-119). Whereas plasma androstenedione may occasionally be elevated, the urinary 17-ketosteroids, including dehydroepiandrosterone, are usually normal, with the occasional patient presenting with a slightly elevated level. An elevated testosterone/androstenedione ratio generally

suggests the presence of an androgen-secreting ovarian tumor, most likely an SLCT. Recognizing that certain gonadotropin-releasing hormone (GnRH) agonists modulate androgen production by downregulating gonadotropin levels and through a direct effect on the ovary, Pascale et al. (124) demonstrated successful suppression of testosterone and androstenedione in five virilized women with the administration of GnRH agonists. Their data suggest that androgen-secreting tumors of the ovary appear to be less autonomous than such tumors originating in the adrenal gland. Surgical excision of the SLCTs results in a precipitous drop in androgen levels and, over time, partial to complete resolution of the clinical manifestations associated with androgen excess is observed.

The coexistence of other diseases with SLCTs has been chronicled. The frequency with which thyroid disease is observed in these patients appears to exceed mere chance. Furthermore, several cases of other mesenchymal tumors have occurred in patients with SLCTs, including sarcoma botryoides of the cervix as well as Ollier's disease (118,125). The latter is a rare disease, but it is associated with other SCSTs, specifically JGCTs, as noted above. Finally, there appears to be a tendency toward familial occurrence (118).

Pathology

Gross Features

SLCTs vary in size from small to huge masses, but most are between 5 and 15 cm in diameter. The majority are solid, often yellow, and lobulated (Fig. 25.5), but many are solid and cystic. Pure cystic tumors are exceptionally rare, in contrast to GCTs. Poorly differentiated tumors tend to be larger than more differentiated tumors, and more frequently contain areas of hemorrhage and necrosis (118). Tumors with heterologous or retiform components are more often cystic than other tumors in this category (120,121,123,126). The heterologous tumors occasionally simulate mucinous cystic tumors on gross examination, and retiform tumors may contain large edematous intracystic papillae, resembling serous papillary tumors, or may be soft and spongy, with varying degrees of cystification (123).

Figure 25.5 Sertoli-Leydig cell tumor. The sectioned surface of the tumor is focally lobulated and was yellow in the fresh state.

Microscopic Features

Well-differentiated SLCTs are characterized by a predominantly tubular pattern (127). On low-power examination, a nodular architecture is often conspicuous, with fibrous bands intersecting lobules composed of small, round, hollow, or, less often, solid tubules lined by well-differentiated cells and separated by variable numbers of Leydig cells. Rarely the tubules appear pseudoendometrioid (128).

SLCTs of intermediate and poor differentiation form a continuum characterized by a variety of patterns and combinations of cell types (117-119). Some tumors exhibit intermediate differentiation in some areas and poor differentiation in others; less commonly, tumors of intermediate differentiation contain well-differentiated foci. Both the Sertoli cells and the Leydig cells may exhibit varying degrees of immaturity. In tumors of intermediate differentiation, immature Sertoli cells have small, round, oval, or angular nuclei, generally scanty cytoplasm, and are arranged typically in ill-defined masses, often creating a lobulated appearance on low power; solid and hollow tubules, nests, broad columns of Sertoli cells, and, most characteristically, thin cords resembling the sex cords of the embryonic testis are often present (Fig. 25.6). These structures are separated by stroma, which ranges from fibromatous to densely cellular to edematous, and typically contains clusters of well-differentiated Leydig cells (Fig. 25.6). Cysts containing eosinophilic secretion may be present, creating a thyroid-like appearance, and follicle-like spaces are encountered rarely. The Sertoli cell and Leydig cell elements, singly or in combination, may contain varying and sometimes large amounts of lipid, in the form of small or large droplets. When a significant amount of the stromal component comprises immature cellular mesenchymal tissue with

high mitotic activity resembling a nonspecific sarcoma, the tumor is poorly differentiated.

Fifteen percent of SLCTs have a substantial retiform component, and are so designated because they are composed of a network of elongated tubules and cysts, both of which may contain papillae, resembling the rete testis (33). This pattern is usually accompanied by other patterns of SLCTs, but sometimes an entire tumor has a retiform pattern.

Heterologous elements occur in approximately 20% of Sertoli cell tumors (124,129). In a series of these tumors, 18% contain glands and cysts lined by moderately to well-differentiated intestinal-type epithelium (124). Mesenchymal heterologous elements, encountered in 5% of Sertoli cell tumors, include islands of cartilage arising on a sarcomatous background, areas of embryonal rhabdomyosarcoma, or both (129).

Natural History

SLCTs display characteristics that differ markedly from their epithelial counterparts, notably in regard to their malignant potential. Despite an average size of approximately 16 cm, only 2% to 3% of SLCTs have demonstrable extraovarian spread at the time of detection. Furthermore, Young et al. (63) identified only 29 clinically malignant cases in their series of 220 SLCTs observed at varying intervals, and they noted an 18% malignancy rate among 164 patients with adequate follow-up. At least in part, the more favorable prognosis reflects the abrupt onset of androgenic manifestations and the early detection of nonspecific symptoms, which promote prompt medical assessment. Nevertheless, the natural history of the malignant variant includes early recurrences, with approximately two-thirds becoming evident within 1 year of treatment and only 6% to 7% recurring after 5 years. The abdominal cavity (including the pelvis) and the retroperitoneal nodes are the most frequent sites for recurrences. In addition, the contralateral ovary, lungs, liver, and bone are other reported sites of recurrent metastatic disease. The collective salvage rates in patients with clinically malignant disease are low, with extrapolated estimates being less than 20%.

Prognostic Factors.

Stage is the most important predictor of outcome in SLCTs. Fortunately, 97% of SLCTs are reportedly stage I at diagnosis, and less than 20% of these localized tumors become clinically malignant. The most cogent phenotypic prognostic determinant for stage I SLCTs is the degree of histologic differentiation (117-119). Approximately one-half of the reported SLCTs are of intermediate differentiation, 10% are well differentiated, 20% are heterologous, and the remainder are poorly differentiated. No extraovarian spread or subsequent recurrences were encountered by Young and Scully (127) among 23 well-differentiated SLCTs. However, approximately 10% of intermediate and 60% of poorly differentiated tumors, as well as 20% of heterologous tumors, demonstrated clinically malignant behavior (118). The heterologous tumors contain either endodermal elements such as gastrointestinal epithelium and carcinoids or mesenchymal elements including skeletal muscles and/or cartilage. The endodermal elements are typically associated with intermediately differentiated homologous elements and represent 75% of the heterologous SLCTs. Their corresponding prognosis parallels that of the intermediately differentiated homologous tumors. In contrast, heterologous tumors containing mesenchymal elements account for 5% of all SLCTs and invariably coexist with a poorly differentiated homologous component. The clinically aggressive malignant behavior of poorly differentiated heterologous tumors is evidence by the extremely low rates of survival (118).

Retiform patterns, tumor size, mitotic activity, and tumor rupture appear to increase in frequency because the degree of tumor differentiation decreases (117-119). Approximately 10% of neoplasms express histologic patterns resembling the rete testis. They are more commonly observed in younger patients (average age, 15 years) and are generally larger, possibly secondary to the less frequent association of androgenic manifestations and, hence, a later clinical presentation (120-123). SLCTs harboring a retiform pattern are associated with a 20% rate of malignancy, significantly higher than the 12% rate in nonretiform SLCTs. Young and Scully (123) noted that 14 of 25 retiform cases were of intermediate differentiation, with 1 demonstrating poorly differentiated homologous histology and 10 exhibiting heterologous elements (3 intermediate and 7 poorly differentiated). Arguably, the less favorable prognosis reflects the frequency of associated heterologous and/or poorly differentiated homologous lesions. This concept is supported by the finding that the majority of the metastatic lesions do not contain retiform patterns (123). However, the adverse characteristics of the retiform component are during examination of tumors of intermediate differentiation. Although only 4 of over 100 reported intermediately differentiated SLCTs were clinically malignant, 3 of the 4 contained retiform patterns (118).

Tumor size, mitotic activity, and rupture have been reported to influence prognosis (117,118). The size, mitotic index, and rupture frequency appear to increase because histologic dedifferentiation increases. Notwithstanding these associations, substratification of intermediate and poorly differentiated lesions according to these parameters identifies significant prognostic differences.

The frequency of androgen excess has been addressed above, with 50% or more of patients diagnosed with SLCTs either directly or indirectly displaying clinical manifestations of hyperandrogenism. Serum testosterone levels are invariably elevated when virilization is present, and selective venous catheterization has documented the ovary as the site of origin (130,131). In addition, immunostaining was positive for testosterone in eight SLCTs analyzed, including a limited number of tumors from patients without clinical signs or symptoms of androgen excess (2,132). The Leydig cells, as anticipated, were shown to be the cell of origin for the synthesis of testosterone. Following cytoreductive surgery, serum testosterone levels are rapidly cleared from the circulation and have been reported on occasion to increase again due to the burden of recurrent metastatic disease.

Other unique secretory products, namely, inhibin and alpha fetoprotein (AFP), have been reported in a limited number of SLCTs and are proteins generally equated with GCTs and germ cell tumors, respectively (121,123,131-133). In addition to GCTs, the Sertoli and Leydig cells have been shown to produce inhibin in testicular tissues, and presumably these same cell types are the site of origin in the SLCTs. Motoyama et al. (133) summarized the literature and reported the 14th case of an elevated serum AFP accompanying SLCTs. A clinically malignant course was appreciated in 43% of the described population, which had a mean age of 16 years. In addition, the majority (57%) was described as having a retiform

component, a frequency substantially higher than the 10% usually seen in larger SLCT samples. Preferential AFP sampling may account for a portion of this seemingly unusually high frequency in that, histologically, the retiform pattern may be confused with a yolk sac tumor, particularly in the absence of clinical androgenic manifestations. The Sertoli and Leydig cells appear to be the cells of origin for AFP within the tumor. Employing immunostaining, Gagnon et al. (132) confirmed that Leydig cells appear to be the predominant site for AFP synthesis, but Sertoli cells are also capable of producing this oncoprotein. Testing four retiform and four nonretiform SLCTs, they demonstrated a 50% positivity rate in both histologic subtypes. The precise frequency of both inhibin and AFP positivity and their correlation with disease activity await larger confirmatory assessments.

OVARIAN SEX CORD TUMOR WITH ANNULAR TUBULES

In 1970, Scully (70) described a limited series of unique ovarian tumors characterized by either simple or complex ring-shaped tubules, and proposed the morphologic designation ovarian sex cord tumor with annular tubules (SCTATs). The distinctive cellular elements of these neoplasms were judged to be histologically representative of an intermediate between Sertoli cell and GCTs. Shen et al. (134) reported that SCTATs accounted for 6% of the sex cord tumors treated at their institution. An association with PJS was recognized by Scully, and in a subsequent report of 74 cases of SCTAT, Young et al. (135) noted that approximately 1 in 3 SCTATs occurred in patients with PJS. Ovarian sex cord tumors with annular tubules occurring in association with PJS are typically small (many microscopic), multifocal, calcified, and bilateral. The average age of presentation is the early to mid-portion of the fourth decade of life (135,136). The non-PJS tumors are considerably larger, seldom multifocal or calcified, and invariably unilateral. The average age of these patients is the mid- to latter portion of the third decade of life.

Abnormal vaginal bleeding is the most common presenting complaint, including menstrual irregularities during the reproductive era and postmenopausal bleeding during the mature years. Menometrorrhagia followed by prolonged episodes of amenorrhea is common in non-PJS patients. Abdominal pain or discomfort is less frequently encountered, but generally accompanies grossly involved adnexa or other incidental pelvic pathology. In addition, the signs and symptoms accompanying intussusception secondary to colonic polyp formation may be manifested in PJS-associated patients. The majority of PJS-associated SCTATs are not detectable via clinical examination and are appreciated unexpectedly during surgical or pathologic assessment. In contrast, the majority of non-PJS SCTATs are palpable on abdominal and/or vaginal examination. Although these tumors are seldom encountered during the first decade of life, isosexual precocity is invariably witnessed when SCTATs are diagnosed in affected children (135-138).

Considering the rarity of both PJS, an autosomal dominant disorder, and SCTAT, the frequent concurrency of these two processes suggests a potential linkage in their pathogenesis. Approximately 36% of SCTATs are observed in patients with PJS. In addition, 15% of PJS-associated SCTATs also develop adenoma malignum of the cervix (AMC), a neoplasm that defies early diagnosis and is associated with a relatively high mortality rate (135,139-141). A recent report of 34 patients with PJS demonstrated a significantly elevated risk (relative risk = 20.3) of breast and gynecologic malignancies in women (142); one patient had a Sertoli–Leydig tumor and three had sex cord tumors with annular tubules. The PJS gene was mapped to chromosome 19p13.3 (143) and was later identified as a novel serine–threonine kinase, STK11 (144). Because of the wide variety of malignancies occurring in individuals with PJS, STK11 is believed to function as a general tumor-suppressor gene.

Contingent on the patient's age, precocious puberty, menstrual irregularities, or postmenopausal bleeding are clinical manifestations of SCTATs, indirectly attesting to their endocrine activity (135-139,141,145,146). These signs of hyperestrogenism and the corresponding effects on the endometrium were readily recognized in the initial description of these unique tumors (62). Numerous reports have confirmed the presence of endometrial hyperplasia and/or polyp formation, particularly in PJS-associated SCTATs. Although similar signs in endometrial histology can be observed in non-PJS SCTATs, clinical histories of menorrhagia followed by episodes of amenorrhea are more frequent (134-137,145,146).

Endometrial sampling in a limited population of such patients has demonstrated a spectrum from atrophic glandular to secretory or decidualized endometrium, suggestive of significant levels of progesterone production (134,136,146). Assessment of circulating steroid levels has confirmed the presence of excessive estrogen in essentially all SCTAT cases (134,145-147). However, normal progesterone levels have been observed in PJS-associated tumors, but elevated quantities of progesterone have been documented in non-PJS patients (134,145-147). Shen et al. (134) demonstrated elevated estrogen and progesterone levels (and normal testosterone levels) in two SCTAT patients without PJS, documenting glandular atrophy and decidual stromal changes. Utilizing selective ovarian venous sampling, Crain (146) demonstrated a significant progesterone gradient between peripheral and ovarian venous serum in a non-PJS patient with pseudodecidual changes of the endometrium. Complete resolution of the manifestations attributed to these hormonal imbalances is routinely observed, with surgical extirpation of the ovarian neoplasm.

Pathology

Grossly, the PJS-associated tumors are small, solid and yellow. The non-PJS-associated neoplasms, which are almost always grossly visible, may be similar, but in some cases are solid and cystic or mostly cystic. This tumor is characterized microscopically by the presence of simple and complex annular tubules (Fig. 25.7). The simple tubules have the shape of a ring, with the nuclei oriented around the periphery and around a central hyalinized body composed of basement membrane material; an intervening anuclear cytoplasmic zone forms the major component of the ring. The more numerous complex tubules are rounded structures comprising intercommunicating rings revolving around multiple hyaline bodies. In patients with PJS, the tumors are typically multifocal and exhibit calcification.

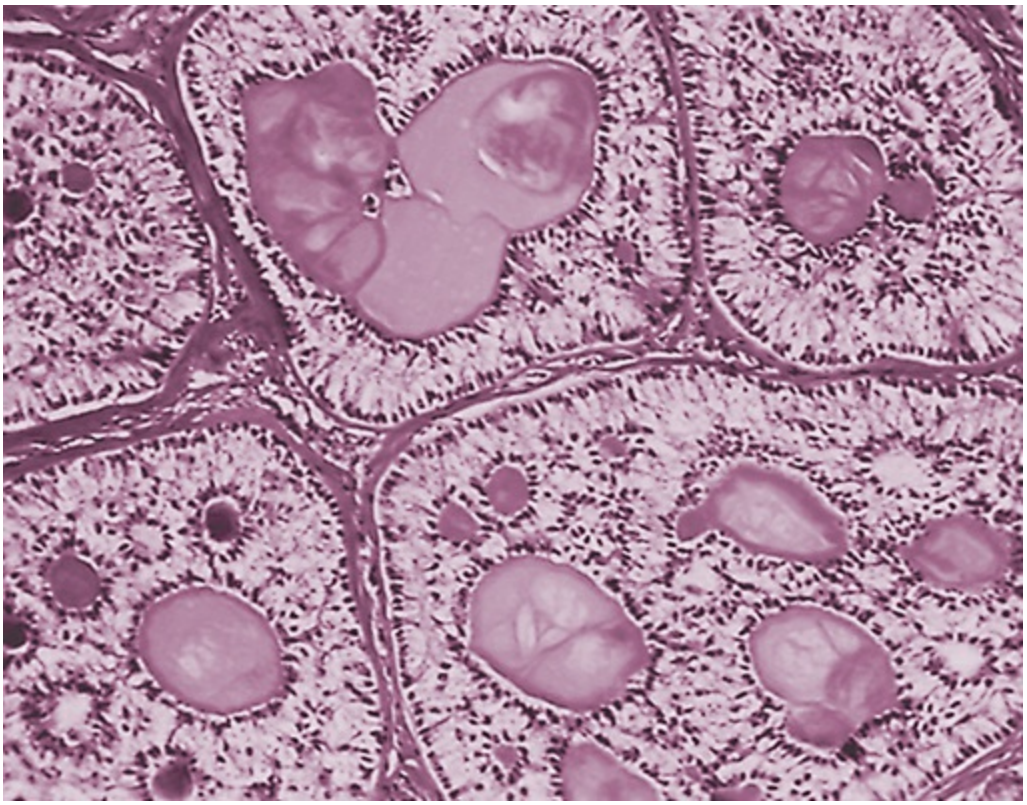

Figure 25.7 Sex cord tumor with annular tubules. Numerous rounded tubules encircle multiple hyaline bodies.

Prognostic Factors

Notwithstanding their histologic similarities, the differences in the natural history and long-term prognosis for SCTATs associated with PJS and SCTATs independent of PJS are readily apparent. Those detected in women with PJS are benign. Important in the management of this entity, however, is the recognition that approximately 15% of these patients will harbor an AMC. In addition, there are almost always exceptions to the rule. Barker et al. (148) reported a 54-year-old woman with SCTAT and PJS demonstrating aggressive malignant behavior, with multiple recurrences. In their review of the literature, the authors identified two previous such patients. Because of delayed declaration of symptoms, the diagnosis of AMC is frequently made following examination of the hysterectomy specimen. In a recent review by Srivatsa et al. (141), the prognosis for PJS patients with SCTAT and AMC is ominous, reflecting high AMC recurrence rates and refraction to treatment.

Based on the compiled data from four reported series including 63 patients with SCTATs and without clinically apparent PJS, the rate of malignancy was approximately 20% (134-137). Primary extraovarian extension and/or frequency of recurrence has been correlated with the original tumor size and mitotic activity. The tumor characteristically has a relatively long doubling time, a propensity for lymphatic dissemination, and is apt to remain lateralized. Because the primary ovarian lesion is invariably unilateral, the lymphatic metastases are invariably ipsilateral, extending within the confines from the paraaortic region to the supraclavicular area. The nature of the retroperitoneal metastases generally facilitates surgical resection and repeat cytoreduction. This tumor's indolent growth pattern, coupled with the relative ease of resection, affords patients extended palliation.

Because SCTATs possess characteristics of both granulosa cells and Sertoli cells, tumor markers elicited by either or both cell types indicate that diagnosis and surveillance of these tumors may be utilized, as well. The increased serum estrogen levels and corresponding clinical manifestations recognized in SCTATs suggest that monitoring hormone levels may be useful. Unfortunately, serum estradiol lacks adequate sensitivity, particularly when the residual tumor volume is limited. However, recent reports demonstrate the potential value and sensitivity of two unique secretory proteins as tumor markers for SCTATs. Gustafson et al. (147) illustrated the applicability of monitoring serum inhibin and MIS in the management of a patient with advanced, recurrent SCTAT. More recently, Puls et al. (149) reported an excellent correlation between serum inhibin and MIS levels and the clinical status of a patient with SCTAT during administration of chemotherapy (CT). The ultimate utility of these tumor markers awaits a study achieving accrual of sufficient numbers of patients with SCTATs to address adequately sensitivity and specificity issues.

SCSTS, UNCLASSIFIED

This ill-defined group of tumors, which accounts for less than 10% of tumors in the sex cord–stromal category, comprises those in which a predominant pattern of testicular or ovarian differentiation is not clearly recognizable. Talerman et al. (150) have recently segregated proposed the designation "diffuse nonlobular androblastoma" for this group of tumors. The six ovarian tumors they reported were mostly estrogenic and had a predominant diffuse proliferation of cells resembling theca cells, granulosa cells, or both, but five of the six cases also contained steroid-type cells and tubules typical of Sertoli cell neoplasia.

SCSTs may be particularly difficult to subclassify when they occur in pregnant patients because of alterations in their usual clinical and pathologic features (151). Their nature is rarely suggested clinically because, during pregnancy, estrogenic manifestations are not recognizable and androgenic manifestations are rare. In one study, 17% of 36 SCSTs that were removed during pregnancy were placed in the unclassified group, and many of those classified in the granulosa cell or Sertoli–Leydig cell category had large areas with an indifferent appearance (151).

Gynandroblastoma

Gynandroblastoma is an extremely rare SCST (if strict morphologic criteria are followed to establish the diagnosis).

Microscopically, these tumors must demonstrate readily identifiable (at least 10%) granulosa cells and tubules of Sertoli cells. Not surprisingly, the corresponding stromal cells, namely, theca and/or Leydig cells, may also be present in varying degrees. In a recent review of the world literature, Martin-Jimenez et al. (152) were able to identify only 17 authenticated cases of gynandroblastoma. Patients presented at an average age of 29.5years (range, 16 to 65 years), with primary symptoms of menstrual disturbances consistent with the predominant functional status of the tumor. Commonly, a hyperandrogenic clinical profile is elicited, but signs and symptoms of excessive estrogens or no endocrine manifestations can be encountered. Amenorrhea, hirsutism, and clitorimegaly are frequently noted in association with elevated testosterone levels. Conversely, the common end-organ responses to hyperestrogenism include menometrorrhagia, postmenopausal bleeding, and endometrial hyperplasia. Although the unilateral masses are typically small, 75% are palpable prior to surgical exploration and are characterized by well-differentiated ovarian and testicular constituent elements. Regardless of the associated hormonal activity, gynandroblastomas are considered to be of low malignant potential. To date, only a single case was reported to be clinically malignant resulting in the death of the patient (153). A gynandroblastoma in pregnancy has also been reported (154).

Steroid Cell Tumors

SCTs constitute only 0.1% of all ovarian neoplasms. The predominant components of these tumors are steroid hormone–secreting cells, including lutein cells, Leydig cells, and adrenocortical cells. Until recently, the term *lipid cell tumors* was applied to these neoplasms, but Hayes and Scully (155) noted that 25% of such designated tumors did not contain appreciable intracellular fat. Hence, the functional designation SCT was suggested and stratified into three subclasses: stromal luteoma, Leydig cell tumor, and SCTs not otherwise specified (SCTNOT). The stromal luteoma category was introduced in 1964 to describe small neoplasms in the steroid cell family that were almost certainly of stromal origin. However, it is now felt that they are best considered, simply, small SCTs and do not have sufficiently unique aspects to merit separate classification. Leydig cell tumors, are, however, sufficiently distinctive as to merit classification from the larger body of overall SCTs placed in the group of SCTNOT.

Leydig Cell Tumors

Leydig cell tumors are rare. By combining two reviews (156,157) that summarize the English-language literature prior to and after 1966, 38 Reinke-positive cases affording adequate abstraction were identified. These invariably unilateral tumors are typically small, ranging in size from 0.7 to 15 cm, with a mean of 2.7 cm, and are therefore frequently not detectable via clinical examination or pelvic imaging. The average age at diagnosis is 58 years (range, 37 to 86 years), with only a small percentage occurring prior to the climacterium. The initial clinical manifestations are usually consistent with a hyperandrogenic state. Overt signs of virilization are observed in greater than 80% of the patients. These include one or more of the following: hirsutism, acne, deepening of the voice, breast atrophy, clitorimegaly, and male pattern baldness. In contrast to the frequently dramatic onset and progression of virilization witnessed with SLCTs, ovarian Leydig cell tumors are generally characterized by a more indolent course. Paraskevas and Scully (156) reported an interval of 7 years between recognized onset of signs and symptoms of androgen excess and diagnosis. Analysis of serum androgens demonstrated that testosterone was consistently elevated when urinary 17-ketosteroids were normal or marginally increased. These observations suggest minimal production of androstenedione or dehydroepiandrosterone. Conversely, estrogenic manifestations are occasionally witnessed, such as irregular menses or postmenopausal bleeding (156,157). Pathologic assessment of the uterus may reveal endometrial hyperplasia, polyp formation, and/or carcinoma in the presence or absence of leiomyomata and/or myohypertrophy. Whether the hyperestrogenic features are a result of tumor secretion of estrogens, or peripheral conversion of androgens to estrogens, remains to be ascertained.

Pathology

Histologically, Leydig cell tumors are typically composed of a monotonous proliferation of cells with abundant eosinophilic cytoplasm, and they less often have pale foamy lipid-rich cells than SCTNOT. The cells are predominantly cytologically bland, but bizarre nuclear atypia may be encountered this is almost always unassociated with mitotic activity, and should not lead to concern for malignancy. Roth and Sternberg (158) subdivided these tumors according to location and possibly the cell of origin, namely, Leydig cell tumors of hilar type versus nonhilar type. Whereas the latter presumably arise from ovarian stromal cells and are extremely rare, the former tumors are located in the hilus of the ovary and encroach on or extend into the ovarian stroma to varying degrees. Other features of Leydig cell tumors (including location in the ovarian hilus or adjacent to nonmedullated nerve fibers, association with hilar cell hyperplasia, fibrinoid vascular changes in the tumor, and clustering of cells around vessels) indicate that tumors lacking crystals of Reinke should likely be considered Leydig cell tumors (156).

Prognostic Factors

In a review of the English literature through 1988, 38 Reinke-positive cases were accrued and only a single case of a clinically malignant lesion was identified (156,157). Based on tumor size (15 cm) alone, this sole example might be considered an outlier. Hence, similar to stromal luteomas, ovarian Leydig cell tumors are essentially benign neoplasms with primary postsurgical concerns consisting of regression of the androgen-induced alterations. Generally speaking, significant regression is witnessed, but significant residual sequelae are appreciated in approximately one-half of the patients.

Steroid Cell Tumors, Not Otherwise Specified

Neoplasms identified as SCTs but lacking the specific characteristics of Leydig cell tumors are collectively classified as SCTNOS. The average age at presentation of patients harboring SCTNOS is 43 (10 to 15 years earlier than Leydig cell tumors); the tumors have been diagnosed from early childhood to the ninth decade of life (159). These generally solid yellow tumors are usually larger than Leydig cell tumors. The average size at diagnosis is approximately 8.5cm. Furthermore, a higher frequency of bilaterality (5%) in advanced disease is encountered with these neoplasms. In their review of 63 collated cases, Hayes and Scully (159) reported that 81% of cases were localized (stage I), 6% were stage II, and 13% were stage III or IV. Curiously, they noted that the average age (54 years) of patients with advanced disease was 10 years older than the group as a whole. At least in part, these findings reflect the absence of documented advanced malignancies during the first two decades of life.

Clinical signs and/or symptoms of androgen excess ranging from heterosexual precocity in prepubertal girls to amenorrhea, hirsutism, and/or virilization during the reproductive and/or postmenopausal age prompt the majority of patients to seek medical advice (159,160). Not infrequently, these androgenic changes may have been present for many years (161). Additional concerns at presentation include increasing abdominal girth, reflecting tumor size and, rarely, ascites, abdominal pain, Cushingoid symptoms, and irregular uterine bleeding. The latter may represent clinical manifestations of estrogen excess (159,162), which has been suggested to occur at a frequency of 6% to 23%. Whether the source of estrogen is *de novo* synthesis by the tumor or from peripheral conversion of androgens remains to be determined. Isosexual precocious pseudopuberty has been detected in young girls harboring SCTNOS (159,163,164). An additional 10% to 15% of patients are asymptomatic, with tumors detected incidentally during routine pelvic examination or at the time of hysterectomy or other surgical interventions.

The steroid hormone–secreting capacities of SCTNOS are more diverse than those of most SCSTs. Whereas approximately one in four patients does not demonstrate clinical manifestations of hormonal imbalances, the majority of patients with SCTNOS show evidence of androgen excess (10% to 15% estrogen excess), and a lesser percentage show evidence of cortisol excess. These excesses are demonstrable via assessment of end-organ responses and serum/plasma steroid levels. Whereas elevated plasma levels of corticosteroids are typically observed in conjunction with SCTNOS, the

number of overt presentations with Cushing's syndrome is limited (163,165-167). However, 17% of the clinically malignant tumors reported by Hayes and Scully (159) were associated with Cushing's syndrome. The serum testosterone and androstenedione levels are invariably elevated, as are urinary 17-ketosteroids; presumably, the latter reflect the level of excess androstenedione production.

Pathology

Gross Features

These tumors are typically solid, well-circumscribed, occasionally lobulated (Fig. 25.8), and on average measure 8.4 cm in diameter (159). Approximately 5% are bilateral. They are typically yellow or orange but are occasionally red, dark brown, or black. Necrosis, hemorrhage, and cystic degeneration are occasionally observed.

Figure 25.8 Steroid cell tumor, unclassified. The sectioned surface of the tumor is lobulated and was yellow-orange in the fresh state. This tumor was from a 9-year-old virilized girl.

Microscopic Features.

On microscopic examination, the tumor cells are typically arranged diffusely but occasionally grow in nests, irregular clusters, thin cords, and columns. The polygonal to rounded tumor cells have distinct cell borders, central nuclei, and moderate to abundant amounts of cytoplasm varying from eosinophilic and granular to vacuolated and spongy (Fig. 25.9). In approximately 60% of the cases, nuclear atypia is absent or minimal and mitotic activity is low (less than 2 MFs per 10 HPFs). In the remaining cases, grades 1 to 3 nuclear atypia (Fig. 25.3) is present, usually associated with an increase in

mitotic activity (up to 15 MFs per 10 HPFs). Occasional small SCTs (formally placed in the stromal luteoma category) are associated with hyperthecosis, which may contribute to the androgenic manifestations in such cases.

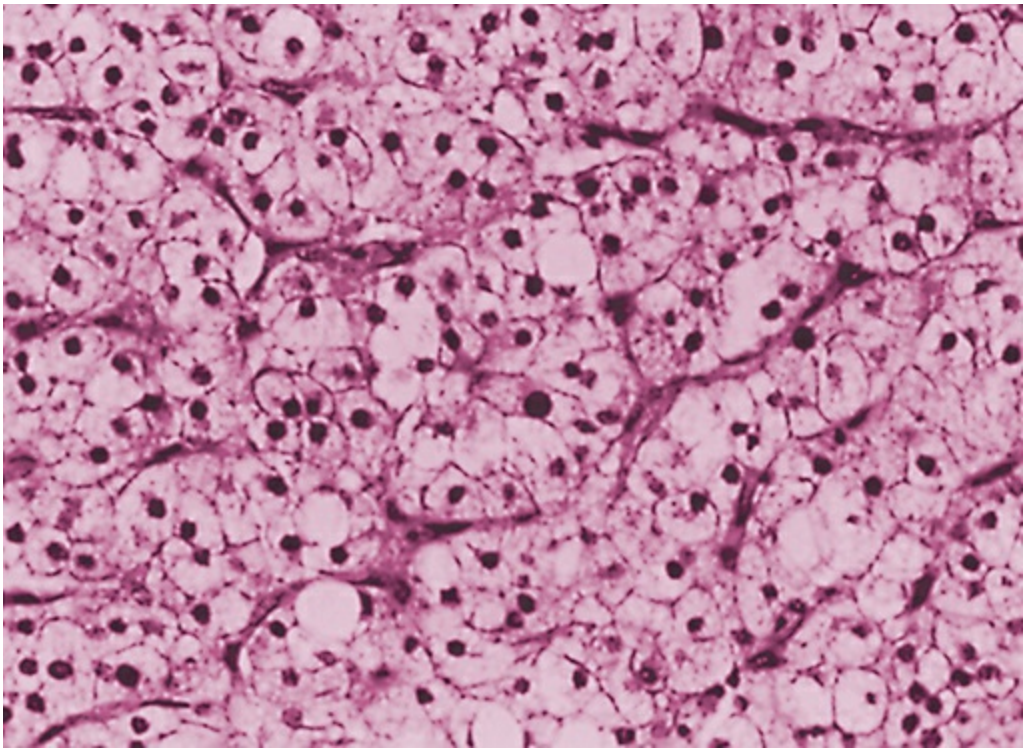

Figure 25.9 Steroid cell tumor. The tumor cells are large and rounded and laden with lipid vacuoles.

Prognosis.

In contrast to the benign natural history of Leydig cell tumors, SCTNOS are associated with an appreciable rate of clinical malignancy (although there may be a reporting bias). In the largest series in the literature, 43% of patients with follow-up of 3 or more years demonstrated extraovarian disease, either at primary surgery or during subsequent follow-up (168). Unfortunately, to date, salvage therapy has been abysmal. Multiple factors appear to correlate with the frequency of disseminated disease including age, stage, tumor size, mitotic activity, tumor necrosis, hemorrhage, and symptoms of Cushing's syndrome. The average age of patients with clinical malignancies is 16 years older than patients without metastatic disease and 3 or more years of observation. No clinically malignant cases have been reported to date in patients younger than 20years of age. All malignant SCTNOS were reported to measure 7 cm or more in greatest diameter (159). In fact, 78% of all tumors 7 cm or larger were malignant, whereas only 21% of all benign tumors exceeded this dimension. The most cogent determinant correlating with malignant potential was mitotic activity, with 92% of malignant tumors displaying 2 or more MFs per 10 HPFs. Similarly, in the presence of necrosis, 86% were malignant; if hemorrhage was present, 77% were malignant. In addition, three of four patients (17% of all malignant cases) with recognizable Cushing's syndrome harbored clinically malignant disease (159).

Although the majority of recurrences become clinically manifest within 3 years of diagnosis, Hayes and Scully (159) reported that 22% of recurrences occurred after 3 years and that, in fact, all of these cases occurred after 5 years; the longest interval was 19 years. Therefore, the duration of posttreatment surveillance should be adjusted accordingly. The only currently available utilizable markers for SCTNOS include the steroid hormones that were elevated prior to definitive treatment.

TREATMENT

The definitive management of SCSTs is dependent on one or more of the following: surgical stage, histologic subtype, patient's age and desire for fertility preservation, and various prognostic factors. Surgical resection alone is sufficient for SCSTs lacking malignant potential. Postoperative adjunctive therapy should be considered for patients with advanced disease and SLCTs with poor differentiation or mesenchymal heterologous elements (169).

Operative Management

Surgery remains the cornerstone of treatment for patients with SCSTs. Following sampling of peritoneal washings for cytologic assessment, inspection and palpation of the viscera are conducted to detect macroscopic disease. Resection of the ovarian tumor constitutes sufficient therapy for the essentially benign neoplasms, including thecomas, fibromas, gynandroblastomas, stromal luteomas, Leydig cell, sclerosing stromal, Sertoli cell, and well-differentiated SLCTs. Furthermore, sex cord tumors with annular tubules associated with PJS are also considered benign and can be similarly managed, but it is imperative that the endocervix be evaluated and subsequently monitored for the potential development of an AMC.

Upon histologic confirmation of GCTs, intermediate or poorly differentiated SLCTs, SCSTs with annular tubules independent of PJS, and SCTNOTs, surgical staging is required. This includes multiple peritoneal biopsies, omentectomy, and resection of grossly suspicious pelvic or paraaortic lymph nodes. Careful inspection of the peritoneum is critical because residual disease is strongly correlated with recurrence. However, there appears to be little benefit to performing routine lymphadenectomy in the absence of grossly suspicious lymph nodes. In three series totaling 180 patients with GCTs and SLCTs, no lymph node metastases were found among those who underwent pelvic and/or paraaortic lymphadenectomy (170-174). Furthermore, isolated retroperitoneal recurrences are rare. In 34 patients with recurrent GCTs, 2 recurred in the retroperitoneum only; 2 in the pelvis and retroperitoneum; and 1 in the pelvis, abdomen, and retroperitoneum (170). In another series of 87 patients, only 2 of 18 recurrences were isolated to the retroperitoneum (171). Overall, approximately 10% to 15% of first recurrences involve the retroperitoneum. Following careful surgical staging, in the absence of extraovarian disease, conservation of the uterus and contralateral ovary is reasonable in patients wishing preservation of fertility. In a review of the 1988 to 2001 SEER database, Zhang et al. (175) identified 376 patients with ovarian SCST. The survival for the group of 110 patients with stage I–II disease who underwent conservative surgery without hysterectomy was similar to that of patients who underwent standard surgery. For older patients or those with advanced-stage disease or bilateral ovarian involvement, abdominal hysterectomy and bilateral salpingo-oophorectomy are usually indicated. Others have reported conservative management for patients with advanced JGCTs treated with cytoreduction and CT, leading to prolonged disease-free intervals and multiple pregnancies (172). However, if the uterus is preserved, a thorough curettage must be performed in all patients with estrogen-producing tumors whether they are considered to be benign or potentially malignant (173). If maintenance of fertility is not a concern, a hysterectomy and residual salpingo-oophorectomy should be performed. Although no randomized evidence exists pertaining to the efficacy of cytoreduction in SCSTs, based on the benefits observed with their epithelial counterparts, we endorse an aggressive maximum effort at primary surgery if metastatic disease is encountered. In a recent multivariate analysis of 176 patients with GCTs, only residual disease after primary surgery and tumor size were predictive of recurrence (37). The value of secondary cytoreduction continues to be controversial, but appears to be meritorious for the more indolent tumor types such as GCTs and SCTATs not associated with PJS. Repeat cytoreduction frequently affords these patients extended palliation, and should be considered the cornerstone for treatment of recurrent disease.

Postoperative Management and Management of Recurrent

Granulosa Cell Tumors (Adult)

The vast majority of women with stage I disease have an excellent prognosis after surgery alone, and do not require adjuvant therapy. For those with stage IC disease, consideration can be given to adjuvant therapy on an individualized basis. However, the management of stage IC GCT remains controversial. Recently, in a study of 104 women with stage I GCTs, Wilson et al. (34) observed higher relapse rates (43% vs. 24%; $p = 0.02$) and shorter time to relapse (10.2 vs. 16.2 years; $p = 0.007$) in patients with stage IC versus stage IA disease. Most women presenting with stages II–IV disease would be advised to have postoperative therapy, depending on their individual characteristics. However, in some centers in the United States and Europe, patients with metastatic disease are initially treated with surgery alone and only receive CT at the time of relapse.

Whereas some investigators have reported improved outcomes in patients treated with adjuvant radiation therapy (RT), other investigators have found no clear value to the use of adjuvant RT (4,6,17,176). Because of the rarity of GCT, it is difficult to conduct prospective trials in these patients. Two retrospective reports provide some data on the use of RT. Savage et al. (177) reviewed the courses of 62 women treated for adult GCTs at the Royal Marsden Hospital from 1969 to 1995. Thirty-eight (61%) had stage I disease. Eleven of the stage I patients had adjuvant pelvic radiation. The 10-year disease-free survival of these patients was 77% versus 78% for stage I patients treated with surgery alone. Unfortunately, neither complete surgical staging information nor the features that led to the selection of patients for adjuvant radiation was provided. For eight patients with inoperable disease (or residual disease postoperatively), radiation resulted in complete responses in four (50%) that lasted 16 months to 5 years.

Wolf et al. (176) reported on 34 patients with GCTs treated with radiation at the M.D. Anderson Cancer Center, 14 of whom had measurable disease. Six of the 14 (43%) had a clinical complete response. Three of the responders were alive without evidence of disease 10 to 21 years after radiation.

The Gynecologic Oncology Group (GOG) has reported the largest series of women with ovarian SCSTs treated with CT. They used four cycles of cisplatin, bleomycin, and etoposide (BEP) (178). Eligible patients had incompletely resected stage II to IV or recurrent disease. Seventy-five patients entered, but 18 were ineligible because of incorrect histology or disease status. Of the 57 eligible patients, 41 had recurrent disease and 16 had primary disease. Thirty-nine had gross residual disease following surgery. Forty-eight had GCTs, seven had SLCTs, one had a malignant thecoma, and one had an unclassified SCST. This CT combination was considered to be active, with 11 of 16 primary-disease patients and 21 of 41 recurrent-disease patients remaining progression-free at a median follow-up of 3 years. Recognizing the prolonged natural history of these tumors, longer follow-up of this cohort will be important. The regimen was fairly toxic, with two bleomycin-related fatalities among the first six patients treated with the initial bleomycin dose of 20 U/m^2 (maximum 30 U) weekly for 9 weeks. The bleomycin dose was then reduced (20 U/m^2 every 3 weeks × 4 cycles), with no further toxicity. Grade 4 myelotoxicity occurred in 61% of the patients. The value of bleomycin in the treatment of this tumor type remains in question (179).

Gershenson et al. (180) also reported on the use of BEP in a group of nine women with poor prognosis of SCSTs of the ovary with poor prognosis (seven had metastatic disease). The median PFS was 14 months, with a median survival time of 28 months. In the same report, these investigators describe activity with paclitaxel in patients with GCTs who failed platinum-based therapies. In an earlier series, Gershenson et al. (168) found that cisplatin, doxorubicin, and cyclophosphamide showed activity in the treatment of metastatic ovarian stromal tumors, including two SLCTs. The overall response rate was 63% in this series.

The management of patients with recurrent disease must be individualized. The majority of relapses occur in the pelvis or abdomen, but liver, lung, or bone recurrences are also observed. Given the characteristic indolent growth pattern of GCTs, with long disease-free intervals, surgical resection of disease recurrence is often the initial step in the management of appropriate patients. Pecorelli et al. (181) treated 38 patients with advanced ($n = 7$) or recurrent ($n = 31$) GCTs with

cisplatin, vinblastine, and bleomycin (PVB) in a prospective trial through the European Organization for Research and Treatment of Cancer. Of the seven women who presented with advanced disease (stages II to IV), one was alive and disease-free at 81 months. Five died between 4 and 12 months after the start of PVB, and another was alive with disease at 2 months. Among the 31 women with recurrent disease, 7 were alive without further evidence of disease 24 to 81 months from the start of PVB. Consistent with the indolent course observed with GCTs in some women, another 11 patients were alive with disease at a mean of 45 months from the start of PVB (median, 39 months).

The wisdom of using a germ cell–like regimen for stromal tumors is questionable. Uygun et al. (182) reported on a small series of 11 women with recurrent GCTs. Most had cyclophosphamide, Adriamycin (doxorubicin), and cisplatin in the adjuvant setting. Four were treated with cyclophosphamide and cisplatin for recurrence and survived 35 to 73 months after recurrence.

Taxanes have also been reportedly active in SCSTs. A case report documented a dramatic response to paclitaxel in a patient with a GCT 2 years following cessation of platinum-based therapy (183). Subsequently, Brown et al. (184) reported a retrospective review of the M.D. Anderson Cancer Center experience with taxane therapy in 44 patients with newly diagnosed or recurrent SCSTs. Eleven patients received paclitaxel and a platinum drug for newly diagnosed SCSTs; all were alive at the time of the study, with a median follow-up of 52 months. Of 37 patients treated with a taxane for recurrent SCST, 7 had no measurable disease after secondary cytoreductive surgery, and 30 had measurable disease. The response rate in the latter cohort was 42%. In a follow-up study, Brown et al. (185) retrospectively compared the efficacy and side effects of taxanes, with or without platinum, with the combination of BEP. The outcomes of the two groups were similar, but the side effects associated with the BEP regimen appeared to be greater. The authors concluded that taxane and platinum CT warrants further investigation in SCSTs. The GOG recently completed accrual on a phase 2 trial of paclitaxel in women with stromal tumors with measurable disease (GOG protocol 187)—either previously untreated or recurrent. Results are pending. In addition, a GOG randomized phase 2 study of paclitaxel and carboplatin versus BEP in patients with SCSTs is ongoing.

Given the overall experience with cytotoxic CT for SCSTs over the past 3+ decades, it appears that these neoplasms are only moderately chemosensitive. Two recent studies have further elucidated this perspective. In a report of 27 patients with GCTs who received CT, nine patients had measurable disease and were evaluable for response (186). One (11%) of these patients had a complete response, and one (11%) had a partial response, for an overall response rate of 22%. The authors also evaluated 15 studies including 224 patients with measurable disease who received CT, and noted a response rate of 50%. However, they emphasized the lack of standardized response criteria, making a valid comparison very difficult.

Meisel et al. (187) reported a retrospective cohort study of 118 patients with GCTs, 10 (8%) of whom received adjuvant CT. Thirty-two patients experienced at least one relapse. The authors were unable to discern any definite benefit of treatment with CT for relapse compared with other strategies—surgery alone, hormonal therapy, RT, etc. However, the numbers were quite small. They concluded that adjuvant therapy did not appear to improve time to first relapse.

Considerable rationale exists for the utilization of hormone-based approaches in GCTs. A proportion of these tumors express steroid hormone receptors (188). Responses of GCTs, occasionally long-term, to medroxyprogesterone acetate and to GnRH antagonists have been reported (189-193). Fishman et al. (194) treated six patients with recurrent or persistent GCTs with monthly intramuscular injections of leuprolide acetate. Four patients had received prior cisplatinum-based CT. Five patients had evaluable disease: two had partial responses and three had stable disease. The leuprolide was well tolerated.

Aromatase inhibitors have also been used in GCTs. Three reports have documented remissions in seven women who received aromatase inhibitors for recurrent GCTs (195-197).

In a systematic review of 415 potentially relevant studies, van Meurs et al. (198) identified 19 eligible studies that included 31 patients with GCTs treated with 38 evaluable hormonal therapies. Overall, the authors reported a 25.8% complete response rate and a 45.2% partial response rate. Four patients had stable disease, and five had disease progression. Median PFS was 18 (range 0 to 60) months.

Antiangiogenesis drugs have also demonstrated activity in SCSTs. Farkkila et al. (48) found that VEGF and VEGF-2 were highly expressed in primary and recurrent GCTs. In addition, although VEGF protein expression was not predictive of tumor recurrence in this series, high levels of circulating VEGF were found in the serum of women with primary GCTs. Tao et al. (199) reported on eight patients with recurrent GCTs (seven adults and one juvenile) who were treated with bevacizumab. One patient had a complete response and two had a partial response. The GOG conducted a phase 2 trial of bevacizumab in 36 women with recurrent sex cord–stromal ovarian tumors (200). The majority (32 patients) had GCTs, and four had unclassified SCSTs. These 36 patients received a total of 491 cycles of bevacizumab, with a median of 9 treatment cycles per patient. Six (16.7%) patients had a partial response, and 28 (77.8%) had stable disease. The median PFS was 9.3 months. There is also an ongoing French randomized phase 2 trial comparing bevacizumab plus weekly paclitaxel followed by bevacizumab maintenance therapy, versus weekly paclitaxel followed by observation, in patients with recurrent ovarian SCSTs.

Garcia-Donas et al. (201) have also suggested that ketoconazole (a CYP17 inhibitor) may have benefit in metastatic GCTs, reporting on a patient with recurrent GCT who remained progression-free for 10 months while on the drug.

Granulosa Cell Tumors (Juvenile)

Calaminus et al. (202) reported the outcome of 33 patients with JGCTs—24 treated with surgery alone and 9 with surgery and cisplatin-based CT. There have been 6 relapses, with 60 months median follow-up: 2 of 20 stage IA, 2 of 8 stage IC, and 2 of 5 stage IIC to IIIC. Three patients with stage IIC to IIIC disease treated with adjuvant cisplatinum-based therapy remained disease-free at 46 to 66 months after diagnosis. Furthermore, Powell and Otis (203) reported short-term disease control in two teenagers with stage III JGCTs following surgery and cisplatin-based CT.

German investigators published their 15-year experience (1985 to 2000) with 54 SCSTs in children and adolescents (75). Forty-five were JGCTs. Twelve received adjuvant CT for stages IC to IIIC disease. BEP and cisplatin, etoposide, and ifosfamide (PEI) were the most commonly used regimens. Six patients remained in remission after adjuvant CT 15 to 106 months later. A seventh developed a contralateral JGCT 10 years after her initial primary tumor. Five of the 12 have recurred, 3 of whom died 16 to 28 months from diagnosis.

Powell et al. (204) reported a patient with long-term disease-free survival (DFS) following salvage CT for recurrent JGCT. The patient had presented with stage IIIC disease, initially treated by resection of all gross disease followed by carboplatin and etoposide for 6 cycles. She recurred 13 months later with limited disease in the liver and a mass at the inferior aspect of the spleen. She underwent gross total resection followed by six cycles of bleomycin and paclitaxel. The patient was disease-free 44 months later, delivering a normal baby at Caesarian section.

Recently, Benesch et al. (205) reported a case of a 4 1/2-year-old patient diagnosed with a stage IA JGCT. One year after diagnosis, the patient developed a recurrent in a paraaortic lymph node, which was treated with surgery, RT, and conventional treatment followed by high-dose CT. Seven months later, she was diagnosed with a second relapse in a paratracheal lymph node treated with surgery and RT followed by a 2-year course of a combination of bevacizumab, paclitaxel, thalidomide, and pegylated interferon. At the time of the report, the patient was in complete remission 6 years after the second relapse.

Auguste et al. (206) sequenced the transcriptome of four JGCTs and compared them with control transcriptomes. They detected in-frame duplications within the oncogene AKT1 in >60% of the tumor specimens studied. These observations may hold promise for the future use of targeted therapeutics in this tumor type.

Sertoli–Leydig Cell Tumors

Therapy for those few individuals presenting with high-stage SLCTs, as well as for individuals with recurrent disease, must be individualized. The effectiveness of RT is unknown (119). Reports exist of responses to vincristine, actinomycin D, and cyclophosphamide and cisplatin, doxorubicin, and cyclophosphamide (168,207). Schneider et al. (75) reported on

three patients with SLCTs who were treated with platinum-based CT. One patient with stage IC disease with intermediate differentiation received two cycles of the combination of cisplatin and etoposide and was disease-free at 47 months. Two other patients, both of whom had stage IC poorly differentiated SLCTs, were dead of tumor at 7 and 19 months, respectively, after receiving either BEP or PEI. Given the functional hormonal nature of many of these neoplasms, consideration could also be given to some form of hormonal manipulation, such as luteinizing hormone–releasing agonists or antagonists (208).

Recently, the Italian cooperative group, Multicentre Italian Trials in Ovarian Cancer, reported their experience with 21 patients with SLCTs (209). Five patients received adjuvant CT—platinum-based CT in four (BEP in two and paclitaxel/carboplatin in two), and one received the combination of methotrexate, 5-fluorouracil, and cyclophosphamide. Three of the five patients subsequently died of disease. Seven patients (one stage IAG1, three stage IAG2, one stage ICG2, and two stage IIICG3) relapsed, four of whom had stage IA disease and did not receive adjuvant CT. Five of these patients were treated with surgery plus CT, one received CT alone, and one received palliation only. All six patients who received CT were treated with platinum-based regimens—either BEP or paxlitaxel/carboplatin. At the time of the report, two patients—one with stage IAG1 and one with stage IAG2—were clinically disease-free, and the other five died of disease.

Gui et al. (210) reported 40 cases of stage IA or IC ovarian SLCTs seen at Peking Union Medical College Hospital in Beijing, China, between 1966 and 2009. Of 34 cases with intermediate or poor differentiation, 23 received adjuvant CT (platinum-based CT, 17; nonplatinum-based CT, 6) following surgery. None of the 23 patients relapsed, whereas 2 of 11 patients who did not receive adjuvant CT relapsed.

Sex Cord Tumor with Annular Tubules

Given the rarity of this tumor, the collective experience with systemic therapy for SCTATs is scant. Their endocrine activities suggest that the tumors may retain responsiveness to perturbation of gonadotropin levels. A case report documents a complete response to etoposide, bleomycin, and cisplatin in a patient with recurrent SCTAT (149). A more recent Chinese report of 13 patients with SCTAT noted that six (46.2%) patients experienced 14 recurrences (211). Two of these patients achieved a complete response without further recurrence after secondary cytoreductive surgery and CT with platinum, etoposide, and bleomycin or platinum, vinblastine, and bleomycin. Three patients achieved a partial response and were alive with disease at the time of the report after surgery and/or RT.

MOLECULAR PATHOGENESIS

Our current knowledge regarding various autocrine and endocrine regulatory mechanisms influencing ovarian function, the overexpression of inhibin in several SCSTs, the alterations in ovarian steroidogenesis, and the changes in circulating gonadotropin levels in SCSTs provides clues regarding the pathogenesis of these tumors. Investigations to date exploring the interactive regulatory mechanisms of inhibin, activin, follistatin, and FSH have predominantly included the more common GCTs. FSH provides a fundamental regulatory role in the differentiation processes of granulosa cells during the early stages of follicle development. Specifically, FSH stimulates cell proliferation (mitosis), increases the availability of cell-surface prolactin and luteinizing hormone receptors, and induces aromatase activity, resulting in increased estradiol production. Other growth regulatory factors such as insulin-like growth factor (IGF) and epidermal growth factor modulate these actions, including the enhancement of the mitogenic effects of FSH. In addition, FSH secretion from the anterior pituitary is modulated in part by the serum levels of inhibin, activin, estrogens, and/or androgens.

Inhibin, a heterodimeric glycoprotein hormone composed of an α-subunit and one of two β-subunits, is secreted by the granulosa cells of the ovary (212). Inhibin A consists of αA and βA; inhibin B consists of αB and βB. Petraglia et al. (213) demonstrated that serum inhibin B was dramatically increased in eight of nine patients with GCTs, whereas inhibin A was slightly increased in all patients. Its major physiologic function is to inhibit the secretion of FSH by the anterior pituitary

gland (214). Inhibin is expressed in excessive quantities by GCTs. Although it maintains its regulatory function pertaining to FSH suppression, it appears to be ineffective in controlling estrogen production and cell proliferation within the gonad. Robertson et al. (215) reviewed the various serum-based assays for inhibin.

Activin, also a peptide hormone of ovarian granulosa cell origin, is composed of two β-subunits that are identical to those of inhibin. In contrast to inhibin, activin stimulates the secretion of FSH, induces the production of estradiol when having a negative impact on progesterone production, and promotes granulosa cell differentiation (214).

Lin et al. (216) performed comparative genomic hybridization of a set of 37 adult-type GCTs (36 primaries, 1 recurrence) obtained from five hospitals in Taiwan. All patients had stage I disease except for one stage III patient with limited disease at initial diagnosis. Twenty-two (61%) of the 36 primary tumors had chromosomal imbalances. The nonrandom changes included loss of 22q in 31% of tumors, gain of chromosome 14 in 25% of tumors, and gain of chromosome 12 in 14% of tumors. Monosomy 22 frequently coexisted with trisomy 14. High-level amplification, as can be seen in many aggressive carcinomas, was not detected in any of these GCTs. Similar findings have been reported elsewhere (217,218). As a sole abnormality, trisomy 12 has also been found in fibromas and fibroepitheliomas, in addition to GCTs (219,220). Menczer et al. (221) looked for HER2/neu expression in 12 GCTs and saw no immunohistochemical (IHC) staining. An Austrian group examined the IHC expression of the HER family of receptors—HER1 (EGFR), HER2, HER3, and HER4—in 38 adult GCTs and 2 of the juvenile type (222). Thirty-one cases (77.5%) were positive for at least one of the receptors (EGFR, HER3, or HER4). None of the 40 cases showed a positive reaction for HER2. Twenty-six of 40 (65%) showed reactivity for EGFR. HER3 and HER4 expression was observed in 18 (45%) and 23 (57.5%) tumors, respectively. Kusamura et al. (223) investigated HER2 expression in 18 GCTs: all cases were negative. They also showed a markedly low likelihood of IHC staining for p53 and low proliferative indices in these tumors. Richards et al. (224) used a mouse model to investigate granulosa cell tumorigenesis. They showed that formation of GCTs by stable activation of β-catenin (CTNNB1) in granulosa cells is accelerated by concomitant *Kras* activation or PTEN loss. It has yet to be confirmed if these are crucial pathways in the development of GCTs in humans.

Shah and colleagues (225) performed whole-transcriptome paired-end RNA sequencing on four GCTs. They discovered a point mutation, missense point mutation, 402C→G (C134W), in *FOXL2*, a member of the forkhead–winged helix family of transcription factors. This gene is known to be involved in ovarian differentiation, is required for the normal development of granulosa cells, and may alter cell cycle progression and apoptosis (226,227). They and others have demonstrated that FOXL2 mutations are present in over 95% of GCTs, but a small minority of JGCTs (228,229). These results support a molecular basis for the disparate clinical course observed between JGCTs and AGCTs, provide a means to improve diagnosis in difficult cases, and suggest that *FOXL2* is a key driver of GCT pathogenesis. Molecular studies of JGCTs are limited, but in one investigation AKT1 duplication was identified in >60% of JGCTs tested. These findings may lead to useful therapeutic targets in the future (206,230).

Another major finding has been that of *DICER1* mutations in ovarian SCSTs (231-233). Schultz et al. (231) reported that, among 296 kindreds including 325 children with pleuropulmonary blastoma (PPB), 3 children had both PPB and SLCT. Among family members of PPB patients, they identified six ovarian SCSTs. Germline *DICER1* mutations were identified in four of six patients with SCSTs from PPB kindreds and in two of three children with ovarian SCSTs and no personal or family history of PPB. In another report, Heravi-Moussavi et al. (232) found somatic *DICER1* mutations in the RNAse IIIb domain in 26/43 (60%) SLCTs, including 4 tumors with additional germline *DICER1* mutations. Thus far, discovery of these mutations has translated into a therapeutic target.

Chu et al. (234) examined the estrogen receptor (ER) isoform gene expression in a small series of GCTs and serous cystoadenocarcinomas of the ovary (four of each). They demonstrated widespread expression of ER-α in both tumor types but at relatively low levels, similar to or less than what is seen in the endometrium. ER-β expression in the GCTs, however, was severalfold higher than that of ER-α. Fuller and Chu (235) have provided an informative review of various signaling pathways that are important in the regulation of growth, differentiation, and apoptosis of normal granulosa cells, which may contribute to the molecular pathogenesis of GCTs. Because of the important role of the IGF system in development of the dominant follicle, and its contribution to epithelial ovarian cancer, Alexiadis et al. (236) characterized

the expression of several components of the IGF system in a series of nine GCTs. Interestingly, pregnancy-associated plasma protein-A (PAPP-A) expression was highest in the GCTs. PAPP-A is a metalloproteinase synthesized by granulosa cells, the activity of which leads to increased IGF bioavailability. Anttonen et al. (237) studied samples from a cohort of 80 GCT patients from the University of Helsinki and examined several growth regulatory factors known to be important in normal granulosa cell function, including anti-Müllerian hormone, inhibin-α, and GATA transcription factors. They found a correlation between high GATA4 expression and higher likelihood of recurrence. Interestingly, GATA4 and SMAD3 appear to cooperate to reduce GCT cell apoptosis and may contribute to the oncogenic phenotype observed with FOXL2 mutations (238).

The natural history of SCSTs is uniquely different from that of their epithelial counterparts and provides an intriguing tumor model. The vast majority of these neoplasms are characteristically of low malignant potential. They are typically unilateral and remain localized, retain hormone-secreting functions consistent with their well-differentiated appearance, and recurrences, when encountered, are usually delayed. In contrast, a small percentage of otherwise phenotypically similar tumors demonstrate a more virulent course and are generally refractory to therapy. The SCST subtypes display a bimodal age distribution, notably with JGCTs, SSCTs, SLCTs, and SCTATs, occurring predominantly during the first three decades of life. The association of these tumors with several uncommon congenital disease entities, such as enchondromatosis, leprechaunism, and PJS, provides clues to their underlying genetic etiologies. Uniquely, several of these functioning neoplasms, including AGCTs, JGCTs, SLCTs, and SCTATs, overexpress growth-regulatory substances including inhibin, MIS, and follicle-regulating protein. Given the limited number of ovarian SCSTs available for study, our current understanding of the mechanism of oncogenesis in these tumors is understandably limited.

SUMMARY

The principal problem related to the study of SCSTs and the development of effective therapy is their rarity. Although this interesting group of tumors has been studied extensively from a histologic standpoint, there are surprisingly few features that distinguish tumors more likely to recur or have aggressive behavior, and much of the information is conflicting.

Surgery remains the cornerstone of treatment for patients with SCSTs. Furthermore, for young patients desirous of fertility preservation, fertility-sparing surgery is possible in a large proportion of cases because these tumors tend to be unilateral and nonmetastatic. Patients who appear to have a worse prognosis, and for whom postoperative therapy would appear to be indicated, include those with metastatic SCSTs of any histotype and those with stage I poorly differentiated SLCTs. For patients with SCSTs confined to the ovary, postoperative therapy is not recommended. For those with stage IC disease, the issue of postoperative therapy is unresolved.

Standard postoperative treatment consists of platinum-based CT. The BEP regimen is currently the most popular combination. However, this is a relatively toxic regimen, hence the interest in alternative combinations, such as taxane/platinum chemotherapy. However, more study of this latter combination is warranted. An ongoing GOG study should help resolve the issue. In general, available experience with CT to date suggests that any regimen may be only moderately effective, and of those who do benefit, only about 50% enjoy a durable remission.

INTERNATIONAL PERSPECTIVES

Ovarian Sex Cord–Stromal Tumors in Israel

Uzi Beller, MD

This is an excellent chapter discussing tumors not often seen in our daily practices. Although they are rare, it is of utmost importance to manage them appropriately because they commonly occur in young women of reproductive age. The authors of this chapter have been "global consultants" on the management of ovarian sex cord-stromal tumors for the past four decades, providing their colleagues with guidance on the conservative management of these tumors and the preservation of fertility in these young women.

The thorough understanding of the biology and, most importantly, the natural history of these rare tumors is mutual to all parts of the world, and one finds minimal deviation between continents or countries in this respect.

This chapter is a solid reference for practitioners for managing their patients and for medical students and trainees for learning about these tumors and how to treat them. With today's knowledge and understanding of sex cord-stromal tumors of the ovary, young women can be safely treated with preservation of fertility following the guidelines presented in this comprehensive chapter.

Beyond platinum-based CT, there is no consensus concerning recommended second-line or salvage therapy. Hormonal medications clearly have some degree of activity in GCTs. Antiangiogenesis agents hold promise. In addition, there is probably a limited role for radiation. This gap in our armamentarium underscores the need for novel target-based therapeutics developed through the study of the genes and pathways involved in the pathogenesis of these neoplasms. Thus far, the association of GCTs with FOXL2 mutations, the association of JGCTs with AKT1 mutations, and the association of some SLTs with DICER1 mutations have not translated into targeted therapies. However, the future appears bright for identification of novel therapies for this group of rare ovarian tumors.

CHAPTER 26 Gestational Trophoblastic Disease: Molar Pregnancy and Gestational Trophoblastic Neoplasia

Julian C. Schink and John R. Lurain

INTRODUCTION

Gestational trophoblastic disease (GTD) describes a continuum of interrelated lesions that arise from abnormal proliferation of placental trophoblasts, ranging from benign hydatidiform mole to invasive mole, malignant choriocarcinoma (CCA), placental site trophoblastic tumor (PSTT), and epithelioid trophoblastic tumor (ETT) (Table 26.1). Hydatidiform moles, both complete and partial, are benign lesions that resolve following uterine evacuation in the vast majority of cases. Persistent GTD refers to disease that does not resolve after molar evacuation or that becomes malignant and requires active management. Invasive moles, CCA, PSTT, and ETT, are collectively referred to as gestational trophoblastic neoplasia (GTN), with varying degrees of malignant potential. GTN most commonly arises after a molar pregnancy, though it can develop after any pregnancy. Historically, GTD was associated with high rates of morbidity and mortality. Hydatidiform mole was associated with serious medical and surgical complications, and the mortality rate for invasive mole approached 15%. The mortality rate for CCA was near 100% if metastatic disease was present and 60% for nonmetastatic disease even if hysterectomy was performed. Earlier detection with ultrasonography, the use of human chorionic gonadotropin (hCG) as a disease-specific biomarker, advances in uterine evacuation, and the introduction of chemotherapy (CT) into the management of GTN have significantly decreased the risk of death associated with GTD and have allowed many women to preserve their fertility after treatment. This chapter will describe the epidemiology and pathology of molar pregnancy and GTN and will discuss the changes in diagnosis and management that have transformed GTN from one of the most deadly to one of the most curable solid tumors in women, with cure rates higher than 90% even in the presence of metastasis (1–3).

EPIDEMIOLOGY

Epidemiologic data for GTD are unreliable, primarily because of inconsistent case definitions, no centralized databases, and the rarity of certain forms of the disease. Similarly, defining the risk factors that contribute to the development of GTD has been challenging, with an inability to adequately identify at-risk populations and a lack of control groups (4). Based on available data, hydatidiform mole develops in women during their reproductive years, with an incidence that varies widely across different geographic regions. In North America, Australia, New Zealand, and Europe, the incidence of molar pregnancy has been reported as 0.6 to 1.1 per 1,000 pregnancies, but it is two- to three-fold higher in Southeast Asia and Japan (2.0 per 1,000 pregnancies) (5–8). In Taiwan, hydatidiform mole occurs in 1 of 125 pregnancies, whereas the incidence in the United States is approximately 1 in 1,500 pregnancies. In a study from Ireland, the incidence of complete and partial mole was reported as 1 in 1,945 and 1 in 695 pregnancies, respectively (9).

Despite this geographic variation, the risk of hydatidiform mole has not been linked to any specific ethnic or racial differences, cultural factors, or differences in reporting of hospital-based and population-based data (10–12). However, several studies have reported a link between molar pregnancy and socioeconomic and dietary factors, specifically that the risk of complete molar pregnancy increases with decreased consumption of vitamin A (carotene) and animal fat (13,14). Regions with a higher incidence of vitamin A deficiency also have a higher incidence of molar pregnancy. A history of infertility is also associated with increased risk of complete and partial mole (15), and a history of spontaneous abortion increases the risk of both complete and partial moles two- to three-fold compared with women without a history of miscarriage (15–17).

The two strongest risk factors for complete hydatidiform mole are maternal age and prior molar pregnancy (17). Both very young women and women over the age of 40 have a higher risk of complete molar pregnancy, with older women having a 5- to 10-fold higher risk (18,19). In women over the age of 50, one in every three pregnancies is molar (4). These observations suggest that the ova of older women are predisposed to the abnormal fertilization events that lead to hydatidiform mole. The risk of a second complete molar pregnancy is 1%, approximately 10- to 20-fold higher than the risk of molar pregnancy in the general population (20,21), and the risk of a third mole is 15% to 20% (22,23), regardless of a change in partner (24).

Familial repetitive hydatidiform mole (17) has been linked to a missense mutation in the *NLRP7* locus (25,26) on chromosome 19 (27); in one report, this mutation was present in 60% of patients who had two molar pregnancies (28). The mutated gene is involved in maternal imprinting (29) and is seen in familial clusters of complete moles of biparental origin rather than androgenetic origin (26,30).

There is less information regarding the epidemiology of partial molar pregnancy, though it is clear that it differs from that of complete molar pregnancy (18,19). Partial mole does not appear to be linked to vitamin A deficiency (31) or advanced maternal age (17), but is associated with a history of irregular menstruation and use of high estrogen–containing oral contraceptives (31).

Locally invasive GTN develops in approximately 15% of patients after molar evacuation. CCA occurs in 1 in 50,000 pregnancies (including term, miscarriage, abortion, or ectopic) (32). CCA is 1,000 times more likely to develop after a complete molar pregnancy than after other pregnancy events, with half of all CCA cases arising from molar pregnancies. The risk of CCA increases in women with advanced maternal age and prior hydatidiform mole, and is higher in women of Asian, American Indian, and African American descent (12). Menarche after age 12, light menstrual flow, and long-term use of oral contraceptives are also associated with a higher risk of CCA (33), though the association between postmolar GTN and oral contraceptive use is not entirely clear (34,35). Women with type A blood also have an increased risk of CCA

(7,36).

PSTT and ETT are extremely rare forms of malignant GTN, and there are insufficient data to characterize the epidemiology or risk factors. Approximately 95% of PSTT and ETT lesions develop after a term pregnancy or nonmolar abortion (37), often several months or even years later.

PATHOLOGY AND CHROMOSOMAL FEATURES

Trophoblastic Differentiation and GTD

Molar pregnancies and GTN originate from the placental trophoblast, which is derived from the outermost layer of the blastocyst, called the trophectoderm (38). The trophoblast is composed of cytotrophoblast, syncytiotrophoblast, and intermediate trophoblast. Syncytiotrophoblast invades the endometrial stroma upon implantation of the blastocyst and secretes hCG and other proteins to regulate the implantation site microenvironment. Cytotrophoblast fuses with syncytiotrophoblast to form the chorionic villi that cover the chorionic sac. Nonvillous cytotrophoblast differentiates into intermediate trophoblast, categorized as either implantation site or chorion type. Implantation site intermediate trophoblast loses the ability to proliferate but invades the maternal decidua and myometrium in a highly controlled manner, migrating to the maternal spiral arteries to facilitate oxygen and waste transfer between the fetus and the mother (Fig. 26.1).

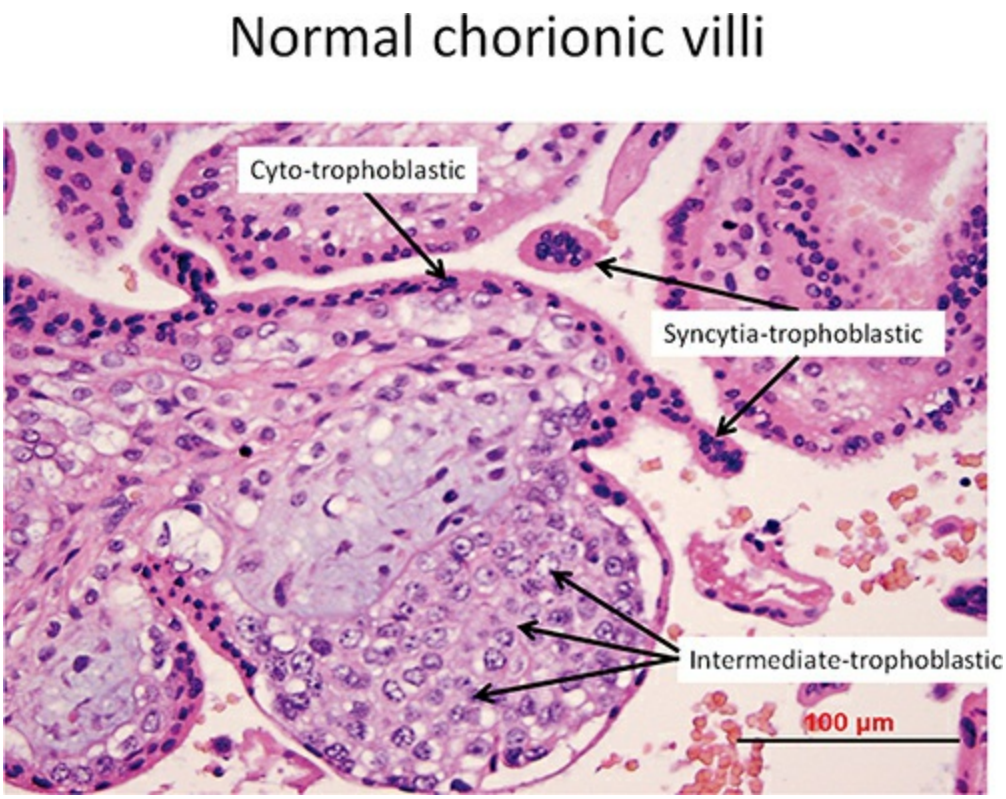

Figure 26.1 Normal trophoblast differentiation. Cytotrophoblast, syncytiotrophoblast, and intermediate trophoblast are labeled in this photomicrograph.

Invasion of healthy trophoblast into the maternal endometrium is a normal, tightly regulated event in pregnancy that is required for the vascular connection between the fetus and the mother. When regulatory mechanisms are impaired, invasive and vascular tumors arise. For example, TGF-β and a proteoglycan, decorin, have an inhibitory effect on nonvillous trophoblast cell growth, migration, and invasion, and this negative regulation is lost in trophoblast lesions

(39,40).

Most GTD lesions (except partial mole) derive from the fetus and not from the mother and, therefore, contain only paternal genetic material (38). A large body of work on the immunobiology of GTD has suggested that a maternal immunologic response is activated by paternal antigens in the trophoblastic cells of GTD lesions, thereby promoting their regression and sensitizing them to CT; conversely, women with persistent GTD or aggressive disease may have greater histocompatibility such that the paternal antigens do not elicit a strong immune response from the mother (41).

All three types of trophoblast can proliferate to produce GTD lesions (42), and each type expresses different antigens that have been useful in the immunohistochemical analysis and differential diagnosis of trophoblastic lesions (43); they may also provide insight into the pathogenic mechanisms underlying GTN (Table 26.2). Expression of Ki-67, proliferating cell nuclear antigen, and p53 is significantly higher in GTD compared with normal tissues and can differentiate between GTD and spontaneous abortion (44). p63 isoforms are differentially expressed in cytotrophoblast and intermediate trophoblast (45) and may be useful in differentiating between PSTT (p63 negative) and ETT (p63 positive). Human leukocyte antigen G is also expressed in intermediate trophoblasts, but not in villous cytotrophoblasts or syncytiotrophoblasts, and may be useful in the diagnosis of various GTD lesions (46). Several growth factors and oncogenes are abnormally expressed in molar tissues and CCA (15,47,48). Both complete mole and CCA overexpress c-myc, c-erb2, and bcl-2. Epidermal growth factor (EGF) receptor was found to be more highly expressed in CCA and complete moles compared with normal placenta and partial moles, suggesting that EGF family members may be involved in GTN pathogenesis (49). In addition, there is increased expression of matrix metalloproteinase (MMP-1 and MMP-2) and decreased expression of tissue inhibitor of metalloproteinase 1 in CCA compared with either hydatidiform mole or normal placenta, implicating the dysregulation of extracellular matrix (ECM) in the invasion and metastasis of CCA (50). Characterizing the molecular pathogenesis of GTD is an active area of research that may reveal new diagnostic and prognostic markers, as well as lead to targeted therapies.

TABLE 26.2 Immunohistochemical Markers for Differential Diagnosis of GTD

Marker	Application
Ki-67, PCNA, p53	Spontaneous abortion (negative)
	GTD (positive)
	CCA (diffusely positive in 50% cells)
	PSTT (>10% labeling index)
p63	PSTT (negative)
	ETT (positive)
HLA-G	Nonvillous IT (positive)
	PSTT (implantation site IT positive)
	ETT (chorionic-type IT positive)
β-hCG	CCA (syncytiotrophoblast positive)
Inhibin α	CCA (trophoblast and IT positive)
	PSTT (diffusely positive)
	ETT (diffusely positive)
hPL	CCA (IT positive)
	PSTT (diffusely positive)
Mel-CAM	PSTT (diffusely positive)
Cytokeratin	CCA (all cells positive)

	PSTT (diffusely positive)
	ETT (diffusely positive)
p57kip2	Complete mole (negative)
	Partial mole (positive)
Cyclin E	ETT (relatively greater staining than placental site nodule)

CCA, choriocarcinoma; ETT, epithelioid trophoblastic tumor; GTD, gestational trophoblastic disease; IT, intermediate trophoblast; PCNA, proliferating cell nuclear antigen; PSTT, placental site trophoblastic tumor.

Hydatidiform Mole

Molar pregnancies arise from the proliferation of villous cytotrophoblast and syncytiotrophoblast, which produces lesions on the maternal decidua (51,52). A comparison of the characteristics and cytogenetics of complete and partial moles is provided in Table 26.3. Complete hydatidiform moles show early uniform enlargement of villi with hyperplastic and atypical trophoblast, and do not contain a fetus/embryo or villous capillaries (Fig. 26.2). Most complete moles (approximately 90%) are 46,XX and arise from the fertilization of an "empty" anucleated egg—missing the pronucleus and maternal chromosomes—by a single sperm followed by duplication of paternal haploid chromosomes (Fig. 26.3) (53,54). The other 10% of complete moles are either 46,XY or 46,XX and are produced by dispermic fertilization of an anucleated egg. Some complete moles can also arise from the loss of maternal chromosomes during the first cleavage. Regardless of monospermic or dispermic fertilization, complete moles contain only paternal chromosomes (androgenetic), though maternal DNA is present in the mitochondria of the egg (55). The presence of excess paternal material leads to trophoblastic hyperplasia, with no formation of a fetus because of the absence of maternal chromosomal DNA. Loss of maternally imprinted genes and extra paternally imprinted genes may also inhibit embryo formation (56).

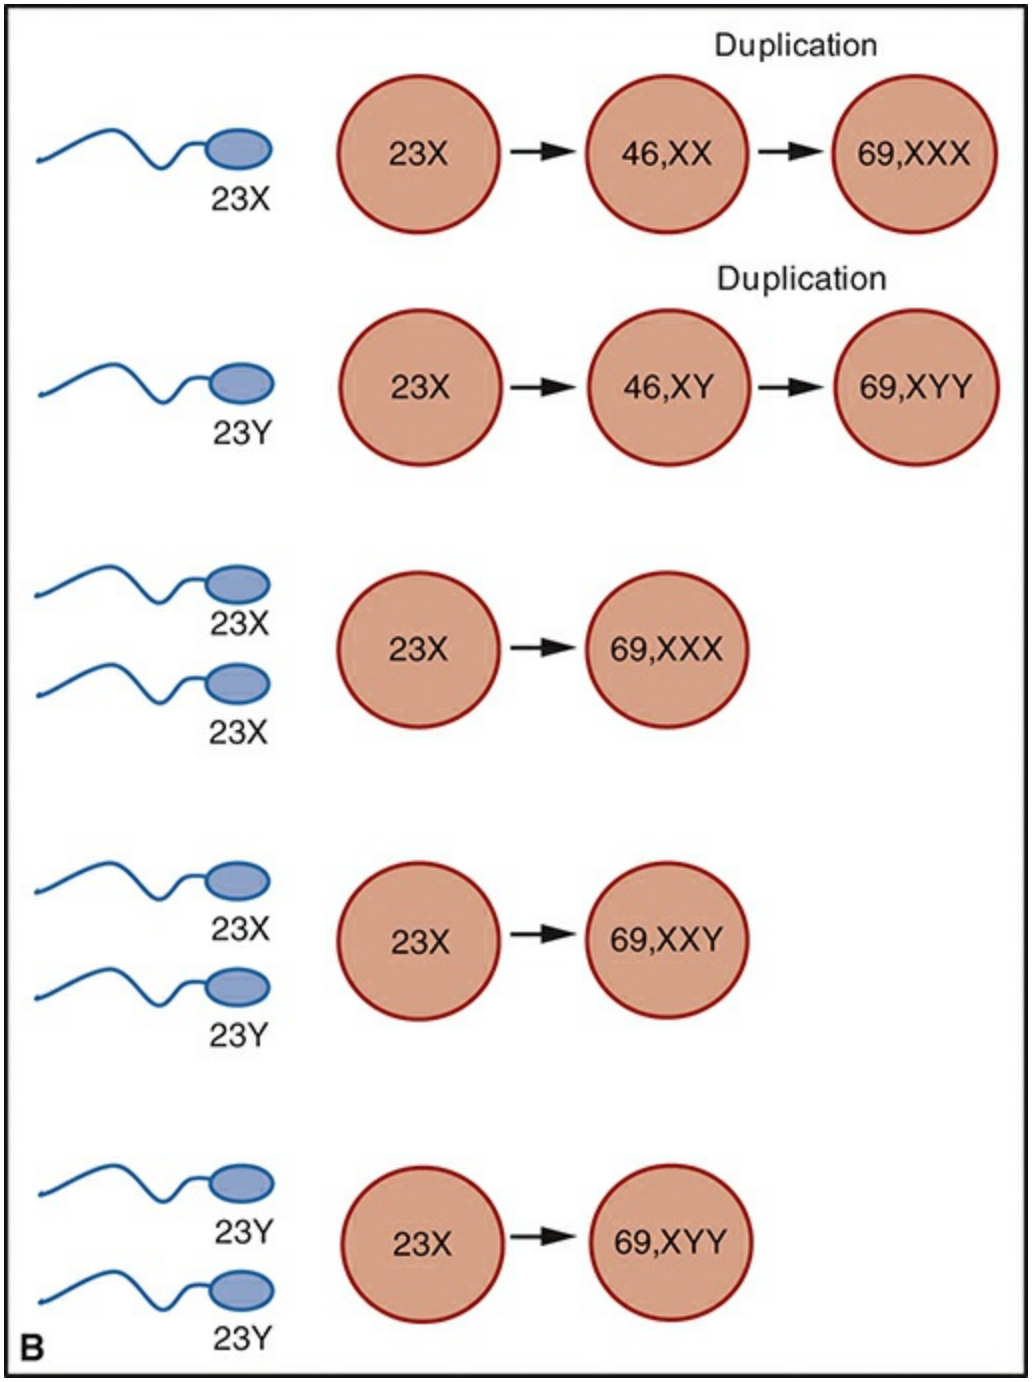

Figure 26.3 Karyotypes of complete and partial hydatidiform mole. A: Complete moles arise from the fertilization of an empty egg with a single sperm that then undergoes duplication (46,XX) or the fertilization of an empty egg with two sperm (46,XX or 46,XY). Complete moles therefore contain only paternal genetic material. B: Partial moles are triploid (69,XXY; 69XYY; or 69XXX) and arise from either dispermic fertilization of a normal egg or duplication of chromosomes in a single sperm after fertilization of a normal egg.

TABLE 26.3 Clinicopathologic Features of Gestational Trophoblastic Diseases

Disease	Pathologic Features	Clinical Features
Complete mole	• Diploid (46,XX and some 46,XY)	• Vaginal bleeding

	• No fetus or embryo • Diffuse swelling of villi • Diffuse trophoblastic hyperplasia	• Large for date uterine size • Bilateral theca lutein cysts • hCG can be >100,000 mIU/mL
Partial mole	• Triploid (69,XXY; 69,XYY; 69,XXX) • Abnormal fetus or embryo • Focal swelling of villi • Focal trophoblastic hyperplasia with mild atypia	• Symptoms of incomplete or missed abortion • Vaginal bleeding • hCG rarely elevated >100,000 mIU/mL
Invasive mole	• Trophoblastic hyperplasia • Swollen villi • Myometrial invasion	• Irregular postmolar vaginal bleeding • Persistent hCG elevation • <15% symptoms of lung/vaginal metastases
Choriocarcinoma	• Mixture of cytotrophoblast and syncytiotrophoblast hyperplasia • No villi • Myometrial invasion and metastatic potential • Hemorrhage • Necrosis	• Irregular postmolar vaginal bleeding • Persistent hCG elevation • Metastases and associated symptoms
PSTT	• Diploid • IT hyperplasia • No villi • Less hemorrhage and necrosis • High potential for lymphatic invasion and metastasis • Focal hCG production	• Low serum hCG • Enlarged uterus • hCG levels normal to 1,000 mIU/mL • Metastases and associated symptoms
ETT	• IT nodules surrounded by hyalinized ECM • Extensive necrotic tissue • Preserved blood vessel structure • Hemorrhage and metastases rare	

ECM, extracellular matrix; ETT, epithelioid trophoblastic tumor; hCG, human chorionic gonadotropin; IT, intermediate trophoblast; PSTT, placental site trophoblastic tumor.

In contrast, partial hydatidiform moles contain fetal/embryonic tissue, and the chorionic villi show varying degrees of focal enlargement and edema, predominantly syncytiotrophoblast hyperplasia, scalloping of the villous outline, prominent stromal inclusions, and functional villous circulation (Fig. 26.4) (57). Like complete moles, the trophoblast is hyperplastic, but shows only mild atypia. In later stages of partial molar pregnancy, the fetus shows congenital abnormalities, such as syndactyly of the fingers and toes (57). The majority of partial moles are triploid, most often 69,XXY, with two sets of paternal chromosomes because of either dispermic fertilization of a normal egg or duplication of chromosomes in a single sperm after fertilization of a normal egg (Fig. 26.3) (51,56,58).

Upper left: large round chorionic villi with cistern formation; Upper right: large irregular contour with extensive trophoblastic proliferation; Lower left: gross morphology of large cystic chorionic villi; Lower right: chorionic villous stromal cells stain negative for p57.

Invasive Mole

Invasive mole is a condition in which hydatidiform mole, with hydropic villi and proliferating trophoblast, has invaded the myometrium through the tissue or veins (Fig. 26.5). Molar villi may be observed on the uterine serosa, and extrauterine tubal and ovarian moles can occur (59). Invasive moles are less hydropic, and trophoblastic proliferation is easily seen (Table 26.3) (57).

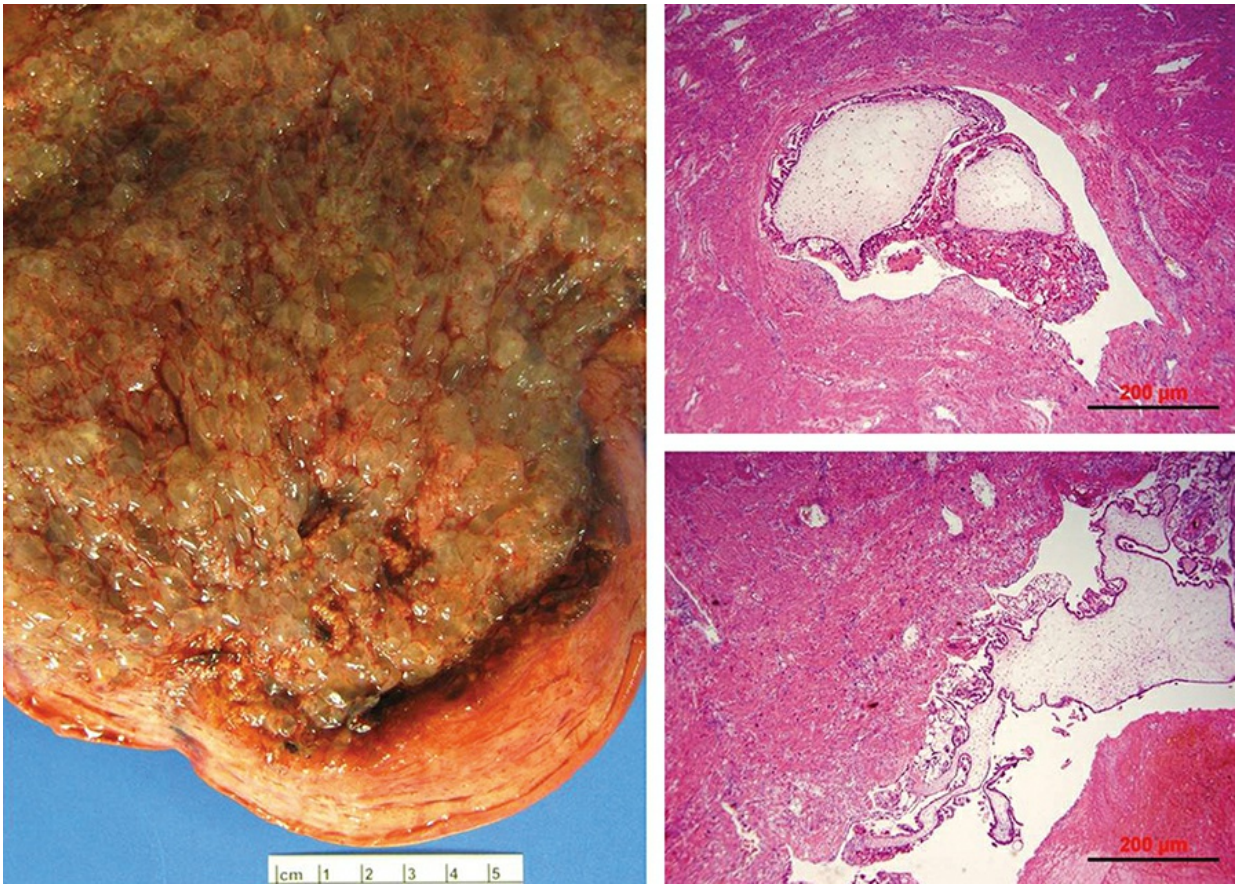

Figure 26.5 Invasive mole. Macrophotograph of molar product of conception that occupies the entire endometrial cavity and invades the myometrium (left panel). Photomicrographs show molar chorionic villi infiltrating into the myometrium (right panels).

Choriocarcinoma

Approximately 2% of women with complete moles may develop CCA, characterized by a mixture of cytotrophoblast and syncytiotrophoblast hyperplasia, hemorrhage, necrosis, and the absence of chorionic villi (Fig. 26.6) (57). Direct invasion of the myometrium and vasculature is also present, which permits metastasis to the lungs, brain, liver, pelvis and vagina, kidney, intestines, and spleen. Immunohistochemical markers can confirm a histologic diagnosis of CCA, with tumors staining strongly for hCG and inhibin α in the trophoblast, human placental lactogen (hPL), and inhibin α in the intermediate trophoblast, and cytokeratin in all trophoblast cells (Tables 26.2 and 26.3) (60). Ki-67 is diffusely expressed in approximately half of the cells (61).

Placental Site Trophoblastic Tumor

PSTT lesions are usually diploid and monomorphic, developing from the placental implantation site intermediate trophoblast after a normal or aborted uterine pregnancy (62). PSTT lesions contain primarily mononuclear intermediate trophoblast without chorionic villi that infiltrates the uterine wall in sheets or cords between myometrial fibers (Fig. 26.7). Compared with CCA, there is less hemorrhage, necrosis, and vascular invasion, but there is a higher risk of lymphatic metastasis. hCG production is focal, leading to relatively lower serum levels (Table 26.3). These tumors may be diagnosed immunohistochemically and may contain diffuse cytokeratin and hPL (63), as well as inhibin α (60) and Mel-CAM (Table 26.2) (61). The Ki-67 labeling index is also usually elevated (>10%) in a neoplastic lesion of nonvillous trophoblast (61).

C: Tumor cells show moderate cytologic atypia and have an increased Ki-67 index (>20%). Tumor cells are also negative for p63 (D), which excludes a diagnosis of epithelioid trophoblastic tumor; are strongly and diffusely positive for human placental lactogen (E) and pan-cytokeratin (G); and are diffusely positive for hCG (F) and inhibin (H). CK, cytokeratin; hPL, human placental lactogen; INH, inhibin.

Epithelioid Trophoblastic Tumor

ETT is a rare malignant tumor that arises from neoplastic transformation of chorion-type intermediate trophoblast (62). These lesions appear as nodules of mononuclear intermediate trophoblast, surrounded by hyalinized ECM within extensive necrotic tissue and with preserved blood vessel structure (Fig. 26.8 and Table 26.3). Intratumor hemorrhage and metastases are rarely observed. ETT tumor cells show diffuse expression of immunohistologic markers, including cytokeratin and inhibin α (Table 26.2) (64). Cyclin E staining is higher in ETT than in placental site nodule and can help in differentiating between the two (64–66).

positive for p63.

MANAGEMENT OF MOLAR PREGNANCY

Clinical Presentation

Approximately 80% to 90% of women with complete hydatidiform mole present with vaginal bleeding, occurring at 6 to 16 weeks' gestation. Women may also present with larger uterine size than expected for gestational date, toxemia, hyperemesis, and hyperthyroidism in the first or second trimester. However, the widespread use of ultrasonography in developed countries and accurate hCG tests to evaluate vaginal bleeding have led to earlier diagnosis of molar pregnancy, and other clinical signs and symptoms are seen less often (Table 26.4) (67). hCG levels can be greater than 100,000 mIU/mL in a complete molar pregnancy, and there are no fetal heart tones (Table 26.3); however, hCG levels vary widely in individual patients, and with earlier ultrasound detection, patients may not present with extremely elevated hCG. It should also be emphasized that a high hCG level alone is not sufficient for a diagnosis of hydatidiform mole, and a confirmatory ultrasound should be performed. In approximately 15% of women with complete hydatidiform mole, ultrasound imaging reveals the presence of bilateral theca lutein cyst enlargement of the ovaries (5,67–70).

TABLE 26.4 The Changing Clinical Signs of Molar Pregnancy

	Incidence (%)	
Clinical Sign	1970s	2010s
Vaginal bleeding	100	90
Uterine enlargement	54	28
Toxemia	22	1
Hyperemesis	28	8
Hyperthyroidism	10	<1
Trophoblastic emboli	2	<1
Bilaterally enlarged ovaries	15	15
Absence of fetal heart sounds	100	100

Partial hydatidiform mole presents quite differently from complete mole. The vast majority of patients—greater than 90%—present with symptoms of incomplete or missed abortion. Vaginal bleeding occurs in 75% of patients with a partial molar pregnancy, and uterine enlargement, hyperemesis, hypertension, hyperthyroidism, and theca lutein cysts are not often seen. Presenting hCG levels are higher than 100,000 mIU/mL in only 10% of patients (70–73).

Diagnosis

Ultrasonography is the primary means of preoperative diagnosis of molar pregnancy, and its introduction has made diagnosis at much earlier stages possible (69,74–76). Ultrasound not only provides information on the type of molar pregnancy, but also determines involvement of the endometrial cavity or myometrium, assesses the risk of uterine perforation, and detects theca lutein cysts and vaginal metastases. The diffuse hydropic swelling of the chorionic villi in complete molar pregnancy is seen as a characteristic vesicular "snowstorm" pattern on ultrasound, with many holes within the placenta and the absence of a fetus (Fig. 26.9). However, because this pattern is also seen in women with missed

abortion, hematometra, or uterine fibroids, ultrasound diagnosis alone is not very specific. When ultrasound diagnosis is combined with elevated hCG and the absence of fetal heartbeat, molar pregnancy is the most likely diagnosis. For partial moles, ultrasonography can detect focal cystic spaces in the placental and the enlarged gestational sac (76). Ultrasound may show the snowstorm pattern and a viable fetus, which may also indicate threatened abortion, fibroid uterus, or twin gestation with a single missed abortion and a complete mole. Partial mole can be confirmed with chorionic villus sampling that shows triploidy.

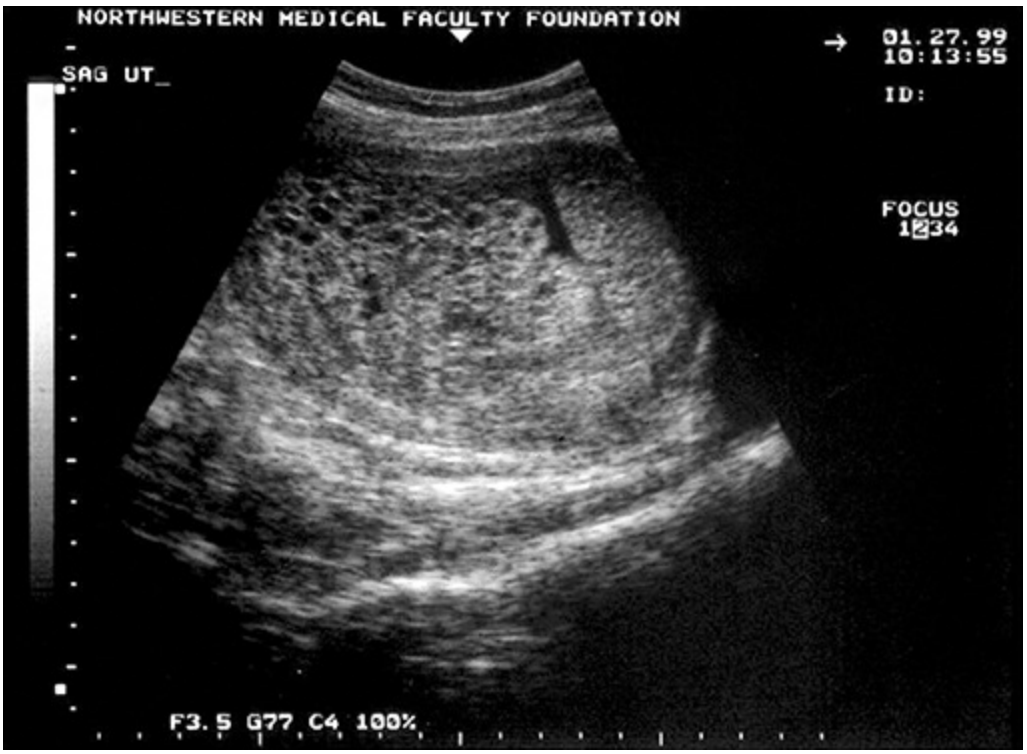

Figure 26.9 Ultrasound of complete hydatidiform mole. The characteristic vesicular "snowstorm" pattern of multiple echoes, appearing as holes within the placenta. No fetus is present.

The most accurate disease-specific marker of GTD is hCG, which is produced by hydatidiform moles and CCA and can be measured quantitatively in the blood and urine. Placental hCG is a glycoprotein of two subunits, a common α subunit that is similar to the α subunit of pituitary hCG and a placenta-specific β subunit. In a normal pregnancy, hCG is essential for maintaining placental vascular supply. As pregnancy progresses, hCG is secreted by syncytiotrophoblasts, increasing to approximately 60,000 mIU/mL at 10 weeks and then declining to a range of values around 12,000 mIU/mL through the remainder of the pregnancy (77). hCG molecules secreted by trophoblast-derived moles and GTN are more heterogeneous than in a normal pregnancy, with transformation of the trophoblast resulting in fragmentation of the hCG molecule, and several forms of hCG are present, including hyperglycosylated, nicked, C-terminal truncated β subunit, free β subunit, nicked free β subunit, and free α subunit (78). Normally, hyperglycosylated hCG is produced by cytotrophoblasts early in gestation and acts as an autocrine regulator of trophoblast invasion of the implantation site and establishment of the fetomaternal circulation. Hyperglycosylated β subunit is produced by GTN lesions and promotes the growth and invasion of the malignant trophoblasts (79).

It is, therefore, essential that quantitative assays used to diagnose or follow-up GTD detect all forms of the hCG protein and its degradation products. In one study, Cole et al. (80) compared several commercially available hCG tests and found significant variations in assay results related to differences in recognition of hCG variants. The most common hCG assay is a monoclonal antibody sandwich assay (81). Complete hydatidiform moles present with markedly elevated hCG, with half of the patients having levels greater than 100,000 mIU/mL (82,83). Because hCG levels in a normal pregnancy

are highest at the end of the first trimester, hCG measurements need to be taken at several times to differentiate a complete molar pregnancy from a normal gestation, multiple gestation, or pregnancy complicated by diseases that are associated with an enlarged placenta. By contrast, hCG levels greater than 100,000 mIU/mL are seen in only 10% of patients with partial moles (71,72).

Diagnosis of complete and partial moles may also include pathologic examination of curettage tissue; however, with the diagnosis of hydatidiform mole occurring earlier in gestation, histologic analysis can be challenging (84,85). Cytogenetic analysis can differentiate between complete mole (androgenetic diploidy), partial mole (diandric triploidy), and hydropic abortus (biparental diploidy). A hydropic abortus can contain enlarged villi, but lacks proliferating trophoblast (57). Immunohistochemical analysis may also help to confirm a diagnosis of molar pregnancy; specifically, p57kip2 expression can differentiate between complete and partial hydatidiform moles (Table 26.2) (86–90). This protein is paternally imprinted and maternally expressed; therefore, the villous cytotrophoblast cells in complete moles, which lack maternal chromosomes, will stain negative for p57kip2, whereas partial moles and hydropic abortus will stain positive. Fluorescence *in situ* hybridization can be used to distinguish between p57kip2-positive partial moles (triploid) and hydropic abortus (diploid) (91). *PHLDA2* is another maternally imprinted gene that can be used to identify partial moles (92).

False-Positive and False-Negative hCG Tests

hCG measurements are a critical diagnostic tool for GTD, but some assays may produce false-positive or "phantom" hCG results (93). False-positive hCG tests, some as high as 800 mIU/mL, can lead to unnecessary surgery and CT in healthy patients (94). These false-positive results are due to the presence of nonspecific heterophilic antibodies that mimic hCG and can interfere with the hCG sandwich assay. These antibodies are present in 3% to 4% of healthy people. Because the large antibody does not pass through the glomerulus into the urine, false-positive hCG test results can be identified by determining hCG levels in the urine. In addition, serial dilution of the serum sample would not show a decrease in the detected antibody.

Luteinizing hormone (LH) can also cross-react with hCG assays, leading to falsely elevated hCG in women with elevated pituitary follicle-stimulating hormone, LH, or hCG. hCG normally increases with age, and perimenopausal and postmenopausal women may have low-level hCG test results. To determine whether the hCG detected in the serum is from the pituitary, women may be given oral contraceptive to suppress LH, followed by simultaneous measurement of LH and hCG (95,96).

Serum hCG may be incorrectly measured by enzyme-linked immunosorbent assay when levels are extremely high because of the "hook effect." These falsely low or negative results are caused by oversaturation of the signaling antibodies used to detect hCG by the assay equipment, and can be avoided by diluting the serum in cases where very high levels are suspected or anticipated (97).

Treatment

Suction evacuation and curettage is the preferred treatment for hydatidiform mole in patients who wish to preserve their fertility (Table 26.5) (98,99). Patients should undergo a preoperative evaluation including vital signs, laboratory tests, and electrocardiogram to identify any medical complications, such as anemia, preeclampsia, and hyperthyroidism. The patient's blood type and hCG levels should also be measured preoperatively. If the patient is hemodynamically stable, the type of molar evacuation procedure can be selected (100,101). If the uterus is greater than 12-week size, ultrasound monitoring should be used to prevent uterine perforation and ensure complete removal of the molar tissue. Suction evacuation and curettage is performed under conscious sedation or anesthesia, and the cervix is dilated to allow passage of a 12- to 14-mm suction cannula into the lower uterine segment. The cannula is rotated to remove the intrauterine contents. Intravenous oxytocin should be started at the onset of the procedure and continued postoperatively for several hours to enhance uterine contraction. Rh-negative patients will also need to receive Rh immunoglobulin during evacuation because

the Rh D factor is expressed by trophoblastic cells (100,101). Gentle sharp curettage should be applied after suction evacuation. At least 2 units of blood should be available because of the risk of bleeding, which increases with uterine size. Postoperative respiratory distress may occur because of trophoblastic embolization, excessive fluid resuscitation, or massive oxytocin infusion. Attention to blood and crystalloid replacement reduces the risk of pulmonary complications, although all patients should be monitored with a pulse oximeter for at least 2 hours after surgery. Patient outcomes can be improved with the judicious use of equipment, ready access to blood products, careful monitoring during the procedure, and anticipation and treatment of complications.

TABLE 26.5 Evacuation of Hydatidiform Mole

Preoperative evaluation and preparation

1. Chest X-ray
2. Complete blood count
3. Electrolytes
4. Baseline oxygen saturation
5. Type and cross 2 units of blood
6. Set up Rho (D) immunoglobulin (RhoGAM) if patient is Rh-negative

Surgical procedure (with ultrasound guidance if uterus is >12 weeks size)

1. Premedication and paracervical anesthesia
2. Dilatation
3. Suction curettage—leave cannula at lower uterine segment until majority of molar tissue has been removed
4. Begin intravenous oxytocin infusion
5. Gentle sharp curettage

Postevacuation

1. Monitor respiratory status and uterine bleeding for at least 2 hours
2. Give RhoGAM if Rh-negative
3. Prescribe contraceptive
4. Follow hCG levels every 2 weeks until 2 consecutive normal results, then every month for 6 months and every 3 months twice

hCG, human chorionic gonadotropin.

For patients who have completed childbearing and do not wish to preserve their fertility, hysterectomy may be performed as an alternative to suction evacuation and curettage (Fig. 26.10). Hysterectomy removes the risk of local myometrial invasion, and focal disease can be ruled out in patients with persistent GTD. The high cost of this procedure and the risk of complications should limit the use of hysterectomy to those patients at high risk of postmolar GTD, including women over the age of 40, greater than gestational date uterine size, theca lutein cysts greater than 6 cm, hCG greater than 100,000 mIU/mL, and medical complications of pregnancy. However, metastatic disease may still be present after hysterectomy, with a 3% to 5% risk of postmolar GTN, and patients should be followed up with serial hCG testing (98).

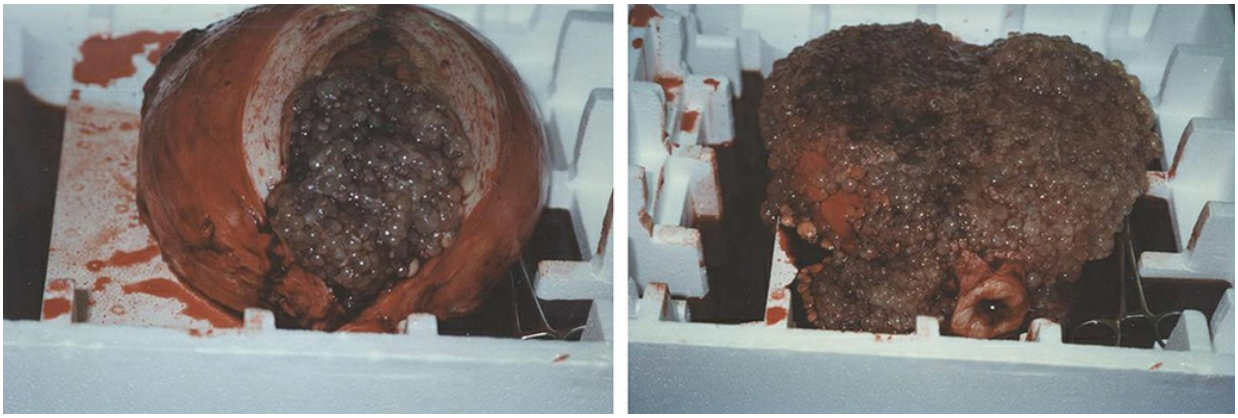

Figure 26.10 In selected patients, hysterectomy may decrease the likelihood of postmolar GTN. This photograph shows a 16-week uterus filled with complete hydatidiform mole.

Medical induction of labor and hysterotomy are not recommended, because of the increased risk of maternal morbidity, including blood loss, incomplete evacuation requiring surgical intervention, and the need for Cesarean delivery in subsequent pregnancies. This approach also increases the risk of trophoblastic dissemination and development of postmolar GTN requiring CT (99).

Use of prophylactic CT—either methotrexate or actinomycin D—at the time of evacuation or immediately afterward can reduce the risk of postmolar GTN from 15%–20% to 3%–8%. However, this approach exposes patients to chemotherapeutic toxicity, but benefits only a small number of patients. Because all patients who are found to have persistent postmolar GTN with serial hCG testing can be cured with CT, in general, prophylactic CT is not recommended. Its use should be limited to those patients who have a greater than normal risk of postmolar GTN, or who are less likely to comply with serial hCG testing during follow-up (102–104).

Molar Pregnancy and Coexisting Fetus

Twin pregnancies of a complete mole and normal fetus occur approximately once in every 22,000 to 100,000 pregnancies and may be difficult to distinguish from partial mole. Ultrasound can usually differentiate between these two scenarios, though cytogenetics may help distinguish a normal viable fetus from a triploid nonviable fetus in a partial mole. Patients with a twin normal/complete mole pregnancy are at higher risk of hemorrhage, preterm delivery, and other complications, as well as a higher risk of persistent GTN. Although suction evacuation and curettage are often recommended to terminate the pregnancy, 40% of these pregnancies will result in a normal viable fetus if left untreated (105–107). Our approach to this very rare situation is to carefully counsel the patient about this risk of life-threatening hemorrhage, pregnancy loss, and prematurity, in support of shared decision-making.

Follow-Up

Clinical findings of successful evacuation include prompt uterine involution, ovarian cyst regression, and cessation of bleeding. Definitive follow-up after molar evacuation requires serial serum quantitative hCG measurements every 1 to 2 weeks until three consecutive normal tests, and then every 3 months for 6 months to 1 year after normalization. More than 50% of patients will achieve a normal hCG within 2 months of evacuation. Women should be counseled to avoid pregnancy after GTD; contraception is recommended for 6 months after the first normal hCG result so that any postmolar elevation in hCG that is detected can be distinguished from the hCG rise that occurs in a normal pregnancy. Oral contraceptives are preferred because they suppress LH and remove any interference with hCG assay measurements. Studies have shown that oral contraceptives do not increase the risk of postmolar GTN (108–110). Fertility preservation is

achieved in over 80% of women with hydatidiform mole. High-risk postmolar disease is more often seen in patients who are not compliant with serial hCG measurements or are lost to follow-up (3). There is a 1% to 2% increased risk of developing a second complete molar pregnancy and a much lower risk of a second partial molar pregnancy (111).

Pregnancy after Hydatidiform Mole

All women with a history of molar pregnancy have a higher risk of developing malignant disease in a subsequent pregnancy (111). After molar evacuation, women should be counseled to wait at least 6 months from the time of hCG normalization to become pregnant. For all future pregnancies, pathologic examination of the placenta and other products of conception and measurement of hCG 6 weeks postpartum are recommended.

Persistent GTD/Postmolar GTN

Postmolar invasive mole or CCA occurs after 15% to 20% of complete and 1% to 5% of partial molar pregnancies, and invasive mole is seen more frequently (85% to 90%) than CCA (10% to 15%) (51,52,58,100,112–117). Approximately half of all cases of CCA arise from a prior molar pregnancy, but only 2% to 3% of all hydatidiform moles will progress to CCA (118). A diagnosis of CCA after a partial mole has been reported as single cases in the literature (51,52,58,119–125). Of women with invasive mole, 15% will have metastatic disease to the lungs or vagina. Most PSTTs and ETTs arise after nonmolar pregnancies, sometimes years after the pregnancy event (64,124,125).

The likelihood of persistent GTD after a molar pregnancy is higher in women who initially presented with marked trophoblastic growth, as indicated by hCG levels greater than 100,000 mIU/mL, excessive uterine size (>20 weeks), and theca lutein cysts greater than 6 cm in diameter. Women who have at least one of these risk factors have a 40% chance of developing postmolar GTN, compared with a 4% risk in those with none of these factors. Other risk factors for postmolar GTN include age greater than 40 years, repeat molar pregnancy, aneuploidy mole, and medical complications of molar pregnancy, such as toxemia, hyperthyroidism, and trophoblastic embolization (100).

At the molecular level, studies have found that women who will develop postmolar disease are more likely to show telomerase activity (126). Conversely, apoptotic activity measured by various techniques is higher in hydatidiform moles that spontaneously regress versus those that go on to develop postmolar GTN (127,128). Other studies have found that hydatidiform moles that are more likely to progress to malignant disease have lower expression of the antiapoptotic gene Mcl-1 (129), ferritin light polypeptide, and insulin-like growth factor–binding protein 1 (130).

For women with persistent GTD, a second curettage can be considered if their WHO score is low (<5). This approach was considered controversial in the past, because retrospective studies showed a variety of results from no benefit and significant perforation risk to significant response (131–134). The recently published results of the prospective clinical trial, Gynecologic Oncology Group study (GOG 242), clearly support the option of second curettage rather than CT for this low risk group of women with post molar GTN. In this study, of 60 women with postmolar GTN, WHO score 0–6, 24 (40%) were able to avoid CT. Grade 3–4 toxicity was limited to one patient with uterine perforation and one patient with hemorrhage requiring transfusion. None of the six women with WHO score of 5 or 6 responded completely to second curettage; therefore it is recommended that this treatment option be limited to patients with a WHO score of 0–4 (135).

Quiescent GTD

Some women with a history of GTD or spontaneous abortion may have a consistently low level of hCG (<200 mIU/mL for at least 3 months) but no detectable disease. In such situations, there is usually no evidence of hyperglycosylated hCG, a finding that, if present, is indicative of cytotrophoblastic invasion. This “quiescent GTD” does not respond to either surgery or CT. It is believed that the hCG being detected in these patients is produced by dispersed foci or individual slow-

growing syncytiotrophoblast cells, with no invasive potential in the absence of cytotrophoblast or intermediate trophoblast.

Approximately one-quarter of patients with quiescent GTD go on to develop active GTN, with detectable increases in both hCG and hyperglycosylated hCG levels (112,113,136,137). These patients may secrete increased hyperglycosylated hCG within 5 years of the initial pregnancy event, weeks to months before a detectable rise in hCG or clinical evidence of GTN (138). To diagnose quiescent GTD, false-positive hCG testing should be ruled out and the patient examined for any evidence of disease. Patients should be monitored closely with periodic hCG testing and should avoid pregnancy (95). CT and surgery should be avoided unless a diagnosis of GTN can be made, based on either a sustained rise in hCG or the appearance of disease.

GESTATIONAL TROPHOBLASTIC NEOPLASIA

Clinical Presentation

The clinical presentation of GTN depends on the pregnancy event, the extent of disease, and histopathology (1–3). Postmolar GTN, either invasive mole or CCA, presents as irregular bleeding after evacuation of a hydatidiform mole (usually a complete mole). Invasive mole is diagnosed clinically rather than pathologically, with persistent hCG elevation after molar evacuation. CCA occurs in association with any pregnancy event, with approximately 25% of cases occurring after abortion or tubal pregnancy, 25% after term or preterm gestation, and 50% after a molar pregnancy. Sometimes, a metastatic vaginal lesion may be disrupted during pelvic examination, which can lead to uncontrolled vaginal bleeding. Women with postmolar GTN may also present with an enlarged, irregular uterus and bilateral ovarian enlargement. There are no signs or symptoms that differentiate between postmolar GTN and GTN arising after a nonmolar pregnancy event, because these symptoms are related to the invasion and metastasis of the tumor. GTN should be considered in patients who present with postpartum bleeding and uterine subinvolution, although other causes include endomyometritis, tumors in other organ systems, or another pregnancy. Uterine perforation and metastases can cause abdominal pain, hemoptysis, melena, or increased intracranial pressure that leads to headaches, seizures, or hemiplegia. Symptoms suggesting pulmonary involvement include dyspnea, cough, and chest pain, and early respiratory failure requiring mechanical ventilation may develop. A diagnosis of GTN should be considered for any woman of reproductive age who presents with pulmonary symptoms (121). Symptoms of brain metastases include vomiting, seizures, headache, hemiparesis, and speech and visual disturbances (139). Liver and gastrointestinal metastases are rare and usually are seen with simultaneous lung or brain involvement; these patients have the lowest survival rate (140). PSTT and ETT often present with irregular vaginal bleeding and an enlarged uterus, with hCG levels from normal to 1,000 mIU/mL, sometimes years after a previous pregnancy. PSTT may also present with liver, lung, or brain metastases, or complications such as neoplastic nephrotic syndrome (124,125).

Diagnosis

The International Federation of Gynecology and Obstetrics (FIGO) defined a set of criteria for diagnosing persistent GTD in 2002 (Table 26.6) (141). Postmolar GTN is usually diagnosed when hCG levels plateau or rise during follow-up after molar evacuation, without histologic diagnosis. An hCG plateau is defined as a less than 10% decline in four measurements taken over 3 weeks. A rise is defined as a greater than 20% increase in three measurements taken over 2 weeks. The presence of elevated hCG in addition to metastases usually indicates CCA, whereas with PSTT and ETT, serum hCG levels are only slightly elevated, making differential diagnosis particularly challenging (64,124,125). The free hCG β subunit may be the best biomarker for diagnosing PSTT and the β core fragment for ETT (38,77). Although a diagnosis of GTN can be confirmed pathologically by examination of curettage or hysterectomy specimens, the placenta, or biopsy of

metastatic lesions, the risk of hemorrhage is too high, and biopsy of vaginal lesions should be avoided (142).

TABLE 26.6 FIGO 2000 Criteria for Diagnosis of Persistent GTD/Postmolar GTN

hCG plateau lasting for four measurements over a period of at least 3 weeks (days 1, 7, 14, and 21)
Rise in hCG of 10% or more for three measurements over at least 2 weeks (days 1, 7, and 14)
Persistence of elevated hCG 6 months after mole evacuation
Presence of a histologic diagnosis of CCA

CCA, choriocarcinoma; hCG, human chorionic gonadotropin.

For any patient with suspected or established GTN, a metastatic workup and evaluation of risk factors is performed (2,3,143) A complete history, physical examination, and laboratory tests (including complete blood cell count, coagulation study, serum chemistries, blood type and antibody screening, and quantitative serum hCG level) should be taken. Radiologic studies should start with a chest X-ray; if abnormal, a CT or MRI of the chest should be performed to detect pulmonary metastases. If the physical examination and the chest X-ray are normal and there are no symptoms of metastasis, other sites of metastasis are rarely present.

In general, we reserve further evaluation for metastatic disease only in the presence of lung metastases. The vast majority of patients with brain involvement (94%) have associated lung metastases; conversely, 20% of patients with lung metastases also have brain metastases. Brain metastases tend to appear in the parietal lobe and on the right side of the brain (Fig. 26.11). To detect central nervous system (CNS) lesions and brain involvement, MRI is significantly more sensitive than CT scan. Cerebrospinal fluid (CSF) hCG testing was a valuable tool prior to the development of CT scan and MRI scanning, but is rarely indicated in practice. If performed, a serum/CSF hCG ratio of less than 60:1 is a sensitive marker of CNS metastasis (143), although false positives can occur if measurements are taken when hCG levels are falling. CT scan of the abdomen, pelvic ultrasound, and MRI may be useful to detect extensive uterine disease and, specifically, to identify patients who may benefit from hysterectomy. Biopsy of metastases is not recommended, because the associated risks of biopsy outweigh the benefits of confirming a diagnosis of metastatic disease.

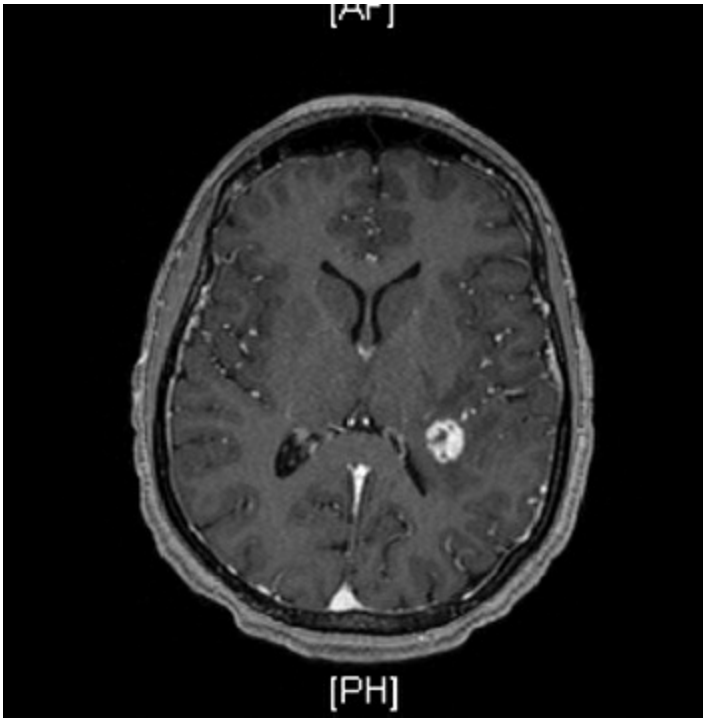

Figure 26.11 MRI of the brain. MRI showing right parietal lobe lesion with central hemorrhage.

Staging and Risk Scoring

In 2002, FIGO adopted a combined anatomic staging system and a modified version of the WHO risk factor scoring system for GTN (Tables 26.7 and 26.8) (144). The FIGO stage is designated by a Roman numeral and is followed by the modified WHO score designated by an Arabic numeral, separated by a colon. The risk score takes into account eight criteria, each of which is given a score from 0 to 4. Treatment of GTN is based on the classification of patients into risk groups defined by the stage and risk factor scoring system (145). The FIGO system is essential for selecting initial therapy for patients with GTN that will ensure the best possible outcomes with the fewest side effects. A recent study found that most patients classified as low risk but who have an initial level of hCG greater than 400,000 mIU/mL will fail initial CT, suggesting that perhaps these patients would benefit from multiagent CT (146). Patients with hCG levels between 100,000 and 400,000 mIU/mL will either respond to a single-agent regimen or require a change in regimen to achieve cure. Note that this staging and risk factor scoring system do not apply to either PSTT or ETT.

TABLE 26.7 FIGO 2000 Staging for Gestational Trophoblastic Neoplasiav

Stage	Description
I	Disease confined to uterus
II	Disease extends outside uterus but is limited to genital structures (adnexa, vagina, broad ligament)
III	Disease extends to lungs with or without genital tract involvement
IV	Disease involves other metastatic sites

Management

The cure rate for high-risk GTN—most commonly CCA—is currently greater than 90%, and for low-risk disease it approaches 100%, primarily because of the inherent sensitivity of trophoblastic neoplasms to CT, the effective use of hCG as a marker of early disease, the referral of patients to specialized centers, the identification of predictive factors of treatment response that has permitted individualization of therapy, and the use of combined surgery, radiation, and CT in the highest risk patients. Management of PSTT and ETT is more challenging because these neoplasms are often resistant to CT, and hCG level is not a strong marker of these diseases (2,3,147).

Low-Risk GTN

Patients in the low-risk group are those with Stage I disease (nonmetastatic) or Stage II and III disease (metastatic) with a risk score of less than 7. Stage I patients with a WHO score of 0–4 may benefit from a second curettage. When CT is indicated, these patients should undergo single-agent treatment with either methotrexate or actinomycin D (148,149), which has achieved survival rates approaching 100%. There are several different CT protocols for low-risk nonmetastatic GTN that have produced comparable results in nonrandomized, retrospective studies (Table 26.9). Taken together, these studies suggest that the 5-day methotrexate or the 8-day methotrexate–folinic acid protocol and the 5-day actinomycin D protocols or the biweekly single-dose actinomycin D protocols are significantly more effective than weekly intramuscular (IM) methotrexate. An ongoing phase III randomized international multi-institutional GOG study (GOG 275) is testing biweekly actinomycin D versus multiday (either 5- or 8-day) methotrexate. Remission rates with each of these protocols vary because of differences in drug doses, schedules, routes of administration, and patient factors. These studies also found that initial resistance to CT is associated with older age, higher hCG, nonmolar antecedent pregnancy, histopathologic diagnosis of CCA, presence of metastases, and higher FIGO score. Common side effects of these regimens are stomatitis, mucositis of the gastrointestinal tract, pleuritis, conjunctivitis, and skin rash.

TABLE 26.9 Chemotherapy for Low-Risk Gestational Trophoblastic Neoplasia	
Regimen	Primary Remission

	Rate (%)
MTX 0.4 mg/kg (max 25 mg)/day IV or IM for 5 days; repeat every 2 weeks	87–93
MTX 30–50 mg/m^2 IM weekly	49–74
MTX 1 mg/kg IM days 1, 3, 5, and 7; folinic acid 0.1 mg/kg IM days 2, 4, 6, and 8; repeat every 15–18 days or as needed	74–90
MTX 100 mg/m^2 IVP, then 200 mg/m^2 in 500 mL D5W over 12 hours; folinic acid 15 mg IM or PO every 12 hours for 4 doses beginning 24 hours after start of MTX; repeat every 18 days or as needed	69–90
Act D 10–13 mg/kg IV every day for 5 days; repeat every 2 weeks	77–94
Act D 1.25 mg/m^2 IV every 2 weeks (max 2 mg/day)	69–90
Alternating MTX 0.4 mg/kg (max 25 mg)/day IV or IM for 5 days and Act D 10–13 mg/kg IV every day for 5 days	100

Act D, actinomycin D; D5W, dextrose 5% in water; IM, intramuscular; IV, intravenous; IVP, intravenous push; MTX, methotrexate; PO, by mouth.

CT is continued until hCG values have returned to normal, and at least one course is administered after the first normal hCG level is achieved. A recent retrospective study compared relapse rates in women from the UK and the Netherlands with low-risk disease who were treated with methotrexate alternating with folinic acid (150). A greater number of patients relapsed with only two consolidation courses than those who received three consolidation courses after reaching the institutional normal hCG value of less than 5 mIU/mL. If hCG levels plateau at a point above normal during treatment, or if toxicity limits the ability to administer the chosen regimen, CT is changed to an alternative single-agent regimen. Multiagent CT is indicated in the event of a significant elevation in hCG, development of metastases, or resistance to sequential single-agent CT. Although there are differences in primary remission rates with each of the CT protocols, the cure rate remains high and most patients are able to preserve their fertility.

The John I. Brewer Trophoblastic Disease Center reviewed 30 years of experience treating low-risk nonmetastatic GTN to determine the most effective therapy, evaluate toxicity, and identify the factors associated with treatment resistance (Table 26.10) (151). Of 253 patients who received initial therapy of single-agent methotrexate (0.4 mg/kg, maximum 25 mg) as an IV push for 5 days every 2 weeks, only 5 required subsequent multiagent CT (90% complete response), and all patients achieved permanent remission. Only 12 patients experienced significant side effects with methotrexate, most commonly stomatitis, leading to a change in therapy to another agent, and no life-threatening toxicities were noted. Resistance to the initial single-agent methotrexate regimen was associated with high pretreatment hCG, nonmolar antecedent pregnancy, and clinicopathologic diagnosis of CCA. These findings are consistent with those of other centers and suggest that the most effective treatment protocol for low-risk nonmetastatic GTN is methotrexate 0.4 mg/kg (maximum total dose 25 mg) IM or IV push given once daily for 5 days every other week (151–168).

Two retrospective case studies compared 5-day IM methotrexate and 8-day methotrexate–folinic acid protocols in patients with low-risk nonmetastatic GTN; one study found that there was no difference in remission rates (76%) (157), and the other reported lower remission rates in patients receiving methotrexate–folinic acid (72%) than in patients receiving methotrexate alone (92%) (167). Gleeson et al. (168) subsequently reported a 69% primary remission rate in patients with nonmetastatic postmolar GTN treated with weekly methotrexate alone and a 75% remission rate with methotrexate–folinic acid.

As an alternative to methotrexate, actinomycin D may be given as an IV push of 10 to 12 μg/kg daily for 5 days every other week or as a single 1.25 mg/m^2 (max dose 2.0 mg/m^2) IV dose every other week (169–173). The primary remission rate for patients with nonmetastatic postmolar GTN was 88% for 5-day actinomycin D and 78% for pulsed actinomycin D (174). However, actinomycin D is more often used as a second-line therapy in patients with methotrexate resistance or with contraindications to methotrexate, because it is associated with higher perceived toxicity, particularly alopecia, and produces local tissue injury in cases of IV extraversion (175).

Several studies have compared weekly methotrexate and biweekly actinomycin D regimens for treatment of low-risk, nonmetastatic GTN. Across three randomized clinical trials, IM methotrexate was associated with lower primary complete response rates (49% to 53%) than pulsed actinomycin D (69% to 90%) (176–178). In the phase 3 GOG study (178), there was a higher complete response for biweekly IV actinomycin D than for weekly IM methotrexate (70% vs. 53%; $p = 0.01$), and in patients with lower risk scores (<5), the response rate was 73% and 58%, respectively ($p = 0.03$). Both regimens were less effective in patients with risk scores of 5 or 6 or if the diagnosis was CCA (complete response: 42% and 9%, respectively). Actinomycin D was associated with a high incidence of grade 1 alopecia and grade 1 nausea. In another randomized study of patients with stage I nonmetastatic GTN, complete remission was achieved in 74% of women who received methotrexate–folinic acid and in 100% of women who received 5-day actinomycin D (179). In a retrospective study of patients with low-risk, mostly nonmetastatic GTN, Abrao et al. (180) reported no significant difference in the complete remission rates with 5-day regimens of methotrexate or actinomycin D or combination therapy (69%, 61%, and 79%, respectively); however, the incidence of side effects was much higher in patients receiving the combination therapy than either single-agent regimen.

For patients with low-risk metastatic GTN (Stage II or III, score <7), single-agent CT with multiday dosing of either methotrexate or actinomycin D is appropriate; however, the biweekly actinomycin D protocols used for nonmetastatic disease should not be used in these patients (Table 26.9). Three specialized trophoblastic disease centers in the United States have reported remission rates of 48% to 67% in patients with low-risk, metastatic GTN with single-agent CT, with 1% to 14% of patients requiring multiagent therapy after failure of single-agent therapy with or without surgery (Table 26.10) (181–183). In this group of patients, resistance to single-agent therapy was associated with pretreatment hCG levels >100,000 mIU/mL, age older than 35 years, a FIGO score >4, and the presence of large vaginal metastases.

TABLE 26.10 Treatment of Low-Risk GTN at the Brewer Trophoblastic Disease Center

Regimens: MTX 0.4 mg/kg (max 25 mg)/day IV for 5 days, repeat every 2 weeks; Act D 10–13 mcg/kg IV every day for 5 days, repeat every 2 weeks

	Complete Remission Rate to Initial Single-Agent MTX	Required Multiagent Chemotherapy or Surgery (%)	Cured (%)
Lurain and Elfstrand (1995) (1962–1990) (151)	89.3% (226/253 nonmetastatic, low-risk GTN)	2	100
Roberts and Lurain (1996) (1962–1992) (183)	65.6% (40/61 metastatic, low-risk GTN)	3	100
Chapman-Davis et al. (2009) (1979–2009) (184)	81% (291/360 FIGO low-risk GTN[a])	6	100

[a]Stage I disease (nonmetastatic) and Stage II and III disease (metastatic), risk score <7.

At the Brewer Trophoblastic Disease Center, we examined risk factors for developing resistance to initial methotrexate therapy in 358 patients with low-risk GTN treated between 1979 and 2009 (Table 26.10) (184). Patients initially received methotrexate 0.4 mg/kg (max 25 mg) IV push daily for 5 days every 14 days. Actinomycin D 0.5 mg IV push daily for 5 days every 14 days was used in 64 patients who developed resistance or toxicity to initial methotrexate CT, and multiagent regimens were used in 20 patients for whom either single-agent CT failed. The complete response rate to initial methotrexate was 81%, and the complete response rate to actinomycin D as secondary therapy was 75% (94% overall complete response rate to sequential single-agent CT). The remaining patients achieved permanent remission with multiagent CT with or without surgery. Resistance to initial methotrexate CT was associated with increasing FIGO score ($p < 0.0001$), clinicopathologic diagnosis of CCA ($p = 0.028$), higher pretreatment hCG ($p = 0.001$), and presence of metastatic disease ($p = 0.018$).

In general, primary treatment failure occurs in 10% to 30% of patients with low-risk GTN and in 30% to 50% of patients with low-risk, metastatic disease. Most patients who are resistant to the initial CT will be placed into remission

after changing to another single-agent CT. Patients with low-risk nonmetastatic disease will rarely require multiagent CT, and approximately 15% of patients with low-risk, metastatic GTN will require multiagent CT with or without surgery. The higher rate of failure of initial single-agent therapy in patients with higher FIGO scores has led some to propose an intermediate risk group of patients who have metastatic disease with scores of 5 or 6. Ideally, treatment failure should be identified as early as possible to limit patient exposure to ineffective CT cycles. Several groups have tried to determine an hCG cutoff value that can predict treatment resistance, in order to allow prompt changes in treatment (185–187). One group found that a cutoff value of 737 mIU/mL was able to predict resistance to 8-day methotrexate with a specificity of 97.5% (188). If treatment change is necessary, the risk score is recalculated to determine the most appropriate second-line regimen.

In patients with low-risk GTN who do not wish to preserve their fertility, adjuvant hysterectomy may be performed with the initiation of CT to reduce the length of treatment required to achieve remission (189). Other indications for hysterectomy in low-risk GTN include persistent, CT-resistant disease in the uterus or to treat uterine tumor hemorrhage.

High-Risk GTN

Chemotherapy.

Patients in the high-risk group have metastatic GTN, either stage IV disease or stage II and III disease with a risk factor score greater than 6. These patients are treated more aggressively with multiagent CT, with or without adjuvant radiation or surgery (Table 26.11). With this approach, cure rates have reached 80% to 90%. Treatment delay or dose reduction because of side effects increases the likelihood of tumor resistance and treatment failure (2,3,147). Historically, a combination treatment of methotrexate, actinomycin D, and cyclophosphamide or chlorambucil (MAC) was used as first-line therapy for high-risk, metastatic GTN and achieved cure in 63% to 71% of patients (Table 26.12) (190,191). Over time, the regimen of choice shifted to a combination of cyclophosphamide, hydroxyurea, actinomycin D, methotrexate with folinic acid, vincristine, and doxorubicin (CHAMOCA) (Fig. 26.12). The primary remission rate in high-risk, metastatic GTN was reported to be 82% with this regimen (192). However, a subsequent randomized trial comparing MAC and CHAMOCA found that the primary remission rate and the cure rate were inferior for CHAMOCA, which also had a more toxic side-effect profile (193). The addition of etoposide to a regimen containing high-dose methotrexate with folinic acid, actinomycin D, and vincristine (EMA-CO) improved both primary remission and survival rates in patients with high-risk GTN (Table 26.12) (194,195). The EMA-CO regimen for high-risk GTN has reportedly complete response rates of 71% to 78% and long-term survival rates of 85% to 94% (196–204). The survival rates exceed the complete response rates because GTN is a unique malignancy where secondary therapies often result in cure. In our study series (200,201,204), we reported complete response rates of 76%, 67%, and 54% and overall survival rates of 92%, 93%, and 92% with EMA-CO treatment, respectively. Deaths occurred only in patients with FIGO stage IV disease with scores greater than 12, and no treatment-related deaths or severe toxicities were seen. Neutropenia was rare, although alopecia and anemia were common, and mild paresthesia and stomatitis occurred in 20% of patients.

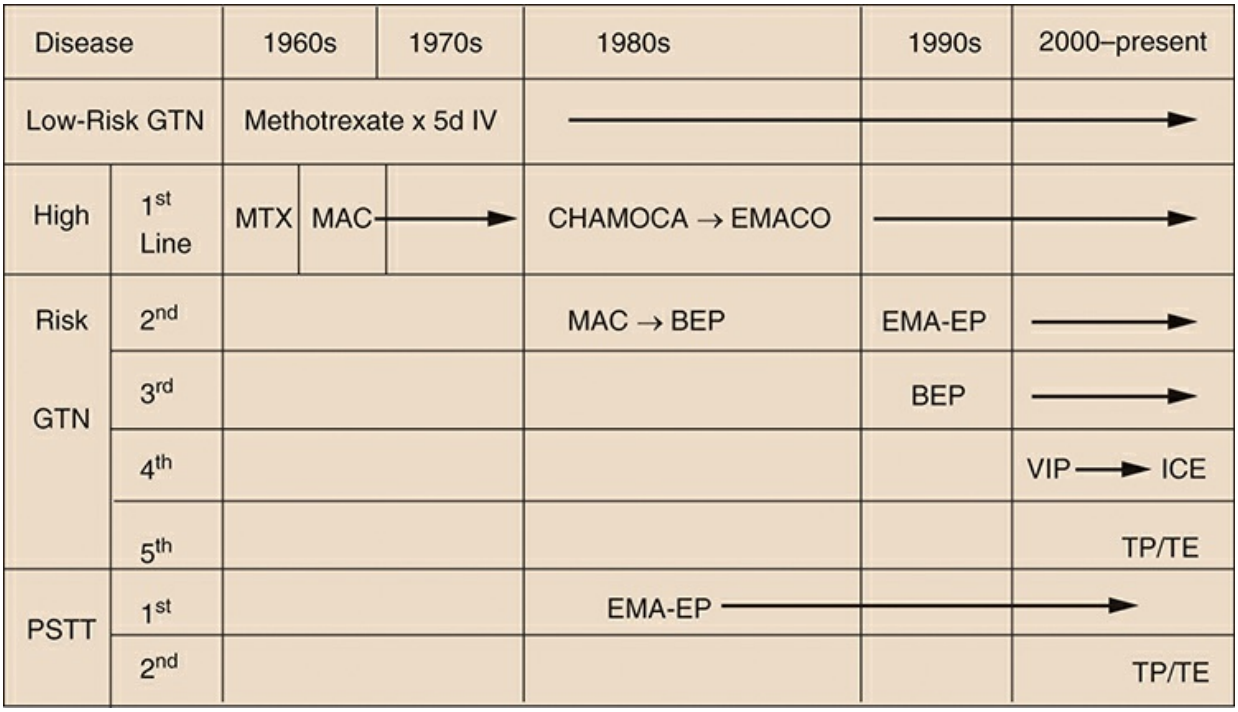

Figure 26.12 Evolution of chemotherapy for GTN at the John I. Brewer Trophoblastic Disease Center. Chemotherapy regimens are shown for low-risk disease, as well as the first-line therapy and subsequent regimens for recurrent or resistant high-risk disease. For PSTT, chemotherapy may be used in patients with metastatic disease and in patients with nonmetastatic disease and poor prognostic factors.

TABLE 26.11 EMA-CO Chemotherapy for High-Risk Gestational Trophoblastic Neoplasia

Treatment Day	Regimen	
1	Etoposide	100 mg/m^2 IV over 30 minutes
	Act D	0.5 mg IVP
	MTX	100 mg/m^2 IVP, then 200 mg/m^2 in 500 mL D5W over 12 hours
2	Etoposide	100 mg/m^2 IV over 30 minutes
	Act D	0.5 mg IVP
	Folinic acid	15 mg IM or PO every 12 hours for 4 doses starting 24 hours after start of MTX (on day 1)
8	Cyclophosphamide	600 mg/m^2 IV
	Vincristine	1.0 mg/m^2 IVP

Cycle repeats every 2 weeks (i.e., days 15, 16, and 22).

Act D, actinomycin D; D5W, dextrose 5% in water; IM, intramuscular; IV, intravenous; IVP, intravenous push; MTX, methotrexate; PO, by mouth.

TABLE 26.12 Treatment of High-Risk GTN at Brewer Trophoblastic Disease Center

Brewer et al. (1968) (190)	MTX and/or Act D followed by MAC: 39% survival

	Initial MAC: 65% survival
Lurain and Brewer (1985) (1968 – 1982) (191)	MAC: 63% (29/46) complete remission
Schink et al. (1992) (1986 – 1991) (195)	EMA-CO: 83% (10/12) complete remission
Escobar et al. (2003) (1986 – 2001) (200)	EMA-CO: 76% (19/25) complete response rate
	92% (23/25) survival
Lurain et al. (2006) (201)	EMA-CO: 66.7% (20/30) complete response rate
	93.3% (28/30) survival
Lurain et al. (2010) (1986 – 2009, FIGO high-risk only[a]) (204)	EMA-CO: 54% (14/26) complete response rate
	92% (24/26) survival

[a]Stage II and III disease, risk score ⩾7 and Stage IV disease.

Patients with widely metastatic disease as evidenced by a very high WHO/FIGO score (>12) are at significant risk for pulmonary, intraperitoneal, or intracranial hemorrhage, this risk may be mitigated by starting treatment with low dose induction chemotherapy. The use of induction low-dose etoposide 100 mg/m^2 and cisplatin 20 mg/m^2 (EP); days 1 and 2, every 7 days has been used at Charing Cross since 1995 to reduce early deaths before commencing EMA-CO. EP induction was given to 23.1% of 140 high-risk patients (33 of 140 patients) with a large disease burden for one to four cycles, and the early death rate was reduced to only 0.7%, compared with 7.2% in the pre-1995 cohort (205).

Though aggressive multiagent therapy is associated with high levels of toxicity, single-agent therapy is not appropriate for high-risk patients, because the success rate of secondary CT after failure of single-agent therapy is only 20% to 50%. Based on current evidence, EMA-CO is the initial treatment of choice for patients with high-risk, metastatic GTN. The regimen has high complete response rates and survival rates, as well as low toxicity that improves patient adherence to treatment and thus reduces the risk of drug resistance. CT is continued for at least two to three courses after the first normal hCG level is achieved.

Radiation

For patients who present with brain metastases, whole brain radiation (3,000 cGy in 200 cGy fractions) or, in selected patients, surgical excision with stereotactic radiation is indicated and is usually performed at the start of CT to lower the risk of hemorrhage (140,206–208). In these patients, the EMA-CO regimen is modified such that methotrexate is increased to 1 g/m^2 with 30 mg of folinic acid every 12 hours for 3 days starting 32 hours after the start of infusion (209). Intrathecal and high-dose methotrexate may also be used in some centers (209,210). Patients are also treated with dexamethasone to decrease edema and phenytoin sodium to prevent seizure. During therapy, patients undergo serial CT scans or MRIs to monitor the lesions. Once a complete response has been achieved, hCG levels in the CSF should be measured, ideally by radioimmunoassay to detect low levels of protein. The plasma to CSF ratio of hCG should be less than 60 (144). Patients with brain metastases have a cure rate of 50% to 80% depending on symptoms and the number, size, and location of brain lesions.

Surgery

Approximately 50% of patients with high-risk, metastatic GTN will require adjuvant surgical procedures, usually hysterectomy and pulmonary resection, for CT-resistant disease or to control hemorrhage and sepsis (211–219). Selected patients with focal disease may be candidates for partial lung, liver, or brain resection. Imaging with fluorodeoxyglucose positron emission tomography (PET), with CT scan for anatomic localization, may help with targeted surgery (220). For

women with excessive vaginal bleeding, selective arterial embolization may be beneficial (221,222). We reviewed a series of 50 patients with high-risk GTN who were treated at the Brewer Trophoblastic Disease Center from 1986 through 2005 with EMA-CO as primary or secondary therapy. Twenty-four patients (48%) underwent 28 adjuvant surgical procedures, and 21 (87.5%) were cured. Fifteen of 17 patients who underwent hysterectomy; 4 of 5 patients who had resistant foci of CCA in the lung resected; all 4 patients who had suturing of the uterus, uterine artery embolization, small bowel resection, and salpingectomy for bleeding; and 1 patient who had uterine wedge resection for resistant CCA survived (213).

Second-Line/Salvage Therapy

Despite the use of multimodal primary therapy, approximately 30% of patients with high-risk GTN will have an incomplete response or will relapse from remission and will require secondary CT (223–230). Risk factors for relapse include the presence of multiple metastases to sites other than the lung and vagina and inadequate first-line CT. Salvage CT with the EMA-EP regimen, in which etoposide and cisplatin have been substituted for cyclophosphamide and vincristine in the EMA-CO regimen, is the most appropriate for patients who have not responded (plateaued low hCG levels) or experienced a relapse (reelevation of hCG after a complete response) to first-line EMA-CO. This regimen is highly toxic and usually requires granulocyte colony-stimulating factor support by the third cycle. Salvage CT combined with surgical excision of persistent tumor will result in cure for most of these high-risk patients (228–230). In patients who have developed resistance to methotrexate-containing protocols, drug combinations containing etoposide and platinum with bleomycin, ifosfamide, or paclitaxel have also been effective (224,231). At the Brewer Trophoblastic Disease Center, we reported on 26 patients with persistent or relapsed high-risk GTN who received secondary platinum-based salvage CT. The overall survival was 61.5% (16/26). Of the 16 patients for whom primary therapy with methotrexate/actinomycin D–based CT without etoposide failed, 10 (63%) had complete clinical responses to bleomycin, etoposide, and cisplatin; etoposide, ifosfamide, and cisplatin; and ifosfamide, carboplatin, and etoposide; and 10 (63%) were cured. Of the 10 patients for whom primary therapy with EMA-CO failed, 9 (90%) had complete clinical responses to EMA-EP or bleomycin, etoposide, cisplatin, but only 6 (60%) subsequently achieved a lasting remission (223). Most recently, we reviewed the effect of etoposide/platinum-based salvage therapy in 49 women (20 of whom were treated secondarily at our center) with high-risk GTN treated between 1986 and 2010 for whom initial multiagent therapy with EMA-CO had failed (Table 26.13) (230). Salvage therapy included etoposide and a platinum agent with methotrexate and actinomycin D (EMA-EP), bleomycin (BEP), ifosfamide (VIP, ICE), or paclitaxel (TP/TE). Of the 28 patients who developed resistance to EMA-CO, 82% achieved lasting complete responses to salvage therapy. Three of four patients who received RT for brain metastases survived, and 82% of patients who required surgical procedures to remove metastases survived. High hCG level at the start of salvage therapy ($p < 0.001$), a higher number of metastatic sites ($p < 0.02$), and metastases to sites other than the lung and vagina ($p < 0.05$) were associated with lower survival in these patients. Patients with metastases in the brain, liver, and gastrointestinal tract have a 75%, 73%, and 50% survival rate, respectively (229).

TABLE 26.13 Secondary Treatment of EMA-CO–Resistant, High-Risk GTN

Regimen	Patients	Complete Response, No. (%)	Survival, No. (%)
EMA-EP	19	11 (58)	9 (47)
BEP	16	11 (69)	9 (56)
VIP	2	1 (50)	1 (50)
ICE	6	4 (67)	3 (30)
TP/TE	3	2 (67)	1 (33)
Totals	46	29 (63)	23 (82)

BEP, bleomycin, etoposide, platinum agent; EMA-CO, etoposide, methotrexate, actinomycin D, cyclophosphamide, vincristine; EMA-EP, etoposide, methotrexate, actinomycin D, platinum agent; TP/TE, paclitaxel, platinum

agent/paclitaxel, etoposide; VIP and ICE, etoposide, platinum agent, ifosfamide.

PSTT and ETT

Because of the relative resistance of PSTT and ETT to CT and the high risk of lymphatic spread, hysterectomy with lymph node dissection is the recommended treatment. Prior to surgery, histologic diagnosis of PSTT with endometrial biopsy or curettage specimen should be confirmed with immunohistochemical staining for the presence of hPL and the absence of hCG. CT should be used in patients with metastatic disease and in patients with nonmetastatic disease and poor prognostic factors, including a long interval between last pregnancy and diagnosis (>2 years), deep myometrial invasion, tumor necrosis, and mitotic count greater than 5/10 high-power fields (232,233). Though we do not know the optimal CT regimen for PSTT and ETT, the current treatment of choice is a platinum-containing regimen, such as EMA-EP or a paclitaxel/cisplatin–paclitaxel/etoposide (TP/TE) doublet. With hysterectomy and CT, the survival rate is approximately 100% for nonmetastatic disease and 50% to 60% for metastatic disease (234–236).

Reasons for Treatment Failure

We identified patients who were transferred to the Brewer Trophoblastic Disease Center after treatment failure elsewhere, in order to determine the causes of treatment failure. We also compared our second-line treatment results from 1979 to 2006 with previous reports from 1962 to 1978 (Table 26.14) (237). The most common reasons for treatment failure for GTN were (1) use of single-agent CT for patients with high-risk disease and (2) inappropriate use of weekly IM methotrexate CT for treatment of patients with metastatic disease, FIGO scores ≥7, and/or nonpostmolar CCA. Successful secondary GTN treatment in these patients improved from 59% during 1962 through 1978 to 93% during 1979 through 2006, most likely as a result of center experience and the use of more effective CT regimens. It is recommended that clinicians request advice from or referral for treatment to centers with expertise in management of GTN for patients who fail single-agent therapy for low-risk disease and for any patient with high-risk disease (238).

TABLE 26.14 Overall Results of Treatment of GTN at the Brewer Center 1962–2006

Treatment Site/Dates	Number	Survival
Primarily at Brewer Center	740	702 (95%)[a]
1962–1978	359	329 (92%)
1979–2006	381	373 (98%)
Secondarily at Brewer Center	64	47 (73%)[a]
1962–1978	37	22 (59%)[b]
1979–2006	27	25 (93%)[b]
Total	804	749 (93%)

[a] $p < 0.05$.

[b] $p < 0.005$.

Follow-Up of GTN

After hCG has returned to normal levels and treatment has been completed, serum quantitative hCG levels should be obtained at 1-month intervals for 12 months. The risk of relapse is approximately 3% in the first year after completing therapy and drops to less than 1% thereafter. Physical examinations are performed at intervals of 6 to 12 months, and other testing is rarely indicated.

Pregnancy after GTN

Successful treatment of GTN with CT has allowed most women to preserve their fertility, despite exposure to drugs that are toxic to the ovary. Most women resume normal ovarian function after CT and exhibit no increase in infertility, however, menopause may occur earlier. Contraception should be maintained during treatment and for 1 year after completion of CT, preferably using oral contraceptives, to allow for uninterrupted hCG follow-up and to permit the ovulation of eggs that may have been damaged by exposure to cytotoxic drugs.

Successful pregnancies have been reported after GTN, without an increased rate of abortion, stillbirth, congenital anomalies, prematurity, or major obstetric complications (22,239,240). There is no evidence for reactivation of disease with subsequent pregnancies, although patients who have had one trophoblastic disease episode have a 1% to 2% risk of a second GTD event, independent of previous CT (4). Therefore, pelvic ultrasound is recommended in the first trimester of any post-GTN pregnancy to confirm a normal gestation. The products of contraception or placentas from future pregnancies should also be carefully examined histopathologically, and a serum quantitative hCG level should be determined 6 weeks after any pregnancy.

Risk of Secondary Malignancies

Because of the relatively short exposure of patients with GTN to intermittent schedules of methotrexate and actinomycin D and the infrequent use of alkylating agents, there are concerns of increased susceptibility to the development of other malignancies. A retrospective study in 1996 from Charing Cross demonstrated an increased use of etoposide-containing drug combinations for treatment of GTN that has led to an increased risk of secondary malignancies, including acute myelogenous leukemia, colon cancer, melanoma, and breast cancer (241). Because of this, and an association with alopecia and severe nausea, the use of etoposide-containing regimens is limited to patients with high-risk disease. A follow-up study from Charing Cross, in 2015, looked back at the original cohort and extending it to include 1903 women treated between 1958 and 2000, with follow-up beginning in 2006. They found: “Subsequent cancer risks for patients cured of gestational trophoblastic tumors with modern chemotherapy appear similar to those of the normal population with no overall increased risk of malignancy after MTX-FA or EMA-CO. However, there was evidence of an increased risk of leukemia after EMA-CO and some evidence of other site-specific increased risks based on small patient numbers. All major treatments except MTX-FA increased the risk of early menopause.”(242).

CONCLUSIONS

The more widespread use of ultrasound to evaluate patients who present with vaginal bleeding has led to earlier diagnosis of hydatidiform mole. Although hCG is a disease-specific marker for complete molar pregnancy, levels vary widely in individual patients, and those who are diagnosed with earlier-stage disease may not show highly elevated hCG. The majority of patients with molar pregnancy are successfully treated with suction evacuation and curettage, and the risk of a second molar pregnancy or development of postmolar neoplasia is low (1).

Cure rates for both nonmetastatic and low-risk, metastatic GTN should approach 100% with the judicious use of second curettage or initial single-agent methotrexate or actinomycin D. Approximately 20% of low-risk patients will develop resistance to the initial chemotherapeutic agent, but 90% will be cured by the use of sequential single-agent treatment. Eventually, approximately 10% of patients will require multiagent CT, with or without surgery, to achieve remission. With aggressive, multimodality therapy—EMA-CO with adjuvant RT or surgery as indicated—cure rates for high-risk GTN have reached 80% to 90%. Though one-third of high-risk patients fail first-line therapy or experience a relapse from remission, salvage therapy with platinum-containing drug regimens, with or without surgery, will cure most patients with resistant GTN (147).

SECTION IV
SPECIAL MANAGEMENT TOPICS

CHAPTER 27 Breast Cancer

David A. Edmonson, Tina Rizack, Margaret M. Steinhoff, C. James Sung, Hanan I. Khalil, Jarslow T. Hepel, Sonali V. Pandya, Robert D. Legare and Don S. Dizon

INTRODUCTION

Breast cancer is the most common cancer in women, diagnosed in 1.2 million women worldwide each year. Treatment paradigms require an understanding of the natural history of the disease, including the various patterns of metastases and recurrence, and both the prognostic and predictive factors that may influence both response to treatment and overall survival (OS). In addition, the complexities that govern medical and surgical decisions make the management of breast cancer far more complicated than that of other disease sites. This chapter will provide the essential information regarding breast cancer, with an emphasis on recent developments. It stresses an interdisciplinary view of disease management by providing the foundational aspects of breast disease and treatment.

EPIDEMIOLOGY

Each year, more than 200,000 women and more than 2,000 men are diagnosed with breast cancer in the United States. It is estimated that one in eight women will be diagnosed with breast cancer in their lifetime. Fortunately, mortality from breast cancer has been steadily declining since 1990, at a rate of 3.1% per year in women under 50 years of age and 2.1% per year in older women (1). Still, more than 40,000 women succumb to breast cancer each year, making it the second most lethal malignancy behind lung cancer.

RISK FACTORS

Risk factors for breast cancer have been well characterized (Table 27.1). In general, factors associated with increased exposure to estrogen are well established. This includes female gender, early menarche, late menopause, later age at first pregnancy, and nulliparity. The use of combined estrogen and progesterone hormone therapy is a risk factor, although the Women's Health Initiative demonstrated that estrogen-only preparations (only indicated for women without an intact uterus) resulted in a lower risk of breast cancer (2). Of note, there is no evidence that oral contraceptive use increases risk (3), and a 2015 meta-analysis of women undergoing hormonal treatment for infertility came to similar conclusions (4). Among modifiable risk factors, obesity, weight gain in later life, and the consumption of alcohol have been identified in prospective observational studies (5). Race is a risk factor as well, though some data suggest it may be tumor-type specific. For example, Warner et al. (6) showed that Black women had a 21% higher risk of breast cancer–specific death,

but this appeared limited to hormone receptor–positive tumors; there were no differences in survival among women with triple-negative or human epidermal growth factor-2 (HER2)–positive tumors. Family history is also a strong epidemiologic risk factor, and clinical models, such as the Tyrer–Cuzick, Gail, and Claus models, can assist in the prediction of breast cancer risk (7). Beyond classification of risk based on family history (familial risk), familial risk attributed to genetic mutations have been characterized. Among the best characterized are mutations involving BRCA1, localized to chromosome 17q21, and BRCA2, on chromosome 13q12-13, both of which confer a risk for breast cancer as high as 80% among carriers (8,9). However, genetic mutations beyond BRCA1 have also been characterized that carry an increased risk of breast cancer, including Li–Fraumeni syndrome (TP53), hereditary diffuse gastric cancer (CDH1), CHEK2, a member of the Fanconi Anemia–BRCA pathway involved in checkpoint function, and DNA repair mediated by BRCA1 and p53, and PALB2, another gene in the same pathway (7).

TABLE 27.1 Risk Factors for Breast Cancer

Increased Estrogen Exposure	Female gender Early menarche Late menopause Use of postmenopausal estrogen/progesterone hormone therapy
Parity	Late age at first pregnancy Nulliparity
Lifestyle Factors	Obesity Weight gain later in life Alcohol consumption
Race	Black race
Family History	Breast cancer in first-degree relatives Male breast cancer
Genetic Mutations	BRCA1/2 TP53 CDH1 CHECK2 PALB2
Environmental	Prior radiation exposure Night shift work Polycyclic aromatic hydrocarbon exposure
Breast Findings	Benign breast lesions Dense breast tissue

Environmental risks include prior radiation exposure, chemical exposure, and work/lifestyle factors. Work evaluating the long-term effects of environmental factors has established prior radiation exposure as an additional risk factor. The therapeutic use of mantle-field radiation in women with lymphoma and the sequelae of the atomic bombing of Japan in World War II identified the heightened risks of breast cancer, particularly in young women. This was shown in a study by Hancock et al. (10), which noted that radiation exposure in women with Hodgkin disease had an elevated risk of breast cancer compared to normal women, which increased by 6 to 15 fold, beginning approximately 10 years after completion of therapy.

Chemical exposure is of increasing interest as a possible risk factor for the development of breast cancer. Several observances seem to suggest that there is some type of cause–effect relationship. In several regions of the country, there are unusually high incidences of breast cancer. In the 1990s, NIEHS and the National Cancer Institute cofunded the Long Island Breast Cancer Study Project (11,12). This was one of the largest and most comprehensive studies conducted exploring the possible link between breast cancer and environmental exposures, which evaluated three widespread

pollutants, organochlorine pesticides (DDT), its metabolite DDE, polychlorinated biphenyls, and polycyclic aromatic hydrocarbons (PAHs), all of which were common within the Long Island area. The study showed that there was a modest increased risk of breast cancer with PAH exposure; however, no other definitive relationship between chemicals and breast cancer risk could otherwise be identified.

Multiple studies have looked at the relationship between night shift work and increased risk of breast cancer. A 2013 meta-analysis of 10 studies by Wang et al. (13) showed a pooled adjusted relative risk (RR) of 1.19 for those "ever exposed to night shift work and breast cancer". A dose–response relationship was also suggested, with a 3% increase in risk for every 5 years exposed to night shift work. More alarming is that their work suggested that an increase of 500 night shifts would result in a 13% increase in breast cancer risk.

The theoretical association appears to involve disruption of normal circadian rhythms, which may result in the suppression of melatonin output, with disruptions in pathways associated with melatonin, including angiogenesis, oxidation, and immune regulation. Lower levels of melatonin may also result in continuous production of estrogen as well as altering the estrogen receptor (ER), thus, increasing the risk of breast cancer (13–15).

Multiple studies have identified an association between breast cancer and breast findings, including the presence of benign breast lesions and increased density of breast tissue. For example, in a study by Hartmann et al. (16), the RR for breast cancer ranged from 1.27 for nonproliferative lesions to 1.88 for proliferative lesions without atypia to 4.24 in lesions with atypia, and this risk persisted for as long as 25 years after biopsy. Boyd and colleagues (17) reported on the association between risk and breast density (measured in percentage of the total breast). Using 1,112 matched case–control pairs they determined the association between risk and reported that women with density of 75% or greater had a significantly increased risk of breast cancer (odds ratio [OR] 4.7, 95% CI 3.0 to 7.4), with younger women notably at greatest risk.

ANATOMY

The breast is a modified sweat gland composed of two components: the large ducts and the terminal duct-lobular unit (TDLU), surrounded by adipose and fibrous tissue, lymphatics, nerves, and blood vessels. The surface of the breast is attached to the underlying fibrous tissue *via* Cooper ligaments, and the mammary gland lies over the pectoralis major muscle extending vertically along the second to sixth ribs and horizontally from the sternum to the anterior midaxillary line. The axillary tail comprises mammary tissue as well and extends laterally from the chest wall into the axilla. The large duct system of subsegmental, segmental, and lactiferous ducts converge and empty onto the nipple. The TDLU is the most distal part of this branching ductal system, and is felt to be the site of origin of most pathologic entities of the breast, including fibrocystic changes, ductal hyperplasias, and the majority of carcinomas (18). It is connected to the subsegmental ducts and represents the secretory unit of the gland.

Mobility of the breast tissue over the chest wall is through the retromammary bursa, which lies between the superficial and deep fascia. The vast lymphatic system of the breast is composed of a network over the entire surface of the chest, neck, and abdomen, with increased density under the axilla. There are three main lymphatic pathways of the breast: the axillary pathway, which drains the upper and lower halves of the breast into the lateral axillary nodal chain; the transpectoral pathway, which drains into the supraclavicular nodes; and the internal mammary (IM) pathway, draining the inner halves of the breast into the nodes of the IM chain.

NATURAL HISTORY OF BREAST CANCER

Breast cancers can have predictable features. For example, breast cancer is more likely to be diagnosed in the central or

outer quadrants of the breast than in the inner regions (19), and some studies suggest that more cancers occur in the left rather than the right breast (20). Within the breast, cancer travels along ducts (intraductal carcinoma), and the process of invasion begins when the tumor erodes through the basement membrane. Continued growth results as the tumor spreads along adjacent lobules, breast lymphatics, perineural routes, and vascular spaces. When it involves the dermal lymphatics, the overlying dermis becomes edematous and red with the classic appearance of peau d'orange. Continued growth of the primary tumor can result in the involvement of the pectoralis and intercostal muscles, ribs, and the clavicle.

While less frequently encountered, locally advanced or metastatic disease at diagnosis is sometimes seen in clinical practice. Tumor spread can occur locally by direct extension, lymphatically, or *via* intravascular means. Lymphatic spread of tumor from the breast travels to the locoregional nodes of the chest: the axillary, intramammary, and supraclavicular nodal basins, and increasing tumor size is a well-known predictor of nodal involvement. A medial or central lesion of the breast is more likely to metastasize to the IM nodes than outer quadrant lesions, and this has been theorized to explain their worse prognosis compared to upper outer breast tumors (19). Vascular invasion can be observed, even with small tumors.

Metastatic disease from breast cancer can occur in any organ site. Lee (21) reviewed the published autopsy series in a 1983 report that included more than 2,000 women who had died of breast cancer. The most commonly involved organs were the lungs, bones, nodes, and liver. The pleural space, adrenal glands, and brain represented the next most commonly involved sites. Bloom (22) compared a group of women with untreated breast cancer with a cohort of patients treated with radical or modified radical mastectomy, with or without irradiation, and reported overall 10-year survival rates of 3.6% in the untreated cohort versus 34% in the treated group.

CLINICAL PRESENTATION OF BREAST CANCER

In countries where mammographic screening is established, women will often present with an abnormal mammogram. However, presentation with a clinical breast mass or even advanced disease still occurs in resource-rich countries, though it is more common in resource-poor settings. For women in their childbearing years, a delay in diagnosis may be attributed to benign causes such as recent trauma, changes with pregnancy, or due to breast-feeding. For women presenting with a mass, signs and symptoms of disease include breast tenderness, skin changes, bloody nipple discharge, or changes in the shape and size of the breast, with or without axillary adenopathy. Rarely do women present only with axillary adenopathy without evidence of a breast primary (occult breast carcinoma). Lastly, inflammatory breast cancer (IBC) presents as a tender, red, and swollen breast, often mistaken for mastitis. A crusting rash emanating from the nipple is sine qua non for Paget disease of the breast, which is almost uniformly associated with an underlying malignancy. Rarely will women present with metastatic breast cancer (MBC), a phenomenon more likely in resource-poor areas.

BREAST IMAGING

Breast imaging can be performed as a screening tool in asymptomatic women to detect early cancer, in high-risk women, or as a diagnostic examination in women suspected of having breast cancer or previously treated for breast cancer. Mammography remains the most widely used technique for screening, and it is the only modality proven to decrease mortality. Computer-aided detection (CAD), a tool designed to help the radiologist improve the detection of breast cancer, is frequently used by interpreting radiologists; the benefits and consequences will be reviewed.

Modalities such as ultrasound (US) and magnetic resonance imaging (MRI) serve as adjunct tools in the diagnostic setting or high-risk screening. In addition, breast tomosynthesis is used in some centers as an additional technique.

Mammography

The efficacy of mammography has been widely established by multiple randomized controlled trials demonstrating absolute mortality reduction, achieved by mammography's ability to detect both ductal carcinoma in situ (DCIS) and invasive breast cancer at a smaller size and earlier stage than in unscreened women. However, the value of mammography has also been called into question recently. A 2012 meta-analysis performed by the Independent United Kingdom Panel on Breast Cancer Screening that included 11 randomized trials confirmed that mammography is associated with a 20% reduction in breast cancer mortality (23), and other studies suggest that women between 40 and 69 years stand to benefit the most, particularly if implemented for at least 10 years (24). In 2014, long-term follow-up data from the Canadian National Breast Screening study were reported (25). Pooled results for women aged 40 to 49 years and 50 to 59 years showed no decrease in breast cancer mortality associated with screening. The cumulative breast cancer mortality was unchanged regardless of screening mammography (hazard ratio [HR] 0.99, 95% CI 0.88 to 1.12). Whether this points to flaws in trial design or is due to improvements in systemic management for newly diagnosed breast cancer are points that remain controversial.

In 2009, the United States Preventive Services Task Force reported modified recommendations for screening that include: biennial screening mammography for women aged 50 to 74 years and recommendations against routine screening mammography in women aged 40 to 49 years (26). In lieu of routine screening in younger women, the task force favored an individualized approach based on the goals and preferences of patients balanced with careful consideration of the risks and benefits of mammography in this particular population. Since then, the American Cancer Society has released guidelines as well and recommends routine screening starting at 45 years, at which point annual mammography should be conducted until age 54, after which they can transition to biennial screening (27). However, other organizations, including the American College of Radiology (ACR) (28) and the American College of Obstetrics and Gynecology (29), still recommend routine mammographic screening starting at age 40.

It is important to recognize that not all cancers will be found by mammography (30,31). For example, Esserman et al. (30) evaluated 866 patients to evaluate the impact of screening mammography and reported that 15% and 30% of women have either mammographically occult disease or will present with an interval breast cancer (i.e., cancer presenting in between mammograms), respectively. In a screening population, up to 10% of patients will be "recalled" for additional imaging, either additional mammographic views, spot compression views to determine if the area represents superimposed tissue versus a true mass or magnification views to better characterize calcifications, or US evaluation to determine the solid or cystic nature of a mass. Of all positive screening examinations, approximately 5% to 10% will have a diagnosis of cancer. Of all recommended biopsies, 25% to 40% will be positive for cancer. It is anticipated that the addition of tomosynthesis to two-dimensional conventional mammography will effectively decrease the "recall" rate and positive screening rate, and decrease the anxiety caused to patients. It is also expected to increase the sensitivity of mammography.

Mammography Regulations and Reporting

The Breast Imaging Reporting and Data System (BIRADS), first published in 1993, is a lexicon developed by the ACR to standardize terminology used in reporting findings on mammograms (32). It includes terms for describing features of masses (shapes and margins) and calcifications (morphology and distribution). It defines final assessment categories to describe the radiologist's level of suspicion about a mammographic abnormality to comply with the federally mandated Mammography Quality Standards Act (MQSA) regulations. All mammograms must be assessed, with a final BIRADS category of 0 to 6 (Table 27.2).

TABLE 27.2 BIRADS Assessment Categories

BIRADS 0	Examination is not complete. Often means additional workup is needed (e.g., spot compression, US)
BIRADS 1	No change in examination from prior; no abnormal findings appreciated

BIRADS 2	Benign finding, detected at routine screening. This includes breast cyst, fibroadenoma, fatty densities, surgical scar, scattered microcalcifications, and the presence of breast implants
BIRADS 3	Probably benign finding; typically, a 6-month follow-up will be needed. Findings included are tiny clusters of calcifications, focal asymmetric areas of nonpalpable fibroglandular densities, focal findings such as a dilated duct, generalized distribution of lesions, such as calcifications
BIRADS 4 4A 4B 4C	Suspicious or indeterminate findings identified. A biopsy should be performed. Finding associated with a low suspicion of breast cancer Finding associated with an intermediate suspicion of breast cancer Finding of moderate concern of being cancer
BIRADS 5	Very high probability of breast cancer, which requires immediate action
BIRADS 6	Imaging of a known cancer, proven by biopsy

Categorization of Breast Density
Almost entirely fatty
Few areas of fibroglandular density identified
Heterogenous density, which may obscure a small mass
Extreme density, associated with a lower sensitivity of mammography

The report must include the date of comparison films, the indication for the examination (screening, recall, clinical finding, or follow-up), an assessment of overall breast composition to indicate the relative possibility that a lesion may be hidden by normal tissue, limiting the sensitivity of the examination, a description of any significant findings, and an overall summary impression.

Diagnostic Mammography

Diagnostic mammography is reserved for women with clinical signs or symptoms that suggest breast cancer (palpable mass, skin thickening, nipple retraction, or nipple discharge); recalls for further mammographic evaluation due to abnormal screening examination; or personal history of breast cancer. Patients with breast augmentation may be considered diagnostic because of more effort and time involved with obtaining necessary views, but should be audited in the screening group.

Film versus Digital Mammography

Film mammography is extremely effective and has been widely accepted as a screening modality for the past 20 to 30 years. With this technique, the mammography images are recorded as hard copy on film and developed by the technologist, then presented to the radiologist for review. Digital mammography uses a digital detector to replace the screen-film of conventional mammography. Radiation transmitted through the breast is absorbed by an electronic detector, with a response faithful over a wide range of intensities. The recorded information can be displayed using computer image–processing techniques to allow arbitrary settings of image brightness and contrast without need for further exposure to patients. The lower system noise would be expected to enhance the visibility of subtle contrast differences between tumors and normal background tissue. The processes of image acquisition, storage, and display are separated, allowing optimization of each. The average patient dose of radiation is slightly lower than that of film mammography.

Examination time for each patient is shorter, permitting increased patient throughput. Images are more easily archived and accessed in Picture Archiving Communication Systems (PACS).

The Digital Mammographic Imaging Screening Trial reported a benefit of digital over screen-film mammography in certain groups of women (33). In this study, 49,528 asymptomatic women presenting for screening mammography at 33 sites in the United States and Canada underwent both digital and film mammography, with the examinations interpreted independently by two radiologists. While in the entire population the diagnostic accuracy of digital and film mammography was similar, the accuracy of digital mammography was significantly higher than that of film mammography in the following groups: women under the age of 50 years, women with heterogeneously dense or extremely dense breasts on mammography, and premenopausal or perimenopausal women. The results are understandable, because the technical advantages of digital mammography permit x-ray transmission manipulation to enhance visualization of subtle changes in tissue over the entire breast. It is known that the major limitation of mammography is that cancer can be hidden by adjacent breast tissue; with digital mammography, the visibility of a mass or cancer present in an image can be increased if contrast is adjusted.

The effect of transition to digital mammography from film screen was evaluated in a separate study that audited practice data from baseline year of film screen, year 1 digital, year 2 digital, and year 3 digital (34). In this practice, there was an increase in the recall rate with digital mammography (6.05 recall rate with film screen to 7.1% to 8.5% with digital technique), which persisted as a higher rate even at year 3. However, the cancer detection rate also increased for at least 2 years after the transition to digital, suggesting that cancers that may have been obscured with film screen mammography were more likely to be visible by digital technique. Overall, calcifications were significantly better seen by digital technique, an important point because calcifications often mark earlier, more treatable, disease.

Computer-Aided Detection

CAD allows for the identification of suspicious findings on mammograms to assist the radiologist's interpretation. A 2008 meta-analysis reported that CAD demonstrated no significant impact on the cancer detection rate (OR 1.04, 95% CI 0.96 to 1.13) and was associated with an increased rate of recall (OR 1.10, 95% CI 1.08 to 1.12) (35). However, the quality of the data was comprised due to significant heterogeneity in the studies included.

A prospective trial sought to evaluate the impact of double reading versus single reading plus CAD (36). There was no significant difference in the double reading regimen versus the single reading with CAD regimen for identification of masses or microcalcifications. However, more parenchymal deformities were detected in the double reading regimen, while more asymmetric densities were found by single reading plus CAD. In addition, there was a significant trend for improved cancer detection in women with dense breasts with double reading. Despite overall equivalence, double reading is costlier and more time consuming compared to single reading with the aid of CAD. As a result, CAD is likely to continue to be more widely used.

Ultrasound

Ultrasonography is a valuable adjunct to mammography, largely due to being widely available and relatively inexpensive. It is typically indicated for targeted examination, most often to determine the cystic versus solid nature of a mass, and is often used to characterize lesions as more likely to be benign or malignant. Prevalence-screening studies in women with radiographically dense breasts, especially younger women, have shown that targeted breast US may be useful. In one experience that included more than 800 women 30 years or younger presenting with a focal breast sign or symptom, targeted US had 100% sensitivity and negative predictive value (37). However, the limitations of breast US as a screening tool are well-known, as it requires a skilled operator, is labor intensive, and lacks standardized examination technique and interpretation criteria. Moreover, it does not detect microcalcifications, which can signal the earliest forms of cancer, the in situ disease.

Tomosynthesis

Tomosynthesis is a three-dimensional mammographic technique allowing better visualization of breast lesions by minimizing effects of overlapping tissue. The acquisition of images mimics conventional mammography with breast positioning and compression. Multiple low-dose images are obtained at different angles during a sweep of the x-ray tube, resulting in a digital data set which can be reconstructed into tomographic sections through the breast. Digital breast tomosynthesis was approved for clinical use in February 2011.

There are no prospective studies of tomosynthesis versus routine mammography, despite its availability. However, retrospective studies suggest it can be useful as a single test or in combination with digital mammography. For example, the largest retrospective study compared digital mammography alone (n = 281,187) or in combination with tomosynthesis (n = 173,663) (38). The addition of tomosynthesis resulted in a higher positive predictive value for recall from 4% to 6% and for biopsy from 24% to 29%. This resulted in 16/1,000 fewer recalls and 1.2/1,000 more cancers detected.

Tomosynthesis has been implemented in larger imaging centers across the United States. It is expected that within a few years there will be more data available to better determine the utility of tomosynthesis. It is unknown whether there will be additional cost or reimbursement for the procedure. The technique as of now is being reimbursed as for two-dimensional digital mammography. However, the equipment is expensive and the reading time for the radiologist is increased, with multiple more images to be interpreted. As more breast imagers become adept at the technology, a clearer sense of the increased reading time will be available.

Given its ability to minimize the effects of overlapping tissue, tomosynthesis is expected to be more beneficial in women with dense breasts, and may not yield more information in women with fatty breast tissue, in whom lesions are less likely to be obscured by overlapping tissue. However, more large scale trials will need to be performed to evaluate who will best benefit from the examination.

Breast MRI

MRI of the breast has evolved over the past 2.5 decades from a research tool to the most sensitive imaging modality in the detection of breast cancer, particularly for women deemed at high risk for breast cancer. Contrast-enhanced breast MRI is the most accurate modality in the clinical evaluation and staging of breast cancer. For breast lesion detection, intravenous injection of gadolinium-based contrast enhancement allows visualization of breast cancer against the background of glandular tissue. This distinction relies on the determination that tumor angiogenesis and surrounding tissue permeability allow contrast uptake within cancer. That is, a significant number of invasive tumors demonstrate rapid wash-in of contrast by 2 minutes and washout with time. Significant overlap between the enhancement pattern of benign and malignant processes exists, which must be recognized, and which lowers the specificity of breast MRI.

Technical standards for breast MRI are set by the ACR for proper imaging, interpretation, and accreditation (39). MRI of the breast should be performed with a dedicated breast coil, using at least a 1.5 Tesla magnet, and imaging parameters should be instituted to optimize high spatial and temporal resolution. MRI with a 3 Tesla magnet is evolving and slowly spreading; however, its advantage over the more commonly used 1.5 Tesla magnets is not known yet.

Ample data support the superiority of MRI over all other breast screening modalities, including mammography, US, and scintigraphy. MR sensitivity for the detection of invasive breast cancer ranges between 71% and 100%, though specificity is low at approximately 65%, likely due to overlap in the enhancement patterns between benign and malignant lesions (40,41). In general, the estimated negative predictive value of MRI is high, ranging between 90% and 95%. Although previous studies in DCIS showed low and variable sensitivities, with improved techniques, contemporary studies suggest it is more accurate than even mammography. For example, in one study of 79 women with pathologically proven DCIS, the detection rate for mammogram and MRI was 91% and 85%, respectively. However, when compared by the size of disease, MRI was significantly more accurate, especially in women under 50 years (42).

Breast MR reporting is standardized based on the ACR BIRADS MR lexicon, which incorporates terminology and

specific descriptors of breast MRI findings, in addition to assigning a final BIRADS category in the assessment, similar to mammography. The fifth edition of BIRADS introduced some changes to the prior MR BIRADS lexicon. By definition, an enhancing focus is less than 5 mm, and any space-occupying lesion 5 mm or larger constitutes a mass. Masses are evaluated based on shape, margin characteristics, internal enhancement, and kinetic analysis. To mention some descriptors of malignancy, an irregular mass, spiculated margins, heterogeneous/rim enhancement, and rapid wash-in and washout kinetics are characteristic of malignancy. Nonmass enhancement (NME) can be focal, linear, segmental, regional, or diffuse. The typical MR appearance of DCIS is NME in a linear or segmental distribution. As such, analysis of breast MR–enhancing lesions involves analyzing both lesion morphology and kinetics of enhancement to provide the most specificity in lesion characterization.

Screening Breast MRI

For women at high risk for breast cancer, breast MRI is a validated screening modality in addition to mammography. Studies have demonstrated that MRI is much more sensitive than even mammography or US in these patients. As an example, Kuhl et al. (43) conducted a surveillance study that included more than 500 women at high risk for breast cancer, defined by family history and/or genetic mutational analysis. With a median follow-up of 5.3 years, MRI was found to be far more sensitive than either mammogram or US (91% vs. 33% and 40%, respectively). Among women deemed at "higher" risk, the sensitivity favored MRI over mammogram (100% vs. 25%), although specificity was equivalent (96% to 97%). Additional work showed that MRI can detect a tumor in approximately 4% of high-risk women with mammographically occult breast cancer (44). In another study of high-risk women screened with all three modalities, 33% of cancers were visible by MR only, compared to 11% by mammography only, and 3% by US only (45). These data were validated by two recent review studies that evaluated more than 4,000 women and found that breast MR sensitivity alone ranges from 71% to 100%, mammography from 25% to 50%, mammography with US from 48% to 67%, all modalities together from 80% to 100%, and MR specificity from 93% to 98% (46,47).

In 2007, the American Cancer Society published new guidelines for high-risk screening with MRI based on scientific evidence and expert opinion (Table 27.3) (48). According to these new guidelines, high risk is defined as a lifetime risk of 20% to 25% or greater, being a, BRCA gene mutation carrier or first-degree relative of a BRCA carrier, women treated at an early age with chest radiation, and hereditary syndromes that place women at high risk for breast cancer. Currently, there are not enough data to support for or against annual breast MRI in women with a personal history of breast cancer or with high-risk lesions, and these patients are to be assessed on a case-to-case basis.

TABLE 27.3 Criteria for Use of an Annual MRI as an Adjunct to Mammography as a Screening Test for Breast Cancer

Known BRCA mutation
First-degree relative of a known BRCA mutation carrier (but otherwise not tested)
Personal risk of breast cancer exceeds 20% (using risk prediction models)
Prior radiation to the chest before the age of 30
Known familial genetic syndrome with an increased risk of breast cancer (e.g., Li-Fraumeni)

Breast MRI also serves to screen the contralateral breast in women with recently diagnosed breast cancer. A recent multicenter prospective trial evaluating contralateral breast cancer in women with recently proven breast cancer found clinically and mammographically occult breast cancer in 3.1% of 969 women, with a sensitivity of 91% and a negative predictive value of 99% (49).

Preoperative Evaluation of Breast Cancer

There are several clinical scenarios in which breast MRI is useful in addition to mammography, with the most common

indication being preoperative staging of a newly diagnosed invasive cancer or DCIS. Breast MRI can delineate clinically and mammographically occult additional disease, including in situ disease associated with invasive cancer, and can detect noncalcified DCIS. In that regard, MRI is superior to mammography or US in defining local extent of the disease and can identify additional sites of disease. As an example, Liberman et al. (50) found that 48% of women who underwent preoperative MRI of the breast had additional foci of disease unsuspected by mammography. In a separate study by Girardi et al. (51), additional mammographically occult cancer was detected in 9% of patients staged with MRI preoperatively. As such, the addition of breast MRI can aid in surgical planning, including decisions regarding the role of mastectomy or the consideration for neoadjuvant chemotherapy (NACT).

However, the use of preoperative breast MRI is not without controversy. Braun et al. (52) evaluated the influence of preoperative MRI on surgical management in a retrospective study that included 160 patients with operable breast cancer and reported that it changed the clinical management in 27.5% of patients. This included findings of more widespread disease than otherwise suspected in 19% of cases. However, they also noted that 14 cases (9%) required additional surgical procedures for what was ultimately found to be benign pathology. Further fueling the controversy are the results of the comparative effectiveness of MRI in breast cancer (COMICE) trial, which included more than 1,600 patients randomly assigned to a preoperative MRI or not (53). This trial showed that MRI did not decrease surgical negative margins and was associated with a higher rate of mastectomy. However, more recent data suggest a more positive role of preoperative MRI, whereby Obdeijin et al. (54) and Sung et al. (55) found significantly lower reexcision rates of 18.9% and 29%, respectively, in patients staged with preoperative MRI as opposed to reexcision rates of 37.4% and 45% with no MRI. Another study by Fortune–Greeley et al. (56) in 2014 demonstrated that there is a 40% reduction in the rate of reexcision of invasive lobular cancer with MR, without increasing the mastectomy rate. The effect of MRI staging on patient mortality outcome is still unknown. On the basis of these findings, we support a thoughtful approach to the role of preoperative MRI and feel it is a reasonable test for women with dense breasts, especially if they have a histologic diagnosis of invasive lobular cancer.

Breast MRI: Other Roles

Recurrence following breast conservation therapy is better detected by MRI than mammography or US, with high specificity and negative predictive value (57). In addition, MRI has a role in determining the response to NACT, and it is more reliable than mammography or US in that respect. However, while MRI may not show residual enhancement following chemotherapy, it is not 100% accurate in the detection of residual disease. In at least one report, MRI was associated with a 23% risk of underestimation (58). For women presenting with suspicious clinical findings for breast cancer and negative conventional imaging tests, MRI of the breast has an added value. These instances include a woman with a palpable suspicious mass, women with metastatic axillary lymph nodes but no mammographically defined breast primary cancer, and those with pathologic unilateral nipple discharge or Paget disease and a negative mammogram and US. MRI use to workup mammographic calcifications or other mammographic abnormality is discouraged, and suspicious findings should undergo core biopsy. A helpful role of MRI in such clinical scenarios would be to delineate the extent of disease and to rule out an underlying occult invasive component.

BREAST PATHOLOGY

Fibrocystic Changes

The breast ducts and lobules can show a wide range of benign nonproliferative and proliferative epithelial lesions. Nonproliferative lesions include cysts (macroscopic and microscopic), duct ectasia, fibrosis, and apocrine metaplasia.

Proliferative lesions were first separated into different risk categories based on the work of Dupont and Page (59). Compared to normal breast (Figs. 27.1 and 27.2), patterns associated with a mildly increased risk (~two-fold) of subsequent breast carcinoma are considered proliferative changes, and include usual ductal epithelial hyperplasia (Fig. 27.3), lobular hyperplasia, sclerosing adenosis, radial scars, and intraductal papillomas (60). Both sclerosing adenosis and radial scars (Figs. 27.4 **and** 27.5) show distortion of normal breast architecture, and this irregular gland pattern may mimic an invasive carcinoma. These benign proliferations maintain a normal myoepithelial cell layer, which can be highlighted by immunohistochemical (IHC) stains. Intraductal papillomas have fibrovascular cores lined by myoepithelial cells and one or more layers of epithelial cells (Fig. 27.6). Papillomas involving large ducts near the nipple may cause a bloody nipple discharge.

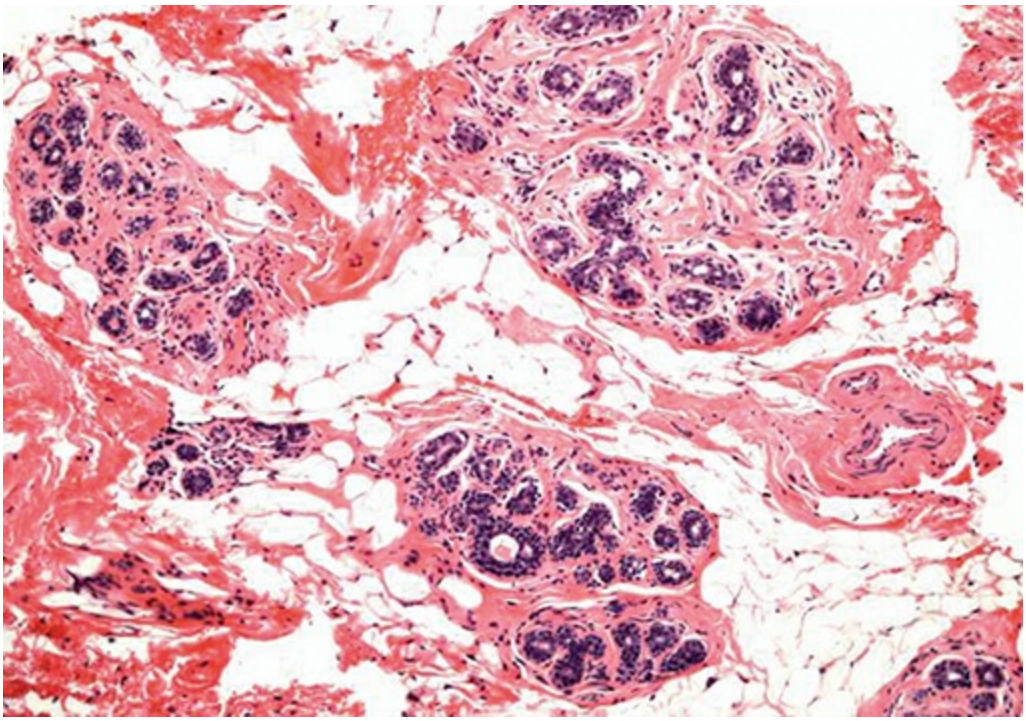

Figure 27.1 Normal breast lobules. Three TDLUs are surrounded by adipose and fibrous tissue.

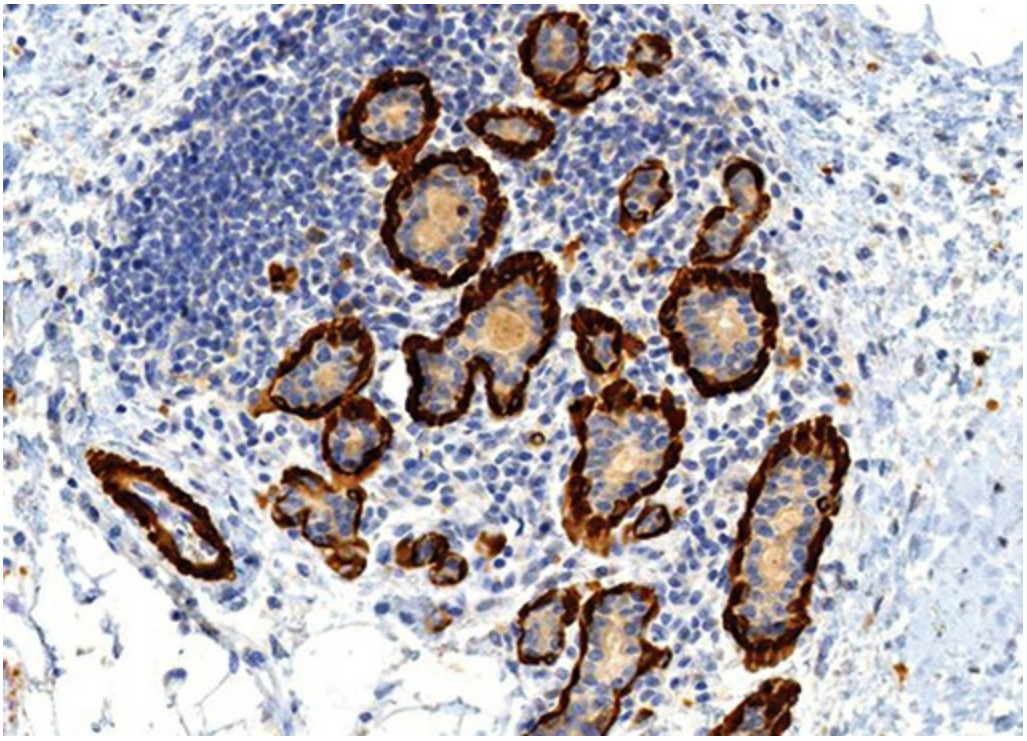

Figure 27.2 Normal breast lobule. Presence of myoepithelial cells is illustrated by positive staining for smooth muscle myosin heavy chain.

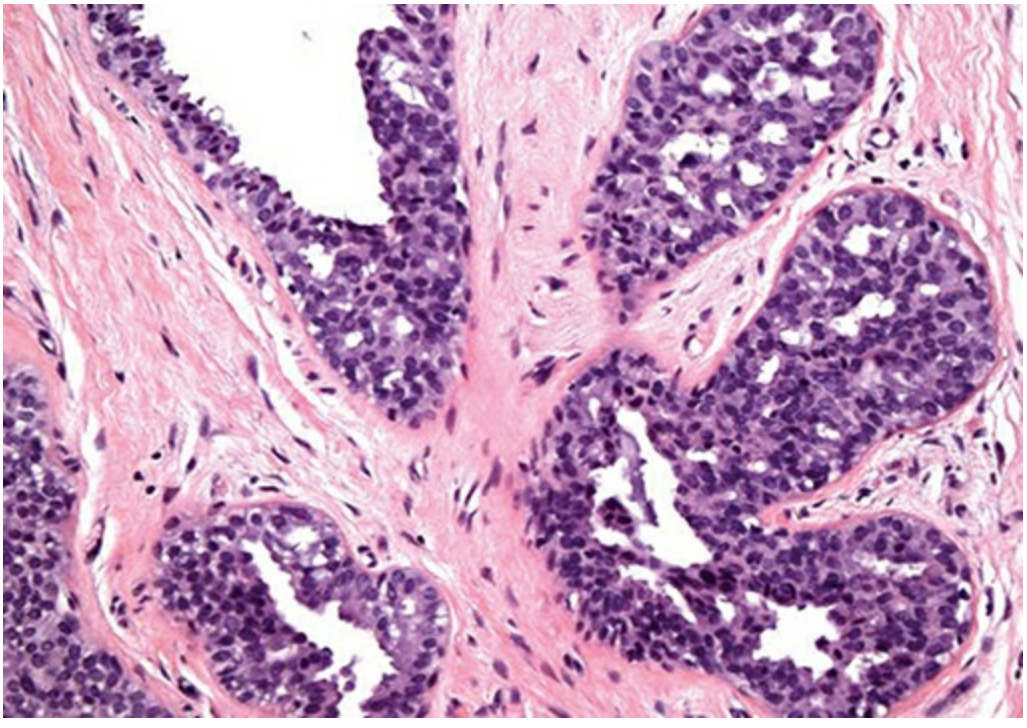

Figure 27.3 Usual ductal hyperplasia. Slightly expanded ducts are filled with hyperplastic ductal epithelial cells and myoepithelial cells in an irregular fenestrated growth pattern.

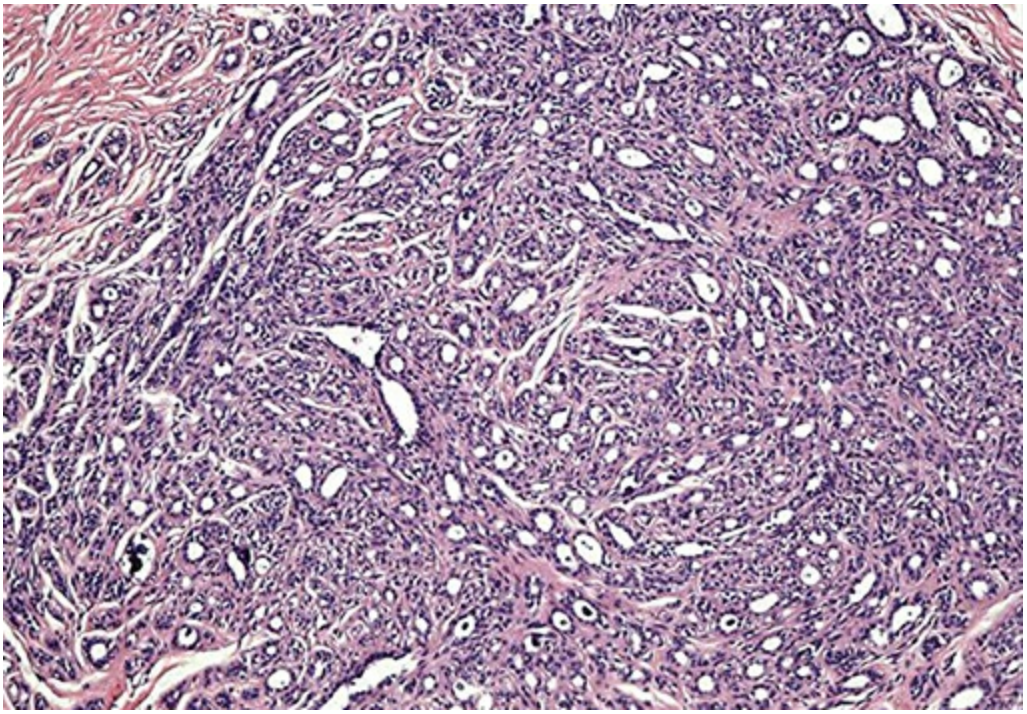

Figure 27.4 Sclerosing adenosis. A well-developed lobulocentric distribution of dilated ducts and overgrowth of spindly myoepithelial cells may be mistaken as malignancy in core biopsy or frozen section.

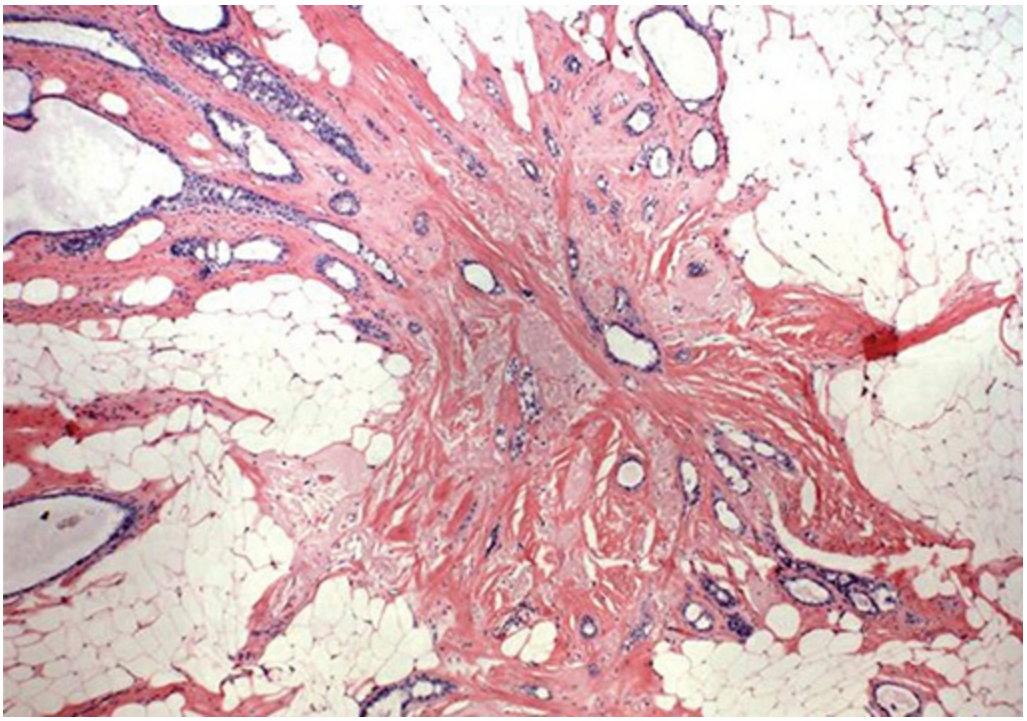

Figure 27.5 Radial scar. A stellate lesion with irregular ducts radiating from the elastotic center, the entrapped glands may mimic an invasive ductal carcinoma.

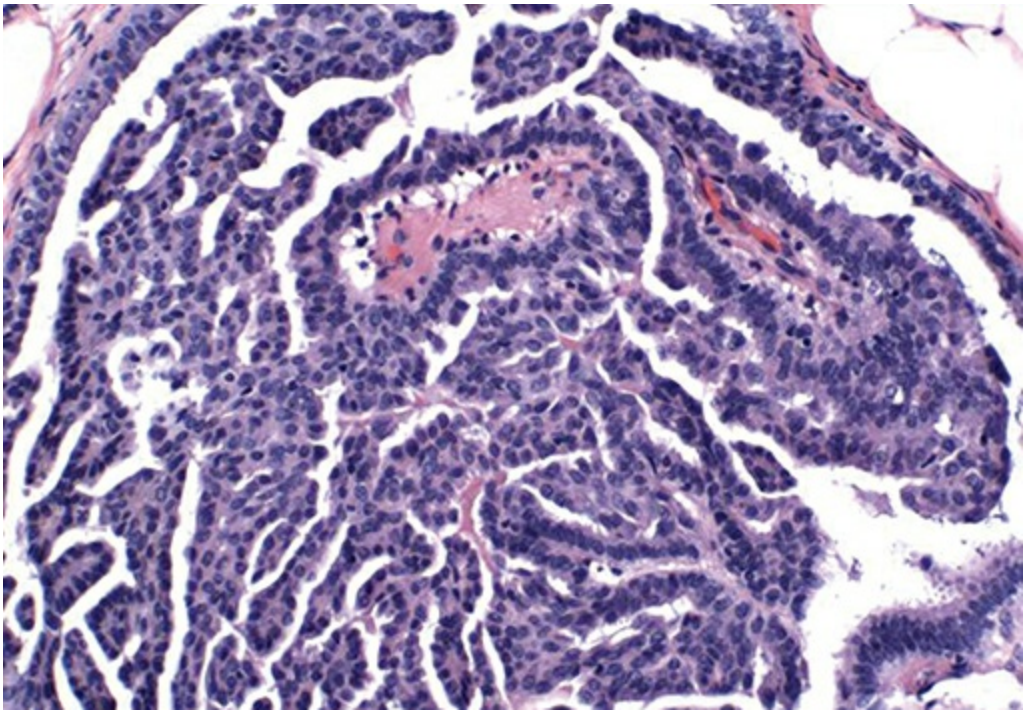

Figure 27.6 Intraductal papilloma. A well-circumscribed papillary proliferation fills a dilated duct. The presence of fibrovascular core of the papillae indicates benignity.

Atypical ductal hyperplasia (ADH) and atypical lobular hyperplasia (ALH) are associated with an approximately fivefold higher increased risk of subsequent breast cancer (60). ADH is characterized by architectural patterns approaching that of in situ carcinoma, while ALH shows expansion of the lobule by a loose, monomorphic cell population (Figs. 27.7 **and** 27.8). Reproducibility of the diagnosis of ADH is still problematic, but more uniform criteria are now used by most pathologists (61). There is still controversy as to whether size criteria should be used to separate ADH from low-grade DCIS (two completely involved ducts or 2 mm). ADH can also involve a radial scar or intraductal papilloma.

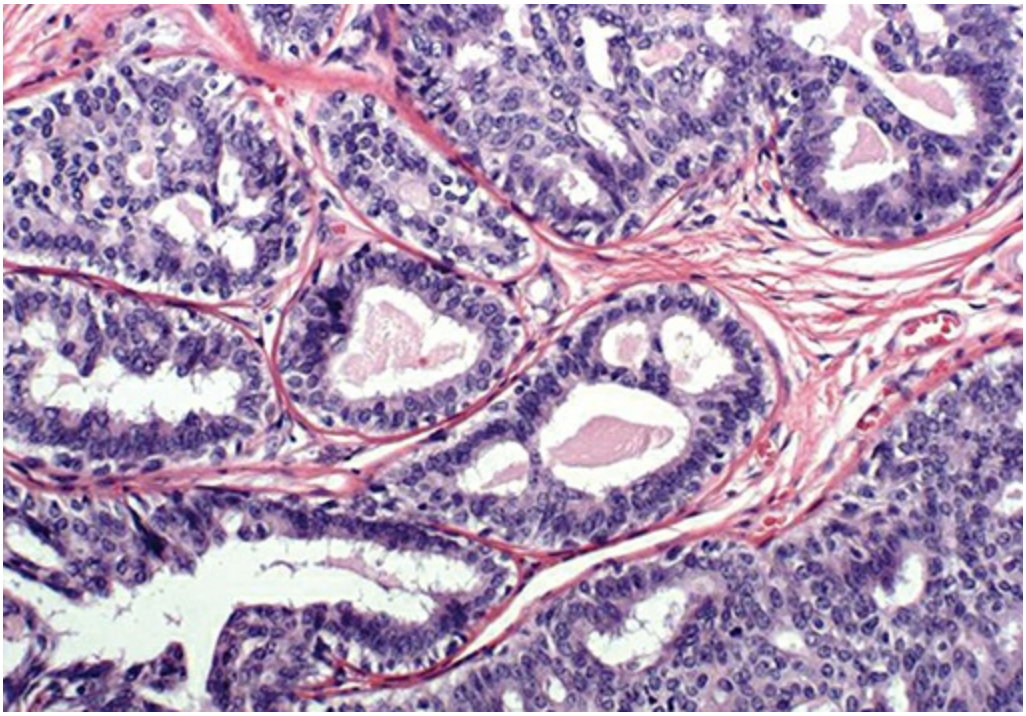

Figure 27.7 ADH. The proliferation has a cribriform growth pattern approaching that of

a DCIS, but the microlumens are more irregular in sizes and shapes.

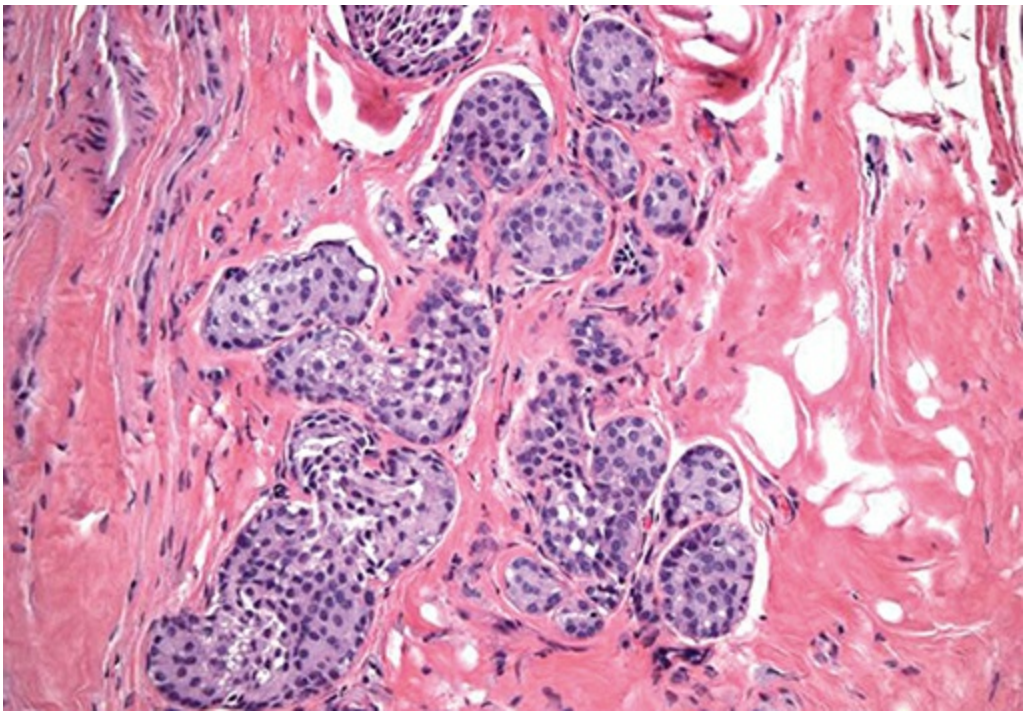

Figure 27.8 ALH. The lobular glands are somewhat expanded with a loose monomorphic cell population.

A newly appreciated group of lesions are columnar cell change, columnar cell hyperplasia, and flat epithelial atypia (Figs. 27.9 **and** 27.10). These lesions were originally described by Azzopardi (62), and their significance has been reappraised due to their frequent association with mammographically detected microcalcifications (63). More recently, it has been noted that flat epithelial atypia (Fig. 27.11) has a high association with low-grade DCIS (64) and invasive tubular carcinoma (65). Molecular studies may be able to further characterize these lesions and their role in breast carcinogenesis.

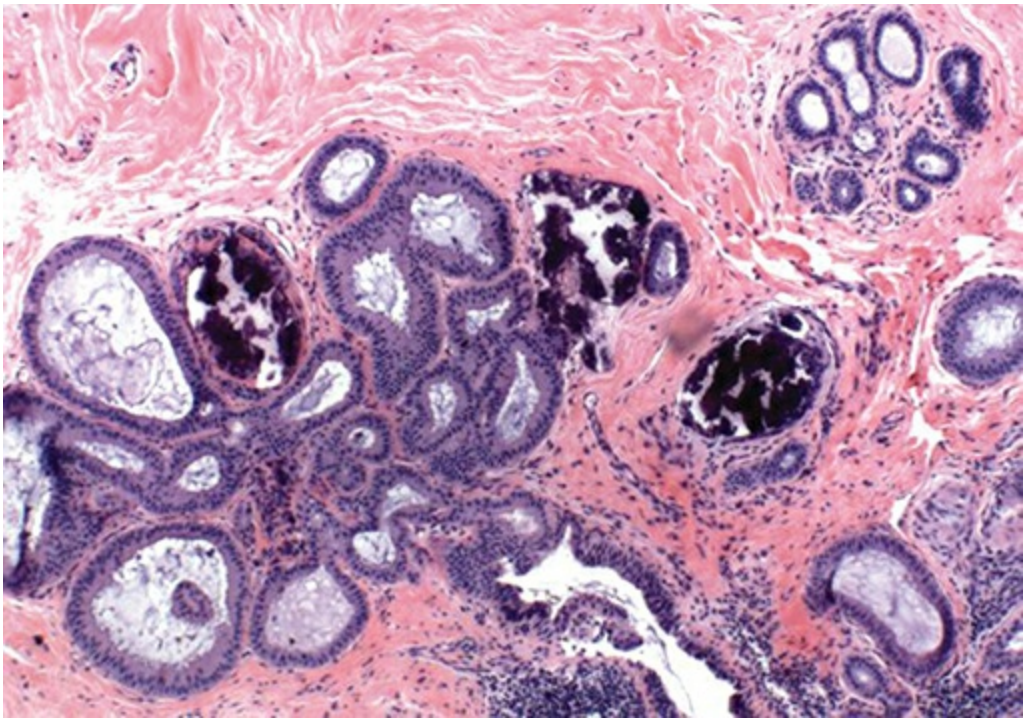

Figure 27.9 Columnar cell change. Variably dilated acini with microcystic change lined by columnar cells, frequently associated with luminal secretions and/or microcalcifications.

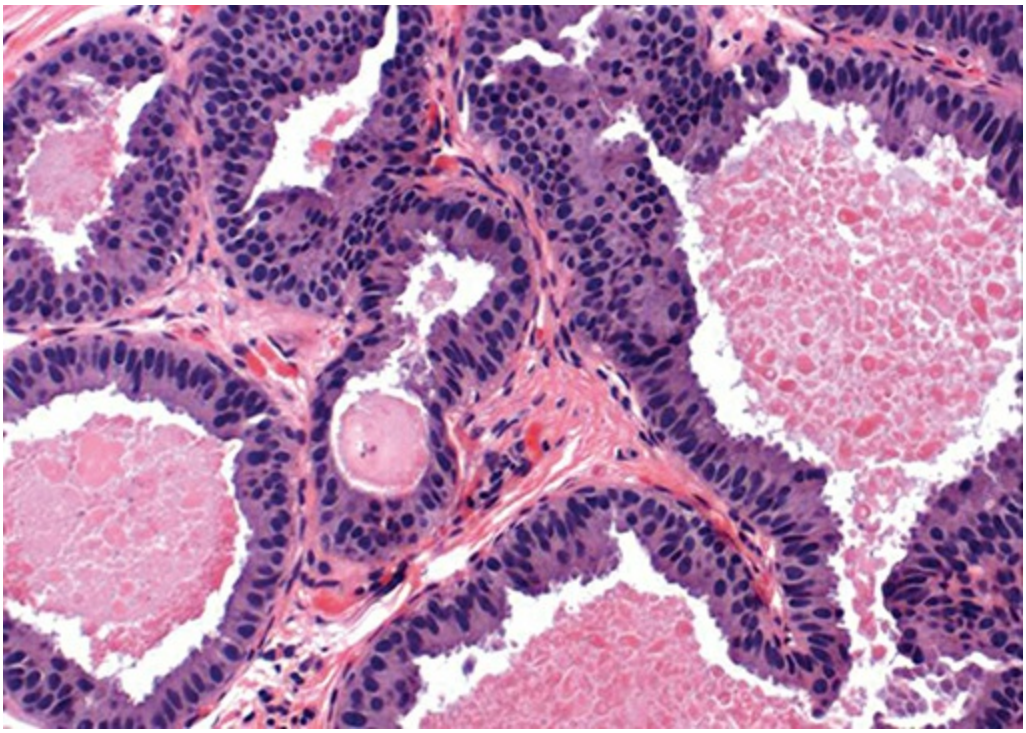

Figure 27.10 Columnar cell hyperplasia. Columnar cell change with piling up of several layers or stratification associated with luminal secretions.

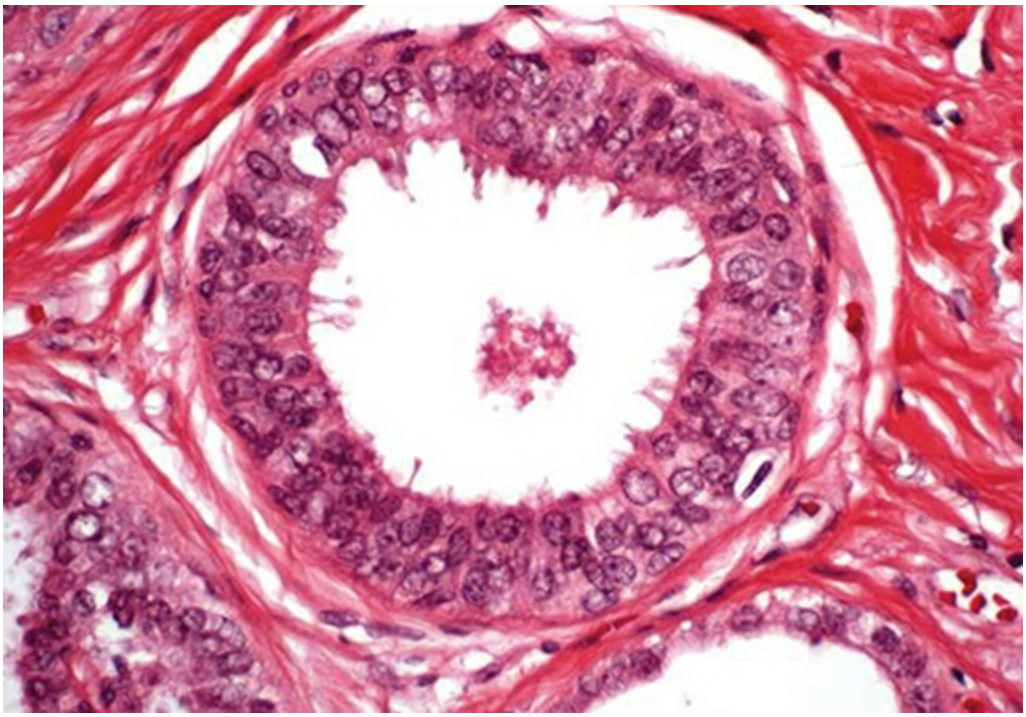

Figure 27.11 Flat epithelial hyperplasia. This is a columnar lesion characterized by mildly atypical epithelial cells, which may represent a precursor of or the earliest morphologically recognizable form of low-grade DCIS.

Ductal Carcinoma In Situ

DCIS or intraductal carcinoma is a heterogenous group of lesions with the proliferation of malignant cells confined within the ductal system. Traditionally, DCIS was classified on the basis of its architectural pattern, often dichotomized as comedo and noncomedo types. Noncomedo patterns include solid, cribriform, micropapillary, clinging, and papillary types. Combinations of these patterns are not uncommon in a biopsy. Several grading schemes incorporating both architectural and nuclear features have been proposed, but the Holland version, in which nuclear features predominate, was most reproducible in one study (66). The presence of intraluminal necrosis and calcifications is usually noted, along with the nuclear grade and pattern(s).

Comedo-type DCIS (comedocarcinoma) shows a solid proliferation of large, pleomorphic nuclear grade 3 epithelial cells with numerous mitoses and central necrosis containing cellular debris, so-called “comedo-necrosis” (Fig. 27.12). The necrotic material often becomes calcified, and these coarse calcifications have a distinctive mammographic appearance outlining the ductal system (“casting calcifications”). Periductal fibrosis and inflammation is common in comedo-type DCIS and can be a diagnostic problem, as microinvasion is a feature more frequently associated with comedo-type DCIS than other patterns (67). Extension of the large pleomorphic cells into the distal lobular unit is a pattern known as “cancerization of lobules.”

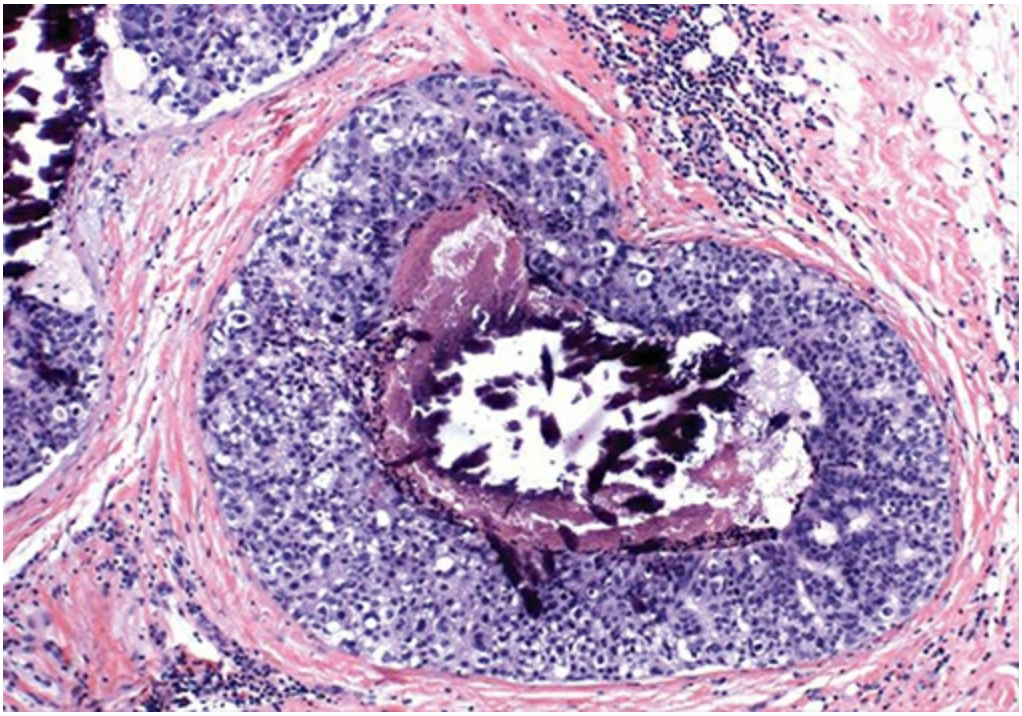

Figure 27.12 Comedo-type DCIS. Markedly expanded ducts are filled with high-grade neoplastic ductal cells with central necrosis and calcifications.

The solid, cribriform, papillary, and micropapillary patterns of noncomedo DCIS are usually composed of uniform low-grade or intermediate-grade nuclei. Cribriform patterns show smooth, rounded, “punched-out” spaces (Fig. 27.13). The micropapillary subtype does not contain fibrovascular cores, whereas papillary DCIS does (Fig. 27.14). The “clinging” or “flat” type of DCIS may have either low- or high-grade nuclei. Microcalcifications may be associated with these noncomedo patterns and may be detected by mammography. Their pattern of distribution is less specific than that of the comedo DCIS and may be similar to that seen in benign conditions. Lesion size is often problematic by pathologic evaluation, as most DCIS is not grossly evident. It is not practical to submit all tissue from an excisional biopsy for microscopic evaluation, so sectioning is guided by the type of lesion and radiographic findings. Mammography can often give a more accurate size of the lesion, but only in tumors that are entirely marked by calcifications. Margin width is most

easily measured microscopically in perpendicular sections, which requires the presence of colored inks for unique identification of each margin.

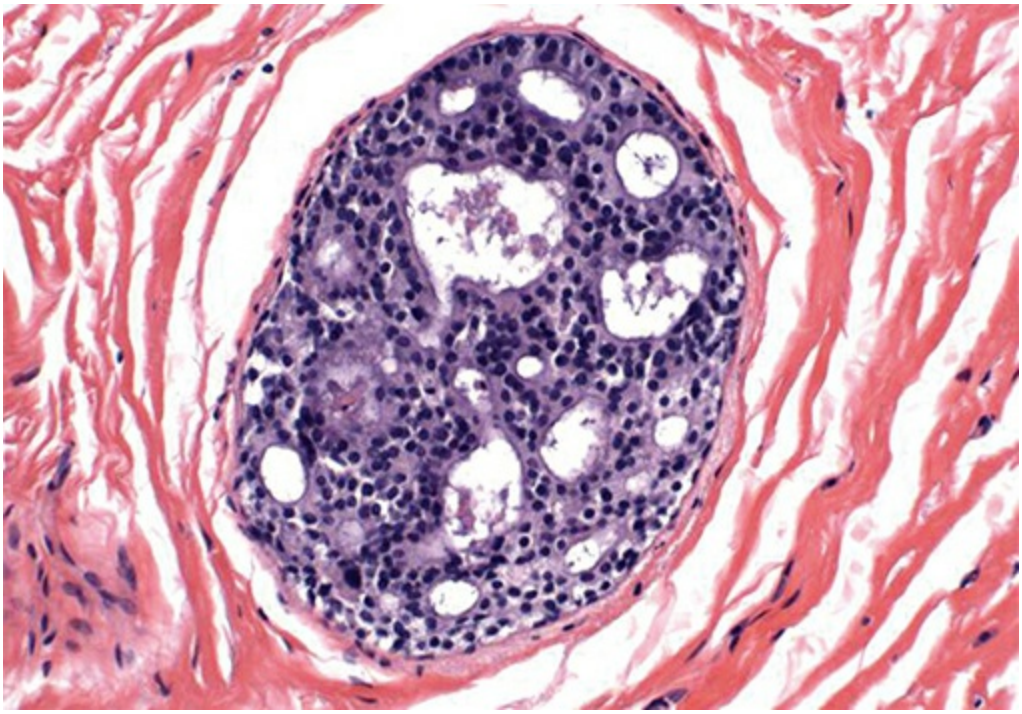

Figure 27.13 Cribriform DCIS. Expanded duct is filled with low-to-intermediate-grade neoplastic cells forming secondary rigid cribriform microlumens resembling “punched out” spaces.

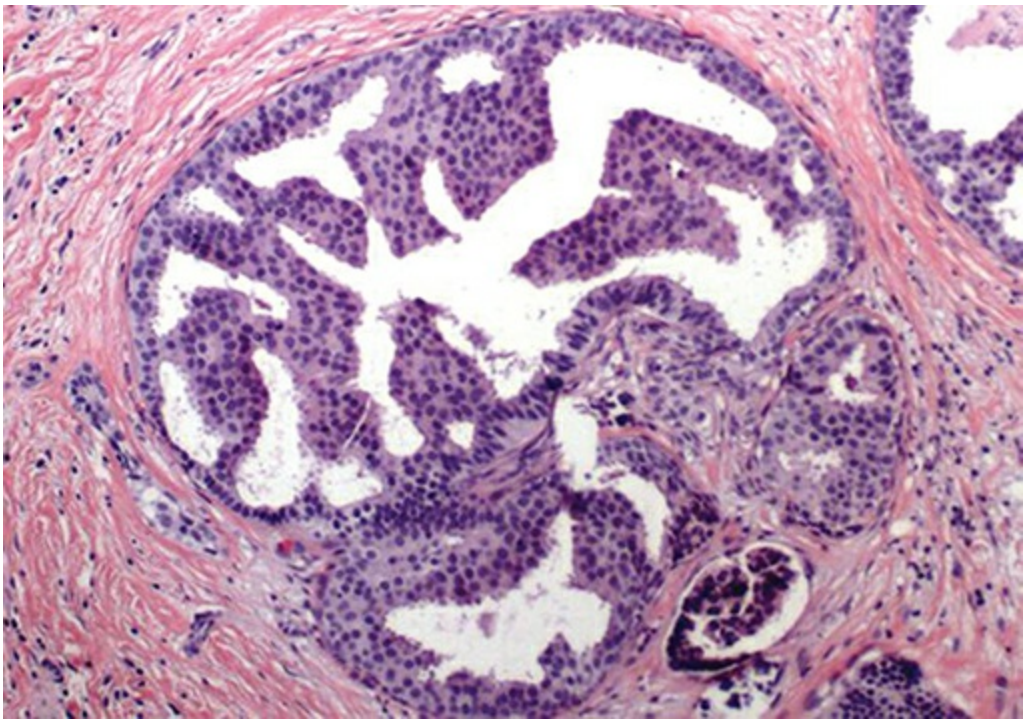

Figure 27.14 Micropapillary DCIS. Low-grade neoplastic ductal cells form papillary fronds in an expanded duct. The papillary fronds lack fibrovascular core.

Paget Disease of the Nipple

Paget disease of the nipple reflects direct extension of DCIS, usually high grade, into the lactiferous ducts and adjacent skin. Clinically, the nipple appears excoriated. The DCIS may or may not be accompanied by invasive carcinoma. Histologically, the Paget cells are large round cells with prominent nucleoli and pale cytoplasm. They occur singly within the layers of the epidermis, or may form groups at the dermal–epidermal junction, mimicking malignant melanoma (Fig. 27.15). Lesional cells of Paget disease are positive for carcinoembryonic antigen (CEA) or cytokeratin 7 (CK7) and negative for Melan-A and HMB-45 (Fig. 27.16).

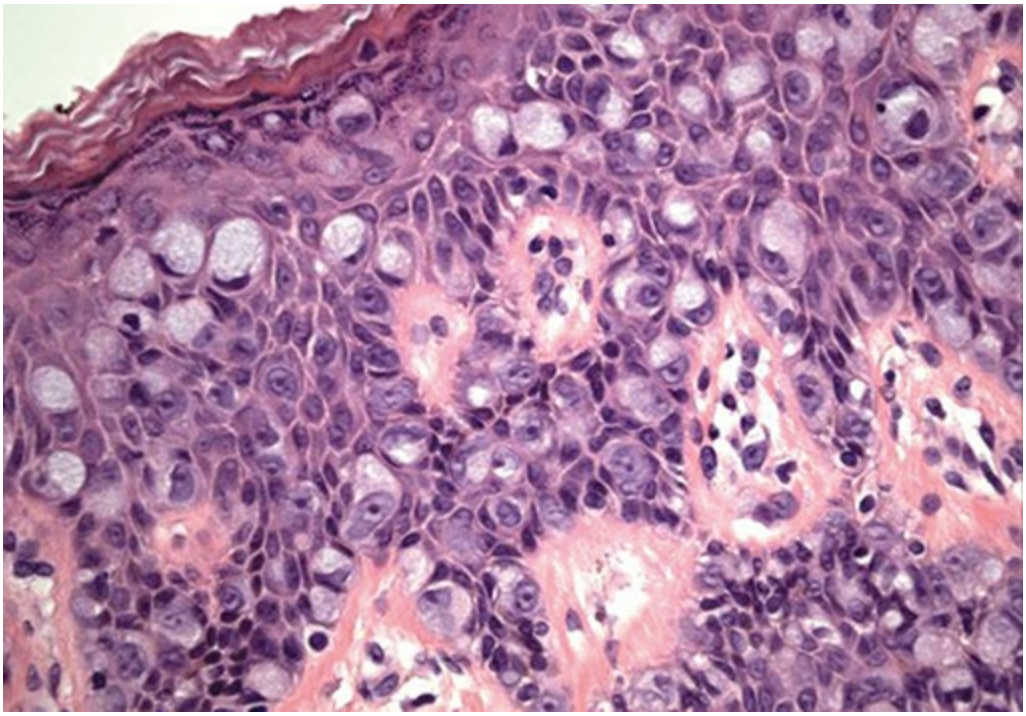

Figure 27.15 Paget disease. Large, round, pale neoplastic cells occur singly within the epidermis, mimicking malignant melanoma.

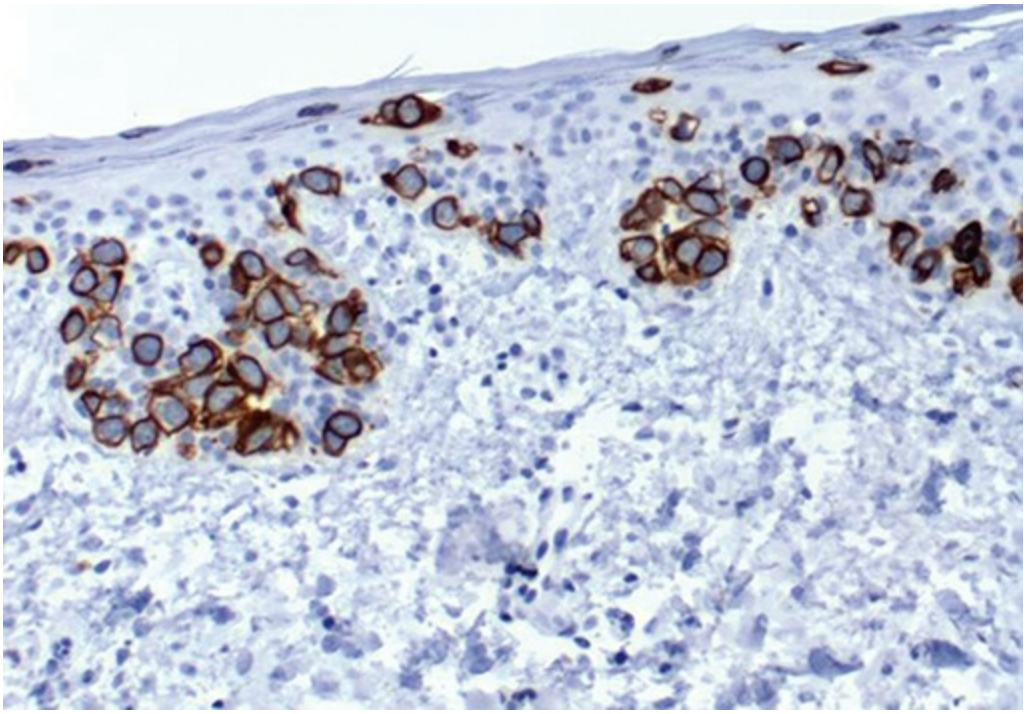

Figure 27.16 Paget disease. Paget disease cells are positive for CEA or CK7 and

negative for Melan-A and HMB-45, which are positive in malignancy melanoma.

Lobular Carcinoma In Situ

Lobular carcinoma in situ (LCIS) was first described by Foote and Stewart in 1941 and has been an enigma ever since. It is a multicentric lesion, with no identifying features on gross or radiographic evaluation, and is often found as an incidental finding in biopsies performed for another reason. Histologically, in classic LCIS, the lobule is distended by a monomorphic population of small uniform cells with round nuclei and scant cytoplasm (Fig. 27.17). The cells may extend into the adjacent duct, growing beneath the normal ductal epithelium, a pattern known as “pagetoid spread.” There is continuing controversy as to whether LCIS is an obligate precursor of invasive lobular carcinoma or just a marker of overall increased cancer risk in either breast. Certainly, LCIS is often found adjacent to invasive lobular carcinoma. The term “lobular neoplasia” is often used to encompass both LCIS and ALH, which have identical cytologic features, but minor differences in architecture.

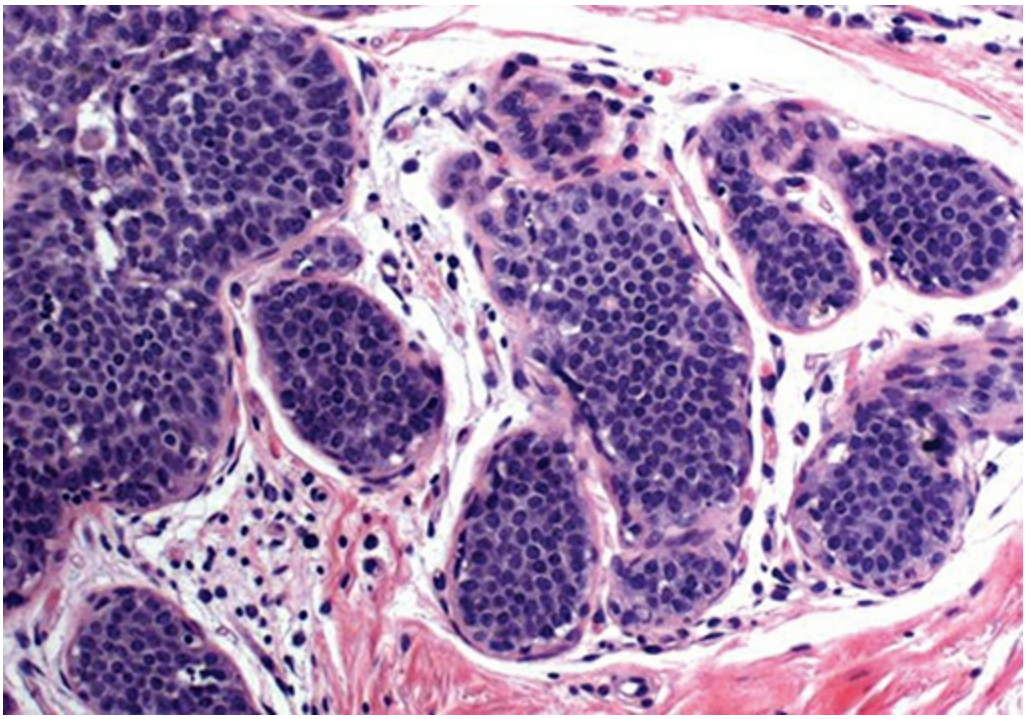

Figure 27.17 LCIS. An expanded lobule is markedly distended by a monomorphic population of small uniform cells. The underlying lobular architecture is still recognizable.

Pleomorphic LCIS

This pattern of in situ disease involves larger ducts and mimics the solid pattern of DCIS (68). The cells are evenly spaced, slightly dyscohesive, and may have visible intracytoplasmic lumina (Fig. 27.18). Immunohistochemistry for E-cadherin demonstrates loss of this membrane protein (Fig. 27.19). Treatment should be similar to DCIS, as this pattern of LCIS is considered a precursor lesion of invasive carcinoma rather than just a risk factor for subsequent disease (69).

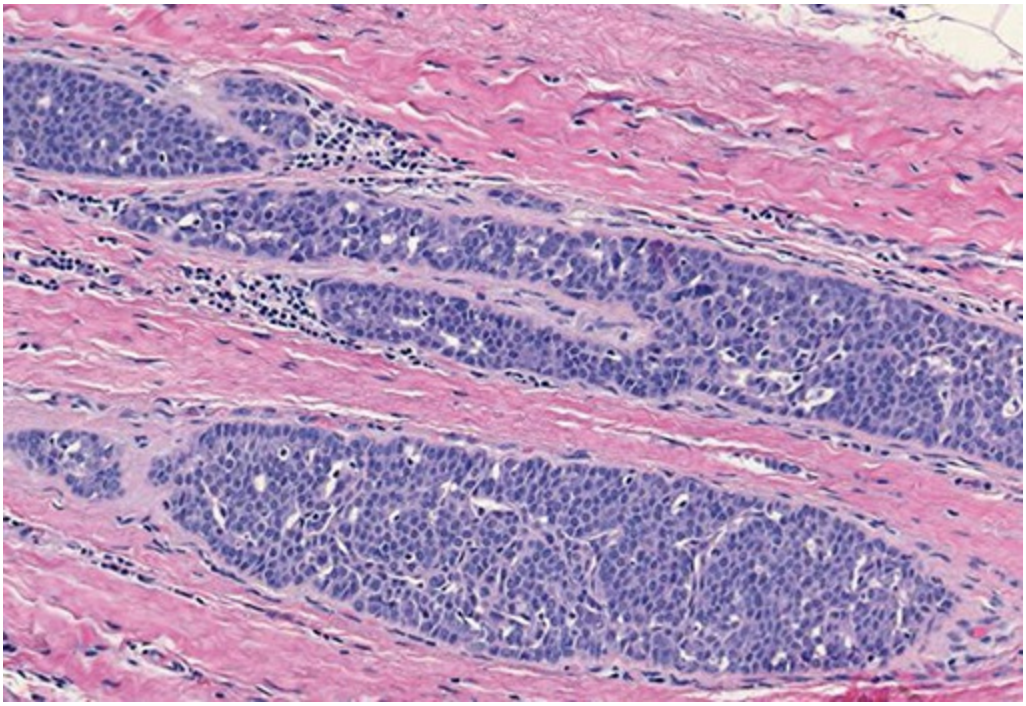

Figure 27.18 Pleomorphic LCIS. This pattern of LCIS involves larger ducts with evenly spaced and slightly dyscohesive tumor cells, mimicking solid pattern of DCIS.

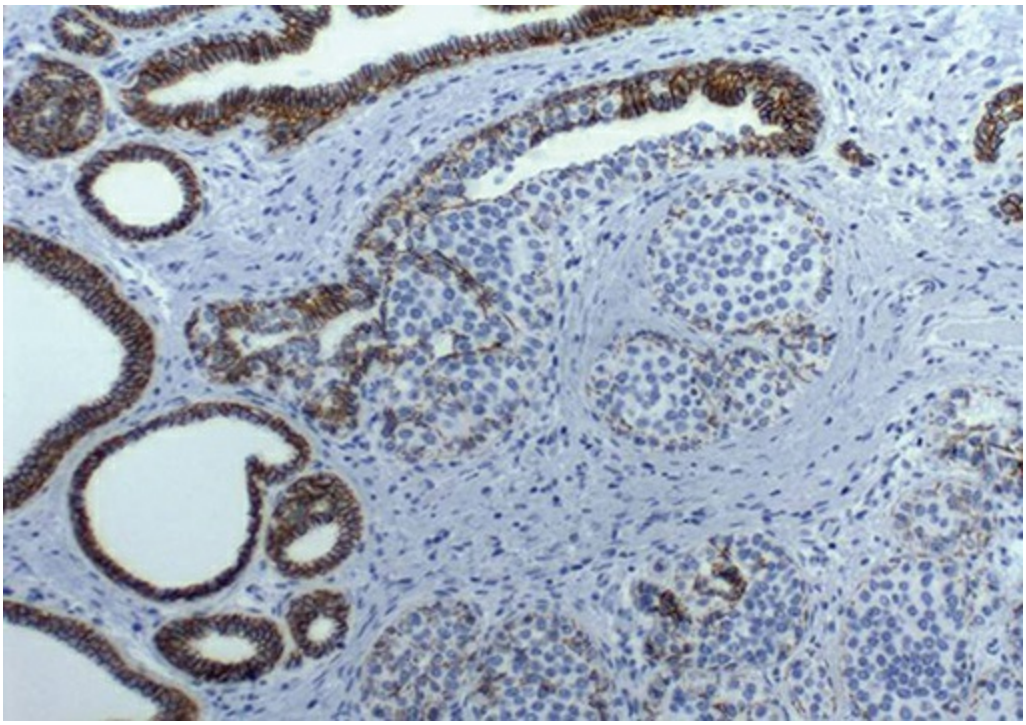

Figure 27.19 LCIS. Loss of membranous e-Cadherin staining of LCIS in contrast with adjacent normal ducts with positive staining.

Invasive Carcinoma

Invasive carcinoma of the breast is defined by the presence of stromal invasion, usually manifest by a fibrotic, desmoplastic stromal reaction around the invading cells. Tumor may be microinvasive (<1 mm) within an area of DCIS or may form an obvious tumor mass, clinically or radiographically. Tumors are classified by the pattern of growth into ductal

and lobular forms. Breast carcinoma is surgically staged using the AJCC staging system based on the size of the invasive component. Synoptic checklist reporting using templates devised by the College of American Pathologists (CAP) aids in ensuring that all important pathologic features are documented. DCIS may be focally present adjacent to the invasive component or intermixed with invasive tumor. The term “EIC” denotes a tumor with an extensive in situ component, defined as at least 25% of the tumor mass.

Invasive Ductal Carcinoma

The majority of invasive tumors of the breast are ductal and have varying morphologic patterns that have led to several subclassifications. Most of the special types listed below are distinguished because they have an extremely good prognosis. The majority of tumors (～75%) have no specific features and are designated carcinoma not otherwise specified or carcinoma of no special type. These tumors may be composed of small glands, tubules, solid cords, or nests of cells with varying degrees of cytologic atypia surrounded by a reactive (desmoplastic) fibrous stroma (Fig. 27.20). The recommended grading system is the Nottingham modification, which is based on adding scores for architectural pattern, nuclear pleomorphism, and mitotic count (Table 27.4) (70). Grade 1 tumors (well differentiated) have 3 to 5 points, Grade 2 tumors (moderately differentiated) have 6 to 7 points, and Grade 3 tumors (poorly differentiated) have 8 to 9 points. While initially applied only to invasive ductal carcinoma, this system can also be applied to invasive lobular carcinomas and has been validated in numerous studies (71).

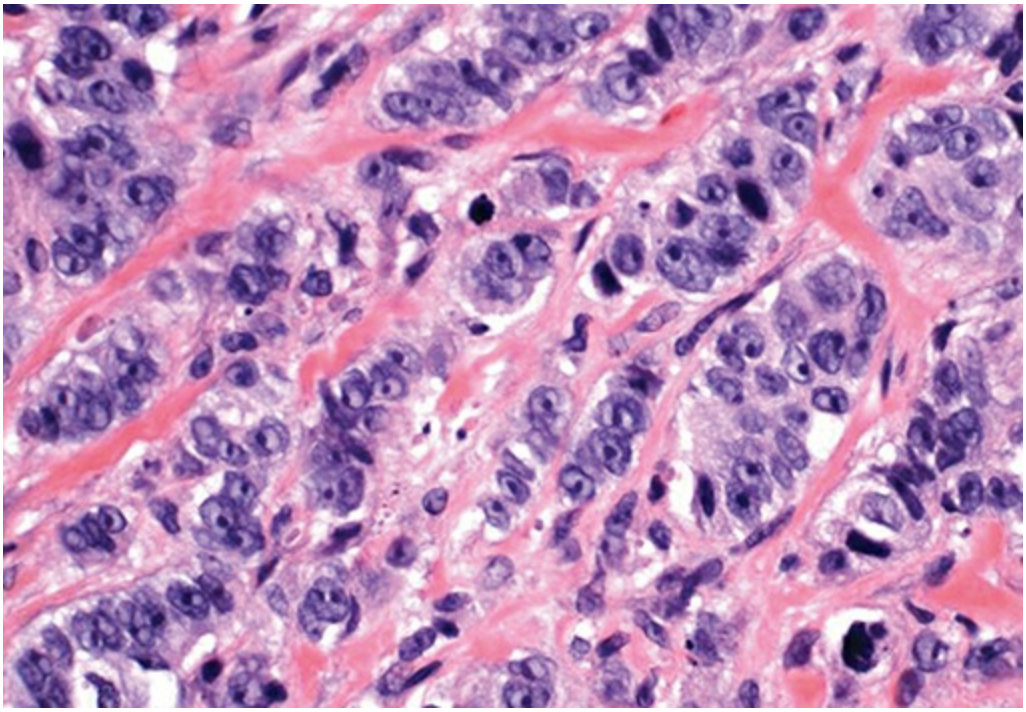

Figure 27.20 Invasive ductal carcinoma. Small solid cords of neoplastic cells with moderate-to-severe cytologic atypia are surrounded by a fibrous stroma.

TABLE 27.4 Modified Nottingham Histologic Scoring System for Invasive Breast Tumor Grade

Glandular (acinar)/tubular differentiation	
1 point	>75% of tumor area forming glandular/tubular structures
2	10% to 75% of tumor area forming glandular/tubular structures

points	
3 points	<10% of tumor area forming glandular/tubular structures
Nuclear pleomorphism	
1 point	Nuclei are small with little increase in size compared to normal breast epithelial cells, regular outlines, uniform nuclear chromatin, and little variation in size
2 points	Cells are larger than normal with open vesicular nuclei, visible nucleoli, and moderate variability in both size and shape
3 points	Cells have vesicular nuclei, often with prominent nucleoli, exhibiting marked variation in size and shape, occasionally with very large and bizarre forms
Mitotic count	
1 point	≤7 mitoses per 10 high-power fields
2 points	8–14 mitoses per 10 high-power fields
3 points	≥15 mitoses per 10 high-power fields

Overall grade: Grade 1: 3 to 5 points; Grade 2: 6 to 7 points; Grade 3: 8 to 9points.

Special Types

Mucinous Carcinoma

Mucinous (or colloid) carcinoma usually occurs in postmenopausal women. The tumor is well circumscribed and may have a gelatinous gross appearance. Microscopically, nests of uniform small cells are surrounded by pools of mucin (Fig. 27.21). The in situ component is minimal, but may also show intraductal mucin production. Pure mucinous tumors are low grade and have an excellent prognosis, with a low risk of lymph node metastasis (72). This is not true, however, of mixed carcinomas with a prominent nonmucinous, usual invasive ductal carcinoma component.

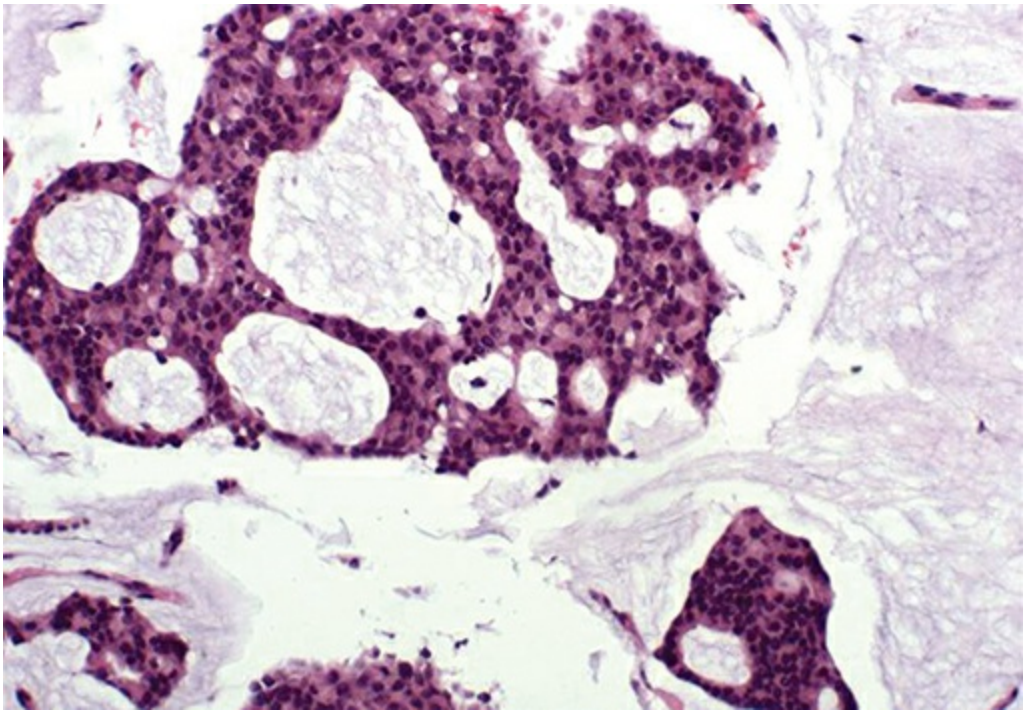

Figure 27.21 Mucinous carcinoma. Nests of low-grade neoplastic cells in a cribriform pattern are surrounded by a large pool of mucin, rendering a gelatinous gross appearance.

Tubular Carcinoma

Tubular carcinoma is a well-differentiated invasive carcinoma composed of small glands or tubules that can be difficult to distinguish from some benign lesions, especially radial scars. The tubules are arranged haphazardly, often with a surrounding cellular stroma. They are somewhat angular with open lumens and are lined by a single layer of monomorphic epithelial cells (Fig. 27.22). Myoepithelial cells are absent, and IHC for myoepithelial markers (smooth muscle myosin heavy chain, calponin, p63, and/or CD10) is helpful in confirming the diagnosis on needle biopsy. Within this group, tumors with at least 75% tubules and grade 1 nuclei have an excellent prognosis (73). Invasive tubular carcinoma is often associated with a low-grade micropapillary or cribriform DCIS or adjacent atypical columnar cell lesions (65). Tubular carcinomas are small, usually less than 1 cm, and are frequently detected by screening mammography. Tumors with a component of usual invasive ductal carcinoma should not be included in this category. Invasive cribriform carcinoma, which also has a good prognosis, may be mixed with tubular carcinoma.

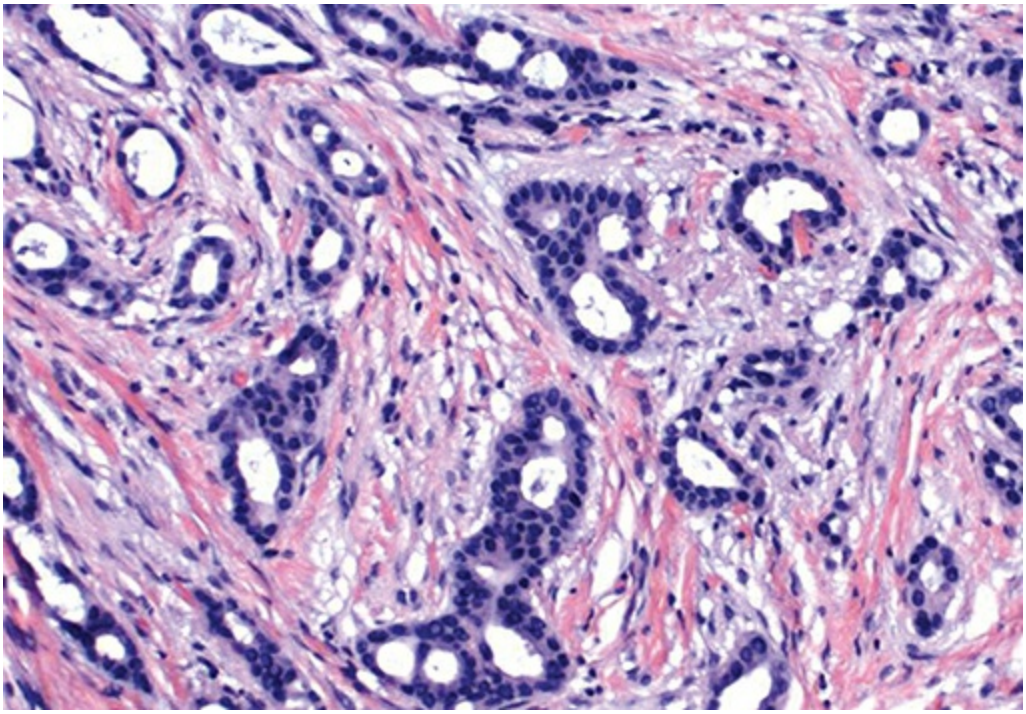

Figure 27.22 Tubular carcinoma. Well-formed angular, oval, and tubular glands with a single layer of neoplastic ductal cells diffusely infiltrate a desmoplastic fibrous stroma. Myoepithelial cells are absent from these tubules.

Medullary Carcinoma

Medullary carcinomas occur more commonly in women under 50 and have a higher frequency in BRCA1 mutation carriers. Clinically, the tumor is well circumscribed and may mimic a fibroadenoma. Microscopically, the tumor is composed of solid syncytial sheets of large anaplastic cells with pleomorphic nuclei, prominent nucleoli, and abundant mitotics (Fig. 27.23). Gland formation is absent. The tumor has a pushing border and is surrounded by a dense lymphoplasmacytic infiltrate. Only tumors with this strict morphology and no component of typical invasive ductal carcinoma have a good prognosis.

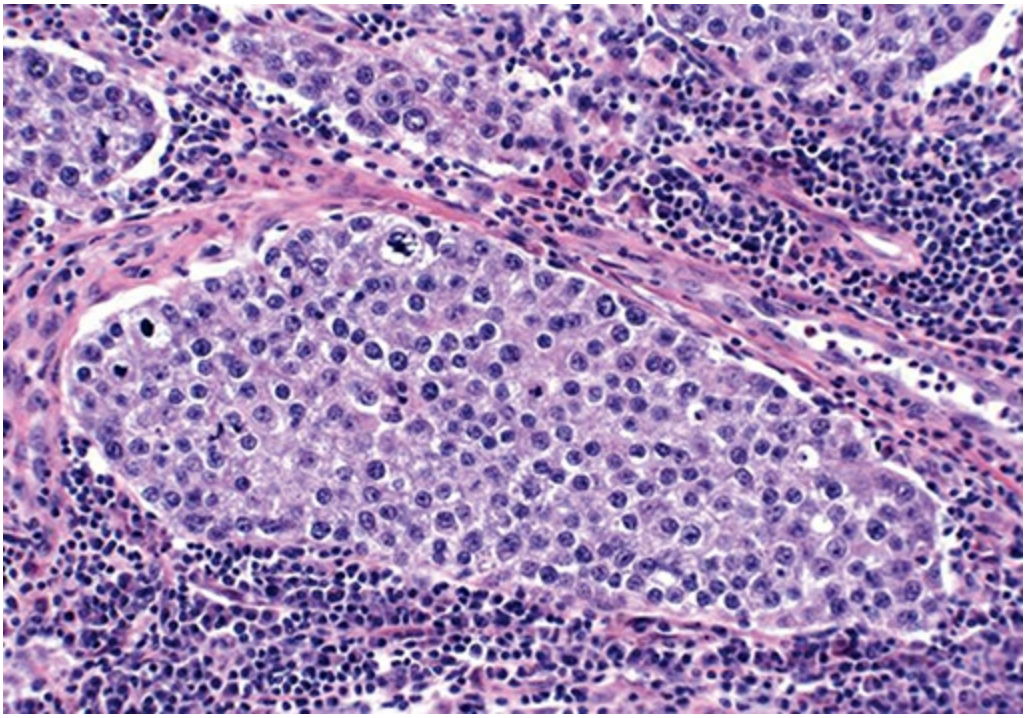

Figure 27.23 Medullary carcinoma. Highly pleomorphic neoplastic cells in a syncytial sheet pattern are surrounded by a diffuse lymphocytic infiltrate.

Micropapillary Carcinoma

Micropapillary carcinoma is a recently described entity with a characteristic morphology, high incidence of positive nodes at presentation despite small tumor size, and poor OS (74). The tumor is composed of small clusters of malignant cells floating within small clear spaces resembling lymphatic channels (Fig. 27.24). Most tumors have high nuclear grade and true lymphatic space invasion. A component of usual invasive ductal carcinoma may be present.

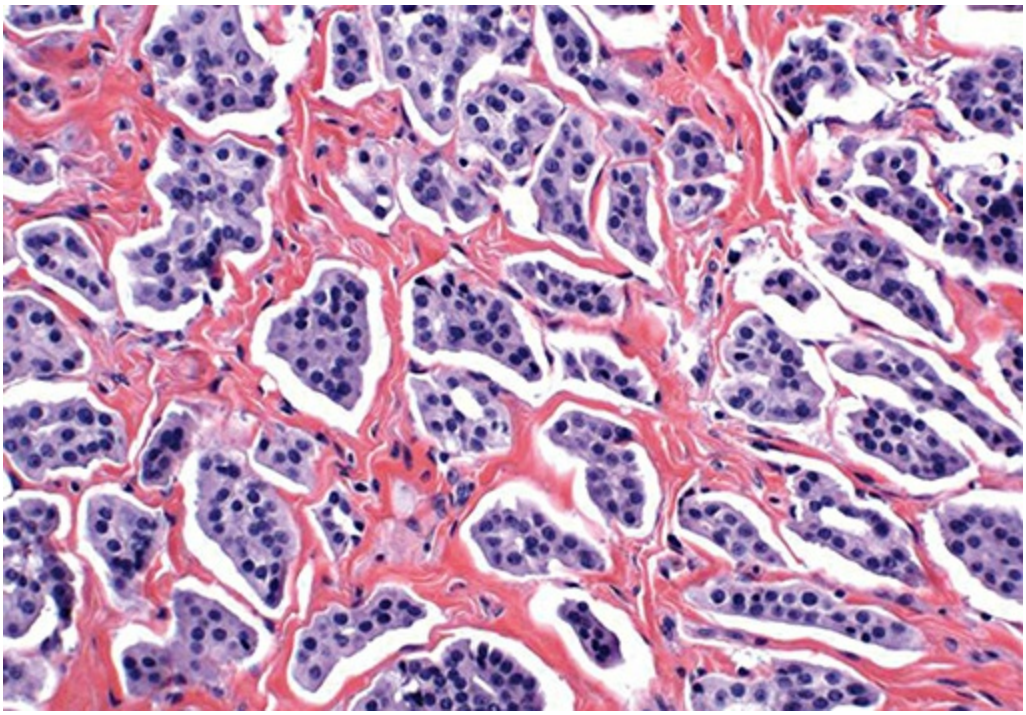

Figure 27.24 Invasive micropapillary carcinoma. Small clusters of intermediate-grade

neoplastic cells lie within small clear spaces of a fibrocollagenous stroma mimicking tumor cells in angiolymphatic spaces. The tumor cells display reversed polarity, whereby the E-Cadherin negative luminal (apical) edge of the tumor cells is at the periphery of the tumor clusters.

Papillary Carcinoma

Papillary carcinoma is a rare subtype. Several different entities are encompassed within this terminology. Solid papillary carcinoma and encapsulated (intracystic or encysted) papillary carcinoma have indolent behavior like a DCIS, although they lack surrounding myoepithelial cells (Fig. 27.25) (75). Encapsulated papillary carcinoma forms a well-circumscribed mass and may have DCIS present in adjacent ducts. Invasive papillary carcinomas have evidence of destructive stromal invasion adjacent to larger solid nests.

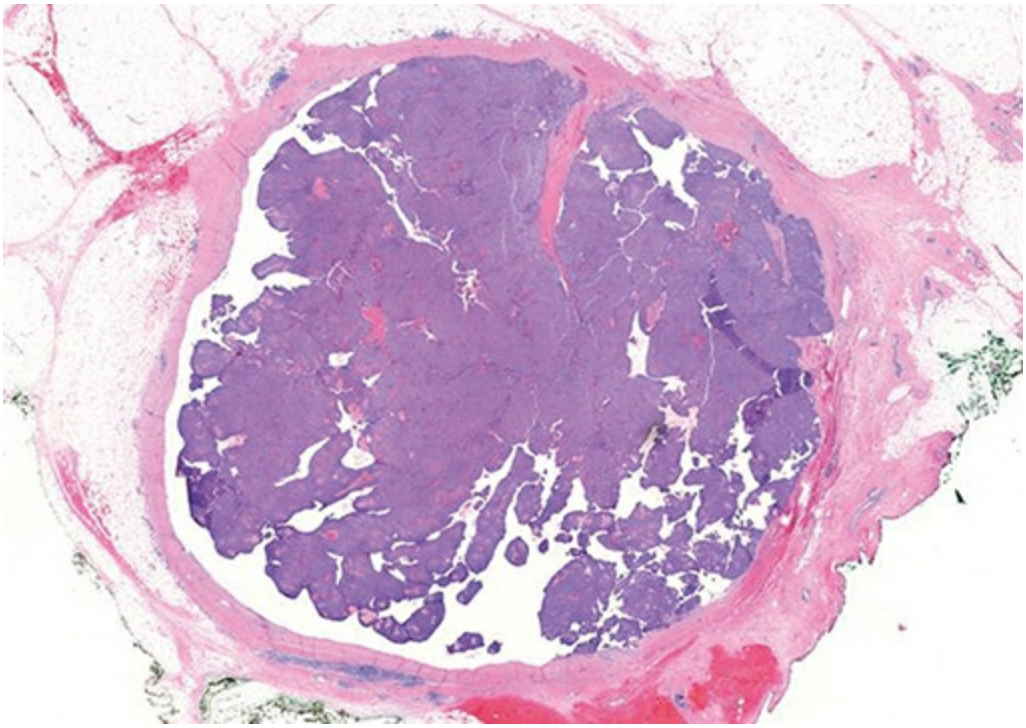

Figure 27.25 Solid or encapsulated (intracystic) papillary carcinoma. Low power shows a well-circumscribed tumor with branching network of fibrovascular stroma. A cystic formation is not necessary for the diagnosis.

Inflammatory Carcinoma

The term “inflammatory carcinoma” originated as a clinical term to describe a patient presenting with a reddened edematous breast suggesting mastitis. Skin biopsies from such patients often show tumor thrombi in dermal lymphatic channels (Fig. 27.26), but this is not true in every case.

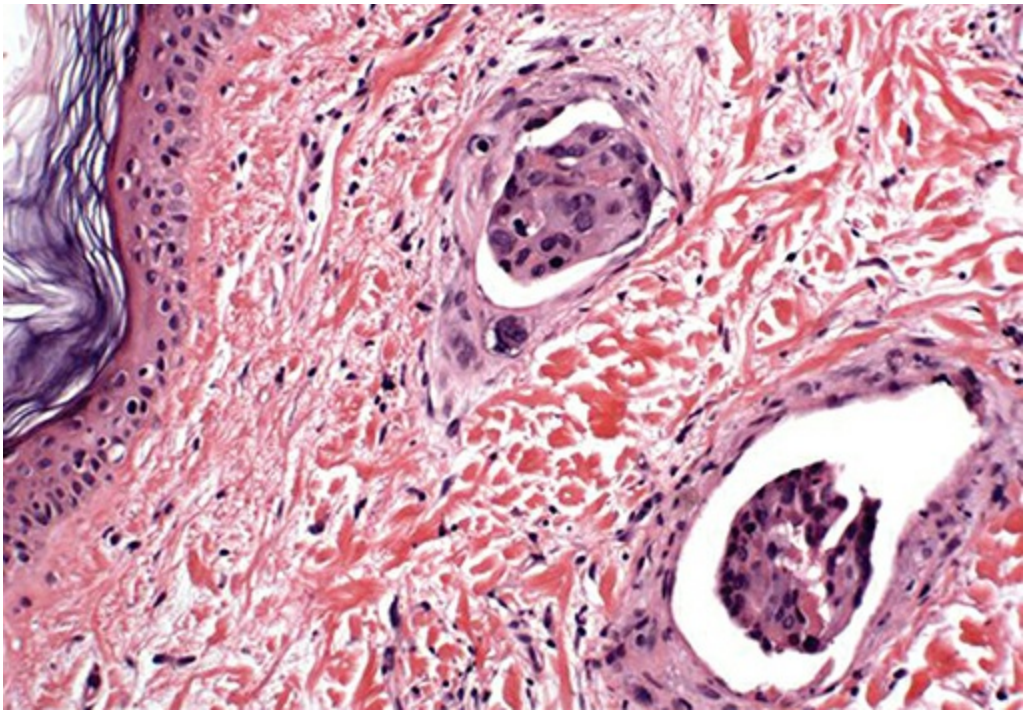

Figure 27.26 Inflammatory carcinoma. Carcinomatous emboli are present in dilated dermal lymphatics.

Invasive Lobular Carcinoma

Invasive lobular carcinoma comprises approximately 10% of all breast cancers. The classic form of invasive lobular carcinoma is composed of small monotonous tumor cells with scant cytoplasm growing in linear columns (“Indian file”) or in concentric (“targetoid”) patterns around normal ducts and lobules (Figs. 27.27 and 27.28). A mild stromal desmoplastic reaction may be present around the tumor cells, but many invasive lobular carcinomas do not form a discrete tumor mass. This diffuse growth pattern can be a problem when attempting conservative surgical excision, and tumors are frequently upstaged after surgery (76).

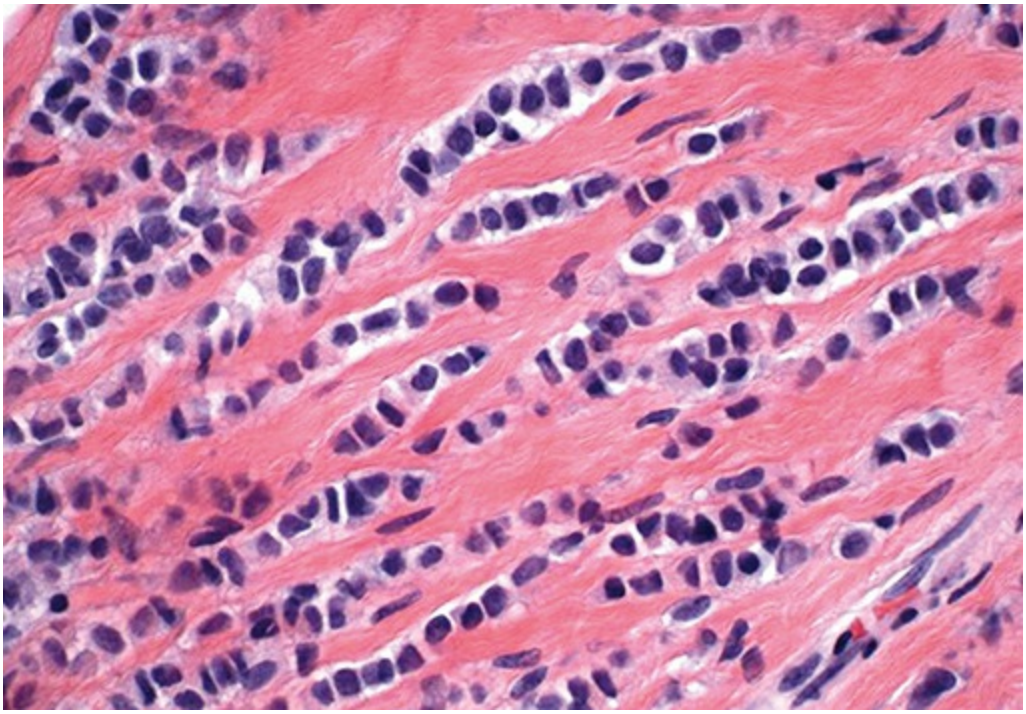

Figure 27.27 Invasive lobular carcinoma. Small monotonous tumor cells invade in linear "Indian file" pattern.

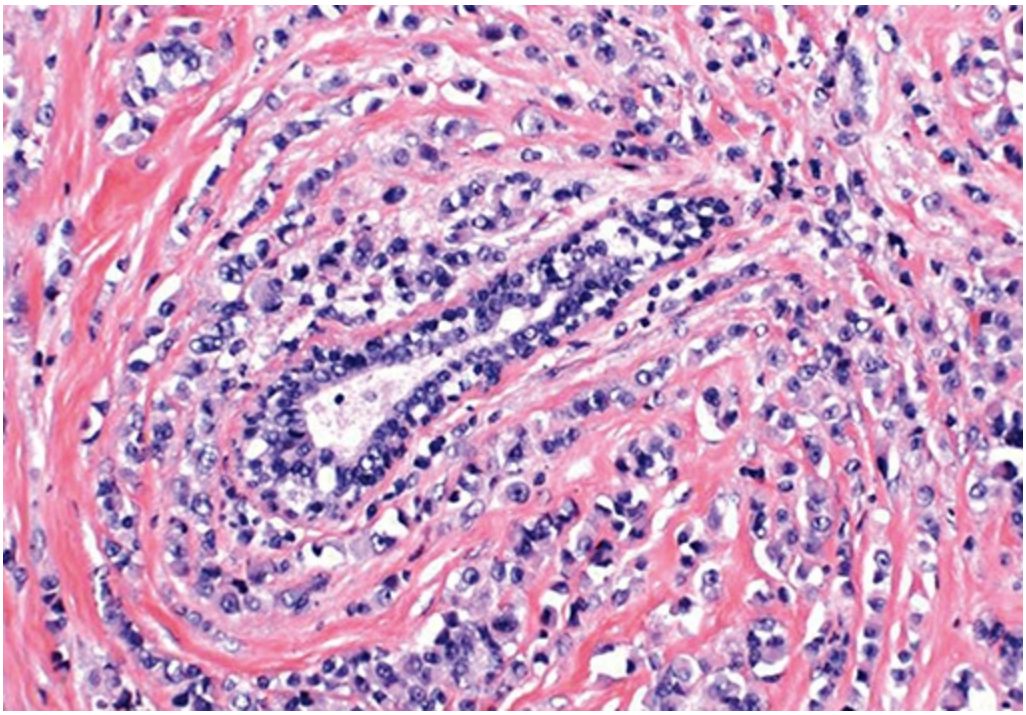

Figure 27.28 Invasive lobular carcinoma. Tumor cells infiltrate in a concentric pattern around a normal duct.

Variant forms of invasive lobular carcinoma include alveolar, solid, and trabecular patterns and are composed of the same monomorphic small cells. Signet ring cell carcinoma (Fig. 27.29), in which the cells contain prominent intracytoplasmic vacuoles, is considered a variant of invasive lobular carcinoma due to its similar growth patterns. Another variant is pleomorphic lobular carcinoma, in which the columns of cells show marked nuclear atypia.

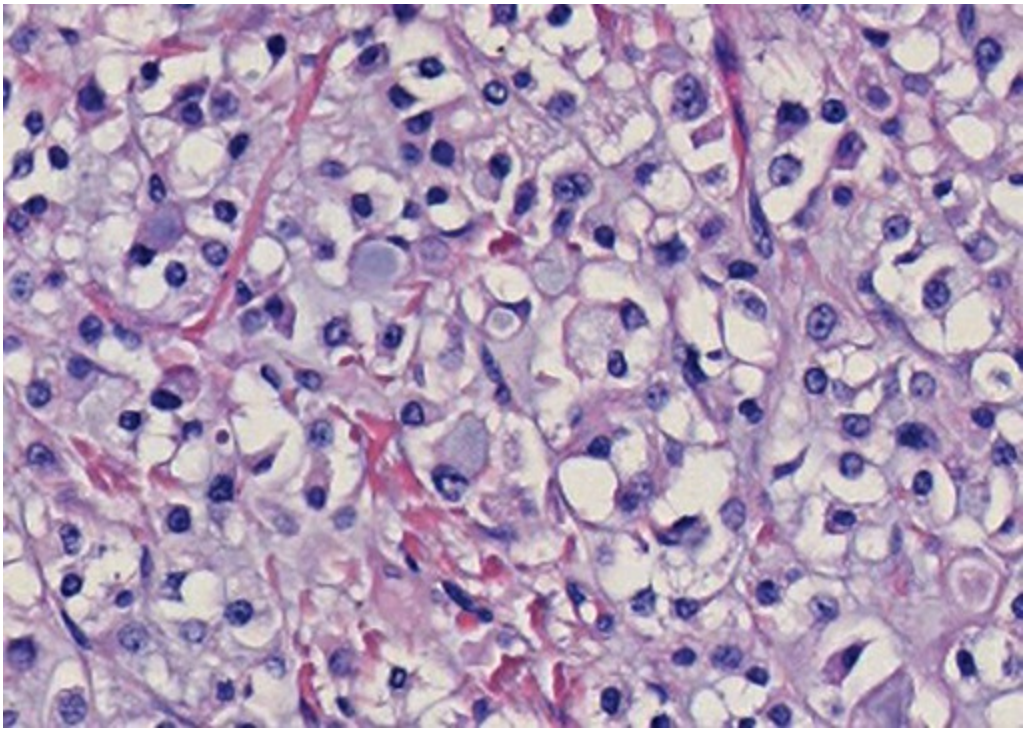

Figure 27.29 Signet ring cell carcinoma. Tumor cells contain a large amount of intracytoplasmic mucin, which pushes the nuclei to the cell periphery, thus resembling signet rings.

Stage for stage, the prognosis of patients with invasive lobular carcinoma is no different from invasive ductal carcinoma. However, the patterns of metastatic disease are different, with lobular carcinomas having a propensity to metastasize to the meninges and peritoneal and pleural surfaces. Invasive lobular carcinomas and mixed lobular and ductal invasive carcinomas appear to be more frequent in postmenopausal women taking combination hormone replacement therapy (77).

Tubulolobular Carcinoma

This tumor shows a mixture of invasive lobular and tubular carcinoma growth patterns with low-grade nuclei. The mixed architectural pattern parallels the expression of markers of ductal and lobular differentiation, and these tumors appear to have a good prognosis.

Other Tumors

Metaplastic Carcinoma

The term “metaplastic carcinoma” is used to describe tumors with prominent morphologic patterns different from usual ductal and lobular patterns. The term encompasses epithelial tumors (carcinomas) showing squamous cell differentiation, monophasic spindle cell carcinoma, and biphasic tumors with both epithelial and mesenchymal elements (Fig. 27.30). Spindle cell (sarcomatoid) carcinomas express epithelial markers (cytokeratins) despite their spindle cell morphology and are aggressive tumors with a high rate of extranodal metastases. Biphasic tumors (biphasic sarcomatoid carcinoma or carcinosarcoma) may contain heterologous elements, such as malignant cartilage or bone (Fig. 27.31).

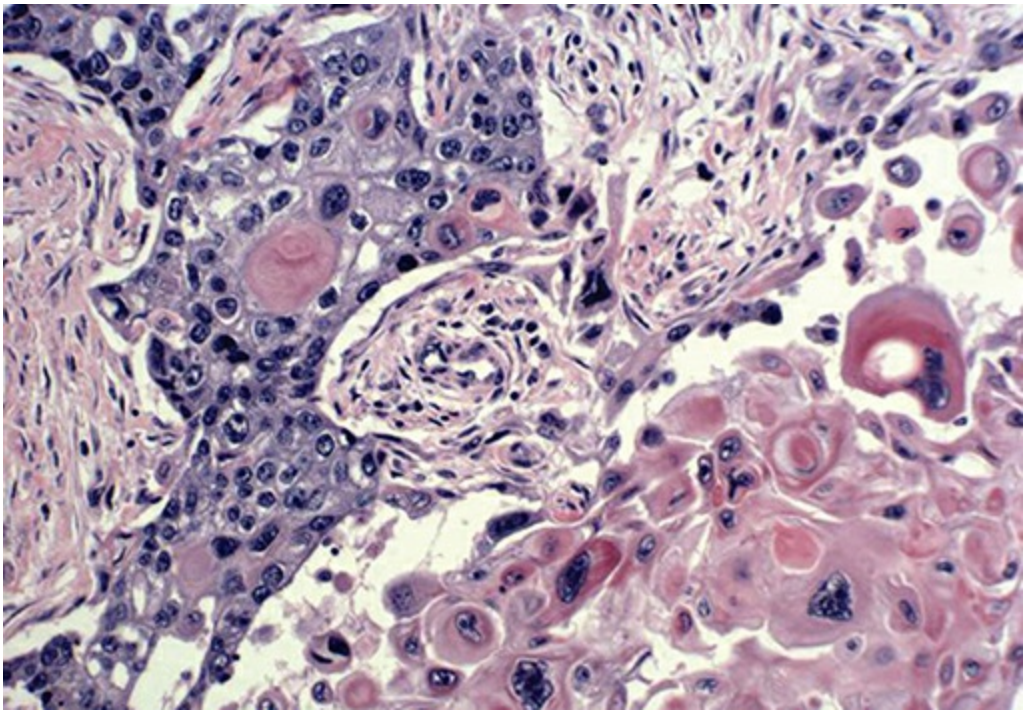

Figure 27.30 Metaplastic carcinoma. The area to the right of this poorly differentiated invasive breast carcinoma shows squamous differentiation.

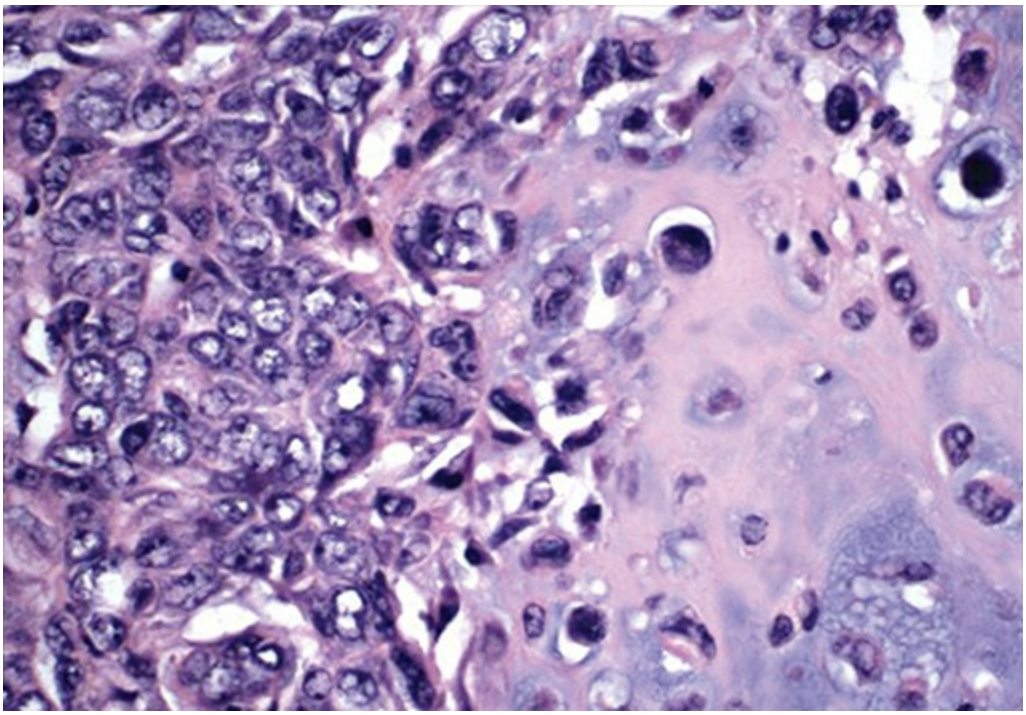

Figure 27.31 Metaplastic carcinoma. A well-developed cartilaginous focus is seen in this poorly differentiated invasive carcinoma with chondroid differentiation.

Phyllodes Tumors

Phyllodes tumors, formerly known as “cystosarcoma phyllodes” are biphasic tumors similar to fibroadenomas with a spectrum of morphology and biologic behavior. The median age at diagnosis is 45, which is several decades longer than that of fibroadenoma. These tumors are grossly well circumscribed but are infiltrative on microscopic examination. They

are composed of benign glandular elements with a prominent stromal component showing varying degrees of hypercellularity, nuclear atypia, and mitotic activity (Fig. 27.32). The older term “cystosarcoma phyllodes” refers to the leaflike architectural pattern with intervening cystic spaces. While features such as size, mitotic activity, and cellular atypia correlate with clinical behavior, attempts to reliably divide these tumors into benign and malignant forms are not always successful. The lower grade tumors tend to recur, especially if incompletely excised due to the subtle infiltrative margin. Overall, lymph node metastases are uncommon and surgery is the primary treatment.

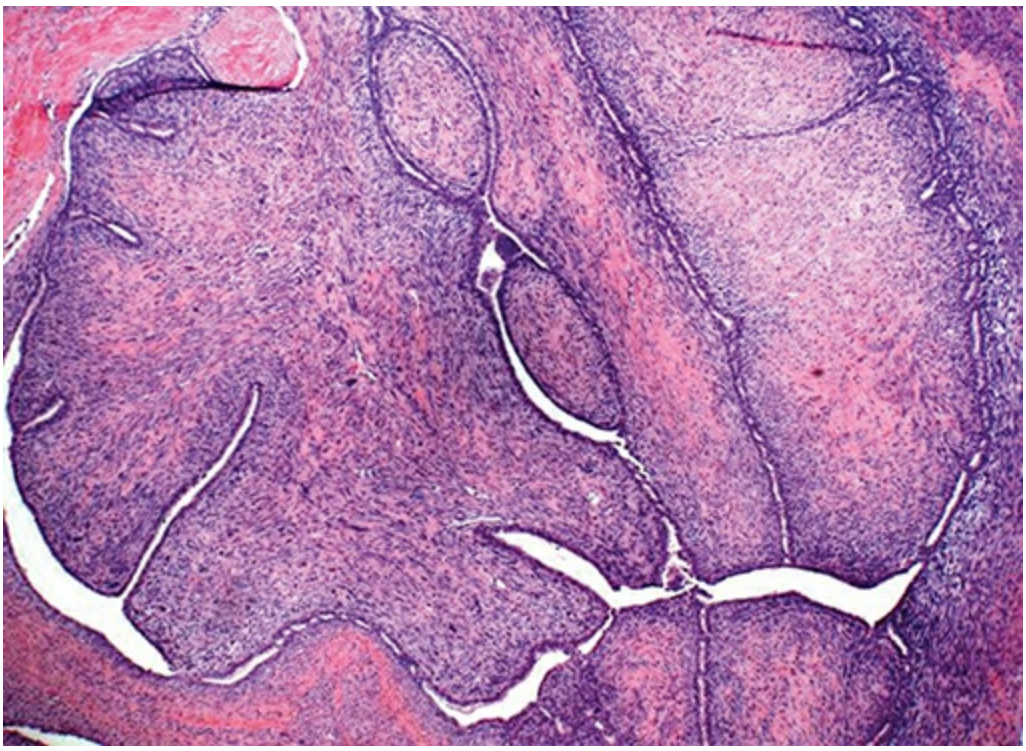

Figure 27.32 Phyllodes tumor. Phyllodes tumors have leaflike architectural pattern with intervening cystic spaces. They are composed of benign glandular elements with a prominent stroma showing varying degrees of hypercellularity, nuclear atypia, and mitotic activity.

Angiosarcoma

Angiosarcoma is the most common primary sarcoma of the breast and may be associated with previous radiation therapy (RT). The tumors are composed of anastomosing vascular channels lined by endothelial cells, which range from mildly atypical to frankly malignant. The distinction between a benign angioma and a low-grade angiosarcoma can be difficult to determine on a small biopsy. Other histologic patterns of primary breast sarcoma also occur.

REQUIRED TESTS ON BREAST CANCER

Measurement of ER in breast cancers is performed to predict the response of an invasive tumor to endocrine therapy or the benefit of hormonal therapy for risk reduction in cases of in situ carcinoma. Progesterone receptor (PR) is an ER-regulated gene product with similar prognostic implications. Hormone receptors can be measured biochemically by ligand-binding assays or by IHC techniques using monoclonal antibodies directed against the receptor protein (Fig. 27.33). Correlation between the two techniques is high (78). With today’s smaller tumors usually diagnosed by needle core biopsy, IHC is the preferred method of analysis. This method also allows for the distinction between invasive tumor, in situ tumor,

and nontumor elements. The American Society of Clinical Oncology (ASCO) and CAP published a joint guideline containing an algorithm for testing, interpretation, and reporting, as well as requirements for standardization and validation of testing techniques (79). Both the percentage of cells stained and the intensity of the staining should be reported. A positive result is defined as greater that 1% of cell nuclei staining positive.

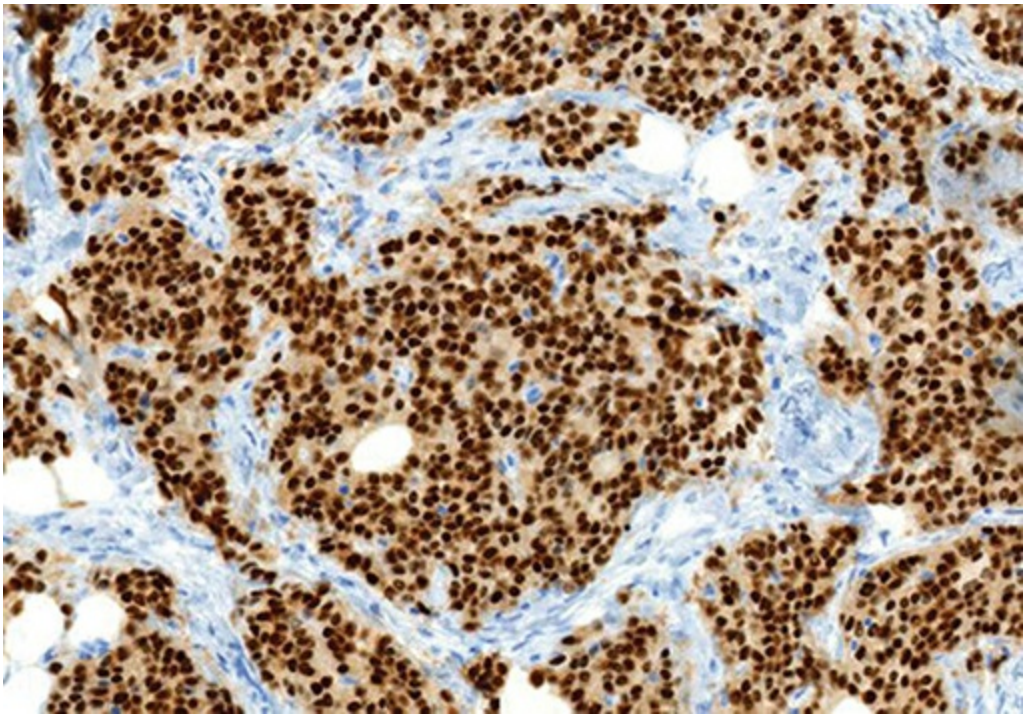

Figure 27.33 Positive ER. Greater than 90% of tumor cells of this invasive ductal carcinoma are strongly positive for ER.

HER-2/neu

HER-2/neu, or c-erbB2, is an oncogene whose protein product is a membrane receptor tyrosine kinase. Overexpression of HER2 is associated in most, if not all, cases with the presence of additional copies of the gene that codes for the HER2 protein on chromosome 17. While the cause of this HER2 gene amplification, which is found only in the patient's breast cancer cells, is not understood, its biologic implications are clear—increased density of HER2 on the surface of the malignant cells leads to the formation of both homo- (HER2:HER2) and heterodimers with other members of the HER receptor family (HER1, HER3, and HER4), triggering activation of tyrosine kinases associated with the intracellular portions of the receptors, which in turn trigger a number of signaling pathways that enhance cancer cell growth and proliferation, resistance to apoptosis, and metastatic potential.

Amplification of HER-2/neu is seen in most cases of comedo-type DCIS and in approximately 20% to 30% of invasive ductal carcinomas, usually of high grade. It can be detected by IHC for the protein product or by gene amplification techniques, such as fluorescence in situ hybridization (FISH) or chromogenic in situ hybridization. Increased copy number is closely associated with elevated protein expression. Amplification of HER-2/neu identifies a subset of patients with a poor prognosis who benefit from treatment with trastuzumab, a monoclonal antibody directed against the HER-2/neu receptor.

The ASCO and the CAP defined criteria for HER2-positive (HER2+) breast cancer (80). These guidelines were revised in 2013 as follows: 1) at least 10% of the tumor's cells exhibit uniform intense membrane staining (3+) for HER2 by IHC stain (Fig. 27.34); or 2) their tumor cells display either an average of six or greater HER2 signals per cell; or 3) a ratio of HER2 to chromosome 17 (using a centromeric probe) (HER2/CEP17) signals by in situ hybridization (ISH) of ≥2 (regardless of HER2 copy number); or 4) HER2/CEP17 ratio <2 with an average HER2 copy number ≥6 per cell (Fig.

27.35).

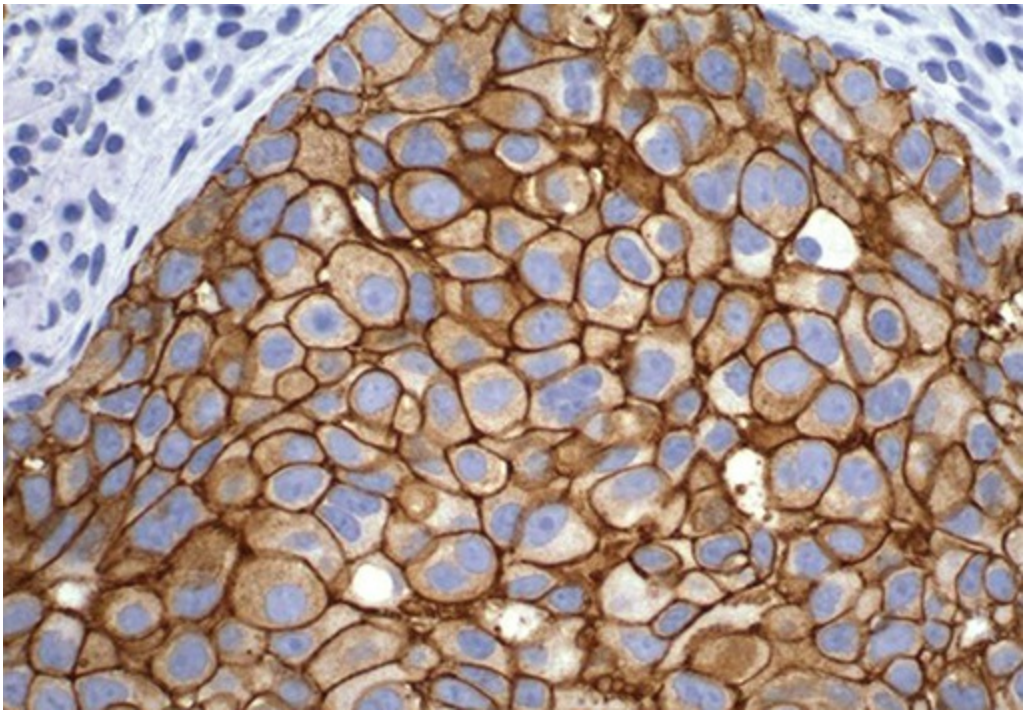

Figure 27.34 Positive HER-2/neu. Strong (3+) Her-2/neu membrane immunoreactivity is seen in this invasive ductal carcinoma.

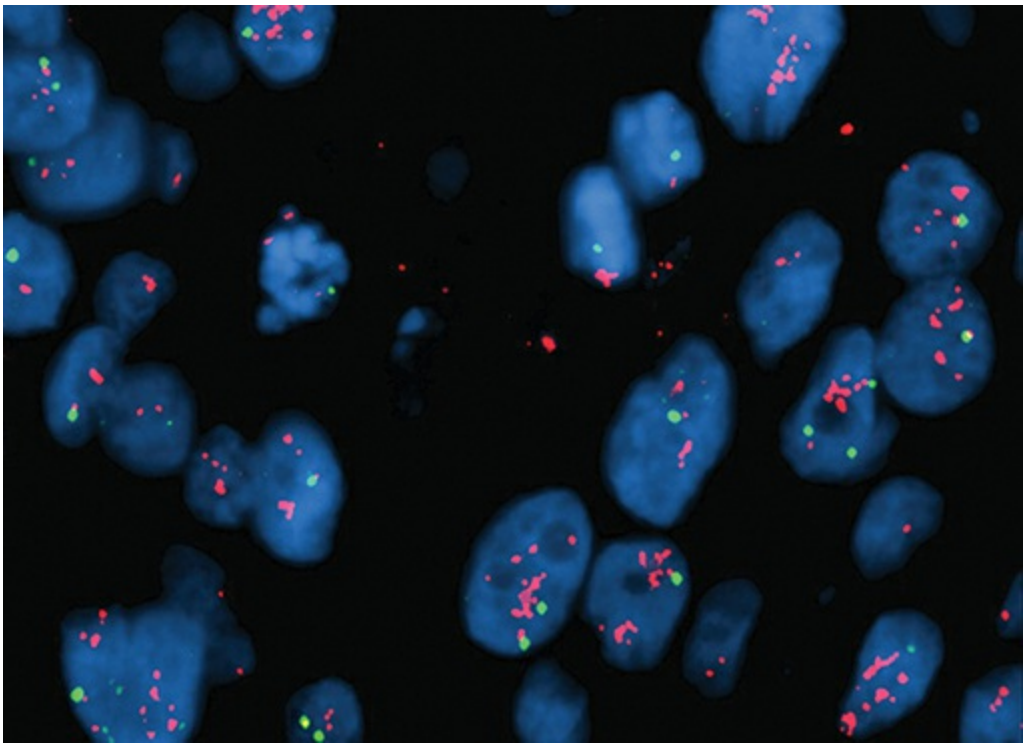

Figure 27.35 Amplification of HER-2/neu gene (red dots) by FISH. The centromere of chromosome 17 appears as green signals.

Other Markers

Proliferation rate measured by flow cytometry (S-phase fraction), DNA image cytometry, or IHC (Ki67 MIB-1 antibody) has a relation to clinical outcome (81). However, these and other markers suffer from problems with standardization of results between laboratories (82).

Genomic Studies and Breast Cancer Subtypes

Molecular techniques have shown that breast cancer is a heterogeneous disease. Perou et al. (83) were the first to use gene expression profiling to classify breast cancers into distinct molecular groups based on the expression of distinct "intrinsic" genes. Luminal A tumors show high expression of ER and related genes, with low proliferation. Luminal B tumors also show expression of ER but have high proliferation and show variable expression of PR and HER2. The HER2-enriched group of tumors express the HER2 oncoprotein and related genes, with variable expression of hormone receptors. Basal-like tumors express basal (myoepithelial) markers like cytokeratin 5/6 and epidermal growth factor (EGFR), and typically lack expression of ER, PR, and HER2 (triple-negative tumors). This subgroup of tumors is the most frequent type found in BRCA1-associated breast cancer. The molecular subtyping of breast cancers has begun to identify unique therapeutic options for the different tumor types, and this remains an important area of therapeutic research (84).

SURGICAL MANAGEMENT

In Situ Disease

In the past, DCIS was managed, like any breast cancer, by mastectomy. This was effective from a cancer point of view and resulted in a local recurrence rate of only 1% (85). However, current treatment mirrors the approach to early invasive breast cancer, and breast conservation therapy is the standard of care for most cases. It should be noted, however, there are no phase III studies comparing breast conservation therapy with total mastectomy in DCIS.

For women with DCIS, margin status and the size of the lesion appear to be significant factors related to risk of recurrence (86,87). Despite the use of breast-conserving treatment (BCT), some women may still require mastectomy, and for these patients, the indications for mastectomy for DCIS include: (1) persistent positive margins after wide local excision; (2) multicentric disease (i.e., DCIS involving more than one quadrant); and (3) a large tumor-to-breast size ratio for which breast-conserving surgery (BCS) would result in a personally defined cosmetically unacceptable result (88). All women who undergo mastectomy should also have a sentinel lymph node biopsy performed to ensure the absence of occult invasive disease.

While sentinel node biopsy is standard for women with DCIS undergoing mastectomy, it is not entirely clear if it plays a role in BCT. In the largest series looking at this issue, nodal involvement was seen in only 5% of cases; however, 70% of these metastases were detected only by IHC staining (89). In general, we typically consider lymphatic mapping for women with a span of DCIS greater than 4 cm or those who present with a mass on mammography. Other considerations include women with palpable DCIS, high-grade DCIS on core biopsy, and the presence (or question of) microinvasion.

Early Invasive Disease

Early invasive breast cancer, defined as tumors less than 2 cm in size, is almost uniformly diagnosed by imaging modalities (e.g., mammogram and/or breast US or MRI). The diagnosis is often established by core needle biopsy. In general, these patients are treated with wide local excision as part of BCT. Contraindications to this include multicentricity, a poor breast–tumor volume ratio, and women in whom RT is contraindicated (e.g., serious connective tissue disorders, pregnancy, or prior irradiation). Particular attention to the location of the tumor, its palpability, fixation to the skin or underlying chest

wall, cutaneous changes, nipple irregularities, and regional nodal assessment are paramount.

The aim of BCS is to resect the primary tumor with clear margins. This can be achieved either with the needle localization technique or one of the other many techniques that have been described in the literature to localize the lesion, such as intraoperative US localization (90) or radioisotope-guided resection (91).

For women undergoing wide local excision, the ideal margin for breast cancer in a wide local excision continues to be a controversial topic. However, a consensus statement supported by both the Society of Surgical Oncology (SSO) and American Society of Therapeutic Radiation Oncology (ASTRO) and based on a meta-analysis of 33 studies, including more than 28,000 patients was released in 2014 (92). The report concluded that positive margins are associated with a two-fold increased risk in in-breast tumor recurrence (IBTR) rates, compared to negative margins. The risk is not altered by differences in biology, endocrine therapy, or a radiation boost. However, wider surgical margins do not significantly reduce the risk of IBTR, regardless of patient age, less favorable biology, or extensive intraductal component. Given these results, the consensus statement adopts an adequate margin when there is pathologically no evidence of invasive tumor at the surgically inked margin.

In 2015, Chagpar et al. (93) reported the results of a randomized trial evaluating the role of resecting additional tissue circumferentially around the tumor cavity (called cavity shaved margins) on outcomes in more than 200 women undergoing BCS (i.e., partial mastectomy) for stage 0 to III breast cancer. The median age of the patients was 61 years (range, 33 to 94). Of those enrolled, 23%, 19%, and 53% had invasive cancer, DCIS alone, or both, respectively. Compared to those who did not undergo shaved margins, shave margins resulted in a significantly lower rate of positive margins (19% vs. 34%, $p = 0.01$) and were subjected to less second surgical procedures (10% vs. 21%, $p = 0.02$).

Locally Advanced Breast Cancer

Locally advanced breast cancer (LABC) is variously defined, though reasonable definitions include patients with a primary tumor size greater than 3 to 5 cm, involvement of the chest wall, skin ulceration or satellitosis, and/or positive axillary nodes. For these patients, the evolving standard is to offer neoadjuvant therapy prior to any planned surgical treatment. From a surgical standpoint, neoadjuvant treatment is associated with a higher rate of breast conservation, without a reduction in either disease-free survival (DFS) or OS, without an increase in the complication rate of surgery, and without delay in onset of further postoperative treatment (94). The use of NACT does result in a 30% to 40% decrease in the incidence of axillary nodal involvement and up to a 20% complete response rate in responding patients (95–97).

Approximately 25% of patients who are not candidates for breast conservation before treatment will be candidates for BCT after the administration of NACT. All patients considered for NACT should undergo an axillary evaluation to help establish the nodal stage. For women with clinically evident nodal disease, a needle biopsy can be performed, with either axillary US with needle biopsy, or sentinel node biopsy in nonpalpable disease. For women with clinically negative axillary examination, further workup is necessary, because clinical examination is associated with a false-negative rate in excess of 20%. US with fine needle aspiration cytology of suspicious nodes has a reported sensitivity and specificity of 36% to 92% and 69% to 100%, respectively (98,99).

For women with no evidence of axillary node involvement prior to NACT, sentinel node biopsy is often used in this population, although the timing remains controversial. Mamounas (100) reviewed the experience of the National Surgical Adjuvant Breast and Bowel Project (NSABP) B-27 clinical trial and reported that a sentinel lymph node can be identified in 85% and is falsely negative in 11%, confirming that sentinel node biopsy after NACT is both feasible and accurate. Of interest, they also reported that 30% to 40% of patients with a positive sentinel node biopsy before neoadjuvant therapy are downstaged after treatment and may not require axillary dissection.

For patients treated with neoadjuvant therapy, clinical and radiologic assessment should be performed following the completion of 2 to 3 cycles (Fig. 27.36). For those patients who are candidates or otherwise opt to proceed with surgery, a decision to proceed with mastectomy or BCS depends on clinical factors. The contraindications for breast conservation in this setting are similar to those for primary BCT and include residual tumor >5 cm, skin edema or involvement, chest

wall fixation, diffuse calcifications on mammogram (obtained posttreatment), multicentric disease, and contraindications to RT.

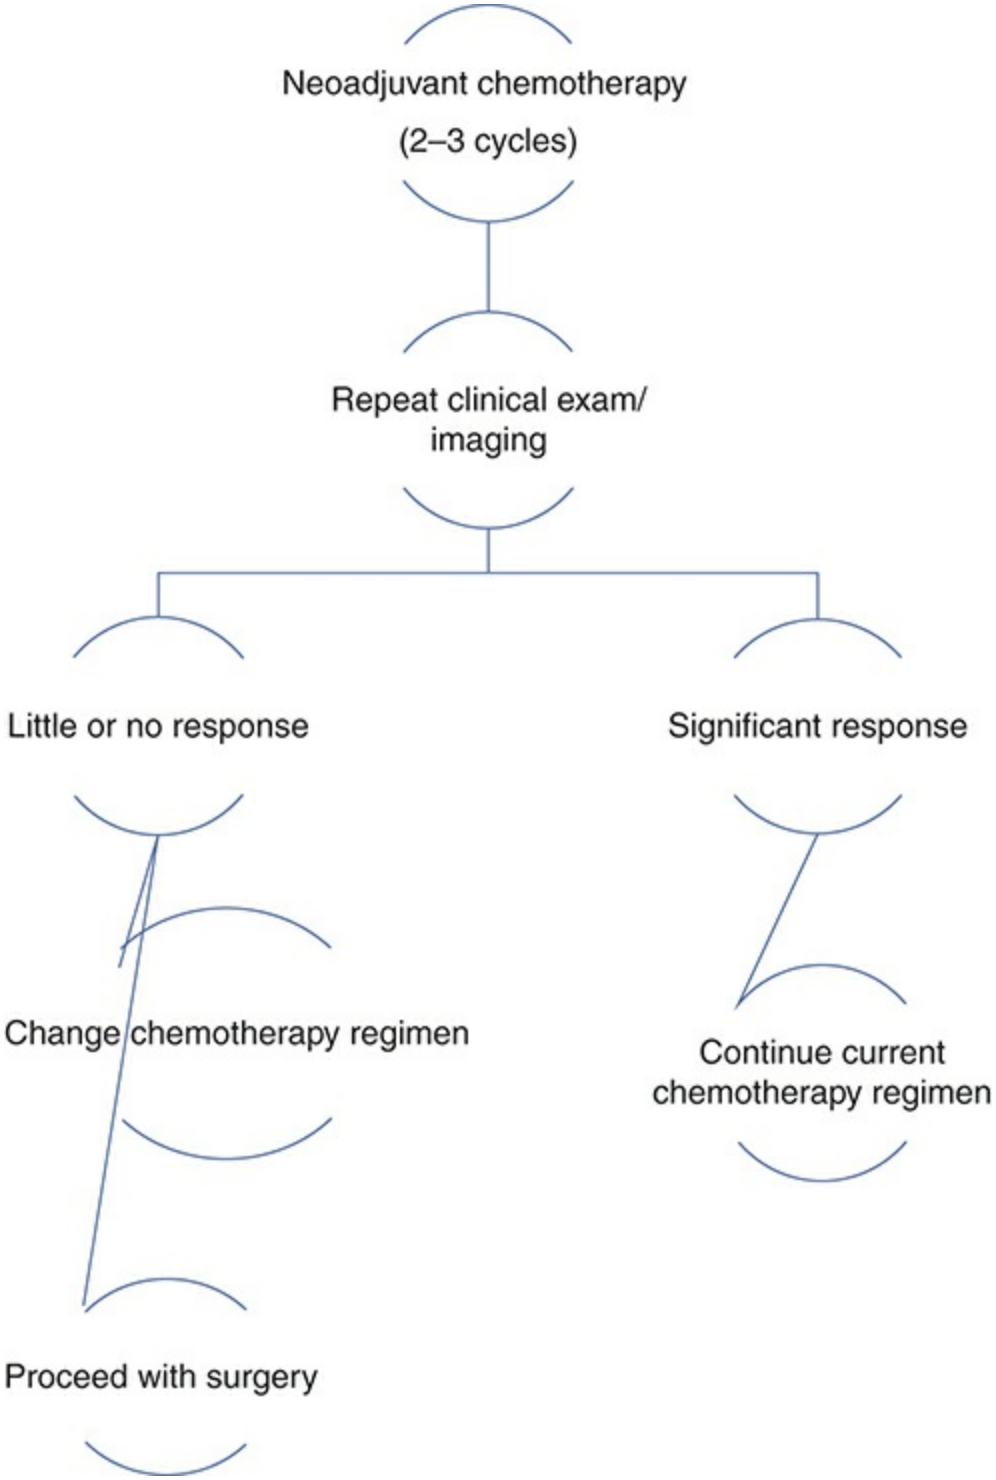

Figure 27.36 Neoadjuvant treatment of breast cancer: an algorithm.

Early consultations with both plastic surgery and radiation oncology should be performed in patients undergoing mastectomy who express an interest in immediate reconstruction, preferably before any surgery takes place. Immediate reconstruction can be associated with a slightly higher rate of complications, which may result in a delay in postoperative treatment. In addition, those who undergo RT may experience issues with cosmesis.

Management of the Axilla

Women without clinical evidence of axillary involvement from invasive breast cancer are managed with a sentinel node biopsy to stage the axilla. In contrast, a complete axillary lymph node dissection (ALND) is indicated in the following situations: node-positive disease at presentation; IBC; clinical stage T4 breast cancer; failed sentinel node mapping during surgery; and axillary recurrence after prior breast cancer treatment. The NSABP B-32 trial evaluated the impact of sentinel node biopsy with or without ALND in more than 5,600 women, almost 4,000 of whom had pathologically node-negative disease (101). Compared to women who underwent both procedures, there was no difference in OS in those undergoing sentinel node biopsy alone (HR 1.20, 95% CI 96 to 1.5), and 8-year OS rate estimates were 90% and 92% in the sentinel node–only group and the combined procedure group, respectively. There was also no difference in DFS or regional node recurrences as first events (14 vs. 8, respectively).

Traditionally, all patients with a positive sentinel node biopsy underwent an ALND. However, contemporary clinical trials have challenged this paradigm. The American College of Surgeons Oncology Group Z-0011 study (Z11 study) was designed to determine whether ALND was necessary for survival or local control in the setting of BCS with whole breast irradiation and adjuvant systemic therapy in patients with SLN metastases, specifically with one to two positive sentinel nodes (102). This phase 3 study prospectively enrolled 891 patients with T1-2 tumors and a clinically negative axilla undergoing BCT with whole breast radiation. In this group, patients with one to two positive sentinel nodes identified at surgery were randomized to undergo ALND or no further treatment. With a median follow-up of 6.3 years, the OS rate was 91.8% in the ALND group versus 92.5% in the sentinel node biopsy group alone. The rate of nodal recurrence in the sentinel node-only arm was 0.4% and 0.9%, respectively. There was no significant difference in OS or locoregional recurrence between the two groups, despite a 27% rate of pathologic node involvement among the group who underwent ALND. Of note, all patients received whole breast radiation (third field nodal irradiation was not allowed), and the overwhelming majority received adjuvant systemic therapy (96% in ALND arm and 97% in sentinel node biopsy arm). In addition, the study did not include patients who received NACT or underwent mastectomy.

The International Breast Cancer Study Group (IBCSG) 23-01 evaluated 931 patients, of whom 464 underwent ALND and 467 did not (103). Ninety-one percent of patients in both groups underwent BCS and 9% underwent mastectomy. The purpose of the multicenter randomized controlled trial was to identify whether ALND might be overtreatment in patients who have micrometastases only in the sentinel node. The enrollment eligibility criteria was broadened to include tumors ≤5 cm and one or more micrometastases (<2 mm) in the sentinel nodes, multifocal or multicentric tumors. At median follow-up of 5 years, there was no difference in DFS or OS between the arms, despite a 13% pathologic finding of positive nonsentinel nodes in those who underwent ALND. The rate of regional recurrence in the no-ALND arm was <1%, comparable to findings of other studies.

Lastly, the EORTC 10981–22023 AMAROS (After mapping of the Axilla: Radiotherapy or Surgery) trial was a randomized, multicenter, open-label phase 3, noninferiority trial that evaluated radiotherapy versus surgery of the axilla after positive sentinel node biopsy (104). In this analysis, 17% underwent mastectomy in the ALND group and 18% underwent mastectomy in the axillary radiotherapy group. Eighty-two percent underwent BCS in both groups. A median of two sentinel nodes was excised in both groups, and a median of one sentinel node was positive, of which 59% had macrometastasis in the ALND group and 62% had macrometastasis in the axillary radiotherapy arm. The results showed no significant difference between the two groups (ALND vs. axillary radiotherapy) in 5-year axillary recurrence, DFS, and OS. There was a higher incidence of lymphedema and more severe symptoms of lymphedema in the dissected group.

Technique of Axillary Lymph Node Dissection

In the United States, standard practice for ALND requires removal of level I and level II lymph nodes. Level I is defined as nodal tissue lateral to the pectoralis minor muscle, and level II is defined as nodal tissue posterior to the pectoralis minor muscle. Level III nodes (nodal tissue medial to the pectoralis minor muscle) are generally not included in the dissection due

to increased morbidity. Retrieval of level III nodes requires transection of the pectoralis minor muscle. Interpectoral nodes (Rotter nodes) should be removed if suspicious. At minimum, 10 nodes should be retrieved during the procedure. The axilla is bounded by the axillary vein superiorly, the serratus anterior muscle medially, the latissimus dorsi muscle laterally, the subscapularis muscle posteriorly, and the clavipectoral fascia anteriorly. The thoracodorsal nerve to the latissimus muscle and the long thoracic nerve to the serratus anterior muscle is preserved. If possible, the main trunk of the intercostobrachial nerve is also preserved to decrease the risk of arm paresthesias. The risk of lymphedema with this procedure is quoted at 6% to 50% (105,106).

Sentinel Lymph Node Biopsy

The sentinel lymph node biopsy is performed using radioactive colloid material (technetium 99), blue dye (methylene blue or lymphazurin blue), or a combination of both. Using both the radioactive colloid and the blue dye increases the identification rate to 95%. The sentinel lymph node identification rate with a periareolar/subareolar injection of the radiocolloid and blue dye injection is higher than that with a peritumoral injection. The radioactive colloid is typically injected in the Nuclear Medicine department, and a lymphoscintigram, which shows the lymphatic drainage pattern of the tumor, is obtained. The vast majority of drainage is in the ipsilateral axilla. Additionally, blue dye is injected prior to surgery. During the surgery, a separate axillary incision is made to perform the procedure. Dissection includes incising the clavipectoral fascia to enter the axilla. The axilla is interrogated with a handheld gamma probe to identify sentinel node(s). The sentinel node can be “hot,” “blue,” or “hot and blue.” The radiotracer facilitates identification by emitting high activity sound (“hot node”), and the blue dye stains the node, assisting in the visualization of the sentinel node (“blue node”). The node is carefully dissected from the surrounding tissue. Each sentinel node is excised and counted over 10 seconds. For sentinel lymph node identification with radioactivity, the node with counts greater than the 10% of the most radioactive node is excised. If blue dye is used, any blue node or node with an adjacent blue-stained lymphatic is a sentinel node. Before completion of the procedure, the axilla is palpated for any grossly abnormal nodes, as false negativity is common with nodes replaced by tumor.

An anatomical description by Clough divided the axilla into four zones, separated by the lateral thoracic vein and the second intercostal brachial nerve. In this scheme, in 242 stageI/II breast cancer patients, the sentinel node was identified medial to the vein 98.2% of the time, usually below the nerve (86.8%.) The upper lateral zone, adjacent to the lymphatic drainage of the arm, never contained the sentinel node (107). The lower axilla is the most common location of the sentinel node(s). While lymphatic mapping to the IM chain has been performed, its impact on outcome remains unclear.

Intraoperative assessment of sentinel lymph nodes using touch imprints and routine IHC staining is used by some to enable an immediate therapeutic lymphadenectomy if the nodes are positive, thus sparing the patient from a second procedure. However, intraoperative assessment may have unacceptable rates of false-negative results, ranging from 36% to 71% (108).

Oncoplastic Surgery

Immediate reconstruction after mastectomy is safe from an oncologic perspective and beneficial to a patient’s well-being. A more ideal technique of complete resection of the breast with preservation of the unaffected structures was primarily championed by Simmons et al. (109). They compared recurrence patterns in women treated by skin-sparing mastectomy (SSM) versus non-SSM and demonstrated local recurrence rates of 3.90% and 3.25%, respectively, with an equivalent distant recurrence rate of 3.9% at 5 years. A subsequent 2010 meta-analysis of SSM/nipple areolar sparing mastectomy (NSM) versus non-SSM confirmed these findings, reporting equivalent local recurrence rates (6.2% vs. 4.0%) regardless of technique, with a follow-up of 37.5 to 101 months (110). This technique has been extended to patients with more advanced disease treated with NACT.

While the reconstructed breast has proved to appear more natural, the desire for improved breast conservation remains

paramount, with a goal of providing not only the greatest assurance of nipple-areolar function, but to a lesser extent, minimizing the sense of loss by the patient. Adopting techniques from breast reduction, breast surgeons have now expanded their armamentarium in achieving cosmetically desirable lumpectomy. Incorporation of breast reduction or mastopexy with lumpectomy has yielded successful results that translate into improved cosmetic outcome for patients with either macromastia or ptotic breasts. More recently, an array of techniques has been developed that utilize simple reshaping or local tissue transfer to diminish skin retraction post lumpectomy (111). The essential goal of oncoplastic surgery is greater attainment of clear margins, reduced reexcision and mastectomy, and ultimately, improved patient satisfaction and well-being.

SYSTEMIC THERAPY

Cytotoxic chemotherapy and biologic agents against HER2 are commonly given to patients with early- and advanced-stage breast cancer whose disease is either hormone-insensitive (ER- and PR-negative), has developed resistance to endocrine therapy, has high-risk features, including low expression of ER and PR, HER2 gene amplification, high grade or a high proliferative rate, evidence of rapid tumor growth, or, in patients with metastatic disease, has evidence of extensive involvement of one or more vital organs. Concepts that often arise in the discussion of chemotherapy are detailed in Table 27.5. In addition, commonly used agents in the adjuvant and metastatic settings for breast cancer are listed in Tables 27.6 **and** 27.7.

TABLE 27.5 Concepts around Chemotherapy for Breast Cancer

Dose intensity	For many chemotherapeutic agents, higher drug concentrations result in increased killing of cancer cells in vitro (or a dose-response curve). However, it is not entirely clear that increasing dose improves outcomes in breast cancer. For example, high-dose therapy with autologous hematopoietic stem cell transplantation appeared promising in early trials, but this was not borne out in randomized trials and has since been abandoned.
Dose density	The administration of similar or lower doses of one or more agents more frequently. This often allows administration of a higher overall dose of a drug with less toxicity, and also may increase the drug's cytotoxic effects by increasing the likelihood of catching a higher proportion of cancer cells in the most vulnerable phases of their cell cycle.
Non-cross-resistant drug combinations	Using agents, either concurrently or sequentially, with different mechanisms of action, different mechanisms of drug resistance, and, when possible, nonoverlapping toxicities. Switching to a non-cross-resistant drug or regimen may improve response, even when the patient is responding to the initial regimen.

TABLE 27.6 Agents Used in the Treatment of Breast Cancer

Adjuvant or Neoadjuvant Setting	Metastatic Setting
Anthracyclines • Doxorubicin + Cyclophosphamide (AC) • Epirubicin + Cyclophosphamide (EC)	Anthracyclines • Doxorubicin or Epirubicin • Liposomal Doxorubicin
Taxanes • Paclitaxel (weekly, every 2 weeks) • Docetaxel (every 3 weeks)	Taxanes and other Microtubulin Targeted agents • Paclitaxel • Docetaxel • nAb-paclitaxel • Ixabepilone

	• Eribulin • Vinorelbine
Cyclophosphamide (IV)	Cyclophosphamide (Oral)
Fluoropyrimidines • 5-FU in combination with Cyclophosphamide and Methotrexate (CMF)	Fluoropyrimidines • 5FU • Capecitabine
Platinum agents • Carboplatin	Platinum agents • Carboplatin • Cisplatin
HER2-directed agents • Trastuzumab • Pertuzumab	HER2-directed agents • Trastuzumab • Pertuzumab • Ado-Trastuzumab Emtansine • Lapatinib
Endocrine therapy • Tamoxifen • Aromatase inhibitors • GnRH Analogs	Endocrine therapy • Tamoxifen • Aromatase inhibitors • Fulvestrant • GnRH Analogs
	CDK Inhibitors • Palbociclib + Letrozole
	mTOR Inhibitors • Everolimus + Exemestane
	Gemcitabine Etoposide

TABLE 27.7 Acceptable Regimens for Breast Cancer[a]

Doxorubicin + Cyclophosphamide (AC, every 2 weeks)	AC→Paclitaxel (weekly × 12)
AC→Docetaxel (every 3 weeks)	Docetaxel + Cyclophosphamide (TC)
Cyclophosphamide, Methotrexate, 5-Fluorouracil (CMF)	Carboplatin + Docetaxel[b]

[a]All regimens can be combined with trastuzumab for HER2-positive breast cancer treatment.

[b]Typically reserved for HER2-positive breast cancers, in combination with Trastuzumab.

Neoadjuvant Chemotherapy

Preoperative or NACT is the standard treatment for women with locally advanced, unresectable breast cancers and for women with large breast tumors who would require a mastectomy but desire an attempt at breast conservation, unless the patient is too old or frail to tolerate chemotherapy. In LABC, NACT often renders the patient resectable, and sometimes even a candidate for BCS, as well as eradicating occult metastatic disease and improving DFS and OS.

For patients with resectable breast cancer, a 2005 meta-analysis of studies that compared preoperative with identical postoperative chemotherapy demonstrated equivalent DFS and OS and a significant increase in the percentage of patients able to undergo BCS, though the latter was accompanied by a slightly higher risk of locoregional recurrence (112). Updated results from two neoadjuvant trials conducted by the NSABP (B-18 and B-27) reported a trend toward improvement in DFS favoring preoperative chemotherapy, particularly in patients under the age of 50 (113). While

intriguing, these results should be considered more as hypothesis generating than for treatment guidance.

Evaluating Response to NACT

It is clear that patients with chemoresponsive disease, as indicated by the achievement of a pathologic complete response (pCR), have significantly improved outcomes compared to patients with residual invasive disease in the breast and/or axillary nodes; in the meta-analysis discussed above, pCR was associated with 52% improvements in both DFS and OS (112). However, the optimal method to assess response to NACT is controversial.

In patients with visible or palpable disease, response (or lack thereof) can often be assessed on physical examination. Sequential imaging studies (discussed earlier) can usually indicate whether a patient is responding or not, though occasionally clinically "stable" tumors will prove to be largely or totally replaced with fibrous tissue. However, imaging can be relatively insensitive for assessing the breast and axilla for microscopic disease following resolution of any visible tumor mass or abnormal nodes.

The NSABP utilized a definition of pCR that required the absence of invasive disease in the breast, irrespective of the presence of any residual disease in the axillary nodes (113). In addition, others have reported that the presence of residual DCIS in the breast, in the absence of residual invasive disease, had no impact on survival outcomes (114). Despite these reports, it has become clear that persistent disease in the axillary nodes is associated with higher recurrence rates, while conversion from node-positive to node-negative disease with NACT indicates a good prognosis (115). On the basis of these findings, most contemporary US studies use the absence of invasive disease in the breast **and** axilla (ypT0/isN0) as their definition of pCR.

However, one analysis suggests that breast cancer subtype matters when employing a definition of pCR (116). Using a more stringent definition of pCR that included the absence of either invasive or in situ disease in the breast and negative lymph nodes, pCR was found to correlate with prognosis (measured by both DFS and OS) only in patients with more aggressive cancers (e.g., TNBC, ER-/HER2 positive, and atypical ER-positive tumors), but not in those ER-positive (luminal A) breast cancers. Despite the finding that patients with less aggressive cancers were also less likely to obtain a pCR, they had similar outcomes whether or not they achieved one.

Other investigators suggest that extent of residual disease after NACT may be prognostic in the absence of a pCR. European investigators have used a number of scoring systems, the best known of which is the Miller/Payne grading system, to assess post-NACT pathologic specimens for both residual disease and chemotherapy response, and the results of which have been shown to correlate with DFS and OS (117). In the United States, Symmans and colleagues (118) reported that the size and cellularity of residual invasive disease in the breast and number and size of metastatic deposits in the axillary nodes predicted distant recurrence. These variables are incorporated into a formula called the patient's Residual Cancer Burden (RCB). Of interest, patients with minimal residual disease (RCB-I) appear to be at no greater risk of distant disease recurrence than patients with a pCR (RCB-0), while patients with more extensive residual disease (RCB-II and -III) are at much greater risk of recurrence, especially if their tumor is hormone receptor-negative. RCB analyses have been incorporated into a number of NACT studies, both to stratify non-pCR responses and to validate this methodology.

NACT Regimens

A general principle regarding NACT regimens is that chemotherapeutic agents that have proven effectiveness in the adjuvant setting should have similar efficacy against disease in the breast and axillary nodes as well as occult metastatic disease in the neoadjuvant setting. Thus, there is no reason to use different regimens based on when the chemotherapy is given with respect to surgery. The choice of specific chemotherapy drugs and regimens should be based on our understanding of therapy response as related to tumor biology and patient subsets and is similar to the considerations on the approach to adjuvant treatment.

What to do for patients who are not responding to NACT is unknown. In one trial, patients not responding after four

cycles of the anthracycline-based regimen were switched to docetaxel, and while 55% had a clinical response to the taxane, their pCR rate was only 2%, and their 3-year survival was markedly inferior to the responsive patients (119). In the GeparTrio trial, patients who did not respond with at least a 50% reduction in tumor size after two cycles of TAC were randomly assigned to either four more cycles of TAC or four cycles of vinorelbine and capecitabine (NX) every 21 days (120). While both groups of patients had similar clinical response (51%) and pCR (5% to 6%) rates, a recent update of the trial reported that patients switched to NX demonstrated significant (41%) improvement in DFS compared to patients who continued on TAC. Meanwhile, patients responding after two cycles of TAC were randomized to four or six more cycles of the same regimen, and while the longer treatment duration had only a modest impact on the pCR rate (24% vs. 21%), it did result in significant improvement in DFS.

Treatment for patients who go to surgery after NACT and are found to have significant residual disease is based on their tumor type. Patients with ER-positive tumors typically receive adjuvant endocrine therapy, while patients with HER2+ cancers receive trastuzumab. For all others, there is no evidence that administration of additional chemotherapy, sometimes referred to as "adjuvant after neoadjuvant," in a patient who has received both an anthracycline and a taxane in the preoperative setting will reduce recurrences. As such, adjuvant treatment in these patients is usually not recommended.

HER2-Positive Disease

Given the rapid growth kinetics of HER2+ breast cancers, it is not surprising that a significant percentage of patients with these cancers present with large tumors or locally advanced disease, making them good candidates for neoadjuvant therapy. While the percentage of patients with HER2+ cancers who achieve a pCR with NACT alone, especially those with hormone receptor-negative/HER2+ disease, is relatively high, blocking HER2 signaling clearly enhances the chemosensitivity of HER2+ breast cancers. An analysis of two randomized trials demonstrated significant improvements in pCR rates with the addition of trastuzumab to chemotherapy versus chemotherapy alone (RR 2.07, 95% CI 1.41 to 3.03) (121). Combining trastuzumab with chemotherapy was also associated with a reduction in the relapse rate (26% vs. 39%, 95% CI 0.48 to 0.94) and a trend toward improvement in the risk of death (13% vs. 20% mortality rate).

Given concerns about the risk of cardiac dysfunction associated with concomitant administration of an anthracycline and trastuzumab, combining these agents is typically avoided until further data on the safety of that approach becomes available. Our standard neoadjuvant regimen for a HER2+ patient includes four cycles of doxorubicin and cyclophosphamide (AC) administered every 2 or 3 weeks followed by 12 weeks of weekly paclitaxel plus trastuzumab. It is important to remember that following surgery, all patients should then continue on single-agent trastuzumab to complete a full year of the biologic treatment. Other appropriate neoadjuvant regimens for patients with HER2+ cancers include those used in the adjuvant treatment setting (Table 27.6).

There is continued interest in the administration of dual HER2-targeted treatments together with NACT to overcome potential trastuzumab resistance. The NeoAdjuvant Lapatinib and/or Trastuzumab Treatment Optimization (Neo-ALTTO) trial randomly assigned 453 women with stage II–III HER2+ breast cancers to lapatinib 1,500 mg daily, trastuzumab, or the combination of trastuzumab and lapatinib 1,000 mg daily (122). Patients received 6 weeks of HER2-targeted therapy alone, followed by 12 weeks of weekly paclitaxel (80 mg/m^2) along with their assigned HER2-targeted treatment, then underwent surgery. Compared to those patients treated with trastuzumab or lapatanib alone, those who were treated with both drugs experienced a significantly higher clinical response rate at the end of treatment (67% vs. 30% and 52%, respectively), which was confirmed at the time of surgery (80% vs. 71% and 74%). In addition, these patients had a higher pCR rate (51% vs. 30% and 25%), although it was not reflected by the proportion of patients treated with BCS (41% vs. 39% and 43%).

The NeoSPHERE trial was an open-label randomized phase II trial that enrolled 417 women with operable, locally advanced, or inflammatory HER2+ breast cancer and randomly assigned them to 12 weeks of treatment using one of four regimens: docetaxel (100 mg/m^2 every 3 weeks for four cycles) plus trastuzumab (group A), docetaxel plus trastuzumab and pertuzumab (group B), pertuzumab plus trastuzumab alone (group C), or docetaxel plus pertuzumab (group D) (123).

After surgery, patients on the docetaxel arms received three cycles of 5-fluorouracil, epirubicin, and cyclophosphamide (FEC) and completed a year of trastuzumab, while patients in group C received both docetaxel and FEC followed by trastuzumab. The pCR rates were 29%, 46%, 17%, and 24% in groups A, B, C, and D, respectively. Compared to women with hormone-receptor–positive disease, the pCR rates were generally higher in women with hormone-receptor–negative tumors. Serious (grade 3/4) adverse events in patients treated with docetaxel (groups A, B, and D) included neutropenia, febrile neutropenia, and diarrhea. The addition of pertuzumab to the docetaxel plus trastuzumab combination did not appear to increase toxicity, including cardiac adverse events. These results are fascinating not only because of the higher pCR rate seen on the chemotherapy plus trastuzumab and pertuzumab arm, but also because of the frequency of pCRs associated with dual HER2-targeted therapy alone, raising the intriguing possibility that there may be a subset of HER2+ patients who can be effectively treated without the toxic effects of chemotherapy.

Adjuvant Chemotherapy

The Early Breast Cancer Trialists' Collaborative Group (EBCTCG) published an update on the role of adjuvant chemotherapy in early-stage breast cancer in 2012, and for the first time added an analysis of the benefits of the addition of a taxane (paclitaxel or docetaxel), concurrently or sequentially, to anthracycline-based adjuvant chemotherapy (124). In older trials that included a no-chemotherapy arm, administration of anthracycline-based adjuvant chemotherapy reduced breast cancer recurrences by 27%, resulting in an absolute improvement in the 10-year recurrence rate of 8% (39.4% vs. 47.4%), a 6.5% reduction in breast cancer–related mortality, and a 5% improvement in overall mortality. Chemotherapy regimens that included six cycles of cyclophosphamide with standard doses of either doxorubicin or epirubicin and 5-fluorouracil (CAF or CEF) resulted in larger relative improvements in OS (36%) than regimens in which patients received just four cycles of standard-dose doxorubicin or epirubicin with cyclophosphamide (AC or EC) (22%). Compared to nonchemotherapy controls, administration of cyclophosphamide, methotrexate, 5-fluorouracil (CMF) was associated with a 30% relative reduction in breast cancer recurrence (29.6% vs. 39.8%), which resulted in a 6.2% improvement in breast cancer mortality and a 4.7% improvement in overall mortality. All of these results were highly statistically significant due to the large numbers of women involved (8,575 women in the anthracycline-based trials, 5,253 in the CMF trials). The difference in the outcomes for the control groups likely reflects different patient populations, with only 18% of patients treated on the anthracycline-based trials having node-negative cancers compared to 66% on the CMF trials. Benefits from chemotherapy were essentially equivalent across multiple patient subgroups, including age, node status, hormone receptor status, and tumor grade, and administration of adjuvant endocrine therapy (tamoxifen) did not reduce the benefit of receiving adjuvant chemotherapy.

A number of studies have compared anthracycline-based regimens with standard or near-standard CMF. Studies on which patients (9,527 women, of whom 53% were node-positive) received higher cumulative doses of anthracycline (such as six cycles of CAF or CEF) demonstrated superiority of anthracycline-based therapy, with a relative 11% reduction in breast cancer recurrences, corresponding to a 2.6% absolute benefit, a 20% reduction in breast cancer mortality (4.1% absolute), and a 16% reduction in overall mortality (3.9% absolute). In contrast, studies that compared briefer anthracycline-based regimens, such as four cycles of AC or EC to CMF (5,122 women, of whom 61% were node-positive), failed to show improvement in outcomes.

With regard to the benefits of adding a taxane to anthracycline-based adjuvant chemotherapy, the recent meta-analysis identified an overall relative reduction rate in breast cancer recurrence of 14%, breast cancer mortality of 13%, and overall mortality of 11%. Studies in which the taxane was added to an anthracycline regimen of standard duration demonstrated the greatest benefit for the new class of agents, including a 16% reduction in recurrences (4.6% absolute), 14% improvement in breast cancer mortality (2.8% absolute), and 14% improvement in overall mortality (3.2% absolute), while studies in which patients on the nontaxane arm continued on their anthracycline-based regimen to match the duration of treatment of patients assigned to receive the taxane failed to show significant improvements in outcomes. The aggregate results were consistent across age groups, nodal status, and hormone receptor status. In the majority of studies included

in the 2012 meta-analysis, the taxane (whether paclitaxel or docetaxel) was administered q3weeks, thus potentially underestimating the benefits of dose-dense q2week or weekly paclitaxel.

A meta-analysis of 10 trials that compared standard versus dose-dense adjuvant chemotherapy reported that dose-dense treatment was associated with relative improvements in DFS (17% to 19%) and OS (15% to 16%), whether the dose-dense regimen used similar or modified chemotherapy doses compared to the control regimen. However, this difference was seen only in patients with ER-negative cancers (in whom the DFS benefit was 29%), not in patients with ER-positive cancers (8% benefit, which did not reach statistical significance).

HER2-Negative Disease

For patients with hormone receptor-negative (or triple-negative) breast cancer, adjuvant chemotherapy is often indicated, especially if the tumor size is greater than 10 mm, and regardless of nodal status.

However, for patients with hormone receptor-positive disease, the role of chemotherapy should be individualized, taking into account the substantial risk reduction expected from adjuvant endocrine therapy. Genomic tools are now available to identify patients likely to do well with adjuvant endocrine therapy alone from those who would be expected to receive greater relative benefit from the addition of chemotherapy. Of those available, perhaps the one most widely used in the United States is the Onco*type* DX assay, which is a PCR-based array that measures gene expression by mRNA for a total of 16 cancer-related genes, some of which reflect its level of estrogen stimulation (and thus likely sensitivity to endocrine therapies) and some of which correlate with cell proliferation and metastasis (associated with relative insensitivity to endocrine therapies and potential greater benefit from chemotherapy), relative to five "housekeeping" genes. Paik and colleagues (125) demonstrated that the recurrence score (RS) derived from the levels of expression of these genes is both prognostic for risk of recurrence in untreated patients and predictive of degree of risk reduction achieved with endocrine therapy (specifically tamoxifen) and CMF chemotherapy.

The prognostic significance of a low score among patients with node-negative breast cancer was recently shown in a prospective trial in which more than 1,600 patients with a low RS (≤10) were directed toward observation (126). At 5 years, the rate of survival from invasive breast cancer was 94% and greater than 99% remained free from breast cancer recurrence. OS in this population at 4 years was 98%. Further results from this trial will inform the benefits of adjuvant chemotherapy among women with higher RS. More limited data support its use in patients with a limited number (1 to 3) of involved axillary nodes (127), and this is being tested in an ongoing trial, RxPONDER (SWOG 1007, NCT01272037).

MammaPrint is a microarray-based gene expression assay that measures mRNA levels for 70 genes that reflect tumor proliferation, invasion, and angiogenesis. The score derived from this assay has been shown to be prognostic of risk of recurrence in patients with ER-positive, node-negative cancers (128), but it has not yet demonstrated the ability to predict benefit from the addition of adjuvant chemotherapy to endocrine therapy. This assay is also being studied in a prospective clinical trial called MINDACT (Microarray in Node-Negative Disease May Avoid Chemotherapy, NCT00433589), which is designed to determine if patients with ER-positive disease with 0 to 3 involved lymph nodes considered higher risk by clinical features but low risk by MammaPrint can be spared chemotherapy.

Several contemporary clinical trials have broadened the options for adjuvant chemotherapy in women deemed to be at sufficient risk of recurrence. The U.S. Oncology Trial 9735 enrolled more than 1,000 women (greater than 50% with node-positive disease and greater than 70% with ER-positive disease) and randomly assigned treatment with AC or docetaxel and cyclophosphamide (TC) every 3 weeks for four cycles (129). At a median of 7 years' follow-up, TC remained superior to AC, with a 26% improvement in DFS, which translated into a 6% absolute increase, and a 31% rise in OS (5% absolute benefit). The DFS benefit was apparent independent of age, nodal status, and hormone receptor status (though not statistically significant in the subgroups). Short-term toxicities were comparable across the two arms of the study, but four patients on the AC arm have died of possible late complications of treatment, one with congestive heart failure and three with leukemia or myelodysplasia. Though of relatively modest size, this study has had a major impact on the treatment of patients with low- to intermediate-risk disease in the United States, presumably due to the appeal of

avoiding exposure to an anthracycline without (apparently) sacrificing efficacy. In the NSABP B-38 trial, almost 5,000 women with node-positive, early-stage breast cancer were randomly assigned to one of three regimens: dose-dense AC followed by dose-dense paclitaxel (AC-T), dose-dense AC followed by paclitaxel plus gemcitabine (AC-TG), or a three-drug combination of docetaxel plus AC (TAC) (130). There were no significant differences in either DFS or OS at 5 years between any of the regimens. However, TAC was associated with significantly higher rates of febrile neutropenia (9% vs. 3% with AC-T and AC-TG). The regimens with paclitaxel, on the other hand, were associated with higher rates of neuropathy.

HER2-Positive Disease

The goal of HER2-directed therapy is to block this activation, which also has the effect of enhancing sensitivity to other antitumor treatments. It is now widely indicated in the adjuvant context based on seminal results from three randomized trials that consistently demonstrated substantial improvements in DFS and OS with the addition of trastuzumab during or after standard adjuvant chemotherapy (Table 27.8) (131–135).

TABLE 27.8 Adjuvant Trials in HER2-Positive Breast Cancer

Trial	Regimens	N	DFS (vs. Control)	OS
NCCTG 9831 NSABP B-31	Chemotherapy[a] + Tr vs. Chemotherapy alone	4,045[b]	HR = 0.69 (95% CI, 0.57 – 0.85)	HR = 0.67 (95% CI, 0.48 – 0.93)
HERA	Chemotherapy[c] followed by Tr[d] (1 year) vs. Chemotherapy alone	5,090	HR = 0.76 (95% CI, 0.43 – 0.67)	HR = 0.76 (95% CI, 0.47 – 1.23)[e]
BCIRG 006[f]	AC→D Tr vs. Carboplatin + D + Tr vs. AC→D	3,222	HR = 0.61 (95% CI, 0.48 – 0.76) HR = 0.67 (95% CI, 0.54 – 0.83)	HR = 0.59 (95% CI, 0.42 – 0.85) HR = 0.66 (95% CI, 0.47 – 0.93)

BCIRG, Breast Cancer International Research Group; D, Docetaxel; HERA, Herceptin Adjuvant trial; NCCTG, North Central Clinical Trials Group; NSABP, National Surgical Breast and Bowel Project; Tr, Trastuzumab.

[a]In both studies, treatment was administered for 52 weeks. All patients received four cycles of doxorubicin 60 mg/m2 and cyclophosphamide 600 mg/m2 (AC) every 3 weeks followed by paclitaxel (T), administered at 80 mg/m2 weekly for 12 weeks (NCCTG), or either 80 mg/m2 weekly for 12 weeks or 175 mg/m2 every 3 weeks for four cycles (NSABP). All patients on NSABP B-31 started Tr concurrent with paclitaxel; one-third of patients on NCCTG study started trastuzumab concurrent with paclitaxel; the rest started it sequentially, after completing paclitaxel.

[b]The results were reported as a joint analysis of both studies.

[c]In HERA, less than 25% received both an anthracycline and a taxane.

[d]Patients randomly assigned to Tr were further randomly assigned to 1 versus 2 years of therapy. There was no difference between 1 or 2 years of trastuzumab therapy.

[e]Results are reported with Tr for 1 year. They are confounded by cross-over; 52% of patients on observation ultimately were treated with Tr.

[f]Results of the second interim analysis are presented.

For HER2+ patients in whom chemotherapy is recommended, and provided they have no contraindication to administration of an anthracycline (no characteristics suggesting an increased risk of significant cardiotoxicity), we administer doxorubicin plus cyclophosphamide for four cycles (AC) followed by weekly paclitaxel for 12 weeks. We administer trastuzumab weekly with paclitaxel, but once completed, trastuzumab is administered every 3 weeks to complete 1 year. For patients with any contraindication to treatment with an anthracycline, or for those who, after discussing treatment alternatives, opt not to receive an anthracycline, combining trastuzumab with a nonanthracycline

regimen, such as docetaxel plus carboplatin (TC) is an option.

Given concerns about the incidence of cardiotoxicity seen in patients with HER2+ MBC who received both an anthracycline and trastuzumab, and the demonstrated synergy between trastuzumab and a variety of chemotherapeutic agents in vitro, the Breast Cancer International Research Group (BCIRG) 006 trial was designed to test the efficacy and toxicity of a nonanthracycline–based chemotherapy regimen plus trastuzumab against a standard anthracycline-based chemotherapy regimen with or without trastuzumab (Table 27.8) (131). The use of carboplatin alongside docetaxel and trastuzumab (TCH) was associated with a lower rate of congestive heart failure (0.4%) compared to arms containing doxorubicin (0.4% vs. 0.7% and 2% with AC→D or AC→DTr, respectively), and was also associated with a lower likelihood of a sustained drop in left ventricular ejection fraction (9.4% vs. 11.2% and 18.6%, respectively). In addition to reducing cardiac toxicity, dropping the anthracycline reduced vomiting and mucositis, and appeared to markedly reduce, if not eliminate, the small but real risk (0.33% in patients on AC-T or AC-TH) of developing a treatment-related leukemia.

As with patients treated with anthracyclines, all patients receiving trastuzumab should have cardiac function evaluated prior to starting chemotherapy and prior to starting trastuzumab, after which cardiac monitoring should be individualized based on patient age, baseline ejection fraction, and risk factors for developing cardiac dysfunction. At our institution, we utilize echocardiograms for this purpose. Guidelines from the National Comprehensive Cancer Center Network can be used to modify or hold treatment based on changes to cardiac function (136).

Whether patients with a small HER2+ breast cancer (i.e., less than 1 cm) require treatment (especially 1 year of trastuzumab) is not clear, and there are no randomized data to inform this. The best data come from a single-arm trial that enrolled more than 400 patients with HER2+ tumors (48% of whom had a tumor less than 10 mm in size) treated with single agent paclitaxel weekly for 12 weeks plus trastuzumab (for a 1-year treatment duration) (137). With 4 years of follow-up, the 3-year rates of overall and recurrence-free survival were excellent at 99% for each end point. When evaluated by tumor size (using 10 mm as a cutoff) they did not find a difference in outcomes. While these data do not definitively indicate that patients with small tumors should receive treatment, it does offer support for it in patients who desire adjuvant therapy.

Metastatic Disease

HER-2 Negative Disease

As noted previously, chemotherapy is appropriate treatment for patients with MBC that is hormone-insensitive (ER- and PR-negative) or refractory (having progressed on one or more endocrine therapies), displays aggressive biology (rapid disease progression or early recurrence following adjuvant or neoadjuvant therapy), or is associated with significant symptoms or evidence of extensive or rapidly progressive involvement of vital organs (most often the liver or lungs), which is referred to as visceral crisis. Choice of chemotherapeutic agent or combination of agents depends upon the extent and biology of the patient's disease, her age, performance status and comorbid medical conditions, timing and extent of prior treatment, and her doctor's willingness to accept the risks of various toxicities as a tradeoff for antitumor efficacy, with the understanding that her condition is not curable and that differences in survival with various approaches are modest at best. Common agents used in MBC are listed in Table 27.6.

A 2013 meta-analysis compared combination versus single-agent chemotherapy in this setting and found that there was no difference in OS associated with either approach, even when analyzed by line of chemotherapy, schema of treatment, and dose intensity (138). Interestingly, in an analysis for progression-free survival (PFS; 8 trials, 866 women), combination therapy was significantly associated with a higher risk of progression compared to single-agent treatment (HR 1.16, $p = 0.01$). Combination therapy resulted in significantly higher overall response rates (RR 1.13, $p = 0.008$), but at the expense of a higher rate of febrile neutropenia (RR 1.32, $p = 0.01$).

HER-2 Positive Disease

For women with HER2+ MBC, the optimal first-line regimen is not known, as few have been tested in randomized trials. While taxane-based regimens remain commonly administered, some doctors and patients will opt for regimens not usually associated with hair loss, such as vinorelbine-, gemcitabine-, capecitabine-, or liposomal doxorubicin-trastuzumab. Combinations of chemotherapeutic agents given with trastuzumab may (paclitaxel and carboplatin vs. single agent paclitaxel) or may not (docetaxel and carboplatin vs. single agent docetaxel) produce higher RR and improved time to progression (TTP), but have not been shown to improve OS (139,140).

When a patient has achieved maximal benefit from a chemotherapy-trastuzumab combination or starts to develop cumulative toxicities, she is often switched to single-agent trastuzumab "maintenance" therapy, a logical strategy given the level of activity of single-agent trastuzumab, but this approach has not been tested in a randomized trial. What is clear is that HER2+ patients progressing on treatment retain sensitivity to HER2-targeted therapies. For example, in one study that included patients who had progressed on trastuzumab and randomly assigned to capecitabine with continuation of trastuzumab versus capecitabine alone, combination treatment resulted in a superior TTP (8.2 vs. 5.6 months) and OS (25.5 vs. 20.4 months) (141). Even before these results became available, it had been routine practice in patients with HER2+ MBC who were progressing on one chemotherapy-trastuzumab combination to change the cytotoxic agent but continue trastuzumab.

In addition to trastuzumab, lapatinib has modest single-agent activity in patients with HER2+ MBC who have progressed on trastuzumab; however, in patients previously treated with an anthracycline, taxane, and trastuzumab, the combination of capecitabine and lapatinib bested single-agent capecitabine in terms of TTP (6.2 vs. 4.3 months) and OS (75.0 vs. 56.4 weeks) (142).

For these patients, dual HER2-directed agents may also play a role. In one trial, women with HER2+ MBC who had progressed on one or more trastuzumab-containing regimens were assigned to treatment with single-agent lapatinib versus lapatinib and trastuzumab (143). Patients on the combination arm had a superior clinical benefit rate (24.7% vs. 12%), improved TTP (12 vs. 8 weeks), and a nonsignificant improvement in OS (52 vs. 39 weeks). In the CLEOPATRA trial, 808 HER2+ patients with treatment-naïve MBC received docetaxel plus trastuzumab and were also randomly assigned to pertuzumab or placebo (144). Patients assigned to the dual targeted agents had improved RR (80% vs. 69%), PFS (19 vs. 12 months), and a trend toward improved OS. The addition of pertuzumab was associated with higher rates of diarrhea, mucositis, rash, and febrile neutropenia (14% vs. 8%), but no increase in cardiac toxicity.

Duration of Treatment

The optimal duration of treatment with chemotherapy in MBC is unknown. In general, studies of more prolonged administration of chemotherapy have demonstrated prolongation of TTP but little or no improvement in OS, often associated with increased toxicity and inferior quality of life. A meta-analysis of 11 trials, which compared fixed duration chemotherapy with treatment to disease progression, confirmed prolongation of PFS, with a modest increase in OS. In practice, treatment is often administered until a response plateau is reached (based on imaging studies or tumor marker), development of bothersome cumulative toxicities, or the patient requests a treatment break. In patients with hormone receptor–positive disease, an effort to delay disease progression by initiating some novel (to the patient) form of endocrine therapy is reasonable, though this is not supported by any objective data. Whether to resume chemotherapy as soon as there is evidence of disease progression or to wait until the patient begins to have symptoms is not known, and best left to a joint decision between the patient and her physician.

CHAPTER 28 Management of Infections in Patients with Gynecologic Malignancy

Amar Safdar, Kenneth Rolston and Donald Armstrong

Patients with gynecologic cancer are susceptible to infections. The risk of developing an infection can arise from a number of factors that may be related to the neoplasm and antineoplastic therapy, or both. Tumor encroachment and invasion of adjacent structures, necrosis of expanding tumor mass, surgical tumor excision and removal of internal organs including lymph nodes, and diversion procedures that disrupt protective barriers in the lower and upper female reproductive tract are some of the factors. Patients with these malignancies may also be susceptible to a host of infections due to the presence of drug- or radiation-induced mucositis, severe neutropenia, long-term sequelae of prior abdominopelvic radiation therapy, and the presence of indwelling foreign devices (1,2).

The wide spectrum of causative microorganisms most frequently arise from endogenous vaginal, urethral, and intestinal tract colonization with bacteria and Candida species. The normal aerobic and anaerobic vaginal bacterial flora may be altered in patients undergoing antimicrobial and antineoplastic therapy. Among factors that influence changes in colonization are hormonal dysfunction, alteration in the composition of mucosal secretions including innate immune functions, frequent exposure to broad-spectrum antimicrobial agents, antineoplastic drug and radiation therapy, instrumentation, and prolonged, often multiple hospitalizations. In a recent report, however, patients receiving external-beam radiotherapy for gynecologic malignancy did not experience changes in aerobic microflora in the vagina, cervix, or rectum (3,4). Whereas significant growth in vaginal yeast species occurred during the first 2 weeks after radiation therapy commenced, *Candida albicans* and *Candida tropicalis* were most prominent. The increase of vaginal growth in *Candida* species returned to preradiation levels after 4 weeks (5). Exposure to health care facilities, especially centers that care for immunocompromised oncology patients, has been recognized as a major influence, albeit transient in most instances, in promoting changes in cutaneous, orointestinal, and genitourinary microflora. The changes in vaginal and lower urinary tract microflora occur less commonly, even following repeat exposure to the hospital environment, and are often limited to patients who undergo instrumentation. The health care–associated microorganisms are frequently less susceptible to commonly prescribed antibiotics, and optimum selection of antimicrobial drugs poses a daunting challenge. It is, however, important to appreciate that changes in a host's microflora are in most cases transient, and restitution of normal intestinal and vaginal flora occurs once factors promoting the change have been removed.

The female genital tract is rich in anaerobic microflora. Peptococcaceae are prominent in the normal vaginal bacterial flora. Quantitative vaginal cultures in recent studies showed that anaerobic bacteria outnumbered aerobic bacteria by nearly 10:1; peptococci, *Lactobacillus*, *Corynebacterium*, *Eubacterium*, and *Bacteroides* species are frequently isolated (6). *Escherichia coli*, *Klebsiella* species, and *Enterobacter* species are the aerobic gram negatives, and streptococci, enterococci, and coagulase-negative staphylococcus are gram-positive bacteria isolated from the lower female genital tract. These organisms provide an important reference to local and invasive infections seen in patients undergoing treatment for gynecologic malignancy.

This chapter provides an overview of infections encountered in patients receiving treatment for cancers involving the female reproductive system. A detailed review of specific diseases such as postsurgical abdominopelvic infections, febrile neutropenia, and bacteremia is presented. A focused discussion regarding the changing epidemiology of causative organisms, the increasing rate of infection due to drug-resistant organisms, and an update on new antimicrobial agents is briefly provided.

PATIENTS WITH FEVER

The factors that increase the risk of infection are shown in Table 28.1. Knowledge of underlying predisposing factor(s) is necessary in the selection of appropriate empiric therapy. Antibiotic prophylaxis and/or recent treatment with broad-spectrum antimicrobial drugs have been associated with the risk of infection(s) due to nondrug-susceptible microorganisms, including systemic candidiasis. Awareness of specific cancer and cancer therapy–associated risks, and the host's underlying immune dysfunction, may allow for proper selection of empiric antibiotic therapy in critically ill patients prior to the results of diagnostic microbiologic and radiographic studies being known. It is important to note that patients with gynecologic cancer may have a high risk of polymicrobial infections due to the presence of physiologic microflora resulting from anatomic proximity to the lower intestinal and urinary tracts. In certain infections, such as deep tissue abscess, cellulitis in patients with chronic fistula tract, presence of large necrotic tumor, and history of multiple recent instrumentations, the probability of polymicrobial infection remains high (7). Furthermore, in patients with a known anaerobic bloodstream infection, concurrent bacteremia due to aerobic organism(s) is not uncommon (7). Patients with advanced cancer, history of radiation therapy, and extensive pelvic surgery may develop obstruction to the pelvic venous and lymphatic flow. The aberration in physiologic/anatomic defenses and stagnation heightens the risk of cellulitis, abscess formation, and septic thrombophlebitis. Furthermore, these factors also unfavorably influence response to antimicrobial therapy. Several comprehensive cancer centers and other institutions that care for large numbers of patients with cancer have developed infectious disease consultative services with a special interest and expertise in infections seen in this high-risk patient population. Table 28.2 provides a breakdown of the various infectious and noninfectious causes prompting infectious disease consultation requests from the gynecologic oncology clinical service at the MD Anderson Cancer Center.

TABLE 28.1 Predisposing Risk Factors and Infections in Patients with Gynecologic Tumors

Tumor related
Obstruction of gastrointestinal or urinary tract
Erosion into bowel, urinary tract, peritoneum, or retroperitoneal space
Necrosis of rapidly growing cancer promotes abscess formation
Lymphatic obstruction
Surgery
Aspiration pneumonia
Hospital-acquired pneumonia, including ventilator-associated pneumonia
Wound infection; skin, and skin structure infection
Tissue necrosis due to disruption of blood supply
Infected hematoma
Fistula tract communication between intestinal and urinary tracts

Complicated peritonitis
Septic deep thrombophlebitis
Fasciitis, myositis, and gas gangrene are rare complications
Chemotherapy
Febrile neutropenia
Pneumonia
Neutropenic enterocolitis
Radiation therapy
Enteritis
Urinary tract infection
Poor wound healing
Catheter and implantable devices
Device infection
Peritonitis
Bloodstream infection
Urinary tract infection

TABLE 28.2 Infectious Diseases Consultations Performed for the Gynecologic Oncology Clinical Service at MD Anderson Cancer Center, Houston, Texas[a]

Reason for Consultation	Number (%)
Intra-abdominal/pelvic abscess	43 (11)
Surgical wound infection	41 (10)
Complicated urinary tract infection	38 (10)
Neutropenic fever	36 (9)
Pneumonia	35 (9)
Unexplained fever (including tumor fever)	35 (9)
Bacteremia	32 (8)
Diarrhea (including C. difficile associated)	30 (8)
Nonspecific cutaneous eruption (rash)	21
Leukocytosis/leukemoid reaction	19
Infection with MDR organism[b]	16
Fungemia	11
Varicella-zoster infection	5
Meningitis	2
Miscellaneous[c]	9

[a]Consultations performed by K.R. from January 2001 to December 2011.

[b]MDR—multidrug resistant, defined as resistance to three or more different classes of antimicrobial agents, included cellulitis, wound breakdown/dehiscence.

[c]Included travel and other immunizations.

TUMOR-RELATED INFECTIONS

Tumor-associated infections are dependent on the anatomic site, type, and extent of tumor involvement. In patients with an early stage of locally involved cancer such as stage I cervical cancer, most infections remain localized to the vagina, whereas in patients with advanced cervical cancer, infections may involve the uterus, fallopian tubes, ovaries, and other deep pelvic structures and retroperitoneum. Infections may present as tubo-ovarian or deep pelvic abscess, endometritis, and less frequently pyometra (Figs. 28.1–28.3). Extension of these infections to adjacent structures may present as ascending pyelonephritis, rectal abscess, and complicated peritonitis. These are often serious, requiring surgical debridement or intervention by invasive radiology (8,9). It is also important to note that an infection may be the primary presentation of an undiagnosed malignancy involving the female reproductive tract. In a study of postmenopausal women who presented with tubo-ovarian abscess, nearly half of these patients were subsequently diagnosed with a gynecologic malignancy (10). Therefore, a thorough investigation of possible underlying cancer should be considered in postmenopausal women or those without sexually transmitted diseases who present with tubo-ovarian abscess or pyometra.

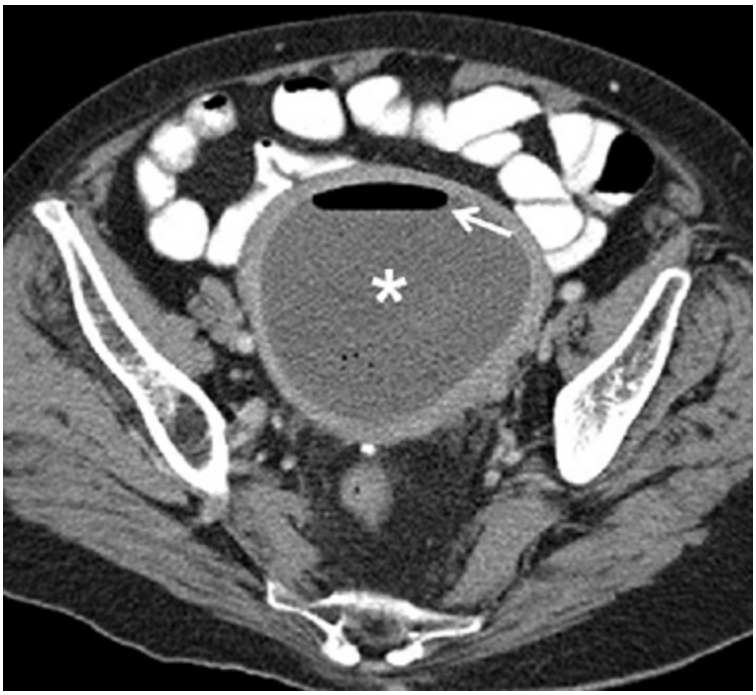

Figure 28.1 A 73-year-old woman with endometrial cancer presented with pelvic pain, fever, and vaginal bleeding. Axial CT scan performed with enteric and IV contrast demonstrates a markedly distended endometrial cavity containing fluid (asterisk). Air is also present, with an air-fluid level (arrow). In a febrile patient, this is highly suggestive of infection/endometritis. At D&C, blood and pus were drained from the uterine cavity, compatible with pyohematometra.

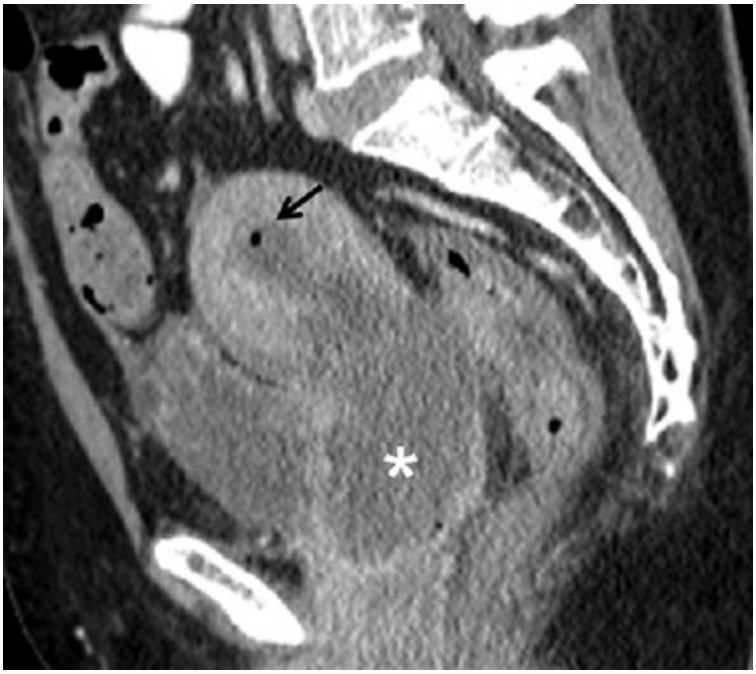

Figure 28.2 A 46-year-old woman with cervical cancer presented with pelvic pain and fever. Sagittal contrast-enhanced CT image demonstrates a large cervical mass (asterisk). There is obstruction of the endometrial cavity, which is mildly distended and contains fluid and air (arrow), compatible with infection/pyometra.

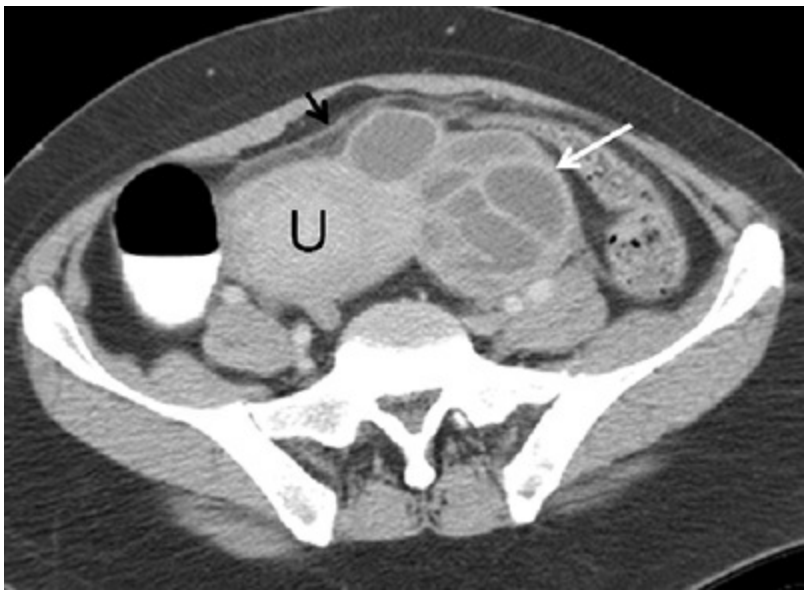

Figure 28.3 A 40-year-old woman with cervical cancer presented with fever and left lower quadrant pain and was diagnosed with tubo-ovarian abscess. Axial contrast-enhanced CT scan demonstrates a complex, multiloculated mass with thick septations (white arrow) to the left of the uterine fundus (u). There are inflammatory changes in the pelvic fat (black arrow).

In a large study conducted at the M. D. Anderson Cancer Center in the 1970s, septicemia, pneumonia, and peritonitis in patients with gynecologic cancer were associated with high infection-associated mortality (11). In the last two decades, in patients at an increased risk for infections, early diagnosis, identification of factors associated with poor treatment outcome, empiric therapy with new-generation broad-spectrum antimicrobial drugs, advances in antineoplastic and target-centered radiation therapy, and improved surgical techniques have substantially improved outcomes. The recent favorable

outcomes for serious systemic bacterial and *Candida* species infections are in most part due to the availability of well-tolerated broad-spectrum antimicrobial drugs. The recent emergence and spread of multidrug-resistant (MDR) organisms, however, may mitigate these advances, such that the treatment course of patients with solid-organ cancer with limited immune suppression, life-threatening septicemia, pneumonia, peritonitis, and abdominopelvic infections may mimic those of the antibiotic nascent era (11).

SURGERY-RELATED INFECTIONS

Patients undergoing surgery for cervical cancer have a higher rate of infectious complications, compared with patients with endometrial cancer who tolerate surgery better and have fewer infections during the early and late postoperative period (12). Pelvic exenteration is performed in patients with advanced and/or treatment-refractory cervical and upper reproductive tract malignancies. Infections remain as serious complications following pelvic exenteration; early postsurgical wound infection and wound dehiscence are not uncommon (13,14). Urinary tract infections frequently occur in patients with urinary fistula and/or in those who develop urethral obstruction. Studies show that greater than 40% of patients undergoing pelvic exenteration for gynecologic and rectal cancer had urinary tract infection, wound dehiscence, or both (13). Late infections such as ascending pyelonephritis may be serious, as they frequently recur and are seen in patients with usually irreparable structural damage to the urinary reservoir such as neobladder, stenosis of urethra, or surgical anastomosis site. Ureterointestinal fistula, stones in the urinary reservoir, and surgical, radiation, or chronic/recurring infection/inflammation-induced narrowing all contribute to increased risk of infections. Unless the anatomical abnormality is corrected, these patients remain at increased risk for recurrent urinary tract infections and complications arising from prolonged systemic antibiotic therapy and repeat hospitalizations.

In a recent large study of over 6,854 patients undergoing surgery for gynecologic cancer at the Cleveland Clinic, the overall frequency of surgical site infection (SSI) was 5.4%. The rate of SSI was 7% in patients undergoing laparotomy, which was three and a half times higher than the rate of SSI following minimally invasive surgery ($p < 0.001$) (15). In those patients who had a laparotomy, independent predictors of SSI included: (a) diagnosis of endometrial cancer, (b) obesity, (c) the presence of ascites, (d) anemia, and (e) perioperative blood transfusion. Furthermore, patients with American Society of Anesthesiologists class ≥3 and those who underwent more complex surgical procedures also had a higher rate of SSI. Significant risk factors for deep tissue or organ SSI were hypoalbuminemia, preoperative weight loss, respiratory comorbidities, complex surgery, and the need for perioperative blood transfusion. Patients who developed SSIs had a significantly longer hospital stay and higher rates of reoperation, development of sepsis, and wound dehiscence. The risk of acute renal failure or 30-day mortality, however, was not adversely impacted by the presence of SSIs in these patients.

In cases of surgically related, suspected infection, empiric therapy includes adequate coverage for possible polymicrobial infection. The choice should include drugs that provide adequate coverage for enteric coliforms, enterococci, including vancomycin-resistant *Enterococcus* species, especially in patients who have known prior intestinal or genitourinary tract colonization due to these drug-resistant bacteria and/or are receiving care at centers with known high prevalence for these pathogens (16). As most infections in this setting may also have an anaerobe as a copathogen, even in patients with negative microbiologic evidence of anaerobic infection, antibiotic selection should entertain unisolated anaerobic bacteria. We recommend secondary suppressive antimicrobial therapy in patients with recurrent deep pelvic infection to reduce morbidity and subsequent hospitalization and surgeries. It is critical to select high-risk patients judiciously so patients are not given prolonged courses of broad-spectrum antibiotics, which is the single most important factor in promoting selection for or less commonly development of *de novo* drug-resistant bacteria and fungi.

Infections remain the main concern in patients following radical vulvar resection and inguinal lymph node dissection. In 67 patients undergoing 112 inguinal lymphadenectomies, early postoperative cellulitis was noted in nearly one-third, and early surgical wound breakdown also occurred in over 20% (17).

Wound Infection

Infected surgical wounds in patients following female genital tract surgery include *Staphylococcus aureus*, including MDR or semisynthetic methicillin-resistant *S. aureus* (MRSA) obtained from health care microflora (health care-associated; HA) or community-acquired (CA) MRSA, which has now become the leading source of MRSA infections in the United States and globally. *Streptococcus* species (group A, B, C, non-Enterococcus D and G) are also common pathogens in this population. Nearly one-third of infections, especially those with involvement of the lower intestinal tract and urinary tract, are less likely to be monomicrobial.

In certain subpopulations of patients who have been receiving systemic corticosteroids for extended periods, patients with morbid obesity, malnutrition, **cancer-related cachexia,** and poorly controlled diabetes mellitus have a higher risk of developing postoperative wound infections. Coagulase-negative *Staphylococcus*, *Streptococcus* species, *S. aureus*, enteric gram-negative bacteria, and *Bacteroides* species are potential pathogens.

Patients who have a complicated hospital course following surgery may develop infections due to organisms acquired from the health care microenvironment. In critically ill patients, infections are treated empirically, and the spectrum of causative organism(s) may not be available at the time of medical decision making. Knowledge of regional and institutional prevalence of drug-resistant organisms is required in prescribing an appropriate treatment regimen. The empiric therapy in patients with prolonged hospitalization and anatomic abnormalities such as enterouretheral, entero- or rectovaginal, or enterovesicular fistula increases the probability of recurrent infection due to resistant HA–gram-negative bacteria such as *Pseudomonas* species, extended-spectrum beta-lactamases and carbapenemases producing Enterobacteriaceae, including *E. coli* and *Klebsiella pneumoniae*. Other nonfermentative gram-negative bacteria like nosocomial *Acinetobacter* spp. and *Stenotrophomonas maltophilia* are often resistant to a wide variety of commonly used broad-spectrum antibiotics; successful treatment for MDR bacterial disease remains a consternating task (18,19).

Intra-abdominal and Pelvic Abscess

An infected collection within the peritoneal cavity may develop as a consequence of breach in the physical barriers resulting from tumor progression and tumor necrosis and may also occur in patients undergoing instrumentation, or as a consequence of reconstructive surgery and implantation of prosthetic devices. The secondary seeding of the intraperitoneal tumor mass in patients with bloodstream infection arising from a different primary source, such as the urinary tract, or antineoplastic therapy–induced orointestinal mucositis or indwelling vascular device may also occur. The spectrum of causative organisms includes enteric bacteria such as *E. coli*, *Enterococcus*, *Staphylococcus* species, *Bacteroides*, and other anaerobes. *Candida* species infection is less frequent in non-neutropenic patients, although patients with high yeast counts in multiple body sites referred as high *Candida* colonization index, exposure to prolonged broad-spectrum antibiotics, poorly controlled diabetes mellitus, systemic corticosteroid use, as well as stay in critical care units and presence of foreign devices may increase the risk for tissue-invasive candidiasis.

Hematogenous or direct seeding of the retroperitoneal space may lead to paraspinal and psoas abscess; these infections escape early detection, as patients may not have high-grade fever, and increase in chronic low back pain remains subject to interpretation. In the absence of a direct extension from the intestinal or urinary tract, these retroperitoneal infections are usually monomicrobial; diagnosis requires prompt computed tomography (CT) or magnetic resonance imaging (MRI) scans and aspiration of the infected collection (Figs. 28.4 **and** 28.5). In tuberculosis endemic regions, *Mycobacterium tuberculosis* must be considered in determining the etiology of these infections, especially in patients in whom the vertebral column is involved.

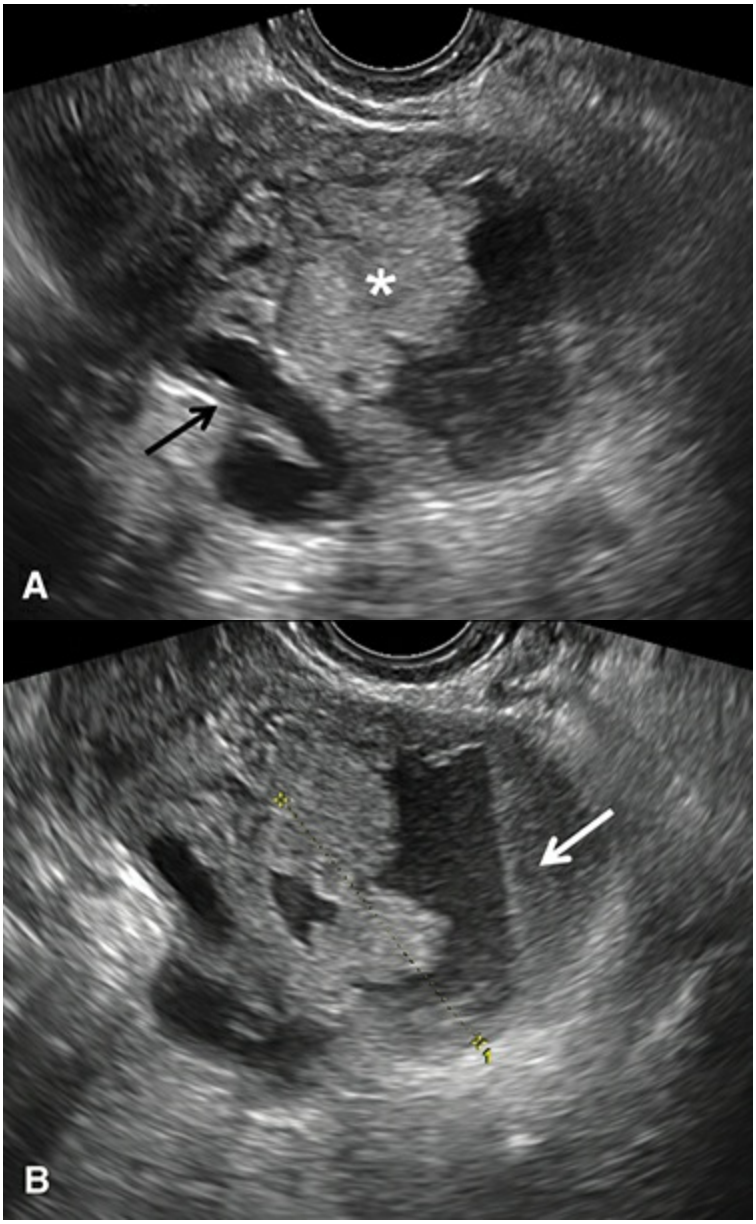

Figure 28.4 A 52-year-old woman with fallopian tube carcinoma initially diagnosed as tubo-ovarian abscess. She presented to the emergency department with left lower quadrant pain and fever. A: Transvaginal ultrasound demonstrates a complex left adnexal mass with a tubular configuration of fluid-filled component (arrow) and a solid component (asterisk). B: Additional image demonstrates fluid-debris level within this mass (arrow). Initially, this was thought to represent a tubo-ovarian abscess; however, the patient had no risk factors for pelvic inflammatory disease. At surgery, fallopian tube carcinoma was found.

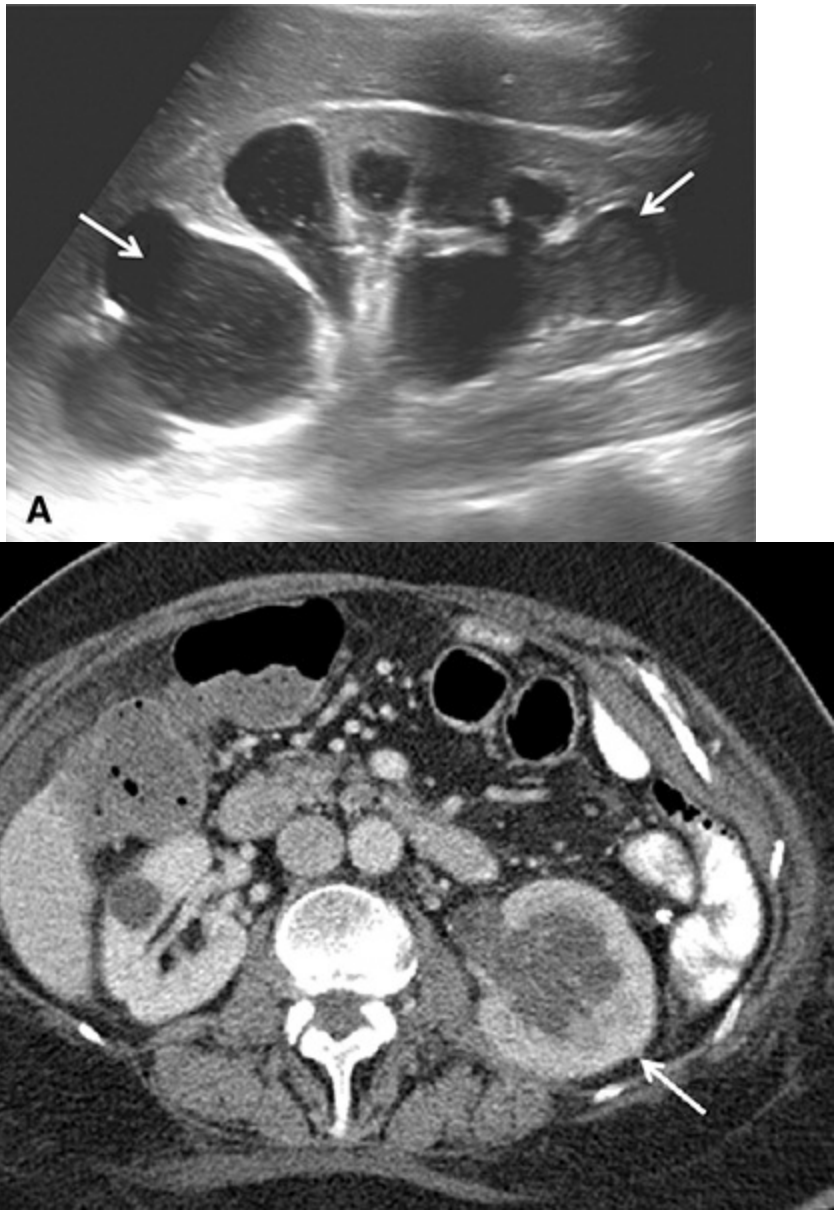

Figure 28.5 A 48-year-old woman with cervical cancer presented with left flank pain and fever. A: Sagittal gray-scale ultrasound image of the left kidney demonstrates marked hydronephrosis compatible with ureteral obstruction secondary to the patient's cervical neoplasm. There is echogenic debris present in the dilated collecting system (arrows) compatible with pus in the setting of pyonephrosis. B: Axial contrast-enhanced CT scan in the same patient demonstrates the enlarged left kidney with hydronephrosis (arrow). There is a delayed nephrogram compared with the right, compatible with obstruction. The left nephrogram is also heterogeneous and there is perinephric inflammatory change compatible with pyelonephritis. The right kidney is normal with the exception of a small cyst.

Pelvic abscesses that develop after instrumentation or following surgery are often polymicrobial, and treatment is directed toward normal intestinal tract and cutaneous microflora (20).

Peritoneal infections following bowel perforation, anastomotic leaks, or fistula tracts may present with fever, abdominal pain, and fistula drainage and/or surgical wound dehiscence. Most infections, as expected, are polymicrobial and Enterobacteriaceae, *S. aureus*, *Streptococcus*, and *Enterococcus* species, including vancomycin-resistant strains, are frequently encountered. *Bacteroides fragilis* and *Clostridium* species are common anaerobes; *Fusobacterium*, *Peptostreptococcus*, and *Eubacterium* occur less commonly. Patients with peritoneal infections following surgery involving

the nonsterile bowel and lower genitourinary tract may also have an increased risk for *Pseudomonas* species infection involving the deep pelvic and lower abdominal tissue and/or organs.

CHEMOTHERAPY AND RADIATION-RELATED INFECTIONS

Patients receiving chemotherapy may have an increased risk of infection; neutropenia for less than a week increases risk of systemic bacterial infections due to *S. aureus*, *Pseudomonas*, *E. coli*, and other coliform bacteria. Patients who remain neutropenic for longer than 5 to 7 days are also at an increased risk for developing tissue-invasive *Candida* species infection (1,2). Disruption of orointestinal and genitourinary tract mucosa compromises an important barrier in the prevention of bacterial and fungal invasion. In patients with severe treatment-induced mucositis, α-hemolytic streptococcal and anaerobic septicemia may lead to devastating consequences including rapidly progressive multiorgan failure, disseminated intravascular coagulation, hemodynamic collapse, and death (21).

Radiation therapy in patients with vulvar, vaginal, and cervical cancer causes microvascular damage to the tissue and may lead to difficult-to-treat intestinal, vaginal, and urologic complications.

Increased doses of radiation for gynecologic cancer have been associated with improved cancer-free survival (22). However, with increased radiation dose, the rate of complications has also risen (23). Noninfectious complications arising from high-dose radiotherapy include damage to the organs in the radiation field, including necrosis of tissue and bone; fistula formation, enteritis, proctitis, aseptic degenerative arthritis of pelvic and sacroiliac joints increase the risk of pathologic fracture. Radiation-induced fibrosis may result in vaginal, rectal, and ureteric stenosis and predisposes to secondary infection due to stagnation and inadequate physiologic drainage (24). In rare cases, patients with radiation-induced necrosis of pelvic bones may present with osteomyelitis; for these patients, a challenging and multifaceted treatment approach is needed for successful outcomes (25). A patient with osteomyelitis in the setting of radiation-induced bone necrosis may need extensive surgical debridement and an appropriate selection of antibiotics for a prolonged period. The excisional defects create additional complexity due to placement of autologous or cadaveric biologic graft prosthetics. A high clinical suspicion remains critical in the timely diagnosis of radiation-related infectious and noninfectious complications.

Bacteremia

Most hematogenous bloodstream infections in adult neutropenic cancer patients are due to coagulase-negative *Staphylococcus*, viridians streptococci, *E. coli*, *Pseudomonas aeruginosa*, and *S. aureus* observed in a prospective case-controlled study (26). In patients with solid-organ cancer, *E. coli* and coagulase-negative *Staphylococcus* account for nearly 40% of bacteremia, whereas *Pseudomonas*, *S. aureus*, and enterococcal bloodstream infections account for 10% or less, each (27). *Klebsiella* species, other Enterobacteriaceae, and *S. maltophilia* are of serious concern and may become prominent bloodstream infections in certain geographic regions.

Cancer patients with bacteremia who present with extensive tissue involvement/infection are significantly less likely to respond to antimicrobial therapy (28). Other factors associated with poor prognosis in bacteremic adult patients with an underlying malignancy include shock, infection due to MDR bacteria, and *Pseudomonas* and *Clostridium* species infection (28).

Bacteroides and *Clostridium* species are the most frequent cause of anaerobic bacteremia, which is most frequently seen in patients with abdominal and pelvic malignancy (28,29). In cancer patients with nonsporulating anaerobes, bacteremia, *B. fragilis*, and *Fusobacterium* are isolated more frequently compared with *Peptostreptococcus* and *Eubacterium* species (30). Polymicrobial infections are more frequent in patients with anaerobic bacteremia compared with aerobic bacterial infections. *E. coli*, *Pseudomonas*, *Klebsiella* species, and among gram-positive cocci *Streptococcus*, *Enterococcus*, and *Staphylococcus epidermidis*, may accompany anaerobic bloodstream infection (30). Concurrent

candidemia is uncommon in patients with bacteremia due to anaerobic bacteria, unless patients (a) have a high *Candida* colonization index, (b) have an indwelling intravascular catheter, (c) are receiving care in a critical care unit, (d) have poorly controlled diabetes, (e) have parenteral nutritional support, or (f) have severe and prolonged treatment-induced neutropenia. Over 90% of patients with nonsporulating anaerobic bacteremia may also have a deep tissue abscess (30). The authors suggest that all patients with gynecologic malignancy who present with anaerobic bacteremia be thoroughly evaluated for an infected abdominopelvic or pelvic collection, which may not be clinically apparent at the time of initial presentation.

Hematogenous *Clostridium* species infection is often seen in patients with gastrointestinal or genitourinary cancer, and acute leukemia (31). Nearly one-third of patients with bacteremia with *Clostridium* species alone and nearly half with polymicrobial infections present with septic shock (31). *Clostridium perfringens* is a common species, and *Clostridium septicum* is uncommon, although serious *C. septicum* infections are seen in patients with intra-abdominal neoplasms (31,32). Diffuse, rapidly spreading cellulitis involving the abdominal wall, groin, and upper thigh area, gas gangrene, and acute intravascular hemolysis indicate the possibility of clostridial infection (33). Early appropriate therapy remains critical in improving response and outcome for patients with deep tissue anaerobic infection with or without accompanying bacteremia.

Febrile Neutropenia

The organisms associated with infections in patients with neutropenia are shown in Table 28.3. *Pseudomonas* spp. is a well-recognized cause of serious systemic infections in febrile neutropenic patients. The other nonfermentative gram-negative bacteria such as *S. maltophilia* have emerged and present as life-threatening pneumonia, bacteremia, or deep tissue infection; these infections are commonly resistant to standard broad-spectrum antipseudomonal antibiotics, and despite appropriate therapy, response may remain suboptimal (18). Patients with peripheral absolute blood neutrophil counts of less than 500 have significantly higher risk of serious infection, especially if the duration of neutropenia is more than 5 to 7 days (1,2). During the first 5 days of neutropenia, bacterial infections are prominent; if neutropenia extends beyond a week, invasive candidiasis becomes a concern; and in patients with greater than 2 weeks of profound neutropenia, invasive mold infections such as aspergillosis may occasionally be encountered. In most patients with gynecologic malignancy, isolation of a mold even from sterile samples does not indicate invasive fungal disease; in patients with no known established predisposing factors (31), these saprophytic molds usually represent colonization or laboratory contamination (34).

TABLE 28.3 Microorganisms Commonly Associated with Infection in Neutropenic Patients

Gram-negative organisms
Escherichia coli
Klebsiella spp.
Pseudomonas aeruginosa
Stenotrophomonas maltophilia
Enterobacter spp.
Gram-positive organisms
Staphylococcus spp. including vancomycin-tolerant organisms
Staphylococcus aureus
Coagulase-negative Staphylococcus such as S. epidermidis and S. saprophyticus
β-Hemolytic streptococci, group A, B, G

α-Hemolytic streptococci (viridans streptococcus spp.)
Enterococcus spp. including vancomycin-resistant strains
Fungia
Candid[a] spp. including C. albicans, C. glabrata, C. tropicalis, and C. parapsilosis

[a]Patients receiving multiple courses of fluconazole therapy or prolonged antifungal suppression or prophylaxis are at higher risk for infections due to drug-resistant C. glabrata and C. krusei.

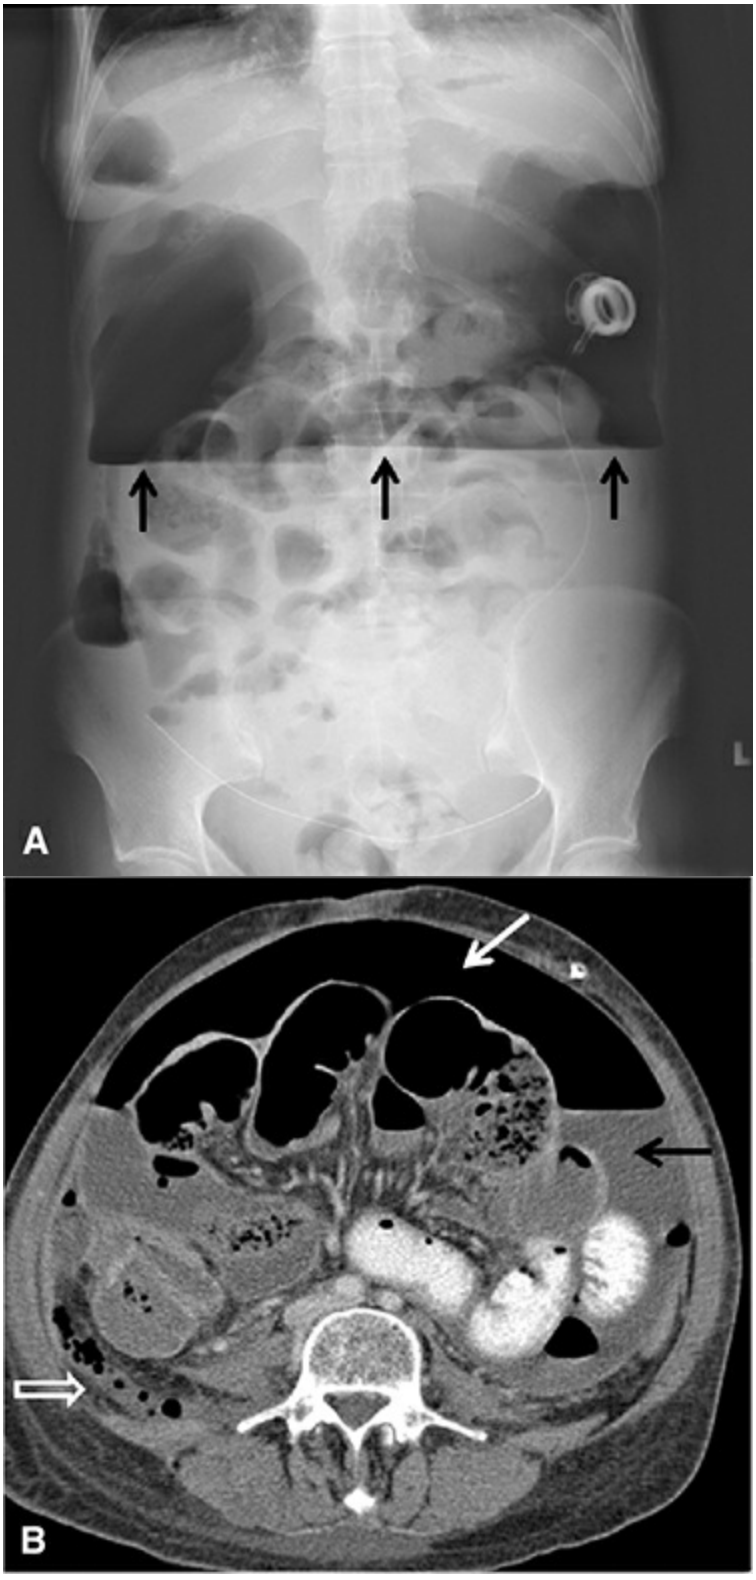
Catheter-Related Bloodstream Infection

In patients with solid-organ cancer, nearly 70% of gram-positive bacteremia is associated with an infected indwelling vascular catheter; similarly, 60% of gram-negative bacteremia is also related to an infected catheter, whereas only 19% of gram-negative bacteremia in patients with hematologic cancer is due to an infected catheter (35). Coagulase-negative *Staphylococcus* remains the most commonly isolated microorganism in blood cultures drawn from an indwelling central venous catheter and is frequently regarded as catheter-related bloodstream infection. Similarly, *S. aureus*, including MRSA bacteremia, may result from an infected indwelling catheter, and successful therapy requires selection of antimicrobial agents that penetrate the biofilm and are effective against the sessile nongrowth stationary phase of the bacteria (36). *S. aureus* bloodstream infections are associated with high rates of complications (37). Patients with solid-organ cancer with catheter-related *S. aureus* bacteremia have a fivefold higher probability of developing intravascular complications such as septic thrombosis and, less commonly, infective endocarditis (37).

Patients with gynecologic malignancy have a higher rate of postoperative infection, catheter malfunction, and unplanned catheter removal following external intravascular catheters compared with subcutaneous/implantable venous access devices (38,39). Nearly one-third of all intravascular catheters were associated with delayed complications in this cancer population; bacteremia was significantly more common in patients with nonimplantable (Hickman catheters) compared with implantable indwelling intravenous devices such as infusaport or peripheral access system ports (40).

IMPLANTABLE DEVICE INFECTIONS

Peritoneal, hepatic, and pleural implantable devices for delivering chemotherapy or drainage of recurring malignant effusions have been successfully used in the last two decades. These devices are well tolerated; major complications including bowel perforation are uncommon, and serious infections are seen in less than 5% of cases (41–46). Overall, infections are seen in less than 20% of cases. While serious infections, including pocket infections, are seldom noticed, when these do occur they should be treated aggressively, with prompt removal of the infected reservoir and appropriate systemic antimicrobial therapy (41) (Fig. 28.6). Abdominal pain and chemotherapy-related discomfort remain the main problems associated with these chemotherapy infusion devices.



A
B

Figure 28.6 A 53-year-old woman with recurrent papillary serous carcinoma of the ovary with serosal bowel implants undergoing intraperitoneal chemotherapy presented with abdominal pain, vomiting, and fever. A: Upright abdominal radiograph demonstrates large amounts of free intraperitoneal air with air-fluid level due to the presence of ascites fluid (arrows). Multiple dilated air-filled loops of bowel are noted. Intraperitoneal chemotherapy infusion catheter is in place with port in the left upper abdomen. These findings are compatible with perforated viscus. B: Axial contrast-enhanced CT scan in the same patient demonstrates a large amount of free intraperitoneal air (white arrow) and ascites fluid (black arrow). There are multiple dilated loops of bowel. There is a mottled gas collection in the right lower quadrant posterior to the cecum (open white arrow). At surgery, perforated cecum was confirmed. C: Large loculated fluid and gas-containing collection in the pelvis is compatible with an abscess (asterisk). The chemotherapy infusion catheter is visualized at the posterior wall of the abscess (black arrow).

Urinary Tract Infection

Patients with gynecologic cancer have an increased risk of urinary tract infection. The factors that promote infections are listed in Table 28.4. Nearly one-third of patients, while undergoing pelvic radiotherapy for gynecologic cancer, may have symptoms of urinary tract infection at the onset of therapy or develop infection during the course of radiation therapy (47). Despite appropriate treatment, infections may recur and require several courses of antibiotic therapy (47). Patients who have undergone pelvic exenteration remain at increased risk for ascending urinary tract infection (14); recurrent pyelonephritis in these patients leads to an increased risk of scarring and permanent renal damage. Older patients with advanced gynecologic and urologic malignancies are now being considered for pelvic exenteration surgery (48). In these and other patients with lower renal reserves, a severe episode of pyelonephritis may precipitate irreversible renal failure, prompting prolonged renal replacement therapy. We suggest that in selected high-risk patients, preemptive antimicrobial therapy or even secondary antibiotic prophylaxis be considered after an episode of urinary tract infection, especially pyelonephritis.

TABLE 28.4 Factors Promoting Urinary Tract Infections

Tumor obstruction
Retrograde urine flow leading to ascending pyelonephritis
Stagnation in patients with outlet obstruction and abscess formation

Instrumentation
Cystoscopy-related introduction of pathogens
Dilatation of strictures
Foreign body
Urethral stent
Percutaneous nephrostomy tube placement/replacement[a]
Surgical drains for extended duration
Radiotherapy
Inflammation of bladder mucosa
Suppression of local innate cellular and acellular immune response
Surgery
Urinary diversions
Organ resection
Lymph node dissection
Anastomotic leak
Chronic surgical wound breakdown
Chemotherapy
Neutropenia
Suppression of local immune surveillance and response to bacterial invasion
Mucosal damage and disruption

[a]Patients undergoing routine replacement of percutaneous nephrostomy tubes may develop transient bacteremia in the event of prior colonization.

ANTIMICROBIAL AGENTS

It is important to refer to the spectrum of local and regional drug resistance among commonly encountered pathogens in selecting appropriate antimicrobials, especially when treatment is initiated empirically, or in patients awaiting microbiologic drug susceptibility results.

SURGICAL ANTIMICROBIAL PROPHYLAXIS

Operative Site

Guidelines for the administration of antibiotics to uninfected patients undergoing pelvic surgical procedures were first proposed by Ledger et al. in 1975 (49). Prophylactic antibiotics are indicated for women undergoing pelvic surgery for malignancy. There have been few studies evaluating this prophylaxis in such cases. Recently, cefazolin was shown to be inferior to cefotetan as a single-dose prophylaxis in women undergoing elective abdominal hysterectomy (50). A placebo-controlled trial showed that using a broad-spectrum cephalosporin plus beta-lactamase inhibitor significantly reduced the

risk of major operation-site infection from 27% in patients not given antimicrobial prophylaxis, whereas none of the patients given antibiotic developed operative-site infection (51).

The overall postoperative infection rate has been as high as 46%, and SSI is seen in nearly one-fourth of patients (52). The risk of postoperative infection is adversely affected by prolonged duration of surgery >5 hours, presence of remote infection at the time of surgery, and duration of hospitalization longer than 3 weeks; in patients with all three risk factors, the relative risk of infections increases to 7.3%, compared with 3% in patients who have only one of these risk factors (52). Risk factors that have been associated with an increased incidence of infection in patients undergoing surgery for reproductive tract neoplasms include lower socioeconomic status, preoperative colonization, failure to administer perioperative heparin, obesity, advanced patient age, a longer operative period, and a longer hospital stay prior to surgery (53,54). Extent of surgery plays a central role in predicting probability and severity of postoperative infections (12–14,54). However, these risk factors were not have not been uniformly reported by investigators.

Clinical Investigation

The overall operative-site infection rate after gynecologic surgery ranges from 6.7% to 44%. One study reported that patients with preoperative cervical colonization did not have an increase in postoperative complications such as duration of hospitalization, operative time, or febrile episodes compared with patients in whom no cervical colonization was demonstrated (55). An overall decrease in significant postoperative infections with the utilization of preoperative antimicrobial prophylaxis was reported in retrospective studies among patients undergoing radical hysterectomy (56,57). The benefit, however, was thought to be associated only with reduced local wound infections (58).

Prospective data have not resolved this issue. The numbers of patients in comparative studies have been small, and the data may therefore be inadequate for detecting a statistically significant difference in infection rates. Rosenshein et al. noted no significant difference in overall operative-site infection after preoperative prophylaxis (59), an observation shared by Marsden et al (60). In contrast, significantly lower incidences of infection following preoperative antimicrobial prophylaxis were reported by Sevin et al. (61) and Micha et al. (62). Sevin et al. reported that a short course (three doses) of prophylaxis was as effective as a long course consisting of 12 doses in preventing major infection after radical hysterectomy (63). If separate operative-site data from prospective studies are combined, the overall incidence of pelvic infection and wound infection was significantly reduced by the administration of prophylactic antimicrobials.

A cost–benefit analysis of three doses of cefazolin antimicrobial prophylaxis showed a 29% reduction in infectious morbidity following vaginal hysterectomy, and an 18% reduction in postoperative infections in patients following abdominal hysterectomy (64).

One patient population that has a significant surgical incision breakdown includes women undergoing radical vulvectomy. Anecdotal experience indicates that the principal pathogens are *S.aureus* and *S. epidermidis*. Not unexpectedly, the administration of broad-spectrum medications, such as piperacillin or mezlocillin, failed to significantly reduce the incidence of postoperative wound infection; 8 of 12 women undergoing radical vulvectomy for vulvar carcinoma who were given single-dose piperacillin or mezlocillin developed postoperative infections (65). We recommend a *Staphylococcus* active antimicrobial for women undergoing radical or modified vulvectomy for vulvar carcinoma. Drain sites fall into the same category. The foreign body undoubtedly contributes to the infections; in our opinion, local attention, rather than broad-spectrum parenteral or oral antibiotics, is the appropriate preventive approach.

AGENT ADMINISTRATION

Intravenous administration of antibiotics is recommended to achieve high serum and tissue drug concentration, and should be given before anesthesia. Antibiotics for women undergoing hysterectomy for benign indications are administered by suppository, by spray, and orally, with significant reduction in operative-site infection (66–68). There are no similar data

for women undergoing hysterectomy for gynecologic cancer, and these routes of administration are presently not advised.

Timing of Drug Administration

The first dose of an antibiotic should be given intravenously in the operating room. Combination regimens and prolonged administration did not appear to offer superior infection prevention when compared with that provided by a single agent given once. If the interval between the first dose and opening of the vagina exceeds 2.5 to 3 hours, a second intravenous dose should be given 15 to 30minutes before the anticipated vaginal entry. This conclusion is based on data provided by Shapiro et al. (69). This has not been clinically studied, but administration at longer fixed intervals has not enhanced protection at hysterectomy for benign indications. In cancer patients who are expected to undergo a prolonged surgical procedure (>4 hours), the dose may be repeated after 4 to 6 hours.

Recommendations

Intravenous administration of 2 g cefazolin should be given in the operating room. Cefazolin provides activity against gram-negative and gram-positive aerobic and anaerobic bacteria; it is an uncommon therapeutic agent and is comparatively inexpensive—beneficial attributes for a prophylactic antibiotic. A single dose of a prophylactic agent did not result in the selection of a resistant species, as did three doses of antibiotics at hysterectomy for benign disease (70). A 1-g dose may suffice, but 2 g was superior to 1 g for vaginal hysterectomy, and three 1-g doses over 16 hours were statistically inferior to a single 2-g dose for cesarean delivery (71). A single dose (1 g) of cefotetan was significantly ($p < 0.05$) superior to 1 g of cefazolin in preventing operative-site infection after elective abdominal hysterectomy for benign diagnoses. The high drug acquisition cost was offset by an overall reduction in hospital costs, owing to fewer infections and shorter hospital stays in patients given cefotetan compared with cefazolin (72). Kobamatsu et al. also found superior protection for women undergoing radical hysterectomy when using expanded-spectrum cephalosporins compared with first-generation agents (73). Other alternatives include ampicillin–sulbactam, although there is little evidence to support this practice; similarly, metronidazole as a single agent may be less effective at preventing infection compared with broad-spectrum cephalosporin agents (74). More prospective data are necessary in patients with gynecologic cancer undergoing surgery.

If the patient is allergic to cephalosporins, or has a history of a type I immediate hypersensitivity reaction to a penicillin, and if she is not allergic to a tetracycline, the recommendation is 100mg doxycycline orally at bedtime the night before surgery, and again on the day of surgery about 3 hours before departure for the operating room. This regimen has been evaluated prospectively in Parkland Memorial Hospital in a nonrandomized study using very few patients and no control regimen. If the woman is allergic to tetracycline, the recommendation is intravenous administration of 900 mg of clindamycin given preoperatively, as for cefazolin. The new generation of fluoroquinolones such as moxifloxacin may be particularly suited for the gynecologic cancer patient scheduled for pelvic surgery because of its aerobic and anaerobic spectrum of antibacterial activity and extended drug half-life. Prospective, controlled studies are needed.

BOWEL PREPARATION

Unobstructed Bowel

In elective gynecologic surgical cases in which no bowel surgery is anticipated, such as a hysterectomy and staging procedure for endometrial cancer, most centers do not utilize a mechanical bowel preparation. However, in more complex cases such as ovarian cancer cytroreduction and pelvic exenteration in which opening or resection of the intestine is likely, the use of mechanical bowel preparation is still used in many centers. There are approximately 10^{11} bacteria in a gram of

feces, making sepsis a major hazard if the colon is opened. It is desirable to reduce the patient's normal colonic microflora to diminish the postoperative infection rate in case it is necessary to perform a colonic resection and reanastomosis. Preparation for colonoscopy is a regimen of clear liquids the day before surgery and 3 tablespoons of Fleet Phospho-Soda in one-half cup of cool water at 4:00 PM and 6:00 PM the day before surgery. Patients should be cautioned to drink eight to ten 8–fluid ounce glasses of clear liquids the day before surgery. Additional clear fluid is acceptable. Some surgeons prefer to add a Fleet enema 2 hours before surgery. An alternative mechanical preparation is whole gut irrigation with chilled polyethylene glycol and electrolyte therapy or a similar lavage solution given orally at a rate of approximately 1 L/h until the rectal effluent is colorless, but for not more than 4 hours.

A recent large cohort, multicenter, randomized trial has placed routine mechanical bowel preparation practice into serious question; in patients who underwent elective colorectal surgery, no difference in anastomotic leak or other septic complications such as fascia dehiscence were noted in the group of patients who had preoperative bowel preparation versus those who did not (75). Enhanced recovery pathways have been proposed internationally to hasten surgical recovery through the attenuation of the stress response. Nelson and colleagues recently reviewed the literature on "enhanced recovery" pathways (ERPs) in gynecologic oncology to assess its efficacy (76). The Enhanced Recovery After Surgery (ERAS) Society was contacted to identify any unpublished protocols. Seven investigations were identified. Common interventions included allowing oral intake of fluids up to 2 hours before induction of anesthesia, solids up to 6 hours before anesthesia, carbohydrate supplementation, intra- and postoperative euvolemia, aggressive nausea/vomiting prophylaxis, and oral nutrition and ambulation the day of surgery. In addition, mechanical bowel preparations, the nil per os (NPO) after midnight rule, nasogastric tubes, and intravenous opioids were not utilized. While no randomized data are available in gynecologic oncology, significant improvements in patient satisfaction, length of stay, and cost were observed in ERP cohorts compared with historic controls. Morbidity, including infectious morbidity, mortality, and readmission rates were no different between groups. Given the above data, the benefit of mechanical bowel preparation in complex cases, such as ovarian cancer cytroreduction and pelvic exenteration, is becoming more and more controversial.

Preoperative oral antibiotics are still recommended by many authorities. In the antimicrobial approach, 1 g each of erythromycin and neomycin is given orally at 1:00 PM, 2:00 PM, and 11:00 PM the day before surgery. This regimen was initially proposed in 1971 by Nichols and Condon (77). An alternative is 1 g each of metronidazole and neomycin at 2:00 PM and at 11:00 PM the day before surgery. There should be no need to add further antimicrobial prophylaxis to 2 g of cefazolin or other agents.

Obstructed Bowel

There can be no mechanical prophylaxis for preoperative management of the obstructed bowel. Treatment principles include fluid and electrolyte therapy with mechanical decompression of the bowel from above and timed surgical intervention. Women with mechanical intestinal obstruction immediately after surgery may respond to conservative treatment with decompression only. If necessary, surgery should be performed within 24 hours of the mechanical obstruction; these patients have the lowest mortality rate. A dose of intravenous antibiotic should be given in the operating room before the procedure, with a second dose given in the recovery room, and a third dose 8 hours later if it is necessary to enter the bowel lumen. The single-agent or combination regimen should provide broad coverage of both gram-positive and gram-negative aerobic and anaerobic bacterial species with a broader spectrum of antibacterial activity than with cefazolin. Evaluation has produced no evidence for a superior regimen. A single agent usually suffices unless the patient is septic, in which case antibiotic combination is appropriate because therapy, not prophylaxis, is necessary.

BUNDLED INTERVENTIONS

A recently described approach in many surgical subspecialties to decrease SSIs is the use of "bundled" interventions. In

this setting, a “bundle” is defined as a set of evidence-based practices performed collectively with the goal of reducing 30-day SSIs. Johnson and colleagues recently reported their outcomes with prospectively implementing a perioperative SSI bundle of sterile closing tray and staff glove change for fascia and skin closure, dressing removal at 24 to 48 hours, dismissal with 4% chlorhexidine gluconate, and follow-up nursing phone call (78). This bundle was added to their prior established (preintervention) elements of patient education, 4% chlorhexidine gluconate shower before surgery, antibiotic administration, 2% chlorhexidine gluconate and 70% isopropyl alcohol coverage of incisional area, and cefazolin redosing 3 to 4 hours after incision. The overall 30-day SSI rate was 38 of 635 (6.0%) among all cases in the preintervention period compared with 2 of 190 (1.1%) in the postintervention period. Overall, the relative risk reduction in SSI was 82.4% (p = 0.01). Many, if not all, of the bundled interventions have been incorporated in many centers to minimize SSIs after gynecologic oncology surgery.

CLINICAL SYNDROMES

Peritonitis and Intra-abdominal Abscess

Etiology

Infection in the patient with pelvic cancer most commonly involves the pelvis and abdomen. The potential causes of infection include complications of the primary tumor, surgery, and antineoplastic therapy including radiation and chemotherapy. The tumor can compromise the integrity of the vaginal wall and allow seeding of endogenous vaginal flora into the pelvic and peritoneal cavities. Previous antibiotics, radiation therapy, and the tumor itself may alter the normal genital flora. The tumor can also erode into the bowel and allow entry of fecal material into the peritoneal cavity. Rare cases of several other syndromes arising from untreated pelvic tumor, including spontaneous clostridial gas gangrene and pneumoperitoneum, have been reported (79). Peritonitis, with or without abscess formation, may occur postoperatively after hysterectomy or with bowel injury. Radiation therapy to the pelvis can cause radiation enteritis, leading to a chronic diarrheal syndrome, which may develop years after radiation therapy is completed. These patients are also at higher risk for bowel adhesions and subsequent obstruction, and subclinical perforation may present as late insidious intra-abdominal or deep pelvic abscess. Macro- and micronutrient **malabsorption** in patients with chronic diarrheal state may enhance susceptibility to severe systemic infections and extenuate the healing process.

Signs and Symptoms

In the patient with pelvic cancer, peritonitis may develop at any time, including at initial diagnosis (e.g., tumor infiltration of bowel), immediately postoperatively, or days or weeks after surgery (e.g., tumor infiltration or radiation therapy). The signs are generally dramatic and familiar: abdominal pain, fever, and signs of peritoneal irritation. However, among postoperative patients or patients who have received radiation or corticosteroid therapy, the physical findings may resemble those typical of a routine postoperative patient, making the diagnosis more difficult. To ensure proper diagnosis, frequent physical examinations and CT scan should be obtained early in the course of the disease.

Abscess formation can also occur in several settings. In some patients, a subclinical microperforation of the bowel is successfully walled off by the body’s immune system, forming a pericolic or intraperitoneal abscess. This has been shown to occur 7 to 10 days after microperforation (80). Fever or mechanical obstruction may be the only presenting sign. Subphrenic, psoas, or liver abscesses may present as a fever of unknown origin and may require a methodical, diligent evaluation for diagnosis. A fistula, usually caused by tumor but also occurring postoperatively, may form between any two organ systems, including the bladder, vagina, bowel, or skin. Persistent suppuration despite therapy or the presence of a

feculent discharge from the skin, bladder, or vagina may suggest the development of a fistula.

Diagnosis

The diagnosis of peritonitis is usually made on clinical grounds. In patients who have clinical evidence of peritonitis but are unable to undergo surgery because of bulky tumor, multiple prior surgeries, or general debility, paracentesis with appropriate cultures may be useful in guiding antibiotic therapy. Radiologic investigation is generally required to diagnose an abscess. Regular plain x-ray films of the abdomen are seldom revealing. A sonogram, CT scan, or MRI of the abdomen may show the collection (Figs. 28.7 **and** 28.8). A gallium scan may also be helpful. In a particularly confusing case in which abnormalities of scans can represent an abscess, metastatic tumor, or postoperative changes, a labeled leukocyte scan may be needed to diagnose the abscess with certainty; presently, however, these scans are seldom used due to inconsistent results and the fact that several days are required to complete the process.

Figure 28.7 A 58-year-old woman with metastatic ovarian cancer presented with fever, abdominal pain, and elevated peripheral white blood cell count. Coronal contrast-enhanced CT scan showed multiple loculated fluid collections in the abdomen and pelvis (asterisk) with central displacement of small bowel loops. There is thickening and enhancement of the peritoneal reflection (arrows). These findings could be seen with either peritoneal carcinomatosis or peritonitis. Aspiration of the fluid was compatible with infection and peritonitis.

Figure 28.8 A 65-year-old woman with recurrent cervical cancer and fistula tract with rectum. A: Axial CT image performed with enteric contrast shows the large recurrent mass in the midline pelvis (black arrow). There are mottled collections of gas and enteric contrast present within this mass (white arrows) suggesting fistulization with bowel. B. Slightly more inferior image demonstrates the contrast-filled rectum (arrow) partially encased by the mass. This was the site of fistulization.

The diagnosis of a fistula requires demonstration of abnormal drainage from one organ system to another. This can be shown by intravenous or intravesical injection of dye for fistulae arising from the bladder, oral or rectal instillation of dye

for those arising from the gastrointestinal tract, or a fistulogram for a fistula involving the skin (Fig. 28.9).

Figure 28.9 A 61-year-old woman with recurrent fallopian tube carcinoma and carcinomatosis status post exploratory laparotomy, partial small bowel resection presented with draining anterior abdominal wall wound. Axial CT scan performed with enteric and IV contrast demonstrates a loop of small bowel adherent to the anterior abdominal wall with enteric contrast-containing tract within the abdominal wall soft tissues (black arrows). There is a contrast-containing collection in the overlying subcutaneous soft tissues. These findings are compatible with enterocutaneous fistula. Additional intraperitoneal abscess is noted (white arrow).

In all cases, laboratory abnormalities, including an elevated leukocyte count, reactive thrombocytosis, an elevated erythrocyte sedimentation rate, C-reactive protein, and abnormal liver function tests, may suggest the diagnosis and direct the workup. The microbiologic diagnosis in each of these syndromes requires culture for aerobes and anaerobes. Blood cultures are only rarely positive. Some patients may have an unexplained bacteremia of enteric aerobic gram-negative rods or anaerobes. This is probably from a microperforation of the bowel. Any patient with pelvic tumor and enteric gram-negative rods or anaerobic bacteremia should be radiologically evaluated for evidence of perforation.

Therapy

Acute, generalized peritonitis where gastrointestinal perforation is suspected usually requires urgent surgery to irrigate the peritoneum and repair any perforation. Broad-spectrum antibiotic coverage with agents such as cefoxitin, ticarcillin–clavulanic acid, piperacillin–tazobactam; metronidazole, clindamycin with ampicillin, and an aminoglycoside such as tobramycin or amikacin is generally effective for the polymicrobial infection. Addition of aminoglycosides is particularly important for patients who have been recently or frequently hospitalized or who have had past courses of antibiotics. These situations predispose the patient to the development of resistant organisms.

Effective treatment of an abscess requires drainage. Percutaneous drainage is adequate in many cases, but laparotomy is occasionally required. Large or persistent abscesses may require placement of a suction drain. Patients with fistulae

often require resection of the involved tissue.

For intra-abdominal infection, intravenous antibiotics directed at the recovered bacteria should continue for at least 10 to 14 days after drainage. Some patients who have been on antibiotics may have evidence of pus but no growth on cultures. In this situation, broad-spectrum antibiotics directed at enteric gram-negative rods and anaerobes should be administered. Laboratory parameters such as leukocyte counts should be followed to determine the exact duration.

Patients who are inoperable can be treated with chronic suppressive therapy, intravenously or orally. Oral agents such as amoxicillin–clavulanic acid (875 mg bid) or clindamycin (450 mg q 6 to 8 hours) may be effective. Ciprofloxacin, moxifloxacin, or levofloxacin alone should not be used in this situation because they provide limited coverage for *Enterococcus* species.

Patients with infections due to vancomycin-resistant enterococci and/or vancomycin-tolerant (81) *Streptococcus* or *Staphylococcus* species may be treated with daptomycin (6 mg/kg daily) or linezolid (600 mg twice daily), usually in combination with drugs with gram-negative and anaerobic activity. Tigecycline may also be used as an alternative; it has broad-spectrum antimicrobial activity including promising *in vitro* results against MDR bacteria such as extended-spectrum beta-lactamase-positive *E. coli*, MDR *Acinetobacter*, *S. maltophilia*, carbapenemases producing *K. pneumoniae*, vancomycin-resistant enterococci, and MDR *S. aureus*. There are limited clinical data for its use in patients with gynecologic malignancy, and due to poor activity against *Pseudomonas* species it should be used cautiously in neutropenic patients and those with prior invasive pseudomonal invasive disease or known bacterial colonization. Furthermore, emergence of drug-resistant bacteria or selection of less-susceptible organisms remains a concern for widespread use of drugs with broad-spectrum antimicrobial coverage. Similarly, antipseudomonal carbapenems such as imipenem-cilastatin and meropenem should also be reserved for seriously ill patients with polymicrobial infection, as emergence and spread of MDR gram-negative bacteria are increasing in immunosuppressed cancer patients (82). Ertapenem, a carbapenem without antipseudomonal activity, was as effective as piperacillin-tazobactam for the treatment of acute pelvic infection (83) and can be administered as a single daily dose, albeit due to lack of enterococcal coverage, it is important to select patients carefully.

Urinary Tract Infection

Etiology

Many clinical situations predispose a patient to urinary tract infection. Urinary tract infection continues to be the leading cause of infectious morbidity in this population. One study showed that half of the patients with pelvic cancer admitted to the hospital because of infection had a urinary tract infection; *E. coli* was the most common organism isolated (84). Another report found that the frequency of urinary tract infections is increased as much as threefold in patients undergoing pelvic irradiation (22–24). Many patients who undergo pelvic surgery require prolonged bladder catheterization, usually with a Foley catheter. These patients may develop the well-recognized infectious complications of chronic bladder catheterization, the most common of which is recurrent infection. In addition, tumor can cause urinary obstruction and subsequent infection. The role of antiseptic or antibiotic-impregnated urinary catheters has not yet been defined.

Signs and Symptoms

Some patients with gynecologic malignancy and urinary tract infection have the familiar clinical picture of dysuria, fever, flank or suprapubic tenderness, elevated leukocyte count, and abnormal urinalysis. In many others, these signs and symptoms are obscured by the rest of the clinical picture. For instance, a postoperative patient may be expected to have abdominal tenderness, an elevated leukocyte count, and fever. The physician should consider the entire clinical setting before embarking on a course of therapy.

Diagnosis

Diagnosis is generally made on the basis of a urine culture, from a "clean catch" or through a catheter, but the initial urinalysis is extremely helpful. Pyuria is expected in any nongranulocytopenic patient with a urinary tract infection. Gram stain of urinary sediment can direct antibiotic therapy in advance of the culture results. A common problem confronting the physician is when patients, especially those with indwelling catheters or nephrostomy tubes, have positive urine cultures but do not appear to be ill. Differentiating colonization from invasive infection is frequently not simple and requires clinical judgment. Any patient who is not severely neutropenic should also have pyuria along with positive urine cultures. The absence of pyuria in a patient with a positive urine culture suggests the likelihood of simple asymptomatic **bacteriuria**. From a practical standpoint, in a clinically stable patient, it is reasonable to withhold antibiotics pending repeated urinalysis and urine culture. If an organism persists, therapy may be considered.

Therapy

Therapy should be based on the sensitivity pattern of the recovered organism. Intravenous antibiotics are reserved for patients with drug-resistant bacteria and those with systemic infection, ascending infection, or pyelonephritis. Optimum duration of therapy in a patient with a urethral stent or a permanent indwelling catheter is often difficult to determine. It is virtually impossible to eradicate an infection in the presence of a foreign body, and removal of the foreign object is highly desirable; however, removal is not always feasible. A patient with a urinary tract infection and a foreign body in the urinary collecting system should be considered for chronic suppressive therapy if she has recurrent infection. In general, among patients with gram-negative rods, chronic suppressive therapy may include ampicillin, trimethoprim-sulfamethoxazole, doxycycline, or an oral fluoroquinolone such as ciprofloxacin. Patients with a chronic enterococcal infection may benefit from chronic suppressive therapy with amoxicillin–clavulanic acid (Augmentin®) or amoxicillin alone or doxycycline.

In patients with pyuria and fever in whom a urinary tract infection is suspected, empiric antibiotic therapy should be given pending urine culture results. Gram stain of urinary sediment may be helpful in directing treatment. However, for those cases in which Gram stain is not helpful, broad-spectrum coverage should be given. For a patient who has had frequent or prolonged hospitalizations, effective coverage of potentially resistant gram-negative rods dictates that two drugs be given, preferably a beta-lactam and an aminoglycoside. Cefazolin (1 to 2 g IV, q 8 hours) and gentamicin (4 to 5 mg/kg/day IV in three divided doses) is a good empiric combination for many patients. For more debilitated patients or those with prolonged hospitalizations and frequent past courses of antibiotics, advanced generation cephalosporin, such as ceftazidime (1 to 2 g IV, q 8 hours) or cefepime (1 g IV, q 8 hours) should be substituted for cefazolin. After culture results are known, antibiotics can be adjusted and the spectrum narrowed. For any gynecologic cancer patient with an unexplained predisposition to recurrent urinary tract infection, a full investigation should be undertaken to exclude obstruction from tumor as the cause.

Wound Infections

There are important variables that influence the development of wound infection after surgery. These include hospital flora, patient microflora, operative technique and variables, patient nutritional status, and competency of innate and adaptive immune function. Women being treated for reproductive tract cancer may be at risk because of specific problems with immunocompetency, prior chemotherapy or radiotherapy, poor nutritional status, hypoproteinemia, being economically disadvantaged, or suffering from an advanced cancer-associated catabolic state. Additional risk factors for incisional infection include obesity, inadequately controlled diabetes, and systemic corticosteroid use. Surgical variables include operative procedures in excess of 4 hours, breaks in surgical technique, capacious inoculum at the operative site, excessive cautery, passive drains, shaving of the area in which the incision is made immediately before surgery, and placement and types of sutures. Infections may range from a mild cellulitis to a devastating fasciitis, deep infection with

myonecrosis, and mixed anaerobic–aerobic synergistic abdominopelvic gangrene (85).

Cellulitis

Etiology

Cellulitis is a relatively frequent occurrence. The presence of a foreign body in a wound is an unavoidable risk factor in many cases, but this variable should be removed or reduced as much as possible. Devitalized tissue, especially fat, can also act as a foreign body. Excess cautery causes thermal injury; the charred tissue may act as a foreign body. The presence of significant amounts of devitalized tissue usually produces a wound defect. A mechanical wound retractor can cause fat necrosis, and there appears to be only minimal ability to resorb these areas during wound healing. These areas should be carefully identified and excised before closing the wound. If drains are used, they should be closed, and drains should be vacuumed. Drains should not exit through the wound but rather through an adjacent puncture site, and they should be removed as early as possible. *S. aureus* is recovered from 50% or more of wound infections. If the operative procedure involves transection of the vagina, the infections may harbor other species of normal flora of the lower reproductive tract, such as gram-positive and gram-negative anaerobes and Enterobacteriaceae. Cellulitis of the leg occurs with increased frequency in patients after vulvectomy (86). The affected leg is not always edematous. Group B beta-hemolytic streptococci are frequently recovered. Prophylactic therapy with oral penicillin may reduce recurrences in some patients (86). Increased prevalence of penicillinases among clinical streptococcal isolates cautions against penicillin preparation without beta-lactamase inhibitor.

Signs and Symptoms

Cellulitis is almost uniformly associated with pain and erythema in the incisional margins, with an increase in local skin and tissue temperature, and many times with fever. Incisions are usually tender at examination. Incisional cellulitis may not become evident until the fourth postoperative day or later.

Diagnosis

The infected surgical incision should be explored. This can frequently be performed at the bedside. Opposing skin edges in such incisions are usually separated without difficulty and may expose underlying purulent material, seromas, hematomas, or any combination of these. The wound should be explored thoroughly, and if the wound shows unusual features, aerobic and anaerobic cultures should be obtained. Foreign bodies such as sutures or drains should be removed, and obviously necrotic areas should adequately be debrided. It is important to document deep fascial integrity. If this cannot be done at the bedside, it should be performed in the operating room.

Therapy

The wound should be packed open with fine-mesh gauze approximated to the incisional margins and changed with each dressing change. The dressing is changed two to four times daily, avoiding harsh chemical and repeat mechanical debridement in the absence of necrotic tissue. Commonly used solutions are hydrogen peroxide, acetic acid, and Dakin's solution (0.25% sodium hypochlorite). In general, these debriding solutions should be removed from the wound with sterile normal saline before packing because they may impede healing. Except in unusual instances, it is unnecessary to administer parenteral antimicrobials. These incisions may be left open to heal by secondary intent, or they may be closed before discharge from the hospital after the margins exhibit healthy viable granulation tissue. The optimal time for

secondary closure is about the 4th day after institution of wound therapy. Studies have shown that normal wound healing occurs as long as the hematocrit exceeds 17%, but that a lower level will impede healing (87).

Necrotizing Fasciitis

Necrotizing fasciitis is a potentially life-threatening infection of the soft tissues above deep fascia that can involve the abdominal wall or vulva with extension to the proximal thighs and buttocks (87). There are several descriptive names for this infection, such as beta-hemolytic streptococcal gangrene, hospital gangrene, gram-negative anaerobic cutaneous gangrene, nonclostridial gas gangrene, gangrenous erysipelas, or synergistic necrotizing cellulitis, but the name used by most is that coined by Wilson in 1952, that is, necrotizing fasciitis (88). This significant infection has been reported in patients with endometrial cancer following irradiation and hysterectomy (89–91). It has also been found in endopelvic fascia, in a suprapubic catheter site during chemotherapy, in the vulva in diabetes, and after diagnostic laparoscopy (92–97).

Etiology

Bacteria recovered from necrotizing fasciitis–infected sites include anaerobes, particularly *Peptostreptococcus*, *Prevotella*, and *Bacteroides* species, as well as *E. faecalis, S. aureus*, and Enterobacteriaceae. These bacteria produce large quantities of proteolytic and other enzymes and toxins that allow rapid spread to contiguous tissues. Superficial vessels are occluded, depriving the affected areas of oxygen, other nutrients, and antibiotics. This deprivation interferes with bacterial eradication. Patients at particularly high risk of developing this infection include women older than 50 years of age and those with arteriosclerotic heart disease, diabetes, or other chronic diseases.

Signs and Symptoms

Early in the course of necrotizing fasciitis, the signs and symptoms are those of any wound cellulitis. Because there is no response to the usual methods of therapy, antibiotic therapy will frequently be initiated. The infection, however, seems to smolder initially, then rapidly progresses to involve the wound and to produce clinical sepsis. Mortality rates for this infection have been as high as 76%. The degree of disease evident on the skin is only a small fraction of the total amount of tissue that is involved because the skin is not the primary area of infection. Hallmarks of this infection include severe pain in contrast to scant physical findings, edema that is unusual for the apparently minimal degree of infection, and superficial tissue crepitus may be present. The skin overlying the affected area becomes blue or brown as the disease progresses, and there may be formation of bullae. Edema progresses, and there may be seepage of grayish fluid from the skin and does not bleed if cut. Lack of familiarity with this infection and failure to recognize its signs may delay diagnosis. Even when recognized and treated early, there is a high mortality rate.

Diagnosis

Diagnostic criteria as first outlined by Fisher et al. include (98) the following:

1. Extensive necrosis of the superficial fascia with widespread undermining of surrounding tissue
2. A moderate to severe systemic toxic reaction
3. Absence of muscle involvement
4. Failure to demonstrate *Clostridium* species in the wound or blood cultures
5. Absence of major vascular occlusion

6. Histologic demonstration of intense leukocytic infiltration, focal necrosis of the superficial fascia and surrounding tissues, and microvascular thrombosis

Early diagnosis followed as soon as possible by appropriate treatment produces the highest cure rate. Radiologic evaluation, particularly with MRI, may confirm the diagnosis rapidly and should be ordered whenever the disease is suspected. The average interval between diagnosis and initiation of treatment is approximately 5 days. If the interval is 4 days or less, survival rates are high, but an interval of 7 days or more is more likely to result in patient death because even intense antimicrobial therapy is rarely successful at this late stage.

Therapy

Although the administration of broad-spectrum antimicrobials is important, wide and often disfiguring surgical debridement is the treatment required for preservation of life. The excision must extend to areas that bleed. Adjunctive therapy with whirlpool baths and perhaps hyperbaric oxygen may be considered early in the course of the disease.

Clostridial Myonecrosis

Clostridial myonecrosis (gas gangrene) was described by Altmeier (99). It is an infection that occurs in muscle and adjacent tissues beneath the deep fascia and is seen most commonly after trauma. However, it can be seen after intra-abdominal surgery or surgery in an area that has been contaminated by feces. Mortality rates are about 25%, and poor prognostic factors are leukopenia, advanced age, renal failure, and intravascular hemolysis.

Etiology

Clostridial myonecrosis is caused by *C. perfringens* (80% to 95%), *C. novyi* (10% to 40%), or *C. septicum* (5% to 20%). It is usually seen in association with gastrointestinal mucosal ulceration or perforation because *Clostridium* species are normal inhabitants of the gastrointestinal tract. *C. perfringens* may be isolated from as many as 20% of women with upper genital tract infections not involving sexually transmitted diseases. The mere presence of *C. perfringens* in a wound does not mean that the patient will develop gas gangrene; it develops in only 1% to 2% of wounds in which that species can be isolated.

Signs and Symptoms

Early signs and symptoms of clostridial myonecrosis are tense edema in tissue that is extremely tender and pain that rapidly intensifies. If an incision is open, it is not uncommon to see a swollen, herniated muscle. There is frequently a serosanguinous, dirty discharge that has many gram-positive or gram-variable rods but few leukocytes. There may also be gas bubbles, and the secretions have a particularly sweet, offensive odor. The surrounding tissue frequently has crepitus. The skin becomes red to green-purple and then turns yellow before becoming a characteristic bronze color. The usual incubation period is about 2 to 3 days, but it can be as short as 6 hours. With progression of the infection, the patient becomes obviously ill, pale, and sweaty, with increased pulse rate and decreased blood pressure. Temperature is usually elevated, but hypothermia and shock may occur early in the course of the illness.

Diagnosis

A positive wound culture may accompany the characteristic signs and symptoms of clostridial myonecrosis. X-ray films of the affected area frequently show gas deep in the tissues. Blood cultures grow clostridia in approximately 15% of the

cases. It is common to find a decrease in hemoglobin and an increase in circulating leukocytes. Involved muscle is pale and edematous, with loss of elasticity, and it does not bleed or contract with stimulation. Histologic findings demonstrate coagulation necrosis of muscle fibers.

Therapy

Clostridial myonecrosis is another infection that requires prompt and extensive debridement in the operating room. Cultures must be performed, and because clostridia may develop plasmid-mediated antibiotic resistance, repeated cultures with sensitivity testing may be required if a patient is slow to respond. In addition to wide debridement, the treatment of choice is penicillin G at a dose of 1 to 2 million units every 2 to 3 hours. Gram stain also may indicate the presence of gram-negative bacteria, in which case coverage should be provided for those bacteria as well. Chloramphenicol is as effective against *Clostridium* species as it is against many gram-negative species, although, seldom used due to potentially life-threatening drug toxicity. Metronidazole, imipenem, or clindamycin, all of which have good *in vitro* activity against *C. perfringens*, may be considered. Other antibiotics with good *in vitro* activity include tetracycline, erythromycin, and rifampin. Hyperbaric oxygen may be adjunctive, but its efficacy is uncertain.

Intraperitoneal Catheter Infections

Etiology

Delivery of chemotherapeutic agents through an intraperitoneal catheter has enabled physicians to deliver high concentrations of drug locally while decreasing systemic side effects (44,100). However, intraperitoneal catheters can become infected at the exit site, along the catheter tunnel, or secondary peritonitis may occur in rare cases. *S. epidermidis* is the most common organism followed by *S. aureus* and *Streptococcus* species. Gram-negative bacilli and anaerobes, presumably from the bowel, are also found, especially in patients with polymicrobial infections. Patients who have been treated for bacterial peritonitis in the past may develop peritonitis due to *Candida* species.

Signs and Symptoms

With exit-site or tunnel infections, patients report discomfort at the site. Patients with peritonitis may complain of diffuse abdominal pain, with or without a change in bowel pattern. Fever may be absent in peritonitis, making the diagnosis more difficult because many patients with pelvic tumor have abdominal pain. On examination, patients with exit-site or tunnel infections have redness and sometimes have discharge where the catheter has been inserted. Patients with peritonitis have tenderness, and frequently have abdominal rebound.

Diagnosis

Diagnosis of exit-site and tunnel infections is made clinically, with support from a Gram stain and culture of any discharge. Patients with suspected peritonitis should have withdrawal of peritoneal fluid for cell count and microbiologic evaluation. A rough guideline, derived from experience among patients receiving continuous ambulatory peritoneal dialysis, is that any leukocyte count in peritoneal fluid >100 cells/mm^3 suggests infection. Gram stain and culture should reveal the specific organism. Chemical peritonitis after instillation of chemotherapy can mimic infectious peritonitis. Peritoneal fluid cultures are often not helpful in distinguishing between infectious and chemical peritonitis, especially in infections due to a fastidious organism. Use of biomarkers such as C-reactive protein or procalcitonin remains uncertain.

Therapy

For patients with peritonitis, systemic therapy is advised according to the recovered organisms. Treatment should be continued 10 days or longer, with serial peritoneal fluid cell counts guiding therapy. The peritoneum provides a large absorptive surface, and antibiotics delivered intraperitoneally readily enter the intravascular space; however, we suggest that intraperitoneal antibiotic therapy should be reserved for patients with serious, treatment-refractory infection. Treatment of fungal peritonitis is a unique problem. Amphotericin B can cause adhesions if delivered intraperitoneally. Echinocandins such as micafungin, caspofungin appear to be the treatment of choice for patients with intra-abdominal and peritoneal candidiasis (101). Fluconazole, which can be administered orally or intravenously, was shown in one study of patients receiving continuous ambulatory peritoneal dialysis to effectively treat *C. albicans* peritonitis and should be avoided in patients with *Candida glabrata* and *Candida krusei* infection (102). Fluconazole may be used for long-term therapy in patients with *Candida* peritonitis who have responded to initial aggressive therapy with micafungin (100 mg IV daily) or caspofungin (70 mg × 1 IV followed by 50 mg IV daily).

Septic Pelvic Thrombophlebitis

Septic pelvic thrombophlebitis, also known as suppurative pelvic thrombophlebitis, is a disorder that has been diagnosed most frequently after antimicrobial therapy for pelvic infection after cesarean section or septic abortion, but it can be seen as a complication of infection after any type of pelvic surgery. The mortality rate observed in 1917 was 52% after surgical therapy (103). Fortunately, this complication of pelvic infection is now very rare. The use of antimicrobial prophylaxis and the enhanced antibacterial activity of current therapeutic regimens are presumed to be paramount in the disappearance of this potentially lethal infection.

Etiology

Septic pelvic thrombophlebitis is clot formation in the pelvic veins as a result of infection. It can be seen after hysterectomy, other pelvic operative procedures including brachytherapy, and in association with pelvic trauma or perirectal abscess. Classically, there is relative venous stasis before phlebitis that develops adjacent to pelvic infection. The intimal lining of the veins is invaded by bacteria, including Enterobacteriaceae, especially *E. coli*, aerobic and anaerobic streptococci, and *Bacteroides*. The veins involved may be the ovarian, hypogastric, or uterine, with essentially equal involvement in the right and left sides. If common iliac veins are involved, clot formation is more frequently seen on the left for unknown reasons. Infected clot may embolize to the lungs, kidneys, liver, brain, and spleen.

Signs and Symptoms

A clinical diagnosis may not be readily evident. Presentation is essentially that of a fever of unknown cause, and the physician must rule out infections such as pyelonephritis, pneumonia, and pelvic or abdominal abscess. The most frequent presentation currently seen is persistence of fever associated with tachycardia after clinical response to antimicrobial therapy for a pelvic infection. Physical examination is normal in most instances, but it may be possible to palpate tender cords in the vaginal fornices. In patients with bacteremia and septic emboli, chills are observed in as many as 67%, pyrexia may be elevated to 41°C, and the variations in temperature may be quite hectic. Dyspnea, tachypnea, pleuritic pain, cough, hemoptysis, restlessness, anxiety, and perhaps angina may all be seen with septic embolization.

Diagnosis

Compatible clinical presentation and CT or MRI scan are used for diagnosis (104). Criteria for diagnosis of venous

thrombosis using CT studies include enlargement of the involved vein(s), sharply defined vessel walls enhanced by contrast media, and a low-density intraluminal mass (105). Diagnosis using MRI is based on intense intraluminal signals from clot in involved veins and a lack of signal with normal blood flow in uninvolved vessels; no contrast agent is needed. Blood culture should be performed if there is suspicion of septicemia. Tests for blood gases, a chest radiograph, and IV contrast-enhanced chest CT scan (or in patients with contraindication to IV contrast use, a ventilation-perfusion scan) may be performed to assess pulmonary embolization. A gallium scintiscan may be necessary to identify very small septic embolic foci in the lungs.

Therapy

Early treatment of venous thrombosis was surgical (103). The first to advocate the use of anticoagulants in addition to antibiotics were Schulman and Zatuchni (106). In some cases antibiotics alone may be adequate, and can be used for patients in whom anticoagulation may be detrimental (107). In the largest published study of heparin therapy, the mean time to become afebrile was 2.5 days, and the average duration of heparin therapy was 8 days (108,109). It is unnecessary to initiate warfarin sodium (Coumadin) therapy in patients without evidence of emboli. Thromboembolism during or after treatment with heparin has not been reported. Antibiotic therapy must be continued. If there is significant improvement in the pulse rate and temperature pattern within 12 to 48 hours after the addition of heparin, reassessment is mandatory. Treatment with low-molecular-weight heparin has not been studied or standardized for this condition (110). Heparin therapy is not without complications. Between 2% and 5% of patients may have an allergic reaction; bleeding occurs in 7% to 10% of patients; and the most devastating effect is the development of the “white clot syndrome” (111). This occurs in <1% of patients, but it may be associated with major limb amputation in 20% of those suffering from it, and death has been reported in nearly half of these patients. This phenomenon is a paradoxical arterial platelet aggregation associated with thrombocytopenia, and it should be suspected in patients with decreasing platelet counts or an increasing requirement of heparin to maintain adequate anticoagulation. The only current indications for surgical intervention are embolization during heparin therapy or lack of response. The usual intervention is placement of a vena cava filter, a procedure usually performed by an interventional radiologist.

Neutropenia and Fever

Etiology

Patients with severe neutropenia are at particularly high risk for severe morbidity and mortality unless empiric intravenous antibiotic therapy is instituted at the first evidence of fever or clinical worsening. Most commonly, the febrile neutropenic patient does not have an obvious source of fever. Even in those with bacteremia, the source is rarely clinically evident. Bacteria often enter the bloodstream through the gastrointestinal tract because of the small chemotherapy-induced disruption of the intestinal mucosa and the accompanying neutropenia and thrombocytopenia. Neutropenic patients may also develop a clinically diagnosed group of infections, including pneumonia and cellulitis. Neutropenic patients with these clinically diagnosed infections may progress very rapidly, may have exceedingly subtle clinical signs and symptoms, and always require early, aggressive therapy of their infections to achieve a response.

Signs and Symptoms

Fever is often the only complaint of patients with neutropenia and bacteremia. Patients receiving chemotherapy should be instructed to take their own temperature at home twice a day (more frequently if a subjective feeling of fever develops) and to contact their treating physician for temperatures above 38.0°C or 100.4°F.

Diagnosis

Diagnosis is made by blood culture. Of all febrile, neutropenic patients from whom blood cultures are obtained, only 10% to 20% have an organism isolated. The others probably have enough organisms to cause fever and systemic illness, but an insufficient burden of microorganisms to be cultivated using current standard culture-based techniques. Coagulase-negative *Staphylococcus*, *S. aureus*, streptococci, *E. coli, Klebsiella* species, and *Pseudomonas* species are frequently isolated bacteria (112). In a recent report of 2,142 patients with febrile neutropenia, 499 (23%) patients developed bacteremia due to gram-positive bacteria (57%) and gram-negative bacteria (34%), and polymicrobial infection was seen in 10% (113). Mortality rates were lowest (5%) in patients with gram-positive infection, followed by 18% mortality with gram-negative bacteremia, and they 13% in patients diagnosed with polymicrobial bloodstream infection (113). Polymicrobial infections are often underreported, and neutropenic patients with intestinal and genitourinary tract mucosal damage have a higher risk of systemic infection due to multiple microorganisms (7).

Therapy

The Infectious Disease Society of America (IDSA) updates guidelines for management of patients with fever and neutropenia. Full consideration of this complex topic is beyond the scope of this chapter (114). In general, a febrile neutropenic patient should receive antibiotics with activity against *P. aeruginosa*, pending results of blood cultures. Numerous regimens are effective, and their use should be determined according to sensitivity patterns for *P. aeruginosa* at a given hospital. In general, good results have been achieved with a beta-lactam antibiotic plus beta-lactamase inhibitor such as ticarcillin–clavulanic acid, piperacillin–tazobactam, or a third/fourth-generation cephalosporin such as ceftazidime or cefepime, or a carbapenem such as imipenem or meropenem with or without an aminoglycoside. Monitoring peak and trough levels of aminoglycosides is recommended to maintain drug levels in optimum therapeutic range and to mitigate drug-induced ototoxicity and nephrotoxicity. The choice of the specific aminoglycoside (e.g., tobramycin, amikacin) is dictated by the sensitivity patterns in a given hospital. Once-daily dosing of aminoglycosides is not recommended for the neutropenic patient but can be given in other settings. The length of therapy for neutropenic patients is determined by many factors and must be individualized. An infectious disease specialist should follow patients with prolonged neutropenia and fever.

Fungal Infections

Etiology

Patients with pelvic cancer may be at risk for the development of fungal infections, particularly those caused by *Candida* species, including *C. albicans*, *C. tropicalis*, *C. parapsilosis*, and *C. glabrata* (115). Infection may include fungemia, pelvic abscess, or infected urinary stents in patients with extensive pelvic disease and urinary outflow obstruction. Risk factors for the development of invasive candidiasis include prolonged courses (7 to 10 days) of intravenous broad-spectrum antibiotics; an intravenous catheter, particularly a central venous catheter; major abdominal surgery; treatment-induced severe neutropenia for longer than a week; and immunosuppressive therapy, especially with corticosteroids. Patients with enteric or colonic fistula or bowel perforation have an increased risk for tissue-invasive candidiasis (116).

Signs and Symptoms

Patients with the appropriate risk factors who have unexplained fevers may be fungemic. Other than fevers, which can include rigors and hypotension and closely resemble bacteremia, there may be no other symptoms. Blood cultures are

positive in only 50% of patients with autopsy-proven disseminated candidiasis. Any blood culture positive for yeast should be considered significant. A full evaluation for a hidden source should be completed, including a thorough reevaluation with history and physical examination, and appropriate laboratory tests that include repeat blood cultures. It is imperative to perform an expert ophthalmoscopic examination for possible *Candida* vitritis, retinitis/retinal abscesses, or endophthalmitis in all patients with presumed, probable, or definite fungemia, since this complication may occur in up to 5% to 15% of patients with fungemia (117).

Presence of multiple body–site *Candida* species colonization proportionally increases the risk of invasive candidiasis, including fungemia and acute disseminated candidiasis (118).

Candida species may cause urinary tract infection in a patient with such indwelling devices as a Foley catheter, internal stents, or percutaneous nephrostomies. Rarely a "fungus ball," consisting of a matted mass of yeast, may cause urinary tract obstruction.

Candida species invasive lung disease is exceedingly rare and may occasionally be seen in critically ill intensive care unit high-risk patients or patients with refractory relapsed acute leukemia and prolonged severe neutropenia. Thus, recovery of any yeast from a respiratory specimen should be considered most likely due to oropharyngeal contamination of lower respiratory tract culture. Unlike patients with leukemia and recipients of allogeneic hematopoietic stem cell transplantation, in patients with gynecologic malignancy invasive mold disease is exceedingly rare. Identification of filamentous fungi, such as *Aspergillus*, should be approached with caution, and mold-active drug therapy reserved for highly immunosuppressed patients with clinical and radiographic features suggestive of invasive aspergillosis (119).

Diagnosis

The diagnosis of a fungal infection is often difficult. The physician must differentiate between invasive disease, which must be treated, and colonization, which does not require systemic antifungal therapy. The recovery of fungi from a urine, sputum, or wound culture does not necessarily mean that the fungus is pathogenic, and clinical judgment must be used to determine if a patient requires therapy. In general, cultures from sterile sites (e.g., blood, cerebrospinal fluid, pleural or peritoneal fluid) should be considered to represent invasive infection until a full evaluation is done. Also, *Candida* recovered from the initial specimen of drainage from an obstructed biliary or urinary tract should be considered to be potentially associated with invasive fungal disease.

With most specimens, however, the distinction between colonization and infection is not so simple. For urine, the presence or absence of pyuria is the simplest and most reliable means of differentiation. Those without pyuria are very likely only colonized and need no therapy. In such patients, a repeat urinalysis and culture may clarify the situation. Recently approved fungal antigen assays including serum beta D glucan and galactomannan have provided much-needed diagnostic sensitivity and specificity in select groups of patients at high risk for invasive fungal disease (120).

Therapy

Treatment options for invasive candidiasis have expanded in recent years. Amphotericin B has the longest record for treatment of invasive fungal infections (115). The optimal duration of therapy for candidemia is not well defined and should be determined by individual responses. However, a 7- to 14-day course of therapy is probably adequate for most episodes (115).

Since the introduction of fluconazole in 1990, the option for invasive candidiasis, severe drug toxicity associated with amphotericin B is observed less and less (115,121). Echinocandins such as caspofungin (70-mg load and then 50 daily IV) showed comparable response in patients with invasive candidiasis versus patients randomized to receive amphotericin B (101). A large prospective trial comparing first two available echinocandins demonstrated 75% efficacy for micafungin compared with 70% in patients treated with caspofungin at the end of antifungal therapy; there were also nonsignificant higher responses among patients with *Candida* peritonitis (67% vs. 40%) and deep tissue abscesses (100% vs. 67%) in

the micafungin verses caspofungin groups, respectively (122). These new classes of drugs offer comparable effectiveness but have fewer side effects than the amphotericin B products.

Patients who have *Candida* species consistently cultured from urine but no evidence of systemic fungal infection may benefit from bladder irrigation with amphotericin B, which reduces or eradicates bladder yeast colonization, and may prevent invasive fungal infection. Fluconazole is increasingly being given for this indication and appears to be effective.

Pneumonia

Etiology

Postoperative pneumonia remains a common cause of fever in any surgical patient, including those with gynecologic cancer. Infection may occur from aspiration during intubation or extubation or from hypoaeration due to "splinting" in patients with severe postoperative pain. Postobstructive pneumonia may occur in patients with tumor metastatic to the lungs. In addition, pneumonia may occur in patients with chemotherapy-induced neutropenia.

Signs and Symptoms

The familiar signs and symptoms of pneumonia are cough, fever, chest discomfort, dyspnea, and evidence of pulmonary consolidation on lung examination.

Diagnosis

The diagnosis is usually suggested by the clinical situation and by the findings on physical examination. These are further supported by chest radiographs and sputum examination and culture. Chest radiography may show consolidation. Gram-negative organisms predominate in the mouth flora of hospitalized patients, so an aspiration pneumonia occurring in a hospitalized patient is typically due to gram-negative rods. Although thought by many to be a substantial contributor, anaerobes are seldom isolated in hospitalized patients with aspiration pneumonia.

Therapy

Empiric, rather than pathogen-directed, coverage of patients with clinical pneumonia following a major surgical procedure is usually necessary and varies according to the setting (123). For a patient who has been hospitalized less than 3 days and has had no other recent hospitalizations or recent courses of oral or intravenous antibiotics, single-drug therapy with levofloxacin or moxifloxacin is adequate (123). For the patient who has been hospitalized for a longer period or who has recently received broad-spectrum antibiotics (increasing the likelihood of infection due to multidrug-resistant organisms), *P. aeruginosa* should be covered by the addition of an aminoglycoside such as gentamicin or tobramycin (3 to 5 mg/kg per day in three divided doses), and a beta-lactam should be selected to cover the usual isolates in that hospital. *S. maltophilia* is now increasingly seen in cancer patients without traditional risk factors such as severe neutropenia, prolonged stay in critical care units, or mechanical ventilation (124). Treatment includes high-dose trimethoprim–sulfamethoxazole (15 mg/kg in three to four divided doses) in combination with a second drug to which the bacteria are susceptible (18). Patients with *S. aureus* pulmonary infection may present with rapid clinical deterioration, and necrotizing pneumonia due to MRSA is often seen as a complication following a recent influenza virus–like illness; postviral bacterial infections are especially serious superinfections and require urgent, appropriate antibiotic therapy. Vancomycin (1 g twice daily), or linezolid (600 mg every 12 hours) may be given in patients with lobar or multifocal pneumonia and history of recent influenza-like illness. Therapy for patients with pneumonia should extend up to 10 to 14 days depending on a) clinical

response; b) concurrent bacteremia; c) presence of empyema or complicated parapneumonic effusion; or d) secondary hematogenous foci of infection dissemination. Various professional societies have codified recommendations for pneumonia management (125).

Diarrhea Associated with Antibiotics or Chemotherapy

Etiology

Diarrhea is a common finding in patients undergoing treatment of gynecologic malignancy. In a study of 351 hospitalized women with gynecologic cancer in the 1980s, 12% developed diarrhea during the course of their hospital stay; 10% had diarrhea due to *C. difficile* (126). In cancer patients *C. difficile*–associated diarrhea (CDAD) is most commonly a result of exposure to broad-spectrum antibiotics, or in some cases chemotherapy alone (126,127).

Signs and Symptoms

Antibiotic-associated diarrhea can occur at any time during an antibiotic course and for at least a month after discontinuation. Patients typically develop abdominal pain, fever, and frequent watery diarrhea defined as three or more unformed bowel movements in 24 hours lasting for ≥2 days; however, CDAD may sometimes cause abdominal pain and fever without diarrhea.

Diagnosis

Any patient with antibiotic- or chemotherapy-associated diarrhea should have a full evaluation of stool, including routine cultures and antitoxin immunoassays or nucleic acid amplification tests (128). In patients with a highly suspicious clinical presentation but no evidence of *C. difficile* toxin in stool, sigmoidoscopy or colonoscopy may reveal intense mucosal ulceration; inflammation and the pathognomonic pseudomembranes are observed in a small number of cases with advanced disease. One study has suggested that evaluation of stool for *C. difficile* toxin is the only cost-effective test (126). A markedly elevated white blood cell count may also be a clue to diagnosis (129). In a recent retrospective study from a tertiary care cancer center, polymerase chain reaction increased the yield of *C. difficile* cases by twofold compared with that of the standard cytotoxic assay (130). Presently, in most secondary and tertiary care medical centers, nucleic amplification assays have largely replaced the less sensitive immunoassays.

Therapy

Oral therapy with metronidazole (250 mg to 500 mg four times daily for 2 to 4 weeks) is adequate to treat most cases of antibiotic-associated diarrhea (127–129). Because of continued reports of vancomycin-resistant bacteria (131), the use of oral vancomycin is restricted in many hospitals. However, response to metronidazole has been compromised in part with the emergence and spread of hypervirulent North American Pulsed Field type 1 (NAP1) *C. difficile* strains in the United States and Europe (132). Most institutions are currently following IDSA guidelines for moderate and severe CDAD; oral vancomycin should be given only to patients with strong suspicion or proven CDAD and those who have not responded to metronidazole. Some patients may require repeated or prolonged courses of metronidazole or oral vancomycin, particularly if their clinical course necessitates continuation of the provocative agent (i.e., continued antibiotics or chemotherapy). Antidiarrheal compounds such as Lomotil or Imodium should not be given routinely. If, however, diarrhea persists after appropriate tests and cultures, symptomatic therapy should be considered. Nitazoxanide is a nitrothiazolide and effectively treats intestinal infestation of *Cryptosporidium* and *Giardia* species; at low concentrations nitazoxanide also inhibits *C.*

difficile. A recent trial showed that nitazoxanide 500 mg twice daily was as effective in eradicating *C. difficile* as metronidazole given 250 mg four times daily (133). Nitazoxanide may be used for patients with metronidazole-refractory or recurrent *C. difficile* colitis, although in our experience the clinical efficacy of nitazoxanide in patients who had failed first-line anti *C. difficile* drugs remains less favorable. In a recent trial fidaxomicin (200 mg twice daily) or vancomycin (125 mg four times daily) orally for 10 days was assessed for clinical response and early relapses (134). The overall response was comparable for both treatment groups; patients treated with fidaxomicin had significantly lower rate of recurrence of *C. difficile* infection associated with non-NAP1 (nonvirulent) strains (134). Currently, this option is being used in patients with relapsed CDAD or those with high risk for relapsed infection.

Noninfectious Causes of Fever

Not all patients with gynecologic malignancy and fever have an infection. Pulmonary embolus, drug-related fever, and tumor-related fever represent the main noninfectious sources of fever; however, other sources such as factitious fever, underlying collagen vascular disorder, autoimmune disorders, and foreign-body-type hypersensitivity reaction, must also be considered. The use of biologic markers such as procalcitonin (PCT) and neopterin levels has been suggested to help distinguish between infectious and noninfectious causes of fever, although further studies are needed to validate these tests prior to routine clinical use (135). Similarly, soluble triggering receptor expressed on myeloid cells-1 (sTREM-1) along with PCT have been suggested to improve recognition of patients with true infection and may help determine whether or not to start empiric antimicrobial therapy (136). Unfortunately, neither PCT nor sTREM-1 by itself has shown consistency in differentiating infectious conditions versus tumor or treatment-related febrile response. It is, however, postulated that a combination of systemic PCT and local and/or systemic sTREM-1 or CRP and/or neopterin may help to distinguish patients with infection from those with noninfectious illness. Results from several randomized intervention studies on PCT-guided antimicrobial therapy in sepsis or pneumonia show PCT may aid in clinical decision-making (136,137). At present, randomized trials to assess the role of select biomarker panels including PCT, neopterin, and sTREM-1 are lacking.

Pulmonary embolus should be considered in a bed-bound or postoperative patient with any combination of fever, chest pain, dyspnea, or an abnormal chest radiograph. Patients with bulky pelvic tumors are also at risk. A high level of suspicion is important, and spiral intravenous contrast-enhanced chest CT scans or ventilation-perfusion scans may establish the diagnosis; in rare instances, a more definite pulmonary angiogram may be performed. Therapy remains anticoagulation with low-molecular-weight heparin. For patients who are unable to tolerate these drugs or who continue to have pulmonary emboli despite therapy, inferior vena caval filters are required.

Many drugs, including antibiotics, may cause fever (138). Patients typically develop fever and a diffuse maculopapular rash after several days of therapy. Eosinophilia, although a helpful sign, is usually lacking. Mild elevations in liver function tests may be present though nonspecific. Atypical presentations of drug fever, including patients without rash or those who develop fever weeks into therapy or after completion of therapy, can also occur. Discontinuing the antibiotic(s) and observing the patient usually make the diagnosis. It is important to remember that some drug fevers may take as long as a week to resolve completely. Supportive measures, such as antipyretics and antipruritics, may decrease symptoms.

The diagnosis of tumor fever can be made only after systematic exclusion of all other potential causes of fever. Most patients with tumor fever have metastatic disease involving the liver or lung. In these patients, the fever may be as high as 40°C, and chills may be absent; when not febrile, these patients often feel relatively well. In patients suspected of having tumor fever, a clinical trial of broad-spectrum antibiotics is given. If the fever does not abate and no other clear infection source is evident, the likelihood of tumor fever increases. Nonsteroidal anti-inflammatory agents such as naprosyn often produce an immediate and sustained response when administered to patients with tumor fever. This should only be done after infectious causes of fever have essentially been excluded, and a trial of broad-spectrum antibiotic therapy has not resulted in defervescence.

CHAPTER 29 Management of Surgical Complications of Gynecologic Cancer Treatment

Andreas Obermair, Donal J. Brennan and Robert E. Bristow

GENERAL COMPLICATIONS OF GYNECOLOGIC CANCER SURGERY

Stroke

Stroke is estimated to occur following gynecologic oncology surgery in less than 1% of patients. Risk factors reflect those in the general population: history of previous stroke or transient ischemic attack, atherosclerosis, hypertension, diabetes, and advanced age (1). The etiology of stroke is attributed to hypoperfusion injury, hemorrhage, or embolism. In contrast to cardiac surgery, the majority of noncardiac stroke is due to cerebrovascular thrombosis, rather than embolic events (2). Hypotension (relative to the patient's baseline blood pressure) increases the risk of stroke in patients undergoing noncardiac, non-neurologic surgery (3,4). Despite this, no evidence is available that intraoperative monitoring or regulation of blood pressure reduces the incidence of stroke. Avoidance of severe hyperglycemia and hypoglycemia is recommended, though there is a lack of consensus regarding glucose targets (2).

Cardiac Events

Major noncardiac surgery is associated with major cardiac events (cardiac arrest, myocardial infarction, heart failure, arrhythmias) in 0.5% to 3.0% (3,5). Perioperative myocardial infarction is associated with a 50% to 70% mortality rate and carries a high risk for future cardiac events. More than half of perioperative myocardial infarctions are unrecognized (asymptomatic non-ST elevation), and the incidence peaks during the first 24 hours postoperatively. Recent myocardial infarction, heart failure, ischemic heart disease, diabetes, renal insufficiency, cerebrovascular disease, obesity, sleep apnea, and poor functional status constitute high-risk factors.

Prevention of perioperative cardiac events should focus on evaluation of risk factors, risk stratification, and maximization of patient function. Good evidence supports the continuation of β-blockers and HMG-CoA reductase inhibitors ("statins") throughout the perioperative period for patients already treated with β-blockers. Perioperative measures should focus on maintenance of normothermia and postoperative monitoring of serum troponin levels.

Deep Vein Thrombosis and Pulmonary Embolism

Deep vein thrombosis (DVT) and/or pulmonary embolism comprise the spectrum of complications known as venous thromboembolism (VTE). VTE following surgery is the most common cause of peri- and postoperative death (6). DVT affects 0.1% of patients each year, but the incidence is significantly higher among patients undergoing surgical treatment for gynecologic cancer, occurring in up to 20% of cases (7).

Patients with gynecologic cancer are at high risk for VTE because of their underlying malignancy, increased age, and the extensive nature of treatment. The underlying mechanism of the development of VTE includes increased release of procoagulant factors, cytokine imbalance, and activation of the antifibrinolytic pathways. Clinical risk factors include a history of VTE, obesity, immobility, trauma, prolonged surgical time, radiation therapy, and increasing complexity of surgery. Patients with the highest risk for developing postoperative VTE have two or more of the following: age greater than 60 years, malignancy, and history of VTE (8). Early ambulation, heparin, low-molecular-weight heparin, and sequential compression devices (graduated compression stockings or intermittent pneumatic compression) are effective in reducing the incidence of VTE (9). The incidence of VTE in patients undergoing major gynecologic cancer surgery is decreased with dual, prolonged (4-week) prophylaxis without increasing bleeding complications (10). Current guidelines recommend VTE prophylaxis for at least 4 weeks following surgery in the absence of bleeding or other contraindications.

Bladder and Ureteral Injury

Injuries to the lower urinary tract (laceration, transection, crush injury, ligation, thermal injury, injury through devascularization) are uncommonly diagnosed intraoperatively; the outcomes of patients who are diagnosed late (urinomas, peritonitis, sepsis, fistula) are worse (11). The risk of bladder/ureter injury ranges between 1.1% and 5.3% in patients undergoing a radical hysterectomy and is approximately 1% in standard hysterectomy for uterine cancer (11–14). Bladder injuries recognized at the time of the initial surgical procedure should be repaired immediately, using a standard two-layered closure of delayed absorbable suture. Bladder injuries diagnosed postoperatively (e.g., fistula) may be treated with an indwelling catheter for a period of several weeks. If spontaneous closure does not occur with prolonged drainage, surgical repair is indicated. Ureteral injuries recognized intraoperatively should be repaired by excising the injured segment of ureter, placement of a ureteral stent, and reapproximating the distal urinary tract (ureteroureterostomy, ureteroneocystostomy with psoas hitch, and possibly a Boari flap). Ureteral injuries detected remote from the initial surgical procedure can be managed by attempted placement of a ureteral stent, which can be accomplished either retrograde via cystoscopy or antegrade via a percutaneous nephrostomy tube. If spontaneous closure does not occur after an observation period of 4 to 6 weeks, or if stent placement is not feasible, surgical repair is indicated. Long-term outcomes are generally excellent.

Injury to Small and Large Bowel

Bowel injuries occur in approximately 1% of patients undergoing surgery for gynecologic cancer. Risk factors include previous surgery, adhesions, and previous radiotherapy. Most bowel injuries are recognized at the time of open surgery; however, this is not the case in laparoscopic surgery. A recent systematic review demonstrated that the rate of bowel injury at laparoscopic hysterectomy for malignancy was 1:246 (15). The majority of injuries occur either during establishment of a pneumoperitoneum or with the use of electrosurgical devices. Approximately 40% of laparoscopic bowel injuries are not recognized intraoperatively, and the mortality rate in this group is as high as 3% (15).

Small bowel enterotomies can be closed in one layer using delayed absorbable suture, while large bowel injuries of greater than 2 cm should be closed in two layers. Small or large bowel injuries require primary bowel resection if the blood supply to the bowel is compromised or if injuries occur at multiple levels. The general principles of management of a bowel injury requiring resection are similar to that of any bowel anastomosis (hand-sewn or stapled). After resection of the injured segment of bowel, the anastomosis must be patent, tension-free, and well vascularized. If any of these three conditions are unmet, the risk of leakage is very high.

Nerve Injury

Poor patient position, improper placement of retractor blades, and radical surgical dissection increase the risk of nerve injury (11). *Neurapraxia* is caused by compression leading to changes in intraneural microcirculation, and is fully reversible. *Axonotmesis* (crush injury) will sever axons, and the function will resolve with gradual regeneration of nerve fibers. Transection of nerve fibers causes aberrant regeneration of the axons (misalignment), resulting in permanent functional losses.

The lumbosacral plexus is at risk for injury during gynecologic surgery. The use of short retractor blades or flexible blades with packs placed under the blades instead of self-retainers may reduce the risk of nerve injury intraoperatively (11). Additionally, avoidance of long-term hip extension (femoral nerve) or flexion (sciatic nerve) in lithotomy position will decrease the risk of nerve injuries.

Hemorrhage

Intraoperative hemorrhage is defined as blood loss greater than 1,000 mL, or any requirement for intraoperative blood transfusion. Significant hemorrhage can be expected in 4% to 7.5% of patients undergoing surgery for advanced ovarian cancer (16). Risk factors include anemia prior to surgery, history of prolonged bleeding, blood-thinning medication and herbs/supplements, and intraoperative hypothermia. The principles of management of intraoperative hemorrhage are local and systemic. Local hemostatic control plus the systemic correction of any coagulopathy are the two crucial aspects of managing any significant hemorrhage.

Local measures include tamponade (packs) or the use of an omental autologous transplant (OAT) patch (17); atraumatic grasping, identification and control of all feeding vessels and bleeding sources; identification of sensitive structures (ureters, nerves); the selective use of sutures, clips, diathermy, patches; and the use of topical hemostatic agents. Internal iliac artery ligation should be considered if other measures fail to control pelvic hemorrhage. Finally, “damage control” surgery, with placement of pelvic packing, transfer to the intensive care unit for stabilization, and return to the operating room for pack removal after 24 to 48 hours, may be a last resort.

Postoperative Ileus

Postoperative adynamic ileus is delayed gastrointestinal tract recovery; it may impair wound healing and increase the risk of infections. Gastrointestinal motility is controlled by the enteric autonomous nervous system and influenced by neural reflexes (interfered with by regional anesthesia), inflammation/trauma (tissue handling) and neurohumoral substances (systemic analgesia). Medical illnesses (e.g., diabetes mellitus) or medications may increase the risk of ileus.

Differentiating postoperative ileus from a mechanical small bowel obstruction (SBO) is critical. Bowel sounds are an unreliable indicator and are usually quiet or absent with ileus, but may be high-pitched or absent with SBO. Computed tomography (CT; with oral Gastrografin) or a water-soluble contrast study is recommended to help differentiate ileus from SBO. Failure of contrast to reach the cecum by 4 hours is highly suggestive that surgical intervention will be required and can help differentiate early postoperative SBO from an ileus. Water-soluble contrast may also be therapeutic and may allow a quicker resolution of an adhesive SBO. The treatment of ileus is conservative and nonsurgical, and includes restriction of oral intake, nasogastric tube suction, intravenous fluid and electrolyte replacement, and discontinuation of systemic opioids if possible. Total parenteral nutrition should be considered after 7 to 10 days without satisfactory oral nutrient intake.

Postoperative SBO

Postoperative SBO results from a mechanical blockage of intestinal motility. Possible causes include herniation of bowel (port sites, internal herniation), early adhesions, intussusceptions, and small bowel tumors. The characteristic presentation

of SBO is that patients initially recover well (pass flatus, tolerate oral intake), but then develop nausea, vomiting, colicky abdominal discomfort, and pain. CT will show a site of bowel obstruction (transition point), gaseous distension of small bowel, and paucity of air in the rectum. Effective management of SBO requires an expedited diagnosis followed by a short (48 to 72 hours) conservative trial of nasogastric suction and fluid resuscitation in the absence of clinical evidence of strangulation such as peritonism, fever, tachycardia, or leukocytosis. Fluid lost from the nasogastric tube should be replaced with additional crystalloid intravenous fluids and potassium supplementation. There are two indications for surgery for SBO: first, failed conservative management, and second, if there is suspicion of strangulation and loss of bowel vascular perfusion.

Surgical Site Infection

Surgical site infections (SSIs) lead to delayed wound healing, revision surgery, increased use of antibiotics, and increased length of hospital stay (18). On average, a patient with an SSI spends 7 days longer in hospital, is 60% more likely to spend time in the ICU, is five times more likely to be readmitted within 30 days of discharge, and is twice as likely to die (19). The incidence rates vary depending on patient factors and type of surgery, and range from 2% to 10% after laparotomy, while the rate is lower with minimally invasive surgery. Risk factors for SSI include concomitant systemic disease (diabetes, anemia, immunosuppression, immunosuppressive therapy with radiotherapy, chemotherapy, or steroids), obesity, advanced age, preexisting infection, hematoma, damaged tissue, extensive surgery, hypothermia, hemorrhage, and use of drains or catheters (20). Infection control programs reduce the rates of SSI by 35% to 41% (21). Prophylactic antibiotics are most effective when administered 30 to 60 minutes preoperatively. A preoperative Chlorhexidine shower is as effective as bar soap or detergents. Trials on antibacterial sutures are ongoing.

DISEASE SITE-SPECIFIC SURGICAL COMPLICATIONS

Surgery for Ovarian Cancer—Cytoreductive Surgery

Acute Complications

Ovarian cancer cytoreductive surgery has evolved to a contemporary approach designed to achieve complete cytoreduction, with an accepted increase in morbidity balanced against the maximal benefit with respect to long-term survival. A comprehensive approach to advanced-stage ovarian cancer must address disease not only in the pelvis; it also frequently involves surgery on the large and small bowel, diaphragm, liver, spleen, and distal pancreas. Recognition and management of associated perioperative complications is critical. The morbidity of extensive surgical cytoreduction is increased with age, poor nutritional status, and poor functional status (22–26).

Surgical staging for apparent “early” ovarian cancer, including retroperitoneal node dissection, may disrupt the lymphatic system and may cause chylous ascites in the short term. Patients will present with ascites in the early postoperative phase and an injury to the urinary collection system needs to be excluded. The aspiration of chylous is diagnostic.

Spillage of ovarian tumors is more common with minimally invasive surgery than with laparotomy and may upstage ovarian cancer, necessitating adjuvant chemotherapy (27). Meticulous surgical dissection, the use of containment devices (bags), and early conversion to open surgery are strategies to minimize the risk of spillage.

The en bloc resection of locally advanced ovarian cancer (radical oophorectomy or modified posterior exenteration) carries an operative mortality of 0% to 8%, with more contemporary series reporting rates of 4% or lower (28–30). Wound complications are seen in 6% to 34% of patients, particularly with severe hypoalbuminemia (<3.0 ng/dL) and large-

volume ascites (31). The estimated blood loss with radical oophorectomy ranges from 800 to 2,900 mL, with as many as 87% of patients receiving blood product transfusion.

Intestinal complications with radical cytoreduction are among the most commonly encountered, with prolonged ileus reported in up to 40% of patients. A large series of 587 patients recently reported an average incidence of postoperative ileus of 30.3% (25.9% without bowel resection, 38.5% with bowel resection) (32). The pattern of spread of ovarian cancer necessitates bowel resection in 19% to 54% of cases (33,34). Colorectal anastomotic leak occurs in fewer than 4% of cases and can lead to abscess, fistula formation, sepsis, and reoperation; the mean time to diagnosis is 19 days (range, 4 to 32 days) (28,29,34–37). Anastomoses below the peritoneal reflection and less than 6 cm from the anal verge are at the highest risk for failure (38). Anastomotic dehiscence can present with insidious symptoms if it is contained, or progressive sepsis with tachycardia, tachypnea, fever, and peritonism if frank fecal peritonitis is present. The investigation of choice to assess a colorectal anastomosis is a CT of the abdomen with rectal contrast.

While there are limited data in gynecologic oncology patient populations, randomized studies on the management of colorectal disorders suggest that mechanical bowel preparation does not lower the risk of anastomotic leak. A recent meta-analysis of 18 randomized controlled trials with over 5,800 patients confirmed that administration of mechanical bowel preparation yielded no difference in anastomotic leak rates (4.4% vs. 4.5%; odds ratio [OR], 0.99 [0.74, 1.13]) or wound complications (9.6% vs. 8.5%; OR, 1.16 [0.95, 1.42]) (39). However, it is sensible to perform a mechanical bowel preparation if a proximal stoma is planned, to prevent a column of stool feeding an anastomotic leak should it occur, or slowing progress following reversal of a loop ileostomy.

Studies of intraperitoneal pelvic drain placement in the setting of a rectal anastomosis similarly suggest no benefit to lowering the risk of anastomotic leak (40). Intestinal diversion has historically been utilized for protection of a rectal anastomosis during primary cytoreductive surgery. Older data suggest that up to 59% of patients requiring rectal anastomosis also underwent protective intestinal diversion with colostomy or ileostomy. Based on more contemporary data, intestinal diversion to “protect” a colorectal anastomosis is not routinely required but may be advisable in patients with very low anastomoses, technically suboptimal anastomoses, or severe hypoalbuminemia (21% leak rate with albumin <3.0 g/dL vs. 3.4% leak rate with albumin >3.0 g/dL) (29,36).

Initial management of anastomotic leak generally requires a laparotomy once the patient has been stabilized. Cardiovascular and respiratory support may be required and broad-spectrum antibiotics should be administered. At laparotomy, great care must be taken not to damage adherent loops of small bowel, and the anastomosis must be exposed and inspected. If a major dehiscence is found, the anastomosis will have to be taken down and a Hartmann’s procedure performed with formation of an end colostomy. Care should be taken to seal the distal stump with a linear stapler; as the bowel may be edematous, the staple line should be oversewn with permanent suture that protects the staple line and may make it easier to identify the rectal stump at future surgeries to restore continuity. If the anastomotic leak is small, the anastomosis seems intact, and only minimal soiling is present, the leak can be oversewn, a washout performed, and a protective loop ileostomy fashioned.

Anastomotic dehiscence can very rarely be managed conservatively. Occasionally, if a leak is contained (classically demonstrated on CT by small air-containing abscess around the staple line) and the patient is clinically well, treatment may simply involve antibiotic therapy and bowel rest. A low colorectal dehiscence in a patient with a covering ileostomy may be managed by transanal drainage, which is usually performed at EUA whereby a Foley Catheter can be placed transanally through the staple-line defect to drain the abscess cavity. Once the abscess has drained the anastomosis will often heal spontaneously.

Upper abdominal procedures including splenectomy, distal pancreatectomy, partial hepatectomy, and diaphragmatic peritonectomy or full-thickness resection may be required to render a patient completely free of visible disease. Development of pleural effusions following diaphragmatic peritonectomy or resection occurs in 9% to 64% of patients, although these can be managed with thoracentesis alone in the majority of symptomatic patients. When full-thickness resections are required, perioperative morbidity has been reported in as many as 20% of patients (41,42). A small postoperative pneumothorax will frequently resolve spontaneously and can be monitored with daily chest radiographs.

Chest tube placement is occasionally required for major resections of the right hemidiaphragm, large pleural effusions, or worsening pneumothorax.

Acute complications associated with splenectomy include hemorrhage, left lower lobe atelectasis, splenic vein thrombosis, arteriovenous fistula between the splenic artery and vein, and infectious morbidity (43,44). Overwhelming post-splenectomy infection, most commonly due to *Streptococcus pneumoniae*, is a serious complication with a prevalence of 3.2% and a mortality rate as high as 70% (45). Vaccinations for pneumococcus, meningococus, and *Haemophilus influenza* type B are the cornerstones of prevention. Postoperatively, antibiotic prophylaxis is recommended.

Distal pancreatectomy is occasionally indicated to achieve complete disease resection and can result in pancreatic fistula (leak) and pancreatic pseudocyst formation (33,46). Intraoperative placement of a closed suction drain in the left upper quadrant can be useful to monitor for signs of early fistula formation and to prevent pseudocyst formation. Mild enzyme leakage has little clinical impact and can be managed with prolonged drainage and standard oral feeding. Enzyme leakage greater than threefold the upper limit of normal more than 3 days after the operation, or the presence of pain, fever, or leukocytosis requires delay of oral nutrition, administration of antibiotics, somatostatin analogues, and parenteral nutrition.

Chronic Complications

Ovarian cancer patients may experience long-term sequelae related to prior cytoreductive surgery, often exacerbated by the presence of disease recurrence or carcinomatosis. More commonly encountered complications requiring operative intervention are mechanical bowel obstruction or anastomotic stricture. SBO in ovarian cancer patients is best approached with an extended trial of bowel rest and decompression with nutritional supplementation unless bowel dilation is greater than 5 cm, at which point the risk of perforation increases. Carcinomatous ileus can be confused with mechanical bowel obstruction; however, this condition is unlikely to be surgically correctable. If mechanical SBO is refractory to conservative measures, surgical options include resection with reanastomosis, diverting ileostomy, enterocolonic bypass, or palliative percutaneous gastrostomy. Associated complications may include anastomotic failure, blind loop syndrome, or short gut syndrome. Finally, late complications may follow extensive resection of the ileum or a right hemicolectomy; these late complications include chronic diarrhea from impaired absorption of water, fat, and bile salts, and problems related to poor absorption of nutrients, including the fat-soluble vitamins and vitamin B_{12}.

Centralization of Ovarian Cancer Surgery Services

An extensive body of data exists supporting the relationship between surgical volume and mortality; however, the mechanisms underlying this association remain elusive. In ovarian cancer, the relationship between hospital volume and outcome has been controversial; however, recent population-based studies demonstrate an independent relationship between high-volume physicians working in high-volume hospitals and improved disease-free and overall survival (47–49).

The relationship between hospital volume and surgical complications is less clear. Population-based data demonstrate that the 30-day readmission rate following surgery for stage IIIC/IV ovarian cancer is 19% (50), which is consistent with previously published single institution studies (51). The most common reasons for readmission are infection (35%), dehydration (34%), ileus/obstruction (26%), metabolic/electrolyte derangements (23%), and anemia (12%) (92). There does not appear to be a significant relationship between 30-day readmission rates and hospital or physician volume; however, readmission is an independent predictor of reduced overall survival (50).

An analysis of the Agency for Healthcare Research and Quality's Nationwide Inpatient Sample demonstrated that the overall complication rate after surgery for ovarian cancer is 22% (52). Complications are significantly increased in high-volume compared to low-volume hospitals, possibly reflecting a more aggressive approach to cytoreduction. However, patients who experience a complication in a low-volume hospital are almost 50% more likely to die, suggesting that failure to rescue from complications is an important source of the volume-based variation in ovarian cancer outcomes (52).

Although the multifactorial nature of the relationship between volume and outcome in ovarian cancer surgery requires further investigation, it is clear that hospital and physician volume do predict improved survival; this is not due to a reduced complication rate, but may be related to the availability of multidisciplinary teams to manage complications in a timely and appropriate manner.

Surgery for Uterine Cancer

Acute Complications

Until recently, total abdominal hysterectomy was considered the standard surgical approach to hysterectomy for uterine cancer. However, minimally invasive surgical techniques have become increasingly popular due to their favorable outcomes in treatment. To date, three prospective randomized controlled clinical trials are available to compare outcomes from open and laparoscopic surgery for uterine cancer (12–14). The Gynecologic Oncology Group (GOG) **LAP2 Trial (GOG 222)** recruited a total of 2,616 women (12). Patients were eligible if they had clinical stage I to IIA uterine cancer; all histological cell types were allowed; and all patients had to have undergone pelvic and aortic lymph node dissection. The Australian **LACE Trial** enrolled 760 patients. Patients were eligible if they had endometrioid cell type, clinical stage I disease; patients were not eligible if they had a uterine size larger than 10 weeks gestation, had evidence of extrauterine spread (ovarian masses, enlarged lymph nodes), or were unfit for surgery due to medical comorbidities (14). The **Dutch TLH Trial** aimed to compare outcomes in early-stage endometrial cancer treated by laparoscopy or laparotomy. Patients with early-stage endometrial cancer (endometrioid cell type, FIGO grade 1 or 2, clinical stage I disease, negative endocervical curettage) or complex endometrial hyperplasia with atypia were eligible (13). Intraoperative surgical complications were comparable in all three trials.

In the LAP2 trial, postoperative surgical complications were significantly more common in patients who had a laparotomy than in patients who had a laparoscopic procedure (21% vs. 14%). Postoperative ileus (8% vs. 4%) and cardiac arrhythmia (2% vs. 1%) were significantly more common in patients in the open/laparotomy group. In the LACE trial, the open/laparotomy group had a 44% higher incidence of postoperative complications (18.6% in open, 12.9% in laparoscopic) compared to patients in the laparoscopy arm. The incidence of serious adverse events was 74% higher in the open group compared to the laparoscopy group (14.3% for open, 8.2% for laparoscopy). Wound infections or dehiscence were the main contributors to the difference in postoperative complications between laparoscopic (2.0%) and open (8.9%) groups. An open surgical approach (laparotomy), higher Charlson's medical comorbidities score, moderately or poorly differentiated tumors on curetting, lower performance status prior to surgery, obesity, and anemia were independently associated with an increased risk for surgical adverse events (53). Patient's age at surgery was not a risk factor for surgical complications. The Dutch TLH trial recorded comparable postoperative surgical complications in the open and the laparoscopic group (10.6% open/laparotomy; 11.9% laparoscopy). Interestingly, the incidence of postoperative complications was similar among all three trials for patients randomized to the laparoscopic arm (ranging from 11.9% to 14%). In contrast, the incidence of postoperative complications in the open/laparotomy arm was significantly lower in the Dutch TLH trial (10.6%) compared to LACE (18.6%) or LAP2 (21%). In the Dutch TLH trial, no patient required a retroperitoneal node dissection, whereas in the U.S. LAP2 trial, all patients required a pelvic and aortic lymph node dissection. In the Australian LACE trial, approximately half of patients had a retroperitoneal node dissection; however, no differences in the incidence of acute surgical complications were observed between the treatment arms when stratified by nodal dissection status.

Hysterectomy is irrevocably associated with loss of fertility, which should be considered in the context of young women desiring a family. Alternative options currently evaluated in clinical trials include systemic and intrauterine progestin treatment and may result in total pathological responses in up to 50% to 70% of patients (54).

Chronic Complications

Lymphedema and lymphocele are the main chronic complications following surgery for uterine cancer, and the incidence varies depending on the type of surgery and extent of lymph node removal. Overall, lymphedema occurs in 20% of patients following hysterectomy with lymphadenectomy (55). Obesity, the number of lymph nodes removed, the extent of surgery, postoperative infection, radiation therapy, and postoperative DVT increase the risk of developing lymphedema. Lymphoceles are an accumulation of lymphatic fluid in dead space due to postoperative leakage of lymphatic fluid coupled with incomplete lymphatic reabsorption. Most lymphoceles are asymptomatic and found incidentally. The true incidence is therefore unknown (range, 0% to 58.5%) (56–58).

Morcellation

The use of power morcellation in gynecological surgery has come under scrutiny recently following a case of inadvertent dissemination of an unrecognized leiomyosarcoma, which was highlighted by a Food and Drug Administration (FDA) safety notice (59).

First described in 1993 (60), electric power morcellators have become an important adjunct to minimally invasive gynecologic surgery and were used in up to 15% of minimally invasive hysterectomies in the United States up to 2012 (61) resulting in a significant proportion of women avoiding a laparotomy. Compared to a minimally invasive approach, laparotomy is associated with a prolonged hospital stay, more postoperative pain, increased wound complications, venous thromboembolism, and incisional hernias (62).

Increased scrutiny of power morecellation has not only focused on the inadvertent dissemination of unrecognized malignancy but also on other morcellation-related complications. A review of the FDA Manufacturer and User Facility Device Experience database identified 55 complications (11 involving more than 1 organ) including 6 deaths from 1993 through 2013. Bowel injuries (n = 31) were the most commonly reported complications, followed by vascular injuries (n = 27) and injuries to the kidney (n = 3), ureter (n = 3), bladder (n = 1), and diaphragm (n = 1) (61).

Occult uterine malignancies may be present in 9 to 100 per 10,000 women undergoing power morcellation (59,63–65). Multiple studies have demonstrated that patient age is the most important risk factor and morcellation should be avoided in postmenopausal women (66). Given the association between tamoxifen and uterine sarcoma it is advisable to avoid morcellation in these patients, but women are also at risk of inadvertently being diagnosed with endometrial cancers following morcellation of specimens.

While much of the controversy involves the use of electric power morcellation, morcellation can also be used as a surgical technique in vaginal and open surgery with or without the use of power morcellators. The major risk of morcellation is peritoneal seeding of an occult malignancy. Three retrospective cohort studies included patients who underwent exploratory surgery shortly after inadvertent morcellation of a presumed stage 1 uterine sarcoma (64,67,68). Nine of 31 patients (29%) with presumed stage 1 leiomyosarcoma had disseminated peritoneal disease at their second procedure, and five of nine patients (55%) with STUMPS had peritoneal nodules (69). Although some studies suggest that morcellation of stage 1 leiomyosarcoma is associated with a worse outcome, these data should be interpreted with care given the aggressive and unpredictable nature of this disease. Although the numbers are relatively small, this data agrees with previous studies that advocated completion surgery and restaging of uterine malignancy found inadvertently after morcellation for presumed benign disease (68). Data are lacking with respect to the risks associated with inadvertent morcellation of endometrial carcinoma.

Surgery for Cervical Cancer: Radical Hysterectomy and Pelvic Exenteration

Acute Complications

Radical hysterectomy for early-stage cervical cancer is associated with a major complication rate (excessive blood loss, urinary/gastrointestinal tract injury, nerve injury) of 5% to 10%. Vesicovaginal and ureterovaginal fistulas occur in 1% to 3% of cases and typically present within 14 days of surgery with urinary leakage per vagina, commonly associated with pain or fever (70). A CT-Urogram with IV contrast is usually diagnostic for a ureteric fistula. If an injury to the urinary tract is suspected, a cystoscopy with or without a retrograde pyelogram, instillation of methylene blue dye intravenously or via retrograde instillation into the bladder can also help to distinguish a vesicovaginal from ureterovaginal fistula or a combined ureteric plus vesicovaginal fistula.

Small vesicovaginal fistulas can often be managed with prolonged catheterization and continuous decompression of the bladder for 4 to 6 weeks. Ureterovaginal fistulas can often be managed with ureteral stenting or percutaneous nephrostomy.

For nonhealing fistulas, larger fistulas (>1 cm), or complex fistulas involving both ureter and bladder, surgical management with closure is indicated. Typically closure is optimal in a dry environment and can be approached vaginally with a Latzko partial colpocleisis if the defect is small, apical, and not in proximity to the ureter. Bulbocavernosus or Martius fat pad grafts can also be used (71). Trigone involvement or larger complex fistulas are best approached abdominally with re-implantation of the ureter(s) into the bladder or a layered closure with or without an omental flap (72). Urinary retention due to sensory loss and voiding dysfunction are well-recognized complications of radical hysterectomy and result from the denervation of the bladder during the parametrial dissection. Most patients are managed with prolonged bladder decompression for 3 to 7 days with a transurethral or suprapubic catheter. A retrograde voiding trial is recommended to assess for bladder function prior to removal of the catheter, and postvoid residual values of less than 100 mL are generally acceptable.

Minimally invasive approaches to radical hysterectomy, including both traditional laparoscopic and robotically assisted techniques, may offer several health-related benefits including less pain, shorter hospital stay, and more rapid return to full activity than the abdominal approach. However, the incidence of vaginal cuff complications/dehiscence (1.6% to 4.1%) may be higher than that observed with laparotomy (<0.5%); there is also a potential higher risk for nerve injuries (73,74).

Total pelvic exenteration (TPE) is primarily indicated as salvage therapy for cervical cancer patients who have failed radiation therapy or require combined treatment of recurrence in the central pelvis. Acute perioperative morbidity related to TPE is high, with up to 75% of patients experiencing a major complication, and mortality rates of 1% to 5% are typical. Furthermore, reoperation rates to address major complications are high, with rates of 16% to 25.6% reported in the literature (75,76). Morbidity of TPE is attributable to long operative times, compromised healing of the irradiated field, and the complexity of the surgical reconstruction. Significant blood loss, infectious morbidity primarily involving the urinary tract, sepsis, wound complications, fistulas, ileus, and anastomotic leaks of the intestinal or urinary anastomosis are some of the more commonly reported complications. Sepsis, adult respiratory distress syndrome, heart failure, pulmonary embolus, and multiorgan system failure are typical terminal events.

The acute complication rate for both urinary continent and incontinent and urinary diversion ranges from 17% to 20%; these complications include urinary leak, fistula, or anastomotic failure (77). Such problems can be managed conservatively in many cases with prolonged conduit drainage and diversion with percutaneous nephrostomy. Refractory leaks may require surgical revision of the reservoir. Despite the high risk of complications, 5-year survival is in the range of 50% (76,78,79).

Chronic Complications

Urinary retention following radical hysterectomy is usually self-limited; however, long-standing bladder dysfunction may require patient intermittent self-catheterization. Long-term rectal dysfunction is similarly encountered and manifests as constipation or urgency. Nerve-sparing radical hysterectomy, which preserves autonomic and splanchnic innervation to the

bladder and rectum, has been reported to decrease bladder and rectal morbidity (70,80). Ureteral strictures are encountered in 1% to 3% of patients and may present with fever and pain, but may be asymptomatic and can lead to loss of renal function. Management is with ureteral stent placement, if possible, or percutaneous nephrostomy placement. Rarely, a ureteric re-implantation may be required. Colonic stomas may be prone to prolapse, hernia, or stricture. However, the most commonly reported intestinal complication is bowel obstruction. Unlike early postoperative bowel obstruction, late obstructions are more likely due to adhesive disease or disease recurrence. Sexual dysfunction is an underreported long-term side effect following radical hysterectomy (81).

Patients undergoing pelvic exenteration are at risk for a number of long-term complications. Urinary diversions are prone to stomal stricture, chronic urinary tract infection, renal dysfunction, nephrolithiasis, metabolic alterations, and difficulty with accessing the reservoir (78,79). Reestablishing intestinal continuity after exenteration has been advocated to minimize the long-term psychosocial and quality-of-life issues surrounding two permanent abdominal stomas but has been associated with a higher risk of reoperation (50% to 60%) and disease recurrence (79). Sexual dysfunction and distorted body image are common problems associated with pelvic exenteration.

Surgery in the Irradiated Field

Radiation induces a complex series of tissue changes including vascular sclerosis and tissue ischemia, the end result of which is fibrosis. Tissue planes are obliterated and healing is compromised. It is estimated that approximately 5% to 7% of patients who undergo radiation therapy for cervical cancer will experience major treatment complications that require surgery (82). The most common sites of intestinal injury in patients who undergo pelvic irradiation are areas that typically lie in the pelvic field. The terminal ileum is the most frequent site of late injury, because of the greater radiosensitivity of the small intestine compared with the colon. The most common indications for reoperative surgery in patients irradiated for cervical or endometrial cancer are intestinal stricture (44%), intestinal fistula or perforation (32%). Radiation damage frequently leads to matted loops of distal ileum densely fixed in the pelvis associated with obstruction or fistula. In the setting of intestinal necrosis, perforation, or abscess formation, resection should be attempted if it can be done without undue risk of damage to adjacent structures. Alternative, more conservative approaches such as intestinal bypass procedures are less morbid, but may lead to the development of blind loop syndrome or result in subsequent spontaneous perforation or fistula formation. In a series of 77 patients who underwent surgery for radiation injury to the small intestine, no difference in short-term complications was noted between patients who underwent resection compared to those who underwent bypass (83).

Urinary tract complications that may lead to surgery in a previously radiated patient include radiation-induced nonhealing or complex ureterovaginal or vesicovaginal fistulas and ureteral strictures, which may compromise renal function. Asymptomatic strictures are more common and underreported in the literature, and may lead to a silent loss of renal function. Most cases of radiation injury to the lower urinary tract can be managed conservatively with ureteric stent placement, percutaneous nephrostomy, or attempts at endoureteral dilation. Recurrent cancer must always be considered, and the appropriate diagnostic biopsies and imaging obtained, prior to consideration for surgical correction or urinary diversion (84).

Surgery for Vulvar Cancer

Acute Complications

Surgical innovation in vulvar cancer evolved as a way to minimize the risk of surgical complications associated with the en bloc radical vulvectomy and bilateral inguinal lymphadenectomy popularized by Stanley Way in the 1950s, rather than from a concern about poor survival outcomes. Vulvar or groin wound breakdown occurs in as many as 50% of patients

following radical vulvectomy (85–87). Development of a wound infection is predictive of future wound breakdown and lymphedema (86). Risk factors include increased patient age, obesity, diabetes mellitus, smoking, and prior radiation to the groin. The use of myocutaneous, cutaneous, or skin flaps can reduce tension on suture lines, prevent wound breakdown or infection, and improve cosmetic and functional outcome. A nonrandomized, prospective study showed a reduction in wound breakdown for patients undergoing radical vulvectomy with lymph node dissection and hyperbaric oxygen therapy (88).

Contemporary management of vulvar cancer is tailored to the size and location of the primary tumor, and generally consists of radical partial vulvectomy or wide radical excision combined with ipsilateral or bilateral inguinal lymphadenectomy through separate groin incisions (89). The incidence rates of wound infection, cellulitis, and wound breakdown are 21% to 39%, 21% to 57%, and 17% to 39%, respectively. Optimizing glucose control in patients with diabetes mellitus, using appropriate antibiotic prophylaxis, and sparing the saphenous vein are important prevention strategies (90). Compared to systematic groin node dissection, sentinel lymph node biopsy (SLNB) is associated with a reduction in groin wound breakdown (11.7% vs. 34%) and cellulitis (4.5% vs. 21.3%) (91).

Chronic Complications

Chronic complications from vulvar cancer surgery are often a result of groin node dissection. As many as 50% of patients requiring a groin dissection will experience a long-term complication related to the procedure. Lymphedema occurs in 14% to 48% of patients requiring surgery to the vulva and the groins and in almost 100% of patients requiring postoperative radiation treatment. Lymphedema presents as leg swelling or heaviness of the lower limbs (92). It is regarded as the most debilitating long-lasting side effect from vulvar cancer surgery and results in an inability to perform daily activities, impacts psychological and social well-being, and represents a significant financial burden associated with the treatment (93). Obesity, the number of lymph nodes removed, extent of surgery, postoperative infection, radiation therapy to the groins, and postoperative DVT increase the risk of developing lymphedema after groin dissection (94). SLNB has been associated with a 1.9% incidence rate of lymphedema, compared with 25.2% in patients undergoing systematic groin dissection (91). Lymphocele formation develops in 7% to 19% of patients after inguinal–femoral lymphadenectomy (85).

Over half of women who undergo vulvectomy report sexual dysfunction and psychological issues resulting in dyspareunia, problems with micturition, negative feelings about body image, decreased desire, and inability to orgasm (93). Providing information before and after surgery that details how the treatment may affect sexuality and change anatomy, as well as the provision of methods for how to cope with feelings regarding the illness, may decrease anxiety. The FACT-V questionnaire is a valid and reliable tool that can measure the impact of treatment on QOL and improve standardization or quality-of-life research efforts.

CHAPTER 30 Management of Pain

Russell K. Portenoy, Ebtesam Ahmed and Pauline Lesage

The heterogeneous patient population managed by gynecologic oncologists presents a broad range of problems in pain management. Acute pains are highly prevalent, including the rather straightforward incisional pain that follows surgical procedures. Chronic pain occurs in the context of numerous other physical and psychosocial symptoms, often in the population with advanced disease. Gynecologic oncologists have the opportunity to treat pain across all of these contexts, and in so doing, assist patients in maintaining an acceptable quality of life throughout the course of the illness.

SCOPE OF THE PROBLEM

Persistent pain is experienced by almost two-thirds of cancer patients with metastatic disease, more than half of those receiving antineoplastic therapy, and about one-third of cancer survivors (1–3). The limited data specific to gynecologic tumors mirror these rates (4,5). For example, a retrospective survey that evaluated 88 women with advanced cervical cancer observed that pain was reported by 81% and was considered to be one of the predominating symptoms by treating clinicians (6). Persistent pain may be related to tissue injury caused by the neoplasm itself, a late effect of an antineoplastic therapy, or a pathology unrelated to the cancer (7–9); most patients with persistent pain have active disease and pain that can be attributed directly to the tumor.

Observational studies suggest that an opioid-based therapeutic regimen can provide satisfactory relief of chronic cancer pain in 70% to 90% of patients (10,11). Undertreatment remains a serious problem, however, despite the availability of well-accepted guidelines for pain management (12–18).

Although the prevalence of severe acute pain in patients with gynecologic cancers has not been determined, and is likely changing with the increasing use of minimally invasive procedures, it is nonetheless presumed to be extremely common. Although acute pain is potentially controllable in a very large majority of cases, some scenarios such as the management of acute postoperative pain after ambulatory surgery pose challenges.

Patients with cancer, and particularly those with advanced disease, also experience numerous symptoms other than pain. Across cancers, the most common of these symptoms are fatigue and psychologic distress (3). Studies suggest that distress is often multifactorial and determined by interactions involving multiple symptoms, physical losses, and psychologic, social, or spiritual concerns (17). Pain may or may not be the predominating source of distress at any point in time. Other symptoms, such as fatigue, may be perceived to be the most distressing symptom adversely affecting quality of life (19). When pain is accompanied by significant fatigue, assessment of the latter symptom and treatment of its causes may become the focus of care (15) in the hope that improved fatigue may enhance the positive impact on quality of life achieved from pain reduction. A therapeutic approach that addresses concomitant symptoms of any type may yield similar benefits.

ASSESSMENT OF CANCER PAIN

The assessment of chronic pain in patients with gynecologic cancer requires an understanding of its phenomenology, pathophysiology, and syndromes. This assessment should also consider the broad range of physical, psychologic, and social disturbances concurrently experienced by these patients. Patients with acute pain, particularly acute postoperative pain, pose less complex management problems, but could still potentially benefit from a comprehensive assessment. The patient's description of the pain, findings on physical examination, objective data from imaging and other tests, and information about the extent of the malignant disease and its treatment are all utilized to assess the likely etiology and underlying pathophysiology of the pain and, if possible, to identify a specific cancer syndrome (20).

National medical organizations have developed guidelines in an effort to more effectively detect and monitor pain. The Joint Commission on Accreditation of Healthcare Organizations developed a standard requiring that pain be assessed initially and periodically in all hospitalized patients. The National Comprehensive Cancer Network Adult Cancer Pain Guidelines require a formal pain assessment, measurement of pain intensity, reassessment of pain intensity at specific intervals, psychosocial support, and specific educational material (15).

Definition of Pain

According to the International Association for the Study of Pain, pain is "an unpleasant sensory and emotional experience associated with actual or potential tissue damage, or described in terms of such damage" (20). This definition underscores the important observation that the pain reported by a patient may be perceived by the clinician to be greater than or less than the observable degree of tissue injury. When pain is acute, and when it is persistent and clearly related to tumor injury, a physical process capable of explaining the pain can usually be identified and is often considered an adequate explanation for the pain. Even in these contexts, however, a careful assessment of psychosocial disturbances is needed to clarify the extent to which pain expression is influenced by factors other than tissue damage.

The definition of pain can be further clarified by the distinctions among nociception, pain, and suffering (Fig. 30.1) (21). Nociception is the physiologic process activated by potentially tissue-damaging stimuli. Clinically, nociception is inferred to exist whenever tissue damage is identified. Pain is the perception of nociception and, like other perceptions, can be determined by more than the activity in the sensorineural apparatus alone. Pain that persists after tissue injury heals illustrates the importance of processes other than nociception when pain becomes chronic.

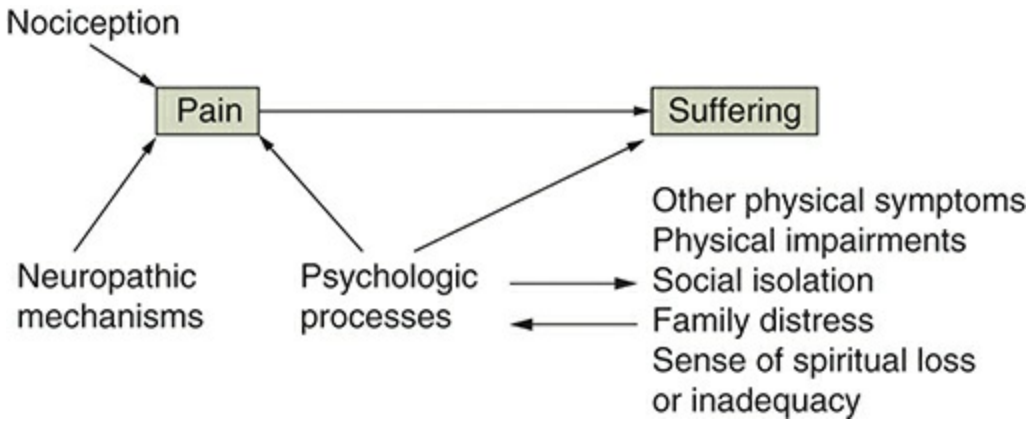

Figure 30.1 Distinctions and interactions between nociception, pain, and suffering. Source: Reproduced with permission from Portenoy RK. Cancer pain: pathophysiology and syndromes. Lancet. 1992:339:1026–1031.

Suffering, or "total pain," can be defined as a more global aversive experience determined by numerous perceptions, one of which may be pain. Among the many other factors that may contribute to suffering are the perception of physical deterioration, the experience of symptoms other than pain, psychologic disturbances (e.g., depression or anxiety), disruption in the family, social isolation, and fear of death. Just as an inordinate focus on nociception, rather than pain, can

lead to interventions that reduce tissue damage without alleviating pain, an emphasis on pain management alone in patients with profound suffering determined by other factors can fail to mitigate the burden of illness even if physical comfort is enhanced (22,23).

Evaluation of the Pain Complaint

The comprehensive assessment of pain should include information about temporal characteristics (onset and duration), course (stable or changing since onset, relatively constant, or widely fluctuating), severity (both average and worst), location, quality, and provocative and palliative factors. This evaluation is complemented by information about the patient's extent of disease, related medical and psychosocial conditions, present and past pain management strategies and their outcomes, and the impact of the pain on the patient's daily life and functioning (1,23). Information about the patient's and family's knowledge of, expectations about, and goals for pain management is also salient (24).

Characteristics of Pain

Intensity

The measurement and recording of pain intensity is an essential element in the comprehensive assessment of pain. The most common approaches are a verbal rating scale (none, mild, moderate, severe, excruciating), a numerical scale (where 0 is no pain and 10 is the worst pain imaginable), and a visual analogue scale (VAS) that uses a 10-cm line anchored at one end by the words "no pain" or "least possible pain" and at the other end by "worst possible pain." There are also a variety of scales that use drawings of faces (from smiling to distress) or other types of drawings that may be used for patients who cannot manage other types of tools (e.g., Wong–Baker Pain Rating Scale for children). The choice of scale is less important than consistency in its use over time.

Formal instruments have also been developed that describe pain in multiple dimensions. An example is the Brief Pain Inventory (BPI), a patient self-rating scale that assesses pain intensity and pain interference in various areas of function (25). A short-form version of the BPI (BPI-SF) and translations in multiple languages are available. Examples of older multidimensional pain measurement tools are the McGill Pain Questionnaire (26), which assesses the sensory, affective, and evaluative components of pain, and Memorial Pain Assessment Card, which measures pain intensity, pain relief, and mood on VASs and verbal scales (27). Multidimensional pain scales may be particularly useful in pain research. A consensus has emerged highlighting the importance of multidimensional pain assessment in studies that evaluate pain treatments (28).

Temporal

Acute pain usually has a well-defined onset and a readily identifiable cause (e.g., surgical incision). It may be associated with anxiety, overt pain behaviors (moaning or grimacing), and signs of sympathetic hyperactivity (including tachycardia, hypertension, and diaphoresis).

In contrast, chronic pain is characterized by an ill-defined onset and a prolonged, fluctuating course. Overt pain behaviors and sympathetic hyperactivity are typically absent, and vegetative signs, including lassitude, sleep disturbance, and anorexia, may be present. A clinical depression evolves in some patients. Most patients with chronic cancer pain also experience periodic flares of pain, or "breakthrough pain," an observation with important therapeutic implications. (29–31).

Topographic

The distinctions among focal, multifocal, and generalized pains may influence both the assessment and treatment of the patient. Some therapies, such as nerve blocks, specifically depend on the specific location and extent of the pain.

The distinction between focal and referred pain is similarly important. Focal pains are experienced superficial to the underlying nociceptive lesion, whereas referred pains are experienced at a site distant from the nociceptive lesion. Pain may be referred from a lesion involving any of a large group of structures, including nerve, bone, muscle, or other soft tissue, and viscera (32). Various subtypes can be distinguished: (a) pain referred anywhere along the course of an injured peripheral nerve (such as pain in the thigh or knee from a lumbar plexus lesion); (b) pain referred along a course of the nerve supplied by a damaged nerve root (known as radicular pain); (c) pain referred to the lower part of the body, usually the feet and legs, from a lesion involving the spinal cord (called funicular pain); and (d) pain referred to a site remote from the nociceptive lesion and outside the dermatome affected by the lesion (e.g., shoulder pain from diaphragmatic irritation).

Knowledge of pain referral patterns is needed to target appropriate assessment procedures. For example, a patient with recurrent cervical cancer who reports progressive pain in the inguinal region may require evaluation of numerous structures to identify the underlying pathology responsible for the pain, including the subjacent pelvic bones and hip joint, pelvic sidewall, paraspinal gutter at an upper lumbar spinal level, and intraspinal region at the upper lumbar level.

Etiology

The etiology of acute pain is usually clear-cut. Further evaluation to determine the underlying lesion or pathophysiology of the pain is not indicated unless the course varies from the expected. In contrast, the etiology of chronic pain may be more difficult to characterize. In most cases, pain is due to direct invasion of pain-sensitive structures by the neoplasm (1,3). The structures most often involved are bone and neural tissue, but pain can also occur when there is an obstruction of hollow viscus, distention of organ capsules, distortion or occlusion of blood vessels, and infiltration of soft tissues. The etiology of pain in less than a quarter of patients relates to an antineoplastic treatment, and less than 10% of patients have pain unrelated to the neoplasm or its treatment (33).

Pathophysiology

Clinicians have found it useful to characterize pain according to inferences related to pathophysiology. Although this type of classification greatly simplifies a very complex biology, it has been effectively used to help guide treatment.

Pain is labeled *nociceptive* if it is inferred that the sustaining mechanisms involve ongoing tissue injury involving either somatic or visceral structures. The diagnosis is made based on the finding of tissue injury and the quality of the pain. The quality of somatic nociceptive pain is typically described as aching, stabbing, throbbing, or pressure-like. The quality of visceral nociceptive pain is largely determined by the structures involved. Obstruction of hollow viscus is usually associated with complaints of gnawing or crampy pain, whereas injury to organ capsules or mesentery is associated with an aching or stabbing discomfort.

Pain is labeled *neuropathic* if the evaluation suggests that it is sustained by abnormal somatosensory processing in the peripheral or the central nervous system (CNS) and there is some identifiable neurologic injury. Neuropathic pain represents approximately 40% of cancer pain syndromes and can be disease-related (e.g., tumor invasion of nerve plexus) or treatment-related (chemotherapy-induced painful polyneuropathy) (34). Among those with metastatic disease, neuropathic pain usually results from neoplastic injury to peripheral nerves.

Neuropathic pain is diagnosed on the basis of the patient's verbal description of the pain and evidence of injury to neural tissue. Patients may use any of a variety of verbal descriptors but specific terms, such as "burning," "shock-like," or "electrical," are particularly suggestive of neuropathic pain (35). Areas of abnormal sensations are often found on physical examination. These may include hypesthesia (a numbness or lessening of feeling), paresthesias (abnormal nonpainful sensations such as tingling, cold, or itching), hyperalgesia (increased perception of painful stimuli), hyperpathia (exaggerated pain response), and allodynia (pain induced by nonpainful stimuli such as a light touch or cool air).

Psychogenic pain, a conventional term for some of the disorders labeled in psychiatric parlance as somatoform disorders, reflects the clinical impression that pain results primarily from psychopathologic processes. Although psychologic factors and comorbid psychiatric disorders often influence pain expression, psychogenic pain itself appears to be rare.

Although the diagnosis of psychogenic pain is seldom appropriate, the existence of this condition emphasizes the importance of psychosocial and psychiatric evaluation as part of the pain assessment. The diagnosis of comorbid psychiatric disorders can lead to important therapeutic opportunities. The prevalence of major depression in heterogeneous populations with cancer approaches 10% and may be much higher in various subgroups, including patients who are newly diagnosed (36–38).

If the assessment of the pain does not provide enough information to categorize it using one or more of these labels, it is important to acknowledge this and avoid labeling the patient with a term that may direct care inappropriately. The greatest concern in this regard is the labeling of pain as psychogenic when the assessment does not yield positive evidence of a psychiatric disorder but an alternative answer is lacking. In this case, it is better to label the pain *idiopathic* than to speculate about underlying factors that are not clearly demonstrable from the evaluation.

Pain Syndromes

Efforts to improve the assessment of cancer pain have been greatly encouraged by the description of numerous pain syndromes, each of which is defined by a cluster of symptoms and signs (39,40). Syndrome identification in patients with gynecologic cancers can help direct the diagnostic evaluation, clarify the prognosis, and target therapeutic interventions (Tables 30.1 and 30.2).

TABLE 30.1 Cancer Pain Syndromes

I. Pain associated with direct tumor involvement
   - A. Due to invasion of bone
     1. Base of skull
     2. Vertebral body
     3. Generalized bone pain
   - B. Due to invasion of nerves
     1. Peripheral nerve syndromes
     2. Painful polyneuropathy
     3. Brachial, lumbar, sacral plexopathies
     4. Leptomeningeal metastases
     5. Epidural spinal cord compression
   - C. Due to invasion of viscera
   - D. Due to invasion of blood vessels
   - E. Due to invasion of mucous membranes

II. Pain associated with cancer therapy
   - A. Postoperative pain syndromes
     1. Post-thoracotomy syndrome
     2. Postmastectomy syndrome
     3. Postradical neck dissection
     4. Postamputation syndromes
   - B. Postchemotherapy pain syndromes
     1. Painful polyneuropathy
     2. Aseptic necrosis of bone
     3. Steroid pseudorheumatism
     4. Mucositis
   - C. Postirradiation pain syndromes
     1. Radiation fibrosis of brachial or lumbosacral plexus
     2. Radiation myelopathy
     3. Radiation-induced peripheral nerve tumors

4. Mucositis

III. Pain indirectly related or unrelated to cancer

A. Myofascial pains
B. Postherpetic neuralgia
C. Chronic headache syndromes

TABLE 30.2 Pain Syndromes Commonly Encountered Among Patients with Gynecologic Cancer

Acute pain syndromes
At any stage of disease:
Postoperative pain
Mucositis
In advanced stages of disease:
Recurrent bowel obstruction
Ureteral obstruction
Movement-related pain in brachial/lumbosacral plexopathy
Movement-related pain from bony lesions
Cancer-related chronic pain syndromes
Brachial/lumbosacral plexopathy
Chronic abdominal pain: bowel obstruction, ascites, hepatomegaly
Tenesmoid pain
Bone pain from metastases
Treatment-related chronic pain syndromes
Postmastectomy syndrome
Radiation-induced plexopathy
Chemotherapy-induced peripheral neuropathy (paclitaxel, cisplatin)

MANAGEMENT OF ACUTE PAIN

Although the treatment of patients with acute pain, particularly postoperative pain, is typically less challenging than the long-term management of chronic pain, the outcomes achieved in routine practice settings are often inadequate. Given the potential efficacy of widely used strategies, such as patient-controlled analgesia, less-than-satisfactory outcomes may be more related to systems issues, such as access to a pain service or prolonged pharmacy preparation times, than purely clinical issues. Cancer patients also commonly have concurrent medical problems, psychologic disturbances, and prior and current drug exposures that may increase the heterogeneity of the population and diminish the likelihood that routine measures provide adequate relief of pain. The need for clinicians and administrators to attend to the problem of acute pain and provide the resources and systems for expert management is therefore particularly important in this population.

“Routine” Approach to Postoperative Pain

Despite great variability in the pharmacokinetics and pharmacodynamics of single opioid doses, many patients with severe acute pain respond adequately to a standard opioid regimen consisting of parenteral doses of a short-acting drug administered "as needed." For example, an opioid-naïve patient with acute severe pain may be treated initially using intravenous morphine 5 mg every 3 hours as needed. If the patient has a history of current opioid use for pain, a higher starting dose is needed and a reasonable guideline would be to initiate dosing so that each intravenous dose is calculated to be equivalent to roughly 5% to 10% of the total opioid consumption during the previous 24 hours. This calculation of equivalent doses is based on the information in an equianalgesic dose table. If the starting dose or interval selected initially is not quickly effective, an increase in the dose or shortening of the dosing interval should be considered.

Acute severe pain generally should be treated with a short-acting drug. Many agents other than morphine are available for parenteral therapy, including hydromorphone, oxymorphone, and fentanyl. Meperidine was often used in the past, and although likely to be well tolerated during brief therapy, is generally not preferred because its toxic metabolite, normeperidine, imparts risks that are not shared by other similar drugs.

The intramuscular route was also commonly used in the past. There is no advantage to this, and painful injections have been supplanted by use of the intravenous route.

The proportion of cancer patients with postoperative pain who will be undertreated by an as-needed dosing schedule can be diminished if several factors are recognized. Most important, titration may be needed. The variability in analgesic requirements may require changes in the starting dose, adjustment in the dosing interval during the immediate postoperative period, or both. Some patients require several dose adjustments. Similarly, variability in pain duration after any particular operation is great and the duration of opioid treatment must be flexible, determined solely by patient response. Some patients have concerns about opioid-induced side effects and addiction, which may augment distress and diminish patient compliance with therapy unless strong reassurance is provided by the physician and other staff.

In some populations, the routine approach to postoperative pain management can be enhanced by the use of a nonopioid analgesic, specifically a nonsteroidal anti-inflammatory drug (NSAID). In the United States, ketorolac, ibuprofen, and acetaminophen all have been approved for short-term parenteral use. In opioid-naïve patients, a standard dose of ketorolac can provide analgesia equivalent to a parenteral dose of morphine of 10 mg. The addition of intravenous ketoprofen (not approved in the United States) to intravenous patient-controlled analgesia with tramadol after major gynecologic cancer surgery was shown to significantly reduce opioid consumption (41). At the present time in the United States, patients who are highly predisposed to opioid side effects or toxicity, such as those with severe preexisting lung disease, may benefit from a trial of one of the intravenous nonopioid analgesics, either in lieu of opioid therapy or in combination with an opioid. Ketorolac and ibuprofen should not be used when NSAID treatment is contraindicated.

Patient-Controlled Analgesia

Patient-controlled analgesia (PCA) has achieved great popularity in the management of postoperative pain and there is strong evidence that it improves analgesia, decreases the risk of pulmonary complications, and increases patient satisfaction when compared with conventional opioid analgesia (42). Theoretically, the self-administration of small doses on a frequent basis allows the patient to tailor the dose to the pain and enhance a sense of personal control while achieving a more stable plasma drug concentration. However, not all studies of this modality have been positive. For example, a randomized, controlled trial of 227 gynecologic cancer patients undergoing intra-abdominal surgery found that patients who were switched from parenteral to oral morphine on the first postoperative day experienced the same degree of pain control as those who received parenteral morphine via PCA pump (43). The latter studies suggest that careful attention to dosing rather than the availability of a pump per se is the key factor in achieving adequate pain control.

If PCA is selected, effective analgesia in the opioid-naïve patient is usually attained using morphine at a dose of 1 mg intravenously every 6 minutes as needed, or another opioid at an equivalent dose. Patients already receiving opioid therapy can be treated using higher-dose PCA. Each intravenous dose of the new opioid may be calculated to be roughly equivalent to approximately 5% of the total daily dose of opioid taken during the prior day, and this dose may be initiated with a

longer initial dosing interval, such as 10 or 15 minutes.

Other Approaches to Acute Pain Management

Advances in pain research have suggested a variety of other strategies that may be useful as adjunctive therapies for acute cancer-related pain, including postoperative pain. Some strategies require the expertise of pain specialists.

Preemptive Analgesia

The administration of an analgesic prior to surgical tissue injury may reduce postoperative pain and opioid requirements, and possibly have long-term benefits. For example, pretreatment with sustained-release morphine or oxycodone reduced postoperative pain and analgesic requirements (44,45). Although this type of approach is seldom used due to conflicting data in the literature and uncertainty about the specific approach likely to be safe and effective in large groups of patients, it may be worthwhile considering if the acute pain is predictable and likely to be a therapeutic challenge.

Postoperative Combination Therapy

As noted previously, the addition of an NSAID in combination with an opioid can augment analgesia and reduce the use of opioids, potentially leading to reduction of opioid side effects. A recent controlled trial, for example, demonstrated that postoperative celecoxib improved outcomes and was well tolerated in patients undergoing laparoscopic surgery (46). Equally important, there is now substantial data demonstrating that the combination of an opioid and gabapentin, a neuronal calcium channel modulator widely used for the treatment of chronic neuropathic pain, improves a range of outcomes in diverse surgeries, including hysterectomy (47).

Intraspinal Analgesia

Epidural analgesia is now common practice in many hospitals. There is strong evidence favoring this approach over parenteral opioid therapy for some patients (48,49). Pain may be controlled with fewer opioid side effects and at a lower risk of some postoperative complications (50). Some studies suggest benefits that are prolonged into the recovery phase after surgery, but the extant data are insufficient to judge these benefits adequately (51). Some side effects are more likely with this technique than with conventional systemic opioid therapy, including pruritus and hypotension. Staff with special competencies are needed to implement the approach safely. Given the extant evidence, patients undergoing major gynecologic surgery should be considered for epidural analgesia if the resources exist to provide it. Although there is less clinical experience in the use of subarachnoid opioid administration for postoperative pain, the technique can also provide excellent relief (52).

Regional Anesthetic Techniques

There are numerous regional anesthetic techniques that may be useful for the management of acute pain. The simplest is the application of local anesthetic at the surgical site. Topical anesthetics that are longer acting are in development and may offer substantial benefits in the future.

Neural blockade capable of denervating the painful site is a potential approach in most types of surgery. Catheters that deliver local anesthetic at a dose high enough to produce a sensory block can be placed in the epidural space or along peripheral nerves or plexus. Regional anesthesia can be used during an operation and then continued into the postoperative setting for pain control.

Other Approaches

Transcutaneous electrical nerve stimulation (TENS) has been suggested as a useful modality for incisional pain after abdominal surgery (53). Despite the evident simplicity and safety of the approach, and its obvious potential, it has been used very little in this setting.

Cognitive approaches, including stress reduction, relaxation, hypnosis, and distraction techniques, may also reduce postoperative pain and analgesic requirements (54,55). These techniques are labor intensive and are almost never sufficient as the sole means of analgesia. Nonetheless, studies have established that higher levels of anxiety and depression can negatively influence postoperative pain (56,57), and efforts to reduce anxiety through preoperative education and postoperative psychologic interventions are likely to have salutary effects.

MANAGEMENT OF CHRONIC CANCER PAIN

The successful management of acute postoperative pain is an important concern of the gynecologic oncologist, and optimal pain management should be considered a standard of care. The treatment of chronic pain is a far more challenging problem, however, particularly among those with advanced illness (Table 30.3)

TABLE 30.3 Approaches Used in the Management of Chronic Cancer Pain

Cancer Pain, Symptom Distress, and Palliative Care

Most cancer patients who experience chronic pain also develop other physical and psychologic symptoms. Pain, fatigue, and psychologic distress are the most prevalent symptoms across cancer populations (58). As described before, the pain assessment should identify and evaluate nonpain symptoms so that concurrent therapy of the most problematic symptoms can be initiated.

Symptom distress, in turn, is only one aspect of the multifaceted problem of suffering (59,60). The assessment of suffering requires an evaluation in multiple domains, including the physical, psychologic, social, and spiritual. Palliative care has emerged as a therapeutic model (61) focused on the assessment and management of problems that relate to these domains and to other domains codified by specialists in the field (62). In the United States, palliative care is a formal medical subspecialty (Hospice and Palliative Medicine); specialist certification is also available for nurses, social workers,

and chaplains.

Specialist palliative care is now being provided by institution-based consultation services in most US hospitals. Community-based palliative care for patients with advanced illness and short life expectancy is provided through more than 6,000 hospice agencies in the United States. Community-based, specialist-level palliative care is emerging now, and is likely to become more available in the future.

The broad focus of palliative care on the relief of illness burden experienced by the patient and family may translate into numerous specific interventions, which often include goal setting and advance care planning discussions, symptomatic therapies, treatments to address psychosocial or spiritual distress, concrete services in the home, and efforts to manage caregiver distress and burden. The oncologist is key in providing these interventions during most of the patient's illness. This effort, overall, may be considered early integration of generalist-level palliative care into routine oncologic practice. Referral to specialist services to address complex needs, or provide hospice home care services during the period when death is anticipated relatively soon, is central to the role of the generalist.

In a provisional clinical opinion, the American Society of Clinical Oncology (ASCO) addresses the integration of palliative care into standard oncology care (63).

General Principles of Chronic Pain Management

The development of a successful strategy for pain management must include consideration of the etiology and pathophysiology of pain, the patient's medical status, and the goals of care. Although the main approach for the management of cancer pain is opioid-based pharmacotherapy, other interventions, including disease-oriented treatments (e.g., surgery, chemotherapy, or radiation) or other analgesic techniques, may be appropriate in selected cases.

Role of Primary Therapies

Effective treatment of the pathology underlying the pain can be analgesic. Primary treatment includes antineoplastic therapies and interventions directed at specific structural pathologies (e.g., lysis of adhesions). There is evidence in a limited number of cancers that specific chemotherapy regimens yield analgesic effects and it is a common observation that patients who attain a partial or complete response also experience improved symptoms. In a study of patients with metastatic breast cancer, for example, palliative chemotherapy with doxorubicin with or without vinorelbine resulted in an improvement of pain in 60.4% of the 111 patients who suffered from pain at baseline (64,65); although patients with an objective tumor response were more likely to have an improvement in pain (84.9%), fully 61% of patients with stable disease also benefited. In a small study of patients with advanced ovarian cancer, palliative chemotherapy was associated with improvement in symptom control, emotional well-being, and global quality of life (66).

Radiation therapy commonly is used to manage pain and there is evidence that it can provide effective and durable palliation of pain and other symptoms in chemotherapy-refractory patients with ovarian cancer (67,68). Radiation therapy can also provide analgesia to as many as 80% of those treated for bone metastases (69). Patients with widespread bone metastases or bone pain refractory to local field radiotherapy may benefit from treatment with radiopharmaceuticals, such as strontium 89 or samarium-153 (70). In addition, analgesia may be an expected result when radiation is used to treat epidural disease, tumor ulceration, cerebral metastases, superior vena cava obstruction, and bronchial obstruction.

Unfortunately, many patients with chronic cancer pain have no options for further primary therapy with analgesic intent. The approach to these patients involves a diverse group of analgesic treatments. Several concurrent interventions are often required to manage pain. The benefits of analgesic therapies must be balanced against their risks and the burden of therapy. Repeated assessments are essential in this process and often lead to adjustments in the therapy.

THERAPEUTIC APPROACHES: PHARMACOLOGIC MANAGEMENT

Prospective trials indicate that more than 70% of patients can achieve adequate relief of cancer pain using a pharmacologic approach (12–14). Effective pain management requires expertise in the administration of three groups of analgesic medications: NSAIDs, opioid analgesics, and adjuvant analgesics. The term *adjuvant analgesic*s is applied to a diverse group of drugs that also have primary indications other than pain but can be effective analgesics in specific circumstances, such as in the treatment of neuropathic pain.

A model approach to the selection of these drugs, known as the "analgesic ladder," was developed by the World Health Organization (WHO) in the 1980s and remains influential today (Fig. 30.2) (71). According to this approach, patients with mild-to-moderate cancer-related pain are first treated with acetaminophen or NSAID. This drug is combined with an adjuvant drug that can be selected either to provide additional analgesia (i.e., an adjuvant analgesic) or to treat a side effect of the analgesic or a coexisting symptom. Patients with moderate-to-severe pain, and those with less severe pain that does not respond to a trial of an NSAID, should be treated with an opioid conventionally used to treat moderate pain (sometimes designated a "weak" opioid). This drug may be combined with acetaminophen or an NSAID and an adjuvant drug if there is an indication for one. Those patients with severe pain and those with moderate pain that does not respond to the initial opioid should receive an opioid conventionally used for severe pain (sometimes designated a "strong" opioid), which may be combined with acetaminophen or an NSAID, or with an adjuvant drug, as indicated.

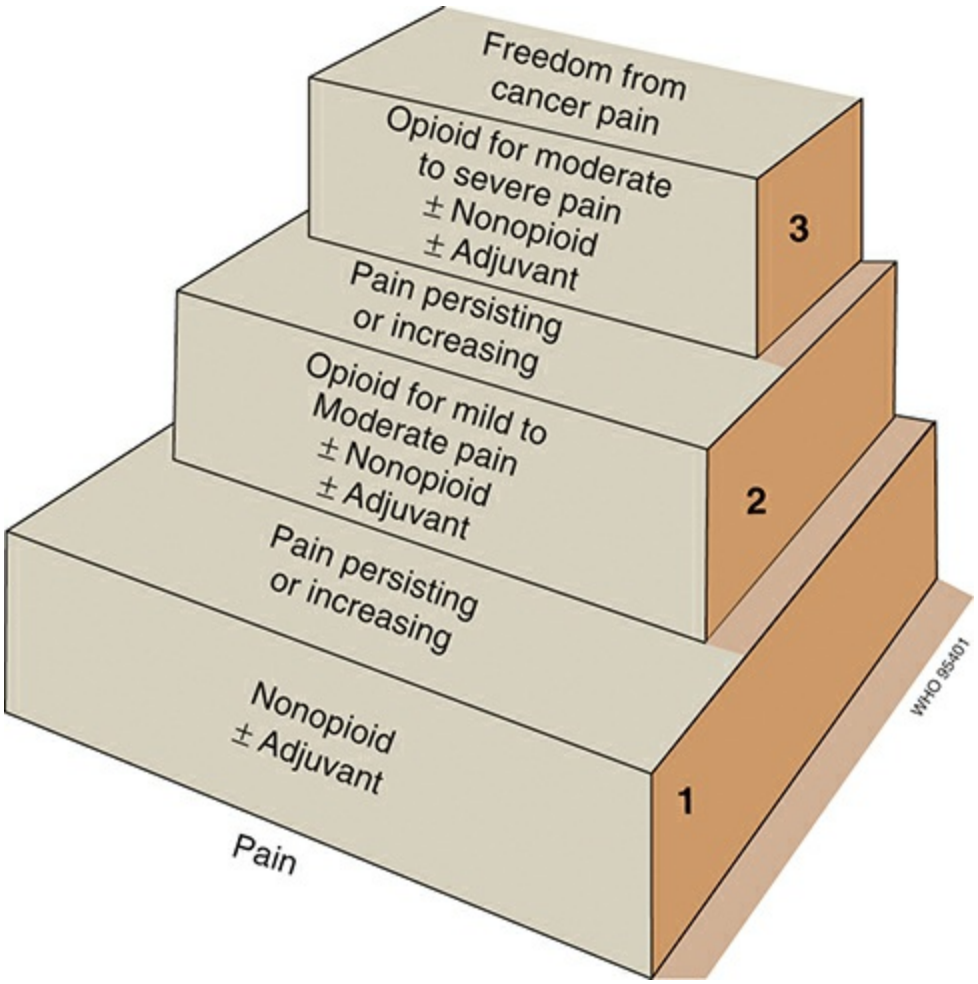

Figure 30.2 The three-step "analgesic ladder" proposed by an expert committee of the Cancer Unit of the World Health Organization.
Source: Reproduced with permission from the World Health Organization. Cancer Pain Relief, 2nd Ed. Geneva, Switzerland: World Health Organization; 1996.

The analgesic ladder is important historically, and is still widely cited in the developing world in an effort to encourage policy makers to expand medical access to opioid drugs. In most developed countries, however, it is not an adequate clinical guideline, given the availability of numerous opioid formulations and other analgesic modalities. Nonetheless, the fundamental concept promoted by the analgesic ladder model—opioid therapy on a long-term basis should be considered the mainstay for the therapy of chronic moderate-to-severe pain related to active cancer—remains widely accepted and a very important message of the original paradigm.

Nonsteroidal Anti-inflammatory Drugs

In the United States, the nonopioid analgesics comprise acetaminophen and the NSAIDs (Table 30.4). These drugs have a well-established role in the treatment of cancer pain (72,73). On the basis of clinical observations, NSAIDs appear to be especially useful in patients with bone pain or pain related to grossly inflammatory lesions, and relatively less useful in patients with neuropathic pain. In addition, NSAIDs have an opioid-sparing effect that may be helpful in preventing the occurrence of dose-related side effects (74).

TABLE 30.4 Nonsteroidal Anti-Inflammatory Drugs (NSAIDs)

Class and Generic Name	Approx. Half-Life (h)	Dosing Schedule	Recommended Starting Dose[a]	Comment[b]
P-aminophenol derivatives				
Acetaminophen[c]	3–4	q 4–6 h	650 mg q 4 h (5 doses daily)	Overdosage produces hepatic toxicity. Not anti-inflammatory and therefore not preferred as first-line analgesic or coanalgesic in patients with bone pain. Lack of GI or platelet toxicity; at high doses, liver function tests should be monitored.
Napthylalkanones				
Nabumetone	22–30	q 24 h	500–1,000 mg q 12 h	Appears to have a relatively low risk of GI toxicity; once-daily dosing can be useful.
Salicylates				
Acetylsalicylic acid[c]	3–12[d]	q 4–6 h	650 mg q 4 h (5 doses daily)	Standard for comparison. May not be tolerated as well as some of the newer NSAIDs.
Diflunisal[c]	8–12	q 12 h	1,000 mg × 1, then 500 mg q 12 h	Less GI toxicity than aspirin
Choline magnesium trisalicylate[c]	8–12	q 12 h	500–1,000 mg q 12 h	Choline magnesium trisalicylate and salsalate have minimal GI toxicity and no effect on platelet aggregation despite anti-inflammatory effects. May therefore be particularly useful in some cancer patients.
Salsalate	8–12	q 12 h	500–1,000 mg q 12 h	

Proprionic acids				
Ibuprofen[c]	3–4	q 4–8 h	400–600 mg q 8 h	Available over-the-counter.
Naproxen[c]	13	q 12 h	250–500 mg q 12 h	Available as a suspension.
Naproxen sodium[c]	13	q 12 h	275–550 mg q 12 h	—
Fenoprofen	2–3	q 6 h	200 mg q 6 h	—
Ketoprofen	2–3	q 6–8 h	25–50 mg q 8 h	—
Flurbiprofen[c]	5–6	q 8–12 h	100 mg q 12 h	—
Oxaprozin	40	q 24 h	600 mg q 24 h	Once-daily dosing may be useful.
Acetic acids				
Indomethacin	4–5	q 8–12 h	25 mg q 8 h	Available in sustained-release and rectal formulations. Higher incidence of side effects, particularly GI and CNS, than propionic acids.
Tolmetin	1	q 6–8 h	200 mg q 8 h	
Sulindac	14	q 12 h	150 mg q 12 h	Less renal toxicity than other NSAIDs.
Diclofenac	2	q 6–8 h	25 mg q 8 h	
Ketorolac[c]	4–7	q 4–6 h	30–60 mg load, then 15–30 mg q 6 h (parenteral); 10 mg q 6 h (oral)	Only parenteral formulation available. Approved for postoperative use. Experience too limited to evaluate higher doses.
Oxicams				
Piroxicam	45	q 24 h	20 mg q 24 h	Administration of 40 mg for over 3 weeks is associated with a high incidence of peptic ulcer, particularly in the elderly.
Fenamates				
Mefenamic acid[c]	2	q 6 h	250 mg q 6 h	Not recommended for use longer than 1 week and, therefore, not indicated in cancer pain therapy.
Cox-2 inhibitors				
Celecoxib	11	q 12 h	100–200 mg q 12 h	Fewer GI side effects; no effect on platelet function.

Note: CNS, central nervous system; GI, gastrointestinal.

[a]Starting dose should be one-half to two-thirds of the recommended dose for the elderly, those on multiple drugs, and those with renal insufficiency. Doses must be individualized. Low initial doses should be titrated upward if tolerated and clinical effect is inadequate. Doses can be incremented weekly. Studies of NSAIDs in the cancer population are meager; dosing guidelines are thus empiric.

[b]With all NSAIDs, stool guaiac and liver function tests, BUN, creatinine, and urinalysis should be monitored; frequency of monitoring should be increased for those on relatively high doses.

[c]Pain is approved indication.

[d]Half-life of aspirin increases with dose.

NSAIDs inhibit the enzyme cyclooxygenase (COX) to reduce production of peripheral and central prostaglandins, and this action presumably underlies their analgesic effects. There are multiple forms of COX. COX-1 is relatively more constitutive, physiologically active in many tissues, and COX-2 is relatively inducible, produced as part of the inflammatory cascade. Compounds that are more selective for COX-2 than COX-1 have a lower risk of inducing gastrointestinal adverse effects (75,76), and some drugs that are relatively COX-2 selective have been labeled in this way and promoted for their enhanced gastrointestinal safety. In the United States, the only drug of the latter type now on the market is celecoxib. Rofecoxib and valdecoxib were previously available, but were taken off the market due to concerns related to cardiovascular safety.

The clinical decision to offer an NSAID to a patient with cancer usually hinges on the assessment of drug-related risk. Gastrointestinal toxicity is well recognized, and in recent years, cardiovascular safety has become a prominent concern. Based on numerous studies, it is most reasonable to conclude that all NSAIDs are prothrombotic and pose an increased risk of peripheral vascular disease, myocardial infarction, transient ischemic attacks, and stroke (77–79). Mechanistically, this risk is associated with COX-2 inhibition, whether produced by the nonselective COX-1 and COX-2 inhibitors or by the COX-2 selective drugs. Although the risk varies across drugs, large comparative studies have been retrospective and results have been conflicting. In the United States, all NSAIDs now have a boxed warning in the package insert, which offer cautions about both gastrointestinal and cardiovascular risks. Among all commercially available NSAIDs, naproxen generally is viewed as having the lowest risk of cardiovascular toxicity.

All NSAIDs may also produce varied adverse renal effects. Fluid overload, acute nephritis, and chronic kidney disease are potential problems. All these may cause hepatotoxicity, and a bleeding diathesis is possible with most.

Although all NSAIDs have the potential to produce adverse gastrointestinal effects, ranging from pain or nausea to frank ulceration and hemorrhage, there are important drug-selective differences. The COX-2 selective agents, such as celecoxib, are less likely to cause these effects, as are several of the so-called nonselective agents, such as ibuprofen and diclofenac. Co-administration of a proton pump inhibitor, such as omeprazole, or the prostaglandin analogue misoprostol, should also be considered to reduce the risk of gastrointestinal damage induced by NSAIDs (80,81).

Given their risk profile, NSAIDs should be administered with caution to patients with significant predisposing factors for peptic ulcer disease, cardiovascular disease, renal disease, or bleeding diathesis. If there is no strong contraindication for therapy, patients who are predisposed to ulcer disease should be considered for a trial of celecoxib in the United States and patients who may be at relatively high risk of cardiovascular toxicity should be offered naproxen first (79,82,83).

Other factors may also be important in the selection of an NSAID. First, there is substantial variability in the response of individual patients to different agents, and the response to an NSAID in the past should guide drug selection in the present. Second, it may be useful to consider the drug's duration of effect when selecting an NSAID. The need to improve treatment adherence or provide a simpler dosing regimen encourages the use of a drug that can be administered once daily (e.g., nabumetone) or twice daily (e.g., celecoxib and many others), whereas the desire for as-needed dosing suggests the use of a short-duration drug (e.g., ibuprofen). Finally, drug selection may be influenced by cost, which varies greatly among both drugs and pharmacies.

The toxicities associated with the use of NSAIDs are dose-related and often occult until severe morbidity occurs. Although patients with cancer pain are commonly treated with standard doses, it is reasonable to explore the dose range and seek the minimal effective dose for long-term therapy. Dose escalation in poor responders is limited by dose-related toxicities and a ceiling dose for analgesia above which additional dose increments fail to produce more relief (74). If an increase in dose maintains the therapy in the conventionally accepted safe range and provides more analgesia, it should be continued. The lack of additional pain relief following a dose increase, however, suggests that the ceiling has been reached, and the dose can then be lowered to the previously effective dose or the drug can be discontinued. All patients receiving an NSAID should be evaluated periodically for occult fecal blood, changes in blood pressure, and effects on renal or hepatic function.

Opioid Analgesics

Expertise in the administration of opioid analgesics (Table 30.5) is the foundation of cancer pain management. The clinician should have knowledge of opioid pharmacology and a clear grasp of practical guidelines for dosing (15).

TABLE 30.5 Opioid Analgesics

Drug	Dose (mg) Equianalgesic to Morphine 10 mg IM[a] PO	IM	Half-Life (h)	Peak Effect (h)	Duration (h)	Comment[b]
Morphine	20–30	10	2–3	0.5–1.0	3–6	Standard for comparison
Morphine CR	20–30	10	2–3	3–4	8–12	Various formulations are not bioequivalent
Morphine SR	20–30	10	2–3	2–3	12–24	—
Codeine	200	130	2–3	1.5–2.0	3–6	Combined with aspirin or acetaminophen. Usually for moderate pain. Also available without coanalgesic
Hydromorphone Hydromorphone CR	7.5 7.5	1.5 —	2–3 ~11	0.5–1.0 12–16	2–4 ~13	Potency may be greater, i.e., hydromorphone: morphine = 3:1 rather than 6.7:1 during prolonged use
Oxycodone	20	—	2–3	1	3–4	Combined with aspirin or acetaminophen, for moderate pain; available orally without coanalgesic and useful for severe pain
Oxycodone CR	20	—	2–3	2–3	8–12	—
Oxymorphone	10	1	2–3	1.5–3.0	2–4	—
Oxymorphone CR Hydrocodone Hydrocodone CR	20 (oral) 30 (oral) 30 (oral)	— —	2–3 3–4 7–9	1.5–3.0 1–2 5	2–4 4–8 8–12	—
Methadone	20	10	12–190	0.5–1.5	4–12	Although 1:1 ratio with morphine was in single-dose study, there is a change with chronic dosing, and large dose reduction (75%–90%) is needed when switching to methadone. Risk of delayed toxicity
Levorphanol	4	2	12–15	0.5–1	4–6	Usage limited because only 2 mg tablets are available
Fentanyl	—	—	7–12	—	—	Can be administered as a continuous IV infusion or SC infusion; based on clinical experience, 100 μg/h is roughly equianalgesic to morphine 4 mg/h

Fentanyl TTS	—	—	16 - 24	—	48 - 72	Based on clinical experience, 100 μg is roughly equianalgesic to morphine 4 mg
Meperidine	300	75	2 - 3	0.5 - 1.0	3 - 4	Not preferred for cancer patients owing to potential toxicity
Tapentadol Tramadol	__ ___	__ __	4 - 5 6 - 8	1 ～2	4 - 6 3 - 6	Mixed mechanism drugs, having both opioid and monoaminergic mechanisms of action; sometimes used for moderate cancer pain.

[a]Dose that provides analgesia equivalent to 10 mg intramuscular morphine.

[b]All opioids may produce various common side effects, (e.g., constipation, nausea, sedation). Respiratory depression is rare in cancer patients.

IM, intramuscular; IV, intravenous; SC, subcutaneous.

Opioid Classes

Based on receptor interactions, the opioid analgesics can be divided broadly into pure agonists and agonist–antagonists. The pure agonist drugs used in the management of chronic cancer pain are agonists at the μ-receptor subtype. The agonist–antagonist drugs comprise a mixed agonist–antagonist subclass, which includes drugs that are weak antagonists at the μ receptor and agonists at another receptor subtype, and a partial agonist subclass, which includes drugs that are partial agonists at the μ receptor. In the United States, the mixed agonist–antagonist drugs include pentazocine, nalbuphine, dezocine, and butorphanol, and the partial agonists include buprenorphine.

All the agonist–antagonist drugs share properties that together suggest a limited role in the management of chronic cancer pain. These drugs have a ceiling dose for analgesia, and all have the potential to produce an abstinence syndrome in patients already physically dependent on an agonist drug. Some of the mixed agonist–antagonists, particularly pentazocine, are also more likely to produce psychotomimetic effects than the pure agonist drugs. In patients with chronic pain, the lack of oral formulations for all but pentazocine and buprenorphine (sublingual and transdermal formulations) also limits the utility of these drugs. The transdermal buprenorphine patch increases the utility of buprenorphine for chronic pain; it will soon be joined by an intraoral film. The latter drugs have been designed for patients who are opioid-naïve or have very limited opioid exposure, and both this characteristic and its cost presumably will limit its use for cancer pain.

The opioid agonist drugs, the prototype of which is morphine, are preferred in the management of chronic cancer pain. To optimize the administration of these drugs, widely accepted dosing guidelines must be applied systematically.

“Weak” Versus “Strong” Opioids

Unlike the division of the opioids into agonist and agonist–antagonist classes, the distinction between “weak” opioids and “strong” opioids, which was originally incorporated into the WHO analgesic ladder approach (71), is more operational than pharmacologic. None of the “weak” drugs is characterized by a ceiling effect that would limit its use to pain of lesser severity. In the United States, the oral opioids commonly used for chronic, generally moderate pain, include combination products containing acetaminophen plus either codeine, hydrocodone, or oxycodone. Tramadol, a unique centrally acting analgesic with a mechanism of action that is partly opioid, also is generally included with this group, as is tapentadol, a newer analgesic with a mixed mechanism somewhat similar to tramadol. In the United States, the oral opioids used conventionally on the third rung of the analgesic ladder for chronic pain that is generally severe include morphine, hydromorphone, oxycodone, oxymorphone, levorphanol, fentanyl, and methadone.

Although meperidine is sometimes used orally for chronic pain of moderate severity, its risk profile suggests that it should not be selected for the patient with cancer pain. Accumulation of its toxic metabolite, normeperidine, may produce tremulousness, hyperreflexia, myoclonus, and even seizures (84). A similar concern existed with the use of propoxyphene, which is no longer available in the United States.

As suggested by the analgesic ladder, the simplest approach to the management of moderate pain in the cancer patient with limited or no prior exposure to opioids begins with a combination product containing a nonopioid drug and an opioid, usually codeine, oxycodone, or hydrocodone. Codeine is not preferred because genetic variability in its metabolism may be associated with unpredictable relationship between dose and response. After selection of one of these combination drugs, the dose can be increased to maximally safe levels of the coanalgesic; in products containing acetaminophen, this is usually less than 4 g per day. A lower maximal total daily dose—2.6 grams—should be applied in the elderly, patients with any type of hepatic dysfunction, and those who may be unable to comply with the instruction to avoid all over-the-counter medications containing this drug.

Selection of an Opioid for Severe Pain

The selection of an opioid for severe cancer pain is empirical. Traditionally, morphine was considered to be the preferred first-line drug based on worldwide experience, ease of dosing, and the availability of numerous formulations. The intra-individual variability in the response to the different opioids is very substantial, however, and any of the other drugs may yield a better response in the individual patient. This variability also suggests that therapeutic failure with one drug may be followed by remarkable success with another (85).

The predominant metabolic pathway for morphine is glucuronidation to morphine-3-glucuronide (M3G) and morphine-6-glucuronide (M6G), and the accumulation of morphine metabolites may be associated with side effects, such as myoclonus and chronic nausea (86). Renal insufficiency results in accumulation of M3G and M6G (87,88). For this reason, morphine should be administered cautiously to patients with renal insufficiency. Although the supporting data are limited, morphine is often viewed unfavorably when patients have very poor renal function, are on dialysis, or have renal function that is expected to change. In the latter situations, hydromorphone and fentanyl are often preferred (84,89,90).

The selection of an opioid for the treatment of severe cancer pain is also influenced by pharmacokinetic factors, the most salient of which is duration of effect. In an effort to improve adherence and convenience, numerous long-acting modified-release formulations of short half-life opioids have been developed. Oral once-daily or twice-daily formulations of morphine, oxycodone, oxymorphone, hydrocodone, and hydromorphone are available in the United States or other countries. Transdermal fentanyl provides a dosing interval of 2 to 3 days and is preferred by some patients (91).

Although both levorphanol and methadone have relatively long half-lives (Table 30.6), patients typically require doses at least every 6 hours to maintain stable effects. Methadone has become an increasingly popular drug for chronic pain, presumably because of its low cost, potential for unexpectedly high potency, and relatively low abuse potential and low likelihood of diversion by individuals with a history of substance use disorder. Clinical experience suggests that rotation to methadone after inadequate treatment with another opioid can indeed produce surprisingly good results, an outcome that has been speculated to be related to the d-isomer in the racemate formulation that is commercially available in most countries; this isomer is not an opioid, but rather blocks another receptor (the *N*-methyl-d-aspartate (NMDA) receptor) that may potentiate analgesia or reverse some degree of opioid tolerance (92,93).

TABLE 30.6 Commonly Used Pharmacologic Approaches in the Management of Opioid Side Effects

Opioid Side Effect	Treatment
Constipation	Approaches for all patients:

	Increase fluid intake and dietary fiber Ensure coanalgesic or adjuvant (comfort and convenience, etc.) Discuss approaches with patient and select one or more: Daily contact laxative plus stool softener (e.g., senna plus docusate) Daily osmotic laxative Intermittent use of laxative Consider alternative approaches in refractory cases: Opioid antagonist—methylnaltrexone or naloxegol Lubiprostone Prokinetic agent (metoclopramide)
Nausea	Several approaches: If associated with vertigo or if markedly exacerbated by movement, antivertiginous drug (e.g., scopolamine, meclizine) If associated with early satiety, prokinetic agent (metoclopramide) In other cases, dopamine antagonist drugs (e.g., prochlorperazine, haloperidol, metoclopramide) or 5HT antagonists (ondansetron, granisetron, others)
Somnolence, mental clouding	If analgesia is satisfactory, reduce opioid dose by 25% to 50% If analgesia is satisfactory and the toxicity involves confusion, consider a trial of a neuroleptic (e.g., haloperidol) If analgesia is satisfactory and the toxicity is somnolence, consider a trial of a psychostimulant (e.g., methylphenidate or modafinil) Consider pharmacologic approaches to reduce the opioid requirement (addition of a coanalgesic or adjuvant) Consider trial of an alternative opioid If appropriate, consider nonpharmacologic analgesic approaches

Methadone is a challenging drug to use, however, and clinicians must understand its unique pharmacology in order to administer it in a safe manner. Methadone's half-life ranges between 12 and 190 hours, and substantial delayed toxicity has been observed many days after methadone treatment was begun or altered. Its potential to have an unexpectedly high potency when substituting for another opioid increases the challenge of dose selection when starting the drug. It can prolong the QTc interval (94,95), a risk that suggests the need to obtain a baseline ECG, and periodic ECG monitoring thereafter, in patients who may be predisposed to this phenomenon (96,97). Given the increased potential for serious toxicity and the need for prolonged monitoring with methadone, its administration should be undertaken only by clinicians with the knowledge and experience necessary to ensure safety.

Routes of Administration

The oral and transdermal routes are preferred in the management of chronic cancer pain. Alternative routes may be required, however, and the clinician must recognize their indications and be familiar with the accepted approaches.

Transdermal Delivery

The transdermal route of administration is available for the highly lipophilic opioids buprenorphine and fentanyl. Transdermal fentanyl, which offers a 48-hour to 72-hour dosing interval, is preferred by some patients and may be associated with relatively less constipation than oral opioid formulations (98,99). The transdermal route may be very useful for the patient who is unable to swallow or absorb an orally administered opioid. Transdermal fentanyl may not be effective in cachectic patients because the lack of an adequate subcutaneous drug reservoir may result in a relatively higher

level of hepatic metabolism. Patients with very low albumin levels and those with frequent infections may be at relatively higher risk for toxicity from transdermal fentanyl because of sudden increases in the free fraction of fentanyl and increased absorption from the reservoir during fever (100–102).

Although buprenorphine is a partial agonist with a ceiling dose, and a capacity to induce abstinence if administered to a patient who is already physically dependent on another opioid, studies suggest that some patients with severe cancer can benefit (103,104). The transdermal formulation of this drug available in the United States provides a relatively low dose range, which may complicate treatment of severe pain.

Rectal

Rectal formulations of oxymorphone, hydromorphone, and morphine are available in the United States. There is also anecdotal experience with rectal administration of controlled-release morphine or oxycodone tablets. The rectal route is usually considered for patients who are relatively opioid nontolerant and become temporarily unable to take oral medications. The potency of opioids administered rectally is believed to approximate oral dosing (105), absorption is variable, and relative potency may be higher or lower than expected; this depends on a variety of factors, including location of the suppository (low in the rectum, where the blood supply is systemic, or high in the rectum, where blood flows through the portal circulation) and contents of the rectum at the time of dosing (106,107).

Oral and Nasal Transmucosal

Absorption through the oral or nasal cavity can potentially occur with any opioid, and those that are lipophilic and relatively potent may be absorbed sufficiently to have clinical use (108). Multiple types of transmucosal formulations of fentanyl have been approved after having been shown to be safe and efficacious when used as a “rescue” dose for the treatment of breakthrough pain in cancer patients receiving a fixed-schedule opioid. These formulations, which are known as *transmucosal immediate-release formulations (TIRFs),* include an intraoral lozenge, an effervescent buccal tablet, a buccal patch, a sublingual tablet, sublingual spray, and a nasal spray. In the United States, all of these products, including generics, have a mandatory shared risk evaluation and mitigation strategy, the purpose of which is to reduce the risk of abuse and unintentional overdose.

All of the TIRFs are efficacious and have an onset of action faster than orally administered drugs (109–112). A few comparative trials suggest that patients with cancer-related breakthrough pain have better outcomes when treated with these drugs instead of an oral opioid. These data have limitations, however, and the appropriate positioning of these drugs against relatively less costly ones in the therapeutic armamentarium for cancer-related breakthrough pain remains uncertain. Patients who demonstrate that a short-acting oral opioid does not satisfactorily address breakthrough pain due to a slow onset of effect, those with very rapid-onset breakthrough pains, and those who have a particularly good response to fentanyl may be considered empirically for a trial of one of these drugs. There are insufficient data to recommend one formulation over another, and this decision will usually be based on availability, cost, and patient preference. Given the perception that rapid-onset formulations address an unmet clinical need, other formulations are in development.

In some clinical situations, a trial of an injectable formulation placed under the tongue is reasonable. Although there is considerable experience in the use of sublingual administration of concentrated oral morphine solution during the care of patients at the end of life, this drug is relatively hydrophilic, and is poorly absorbed by this route; it is likely that most of the effects obtained occur following enteral absorption after swallowing (113).

Intranasal butorphanol is available, but as noted, this opioid is an agonist–antagonist and has characteristics that make it unfavorable for long-term administration to cancer patients. It is rarely used in this setting. As noted, buprenorphine may be useful in some patients with cancer pain, but the sublingual preparations indicated in the United States for the office-based treatment of substance use disorder provide doses that would rarely meet the needs of the cancer patients with pain.

Parenteral Injection

Patients who are unable to swallow or absorb opioid drugs are candidates for long-term parenteral dosing. Repetitive intramuscular or subcutaneous injections are painful and should rarely be considered. Repetitive intravenous injections may be effective, but these usually require skilled nursing and may be associated with prominent "bolus" effects (toxicity at peak concentration, pain breakthrough at the trough, or both). Repetitive dosing through a "butterfly" needle placed under the skin has been used effectively in end-of-life care, and experience suggests that the needle can be in place for a week without the development of local pain or other problems.

Continuous Infusion

Continuous infusion eliminates the fluctuations in plasma concentration associated with repetitive bolus injections. Any opioid available in an injectable formulation can be used for continuous infusion. The availability of continuous subcutaneous infusion using ambulatory infusion devices has markedly enhanced the clinical utility of infusion techniques, allowing long-term administration of opioids and other drugs in the home environment (114). A diverse group of pumps that range considerably in features, complexity, and cost are now available, and the clinician often has the option of selecting a pump based on the needs and resources of the patient. PCA can be combined with continuous infusion to address episodic pains. In most cities, skilled nursing organizations can assist in the management of therapy at home.

Intraspinal Opioids

The discovery of opioid receptors in the spinal cord provided the foundation for the development of techniques to deliver opioid analgesics intraspinally. Intraspinal administration can provide selective analgesia (i.e., without the sensory or motor blockade produced by local anesthetics) at doses lower than those required systemically. The strongest indication for a trial of intraspinal opioid administration is the occurrence of intolerable somnolence or confusion in patients who are not experiencing adequate analgesia during systemic opioid treatment of pain.

Many methods of intraspinal opioid administration are now in use (115). The most commonly used include a percutaneous epidural catheter, which is usually tunneled to the anterior abdominal wall and there connected to an ambulatory infusion pump; a totally implanted epidural catheter connected to a subcutaneous portal, which in turn is connected to an ambulatory pump; and an intrathecal catheter connected to a totally implanted continuous infusion device. Implantable pump systems, which are refilled percutaneously, are often chosen for patients with life expectancies of three or more months.

A controlled trial that compared neuraxial infusion to comprehensive medical management demonstrated that the spinal opioid treatment improved pain, side effects, quality of life, and even survival (116). Patients with cancer pain that is poorly responsive to systemic therapy should be considered for a neuraxial approach if the resources exist to implement and monitor it.

The preferred drugs for chronic intraspinal infusion are morphine and hydromorphone, but many others are used empirically, and admixtures (e.g., opioid plus local anesthetic or clonidine, or both) are now commonplace. Based on a systematic review of the literature (117), an expert panel created an algorithm for the progressive use of an array of drugs during intrathecal therapy (118). Therapy is initiated with either morphine or hydromorphone. If a second agent is needed, either the local anesthetic bupivacaine or the α_2-adrenergic agonist clonidine may be selected. Clonidine was shown in a controlled trial to be effective in neuraxial analgesia (119). Ziconotide, a unique calcium channel blocker, is also now available in the United States and has been shown to be effective for cancer pain in controlled trials (120). The use of a combination of drugs may help to potentiate analgesia and reduce side effects, such as sensory and motor block, urinary retention, pruritus, and nausea.

Guidelines for the Administration of Opioid Drugs

As noted, all patients who develop moderate-to-severe persistent pain should be considered for an opioid-based regimen. Although the opioid-naïve patient usually is offered a short-acting combination product, it is acceptable to initiate therapy with a long-acting formulation, as long as the dose is appropriate (121). For example, long-acting morphine can be started in the opioid-naïve patient at a dose of 15 mg twice daily, or 20 to 30 mg once daily, depending on the formulation. Long-acting oxycodone or oxymorphone can be started at doses of 10 mg twice daily or 5 mg twice daily, respectively. Transdermal fentanyl can be initiated at 12 μg/hour in opioid-naïve patients. Given the availability of these long-acting formulations in doses appropriate for the opioid-naïve, the decision to start a short-acting or long-acting drug in a patient with new-onset persistent pain is a clinical judgment based on patient preference, convenience, cost and availability, and experience.

If a patient is receiving a short-acting drug, but pain is not controlled, it is conventional practice to switch to a single-entity agonist opioid, typically in a long-acting formulation. Starting doses may be slightly higher if the patient has required regular administration of the short-acting drug. On a daily basis, the milligram dose of a long-acting drug is the same as the short-acting formulation of the same drug.

Following selection of a starting dose, dose adjustment is almost always required. Once a favorable balance between analgesia and side effects is obtained, this is usually maintained for a prolonged time unless there is progression in the pain-producing pathology. Although several large surveys have established that patients with stable disease usually demonstrate stable dosing patterns, most patients with cancer pain do not have stable disease. Recurrent pain or the new occurrence of side effects necessitates another period of dose titration. Inadequate adjustment of the dose is probably the most common reason for unsuccessful long-term management of cancer pain.

In all cases, the dose of an opioid should be increased until acceptable analgesia is produced or intolerable and unmanageable side effects supervene. Ceiling doses for the pure agonist opioids have not been identified clinically, and occasionally doses can become extremely high—equivalent to grams of morphine per day—as upward dose titration proceeds. At relatively high doses, it is important to reassess the nature of the pain, ensure that expressed need for treatment is not related to other factors (e.g., so-called “chemical coping” or the possibility of addiction), and also establish that the benefits of therapy clearly outweigh the side effects and burdens.

Surveys have demonstrated that one-half to two-thirds of patients with cancer pain will experience clinically significant breakthrough pain (122), and it is common to co-administer a short-acting drug—an approach known as “rescue” dosing—to treat it. As described previously, the rapid-onset transmucosal fentanyl formulations have been developed specifically in an effort to improve the management of breakthrough cancer pain.

Treatment of common side effects is an essential element in the successful management of opioid therapy. Patients who experience intolerable toxicity despite treatment should be designated as poorly responsive to the specific drug and route, and an alternative strategy for pain control should be implemented. This may include more sophisticated management of the treatment-limiting side effect, the addition of a pharmacologic or nonpharmacologic analgesic approach that could reduce the opioid requirement, or opioid rotation.

Opioid rotation, or the switching from one drug to another in an effort to improve the outcomes of an opioid regimen, is now widely used, despite guidelines based on experience rather than research (123). Switching requires an appreciation of relative potency, as codified on the equianalgesic dose table (Table 30.6). To switch to another opioid drug or route, the equianalgesic dose table is used to calculate a dose of the new drug that would be theoretically equianalgesic with the old drug or route. With few exceptions, the dosing regimen based on this calculated dose should be reduced by 25% to 50% to account for incomplete cross-tolerance between drugs; a larger reduction, 75% to 90%, is prudent if the new drug is methadone (because of a unique pharmacology in this agent). In contrast, no reduction in the equianalgesic dose is needed if the switch is to transdermal fentanyl (because a reduction is already built into the recommended equianalgesic ratios).

Management of Common Opioid Side Effects

Although there is no maximum dose or ceiling dose for the μ-agonist opioids, the appearance of side effects imposes a practical limit on dose escalation. Given the importance of side effects in determining the response to an opioid, the successful management of common adverse side effects is a fundamental aspect of therapy (Table 30.7) (124).

TABLE 30.7 Adjuvant Analgesics

Indication	Drugs
Neuropathic pain	Antidepressants
	Tricyclic antidepressants
	Amitriptyline
	Desipramine
	"Newer" antidepressants
	Duloxetine
	Anticonvulsants
	Gabapentin
	Pregabalin
	Sodium channel blockers
	Mexiletine
	α_2-Adrenergic agonists
	Clonidine
	Tizanidine
	NMDA receptor antagonists
	Ketamine
	Cannabinoids
	THC
	Topical anesthetics
	Capsaicin
	Lidocaine
	Miscellaneous
	Baclofen
Bone pain	Bisphosphonates (e.g., pamidronate)
	Denosumab Calcitonin
	Radiopharmaceuticals (e.g., strontium 89 and samarium 153)
Bowel obstruction	Scopolamine
	Glycopyrrolate
	Octreotide
Multipurpose	Corticosteroids
	Dexamethasone Prednisone

Constipation is a highly prevalent side effect of opioid therapy (125). It may contribute to abdominal pain, distension, nausea, and worsening anorexia, and occasionally may progress to obstipation and bowel obstruction. The management of drug-induced constipation should begin with the elimination of nonessential constipating drugs and, if possible, an increase in both fluid and fiber intake. Fiber should not be increased in those with possible partial bowel obstruction or marked debility because of the potential for worsening obstruction.

There is broad consensus that the likelihood of opioid-induced constipation is high enough to warrant prophylactic therapy. There are numerous types of laxatives, including bulk-forming agents, osmotic agents, lubricants, surfactants, contact cathartics, prokinetic drugs, and opioid antagonists (126). The conventional first-line approach is a combination of a stool softener, usually docusate, and a cathartic agent, such as senna. Most patients respond to this therapy. The osmotic agent, propylethylene glycol, in a powdered formulation offers another well-tolerated and usually effective approach. Other osmotic agents, such as lactulose, are often tried in more refractory cases. Lubiprostone, a chloride channel opener approved for opioid-induced constipation in noncancer patients, is available in the United States and may also be considered. Other approaches are rarely tried, including trials of metoclopramide, misoprostol, colchicine, or donepezil.

Opioid antagonist therapy, using a drug that does not cause systemic withdrawal, should be considered when constipation has not responded to routine approaches. A parenteral antagonist, methylnaltrexone, is commercially available in the United States and can be used to manage acute constipation, or with dosing 2 to 3 times weekly (127–129). This drug is a large and polar molecule that does not cross the blood–brain barrier. Another peripherally acting opioid antagonist, alvimopan, is approved for the management of postoperative ileus and has a similar mode of action (130). Oral naloxone has very limited oral bioavailability and is sometimes tried for refractory constipation as well; the starting dose of 0.8 mg twice daily may be doubled every 2 to 3 days until favorable effects occur or side effects are experienced (131,132). A new oral agent, naloxegol, is a polyethylene glycol (PEG)ylated form of naloxone and is classified as a peripherally acting μ-opioid receptor antagonist. This drug is approved for opioid-induced constipation in noncancer patients and may be an important addition to the management of refractory opioid-induced constipation (133).

Nausea or vomiting constitutes a problem for some 10% to 30% of cancer patients receiving opioid therapy (134). Potential contributing etiologies should be evaluated and the treatment adjusted accordingly. If the assessment suggests that factors other than opioids are contributing to the nausea, antiemetic therapy may be combined with specific interventions to reverse or minimize these factors. The usual first-line drugs are the dopamine antagonists, including prochlorperazine, metoclopramide, and haloperidol, and the 5HT antagonists such as ondansetron (135). Patients with refractory nausea may need other pharmacologic approaches, such as a corticosteroid or a commercially available cannabinoid such as tetrahydrocannabinol (THC) or nabilone. Some nauseated patients appear to benefit from empirical treatment with a drug used for vertigo, such as meclizine or scopolamine. In difficult cases, combinations of drugs from unrelated classes are often tried.

Sedation or mental clouding is very common when an opioid regimen is begun or the dose increased. Most patients develop tolerance to this effect relatively quickly, but some do not, and some have other factors that cause cognitive impairment and compound the effect of the opioid. If these side effects are mild, reassurance and education are usually sufficient interventions. When toxicity is severe or persistent enough to compromise the benefits of therapy, other interventions are needed. Treatment of potential etiologies other than the opioid, when feasible and indicated, is the first step in management. If pain is well controlled, it is reasonable to try an opioid dose reduction of 25% to 50%.

Symptomatic therapies for opioid-induced sedation or mental clouding should also be considered (Table 30.7). Methylphenidate has been shown to decrease opioid-induced sedation in cancer patients (136,137). The starting dose is 5 mg at breakfast and at lunchtime; dose titration is often needed, while monitoring side effects, including anorexia, jitteriness, anxiety, and insomnia. Other psychostimulants that have been used empirically for this indication include dextroamphetamine, amphetamine, modafinil, and armodafinil (138,139). A role for modafinil in cancer has been suggested by a positive controlled study that demonstrated improvement across cognitive, mood, and fatigue outcome measures, with the maximum benefit at 8 weeks after initiation of treatment. Other drugs that may be considered in refractory cases include the cholinesterase inhibitor donepezil and other psychostimulants such as caffeine, dexmethylphenidate, and

atomoxetine (140,141). A systematic review concluded that the data pertaining to these drugs was insufficient to draw conclusions. Methylphenidate or modafinil are generally considered first.

Tolerance, Physical Dependence, and Addiction

The clinical implications of tolerance, physical dependence, and addiction are commonly misunderstood by patients and clinicians. These misapprehensions may lead to concern about adverse events and, possibly, undertreatment of pain.

Tolerance is a pharmacologic property of opioid drugs defined by the need for escalating doses to maintain effects (142). Patients may have other reasons for declining analgesic effects, however, among which are progressive nociception and increasing psychologic distress. Clinical observations suggest that the most common reason that efficacy declines over time is worsening pain due to progression of a nociceptive lesion. Fear of analgesic tolerance should never delay the implementation of opioid therapy, and tolerance should not be invoked to explain the need for higher opioid doses unless a comprehensive reassessment has failed to identify an alternative explanation.

Physical dependence also is a pharmacologic property of opioid drugs, which is defined by the occurrence of an abstinence syndrome following abrupt dose reduction or administration of an antagonist (142). Neither the dose nor the duration of dosing required to produce physical dependence is known, and it is prudent to assume that all patients who have received an opioid drug for more than a few days have the potential for withdrawal. This implies that dosing should not be discontinued suddenly and that antagonist drugs, including the agonist–antagonist opioids, should be avoided.

Patients who become physically dependent on opioids appear to develop increased sensitivity to the effects of antagonist drugs. Very small doses of naloxone may produce a severe abstinence syndrome. For this reason, the use of naloxone should be limited to patients with symptomatic respiratory depression. When naloxone must be used in patients receiving chronic opioid therapy, only a dilute solution (e.g., 0.4 mg in 10 mL saline) should be administered and incremental doses should be given only until respiration improves. The goal of this intervention is improved respiration and not a return of consciousness, which may be associated with recurrent pain and withdrawal phenomena.

Both tolerance and physical dependence are distinct from addiction. Because the labels applied to patients can determine the attitudes and behaviors of caregivers, it is extremely important that appropriate terms are used to describe these phenomena. Patients who are perceived to have the capacity for withdrawal should be labeled physically dependent and not "addicted."

Addiction is a genetic, psychologic, and behavioral syndrome characterized by craving, loss of control over drug use, compulsive use, and continued use despite harm to the patient or others (143). Although abusable drugs, including opioids, can be shown to have reinforcing effects in animals, the capacity to produce addiction should not be considered an inherent property of the drug. Addiction presumably results from an interaction between the drug and a variety of factors that predispose the individual to develop an addictive pattern of use. These factors probably encompass genetic vulnerability, situational factors, and psychologic disturbances, as well as access to the drug.

Cancer patients who engage in aberrant drug-taking behaviors, such as hoarding or selling, unsanctioned dose escalation, or manipulation of the medical system to obtain additional drugs, may or may not meet criteria for the diagnosis of addiction. If such aberrant behaviors are identified, measures should be taken to eliminate them while a detailed assessment is performed to clarify their meaning (143). In some cases, aberrant drug-related behaviors appear to be driven by uncontrolled pain. This has been termed *pseudoaddiction* and is managed by improved efforts to provide pain relief. Pseudoaddiction can coexist with addiction, however, and care should be taken to ensure that the complaint of pain does not result in a missed diagnosis of addiction. A careful pain history, institution of more controls over prescribing, and monitoring over time should facilitate clarification of these distinctions.

Occasionally, aberrant behaviors are related to a psychiatric disorder other than addiction or to the development of a mild encephalopathy, which leads to confusion about drug taking. Again, these explanations for problematic drug use are not mutually exclusive, and the complexity of the clinical situation requires careful assessment and perhaps referral of the patient to a pain specialist or an addiction medicine specialist (144). The clinician must avoid the stigmatizing label of

addiction for patients who have reasonable alternative explanations for aberrant behaviors, but should be willing to render the diagnosis of addiction in those who actually have this disease.

The risk of true iatrogenic addiction is clearly relevant in judging the overall utility of opioid therapy for chronic cancer pain. There is substantial evidence that this risk is extremely low among those with no prior history of abuse or addiction (145). It is now widely accepted that all patients who are being considered for a trial of an opioid should be evaluated for risk factors that may predict aberrant drug-related behavior, such as a history of substance abuse, a family history of substance abuse, and major psychiatric disorder; however, fear of addiction should not be considered a contraindication to opioid therapy of severe cancer pain. Rather, patients should be stratified by risk before therapy begins, and monitored for aberrant drug-related behavior during the course of therapy. Should concerns arise, the clinician may structure therapy so as to reduce risk, or refer appropriately (146,147).

Adjuvant Drugs

Most patients with cancer pain require multiple drugs for symptom management. Some of these adjuvant drugs are used to treat symptoms other than pain, particularly those that occur as side effects of the opioid (Table 30.7). Other drugs are used in an effort to provide additive analgesia. The latter drugs comprise acetaminophen, the NSAIDs, and the so-called adjuvant analgesics (148). In recent years, the number of adjuvant analgesics has increased substantially, and several have become approved for primary pain indications due to the abundance of evidence for analgesic efficacy.

The adjuvant analgesics are particularly helpful in the treatment of pain syndromes that are often relatively less responsive to opioids, such as neuropathic pain (Table 30.7). In the setting of advanced illness, corticosteroids are commonly used (149); these drugs may also improve anorexia, nausea, and fatigue. Alternatives include specific anticonvulsants and antidepressants. Evidence for analgesic efficacy is best for gabapentin and pregabalin (150–152); for the tricyclic antidepressants, such as amitriptyline and desipramine (153–155); and for the serotonin and norepinephrine reuptake inhibitors, such as duloxetine (156). Gabapentin or pregabalin is usually tried first, given their lack of drug–drug interactions, but sequential trials of various drugs are often required before a well-tolerated and effective adjuvant analgesic is identified.

If the drugs with relatively good evidence of analgesic efficacy in neuropathic pain are not tolerated or are ineffective, trials of other anticonvulsants or antidepressants may be undertaken empirically. Other second-line agents for neuropathic pain include oral sodium channel blockers (e.g., mexiletine) or a brief infusion of lidocaine (157), ketamine (158–161), or a cannabinoid (162,163). At subanesthetic doses, ketamine may be used for treatment of severe refractory pain (158,159). The evidence of benefit is quite limited, however. Cannabinoids are analgesic and a new cannabis derivative, nabiximols (a 1:1 mixture of THC and cannabidiol), is under development specifically for pain related to advanced cancer. There are also several published randomized trials demonstrating at least short-term benefits for smoked (164–166) or vaporized (167,168) cannabis in patients with neuropathic pain, none of which were conducted in patients with cancer-related neuropathic pain. Both the gamma-aminobutyric acid (GABA) agonist, baclofen, and the α_2-adrenergic drugs, tizanidine and clonidine, are sometimes tried in selected patients with refractory neuropathic pain (169,170).

The use of topical agents represents another adjuvant analgesic strategy. A lidocaine patch (171) is available and has shown efficacy in postherpetic neuralgia (172). This formulation is commonly tried for all types of neuropathic and musculoskeletal pains. Topical creams are also used empirically in patients with cancer pain, including compounds containing other local anesthetics, capsaicin, an NSAID, a tricyclic antidepressant, or an opioid (173–175).

Opioid-refractory malignant bone pain is another syndrome for which adjuvant analgesics are often considered. The preferred drugs include bisphosphonates, denosumab (a monoclonal antibody targeting RANK), radiopharmaceuticals, and calcitonin (176–179). Although the bisphosphonates carry the risks of renal insufficiency and osteonecrosis of the jaw, there is evidence that they can improve overall morbidity associated with bone metastases, and a trial of one of these agents is typically considered in the setting of significant bone pain (180).

Adjuvant analgesics are also commonly employed in the setting of bowel obstruction that is not surgically correctable.

Aggressive pharmacotherapy, particularly in those with advanced disease, may control symptoms and obviate the need for drainage procedures. Treatment usually involves the combination of anticholinergic drugs (e.g., scopolamine or glycopyrrolate), octreotide, corticosteroids, and opioids (181).

OTHER APPROACHES FOR CHRONIC PAIN MANAGEMENT

Although most patients with cancer pain can achieve adequate relief with pharmacologic approaches alone, a multimodality strategy should always be considered in an effort to optimize the balance between analgesia and side effects, promote better function, or concurrently manage other problems. Multiple therapies are commonly needed to address the broader palliative care concerns of the patient and family, which derive from the complex interaction between pain and suffering.

When the focus is pain control, there are a large number of noninvasive and invasive approaches that may be considered adjunctive to opioid-based pharmacotherapy. Only a small minority of patients will require an invasive analgesic modality if the other therapies are optimally administered.

Interventional Approaches

The interventional strategies include injections, neural blockade, and implant therapies. Trigger point injections may be considered within the purview of all practitioners. Myofascial pains are extremely common in patients with chronic cancer pain, and the use of local anesthetic injections into painful trigger points may be a useful adjunctive approach in these patients.

The advances in neuraxial infusion of opioids and other drugs, as described previously, have largely supplanted the neurodestructive approaches that were employed in the past for pain syndromes refractory to systemic opioid therapy. Nonetheless, some types of neural blockade continue to be widely used (182).

Temporary somatic nerve blocks may be diagnostic, prognostic, or therapeutic. Diagnostic blocks elucidate the afferent pathways involved in the experience of pain. Prognostic blocks are implemented prior to a neurolytic procedure, and although extensive clinical experience indicates that a favorable response does not predict permanent relief following neurolysis, the failure to achieve pain relief with local anesthetic is commonly viewed as a contraindication to a destructive procedure. Repeated therapeutic blocks with local anesthetic are occasionally used in cancer patients who obtain substantial and fairly prolonged relief after such a temporary block. Recently, local anesthetics have been used to provide more prolonged neural blockade through techniques of perineural or epidural infusion.

Neural blockade with neurolytic solutions, usually alcohol or phenol, have been developed to denervate virtually any area of the body (183). Their use is very limited, however, because of the short-term risks associated with the injection of these substances, such as damage to soft tissues and local hemorrhage or infection, and the longer-term risks of neuritis and deafferentation pain. The one generally accepted exception is celiac plexus blockade for the management of epigastric pain due to neoplastic invasion of the celiac axis. The response to neurolytic celiac plexus blockade in pain due to pancreatic cancer has been observed to be so satisfactory that earlier use is warranted whenever the typical pain syndrome occurs (184–186).

Intermittent nitrous oxide inhalation is an anesthetic technique that has proven useful in the management of severe breakthrough pain in patients with advanced cancer (187). Although the availability of masks that reduce ambient leakage of the gas has increased the potential usefulness of this approach, it continues to be applied rarely.

Neurostimulatory Approaches

It has been appreciated for some time that stimulation of afferent neural pathways may result in analgesia. The best-known

application of this principle is TENS. Other approaches include percutaneous electrical nerve stimulation, dorsal column stimulation, deep brain stimulation, motor cortex stimulation, and transcranial stimulation. Published experience in the use of these modalities for the management of cancer pain is meager (188,189). Surveys of the techniques that have been used most extensively in noncancer pain (TENS and dorsal column stimulation) suggest that the majority of patients will achieve analgesia soon after the approach is implemented but fewer obtain prolonged relief. A trial of TENS is usually considered in patients with neuropathic pain that has been difficult to manage with opioids.

Physiatric Approaches

Although evidence from clinical trials is lacking, the potential for analgesic effects from physiatric therapies, including the use of orthoses or prostheses, occupational therapy and physical therapy, and modalities such as heat, cold, vibration, and ultrasound, is well accepted. For example, refractory movement–induced pains may be partially relieved by bracing the painful part, such as in patients with back pain due to metastatic lesions of the spine and those with arm pain related to a malignant brachial plexopathy; and a well-fitting prosthesis can reduce stump pain. In addition to the potential for salutary effects on symptoms, physical therapy and occupational therapy can potentially forestall painful complications, such as contractures, and generally increase well-being.

Neurosurgical Approaches

Procedures designed to denervate the painful area surgically have been developed for every level of the nervous system from peripheral nerves to cortex. Historically, the most useful approach has been cordotomy. Like neurolytic blocks, however, these procedures are rarely considered now, largely due to the advent of more sophisticated, nondestructive interventions such as neuraxial infusion.

Psychologic Approaches

Some patients or families who present with severe psychologic distress may benefit from a multidisciplinary approach in which psychologic interventions are emphasized within a program designed to palliate symptoms and provide family support. These goals may be accomplished in some cases through referral to a hospice or palliative care program. Occasionally, patients with psychiatric disorders are identified, indicating the need for further assessment and treatment by an appropriate specialist (190).

Specific cognitive and behavioral approaches have also been applied in the management of pain and related symptoms (191). Cognitive approaches include relaxation training, distraction techniques, hypnosis, and biofeedback, all of which may enhance a patient's sense of personal control and reduce pain. Although experienced personnel are required to implement many of these approaches, the nonspecialist can teach several forms of relaxation training. Cognitive–behavioral therapy, which has achieved wide acceptance in the management of noncancer pain, is occasionally considered in patients with limited disease whose level of functional impairment is perceived to be out of proportion to the effects of the neoplasm.

Complementary and Alternative Medicine Approaches

Therapies that are typically considered to be complementary or alternative have had a growing role in pain management (192). These approaches are often very attractive to patients because they endorse a holistic strategy that is perceived as providing hope and self-control. Some interventions that are termed "complementary" are actually used routinely by specialists in pain medicine or palliative care. These include mind–body therapies (e.g., relaxation, meditation, and others), nutritional support, acupuncture, and massage. Interventions such as homeopathy, naturopathy, and many others, are

considered to be far outside the mainstream and are rarely suggested. Healthcare professionals have the difficult task of expressing concerns about some of the latter therapies, while respecting patients' pursuit of complementary treatments that may be beneficial or, at least, pose no significant chance of harm.

CONCLUSION

Pain is highly prevalent among patients with gynecologic tumors. The clinicians involved in the care of these patients have a challenging task in providing state-of-the-art management approaches for both acute and chronic pain. Fortunately, the most effective strategy for both acute and chronic pain, namely, opioid-based pharmacotherapy, is clearly within the purview of all practitioners. The knowledge and skills necessary to optimize this therapy, and integrate it with the broader principles of palliative care, are fundamental to the practice of gynecologic oncology.

CHAPTER 31 Nutrition Support of Patients with Gynecologic Cancer

Priya Simoes and Mark Schattner

Cachexia and weight loss are common manifestations of cancer and exert major impact on quality of life and survival. Malnutrition is a complex, multifactorial phenomenon that leads to progressive weight loss and deficiency of specific nutrients. Both cancer and its various therapeutic modalities contribute to cachexia. Advances in understanding nutritional requirements and intermediary metabolism, and major technologic progress in the ability to provide nutritional support, have made it possible to feed almost any patient with cancer. Nevertheless, the indications for and the appropriate use of the various modalities of nutritional support are still evolving, and many questions remain unanswered.

Malnutrition in most patients with cancer is usually a manifestation of general calorie and protein deficits that result in progressive weight loss and weakness; however, it is important to recognize that in some patients, specific nutrient deficiencies, such as magnesium deficiency or vitamin B_{12} deficiency, can be present even in the absence of weight loss and can contribute significantly to morbidity and even mortality.

Gynecologic malignancies and their multimodal therapies may be associated with severe malnutrition. Although some nutritional problems occur in patients with cervical and endometrial cancer, they are most commonly seen in those with ovarian cancer, particularly in advanced stages when intra-abdominal metastasis severely impairs gastrointestinal function. Because of the high incidence of malnutrition and its impact on the patient with cancer, nutritional assessment and appropriate therapy should be integral parts of the overall treatment plan.

NUTRITIONAL ASSESSMENT

Nutritional assessment in cancer patients is an ongoing process. It should be a part of the patient's initial evaluation and should be updated periodically. It is especially important to determine the nutritional state prior to therapeutic interventions as well as during and after acute illness, to identify those patients who would benefit from nutritional support. The nutritional assessment method used must be simple, accurate, and inexpensive. Anthropometric parameters, serum protein measurements, and immunologic tests have classically formed the basis of the nutritional evaluation; however, they all have significant deficiencies.

Anthropometric and Biochemical Markers

Anthropometric measurements such as weight, skinfold thickness, mid-arm muscle circumference, and creatinine/height index can all provide useful information but have major limitations. Change in weight is the single most useful measurement of nutritional status when the change does not reflect changes in total body water. The often-present edema, effusions, ascites, and intravenous hydration that often accompany treatment limit the use of weight as a nutritional parameter. In addition, inaccuracies in scales and different clothing can provide misleading information on weight changes.

Measurements of skinfold and mid-arm muscle circumference (1) are useful tools in studies but have very limited use in clinical practice. Lumbar skeletal muscle mass, measured by computed tomography (CT), has also been used as a nutritional indicator to determine prognosis and disease recurrence among patients with gynecologic cancers. However, this method requires special imaging software and technical expertise, and its clinical utility is limited (2). A creatinine/height index derived by dividing the patient's 24-hour creatinine excretion by that of a healthy person of the same height offers a sensitive measure of early protein-calorie malnutrition (3) but requires collection of a 24-hour urine specimen and is affected by alterations in renal function, which may not be indicative of the nutritional state.

Low levels of serum proteins such as albumin, prealbumin, transferrin, and retinol-binding protein were classically thought to represent malnutrition. However, in the malnourished sick patient, low levels of these proteins can be nonspecific. They are dependent on intact hepatic synthetic function as well as hydration status. They can be low as a manifestation of severe illness (infection, metastatic cancer, multisystem organ failure) in a normal nutritional state. In addition, they can function as acute-phase reactants and therefore can be normal or elevated in a clinically malnourished patient. Therefore, their role is limited. Similar limitations apply to immunologic parameters such as total lymphocyte count and delayed cutaneous hypersensitivity. In simple starvation, both these measures may be decreased and can return to normal with initiation of nutritional support. However, in the cancer patient undergoing chemotherapy, surgery, or radiotherapy or in the midst of an acute illness, these parameters have little value in the assessment of the nutritional state (4,5).

The above parameters have been combined to create numerous nutritional assessment indices. The most extensively studied is the Prognostic Nutritional Index (PNI), which factors measurements of serum albumin, serum transferrin, triceps skinfold, and delayed cutaneous hypersensitivity (6). Buzby et al. prospectively studied the PNI in patients undergoing gastrointestinal surgery and found that it could accurately stratify patients into high, intermediate, or low risk of developing postoperative complications (7). It must be understood, however, that the index is only as good as the parameters from which it is calculated, and the same limitations outlined above are present in any of these indices.

Subjective Global Assessment

The clinical assessment of the nutritional status has always been used to some extent as part of the general medical history and physical examination. The validity of a formal clinical assessment of the nutritional status was demonstrated in the landmark study by Baker et al., who developed the Subjective Global Assessment (SGA) as a formal clinical assessment of nutritional status (8). The SGA is based on a complete history and physical examination, with emphasis on six areas: change in weight, dietary intake, gastrointestinal symptoms, functional capacity, physiologic stress, and physical signs of nutritional deficiencies. These are used to place the patient into three groups. Group "A" (normal nutritional status) consists of patients without restriction of food intake or absorption, no change in functional status, and stable or increasing weight. Group "B" (mild malnutrition) consists of patients with evidence of decreased food intake and functional status but little or no change in body weight, while those with severe reduction in food intake, functional status, and loss of weight comprise Group "C" (severe malnutrition).

The SGA has consistently been shown to be reproducible and reliable in identifying patients at risk for developing complications associated with malnutrition. In the initial study of 59 patients electively admitted to a general surgical ward, interobserver reproducibility in classification of the nutritional status was 81%, and in a later study of 202 patients, it was found to be 91% accurate (8,9). The initial study by Baker and colleagues showed a significant increase in incidence of infection, use of antibiotics, and length of hospitalization in Group "C" when compared with Group "A" (8). In the follow-up study of 202 patients undergoing gastrointestinal surgery, the rate of septic and nonseptic complications in Group "C" was seven times greater than in Group "A" (9). The SGA provides a simple, reproducible, and accurate method to identify malnourished patients who could benefit from nutritional support. Clinical assessments similar to the SGA have been proved superior to immunologic testing, plasma protein measurements, and bioelectrical impedance in providing a useful evaluation of nutritional status (8–13).

More recently, the SGA has been shown to predict short- and long-term survival and tolerance to chemotherapy among women with ovarian cancer (14,15). It is now considered the preferred method of nutritional assessment for patients with gynecologic cancers (15,16).

PREVALENCE OF MALNUTRITION

The prevalence of malnutrition depends on the tumor type and stage, the organs involved, and the anticancer therapy. Concurrent nonmalignant conditions such as diabetes and intestinal diseases can be important contributing factors.

The prevalence of weight loss during the 6 months preceding diagnosis of cancer was reported from a multicenter cooperative study of patients with 12 types of cancer (17). The lowest frequency (31% to 40%) and severity of weight loss were found in patients with breast cancer, hematologic cancers, and sarcomas. Intermediate frequency and severity of weight loss was found in patients with colon, prostate, and lung cancer (54% to 64%). Patients with cancer of the pancreas and stomach had the highest frequency (over 80%) and severity of weight loss. However, it is worthwhile noting that approximately 35% of the patients with lung cancer lost more than 5% of their body weight. This underscores the fact that even if the tumor does not involve the gastrointestinal tract directly, there can be significant weight loss because of systemic and metabolic derangements and loss of appetite. Furthermore, the study did not report on patients with gynecologic malignancies, in whom weight loss can also be very frequent and severe. Other studies revealed that over 40% of patients receiving medical treatment for a variety of cancers were malnourished (18,19). Among surgical patients in a Veterans Administration hospital, 39% of those undergoing a major operation for cancer were malnourished, as judged by either a nutrition risk index or a combination of weight loss and low serum proteins (20).

Data on the prevalence and impact of malnutrition in patients with gynecologic tumors mirror the observations in patients with other cancers. In a study of 67 consecutive patients hospitalized with gynecologic cancers at the University of Texas, it was found that 54% were malnourished as determined by the PNI (21). In 1983, Tunca (22) examined the nutritional state of gynecologic oncology patients at time of diagnosis using serum albumin, serum transferrin, immune response, and weight loss. Patients with advanced (stage III or IV) ovarian carcinoma had the highest incidence of severe malnutrition, whereas those with cancer of the cervix, endometrium, or vulva reported weight loss with no indication of malnutrition from serum markers or immune response testing. Orr et al. (23,24) assessed the degree of protein-calorie malnutrition and evidence of vitamin deficiency in 78 patients with untreated cervical cancer. The incidence of protein-calorie malnutrition as assessed by anthropometrics, serum markers, and immune testing was directly related to tumor stage: 4% in stage I, 20% in stage II and III, and 60% in stage IV disease (23). Two-thirds of patients with untreated cervical cancer were found to have reduced blood levels of at least one vitamin. Mean serum levels of folate, β-carotene, and vitamin C at the time of admission were all significantly below control values (24). Similar observations of significant protein-calorie malnutrition were seen in 25 patients with endometrial cancer (25). Using the SGA to study 194 patients with gynecologic cancers, Laky showed that 24% of all patients were malnourished. The prevalence of malnutrition was highest in ovarian cancer (67%) and lowest in endometrial cancer (6%) (16).

SIGNIFICANCE OF MALNUTRITION

The impact of malnutrition on the cancer patient was demonstrated in a report by Warren in 1932 (26). Based on data from autopsies, the conclusion was that cachexia was the leading cause of death in a group of 400 patients with various cancers. More recent studies have confirmed the significant impact of malnutrition on the quality of life and prognosis of the cancer patient. In the aforementioned multicenter cooperative study of patients receiving chemotherapy (17), those who presented with weight loss at the time of diagnosis had decreased performance status and survival compared with

those who presented without weight loss. In a study of patients with limited, inoperable lung cancer, weight loss was a major predictive factor for survival (18). The negative impact of malnutrition was also demonstrated in surgical patients with malignant and benign diseases. Malnourished patients undergoing a major operation were at greater risk for postoperative morbidity and mortality than were well-nourished patients (20,27).

The impact of malnutrition on patients with a primary gynecologic malignancy is striking. While examining the role of total parenteral nutrition (TPN) in their patients, Terada and colleagues noted that those patients who developed major complications such as a fistula, wound infection, pneumonia, renal failure, respiratory failure, or those who died had significantly more weight loss and lower serum transferrin levels at the time of presentation (28). They concluded that these parameters might be of value in predicting clinical outcome in patients requiring nutritional support. This was confirmed in a study by Geisler, who found that in patients with ovarian cancer, those who were malnourished had increased postoperative complications. This difference could be mitigated if preoperative nutritional support could reverse the malnutrition (29).

Several other studies have confirmed the relationship of malnutrition to poor surgical outcome in patients with primary gynecologic malignancies. Donato et al. reported that of the 104 patients with ovarian carcinoma undergoing intestinal surgery, those considered to be malnourished on the basis of serum protein measurements and weight loss preoperatively had significantly more infectious complications, while other variables including preoperative bowel obstruction, extent of debulking, number of intestinal procedures, or hand versus stapled anastomosis failed to correlate with the rate of infectious complications (30). Poor nutritional status has been shown to be an independent predictor of prolonged postoperative ICU stay in patients with ovarian cancer (31). Hertlein stratified gynecologic cancer patients at risk for malnutrition using a nutritional risk screening (NRS) tool (NRS 2002). The NRS 2002 was calculated using two components: “impaired nutritional status” and “severity of disease,” which were each given an individual score from 0 to 4. The sum of the two scores constituted the final NRS (32,33). Those with NRS scores > 3 were at increased risk for perioperative infectious (6.9% vs. 3.2%) and noninfectious complications (15.8% vs. 4.5%). They also had longer hospital stay (10 vs. 6 days). Patients with ovarian cancer had the highest prevalence of malnutrition (33). In another study of gynecologic cancer patients undergoing surgery, Uppal and colleagues found that patients with preoperative hypoalbuminemia (defined as serum albumin < 3 g/dL) were 6 times more likely to develop a perioperative complication and 10 times more likely to die within 30 days of surgery compared with those with normal albumin levels (34).

In addition to predicting surgical outcome and perioperative complications, malnutrition is associated with increased neutropenic fever following chemotherapy, prolonged hospital stays, decreased quality of life, and reduced overall survival among women with gynecologic cancers (14–16,21,35).

ETIOLOGY OF MALNUTRITION

Cancer can induce a wide variety of derangements in nutritional status, ranging from generalized malnutrition with severe weight loss and muscle wasting to a single nutrient deficiency. The etiology of malnutrition in the cancer patient is multifactorial. Nutritionally relevant derangements can be induced by the tumor locally (i.e., gastrointestinal obstruction), by malabsorption, or by humoral factors produced by the tumor itself or by reaction of the immune system to the tumor. All modalities of cancer therapy, surgery, radiation, chemotherapy, immunotherapy, and palliative treatments may be associated with side effects and complications that can impair nutritional status.

Cancer cachexia is defined as an ongoing loss of skeletal muscle mass (with or without loss of fat mass) that cannot fully be reversed by nutritional support and leads to progressive functional impairment. It is diagnosed by the presence of these three criteria: (1) weight loss > 5% over the past 6 months (in absence of simple starvation); (2) BMI < 20 and any degree of weight loss > 2%; or (3) appendicular skeletal muscle index consistent with sarcopenia (males < 7.26 kg/m^2; females < 5.45 kg/m^2) and any degree of weight loss > 2% (36).

The etiologic factors of malnutrition in the cancer patient are generally due to three major factors: decreased food

intake, malabsorption, and abnormal metabolism.

Impaired Food Intake and Malabsorption

Both tumor and cancer treatment modalities can lead to decreased food intake through direct effects on the gastrointestinal tract or systemic effects leading to anorexia. Obstruction of the gastrointestinal tract can be caused by any gynecologic malignancy through external compression, or more rarely, by direct invasion. Occasionally, localized obstructions can be relieved surgically or endoscopically; however, obstruction due to peritoneal carcinomatosis seen in advanced ovarian cancer is particularly difficult to manage surgically. Often, draining gastrostomy with parenteral nutrition (when appropriate) is the only option for providing nutrition and symptomatic relief (37,38).

Tumors can induce anorexia without local involvement of the gastrointestinal tract. The pathophysiology of this phenomenon is not well understood. Norton et al. (39) utilized a model of surgically coupled tumor-bearing and normal rats with parabiotic cross-circulation to show that tumor-induced anorexia is mediated by circulating substances. Tumor-induced impairment of smell and taste has been well described (27,40–43), but the mechanism has not been defined. There is growing evidence that glycoproteins, cytokines, and neuropeptides play an important role in the pathogenesis of cancer cachexia. Bernstein et al., (44,45) demonstrated in a rat model that infusion of tumor necrosis factor (TNF) mimics tumor-induced anorexia and these effects are mediated via the area postrema and the caudal medial nucleus of the solitary tract in the central nervous system.

Therapies used for gynecologic malignancies often result in complications that impair nutrient intake and absorption. Surgical interventions can lead to fistulae, short bowel syndrome, infections, and ileus, all of which impair oral intake significantly. In a review of 12 years of colonic surgery in gynecologic oncology patients, the rate for major systemic complications (myocardial infarction, pulmonary embolism, renal failure, sepsis) was 13.7%, and the rate of major bowel complications (abscess, fistulae, hemorrhage, obstruction) was 12.1% (46). Adjuvant radiation and chemotherapy have been shown to increase the incidence of major complications after pelvic exenteration (47).

Radiotherapy can lead to damage of the gastrointestinal tract, most commonly affecting the small bowel, followed by the transverse colon, sigmoid, and rectum. Predisposing risk factors include previous abdominal surgery, pelvic inflammatory disease, thin body habitus, hypertension, and diabetes mellitus (48). In general, a dose of 5,000 rads is the threshold for significant injury. In the acute phase of radiation enteritis, virtually all patients experience anorexia, nausea, and vomiting, which are thought to be mediated by effects of serotonin on the gut (49) and the central nervous system (50). This is followed 2 to 3 weeks later by direct injury to the intestinal mucosa, resulting in diarrhea and mild-to-moderate malabsorption. Most patients will have complete resolution of these acute symptoms. However, a significant minority of patients who received radiotherapy will experience chronic dysfunction of the gastrointestinal tract (51). There is often a latent period of 1 to 2 years, and possibly as long as 20 years, before the symptoms of chronic radiation enteropathy surface (52,53). In a review of 102 patients with radiation enteritis after treatment for cervical or endometrial cancer, the median time to development of severe symptoms such as obstruction or perforation was 18 months (54).

Chronic radiation enteropathy is characterized pathologically by transmural injury leading to submucosal fibrosis, edema, lymphatic ectasia, and obliterative endarteritis, which can induce colicky abdominal pain, diarrhea, steatorrhea, ulceration, perforation, stricture, and fistula formation (48). Yeoh et al. (55) retrospectively studied the effects of pelvic irradiation given for the treatment of cervical cancer in 30 randomly selected women who had undergone radiotherapy 1 to 6 years earlier. Significant dysfunction of the gastrointestinal tract was detected. Nineteen of the patients had frequency of bowel movements, bile acid absorption, and vitamin B_{12} absorption outside of the control range. The authors concluded that abnormal gastrointestinal function is essentially an inevitable long-term complication of pelvic irradiation (55). Huaebye and colleagues (56) prospectively studied the gastrointestinal motility patterns in 41 patients with chronic abdominal complaints after radiotherapy for gynecologic cancer. Impaired fasting motility was found in 29% of patients, and motor response after a meal was attenuated in 24%. Postprandial delay of the migrating motor complex was found to be an independent predictor of malnutrition as assessed by weight loss and serum albumin. Impaired motility of the small bowel,

therefore, is a key factor in the symptoms experienced by patients with chronic radiation enteropathy. Chronic radiation enteritis predisposes to numerous secondary complications. Danielsson et al. (57) studied 20 patients with chronic or intermittent diarrhea occurring two or more years after receiving radiotherapy for gynecologic tumors. Bile acid malabsorption was detected in 65% of patients, while evidence of bacterial overgrowth on D-xylose or cholyl-glycine breath tests was found in 45%. Treatment with bile acid binders or antibiotics resulted in a significant decline in the number of daily bowel movements. In 47 patients with gynecologic malignancies who had gastrointestinal complaints lasting more than 4 months after radiotherapy, Kwitko et al (58). found 19 partial small bowel obstructions, 11 cases of malabsorption, and 5 fistulae. The mortality from radiation damage to the small bowel in this report was 32%. More recently, Boland reported on a 25-year experience with post-resection short bowel syndrome secondary to radiation therapy. The majority of the cases were in women who received pelvic radiation for gynecologic cancers. One-third of these patients developed short bowel syndrome within a year after radiation and two-thirds remained dependent on long-term TPN (59). Improved fractionation of radiotherapy and protective shielding of the intestine where possible have reduced these complication rates (60).

Chemotherapy is often associated with decreased food intake. Mucositis and diarrhea are commonly seen during therapy with cytotoxic agents that affect the replicating cells of the intestinal mucosa, such as 5-flourouracil, methotrexate, and bleomycin. The vinca alkaloids can cause ileus and constipation mediated by toxic effects on gastrointestinal neural pathways, while cisplatin and nitrosoureas are highly emetic (61,62). Significant nausea, vomiting, stomatitis, and diarrhea occur in 15% of patients receiving intravenous taxol and in 55% of those receiving the drug orally (63). In addition to direct effects on the GI tract, chemotherapy in women with gynecologic cancers has significant effects on olfactory and gustatory function, leading to reduced appetite and weight loss (64).

The psychological impact of a malignancy and its associated therapies can also lead to decreased nutrient intake. Depression is a frequent cause of anorexia in this population, with up to 58% of cancer patients having depressive symptoms and 38% meeting criteria for major depression (65).

Metabolic Derangements

Even with normal nutrient intake, patients with cancer are at risk for malnutrition due to inefficient nutrient utilization and wasteful metabolic pathways. Cancer cachexia is associated with altered metabolism of carbohydrates, fat, protein, vitamins, and minerals.

Increase in basal energy expenditure (BEE) has been reported in many but not all studies of patients with malignancy (66–68). In patients with newly diagnosed small cell lung cancer, Russel et al. showed a mean increase of 37% in BEE, which fell substantially in those who responded to chemotherapy (69). Similar findings have been reported for gastric cancer and sarcoma (67,70). Elevated BEE will drop after tumor resection (71). There are limited data on the metabolic rate in patients with gynecologic cancers (72). Dickerson et al. used indirect calorimetry to determine the resting energy expenditure in 31 patients with ovarian cancer and 30 patients with cervical cancer. Fifty-five percent of those with ovarian cancer were found to be hypermetabolic (BEE >110% predicted by the Harris–Benedict equation), while only 13% of patients with cervical cancer were hypermetabolic. These differences could not be explained by differences in the extent of disease, nutritional status, body temperature, or nutrient intake (73).

Abnormalities in carbohydrate metabolism in cancer patients include glucose intolerance and peripheral insulin resistance (74–76). These most often become apparent in the patient with advanced metastatic cancer found to have hyperglycemia, which is refractory to high-dose insulin infusion (77,78). In comparison, in simple starvation, patients are most often euglycemic or hypoglycemic. The hyperglycemia seen in cancer patients is exacerbated by increased hepatic gluconeogenesis. Shaw et al. (79) showed that this increase in glucose production is correlated with tumor burden and decreases after tumor resection.

Lipid metabolism may also be abnormal in patients with a malignancy. There is often increased lipolysis with weight loss, and this leads to a decrease in fat mass, which can be out of proportion to the loss of lean body mass (76). In

addition, patients with cancer are often hyperlipidemic, and this may be mediated by TNF-α. In contrast to normal homeostasis, cancer patients fail to suppress lipolysis with glucose infusion (79,80). Several causes of increased lipolysis have been proposed, including decreased food intake, stress response to illness with adrenal medullary stimulation and increased circulating catecholamine levels, insulin resistance, and release of lipolytic factors produced by the tumor itself or by myeloid tissue cells (81). One such factor has been well characterized. Lipid mobilizing factor (LMF), a 24-kDa glycoprotein produced by tumors has been shown to stimulate increased lipid mobilization from adipocytes. LMF is thought to act through binding of β-adrenergic receptors and subsequent upregulation of mitochondrial uncoupling proteins (82,83). Animal studies have shown that LMF causes loss of body weight (specifically a loss of body fat), which is independent of caloric food intake (84). The activity of LMF in the urine and serum of cancer patients has been shown to correlate with the degree of weight loss and tumor burden (85,86). In addition to its effect on lipid metabolism, there is preliminary evidence that LMF may protect tumor cells from free radical toxicity and may therefore make tumors less responsive to certain chemotherapeutic agents that induce oxidative damage (87).

High total body protein turnover, with increased synthesis and catabolism, characterizes the alterations of protein metabolism seen in cancer patients. This results in depletion of muscle mass and loss of nitrogen, and contrasts with the adaptive decrease in protein turnover seen in patients with uncomplicated starvation (88). TPN given to patients with cancer will result in gains of weight and body fat, net gains of total body nitrogen, but no suppression of the high protein flux (88,89). The predominant mechanism of muscle protein loss in cancer patients is an ubiquitin-associated pathway (90). In this pathway, polyubiquitin chains are attached to proteins, which are then recognized and degraded by a proteasome complex. This pathway is regulated, in part, by proteolysis-inducing factor (PIF). PIF is a 24-kDa glycoprotein produced by human tumors and was found in the urine of cancer patients who were losing weight, but not in the urine of cancer patients who were maintaining their weight. In fact, PIF expression directly correlates with the severity of weight loss. There are multiple mechanisms by which PIF induces weight loss. PIF has a direct effect on skeletal muscle by decreasing protein synthesis and increasing protein degradation by upregulating the ubiquitin-proteasome dependent pathway. PIF also increases the expression of pro-inflammatory cytokines (i.e., interleukin-6 and -8), which independently cause weight loss, and induces the shedding of syndecans (transmembrane proteoglycans), which has been shown to be related to increased metastases and mortality (91–93). Effective treatment of the underlying cancer has been shown to reverse ubiquitin-dependent proteolysis of skeletal muscle (94). Better understanding of this process holds the promise of improving therapy to attenuate the loss of protein seen in patients with cancer.

Cytokines also play an important role in inducing metabolic derangements. Interleukin 6 and TNF are released during interaction of host cells with tumor, and high serum levels are present in patients with advanced cancer and cachexia (95–97). They mediate increased energy expenditure, whole body protein turnover, rise in serum triglyceride levels, and high glycerol turnover (98). TNF causes protein wasting, depletion of body fat, and anorexia in animal models by activation of an ATP-dependent proteolytic pathway (95,99). Genetic polymorphisms may result in higher levels of circulating cytokines and a greater degree of weight loss in some patients compared with others (100). Interventions to downregulate these cytokines result in improved appetite, body weight, and quality of life (96).

The combined effects of these wasteful and inefficient alterations in metabolism make it difficult to restore nutritional status in the patient with cancer and cachexia despite the use of specialized nutritional support.

NUTRITIONAL THERAPIES

There are four types of nutritional therapies: parenteral nutrition, enteral nutrition, oral dietary therapy, and drug therapy aimed at improving appetite and food intake. Depending on the patient's condition, nutritional support in the cancer patient has two distinct objectives: (1) provision of nutrition during anticancer therapies to counteract their nutritionally related side effects and improve outcome following these therapies and (2) support in patients with long-term or permanent severe impairment of the gastrointestinal tract. In these patients, nutritional support may be required for indefinite periods of time.

Results of numerous clinical trials support the use of nutritional support only in limited situations during anticancer therapies. In the group with prolonged gastrointestinal failure, nutritional support may be a lifesaving therapy because patients could die of starvation without TPN or enteral feeding.

Total Parenteral Nutrition

Total parenteral nutrition is an effective method for delivery of nutrients directly into the blood, and thus overcomes the major causes of cancer-induced weight loss, including decreased food intake and dysfunction of the gastrointestinal tract. Survival for more than 20 years in patients nourished exclusively by TPN clearly demonstrates the lifesaving role of this method of nutritional support. Initially, it seemed logical that TPN would be an effective adjuvant therapy for most cancer patients undergoing radiation therapy, surgery, or chemotherapy because of the accompanying cachexia and inability to eat adequately. Randomized studies, however, have shown that TPN only benefits a select subgroup of cancer patients during anticancer therapy.

Efficacy

In patients receiving chemotherapy with or without radiation therapy, TPN can lead to improvements of several nutritional parameters. Both body weight and body fat increase. Deficits of specific vitamins, minerals, and trace elements can be corrected, and hydration status can be improved (88,101). TPN, however, does not alter many of the metabolic derangements encountered in the cancer patient. Increased glucose oxidation and turnover persist as does muscle proteolysis and increased lipolysis (74,79,102,103). Finally, TPN does not stop the overall losses of body nitrogen (104).

The relevant issue for the clinician is the effect of TPN on the morbidity and mortality associated with cancer therapy and whether TPN can allow more intense therapy, as was initially hoped. Numerous randomized trials have examined this issue. Studies of patients undergoing chemotherapy for carcinoma of the ovary (37), lung (105,106), colon (104), testes (107), lymphoma (108), and other tumors (109) have been conducted. However, the patients in these studies were largely unselected. Many were not malnourished and others had adequate oral intake with intact gastrointestinal function, making intravenous nutrition unnecessary, futile, and potentially harmful. Numerous meta-analyses concluded that nondiscriminatory use of TPN in patients undergoing chemotherapy offers no improvement in mortality, response to chemotherapy, or reduction in treatment-associated complications (110–112). This conclusion was echoed in a consensus statement from the National Institutes of Health, the American Society for Parenteral and Enteral Nutrition, and the American Society for Clinical Nutrition (113). The improvement in nutritional parameters afforded by TPN in patients receiving chemotherapy does not necessarily translate into improved clinical outcome. Thus, the routine use of TPN in these patients is not indicated.

There are circumstances, however, in which nutritional support with parenteral nutrition should be considered. These include prevention of the effects of starvation in a patient unable to tolerate oral or enteral feedings for a prolonged period of time (usually more than 7 to 10 days), maximization of performance status in a malnourished patient prior to chemotherapy or surgery, and in patients undergoing bone marrow transplantation (114). TPN may have a stimulatory effect on tumor cell cycle kinetics (115). It was hoped that this effect would induce improved tumor response to cell cycle–specific chemotherapy. Conclusive proof of such a response remains elusive.

A few randomized studies have examined the use of TPN in patients receiving radiotherapy to the abdomen and pelvis (116,117). The role of TPN in the perioperative period has been extensively studied (118–121). At Memorial Sloan Kettering Cancer Center, a prospective study of 117 patients undergoing curative resection for pancreatic cancer randomized to receive TPN or intravenous fluids in the postoperative period showed no benefit from routine use of postoperative TPN (122). The group receiving TPN had a significant increase in postoperative infectious complications. The largest prospective randomized trial investigating the role of TPN in the perioperative setting was the Veterans Administration Cooperative Study. In this study, 395 patients were randomized to receive 7 to 15 days of preoperative and

3 days of postoperative TPN, or oral feeding plus intravenous fluids. TPN did not improve morbidity or 90-day mortality. However, subgroup analysis showed that patients considered to be severely malnourished had fewer infectious complications if they received TPN. The authors concluded that the routine administration of preoperative TPN should be limited to patients who are severely malnourished, unless there are other specific indications (20).

Randomized studies specifically examining the role of perioperative TPN in patients with gynecologic malignancies are lacking. In a report by Terada (28), perioperative parenteral nutritional support was given to 84 of 99 patients. There were no major complications attributed to TPN, but 27% of the patients experienced minor complications: 11% due to central line placement or catheter sepsis, 2% due to fluid overload, and 13% had metabolic complications. There was no report on overall perioperative morbidity or mortality in comparison to patients who did not receive perioperative TPN.

These data and others provided the basis for a consensus statement from the National Institutes of Health, the American Society for Parenteral and Enteral Nutrition, and the American Society for Clinical Nutrition regarding the use of perioperative TPN, which states the following: (a) 7 to 10 days of preoperative TPN in a malnourished patient with gastrointestinal cancer results in a 10% reduction in postoperative complications; (b) routine use of postoperative TPN in malnourished surgical patients who did not receive preoperative TPN results in a 10% increase in complications; (c) if by postoperative day 5 to 10 a patient is unable to tolerate oral or enteral feedings, then TPN is indicated to prevent the adverse effects of starvation. This panel, however, cautioned that in the majority of studies examining perioperative TPN, the amount and type of parenteral nutrition given was not optimal, and patients were often given excess calories. Therefore, the results may differ with the provision of relatively hypocaloric formulas (113). It is reasonable to extend these recommendations to the gynecologic oncology patient undergoing surgery (Table 31.1).

TABLE 31.1 Indications for TPN in Hospitalized Patients with Gynecologic Cancers

Perioperative	• 7–10 days preoperatively in a malnourished patient (who cannot be fed enterally) • Postoperative complications that prevent oral or enteral intake for more than 7–10 days • Enterocutaneous fistula • No indication for routine use
During radiation or chemotherapy	• Maximization of performance status prior to therapy in a malnourished patient who cannot be fed enterally • Severe persistent (more than 7–10 days) mucositis, diarrhea, ileus, or emesis • No indication for routine use
General	• After 7–10 days of inability to tolerate oral or enteral feeding due to any cause

Composition of TPN Solution

Once the decision to proceed with parenteral nutritional support is made, access to a large bore central vein should be obtained. This allows the use of calorically dense, hypertonic solutions, which are often necessary in severely ill patients who may have restriction on the amount of intravenous fluids they can receive. The solution must provide the protein and caloric needs, fluid, minerals, trace elements, and vitamins. Estimates of nutrition requirements are based on weight and adjusted for the degree of physiologic stress encountered by the patient, and there are numerous formulas and charts that provide these. Generally, patients require approximately 30 kcal/kg nonprotein calories, 1 g/kg amino acids, and about 2,000 mL of fluid. As illness severity increases and organs' functions change, adjustments may be required. Nonprotein calories can be provided as dextrose or lipid, and the relative amounts of these should also be individualized. Lipids provide 9 kcal/g compared with 3.4 for dextrose (in dextrose solutions, glucose is present as glucose monohydrate; hence, a gram

contains less than 4 kcal). Lipid calories are particularly useful in patients who have high caloric requirements but cannot tolerate a large fluid load. In addition, lipids are useful in patients with severe pulmonary or hepatic dysfunction as glucose metabolism produces more carbon dioxide, which can add to the burden of the ailing lung and can lead to fatty infiltration of the liver. Up to 60% of caloric requirements can be provided as lipid, but serum triglyceride levels must be monitored closely. Appropriate electrolyte content of TPN solutions is of critical importance. The amounts have to be tailored to the patient's requirements and organ function. Care must be taken to prevent potentially fatal hypokalemia or hypophosphatemia (particularly in the patient with severe weight loss), which can be precipitated by insulin-induced transport of the minerals to the intracellular space when inadequate amounts are given. Other electrolyte disorders, such as cisplatin-induced hypomagnesemia and syndrome of inappropriate antidiuretic hormone secretion (SIADH), are common in the patient with gynecologic malignancy and must be addressed when ordering TPN. The TPN solution must also contain vitamins, minerals, and trace elements. Typically, these are available as standard commercial combination products. However, certain patients require specific modifications. For example, a patient with persistent diarrhea requires zinc supplementation in excess of the amounts present in standard trace element solutions.

Complications

Complications associated with TPN can be classified as catheter related, metabolic, or infectious. Catheter complications most often occur during placement of a central venous catheter and include pneumothorax, hemothorax, arterial injury, and hematoma. These can all be minimized when the procedure is performed by an experienced physician (123). Cobb et al. reported a 3% incidence of pneumothorax, arrhythmia, thrombus, or bleeding during 523 intravenous catheter placements (124). A more recent study of subcutaneous peripheral infusion ports in women with gynecologic malignancies demonstrated a thrombosis rate of 26% during a mean follow-up of 105 days. The authors concluded that other types of vascular access devices may be preferable in this patient population (125). Another study demonstrated a higher rate of catheter-related infections in patients with external central venous catheters compared with subcutaneous infusion ports (126).

Metabolic derangements are frequently encountered during support with TPN, and the prescribing physician must be well versed in the pathophysiology of these disorders. Hyperglycemia is the most common abnormality, and if not corrected, can lead to an osmotic diuresis, dehydration, acidosis, and hyperosmolar coma. One metabolic complication that deserves special mention is the "refeeding syndrome." In chronically ill patients with severe malnutrition, there is often a depletion of total body phosphorus and potassium. The phosphorous deficits may be masked by increased renal phosphorous absorption designed to maintain normal serum levels. When nutritional support is initiated, the infusion of a large glucose load with subsequent surge in insulin leads to increased cellular uptake of phosphorous and potassium, which may induce severe life-threatening hypokalemia and hypophosphatemia (123,127). These disorders cause widespread tissue and organ dysfunction, including muscle weakness, rhabdomyolysis, heart failure, cardiac arrhythmias, and respiratory failure, and may result in death in extreme cases (127,128). Therefore, in patients with evidence of severe undernutrition, nutrition support should be initiated with small amounts of dextrose calories, supplemental phosphorous and potassium, and careful monitoring of serum phosphorous and electrolytes.

TPN has been associated with cholestatic liver disease, as well as fatty infiltration of the liver and glycogen deposition. These abnormalities have been attributed to infusion of excessive glucose calories, imbalance of amino acids, and rarely, fatty acid deficiency (129). Elevation of serum transaminases may occur, but it is generally mild (129,130). Severe liver dysfunction in adult TPN recipients is rare and requires a search for causes other than TPN.

Infections are particularly serious complications in patients with malignancy receiving TPN. In an evaluation of seven studies comparing TPN plus chemotherapy to chemotherapy alone, Klein and Koretz found four studies that showed an increase in infectious complications in patients receiving TPN (117). A meta-analysis by the American College of Nutrition showed a fourfold increase in infections when patients receiving chemotherapy were given TPN (112). In a prospective, randomized study of TPN following pancreatic resection, recipients of TPN had significantly more infectious

complications (122). Data from a VA randomized cooperative study showed that patients with mild-to-moderate malnutrition given perioperative TPN had increased rates of infections, while those with severe malnutrition developed significantly fewer infections when supported with TPN (20). Infectious complications are related to both central venous catheters and a variety of sites (wound infection, abscess, and pneumonia).

Home TPN

Long-term TPN in the home can be a lifesaving treatment in an appropriately selected group of patients. It is clear that cancer patients who have had severe gastrointestinal injury, such as massive intestinal resection or severe radiation enteritis, and in whom the cancer has been cured or is well controlled, benefit from long-term TPN at home (131). A study at the Mayo Clinic examined the outcomes of patients with gynecologic malignancies on home TPN. Inoperable bowel obstruction was the indication for TPN in most of these patients. Quality-of-life parameters, including nausea, vomiting, fatigue, comfort, and morale, significantly improved in patients on home TPN compared with pre-TPN status, especially in those with Karnofsky status > 40 (132). Scolapio described 54 patients treated with home TPN after radiation enteritis. The majority had ovarian cancer, and the main causes of intestinal failure were intestinal obstruction from radiation strictures and short bowel syndrome. Approximately half of the patients initiated TPN within 6 months of completing radiation. Over two-thirds of the patients died due to recurrent cancer. However, survival rates and TPN-related complications were comparable to those in patients with benign diseases like Crohn's disease and intestinal necrosis who required home TPN (133). The role of TPN in advanced or end-stage disease is controversial. For patients with inoperable bowel obstruction due to metastatic ovarian cancer, predicting which patients will benefit from home TPN can be difficult (134). In a review of 9,897 days of home TPN administered to 75 patients with various cancers and intestinal obstruction, it was shown that a Karnofsky performance status greater than 50 at the initiation of TPN could accurately predict which patients would have improved quality of life while on home TPN. The authors concluded that home TPN should be avoided if the performance status is below this level (135). In addition, patients with a life expectancy of less than 2 to 3 months will not benefit from home TPN (103,135). In a study from Yale-New Haven Hospital of 17 patients with inoperable bowel obstruction due to malignancy, patients with ovarian cancer had the shortest survival (39 days) compared to patients with colon cancer (90 days) and appendiceal cancer (184 days) (136). A study from the Mayo Clinic in 52 patients with advanced incurable cancer on home TPN found just two patients with ovarian cancer who survived longer than 12 months (132). A recent study from Brown University evaluated 55 patients with terminal ovarian cancer and found the use of TPN conferred a median survival benefit of 4 weeks (137). Patients on TPN were also more likely to receive concurrent chemotherapy (64% vs. 26%). In another study by Diver et al., 115 women with gynecologic malignancies underwent venting gastrostomy tube placement for malignant bowel obstruction. The median survival of patients receiving TPN was 9.6 weeks versus 4.6 weeks in those not receiving TPN (138).

Currently, the best selection criteria for such patients are a fair or better performance status and the potential for further antitumor therapy (Table 31.2). Only a highly selected minority of patients with end-stage cancer and inoperable bowel obstruction can potentially benefit from home TPN. There are several quality-of-life and ethical issues to be considered among this group of patients, and more data from randomized controlled trials is required.

TABLE 31.2 Indications for Home TPN in Patients with Gynecological Cancers

- Severe chronic radiation enteropathy
- Short bowel syndrome
- Persistent enterocutaneous fistula
- Selected patients with obstruction due to peritoneal carcinomatosis. (Selection based on performance status and potential for further chemotherapy)

Recently developed techniques for placing feeding tubes make it possible to hydrate and feed patients enterally, even in

the presence of gastrointestinal obstruction, and thus obviate the need for home TPN in patients with upper gastrointestinal tract dysfunction.

Enteral Nutrition

Enteral feeding delivers a liquid-nutrient formula into the gastrointestinal tract through tubes placed into the stomach or small intestine. As in oral feeding, an adequately functioning small intestinal mucosa is required for absorption of nutrients. Enteral feeding can overcome many difficulties encountered in patients with a wide variety of gastrointestinal tract dysfunction. A proximal gastrointestinal obstruction can be bypassed; tubes can be placed distal to obstructions as far as the jejunum, and thus circumvent obstructing lesions of the oral cavity, esophagus, stomach, duodenum, or proximal jejunum (139,140). The liquid-nutrient formula can be delivered as a slow, continuous infusion, thus maximizing absorption by a limited intestinal surface, which can be overwhelmed by the higher volume delivered during oral feeding. Such an approach may be useful in patients with radiation enteritis, short bowel syndrome (with adequate remaining short bowel, usually 3 to 4 ft.), or partial obstruction of the bowel.

Route of Administration and Nutrient Formula

Short-term (<2 weeks) access to the gastrointestinal tract can be obtained through nasogastric or nasoenteric tubes. Patients requiring longer nutritional support should have a gastrostomy or jejunostomy tube placed endoscopically, radiologically, or surgically. In comparison to nasal tubes, gastrostomy or jejunostomy tubes are wider (15 to 24 Fr) and therefore less likely to be obstructed by medications or nutrient solutions. In addition, they are fixed in the stomach or the upper intestine and do not migrate into the esophagus. Thus, the risk of aspiration is considerably decreased (139). These tubes are more comfortable and aesthetically pleasing. These benefits were demonstrated in a randomized study of patients after an acute dysphagic stroke, which showed patients fed with a gastrostomy tube had more optimal provision of nutrients, achieved a better nutritional state, and had less mortality than those fed with nasogastric tubes (141). Patients with gastrostomy tubes have been shown in prospective studies to receive over 90% of prescribed feedings compared to only 55% in patients fed through nasal tubes. These differences are largely attributed to nasogastric tube dislodgment (142). In a randomized study of 33 women with gynecologic malignancies, enteral feedings through a needle catheter jejunostomy maintained postoperative nutrition as measured by serum transferrin levels and was associated with few complications (143). The authors concluded that women with gynecologic cancers should have a jejunostomy placed at the time of operation if it is anticipated that long-term nutritional support will be required.

Endoscopically placed percutaneous gastrostomy tube (PEG) has become the procedure of choice for placement of enteral feeding tubes because of its ease, safety, and the ability to perform it on an outpatient basis. Percutaneous jejunostomy (PEJ) tubes can also be placed endoscopically (140). PEJs allow for continued enteral feeding in patients with gastric resection, gastric outlet obstruction, or gastroparesis. Major complications (bleeding, peritonitis, abdominal wall abscess, colonic perforation, and aspiration) from PEG and PEJ placement are rare, occurring in 0% to 2.5% of patients, while minor complications (wound infection, tube migrations, or leak) are seen in 5% to 15% (70,140,144). More than 100 different enteral feeding formulas are currently commercially available. They are designed to provide complete nutrition, single nutrients, or only fluids and electrolytes. Formulas differ in protein concentration, calories, osmolarity, and percentage of nonprotein calories delivered as carbohydrates or fats. Enteral feeding formulas, which provide 1,500 to 2,000 kcal/day, normally contain all the necessary nutrients including proteins, vitamins, minerals, and trace elements. In addition, there are disease-specific formulations for patients with diabetes or hepatic, renal, or pulmonary dysfunction. The choice of formula should be individualized, and it often helps to minimize problems such as diarrhea, bloating, or hyperglycemia.

Enteral solutions may be administered by either bolus feedings or continuous infusion. Bolus feeding is possible when the tip of the feeding tube is in an intact stomach. Up to 500 mL of a feeding formula can be infused over 10 to 15 minutes

by a syringe or gravity into the stomach. The pyloric sphincter regulates flow into the duodenum. All bolus feedings should be done with the patient sitting upright to minimize the risk of aspiration. When the tip of the feeding tube is distal to the pylorus, continuous feeding must be employed to avoid abdominal distention and diarrhea. Rates as high as 150 mL/hour are generally well tolerated (139).

Efficacy

Data from randomized trials examining the efficacy of enteral nutrition given as an adjuvant therapy in patients receiving chemotherapy for a variety of cancers have failed to demonstrate a clear benefit in terms of survival or response to treatment (145–149). The validity of the conclusions of these studies, however, is limited by their small size and poor design. Similar difficulties plague the studies examining the role of standard enteral nutrition in the perioperative period (150–152). Accepted indications for enteral nutrition in cancer patients include (a) obstruction of the upper digestive tract in those in whom enteral access can be safely obtained beyond the site of obstruction, (b) the presence of chronic malnutrition due to inadequate oral intake, and (c) perioperative support of the malnourished patient (153).

Complications

Enteral nutrition is generally safe if careful attention is paid to the following: (a) choice of an appropriate formula, (b) infusion into an appropriate portion of the gastrointestinal tract, (c) use of the correct infusion method, and (d) an ongoing clinical and metabolic monitoring of the patient. The most serious complication of enteral feeding is aspiration, which occurs in 1% to 32% of patients (145). The risk is minimized by keeping patients upright during bolus feedings and using jejuna feedings if there is predisposition for aspiration, gastroparesis, or an impaired gag reflex. Diarrhea is reported in 5% to 30% of patients receiving enteral nutrition (154). While the diarrhea may be related to underlying disorders of the gastrointestinal tract, such as radiation enteritis or short bowel syndrome, a commonly overlooked cause is medications. Patients on enteral feeding often receive magnesium-containing antacids or antibiotics, both of which may induce diarrhea. Metabolic complications include dehydration, azotemia, hyperglycemia, and hyperkalemia. These are usually due to the patient's underlying disease and can be avoided with the choice of the proper formula and careful monitoring.

Home Enteral Nutrition

Home enteral nutrition (HEN) is increasingly being used to provide nutrients and fluids outside the hospital. Cancer is the most common indication for its use and accounts for 42% of all patients receiving HEN (131). It is a safe therapy in patients with cancer, with only a 0.4% annual rate of complications requiring hospitalization (155). The overall 1-year survival for cancer patients on HEN is 30%. However, in patients with cancer of the head and neck who have been successfully treated, HEN has provided good nutrition for periods exceeding 7 years (70,139). Regular medical follow-up is essential to ensure appropriate functioning of the feeding tube and optimization of the nutrition regimen. This form of therapy is useful in patients with gynecologic malignancies with upper gastrointestinal tract obstructions that cannot be treated surgically.

Oral Dietary Therapy

Patients who are able to eat but have impairment of the gastrointestinal tract or have special metabolic requirements may benefit from a specialized oral dietary therapy. Often, this may obviate the need for more costly and complex interventions such as parenteral nutrition. In oral dietary therapy, the regular diet is modified based on the pathophysiologic changes induced by the underlying disorder, with the goal of providing the most optimal nutrition possible. When the main problem is inadequate food consumption, various commercial oral supplements can be used, but usually for only short periods

because of taste fatigue. Some preparations provide complete nutrition, while others are intended to supplement deficits of specific nutrients. Problems common in patients with gynecologic malignancies, such as partial small bowel obstruction, chronic radiation enteritis, and short bowel syndrome, may all be amenable to dietary therapies. In partial small bowel obstruction or motility dysfunction, a diet comprised of frequent, small, calorically dense meals with minimal amounts of fiber is indicated. Patients with radiation enteritis should receive a low-fat, low-fiber, and lactose-free diet. Dietary management of short bowel syndrome patients includes frequent small meals; limitation of fiber, lactose, and simple sugars; taking liquids separately from meals; and supplementation of calcium and zinc orally and magnesium and vitamin B_{12} parenterally.

Bye et al. (156) conducted a prospective, randomized trial of a low-fat, low-lactose diet in 143 women with gynecologic malignancies undergoing radiation therapy. The intervention group had significantly less diarrhea. Diarrhea in the control group correlated with increased fatigue and decreased physical function. The authors concluded that diet intervention during radiotherapy reduced the severity of diarrhea, influenced patients' ability to cope with diarrhea, and gave them more control over their situation.

The successful implementation of prescribed diets depends to a large extent on a dietician converting the prescribed diet to a meal plan and working with the patient to implement it. In a prospective, randomized study of 57 patients undergoing chemotherapy for ovarian, breast, or lung cancer, those who received intensive dietary counseling had improved long-term food intake (157). Similar data have been demonstrated in cancer patients undergoing radiotherapy (158) and in patients with acute leukemia undergoing induction chemotherapy (159).

Postoperative Timing of Oral Feeding

Traditionally, concern for postoperative ileus and impaired bowel function have led to delayed feeding after abdominal surgery. In a prospective randomized trial at the University of Indiana, patients undergoing major gynecologic abdominal surgery were randomized into two groups, the first was advanced to a regular diet after return of bowel sounds and passage of flatus, and the second was fed on the first postoperative day with liquids and then advanced to a solid diet. Early feeding was associated with shorter time to tolerance of a solid diet and shorter duration of hospital stay, but a higher incidence of postoperative emesis (160). Subsequent studies in patients with gynecologic malignancies undergoing abdominal surgery have shown similar results, with quicker recovery of intestinal function, reduced postoperative wound complications, improved quality-of-life scores, and shorter duration of hospital stay in those fed early after surgery (161–163).

Postoperative Immunonutrition

Nutrients such as arginine, glutamine, omega-3 fatty acids, and nucleotides are thought to enhance the immune response, modulate inflammation, and improve protein synthesis after surgery. They are added to enteral formulas or oral diets to improve postoperative wound healing and recovery. Two large meta-analyses have examined the benefits of immunonutrition in the perioperative period in patients undergoing major abdominal surgery. The majority of these patients had gastrointestinal malignancies. There was a reduced rate of infectious complications including abdominal abscesses, pneumonia, and wound infections, as well as noninfectious complications, including anastomotic leaks, in the group receiving immunonutrition. No differences in overall mortality were found among the two groups (164). These findings were supported by a recent study in gynecologic oncology patients at UCSF undergoing laparotomy, given an immune-modulated diet in the perioperative period. Patients receiving immune-modulated diets had lower incidence of wound complications (19.6% vs. 33%), leading the authors to conclude that an immune-modulated diet may be protective for the development of surgical site infections (165). A dose of 0.5 to 1 liter/day for 5 to 7 days prior to surgery is recommended (166). A study in patients with colorectal cancer found an increase in tumor infiltrating CD4 and CD 8 cells after they were given immune nutrition. The authors hypothesized that immune nutrients may reduce infections and exert antitumor

effects by this mechanism (167). Current ESPEN guidelines recommend perioperative immunonutrition for patients undergoing upper gastrointestinal surgery, but no recommendations exist for patients with gynecologic malignancies. ASPEN guidelines recommend its use even among critically ill postoperative patients (168).

Pharmacologic Agents

Agents that will reverse the wasting seen in advanced cancers have long been sought to complement or replace the provision of nutrients via the oral, enteral, or parenteral route. Hormones, appetite stimulants, and most recently, cytokine antagonists have been examined. Studies of growth hormone IGF-I alone or IGF-I with insulin in cancer-bearing rodent models showed significant attenuation of tumor-induced weight loss. In human clinical trials, these agents provided modest gain in weight but no improvement in quality of life or other benefits (169–171).

Hormones

Ghrelin, a potent orexigenic peptide hormone produced by the stomach, has been shown to increase appetite and caloric intake in normal individuals and in animal models of cancer cachexia. It was therefore hypothesized that ghrelin may be an effective treatment for cancer-induced cachexia. One small randomized study showed that intravenous ghrelin led to a marked increase in energy and caloric intake, with no side effects (172). There was concern that its use would be limited by its promotion of cellular proliferation and invasion of certain types of cancer, but a randomized, placebo-controlled, double-blind, double cross-over study demonstrated that ghrelin was safe and well tolerated. Unfortunately, it did not show any change in nutritional intake (173).

Appetite Stimulants

Anabolic steroids have no proven efficacy in treating cancer cachexia. In a murine model, administration of norandrolone propionate resulted in weight gain, but this was largely due to fluid retention (174). In human trials, steroids produced transient improvement of nutritional parameters and appetite, but continued use is associated with negative nitrogen balance, net calcium loss, glucose intolerance, and immunosuppression (171).

Megestrol acetate is a progestational agent that has been shown to improve appetite and ameliorate weight loss in numerous, but not all, studies of patients with cancer and cachexia (171). Doses in these studies ranged from 160 to 1,200 mg/day, and maximal weight gain was generally seen within 8 weeks. However, the change in weight is largely due to increased adipose tissue and edema (175). Nevertheless, improvement in quality of life has consistently been demonstrated in several large prospective studies in patients with cancer cachexia treated with megestrol acetate (176,177). It is generally well tolerated but can exacerbate underlying diabetes mellitus, increase thrombotic risk, and rarely lead to adrenal suppression. Dronabinol, a marijuana derivative, has shown some promise in small studies, improving appetite and causing weight gain; however, large randomized trials are lacking (171).

Cytokine Inhibitors

Inhibitors of cytokines involved in cancer cachexia and anorexia have the potential to be potent agents in the treatment of malnutrition in cancer. Monoclonal antibodies against TNF lead to improved food intake and diminished loss of protein and fat in murine models of cancer cachexia. Similar data are available for anti-IL-6 (178,179) and anti-IFN-γ. Suramin, a direct IL-6 receptor antagonist, decreased several key parameters of cachexia in tumor-bearing mice (180). In a recent study from Japan, a novel inhibitor of IL-1 and TNF-*a* showed that direct injection of the drug into tumor did not alter tumor growth but did result in attenuation of loss of body weight and epididymal fat in tumor-bearing mice (181). Human studies utilizing the anticytokine approach are limited. Pentoxifylline and thalidomide have been shown to inhibit TNF-*a*. In

two small studies, thalidomide at a dose of 200 mg daily attenuated loss of weight and lean body mass in patients with esophageal and pancreatic cancer (182,183). Interestingly, recent data showed that the clinical anticachexia effects of megestrol acetate are due, at least in part, to the inhibition of cytokines (96) (Table 31.3). COX-2 inhibitors like Ibuprofen and celecoxib have been studied for their ability to attenuate the acute-phase response in patients with advanced cancer. However, the data from these studies has remained largely inconclusive (184,185).

TABLE 31.3 Pharmacologic Agents Used for the Treatment of Cancer Cachexia and Anorexia

Class of Agent	Example	Efficacy	Adverse Effects
Hormones	Insulin, IGF, GH	Attenuation of tumor-induced weight loss, no improvement in survival or quality of life demonstrated	Hypoglycemia, Hypokalemia
Anabolic steroids	Oxandrolone, nandrolone	Transient improvement in appetite	Fluid retention, Net loss of calcium and nitrogen, Hyperglycemia, Immunosuppression
Progestational agents	Megestrol acetate	Improved appetite, weight, and quality of life	Weight gain is mostly due to fluid retention and adipose tissue, May exacerbate diabetes mellitus, Rare cases of adrenal insufficiency
Cannabinoids	Dronabinol	Improved appetite and weight gain in small studies	CNS effects (slurred speech, nausea, dizziness, sedation)
Cytokine inhibitors	Pentoxifylline, thalidomide, suramin monoclonal antibodies to IL-1, IL-6, and TNF-α	Improved food intake and attenuation of protein and lean body mass loss	Peripheral neuropathy Rash Daytime somnolence

CNS, central nervous system.

In a recent study, Mantovani et al. showed that combination therapy with megestrol acetate, eicosapentaenoic acid, thalidomide, and L-carnitine increased lean body mass and appetite and decreased resting energy expenditure and fatigue in patients with cancer cachexia (186).

Elemental Supplements and Vitamins

A few preclinical and clinical studies have examined the role of elemental supplements, administered in liquid or powder form, in mitigating the gastrointestinal symptoms following pelvic radiation. However, these supplements are poorly tolerated and have not proven to be of benefit so far (187,188). Antioxidant vitamins such as vitamins C and E have proven to be of some benefit in ischemic reperfusion injury (189). In a study by Kennedy, 20 patients with severe symptomatic radiation proctitis were given vitamins C and E for 4 weeks. The group receiving vitamin supplementation had improvement in diarrhea, bleeding, and fecal urgency (190). Some trials have examined the effect of combined omega-

3 fatty acids, especially eicosapentaenoic acid, and vitamin E in cancer cachexia. However, there is still insufficient evidence to support their use (191,192).

Drugs to Relieve Symptoms

The use of medications to relieve cancer- or treatment-related symptoms that impair oral intake is an important adjuvant to nutritional support in these patients. For example, optimal antiemetic therapy can now adequately control acute and delayed emesis in 70% to 90% of patients (193). Despite this, the incidence of chemotherapy-induced nausea and emesis is underestimated by oncologists and nurses (194). This highlights the importance of a careful history and review of systems when completing a nutritional evaluation of a cancer patient. Many cancer patients assume that nausea and vomiting are normal during treatment and will not report it as a problem unless specifically asked.

ETHICAL CONSIDERATIONS

Prior to the advent of enteral and parenteral feedings, the inability to receive nutrients through oral intake inevitably led to wasting and death. Therefore, in the majority of patients, the natural history of cancer led to death because of dehydration and starvation. In patients with potentially curable or stable disease, nutritional support, when indicated, is an important and often critical part of the overall treatment plan. On the other hand, the role of nutritional support in the terminally ill is a subject filled with ethical and legal dilemmas. These problems come to light when the wishes of the patient or the patient's representative are not in agreement with the recommendations of the physicians. For example, a patient may wish to forego nutritional support despite recommendations that such a therapy should be given. Alternatively, patients or their representatives may want to initiate or continue TPN even after all anticancer therapies have failed and the patient is in a terminal state. Two general principles apply: in the first case, autonomy, and in the second, medical futility.

Autonomy is the right of competent patients to make decisions over their care and implies that the physician must solicit these decisions. It was not until the mid-1960s that autonomy began to supersede the Hippocratic tradition with its emphasis on the authoritarian role of the physician. This principle is clearly outlined in a report from the President's Commission for the study of Ethical Problems in Medicine and Biomedical and Behavioral Research, which states: "The voluntary choice of a competent and informed patient should determine whether or not life-sustaining therapy will be undertaken, while health care institutions and professionals should try to enhance patients' abilities to make decisions on their own and to promote understanding of the available options" (195). With regard to most treatments (surgery, chemotherapy, radiation therapy), the patient's knowledge and experience may be very limited, and thus, the physician's recommendations may form the sole basis for the patient's decisions. This is often not the case with nutrition. People understand the role of nutrition in sustaining life, and it is often hard for a lay person to understand why parenteral nutrition may not be indicated or even harmful when the patient has no other source of nourishment.

The principle of medical futility often surfaces in discussion of nutritional support of the cancer patient, especially if the disease is advanced and unresponsive to therapy. There are four aspects to medical futility (196): (1) lack of physiologic rationale for the proposed therapy; (2) failure of the same therapy in a previous attempt; (3) all possible treatments for the underlying disease have failed; (4) the therapy will not improve quality of life or achieve a goal of care (such as living to see a particular life event). In the case of parenteral (and rarely enteral) nutritional support of the cancer patient, aspects 3 and 4 may be specifically applicable.

It should be noted that these principles, autonomy and medical futility, should govern decisions for both initiation and withdrawal of an ongoing therapy.

Religious beliefs often strongly influence decisions regarding nutritional support. Publicly stated opinions on the subject include: (1) a statement from the Archbishop of Canterbury that removal from life support was permitted if it was better to allow the patient to die (197); (2) a papal statement from Pope John Paul II in 2004 concluded that "Artificial nutrition was

ordinary and proportionate, and as such morally obligatory" as long as it obtains the goals of "providing nourishment to the patient" and "alleviating suffering." While this statement referred specifically to the provision of artificial nutrition in persistent vegetative states, the same principles may be applied to other end-of-life situations (198), and (3) a review of Orthodox Jewish rabbinical decisions that concluded "the imperative to preserve life supersedes, with a few exceptions, quality of life considerations" (199).

The decision to withhold or withdraw parenteral nutrition should involve an explanation that dying patients experience less hunger and thirst and that dehydration may even alleviate symptoms like choking or drowning sensation from secretions, coughing, nausea, and vomiting (200,201). The potential harmful effects of artificial nutrition support, including electrolyte abnormalities, infection, and fluid overload, should also be discussed. Ultimately, the end decision must remain with the patient or his/her surrogate. The American Dietetic association position paper on artificial nutrition and hydration in the terminally ill states "The patient's expressed desire is the primary guide for determining the extent of nutrition and hydration", emphasizing the principle of autonomy (202).

Legally and ethically, an informed adult with the capacity to make decisions has the right to ask for artificial nutrition support to be withheld, even if such a decision results in death. For the gynecologic oncologist, management of the patient with an inoperable bowel obstruction due to peritoneal carcinomatosis is a difficult and recurrent problem. A recent review attempted to outline the role of parenteral nutrition in this population (134). TPN should be considered in only those patients with a good performance status, and careful attention must be paid to medical and symptomatic outcomes, as well as ethical considerations. It is interesting to note the views of patients on various life-sustaining treatments. In a study from the University of Michigan, 90% of women undergoing treatment for a gynecologic cancer could envision a time when they would refuse ventilator support, but only 37% could foresee a time when they would refuse artificial nutrition (203). It is important for the physician and other members of the health care team to inform the patient and the family that in the terminally ill, provision of food and water by enteral or parenteral routes will not improve comfort (204) and, in fact, may add to discomfort (203–206). At Memorial Sloan Kettering Cancer Center, TPN is used infrequently in patients with gynecologic cancer and bowel obstruction due to malignant carcinomatosis who do not receive any further anticancer therapy. TPN is used under these conditions only when it is judged that it will enhance the quality of life of a patient who is not at imminent risk of dying in spite of widely metastatic disease. When considering the chance of improving quality of life, the burden of TPN administration and monitoring and the risk of complications must be considered.

CHAPTER 32 Palliative and Supportive Care

Linda R. Duska, Carolyn Lefkowits and Leslie Blackhall

Palliative care is a critical element of the comprehensive care of women with gynecologic cancer. The World Health Organization (WHO) defines palliative care as "an approach that improves the quality of life (QOL) of patients and their families facing the problems associated with life threatening illness, through the prevention and relief of suffering by means of early identification and impeccable assessment and treatment of pain and other problems, physical, psychosocial and spiritual (1)." This definition, complemented by similar statements from the American Society of Clinical Oncology (ASCO) (2) and the Society of Gynecologic Oncology (SGO) (3), supports the utilization of palliative care throughout the course of disease for women with gynecologic cancer. Provision of palliative care to patients with cancer has been associated with multiple benefits including both improved clinical outcomes (QOL, symptom control, and patient and caregiver satisfaction) and improved health care utilization outcomes (decreased hospital costs, inpatient and intensive care unit [ICU] admissions) (4).

It is essential to distinguish between palliative care and hospice care or end-of-life care. Unlike hospice care, palliative care may be provided at any point in the disease course and can be offered concurrently with disease-directed therapy, including curative-intent therapy (Fig. 32.1). Palliative care focuses on the treatment of symptoms related to both the cancer and cancer therapy, including pain, anxiety, depression, fatigue, and nausea. It also encompasses communication with patients and families about their goals and preferences for care, to ensure that the treatment plan, throughout the disease course, reflects the patient's values and preferences. Patients and their families who are suspicious of the word hospice and reluctant to accept a "hospice consultation" may be willing to accept palliative care if the main purpose is explained accurately: a focus on symptom management with subsequent decrease in suffering. A public opinion survey by the Center to Advance Palliative Care found that the phrase "an extra layer of support" was one that the public found helpful when explaining the role of palliative care (5); this phrase also may be helpful to clinicians when explaining palliative care to patients and families. Another study suggested that the term "supportive care," which is sometimes used synonymously with palliative care, may be more acceptable to referring providers, including oncologists (6). In contrast, hospice care is a specialized end-of-life service, most often covered by the Medicare Hospice Benefit (MHB), which is available to patients with a prognosis of 6 months or less who are no longer pursuing anticancer therapy.

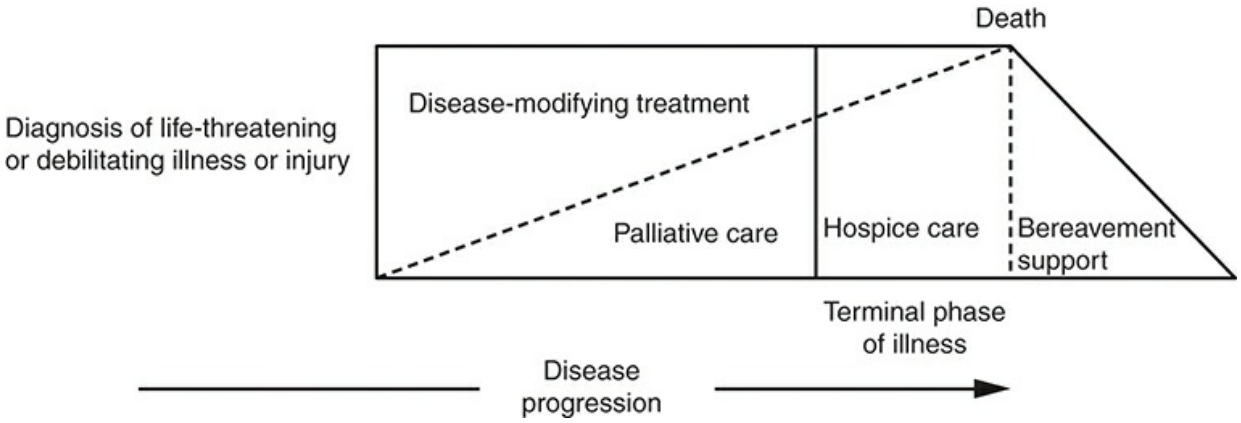

Figure 32.1 The simultaneous care model for palliative care, defined by the Centers for Medicare and Medicaid Services in its proposed Hospice Conditions of Participation and as adapted from the World Health Organization.

Despite concerns that increased attention to symptom management or advance care planning might hasten death by diminishing the focus on life-prolonging therapies, no study of palliative care has ever shown an association between palliative care and shortened life expectancy. In fact, there is some evidence that early integration of palliative care into standard oncologic care may actually prolong life. In the most well known of the randomized studies in cancer patients, 151 patients with newly diagnosed metastatic non–small cell lung cancer were randomized to integration of outpatient palliative care from the time of cancer diagnosis versus usual oncologic care (7). The early palliative care integration group had significant improvements in QOL and mood, as well as a statistically significantly improved overall survival (11.6 vs. 8.9 months, $p = 0.02$), despite less aggressive intervention at the end of life (7). Other randomized studies in general oncology have shown a similar improvement in QOL with the integration of palliative care into active cancer care (8–14), prompting ASCO to write a Clinical Opinion in 2012 stating that "combined standard oncology care and palliative care should be considered early in the course of illness for any patient with metastatic cancer and/or high symptom burden (15)."

It is therefore imperative that gynecologic oncologists be familiar with the tools and management options of palliative care for their patients. This chapter will focus on the scope of palliative care as it applies to women with gynecologic cancer, with special emphasis on the regulations governing palliative care services in the United States. The importance of this topic cannot be overemphasized: The SGO has concluded that "palliative care significantly improves QOL for patients and their families," and the addition of basic level palliative care is included among the SGO's five Choosing Wisely recommendations (3,16). The SGO's position emphasizes the fundamental importance of palliative care to the delivery of high-quality gynecologic cancer care.

SYSTEMS OF PALLIATIVE CARE DELIVERY: SPECIALIZED PALLIATIVE CARE, BASIC PALLIATIVE CARE, AND HOSPICE CARE

It is important to distinguish between basic and specialty palliative care. Specialty palliative care is provided by an interdisciplinary team with dedicated training in palliative care. In contrast, basic (or primary) palliative care can be provided by any clinician who cares for patients with serious illness; in the case of gynecologic cancer, this may include

the gynecologic oncologist, medical oncologist, radiation oncologist, and primary care provider.

Specialty Palliative Care

Core members of the specialty palliative care team include a palliative care–trained physician, nurse or advanced practice provider, a social worker, and a chaplain. Other members may include pharmacists, nutritionists, rehabilitation therapists, and direct care workers. While specialty palliative care is most commonly available as an inpatient hospital consultation service, provision of specialty palliative care is increasing in outpatient clinics (17,18). As of 2010, National Cancer Institute (NCI)-designated cancer centers reported 92% availability of inpatient specialty palliative care consultation teams and 59% availability of outpatient specialty palliative care (compared with 74% and 22%, respectively, for non-NCI cancer centers) (17). In 2006, palliative care (officially called Hospice and Palliative Medicine) was officially recognized by the American Board of Medical Specialties and co-sponsored by multiple other medical boards. Until 2012, clinicians could be "grandfathered in" to board certification in palliative care by documenting a certain number of hours of clinical experience and sitting for written board exams. After 2012, board certification in palliative care requires completion of a 1-year clinical fellowship and written board exams. The data supporting the clinical and economic benefits of early integration of palliative care into standard oncology care are based on trials of specialty palliative care interventions (19).

Basic Palliative Care

Basic palliative care clinical services delivered by non-palliative care specialists is termed "primary palliative care (20)." It is neither feasible, nor desirable, that all palliative care be delivered by specialists. It is not feasible as there are not enough palliative care specialists in the country to care for all patients with serious, life-limiting illnesses. It is not desirable because the inclusion of another set of providers for every woman with gynecologic cancer might cause fragmentation of care, undermining the therapeutic relationship between the patient and her oncologist (20).

Many gynecologic oncologists have been exposed to primary palliative care education during fellowship and feel comfortable caring for their patients' basic needs with respect to symptom management and end-of-life care. A small percentage of gynecologic oncologists are also boarded in palliative care through the efforts of the American Board of Obstetrics and Gynecology; others have completed fellowships in both Gynecologic Oncology and Palliative care. As a result of the growing recognition of the importance of palliative care in this setting, increasing numbers of gynecologic oncologists are becoming boarded in palliative care or becoming familiar with palliative care strategies. Growing interest in palliative care strategies is evidenced by high attendance at SGO courses aimed at teaching symptom management, and interest in the SGO's Palliative Care Network. For gynecologic oncologists, primary palliative care should include core elements of palliative care, such as basic symptom management and aligning treatment choices with patient goals (20). More complex issues, such as existential distress and refractory symptom management, may be better addressed by palliative care specialists (Table 32.1).

TABLE 32.1 Representative Skill Sets for Primary and Specialty Palliative Care

Primary palliative care

• Basic management of pain and symptoms
• Basic management of depression and anxiety
• Basic discussions about
  ◦ Prognosis
  ◦ Goals of treatment
  ◦ Suffering
  ◦ Code status

Specialty palliative care

- Management of refractory pain or other symptoms
- Management of more complex depression, anxiety, grief, and existential distress
- Assistance with conflict resolution regarding goals or methods of treatment
    - Within families
    - Between staff and families
    - Among treatment teams
- Assistance in addressing cases of near futility

Hospice Care

The MHB was first offered in 1983; it is a benefit of Medicare Part A that covers comprehensive end of life (EOL) care (21). To be eligible for the MHB, a patient must be "certified" by two physicians as having a prognosis of 6 months or less. For gynecologic cancer patients, one physician can be the gynecologic oncologist and the other the hospice physician. Eligibility also requires that the patient waive the traditional Medicare parts A and D for care related to the terminal illness, including prescription medications. The hospice benefit applies *only* to care or medications related to the terminal diagnosis; a patient may continue to receive care for coexisting unrelated medical problems covered by Medicare parts A and D and can continue to see her physicians under Medicare Part B coverage. Unlike traditional Medicare benefits, which usually require a 20% co-pay, the MHB coverage is almost 100% for all services including medications (some hospices may require a 5% co-pay).

The hospice benefit is structured as benefit periods (two 90-day periods followed by an unlimited number of 60-day periods). Between benefit periods, the hospice provider must reevaluate and recertify the patient. Patients may revoke the MHB at any time, at which point traditional Medicare coverage is immediately available. There are four levels of hospice care—two outpatient and two inpatient. These include:

- Routine home care—routine palliative care services in the patient's home or nursing facility.
- Continuous home care—intended for crisis management of acute symptoms. It involves intensive home nursing for a minimum of 8 hours during each 24-hour time period.
- General inpatient care—intended for short-term control of acute symptoms that cannot be managed at home. It can be provided by a hospice facility, hospital, or skilled nursing facility (SNF).
- Respite care—intended to give caregivers respite. It is reimbursed for no more than 5 days in each benefit period. Respite care can take place in a hospice facility, hospital, or SNF.

The MHB offers a fixed per diem payment to the hospice program, with rates varying by geographical location. The initial intake of a new patient is particularly time-and resource-intensive and generally costs the hospice far more than the daily per diem; thus it is financially beneficial to the hospice program to have a patient in the program for more than 2 weeks before death. More importantly, late hospice referrals do not give the hospice team enough time to complete the goals of safe and comfortable dying and effective grieving. Data from the National Hospice and Palliative Care Organization show that 34.5% of hospice patients died within 7 days of admission in 2013 (22). Many states offer a Medicaid hospice benefit similar to the MHB. Most private insurers also offer a hospice benefit but these are variable.

The hospice team develops a care plan that meets the individual's needs. The team consists of the patient's physician, the hospice physician (or medical director), nurses, home health aides, social workers, clergy, trained volunteers, and therapists (speech, physical, occupational) if needed. Hospice services are multidimensional. They include pain and symptom management, provision of drugs and medical supplies, assistance with emotional, psychosocial, and spiritual

aspects of dying, and support for the family in caring for the patient.

Retrospective data in nongynecologic cancers suggest that hospice care is associated with no decrease in, or in some cases improved, survival. Family members of hospice patients are more likely to report better QOL, lower rates of physical and psychosocial distress, and better quality of death for their loved ones than patients treated in the hospital at the end of life (23–25). One cohort study retrospectively studied 81 patients with gynecologic cancer who died secondary to cancer recurrence and/or progression and who were offered hospice services. Patients who declined hospice when it was recommended were considered not to have utilized hospice whether or not they ultimately received supportive care. Median time for receiving supportive care was longer in the hospice group (8 weeks vs. 1 week) and patients in the nonhospice group were more likely to have an invasive procedure performed or antineoplastic therapy administered within 4 weeks of death. In the subset of patients with recurrent disease (73%), the median overall survival for patients who chose hospice was 17 months, compared with 9 months for the group not utilizing hospice (26). Other studies have confirmed these results in gynecologic cancer patients, and suggest that between 20% and 60% of patients who die of ovarian cancer utilize hospice (27–29).

PRIMARY PALLIATIVE CARE FOR THE GYNECOLOGIC ONCOLOGIST

Symptom Management

Gynecologic cancer patients often experience both disease- and treatment-related symptoms throughout the course of their illness; the high symptom burden in this population has been well documented (30–32). Symptoms may go unrecognized and therefore untreated for a multitude of reasons. Clinicians may assume that patients will initiate discussions about symptoms, while patients expect their physicians to ask about symptoms. Moreover, patients may have a disincentive to report symptoms to their physician due to fears about prompting a change in treatment, though assessment of symptom burden is required to appropriately identify and address symptoms.

Patient-reported outcomes are the gold standard for quantifying patient experience and/or symptoms (33). Several validated scales exist to measure symptom burden, including the Edmonton Symptom Assessment System and the Memorial Symptom Assessment Scale. More recently, investigation has turned to use of routine recording and monitoring of symptoms through the electronic health record; a recent study of 636 gynecologic cancer outpatients found it to be feasible to electronically record patient symptoms and use that data as a basis for referral to psychosocial and supportive care (34). The National Comprehensive Cancer Network (NCCN) guidelines recommend routine screening by the oncology team for uncontrolled symptoms (35). Management of symptoms in gynecologic cancer patients is thoroughly covered in the SGO White Paper on palliative care (36). Basic tenets of symptom management will be reviewed here.

Pain

Pain management is discussed in detail in Chapter 31.

Nausea and Vomiting

Nausea and vomiting are common symptoms in cancer patients, and have special significance in ovarian cancer because of the high incidence of bowel obstruction in this population. We favor an etiology-based approach to patients with this symptom (37), although a protocol-based approach is often more appropriate for those very close to the end of life (38). The etiologic approach relies on a detailed history, including associated symptoms, timing, frequency, and exacerbating and

relieving factors. A mnemonic for the differential diagnosis of nausea that categorizes by mechanism is VOMIT—Vestibular apparatus, Obstruction, Motility/Mind, Infection/Inflammation, and Toxins/Tumor. Table 32.2 summarizes this approach.

TABLE 32.2 Nausea and Vomiting

	Location	Causes	Symptoms	Symptomatic Treatment	
CNS	Vestibular	Metastatic lesions to CNS	Vertigo, movement related nausea	Scopalamine, meclizine	Uncommon
	Cortical	Increased ICP Anxiety, pain Anticipatory	Headache, neurologic signs Vomiting associated with these symptoms Nausea/vomiting "anticipates" noxious stimulus	Steroids Treatment of pain/anxiety Treatment of noxious stimulus, benzodiazepines, haloperidol, Zyprexa, CBT	Uncommon Uncommon Common
	Chemoreceptor trigger zone D2 (dopamine) 5HT3 NK1 vomiting center Achm H1 5HT2	Drugs (chemotherapy) Metabolic (renal failure, liver failure)	Temporal association with medication or toxin	Pretreatment and prophylaxis 5-HT_3 receptor blockers Phenothiazines Metoclopramide NK1 antagonist	Very common
GI	Stomach	Delayed gastric emptying due to: Mechanical obstruction (partial) Gastroparesis (chemotherapy, opioids) Ascites Paraneoplastic syndrome	Early satiety, bloating, reflux, vomiting of undigested food	Metoclopramide Small frequent, calorie dense meals Therapeutic paracentesis where appropriate Ranitidine/H2 blockers	Very common
	Small and large bowel	Mechanical bowel obstruction (partial or complete) paraneoplastic		Metoclopramide (partial obstruction only) Steroids Octreotide Dietary interventions Ranitidine/H2 blockers Anticholinergics	Common (very common in ovarian cancer)

CNS, central nervous system; ICP, intracranial pressure; CBT, cognitive behavioral therapy.

Causes of nausea and vomiting in the cancer patient can be roughly divided into those that originate from central nervous system (CNS) sites and those that originate from the gastrointestinal (GI) tract. Chemotherapy and other toxins cause nausea and vomiting via their direct effect on the chemoreceptor trigger zone and vomiting centers. Ondansetron and other 5H3 blockers are very effective in reducing chemotherapy-induced vomiting, and have radically improved the QOL for those receiving highly emetogenic chemotherapy (39). These medications cause less sedation and delirium than

phenothiazines, but are extremely constipating; prophylaxis and monitoring for this side effect is imperative. Another targeted agent for chemotherapy-induced nausea and vomiting is the NKI-receptor antagonist class of medications (aprepitant, casopitant, and rolapitant) (40). Phenothiazines are well studied and quite effective but can cause sedation, delirium, and extrapyramidal symptoms. Haloperidol, due to its effects on dopamine, is an effective antiemetic and has minimal side effects when used in low doses (41).

Anticipatory nausea most commonly occurs in the setting of poorly controlled nausea and vomiting caused by chemotherapy, which leads to vomiting in anticipation of chemotherapy. Improved prevention and treatment of the underlying cause of the vomiting is crucial, but may not be sufficient. For patients with severe anticipatory symptoms, behavioral interventions including relaxation techniques, and hypnosis may be used. Benzodiazepine medications (particularly lorazepam) are commonly prescribed for this symptom (42).

Delayed gastric emptying in gynecologic malignancies is due to a variety of causes including chemotherapy-induced gastroparesis, carcinomatosis, ascites, mechanical obstruction, and constipation, is common. Gastric distension, caused by retained food or gastric fluids, activates stretch receptors that feed into the nausea and vomiting centers. Etiologically-based treatment seeks to improve gastric motility through the use of metoclopramide or, less commonly, erythromycin, or to decrease production of gastric fluid through the use of ranitidine, H2 blockers, anticholinergic agents such as scopolamine, or glycopyrrolate (43). Dietary and behavioral interventions are often recommended as well. In selected settings, therapeutic paracentesis can be very effective (44).

The surgical management of malignant bowel obstruction is described below. For the obstructed patient, many of the recommendations above are appropriate, although for the completely obstructed patient, metoclopramide is contraindicated because its use will cause cramping. Octreotide is often recommended for the completely obstructed patient, although recent studies have questioned its efficacy. Steroids are commonly prescribed; however, there is less evidence regarding the efficacy of steroids than of the agents mentioned above (44,45). Pharmacologic management in this setting can be challenging, and attention must be paid to route of administration. Depending on the patient's ability to tolerate oral medications, nonoral options should be considered, including oral dissolving tablets (ondansetron), sublingual preparations (haloperidol), rectal suppositories (prochlorperazine), or intravenous formulations.

Lymphedema

Lymphedema is a prevalent symptom in women with gynecologic cancer; it is underreported and often untreated. In a large, population-based study, morbidity from lymphedema was experienced by 10% of women after gynecologic cancer treatment, with highest prevalence (36%) among vulvar cancer survivors and lowest (5%) among ovarian cancer survivors (46). Needs relating to managing the symptoms of lymphedema were often unmet. Physical therapy, including lymphatic massage and special exercises, can be helpful for patients with lymphedema, in conjunction with compression bandages and garments. The best way to manage lymphedema is to avoid it if possible: for example, by following algorithms such as the Mayo criteria to avoid unnecessary pelvic node dissection, or by performing sentinel lymph node dissection for vulvar cancer rather than complete groin lymphadenectomy when appropriate. Preoperative preparation is also important, as symptoms may be easier for the patient to manage emotionally if they are not completely unexpected.

Neuropathy

Chemotherapy-induced peripheral neuropathy is one of the most common neurologic complications of cancer treatment; up to 90% of cancer patients treated with chemotherapy will have peripheral neuropathy (47). Neuropathy severity generally increases with treatment dose and duration and decreases after treatment stops. Sensory symptoms (such as tingling, numbness, pain) are more likely to improve over time than motor symptoms (such as difficulty with buttons), but in some patients will persist. Classes of medications used for empiric treatment of peripheral neuropathy include anticonvulsants, antidepressants, opioids, non-opioid analgesics, and topical agents, but quality data is lacking (48,49).

First-line therapy usually consists of gabapentin or pregabalin. Gabapentin starting dose is 100 to 300 mg once a day at bedtime, titrated up to 3,600 mg per day in divided doses, if needed. Amitriptyline or nortriptyline can also be used, and have been shown to be efficacious in some studies. One randomized trial showed improvement with use of duloxetine (60 mg/day) over placebo (50).

Constipation

Constipation in the gynecologic oncology patient most commonly arises as a direct effect of disease or as a side effect of medication. Constipating medications commonly used in gynecologic oncology include opioids and selective 5-HT3 antagonists such as ondansetron. Constipation can cause and exacerbate other symptoms including pain and nausea; it must be anticipated and proactively managed. Constipation is a common side effect of opioids, and the only side effect that is not expected to improve or resolve with chronic opioid use. A prophylactic bowel regimen should be considered with every opioid prescription. The percentage of patients treated with an opioid that are offered or prescribed a bowel regimen is considered a quality measure by the Center for Medicare & Medicaid (51). Patients should be counseled regarding constipation at the time of opioid prescription and should be instructed to titrate their bowel regimen to the goal of daily soft bowel movement. Despite widespread use, docusate is not effective as either prophylaxis or treatment. A stimulant laxative such as senna is a good first-line therapy (starting dose 2 tabs q.h.s., max 8 tabs/day, divided b.i.d.). Other pharmacologic options include bisacodyl (PO or PR), or osmotic agents such as polyethylene glycol-3,350 (not a good option for patients with early satiety, as it requires consuming 4 to 8 oz of fluid with every dose), sorbitol, lactulose, and milk of magnesia. Nonpharmacologic options, which can be used to supplement pharmacologic options but are generally not sufficient alone, include increasing activity level and fluid intake. When treating existing constipation, bowel obstruction should be ruled out first, either clinically or with imaging. In addition to the therapies mentioned above, methylnaltrexone, which is a mu-opioid-receptor antagonist, can be used for refractory opioid-induced constipation. Methylnaltrexone is administered 8to 12 mg SQ q.o.d. because of its limited ability to cross the blood–brain barrier, it does not affect analgesia or precipitate opioid withdrawal (52).

Fatigue

One of the most common and distressing symptoms patients with advanced cancer experience is fatigue (53). Fatigue may be elevated at the time of cancer diagnosis, and typically increases during treatment (54). Prevalence estimates of fatigue during treatment range from 25% to 99% depending on the patient population, type of treatment received, and method of assessment (53). In the majority of studies, 30% to 60% of patients report moderate-to-severe fatigue during treatment, which in some cases may lead to treatment discontinuation. While fatigue usually improves in the year after treatment completion, studies of cancer survivors suggest that approximately one-quarter to one-third experience persistent fatigue for up to 10 years after cancer diagnosis (55,56). Cancer-related fatigue is multidimensional and can cause impairment of QOL by producing a negative impact on other domains of life such as the social and emotional domains. Fatigue is particularly present in women with gynecologic malignancy (57). In one study of ovarian cancer patients, fatigue was reported by 67% of patients in the last year of life, increasing to 93% in the last 3 months (58). More than half of women with cervical cancer have fatigue (59). Unfortunately, treatment options for fatigue are limited and the literature on pharmacologic interventions is very heterogeneous. There is evidence to suggest that methylphenidate may be effective, with a Cochrane meta-analysis showing an estimated superior effect for methylphenidate in cancer-related fatigue (60). Studies in breast cancer have suggested physical exercise and psychosocial interventions may also be helpful in treating cancer-related fatigue (61).

Malignant Bowel Obstruction

In gynecologic cancer, malignant bowel obstruction may occur from either a functional obstruction by tumor or a failure of normal peristalsis due to tumor coating the intestinal serosa (carcinomatous ileus). Nonmalignant causes of bowel obstruction may also occur, due to adhesive disease from radical surgery, radiation damage to normal tissue, or scarring from intraperitoneal chemotherapy. Patients most commonly present with abdominal distension, nausea and vomiting, and pain from the distension of the intestinal wall and interrupted peristalsis. In the end-of-life setting with advanced, incurable disease, conservative measures are recommended, with nasogastric drainage for comfort and intravenous hydration. Gastric tubes can be placed for comfort if the bowel obstruction does not resolve with conservative measures. In rare situations, a palliative surgery may be considered. Palliative surgery should be undertaken with caution, as morbidity is 5% to 49% and mortality 5% to 15% (62). Median survival in recurrent ovarian cancer patients after palliative bowel surgery is approximately 12 months (62).

Anorexia/Cachexia

Anorexia, or loss of appetite, is a common complication of advanced cancer. Cancer cachexia is "a multifactorial syndrome defined by an ongoing loss of skeletal muscle mass (with or without loss of fat mass) that cannot be fully reversed by conventional nutritional support and leads to progressive functional impairment (63)." The syndrome of anorexia and cachexia in advanced cancer is mediated by a complex interplay of metabolic, cytokine, and neuroendocrine-mediated events. The mnemonic ANOREXIA addresses potentially reversible causes of anorexia (Aches and pain, Nausea and GI dysfunction, Oral candidiasis, Reactive [or organic] depression or anxiety, Evacuation problems [constipation, retention], Xerostomia [dry mouth], Iatrogenic [radiation, chemotherapy, drugs], Acid-related problems [gastritis, peptic ulcers]) (64). While potentially reversible causes of anorexia should certainly be evaluated and addressed, it is also important for clinicians, patients, and families to understand that in the absence of identifiable reversible factors, anorexia and cachexia are often part of the natural history of the disease process itself. Given the central role that food and feeding play in caretaking in our culture, anorexia is often very distressing to caregivers. It is important to explain to caregivers that with anorexia/cachexia of advanced cancer, the patient is generally not made uncomfortable by their decreased intake; forcing the patient to eat, while well intentioned, is often far more uncomfortable and traumatic for the patient.

Options for pharmacologic therapies for anorexia include prokinetic agents such as metoclopramide (10 mg PO AC and HS), low-dose steroids such as dexamethasone (regimens vary: 2 to 16 mg/d), and progestational agents such as megestrol acetate (MA; regimens vary: 160 to 1,600 mg/day; starting dose usually 400 mg/d), among others. A randomized study in 2010 examined five different pharmacologic regimens for cancer cachexia (medroxyprogesterone [MPA] or MA, eicosapentaenoic acid [EPA], L-carnitine, thalidomide and a combination of MPA/MA, EPA, L-carnitine, and thalidomide). The combination regimen was found to be most effective with increase in lean body mass; decrease in resting energy expenditure; improvement in fatigue, appetite, and QOL; and improvement in Eastern Cooperative Oncology Group (ECOG) performance status (65).

Dyspnea

Dyspnea is a common and distressing symptom in cancer that is present in more than half of all patients with advanced cancer (66) and approximately 40% of those with gynecologic malignancies (67). Acute dyspnea warrants evaluation for pulmonary embolism or pneumonia depending on the clinical circumstances. Patients with fatigue and deconditioning as a result of their malignancy often report dyspnea with exertion as well. Patients with cancer may also have other causes of dyspnea such as chronic obstructive pulmonary disease and congestive heart failure, putting them at higher risk of dyspnea. Severe dyspnea or air hunger is extremely frightening and can lead to panic attacks, while anxiety can also worsen dyspnea. Treatment of the underlying cause is important but may not be possible or provide complete relief of this symptom. Multiple clinical trials testify to the usefulness and safety of opioids, especially morphine, for the treatment of dyspnea in both cancer and non-cancer settings (68). Immediate-release morphine may be given prior to exertion to

increase exercise capacity (69). Benzodiazepines are often recommended for dyspnea when this symptom is associated with significant anxiety, but their use in the ambulatory setting is not currently supported by the literature (66).

Delirium

Delirium is an acute change in mental status that may fluctuate and has several underlying physiological causes. It is characterized by a constellation of features, including acute onset, fluctuating course, altered level of consciousness, inattention, and cognitive impairments (70). It is further characterized based on the level of arousal and psychomotor activity as hyperactive, hypoactive, or mixed. Hypoactive delirium, which is characterized by sedation, lethargy, and psychomotor retardation, can be easily mistaken for fatigue or depression. Delirium in cancer patients is common; prevalence ranges from 10% to 30% in hospitalized patients with cancer and up to 85% in the terminal phase of illness (71). It is associated with significant morbidity, including increased length of hospitalization, functional decline, decreased life expectancy, higher health care costs, and considerable distress for both patients and family members (72). Without a high index of suspicion, it can easily go unnoticed and untreated. Several screening tools for delirium have been validated in patients with cancer, including the Memorial Delirium Assessment Scale, the Delirium Rating Scale-Revised 98, and the Confusion Assessment Method (71). The evaluation of delirium should include a complete history and physical and comprehensive evaluation for reversible etiologies, with the understanding that delirium is often multifactorial (Table 32.3).

TABLE 32.3 Contributing Factors to Delirium

Common and treatable
• Medications (anticholinergics, opioids, sedatives, steroids, antidepressants, H2 blockers, metoclopramide, baclofen) • Withdrawal symptoms from abruptly stopping home medications (benzodiazepines, opiates, SSRIs, barbiturates) • Infection • Constipation • Urinary retention • Uncontrolled pain
Less common but treatable
• Electrolyte disturbances • Anemia • Dehydration • Immobilization • Depression, social isolation • Vision or hearing impairment • Emotional distress • Unfamiliar environment
Less common and less treatable
• Cardiac or pulmonary failure with ischemia, hypoxia, or hypercapnia • Renal failure • Hepatic failure with encephalopathy • Neurologic dysfunction due to brain metastases, seizure activity, or stroke

Tucker RO, Nichols AC. UNIPAC 4. Managing Nonpain Symptoms. Glenview, IL: American Academy of Hospice & Palliative Medicine; 2012.

Management of delirium begins with addressing reversible underlying etiologies. If symptoms persist, both nonpharmacologic and pharmacologic methods may be utilized. Nonpharmacologic strategies include frequent reorientation, lights on and off at appropriate times, family member presence, optimizing sensory input (hearing aids, glasses when indicated), minimizing noise and disruption at night, and encouraging cognitively stimulating activities. For

pharmacologic management, the mainstay of treatment is low-dose Haldol, 0.5 to 2 mg PO or IV q2 to 12 hours. Atypical antipsychotics (including olanzapine, risperidone, quetiapine, ziprasidone, and aripiprazole) have also been used, though they are more expensive and have not been shown to have superior efficacy. Patients receiving antipsychotics should be monitored for side effects including extrapyramidal symptoms and prolonged QT interval. A QTc interval greater than or equal to 500 ms or increase of 60 ms (or 20%) from baseline indicates increased risk of torsades des pointes and should prompt consideration of discontinuation of the antipsychotic and consultation with a cardiologist, taking into account the patient's prognosis and goals of care.

Use of psychostimulants, such as methylphenidate, have been suggested as a possible pharmacologic management for hypoactive delirium. Though no randomized controlled trials have been performed, one small open label prospective trial (73) and several case reports have suggested a benefit. Pharmacotherapy has also been studied to prevent delirium, but a recent review concluded that current evidence is not supportive of use of either cholinesterase inhibitors or antipsychotics for the prevention of delirium (71). Benzodiazepines are occasionally appropriate as an adjunct treatment in patients with agitation refractory to neuroleptics, but for the most part should be avoided given that they can worsen delirium and agitation.

Depression

Depressive symptoms are common among patients with cancer; roughly 45% of patients with solid tumors report depressive symptoms and 15% receive a diagnosis of major depression (74). One study of low-income women with breast or gynecologic cancer found that 17% met criteria for moderate-to-severe depressive disorders. Only 12% of those meeting criteria were receiving medication and only 5% were seeing a counselor or participating in a support group (75). Depressive symptoms in cancer patients have been associated with multiple adverse outcomes including less satisfaction with care, increased use of health services, delayed return to work, reduced QOL, elevated risk of suicide, and increased mortality (74).

Several barriers to the accurate diagnosis of depression are unique to patients with cancer. Standard characterizations of depressive symptoms include both somatic and emotional/cognitive symptoms, but the somatic symptoms (fatigue, weight loss, etc.) are also common symptoms of cancer and its treatment. Additionally, it can be challenging to distinguish between normal and pathological responses to severe illness. Patients with cancer are at risk of both overdiagnosis of depression (if symptoms related to normal grief reaction are over-interpreted as depression) and underdiagnosis (if depressive symptoms in a patient with cancer are believed to be "normal" given the presence of serious illness). The presence of hopelessness, worthlessness, anhedonia, or suicidal ideation can help distinguish clinical depression from grief reaction, as none of these are expected in a normal grief reaction. Temporal variation can also be helpful. Patients experiencing a normal grief reaction will generally have symptoms that wax and wane, whereas patients with depression will have continuous symptoms (76).

While there is no consensus on the single best approach to diagnose depression in patients with cancer, a single screening question such as "are you depressed?" performs reasonably well, with sensitivity of 72%, specificity of 83%, positive predictive value of 44%, and negative predictive value of 94%. The addition of a second question (regarding low interest/pleasure in doing things) improves sensitivity (91%), specificity (86%), positive predictive value (57%), and negative predictive value (98%) (77). These simple screening questions can be used to trigger either a more extensive evaluation or a referral to a mental health or palliative care specialist. Providers must either implement routine depression screening (as recommended by both the NCCN and IOM) or maintain a high index of suspicion to avoid overlooking this common issue and its associated morbidity.

Both psychotherapy and antidepressant medications have shown efficacy in treating depression in patients with cancer. Medication options include tricyclic antidepressants (TCAs), serotonin-specific reuptake inhibitors (SSRIs), and serotonin–norepinephrine reuptake inhibitors (SNRIs). TCAs may be particularly useful if neuropathic pain or insomnia are part of the picture, but their use is often limited by anticholinergic side effects. SSRIs are less sedating than TCAs, but side

effects may include headache, nausea, and insomnia. A recent review of antidepressants concluded that there is no evidence to recommend one over another based on efficacy, and so differences in onset of action, side effects, and available routes of administration may drive choice of medication (78). In gynecologic cancer patients who have neuropathy or neuropathic pain related to their disease or its treatment, use of an SNRI such as venlafaxine or duloxetine may also provide some neuropathic pain relief. TCAs, SSRIs, and SNRIs all take several weeks to achieve therapeutic effect. For patients for whom quicker symptom relief is desired or life expectancy is short, use of a psychostimulant such as methylphenidate is another option. Utilization of mental health professionals should be considered, when available, for complex cases.

Anxiety

Transient anxiety is a near-universal reaction to the stressful circumstances surrounding the diagnosis and treatment of cancer. For a significant number of patients, however, anxiety becomes more severe, pervasive, and disabling, and may impact their cancer treatment and QOL (79). The cancer patient with disabling anxiety will often have had a preexisting mood disorder such as panic attacks, generalized anxiety disorder, or depression. Treatment of this symptom includes pharmacologic and nonpharmacologic methods. Cognitive behavioral therapy (CBT), mindfulness-based stress reduction, supportive-expressive psychotherapy, and relaxation training have all shown utility in the treatment or prophylaxis of anxiety in the cancer patient (80–83). Pharmacologic therapy should emphasize antidepressants, with similar recommendations as those noted above. Benzodiazepines, especially short-acting agents such as alprazolam and lorazepam, are not recommended for long-term use due to their addictive potential, as well as their association with sedation, delirium, and falls (84).

Symptom Management in the Last Days of Life

Despite the fact that most cancer patients say they would prefer to die at home, approximately a third of them will spend their final days in a hospital or an ICU (85). Predicting when a patient is in the final days of her life is not always simple. Hui and colleagues have identified the following physical findings as predictive of 3-day mortality: nonreactive pupils, decreased response to verbal and visual stimuli, inability to close eyelids, drooping of nasolabial fold, neck hyperextension, grunting of vocal cords, upper GI tract bleeding, pulselessness of radial artery, decreased urine output, Cheyne–Stokes breathing, respiration with mandibular movement, and the “death rattle” created by uncleared bronchial secretions (86).

Care in the final days of life should focus on optimizing symptom management and minimizing non-beneficial interventions. Involvement of a specialty palliative care team may be appropriate where available. In a gynecologic cancer population, drowsiness, decreased well-being, anorexia, and tiredness were present in more than 70% of patients in the last week of life (87). When the care of a hospitalized patient transitions to being purely focused on comfort, all medications that are not directly related to comfort should be discontinued. The decision about whether any given medication, such as an antiarrhythmic or an anticonvulsant, should be continued to prevent unpleasant symptoms must be individualized to the patient and her ability to take the medication. In the last few days of life as a patient becomes unable to take oral (PO) medications, medications must be transitioned to sublingual, intravenous (IV), subcutaneous (SC), or per rectum (PR). Medications should be ordered and made available as needed for anticipated symptoms including pain, nausea, dyspnea, delirium, and upper airway secretions. Though noise created by uncleared bronchial secretions (sometimes referred to as “death rattle”) is not thought to be uncomfortable for the patient, it is often distressing to family members and can be treated with anticholinergic medication. Options include glycopyrrolate 0.1 to 0.2 mg IV or SC q4 hours prn, atropine 0.4 mg SC q 15 minutes prn, or scopolamine patch 1.5 mg. Counseling the family that the symptom is not uncomfortable for the patient may help alleviate distress. Though lab tests and telemetry should be discontinued, consideration should be given to continuing to check temperature and respiratory rate, given that fever creates discomfort and should be treated with Tylenol (IV or PR), and tachypnea creates discomfort and should be treated with opioids even in nonverbal patients.

When rounding on a patient in the last few days of life, vital signs and as-needed (prn) medication use should be reviewed with the nurse caring for the patient. If the nurse is inexperienced in caring for patients in the final days of life, a conversation about why certain vital signs are being followed and what signs should prompt administration of prn medications (restlessness, agitation, brow furrowing, tachypnea) may be helpful. Examination of the patient should include at least a general visual inspection for signs of distress or agitation, with note taken of signs reviewed above that may be predictive of death within 3 days. Touching the patient's hand will reveal fever or cool/mottled extremities, if present. Anticipatory counseling should be offered to the family in terms of what to expect as death approaches, but should only be given if the family expresses interest. Consideration should be given to mentioning signs including waxing and waning consciousness, mottled extremities (not painful to patient) and irregular breathing with periods of apnea (family may observe pauses in breathing and think the patient has passed only to have them breathe again) that are a normal part of the dying process. It may be helpful to mention to families that while we do not know for sure whether unresponsive patients process tactile or auditory sensory input, it may be comforting to both patient and family for them to touch and talk to the patient, even after she no longer responds to them. See Table 32.4 for a sample order set for a patient receiving comfort-focused care in the last hours to days of life.

TABLE 32.4 Sample Order Set for End of Life for Non-pain Symptoms

Category	Sample Order	Comments
Vital signs	Temperature and respiratory rate q4 hours prn	Fever should be treated because it causes discomfort; tachypnea should be treated with opioids because it may reflect pain or dyspnea
Mouth care	Oral care q2–4 hours	Particularly important for patients who are unconscious and mouth breathing
Oxygen	Oxygen by nasal cannula prn for comfort	Oxygen is not necessary unless patient is alert and complaining of dyspnea relieved by oxygen, otherwise it is preferable to avoid attaching an additional tube to the patient
Anxiety/Agitation	Lorazepam 0.5–1 mg IV q1 hour prn	In a conscious or semiconscious patient, may consider treating agitation with opioids or Haldol first, as agitation may reflect pain or delirium, and benzodiazepines can worsen delirium and may be sedating
Delirium and/or Nausea	haloperidol 0.5 mg IV q4 hours prn	Important to instruct nursing that haloperidol can be used for nausea
Secretions	Glycopyrrolate 0.2 mg IV q4 hours prn OR Atropine ophthalmic 1% solution 2 drops SL q30 min prn	Sounds related to secretions are not uncomfortable for the patient, but may be treated if they are upsetting to the family
Fever	Acetaminophen 650 mg PO or PR q 4 h prn	In an unconscious patient, fever should be treated with PR Tylenol as fever causes discomfort
Constipation	Dulcolax 10 mg	In patient with life expectancy >24–48 h, consider treating

	PR daily prn	constipation as it can cause discomfort and delirium and a single large bowel movement after suppository will require less frequent moving of the unconscious patient than multiple frequent small bowel movements
Eye Care	Ocular lubricant 1 application both eyes q8 h prn	Particularly important in patients who are unconscious and may not close eyes completely, their eyes may become dry
Nutrition	PO foods and fluids as tolerated for comfort	

Communication

Breaking Bad News

Physicians at all levels of training feel ill-prepared for conversations regarding end-of-life care (88). Although efforts have been made in recent years to improve training in this regard (89), it is estimated that only 5% of practicing oncologists have formal training in breaking bad news or discussing prognosis (90). The literature suggests that patients prefer to have prognostic information, even when the news is worse than expected. Moreover, withholding of bad news may result in a loss of trust between the patient and her physician.

There are several helpful protocols for communication of bad news. One of the best known is the SPIKES protocol, a six-step protocol that incorporates the principles of communication and counseling (91). The SPIKES protocol emphasizes that these conversations should start by clarifying what the patient knows. Information should be provided based on the patient and family members' level of knowledge using clear, nonmedical language; open-ended, empathetic statements; responses to strong emotions; and adequate time for questions. Clinicians should check comprehension frequently and allow moments of silence for processing information.

Prognosis

Talking to patients and their family members about prognosis and end-of-life care is a common and extremely important part of the job of caring for those with life-limiting malignancies. Patients who have a good understanding of their prognosis are less likely to die in the hospital, are more likely to have hospice care at the end of life, and have a better QOL (92). However, many studies continue to document problems with communication. Between a third and three quarters of patients with advanced cancers in recent studies do not understand that their disease is incurable, and most patients have overoptimistic expectations of prognosis (93). Physicians and nurses caring for patients who request aggressive and futile interventions at the end of life based on unrealistic expectations for cure are impacted as well, with several studies documenting moral distress and burnout under these circumstances (94).

Although almost all oncologists agree with the importance of accurate communication regarding prognosis, in practice they tend to avoid or postpone the discussion and instead focus on positive, optimistic formulations about the illness and treatment (95,96). This hesitation to initiate more substantive and realistic discussions of prognosis is often framed in terms of concerns about the impact of such discussions on the patient and, in particular, concerns that such conversations will cause the patient to be depressed, lose hope, and even die more quickly. However, as many have pointed out, physicians who avoid discussing death are also protecting themselves, since talking about this topic causes anxiety, feelings of inadequacy, failure, and loss of control in doctors as well as patients (97).

While there is no evidence that cancer patients who are better informed about their condition have higher rates of depression (95), they do tend to be more satisfied with the communication skills of overly optimistic practitioners (98). This may be because while almost all patients want to be informed of the "truth" in a general way, they also want the truth to be good news and they want their physicians to provide them with hope (99). Almost half of patients with cancer do not want to know their life expectancy even when close to the end of life (100). They "collude" with their physicians in avoiding end-of-life discussions (96). Both patients and family members may misunderstand, discount, or misinterpret negative prognostic information when it is provided (101).

In the face of these serious barriers, it is no wonder that planning for end of life is often lacking in cancer care. The simplistic model in which the oncologist presents full, explicit information regarding prognosis and choices for treatment to the grateful patient who then makes rational choices regarding care by weighing the risks and benefits of treatment disintegrates in the face of the realities of medical practice where prognosis is hard to predict, patients and their family members are distressed and looking for hope, and the oncologist feels internal and external pressure to be optimistic. Several authors have synthesized years of data regarding decisional styles and informational needs of patients and their family members, which may provide a way forward out of the dilemmas outlined above (98,102). One consistent finding is that while many patients do not want to know their prognosis, they do want to know what is going to happen to them: meaning whether or not they can be cured of their cancer and what the treatments can do for them (103). These desires seem contradictory, but in fact may not be so. While patients are often reluctant to hear information about how long they have to live, they are more open to being told that they will, eventually, in some unknown time frame, die of their disease. One way of framing this more qualitative discussion of prognosis is by utilizing the concept of illness trajectory. The illness trajectory of incurable cancer is one of relative stability in functioning until 3 to 6 months prior to death when rapid declines in the ability to perform activities of daily living heralds the onset of terminal stages and is associated with increased risk of harm from systemic treatments (104). Early discussions of the expected course and trajectory of care in these terms can provide the patient and family with a general overview of the goals of treatment, which is to prolong the period of time in which the patient is able to feel well and lead a relatively normal life, while acknowledging that the cancer will eventually be fatal. Describing the clinical signs of progressive disease in terms of functional decline, increasing symptom burden and resistance to disease-specific treatment provides the patient with information that is understandable and useful for advance care planning (ACP) and decision making and gives them a clearer road map for the future. More detailed discussions of life expectancy can be reserved for patients closer to the end of life, when more accurate predictions can be made (105).

This way of framing the discussion avoids the pitfalls of discussing statistical information about length of life. Not only do many patients wish to avoid such discussions, many have a poor understanding of statistics, and struggle to interpret such information. Furthermore, providing accurate prognostic information to an individual patient is very difficult until very close to the end of life since prognosis is a bell curve, and any individual patient can live for much longer or shorter than the average life expectancy of their group. Table 32.5 presents three different ways of discussing goals of care/prognosis. The purely factual statement, while truthful, seems cold and uncompassionate, and may leave the patient feeling uncared for and in search of hope. The hopeful statement, while true, is ambiguous and many patients hearing this might believe that the treatment they are getting is aimed at cure, because of the emphasis on hopeful new research. The doctor using the second formulation is likely to have higher patient satisfaction, but more poorly informed patients. The illness trajectory formulation is aimed at balancing hope with realism and provides the basis for further discussion.

TABLE 32.5 Styles of Communication

Style of Discussion	Example
Factual	Your cancer is incurable. This chemotherapy has a 50% chance of prolonging your life. On average, most people with your cancer live for 3 years if they do chemotherapy and 2 years if they do not do the chemotherapy.

Hopeful	Your cancer is incurable; however, we have some really excellent new treatments and every day there is new research into the causes of cancer and new hope that will allow us to fight this disease.
Illness trajectory	Your cancer is incurable; however, there are many treatments that can prolong your life and improve your QOL, and our hope is that we can keep you feeling well and leading a normal life for as long as possible. Over time, we know that this type of cancer will stop responding well to treatment and when it progresses patients become weaker, need more help at home, and have more side effects from chemotherapy. When that happens we will do everything we can to help you feel as well as possible for as long as possible by treating your symptoms and making sure you can continue to enjoy your life.

Finally, it should be noted that these discussions are best carried out in a collaborative and interprofessional manner. Involvement of nursing, social work, and chaplaincy where appropriate can improve the quality of care and may decrease moral distress for all providers.

Advance Care Planning

Advance care planning is a broad paradigm that includes the steps required to enable patients to guide their future health care so that it is consistent with their goals when they are no longer capable of making decisions for themselves. ACP includes discussions about goals for care at the end of life, designation of a health care power of attorney (HPA), and completion of an advance directive (AD) (also called a living will). ACP has been shown to improve compliance with the end-of-life wishes of patients, enhance patient and family satisfaction with care, and reduce family stress, anxiety, and depression.

Code status is just one component of ACP and may be included in an AD. Code status may be a required part of documentation for a hospital admission, but determining code status is not, or should not, be as simple as asking a patient if she wants cardiopulmonary resuscitation (CPR). A code status discussion should take into account an individual patient's chance for recovery and her underlying values and ideally should take place in the context of a broader discussion about goals of care and care preferences. It is also important to keep in mind that a meta-analysis of hospital CPR outcomes for patients with cancer showed that only 6.7% survived to discharge (9.1% with localized disease and 5.6% with metastatic disease) (106). A recent study of patients with advanced cancer found that after viewing an educational video regarding ACP, fewer patients wanted CPR or ventilation; the patients found the video acceptable and would recommend it to others (107). A randomized trial by the same group found that patients with advanced cancer who viewed a video of CPR were less likely to opt for CPR than those who listened to a verbal narrative (108).

While most patients believe that addressing ACP is an important part of their cancer care (109,110), oncology providers often find it difficult to discuss and assume that patients will be hesitant or even unwilling to have the conversation (111). Retrospective studies of deceased cancer patients found that only 19% had a documented AD (112). One study specific to gynecologic cancer patients found that 54% of gynecologic oncologists deferred end-of-life discussions until the patient experienced a major decline in functional status (113). Another study of women with breast and gynecologic cancers found that 50% of women self-reported completing an AD and 48% had named an HPA, but review of medical records documented an AD and HPA for 24% and 14% of women, respectively (114). A meta-analysis of the cancer literature concluded that "all stakeholders are reluctant to initiate ACP early and prefer to delay ACP until the issues raised, particularly those surrounding preferences for end of life care, are more clinically relevant (115)."

The concept of POLST (physician orders for life-sustaining treatment) originated at the Oregon Health and Science University in the 1990s and is meant to complement (not replace) the AD. The POLST form allows the patient's wishes regarding end-of-life treatment to be expressed in an unambiguous medical order with specific treatment instructions. The use of the POLST form communicates the patient's wishes regarding the use of so-called extreme measures (such as ventilators) but also specifies decisions regarding the use of antibiotics, peripheral nutrition, and other medical

interventions. It is signed by the physician and by the patient or her surrogate and a copy should be placed in the medical record. The POLST form varies from state to state.

Increasing compliance with ACP is a goal of all cancer providers and their patients. However, the literature suggests that patients expect their physicians to introduce the topic, and that cancer patients prefer that this introduction be made by their primary oncologist (115). It is therefore important for gynecologic oncologists to feel comfortable introducing the topic to their patients. ACP can be a process rather than a single discussion and should not be confused with completion of the AD, which is only a small part of the overall process. Inclusion of nonphysician providers may be important in increasing compliance with completion of AD (114).

Running a Successful Family Meeting

One of the most important tools to facilitate communication with people with advanced disease is the family meeting (116). Family meetings (or conferences) are meetings that include the family caregivers, the patient (where possible), and a multidisciplinary group of health professionals, and are undertaken for multiple purposes including: discussing diagnosis, treatment, prognosis; clarifying the goals of care; developing a plan of care for the patient and caregivers; and discharge planning. Most of the data with respect to the utility of family meetings is derived from the ICU setting, with limited data specific to gynecologic cancer patients.

One study from MD Anderson described family meetings for patients with cancer (117), as follows: A formal meeting with the patient and her family was arranged, also including health care providers, a palliative care physician, a social worker, a chaplain, and a case manager. The meeting began with the social worker introducing the participants. The palliative care physician then discussed the clinical scenario, including cancer history and treatment plan, options for symptom management, prognosis including ADs, and discharge planning. The social worker recorded the meeting, making note of any distress shown by the family or the patient.

Not all family meetings can be run with this sort of multidisciplinary model, but gynecologic oncologists can successfully run a family meeting that attends to all the domains of the patient and her family, even with limited resources. Careful planning is essential. Before the meeting, the physician should decide which issues are to be addressed, which providers will be present, where the meeting will take place, and whether or not the patient will be part of the meeting. The goal of the meeting should be clearly stated to all participants, and time should be allowed for all family members to express their opinions.

Teaching Communication

Numerous studies indicate that patient-oncologist communication is suboptimal, particularly when focusing on issues at the end of life (118). Fortunately, communication skills can be taught, even to busy clinicians, as evidenced by the SCOPE trial, performed with medical, radiation, and gynecologic oncologists in the United States (119). Clinicians were randomly assigned to complete a 1-hour interactive CD-ROM program about responding to patients' negative emotions. Oncologists in the intervention group used more empathetic statements and were more likely to respond to negative emotions empathetically. Perhaps most importantly, patients of intervention oncologists reported greater trust in their oncologists than did patients of control oncologists.

Impact of Communication on Outcomes

Good communication can improve quality of care at the end of life. The group from Duke found that, in a cohort of women with persistent or recurrent ovarian cancer, women who had earlier end-of-life discussions with their health care providers had care that more highly conformed with EOL quality measures (28). Additionally, they were less likely to die in the hospital. The authors stressed that early EOL discussions, preferably conducted more than 30 days from death,

increased hospice utilization and were crucial to reducing hospitalizations, ICU admissions, and invasive procedures in the last 30 days of life.

Caregiver Needs

Caregivers, most often family members, are called upon to provide physical care as well as emotional and practical support (120,121). They may experience significant stress in this role, including financial stress if they are unable to continue working while providing care, as well as anxiety about the future. Risk factors for caregiver distress include: other life stresses, poor social support, lower socioeconomic status, younger age, and a closer caregiver–patient relationship (121). Caregivers may be at high risk themselves for health problems resulting from the stress of caring for a gynecologic cancer patient (122). There is therefore a significant need for education of caregivers, who may feel unprepared for their new role, as well as emotional and, where needed, spiritual support (123).

The Australian Ovarian Cancer Study studied the QOL of 99 caregivers of women with ovarian cancer, and reported significantly lower mental and physical QOL for these caregivers when compared to the population norm (121). Mean distress and unmet needs increased over time. Highest unmet needs in the last 6 months of life included managing emotions about prognosis, fear of cancer spread, balancing the caregiver's own needs and the patient's needs, impact of caring on work, and making decisions in the context of uncertainty. Caregiver optimism was associated with improved mental well-being and decreased distress. The authors suggest that caregivers would benefit from early contact with psychosocial staff rather than waiting for post-death referral to bereavement services. Additionally, caregivers having access to providers as well as information resources and support groups may be helpful in fulfilling the need for information that was identified in this study.

QUALITY OF LIFE

There is no common definition for QOL. The WHO defines QOL as an "individual's perception of their position in life in the context of the culture and value systems in which they live and in relation to their goals, expectations, standards and concerns (124)." Health-related QOL, or HRQOL, encompasses symptoms, functioning, psychological well-being, and meaning and fulfillment.

Scales and Measures

Several validated and reliable questionnaires are available for assessment of HRQOL for cancer patients, including the European Organization for Research and Treatment of Cancer (EORTC-QLQ-C30) and the Functional Assessment of Cancer-General version (FACT-G). Domain-specific instruments assess specific domains, such as fatigue or psychological distress. The FACT-G version 4 questionnaire includes the following four subscales: physical well-being, social well-being, emotional well-being, and functional well-being. The subscales can be analyzed separately or together to produce a total HRQOL score. The FACT-G has demonstrated reliability, validity, and responsiveness to change over time (125). The Functional Assessment of Cancer Therapy-Ovarian (FACT-O) is a multidimensional questionnaire developed and validated for use by ovarian cancer patients. There are also specific subscales for cervical cancer (FACT-Cx), endometrial cancer (FACT-En), and vulvar cancer (FACT-V). Higher FACT scores are associated with better HRQOL.

Quality at the End of Life

The National Quality Forum published the following EOL quality performance measures, with a lower occurrence

representing better quality of care: admission to ICU within 30 days of death, hospital admission more than 14 days in the last 30 days of life, more than one hospital admission during the last 30 days of life, more than one ED visit during the last 30 days, death in an acute care setting, initiation of a new chemotherapy regimen in the last 30 days, chemotherapy within 14 days of death, and hospice admission less than 3 days before death (126). In women with ovarian cancer, these aggressive care interventions (ACE) at EOL were not associated with improvement in survival for patients with ovarian cancer, and serve as good general quality indicators for gynecologic cancers (27).

Other groups have provided data specific to gynecologic cancer patients regarding ACE. The group from Montefiore reported that timely palliative medicine consultation was associated with lower ACE scores, but only 18% of patients received a "timely" (defined as 30 or more days before death) palliative care consultation (127). Another study from the same group reported the following retrospective data with respect to ACE: median days in hospital during last 6 months of life was 24 days, 30% of patients had an emergency department visit, and 21% were admitted to the ICU. 50% had terminal extubation and 13% had CPR at the EOL. 76% of patients received chemotherapy during the last 6 months of life and 30% in the last 6 weeks (128). 66% of patients were DNR/DNI, 49% enrolled in hospice (median 16 days, range 0 to 149 days), 64% had a family meeting in this study.

QOL as a Clinical Trial Endpoint

HRQOL has evolved into an important albeit secondary endpoint for many cancer clinical trials. In 2014 the ASCO Cancer Research Committee met to discuss "the design of future clinical trials that would produce results that are clinically meaningful to patients." Clinically meaningful was defined as significantly improved survival, significantly improved QOL, or both (129). Recognizing the importance of a patient's specific symptom burden, the ASCO work group suggested that serial assessment of specific cancer-related symptoms using validated instruments constitutes a meaningful clinical outcome. While ovarian cancer patients are willing to undergo significant toxicity in the front-line treatment setting when cure is possible, they are less accepting of toxicities and impairment in daily routine in the recurrent disease treatment setting (130). The study from Havrilesky et al. (131) confirms this finding: 95 women with advanced or recurrent ovarian cancer were willing to accept a shorter progression-free survival (PFS) to avoid severe side effects of treatment: 6.7 months to reduce nausea and vomiting from severe to mild, 5 months to reduce neuropathy from severe to mild, and 3.7 months to reduce abdominal symptoms from severe to moderate. While PFS remained a driver of patient preference, women were willing to trade PFS time for reduction in treatment-related toxicity.

The Gynecology Oncology Group (GOG) has been incorporating HRQOL endpoints into their phase 3 studies for the past decade. In GOG 240, a randomized trial of chemotherapy with or without bevacizumab in patients with advanced or recurrent cervical cancer, the primary QOL endpoint was the score on the Functional Assessment of Cancer Therapy-Cervix Trial Outcome Index (FACT-Cx TOI) (132). Improvements in overall survival and PFS attributed to the incorporation of bevacizumab into the treatment of advanced cervical cancer were not accompanied by any significant deterioration in health-related QOL, allowing the authors to conclude that the addition of bevacizumab achieved a desirable outcome overall. The GOG has also included QOL as a secondary endpoint in several of its recent phase 3 randomized trials in ovarian cancer (133–136). In one of these studies, the GOG showed for the first time that in ovarian cancer patients, baseline QOL scores predicted overall survival (134), and this has been confirmed by others (135).

Other clinical trial groups have also incorporated QOL as clinical trial endpoints. A well-known and practice-changing example is the CALYPSO study, which has changed the standard of care for women with recurrent platinum-sensitive ovarian cancer, run by the Gynecologic Cancer InterGroup (137). This study was undertaken primarily to identify a treatment regimen for these women that would be non-inferior to traditional therapy and better tolerated from a symptom standpoint. Quality-of-life evaluations (European Organization for Research and Treatment of Cancer Quality of Life Questionnaire C30 version 3.0 and OV-28 version 1.0) were required at 3-month intervals while on treatment, and every 3 months for 1 year from date of enrollment. The primary endpoint was non-inferiority of the less toxic regimen. The study was able to demonstrate that the new regimen was better tolerated than the standard regimen, with improvement in overall

QOL, as well as an improvement in overall survival. Progression-free and overall survival remain the primary endpoints of cancer clinical trials, confirmed by the ASCO 2014 workgroup. However, the inclusion of HRQOL as a secondary endpoint allows a more comprehensive interpretation of results and leads to improved clinical decision-making.

BARRIERS TO THE USE OF PALLIATIVE CARE IN GYNECOLOGIC ONCOLOGY

Lack of Specialty Palliative Care Services

Not all facilities have the ability to provide access to specialty palliative care services. Not-for-profit hospitals and public hospitals were, respectively, 4.8 times and 7.1 times more likely to have a palliative care program as compared to for-profit hospitals (138). On a national level in the United States, there are not enough specialty palliative care providers to see all patients who might benefit (20,139,140). The 2015 *State-by-State Report Card* from the Center to Advance Palliative Care and the National Palliative Care Research Center demonstrates that access to palliative care remains inadequate for millions of Americans living with serious illness, despite continuing growth in the number of US hospitals reporting palliative care programs (141). Access to palliative care services depends on geography, with the highest penetration in the New England (88% of hospitals), Pacific (77% of hospitals), and mid-Atlantic (77% of hospitals) states, and lowest in the west south central (43% of hospitals) and east south central (42% of hospitals) states (138). One-third of hospitals in the United States report no palliative care services of any kind, and one-third of states received a grade of C or D. Access to palliative care in community settings such as nursing homes remains limited for people who are not hospice eligible.

Gynecologic oncologists should be able to provide primary palliative care for their own patients, but not all of them feel trained to provide these services. In fact, the majority of gynecologic oncology fellows report insufficient palliative care education during fellowship, with only 11% reporting a palliative care rotation or formal training (142,143). While both fellowship directors and fellows believe that palliative care education is critical, the formal curriculum is not well developed (144). Future development of formal primary palliative care curricula and institution of this curricula into fellowship training programs will be important in training gynecologic oncologists to provide appropriate care.

Poor Reimbursement

Current reimbursement schedules are not structured to support early integration of palliative care into oncology care. Historically, providers were not reimbursed for end-of-life discussions with their patients, or for addressing advanced directives. However, the Centers for Medicare and Medicaid Services (CMS) recently proposed and finalized regulations that will allow Medicare to pay physicians and other qualified health care professionals for providing ACP (145). Specifically, in a proposed regulation released July 8, 2015, CMS introduced two new billing codes for ACP provided to Medicare beneficiaries. On October 30, 2015, CMS finalized these proposed provisions, allowing physicians and other health professionals to bill Medicare for ACP, as a separate service, starting January 1, 2016. Previous Medicare coverage rules only allowed reimbursement for ACP under very limited circumstances. There are currently no plans for improved reimbursement for palliative care services in conjunction with cancer care.

Institutional Limitations

Institutional limitations include the lack of financial support for specialty palliative care, poor reimbursement for palliative care services, and lack of legislation promoting and supporting the integration of palliative care into routine oncology care (17,140,146). Pay-for-performance quality improvement initiatives have shown promise in facilitating the integration of

palliative care (147).

Misconceptions about Palliative Care

One of the biggest barriers to the use of palliative care is the misconception, by both patients and providers, that it is synonymous with end-of-life care. A public opinion survey noted that 70% of people self-identified as "not at all knowledgeable" about palliative care (148). Data from providers has shown that many lack knowledge of locally available specialty palliative care services, and mistakenly consider palliative care to be synonymous with end-of-life care and thus incompatible with anticancer therapy (148,149). Due to similar misconceptions, cancer center executives worry that the presence of specialty palliative care could negatively affect their hospital mortality rate and national rating (17). One study found that providers preferred the term "supportive care" to "palliative care" and would be more likely to refer patients to a service named "supportive care (6)." When that institution changed the name of their palliative care service to supportive care, they saw a 40% increase in referrals and a change toward referrals earlier in the disease course (150). The IOM report "Dying in America" concluded that "one of the greatest remaining challenges is the need for better understanding of the role of palliative care among both the public and professionals across the continuum of care so that hospice and palliative care can achieve their full potential for patients and their families (139)."

Misconceptions specific to hospice are also prevalent. There remains a significant lack of education on the part of both providers and patients and family members regarding the benefit of hospice, as well as a suspicion on the part of patients that "hospice means they will kill me faster (151)." Claims of "death panels" remain in the common culture and contribute to reluctance on the part of patients to discuss hospice options. A Kaiser Family Foundation survey from 2013 found that more than one-third (35%) of people ages 65 and over incorrectly believed that a panel was created by the Affordable Care Act to make end-of-life decisions for Medicare beneficiaries (152). Other barriers to timely hospice utilization include overestimation of prognosis, the lack of physician awareness of the demonstrated benefits, and the requirement to forgo anticancer therapy prior to hospice enrollment. Education about the benefits and true nature of hospice will be very important in helping our patients to accept this important benefit at the end of life.

IMPROVING PALLIATIVE CARE FOR WOMEN WITH GYNECOLOGIC CANCERS

Education

Most of the primary palliative care for women with gynecologic cancers will be provided by gynecologic oncologists. Several studies have suggested that fellowship trainees, both medical and gynecologic oncology fellows, do not believe they are adequately trained to address most of the palliative care issues they will face during their careers. Medical oncology fellows have reported inadequate training in symptom management, and little training in giving bad news. Several studies address the issue of palliative care delivery education specifically in gynecologic oncology fellowships. The survey data from Eskander suggest that gynecologic oncology fellows felt the education was lacking, with this result obtained by asking specifically about attending gynecologic oncologists, teaching and direct feedback (rather than about a formal curriculum) (142). A similar survey study from Lefkowits et al. (144) noted that 100% of gynecologic oncology fellowship programs had didactic coverage of palliative topics and 48% had an available palliative care rotation. There was, however, no correlation between the topics that were formally taught and the topics that were considered by the faculty to be the most important. There is clearly room for improving the palliative care curriculum and exposure in gynecologic oncology fellowships. The change of the fellowship governing board to Accreditation Council of Graduate Medical Education expected in 2016–2017 and the associated new Milestones should continue to address this important issue.

Partnering with Specialty Palliative Care

One study of gynecologic cancer patients who were discontinuing chemotherapy found that patients who had seen palliative care prior to the decision to discontinue chemotherapy (compared with those who were referred to palliative care only after the decision to discontinue chemotherapy) had better QOL, emotional functioning and social functioning, less depression, less insomnia, and fewer issues with communication. The patients with earlier palliative care integration also received less chemotherapy within the last 6 weeks of life, and earlier palliative care was an independent predictor of improved overall survival. Another study of patients who had died of gynecologic cancer found that 49% had been referred to palliative care, but only 18% had been referred more than 30 days before their death (127). Among a group of gynecologic cancer patients meeting ASCO recommendations for early palliative care integration, only 53% were referred to palliative care (153). These data, taken together with the robust data in the general oncology literature demonstrating benefits of early specialty palliative care integration (4), suggest that we are likely underutilizing specialty palliative care in women with gynecologic cancer. A cost-effectiveness analysis using clinical benefit data from the Temel trial in lung cancer found routine palliative care referral to be at least cost-effective, possibly even cost-saving, for patients with platinum-resistant ovarian cancer. Gynecologic oncology providers should familiarize themselves with the specialty palliative care resources available at their institutions and utilize them liberally, including early in the disease course for patients with advanced disease or high symptom needs. Palliative care enhances both the quality and the value of gynecologic cancer care.

CONCLUSION

The Center to Advance Palliative Care defines palliative care as "specialized medical care for people living with serious illness. It focuses on providing relief from the symptoms and stress of a serious illness…the goal is to improve QOL for both the patient and the family…Palliative care is appropriate at any age and at any stage in a serious illness and can be provided along with curative treatment." Palliative care involves meticulous evaluation and treatment of the symptoms of cancer and the side effects of cancer therapy. It also involves talking frankly and compassionately with patients and caregivers about the disease and its prognosis, and their goals and expectations; it involves optimizing not just quantity, but also QOL. As providers of both surgical and medical oncology throughout the disease course, gynecologic oncologists have unique longitudinal relationships with their patients and are thus well positioned to provide basic palliative care. The education of gynecologic oncology providers must prepare them for that role. With mounting evidence of the clinical and health systems benefits of specialty palliative care, those services are becoming more and more ubiquitous and should be liberally utilized as "an extra layer of support" for patients with complex needs related to symptom management or navigating goals of care. Gynecologic oncology providers must join the WHO (1), the IOM (139), ASCO (2), and the SGO (3) in recognizing that palliative care is an integral component of high-quality, comprehensive, and individualized care for our patients.
