This work is provided "as is," and the publisher disclaims any and all warranties, express or implied, including any warranties as to accuracy, comprehensiveness, or currency of the content of this work.

This work is no substitute for individual patient assessment based upon health care professionals' examination of each patient and consideration of, among other things, age, weight, gender, current or prior medical conditions, medication history, laboratory data, and other factors unique to the patient. The publisher does not provide medical advice or guidance, and this work is merely a reference tool. Health care professionals, and not the publisher, are solely responsible for the use of this work, including all medical judgments, and for any resulting diagnosis and treatments.

Given continuous, rapid advances in medical science and health information, independent professional verification of medical diagnoses, indications, appropriate pharmaceutical selections and dosages, and treatment options should be made and health care professionals should consult a variety of sources. When prescribing medication, health care professionals are advised to consult the product information sheet (the manufacturer's package insert) accompanying each drug to verify, among other things, conditions of use, warnings, and side effects and identify any changes in dosage schedule or contraindications, particularly if the medication to be administered is new, infrequently used or has a narrow therapeutic range. To the maximum extent permitted under applicable law, no responsibility is assumed by the publisher for any injury and/or damage to persons or property, as a matter of products liability, negligence law or otherwise, or from any reference to or use by any person of this work.

Dedication

This book is dedicated to our families: Hae-Young Chi and children Jessica, Stephanie, and Andrew Chi; Amy Berchuck and children Samuel, Jacob, and Benjamin Berchuck; Henry Stoll and children Isabelle, Harrison, and Sophia Dizon-Stoll; Arnold Yashar and children William, Jacob, and Drew Yashar. Their patience, good humor, encouragement, and love have inspired us throughout our careers. In this regard, they have each made significant contributions to this book.

We would also like to express our gratitude to our own esteemed professors who guided and mentored us, and to all of the colleagues we have worked alongside, learned from, and taught over the years. The Gynecologic Oncology community that the readers of this book belong to is dedicated to the advancement of knowledge in the field and its application to outstanding patient care. The considerable progress we have achieved together in the understanding, diagnosis, treatment, and prevention of these cancers is presented in this book. On behalf of the Gynecologic Oncology community, we dedicate this edition of *Principles and Practice of Gynecologic Oncology* to the brave and courageous patients we all serve, and take inspiration in the oath we all share.

HIPPOCRATIC OATH

I swear to fulfill, to the best of my ability and judgment, this covenant:

- I will respect the hard-won scientific gains of those physicians in whose steps I walk, and gladly share such knowledge as is mine with those who are to follow.
- I will apply, for the benefit of the sick, all measures which are required, avoiding those twin traps of overtreatment and therapeutic nihilism.
- I will remember that there is art to medicine as well as science, and that warmth, sympathy, and understanding may outweigh the surgeon's knife or the chemist's drug.
- I will not be ashamed to say "I know not," nor will I fail to call in my colleagues when the skills of another are needed for a patient's recovery.
- I will respect the privacy of my patients, for their problems are not disclosed to me that the world may know. Most especially must I tread with care in matters of life and death. Above all, I must not play at God.
- I will remember that I do not treat a fever chart, a cancerous growth, but a sick human being, whose illness may

affect the person's family and economic stability. My responsibility includes these related problems, if I am to care adequately for the sick.

- I will prevent disease whenever I can, for prevention is preferable to cure.
- I will remember that I remain a member of society, with special obligations to all my fellow human beings, those sound of mind and body as well as the infirm.
- If I do not violate this oath, may I enjoy life and art, respected while I live and remembered with affection thereafter. May I always act so as to preserve the finest traditions of my calling and may I long experience the joy of healing those who seek my help.

Preface

The publication in 2017 of the 7th edition of *Principles and Practice of Gynecologic Oncology* marks the 25th anniversary of the creation of this textbook. The founding editors, William J. Hoskins, Carlos A. Perez, and Robert C. Young, represented the disciplines of Gynecologic Oncology, Radiation Oncology, and Medical Oncology. They created the first multidisciplinary textbook in the field and, in their words, "strove to produce a definitive reference written at the expert level." The focus on multidisciplinary approaches to treatment and a detailed presentation of the literature on which clinical care is based continues to be a guiding principle.

The second set of editors, Richard R. Barakat, Maurie Markman, and Marcus Randall, also represented Gynecologic, Medical, and Radiation Oncology. Over the course of several editions, they incorporated new chapters that reflected dramatic progress in the understanding and treatment of women's cancers. Simultaneously, advances in technology facilitated the use of full color throughout the book as well as increasingly user-friendly online versions that allow access to cutting-edge information at the point of care.

As the new editors of *Principles and Practice of Gynecologic Oncology*, we owe a debt of gratitude to our predecessors. We are proud to continue their tradition of bringing together multidisciplinary expertise that also includes Pathology colleagues. Given the pace of discovery and change within the field, we strove to ensure that this new edition reflects the many advances in the field. To this end, this edition includes an updated chapter on pharmacology of gynecologic cancers and a new chapter on targeted therapies. Several approaches have been developed with collaboration and support from the publisher that will enhance the value of this book for practitioners, researchers, and students.

We are increasingly becoming a single worldwide Gynecologic Oncology community. In recognition of this reality, the most significant change in the 7th edition is an enhanced global focus. This is in dramatic contrast to 25 years ago when this textbook was essentially intended to reflect the standard of care and ongoing advancement of knowledge in the developed world. Today, developed nations have embraced global efforts to eradicate health care disparities. The greatest challenge in Gynecologic Oncology globally is the lack of infrastructure for cervical cancer screening and prevention in resource-poor countries. This results in the deaths of hundreds of thousands of women annually, many of which could be prevented. Treatment of gynecologic cancers also continues to be suboptimal in many of these countries owing to lack of resources and trained personnel, and this leads to unacceptably low cure rates. In the new edition of *Principles and Practice of Gynecologic Oncology*, we invited more international experts as authors of chapters to provide their perspectives on patterns of incidence, mortality, and treatment worldwide. We also established an International Editorial Board that was charged with providing commentary on similarities and differences in management between different countries.

We have given considerable thought to the issue of how best to maintain the relevance of the book between printed editions in an era of instant access to new information on the Internet. Solutions include smartphone access to the content of the textbook with enhanced search capabilities, as well as more frequent online updates as new studies are reported. We also now include online access to a new library of surgical videos to ensure that surgical techniques are not only read, but visualized.

It is our hope that the global focus of the 7th edition will enhance the impact of this textbook by bringing a synthesis of existing knowledge and standards of practice to the entire world. All of those involved in producing this edition are united with its readers in a shared mission to cure and eradicate gynecologic cancers worldwide.

Dennis S. Chi, MD
Andrew Berchuck, MD
Catheryn Yashar, MD
Don S. Dizon, MD, FACP

Acknowledgments

The editors acknowledge the contributions of numerous individuals without whom this book would not have been possible. The talented staff of the publisher Wolters Kluwer, specifically senior product manager Emilie Moyer, editorial coordinator David Murphy, and developmental editor Martha Cushman, provided invaluable encouragement, direction, and guidance during the creative process and in technical execution. Shailaja Subramanian provided outstanding production services. From the Academic the creative process and in technical execution. Shailaja Subramanian provided outstanding production services. From the Academic Office of the Gynecology Service, Department of Surgery, Memorial Sloan Kettering Cancer Center, we acknowledge the invaluable contributions of editors George Monemvasitis and Jenifer Levin. Their attention to detail, patience, and communication skills were of the utmost importance throughout the publication process. Our appreciation for all their efforts cannot be adequately expressed, but we hope they know how much we value their contributions.

SECTION I

ETIOLOGY, PREVENTION, AND MOLECULAR BIOLOGY

1 Epidemiology of Gynecologic Cancers
Louise A. Brinton, Vikrant V. Sahasrabuddhe, Britton Trabert, and Silvia Franceschi

2 Molecular Pathogenesis of Gynecologic Cancers
Andrew Berchuck, Douglas A. Levine, Dariush Etemadmoghadam, and David D. L. Bowtell

3 Hereditary Gynecologic Cancers
Noah D. Kauff, Andrew Berchuck, and Karen H. Lu

4 Invasion, Metastasis, and Angiogenesis
Angeles A. Secord, Charlie Gourley, and Elise C. Kohn

5 Development and Identification of Tumor Serum Markers
Aleksandra Gentry-Maharaj and Usha Menon

6 Cancer Prevention Strategies
Mary B. Daly and Gina M. Mantia-Smaldone

7 Preinvasive Disease of the Lower Genital Tract
Britt K. Erickson, Mark H. Einstein, and Warner K. Huh

SECTION II

DIAGNOSTIC AND THERAPEUTIC MODALITIES

8 Perioperative and Critical Care
James J. Burke II, Scott C. Purinton, and Heather MacNew

9 Surgical Principles in Gynecologic Oncology
Yukio Sonoda, David Cibula, Denis Querleu, Eric Leblanc, and Oliver Zivanovic

10 Diagnostic Imaging
Shaunagh McDermott, Leslie K. Lee, and Susanna I. Lee

11 Biologic and Physical Principles of Radiation Oncology
Beth A. Erickson, Meena Bedi, Firas Mourtada, and Sunil J. Advani

12 Targeted Therapies in Gynecologic Cancers
Stephanie Lheureux and Amit M. Oza

13 Principles of Chemotherapy in Gynecologic Cancer
Stéphanie L. Gaillard and Michael A. Bookman

14 Pharmacology and Therapeutics in Gynecologic Cancer
David S. Alberts, Hilary Calvert, Maria Lluria-Prevatt, Paul H. Sugarbaker, and Bradley J. Monk

15 Immunotherapy of Gynecologic Malignancies
Paul J. Sabbatini, Kunle Odunsi, Jacobus Pfisterer, and Dmitriy Zamarin

16 Clinical Trials Methodology and Biostatistics

Mark F. Brady, Jeffrey C. Miecznikowski, and Virginia L. Filiaci

17 Cost-Effective and Value-Based Gynecologic Cancer Care
Laura J. Havrilesky, Shalini L. Kulasingam, Elizabeth L. Jewell, and David E. Cohn

SECTION I
Etiology, Prevention, and Molecular Biology

CHAPTER 1 Epidemiology of Gynecologic Cancers

Louise A. Brinton, Vikrant V. Sahasrabuddhe, Britton Trabert and Silvia Franceschi

Disease-oriented texts often include a chapter on epidemiology or etiology, which is considered perfunctory if the book is used by therapists whose daily practice is rarely influenced by these considerations. This is not the case for physicians who treat patients with gynecologic cancers because these clinicians have frequent opportunities to interpret epidemiologic findings and make observations of etiologic importance. Moreover, public health measures based on epidemiologic findings influence gynecologic practice perhaps more than any other clinical discipline. In particular, epidemiologic data are critical for the prevention and treatment of cervical and uterine cancers.

From the observation 150 years ago of the rarity of cervical cancer in nuns to the most recent follow-up studies of type-specific human papillomavirus (HPV) infection, determining the cause, natural history, and prevention of this disease has focused on sexual practices and suspect infectious agents. Screening interventions based on natural history studies have fundamentally altered the usual presentation of this disease, and as more information about preceding infectious processes becomes available, even more radical changes in presentation and management are likely.

The probable estrogenic cause of uterine cancer was proposed by etiologically oriented gynecologists decades before its demonstration by epidemiologists. Unfortunately, this did not prevent the largest epidemic of iatrogenic cancer in recorded history (i.e., uterine cancer caused by menopausal estrogen therapy). The resurgent interest in menopausal hormone therapy, effects of progestins added to this regimen, and associated risk–benefit questions are certain to link the epidemiologist and the gynecologist for the foreseeable future. The iatrogenic chemoprevention of endometrial and ovarian cancer through oral contraception has similarly thrust the two disciplines together around issues ranging from basic biology to risk–benefit assessments.

The rich tradition of the mingling of epidemiology and gynecologic oncology has led to better opportunities for prevention, screening, and insights into basic mechanisms of disease than for any other subspecialty concerned with cancer. This chapter is written with the aim of clarifying how epidemiology is an integral part of the effort to reduce the morbidity and mortality from gynecologic cancers in women.

UTERINE CORPUS CANCER

Demographic Patterns

Uterine corpus cancer (hereafter referred to as uterine cancer) is the most common invasive gynecologic cancer and the fourth most frequently diagnosed cancer among women in the United States today. One in 40 will develop uterine cancer during their lives, and it is estimated that there were approximately 54,870 diagnoses during 2015 (1). Uterine cancers are primarily endometrial cancers, with sarcomas comprising only about 3% to 7% of all uterine malignancies, and therefore

most of what is known regarding the epidemiology of uterine cancer relates to endometrial cancer. The average annual age-adjusted incidence of uterine cancer from the Surveillance, Epidemiology, and End Results (SEER) program, a cancer reporting system involving approximately 30% of US residents, was 27.5 per 100,000 women for 2012. The disease is rare before the age of 45 years, but the risk rises sharply among women in their late 40s to middle 60s (**Fig. 1.1**).

The prognosis for uterine cancers is quite good, with an age-adjusted mortality rate of 4.5 per 100,000 women and a 5-year survival rate of approximately 83.8% (2). It is estimated that approximately 10,170 women died from uterine cancer during 2015 (1).

Uterine cancer rates are highest in North America and Northern Europe, intermediate in Southern Europe and temperate South America, and low in Southern and Eastern Asia (including Japan) and in most of Africa (except southern Africa) (**Fig. 1.2**) (3). This is likely due to prevalence differences in a variety of risk factors, including reproductive patterns and obesity, although specific studies to address the impact of such differences have not been undertaken.

Over time in the United States, dramatic changes in the incidence pattern for uterine cancers have occurred. Among Whites, there was a marked increase in incidence that peaked about 1975, a trend that was later linked with the widespread use of menopausal estrogen therapy in the late 1960s and early 1970s (**Fig. 1.3**). In Blacks, there has been a progressive increase in incidence over time, eliminating the previous racial disparity that was observed for many decades. In contrast, mortality rates remain considerably higher for Blacks than for Whites.

Reproductive Risk Factors

Nulliparity is a recognized risk factor for uterine cancer. Most studies demonstrate a two- to threefold higher risk for nulliparous women than for parous women. The association of uterine cancer with nulliparity is believed to be a consequence of prolonged periods of anovulation, although both nulliparity and infertility appear to exert independent effects (4). Mechanisms that may mediate the risk associated with infertility include anovulatory menstrual cycles (i.e., prolonged exposure to estrogens without sufficient progesterone); high serum levels of androstenedione (i.e., excess androstenedione is available for conversion to estrone); low levels of serum sex hormone-binding globulin (SHBG); and the absence of monthly sloughing of the endometrial lining (i.e., residual tissue may become hyperplastic).

It has further been established that the risk of uterine cancer decreases with increasing parity, especially among premenopausal women (5). Recent attention has focused on timing of births. Several investigators have found decreased risks with shorter intervals since a last birth and have suggested that this might reflect a protective effect of mechanical clearance of initiated cells (5).

An understanding of the effects of infertility on cancer risk must also consider relationships according to different methods of birth control, including oral contraceptives (discussed later in this chapter). As elaborated in a recent pooled analysis (6), a number of investigations have noted reductions in risk among users of intrauterine devices (IUDs). The mechanisms involved with this apparent protective effect have not been elaborated, although it is possible that the devices may affect risk by causing structural or biochemical changes that alter the sensitivity of the endometrium to circulating hormones.

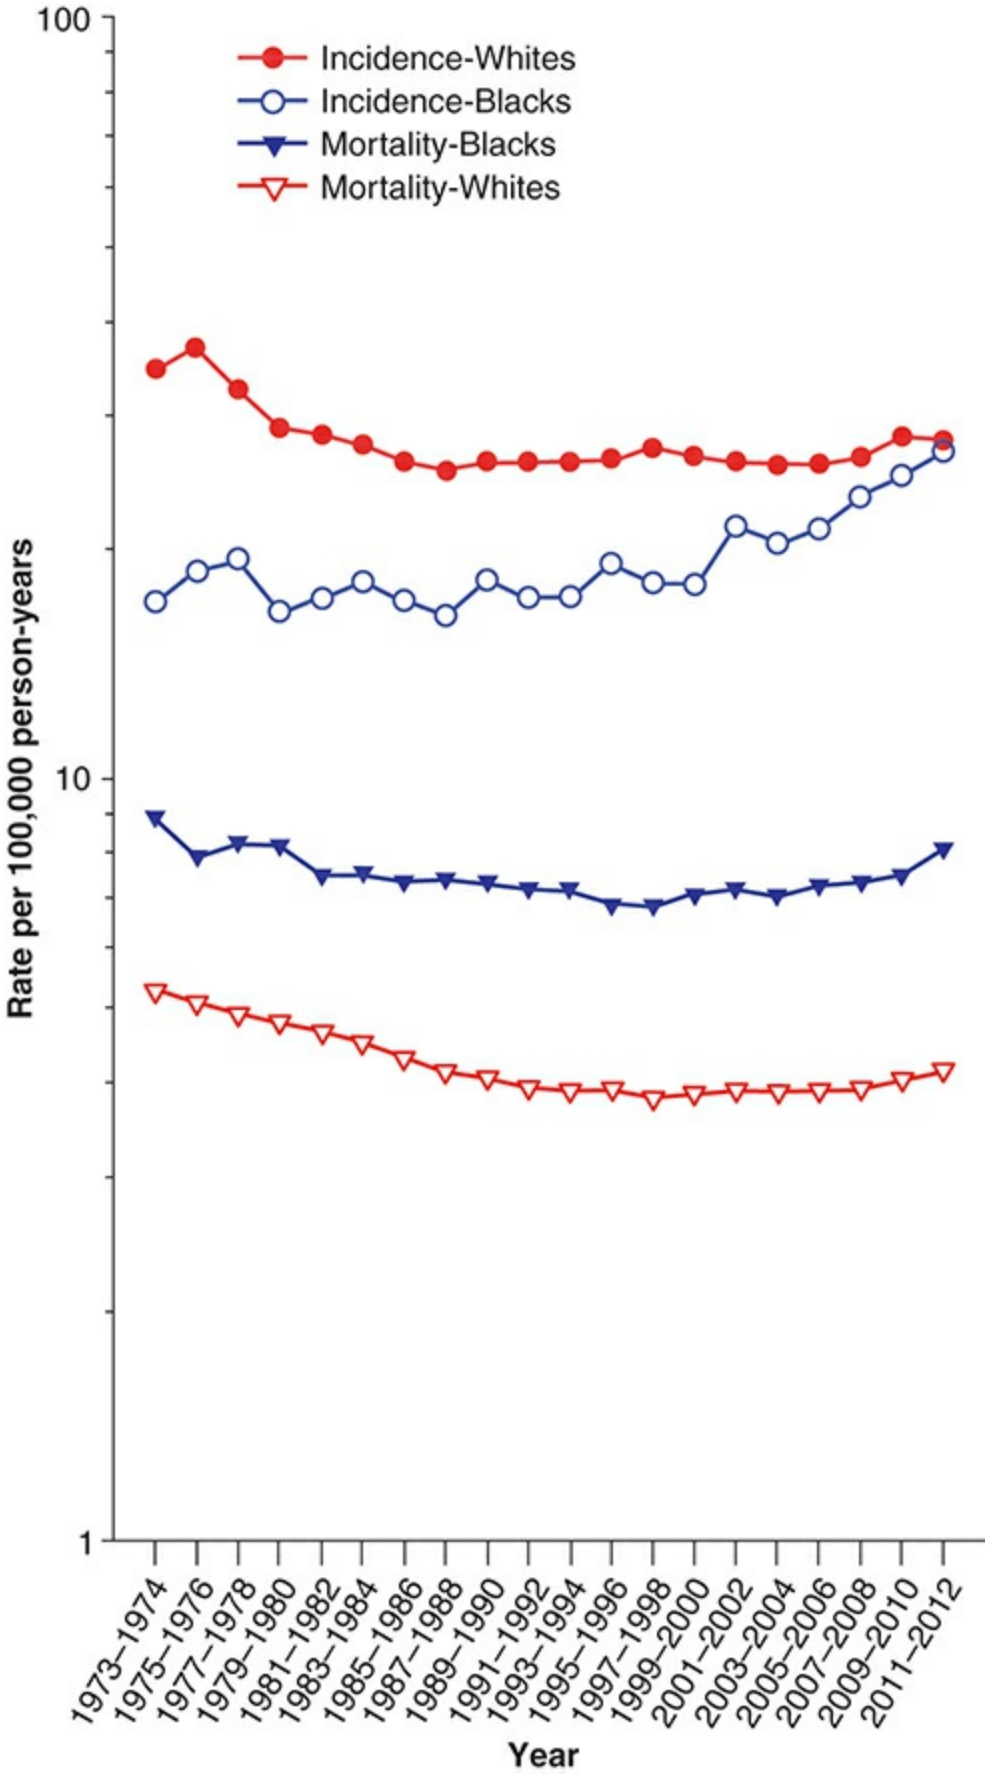

Figure 1.3 Trends in uterine incidence among US women, SEER-9, 1973 to 2012.

The use of fertility drugs has been of concern, given the structural similarity of clomiphene and tamoxifen and the fact that tamoxifen has been extensively linked with elevated risks of uterine cancers (discussed in more detail later). Although earlier studies suggested that fertility drugs might increase uterine cancer risk, the latest investigation on the topic provided no support for a relationship (7).

The potential effects of breast-feeding remain controversial. Although some studies suggest that prolonged lactation may offer protection, this has not been consistently found (5).

Menstrual Risk Factors

Early ages at menarche have generally been related to an elevated risk for uterine cancer. A large multicenter prospective cohort reported a 30% reduction in risk with later as compared with earlier ages at menarche, with the association being strongest for younger women (5). The extent to which this relationship reflects increased exposure to ovarian hormones or other correlates of early menarche (e.g., increased body weight) is unresolved.

Most studies have indicated that age at menopause is directly related to the risk of developing uterine cancer. About 70% of all women diagnosed with uterine cancer are postmenopausal. Investigations support that there is about a twofold increased risk associated with natural menopause after 52 years of age as compared with before age 49. It has been hypothesized that the effect of late age at menopause on risk may reflect prolonged exposure of the uterus to estrogen stimulation in the presence of anovulatory (progesterone-deficient) cycles. The interrelationships among menstrual factors, age, and weight are complex, and there has been substantial speculation regarding underlying biologic mechanisms.

Exogenous Hormones

Oral Contraceptives

The use of combination oral contraceptives has been shown to be associated with marked reductions in the risk of uterine cancer, with the greatest decreases seen among long-term users. In a recent meta-analysis, 5 years of use was associated with a risk ratio of 0.76 (95% confidence interval [CI], 0.73 to 0.78) (8). This reduction in risk persisted for more than 30 years, with no apparent difference in risk across calendar time periods, despite use of higher estrogen dose pills in earlier years.

Menopausal Hormones

It is well established that unopposed estrogens are associated with a 2- to 12-fold elevation in uterine cancer risk (9). In most investigations, the increased risk does not become apparent until the drugs have been used for at least 2 to 3 years, and longer use of estrogens is generally associated with higher risk. The highest relative risks (RRs) have been observed with higher drug dosages and after 10 years of use (up to 20-fold), although it is unclear whether risk increases after 15 years. Most but not all studies have found that cessation of use is associated with a relatively rapid decrease in risk, although a number of studies have found significantly elevated risks persisting for 10 or more years after last usage.

The large body of evidence linking estrogen use to increases in the risk of uterine cancers has led to estrogens being prescribed in conjunction with progestins among women who have not had a hysterectomy, given that progestins cause regression of endometrial hyperplasia, the presumed precursor of uterine cancers. In the Women's Health Initiative (WHI) clinical trial, after 5.6 years of median intervention and 13 years of follow-up, women assigned to 0.625 mg of conjugated equine estrogen plus 2.5 mg of medroxyprogesterone acetate daily had a hazard ratio (HR) of 0.65 (95% CI, 0.48 to 0.89) compared with those assigned to placebo (10). Similar results derive from a number of observational studies, including the Million Women Study in the United Kingdom, where usage of continuous combined therapy resulted in an RR of 0.71 (95% CI, 0.56 to 0.90) (9).

Although studies indicate that the excess risk of uterine cancer associated with estrogens can be significantly reduced if progestins are given for at least 10 days each month (11), some studies have shown that subjects prescribed progestins for less than 10 days per month (sequential users) experience some increase in risk, with only a slight reduction compared with estrogen-only users (12). The sharp contrast between the effects of <10 and ≥10 days of progestin use has led to the suggestion that the extent of uterine sloughing or of "terminal" differentiation at the completion of the progestin phase may play a critical role in determining risk. It remains questionable whether <10 days of progestin administration per month is sufficient for complete protection, particularly for long-term users. Few studies have had large numbers of long-term sequential users, but there is some evidence that this pattern of usage may result in persistent elevations in risk (13).

Studies have shown that the effects of hormonal therapy (both unopposed estrogens and combination therapy) may vary by user characteristics, most notably by a woman's body mass. Investigations have shown that the adverse effects of unopposed estrogens are greatest in nonobese women and that the beneficial effects of combined therapy are greatest in obese women (9,12).

Most data regarding the effects of hormones derive from studies of users of pills. Unresolved is whether the use of estrogen patches, creams, or injections can affect risk; given the relationship of risk with even low-dose estrogens, it is plausible that these regimens may confer some increase in risk.

Tamoxifen

A number of clinical trials have demonstrated an increased risk of uterine cancer among tamoxifen-treated breast cancer patients, with a recent meta-analysis showing a HR of 2.18 (95% CI, 1.39 to 3.42) (14). This is consistent with tamoxifen's estrogenic effects on the endometrium. Elevated risks have been observed primarily within relatively short periods after exposure and among women receiving high cumulative doses of therapy. Certain uterine cancer histologies that are normally associated with a poor prognosis may be especially elevated (15).

Anthropometry and Physical Activity

Obesity

Obesity is a well-recognized risk factor for uterine cancer and may account for up to 25% of cases (16). Very heavy women appear to have exceptionally high risks. Although studies have demonstrated significant positive trends of uterine cancer with both weight and various measures of obesity, including body mass index (BMI [weight/height^2]), height has not been consistently associated with risk. Obesity appears to affect both premenopausal and postmenopausal uterine cancer.

Although initial studies hypothesized that adolescent and long-standing obesity may be more important than adult weight, recent studies support that contemporary weight and weight gain during adulthood are the most important predictors of uterine cancer risk (17). Relationships with obesity appear stronger among women not exposed to exogenous hormones.

Recent interest has focused on determining whether the distribution of body fat predicts uterine cancer risk. A number of studies have shown that central obesity may have an effect independent of overall body size (18), although not all studies confirm this relationship (19).

Physical Activity

Investigations have suggested a potential protective effect of physical activity on uterine cancer risk independent of relationships with body weight. A potential relationship is biologically plausible given that physical activity can result in

changes in the menstrual cycle, body fat distribution, and levels of endogenous hormones. One meta-analysis of prospective studies demonstrated a decreased risk of uterine cancer with moderate-to-vigorous physical activity independent of relationships with known potential confounders, namely, obesity, menopausal hormone therapy use, and parity (20). Both occupational and recreational physical activity appear to result in decreased risks.

Recent attention has focused on inadequate physical activity, specifically sedentary behavior, often measured as sitting time, which has been linked with risk increases (20). However, it is still not clear from the existing studies if the association is independent of moderate-to-vigorous physical activity or body weight (20).

Cigarette Smoking

A reduced risk of uterine cancer among smokers has been reported, with current smokers having approximately half the risk of nonsmokers (21). Cigarette smoking has been linked to an earlier age at natural menopause in some populations and to reduced levels of endogenous estrogens. Reduced risks may be more pronounced in parous or obese patients (22). At present, biologic mechanisms underlying the inverse relationship of smoking to uterine cancer risk remain elusive, although alterations in endogenous hormones or metabolites are likely involved (23).

Dietary Factors

Despite the fact that obesity has been consistently related to uterine cancer, the role of dietary factors remains controversial. Geographic differences in disease rates (i.e., high rates in Western and low rates in Eastern societies) suggest that nutrition has a role, especially the high content of animal fat in Western diets.

Dietary Fat

Although early studies speculated that dietary fat intake (particularly animal fat) might play a role in the etiology of uterine cancers, results from more recent studies have provided inconsistent results. The WHI Dietary Modification Randomized Control Trial that evaluated chronic disease risks related to a low-fat diet revealed no relations with the incidence of uterine cancers (24).

Fruits, Vegetables, and Associated Micronutrients

Some studies suggest a reduction in the risk of uterine cancer related to high intakes of fruits and vegetables (25). Various micronutrients have been implicated as responsible for this association, although their independence from each other and from other risk factors has not been fully resolved (25).

Other Dietary Factors

Given the recognized role of diabetes in the etiology of uterine cancers (see below), a number of studies have assessed risk in relation to carbohydrate intake, glycemic intake, and glycemic load, which are known to increase insulin and estrogen levels. There are suggestions that all three factors may relate to risk (26), although further studies are needed to sort out their independence from other risk factors, including obesity, diabetes, and physical activity levels. In additional research, acrylamides, a probable human carcinogen detected in various heat-treated carbohydrate-rich foods, have been linked with increases in uterine cancer risk (27), while phytoestrogens and omega-3 fatty acids (found in fatty fish) appear protective (28). However, all of these exposures warrant further research to confirm effects.

Alcohol and Caffeine

Although early studies suggested that alcohol consumption might lead to reductions in endometrial cancer risk, the findings may have reflected residual confounding by cigarette smoking. More recent studies suggest either no association or one that is increased only modestly (29).

A meta-analysis of coffee consumption and uterine cancer reported a decreased risk of cancer with one cup or more of coffee per day, with consistent findings across case–control and cohort studies (30). Additional studies are needed to determine whether there are certain subgroups that would especially benefit from increased consumption and to define biologic mechanisms for the association.

Medical Conditions

Clinical reports and several observational studies link polycystic ovarian syndrome (PCOS) with an increase in the risk of uterine cancer, with one meta-analysis showing a nearly threefold increased risk associated with the condition (31). However, the extent to which this relation is independent of obesity remains unclear.

A number of studies, and a recent meta-analysis (32), suggest a high risk of uterine cancer among diabetics, but questions remain as to the independence of this effect from that of obesity. Some studies suggest that a relationship with diabetes persists when analyses are restricted to nonobese women or are adjusted for weight. Several investigations have suggested that metformin use might reduce the risk of uterine cancer, but the latest studies on this issue have not confirmed a protective effect (33).

Studies that have shown stronger relationships of diabetes to uterine cancer risk among obese women have prompted interest in the etiologic role of selected metabolic abnormalities, including hyperinsulinemia. Recent studies have focused on effects of metabolic syndrome, with findings that this may predict risk better than merely a history of diabetes (34).

A variety of other diseases, including hypertension, arthritis, thyroid conditions, anemia, and cholecystectomy, have been suggested to predispose to uterine cancers, although without consistent findings (35). In some of these studies, positive findings may have been partially explained by the correlation of the diseases with other factors. Similar to breast cancer, patients with previous fractures have been found to have a reduced risk of uterine cancer (36), presumably reflecting the association of lowered bone density with altered endogenous hormone levels.

Given speculation that inflammatory processes might play an important role in the development of uterine cancers (37), a number of studies have assessed relationships with use of nonsteroidal anti-inflammatory drugs, with inconsistent results (38).

Host Factors

Women who have a family history of uterine cancer in a first-degree relative have been shown to be at a 1.5- to 2-fold increased risk of developing the disease themselves (39). Familial histories of colorectal cancer are also associated with increases in risk, reflective of several defined cancer syndromes. This includes Lynch syndrome or hereditary nonpolyposis colorectal cancer, a dominantly inherited syndrome associated with mutations in the DNA mismatch repair genes *MSH2*, *MLH1*, and *MSH6*; Cowden syndrome, a rare condition resulting from a mutation in the tumor suppressor gene phosphatase and tensin homolog; and a rare condition associated with the *POLD1* gene that encodes the catalytic subunit of DNA polymerase (39). Patients with Lynch syndrome have been estimated to face a 25% 10-year probability of developing subsequent uterine cancers, suggesting their need for active and early management (40).

Although numerous studies have attempted to identify genetic markers of uterine cancer risk, genome-wide association studies (GWAS) have found only one locus associated with risk, namely, a susceptibility locus close to *HNF1B* (rs4430796), which has also been positively associated with prostate cancer risk and inversely with type 2 diabetes (41). In order to determine whether rare variants may be more predictive, exome-wide association studies (EXWAS) have also

been undertaken, although no variants have reached global significance, suggesting the need for greater power to detect modest associated risks (42).

Environmental and Occupational Risk Factors

Geographic variation in rates of uterine cancer, with high rates in certain industrial areas, has led to the suggestion that certain environmental agents may affect risk. Given the well-recognized influence of hormones on disease, there has been particular concern about a potential role for certain endocrine disruptors, including dichlorodiphenyltrichloroethane (DDT). Several studies have addressed this issue by comparing dichlorodiphenyldichloroethylene levels (the active metabolite of DDT) in the sera of cases and controls, finding no significant differences (43). Studies have also focused on effects of electromagnetic radiation, but results regarding associations with electric blanket or mattress covers have produced mixed results (44).

Data for occupational exposures are limited. Elevated endometrial cancer rates have been found among teachers in California (45) and individuals exposed to animal dust and sedentary work in Finland (46). The extent to which these relationships reflect the influence of social class is unknown.

Etiologic Heterogeneity

In 1983, Bokhman proposed that endometrial cancers could be divided into two broad types: Type I, the predominant form, which has a hormonally driven etiology, and Type II, which is unrelated to typical endometrial cancer risk factors, not associated with endometrial hyperplasia and generally clinically aggressive. Subsequent clinicopathologic studies led to the view that most Type I cancers correspond histologically to endometrioid adenocarcinomas, whereas Type II cancers encompass most nonendometrioid histologic types, with serous carcinoma representing the prototype. Differences in molecular markers according to histology support the notion of at least two broad classes of endometrial carcinoma.

Although it is generally now accepted that there are at least two main biological types of endometrial cancer (and possibly more), most epidemiologic studies have assessed risk factors for endometrial cancer overall—which essentially represent the risks for the predominant Type I tumors, especially in largely White populations. Registry data consistently have shown that Type II cancers occur at older ages and more often affect non-White women, consistent with etiological differences compared with Type I tumors. Recently, several epidemiologic investigations have found that Type II cancers are less strongly linked to classic Type I risk factors, such as obesity, nulliparity, and hormones (15,47), emphasizing that the disease is etiologically heterogeneous.

Biologic Mechanisms Underlying Risk Factor Associations

Many of the identified risk factors are thought to operate through alterations in various endogenous hormones. The majority of studies have found increased risks associated with higher levels of circulating estrogens among postmenopausal women that persisted after adjustment for the effects of body mass (48). There is some evidence that estrogens are less predictive of premenopausal disease, suggesting that anovulation or progesterone deficiency might be more influential.

Less well investigated is whether endogenous hormones other than estrogens are related to uterine cancer risk. It has been suggested that uterine carcinogenesis is dependent on uterine mitosis, which is increased by estrogens and reduced by progesterone, but risk associated with progesterone levels has not been well explored. Several studies have shown positive associations of uterine cancer risk with serum androstenedione and testosterone levels (48). This may reflect a role of chronic anovulation and progesterone deficiency in premenopausal women, whereas after the menopause

aromatase and local conversion of estrone from androstenedione may be involved.

Obesity, which has been shown to reflect elevated estrogen levels, represents a key risk factor for both uterine carcinoma and endometrial hyperplasias, but the mechanisms mediating this are unclear. One cohort study of postmenopausal women showed that elevated serum estrogen levels appeared to account for the majority of the risk associated with obesity (49).

Conclusions

A unified theory of how risk factors for uterine cancer might operate through one common hormonal pathway has been suggested. Estrogen promotes proliferation in the endometrium, which is opposed by progesterone. Therefore, exposure to estrogen, particularly bioavailable estrogen that is weakly bound or unbound to plasma protein, is viewed as a critical carcinogen. Functional ovarian tumors, PCOS, late menopause, and administration of sequential oral contraceptives and menopausal hormone therapies produce higher levels of estrogen exposure without the antiproliferative effects of progesterone. Obesity could also contribute in a variety of ways. Adipose tissue is the primary site for conversion of androstenedione to estrone, which is the primary source for estrogen after menopause. Obesity is associated with higher conversion rates and/or elevated plasma levels of estrogen in postmenopausal women. In addition, obesity is related to lower levels of SHBG and more frequent anovulatory menstrual cycles (i.e., less progesterone). Vegetarianism is associated with lower plasma estrogen levels, presumably on the basis of the relationship of diet composition to estrogen metabolism. The beneficial effects of combination oral contraceptives and continuous progestins added to menopausal hormone therapy presumably operate through the antiestrogenic effects of progesterone. The peculiar age incidence patterns for uterine cancer (i.e., extremely rare under age 45 years, followed by a rapid and progressive rise from ages 45 to 60 years) could also reflect the waning influence of progesterone. Nulliparity, diabetes, the absence of smoking, and race may yet be added to the unifying scheme as knowledge of endocrinologic mechanisms in endometrial tissue increases.

Although there are several identified risk factors for uterine cancer (**Table 1.1**), important gaps in knowledge currently limit a full understanding of the proposed carcinogenic process. We need to understand when in a woman's life obesity matters most and how risk is influenced by weight loss; whether the number of adipocytes, their fat composition, or other factors determine peripheral conversion of androstenedione; and the precise hormonal mechanisms associated with vegetarianism. Perhaps the most important gap is in understanding the basic mechanism of estrogen carcinogenesis. It is unclear whether estrogens are complete carcinogens, classic "promoters" that affect initiated cells, or growth stimulants for abnormal cells or carcinogens that act on vulnerable genetic material. Much of the epidemiologic data point toward estrogens acting at a relatively late stage of carcinogenesis, emphasizing the need for further attention to identify tumor initiators.

TABLE 1.1 Risk Factors for Uterine Cancer

Factors Influencing Risk	Estimated Relative Risk[a]
Older age	2.0–3.0
Residency in North America, Northern Europe	3.0–18.0
Higher levels of education or income	1.5–2.0
White race	2.0
Nulliparity	3.0
History of infertility	2.0–3.0
Menstrual irregularities	1.5
Early age at menarche	1.5–2.0

Late age at natural menopause	2.0 – 3.0
Use of oral contraceptives	0.3 – 0.5
Long-term use of menopausal estrogens	10.0 – 20.0
High cumulative doses of tamoxifen	3.0 – 7.0
Obesity	2.0 – 5.0
Stein – Leventhal disease or estrogen-producing tumors	>5.0
Histories of diabetes, hypertension, gallbladder disease, or thyroid disease	1.3 – 3.0
Moderate-to-vigorous physical activity	0.5 – 0.8
Cigarette smoking	0.5

[a]Relative risks depend on the study and referent group employed.

OVARIAN CANCER

Demographic Patterns

Ovarian cancer accounts for 1.3% of all incident cancers in US women (2). Approximately 1 in 70 will develop ovarian cancer during their lifetime. The average annual age-adjusted incidence for all SEER areas for 2012 was 11.9 per 100,000 women (2). A total of 21,290 new cases were estimated to have been diagnosed in the United States in 2015 (1).

Diagnosis usually occurs at advanced stages; the overall 5-year survival between 2005 and 2008 was only 45.6%. The average annual age-adjusted mortality rate is 7.4 per 100,000 women (2). The estimated 14,180 deaths due to ovarian cancer in 2015 made it the fifth leading cause of cancer death among US women (1). After rising during the mid-twentieth century, age-adjusted mortality rates have been declining by 2.0% per year since 2007 among White women, but have remained stable among Blacks (1). Incidence rates have also slowly declined over the past two decades; ovarian cancer incidence rates decreased by 1.1% per year from 2003 to 2012 (2). Although there is some disparity in mortality rates between US Whites and Blacks (7.7 vs. 6.6 per 100,000 women per year, respectively), the incidence rates by race are more disparate (12.5 per 100,000 women per year among Whites vs. 10.2 among Blacks) (**Fig. 1.4**) (2).

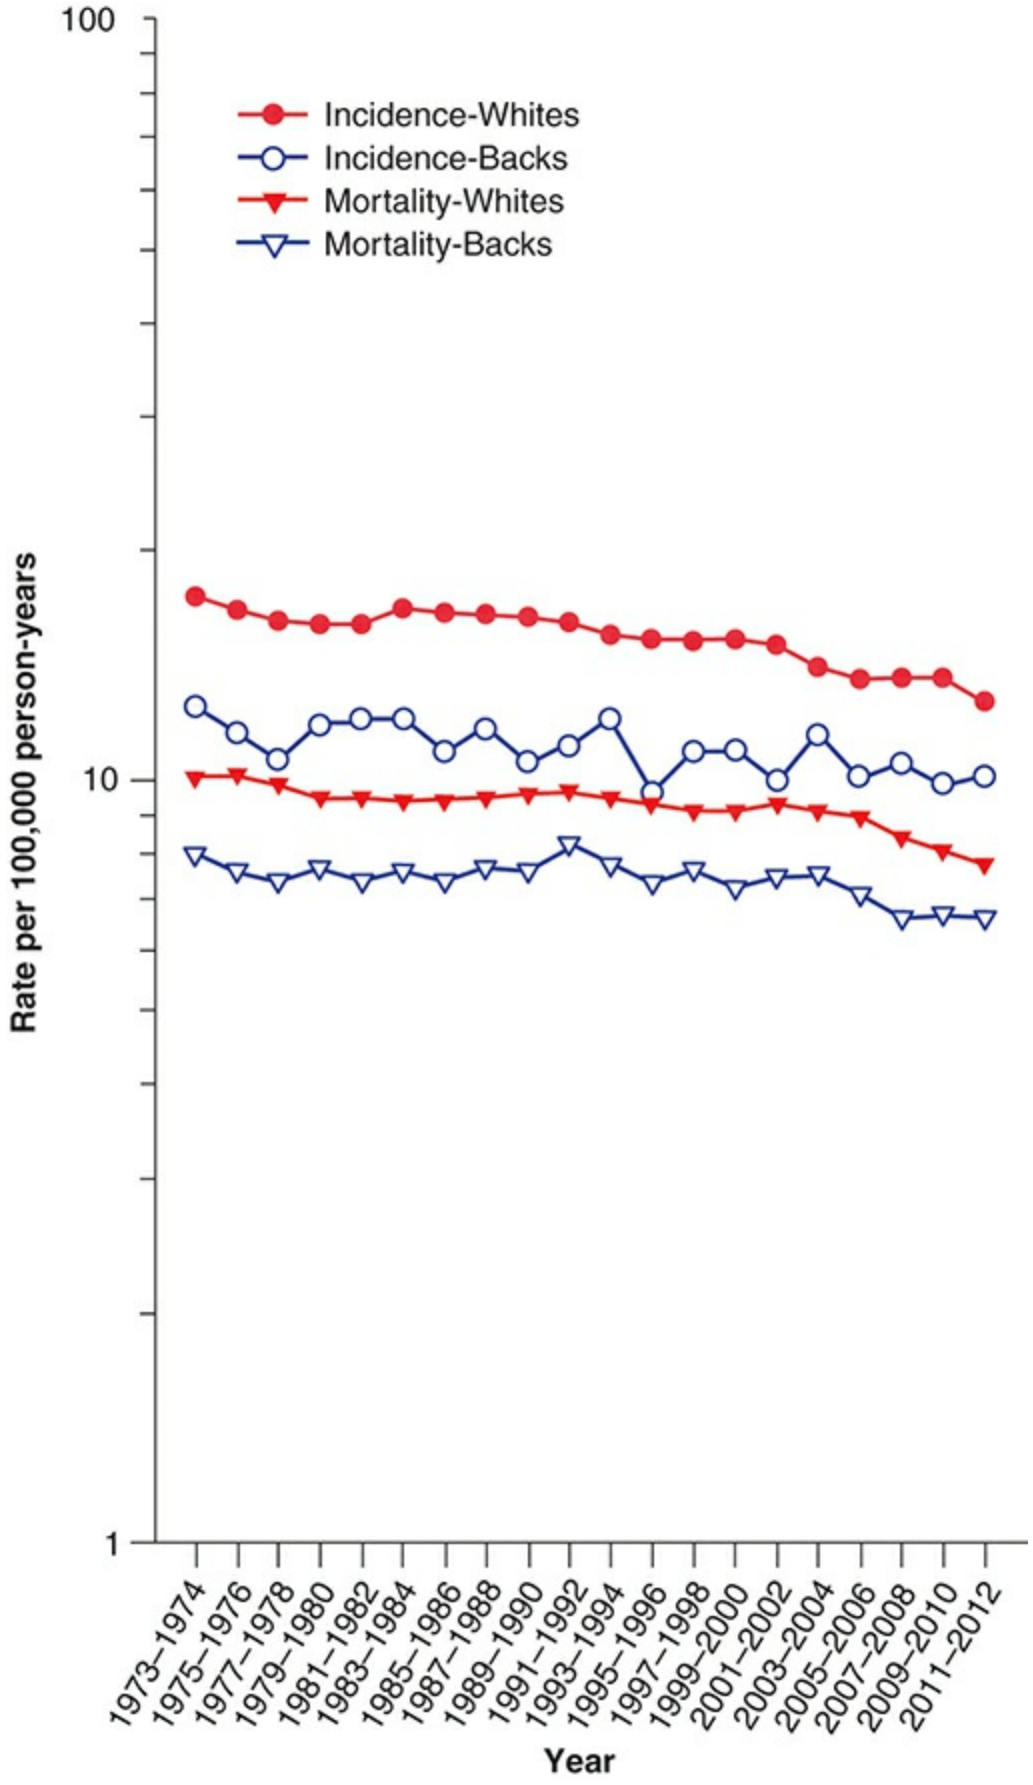

Figure 1.4 Trends in ovarian cancer incidence among US women, SEER-9, 1973 to 2012.

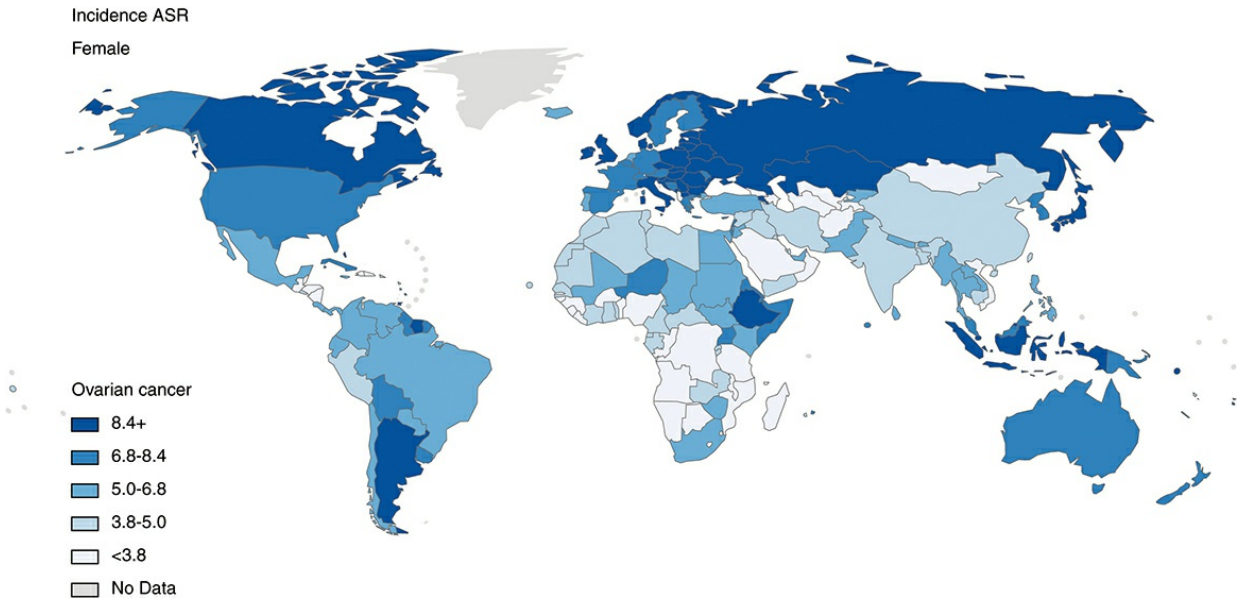

Figure 1.5 Age-standardized international incidence rates for ovarian cancer. (GLOBOCAN, WHO, 2012 © WHO 2105. All rights reserved.)

The highest incidence occurs in European, Scandinavian, and North American countries, whereas the lowest rates occur in African nations and some Eastern Asian countries, such as China (**Fig. 1.5**) (3). Age-standardized rates vary 3.7-fold across countries. Mortality data show a similar but slightly less dramatic pattern (**Fig. 1.6**). The estimated age-standardized mortality rates are 4.6 in more developed regions and range from 2.8 to 3.9 in less developed regions (3). Genetic susceptibility and differences in the prevalence of major ovarian cancer risk factors are likely to explain some of the geographic and racial/ethnic differences in rates; however, few studies have been conducted to address the influence of these factors on rate patterns.

Reproductive Risk Factors

Gravidity is consistently associated with decreased ovarian cancer risk. Compared with nulligravid women, women with a single pregnancy have an RR of 0.6 to 0.8. Each additional pregnancy decreases risk by another 10% to 15%. Although parity results in substantial reductions in risk, there is less certainty regarding the effects of incomplete pregnancies. One study (50) showed no relationship of risk with induced abortions, but an increased risk for women with multiple miscarriages, possibly reflecting a common underlying pathology. Most studies that have adjusted for parity report no residual association with age at first or last birth (51).

Although several early studies showed substantial increases in ovarian cancer risk linked to use of fertility drugs, subsequent studies have generally not confirmed an association, at least for invasive cancers (52). There are, however, lingering concerns regarding whether fertility medications might increase the risk of borderline ovarian cancers, especially given results from a recent large Dutch cohort study (53). Whether this reflects a biologic relationship or merely increased medical surveillance among infertility patients has yet to be determined.

A number of studies have found a reduced risk of ovarian cancer associated with breast-feeding, although it is unclear whether there is a dose–response relation or whether the association is independent of parity. A pooling of two large cohort studies reported an inverse trend in risk with extended breast-feeding that was independent of parity effects (54). Notably, each month of breast-feeding decreased the RR of ovarian cancer by 2%. Suppression of ovulation and decreased gonadotropin levels have been proposed as explanatory of the reduced risk, but further studies are needed to confirm this hypothesis and to clarify relations by histologic subtype.

Menstrual Factors and Gynecologic Surgery

Numerous studies have noted reduced risks among women who have had a simple hysterectomy or tubal ligation. These patients' risks were 30% to 40% lower than the risks among women who had not undergone surgery. One meta-analysis reported a 37% reduced risk of ovarian cancer with tubal ligation and evidence that the reduced risk persists 10 to 14 years after the procedure (55). It has been suggested that surgery offers an opportunity to remove abnormal-appearing ovaries, but this alone is unlikely to explain the protective effect. Partial devascularization and reduced ovarian function or partial removal of tubes, which decreases risk of tubal carcinogenesis, a precursor to serous ovarian cancer, represent possible alternative mechanisms. However, reduced exposure to potential environmental causes of inflammation resulting from tubal ligation or hysterectomy blocking the route of exposure from the outside of the body to the fallopian tube fimbria and ovaries has also been proposed.

A number of studies have linked late age at natural menopause with an increased risk of ovarian cancer, (51) although not all studies have confirmed this relationship. Most studies have not found earlier ages at menarche to increase risk (56), but some have reported weak positive associations.

Hormonal Risk Factors

Oral Contraceptives

Oral contraceptive use has been consistently associated with a lower risk of ovarian cancer. The overall estimated protection is approximately 40% for ever use and increases to more than 50% with 5 years of use or longer. A pooled analysis of 45 studies confirmed that the reduction in risk persists for 30 years beyond last use (57). The lower-dose formulations now in use seem to reduce risk at least as effectively as their higher dose predecessors; of the progestins used does not appear to differentiate risks.

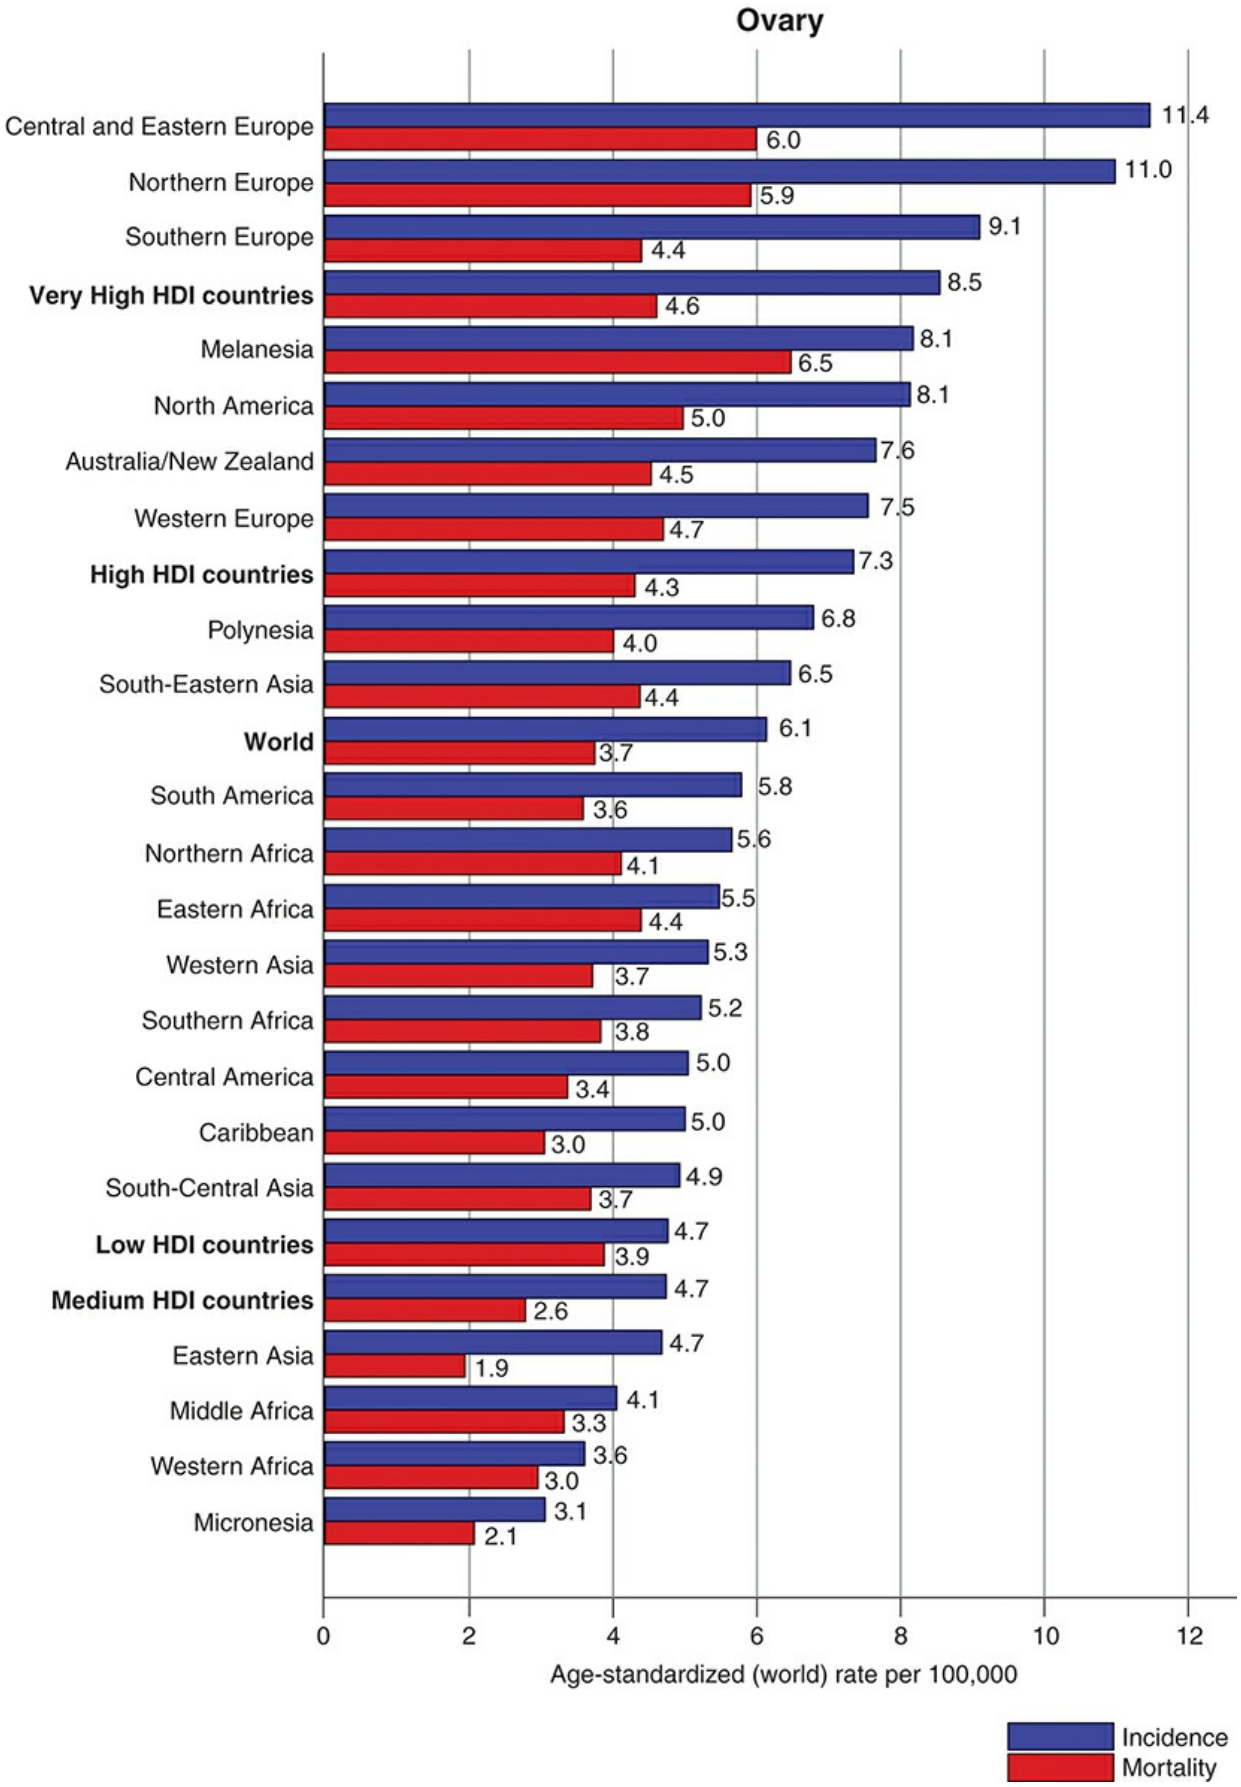

Figure 1.6 Age-standardized incidence and mortality rates for ovarian cancer. HDI, human development index. (GLOBOCAN, WHO, 2012.)

Menopausal Hormones

Unopposed estrogen menopausal hormone therapy has been consistently associated with an increased risk of ovarian cancer. Associations between estrogen plus progestin use and ovarian cancer risk have been less consistent. In the WHI clinical trial, women exposed to estrogen plus progestin therapy had an increased, albeit nonsignificant, risk of ovarian cancer compared with those receiving a placebo (RR, 2.42; 95% CI, 0.64 to 9.12) (58). However, a recent pooled analysis of 52 epidemiologic studies reported similar increased risks of ovarian cancer for both estrogen-only and estrogen plus progestin use (59). Furthermore, the Danish Sex Hormone Register study reported increased risk for both sequential and continuous estrogen plus progestin use (60), suggesting that progestins do not mitigate the increased risk associated with estrogen menopausal hormone therapy.

Endogenous Hormones

Recent interest has focused on the role of endogenous hormones in the etiology of ovarian cancer. Gonadotropins, including follicle-stimulating hormone, have been found to be inversely related to risk (61), whereas endogenous androgens have not generally shown strong risk associations (62,63). One study found some suggestion that free testosterone might play a role in early-onset ovarian cancers (64), but another investigation, which pooled data from three studies, reported null associations with estrogens, androgens, SHBG, insulin-like growth factor (IGF)-1, and associated binding proteins (62). A recent study evaluating early pregnancy hormone levels and cancer development later in life reported increased risk of invasive tumors with higher testosterone and androstenedione concentrations, while estradiol, progesterone, 17-hydroxyprogesterone, and SHBG were not substantially related to risk (65). There remains interest in further exploring the role of endogenous hormones in the etiology of ovarian cancers, especially given that they may interact with immunologic factors, which have been suggested to play an important role in ovarian carcinogenesis.

Medical Conditions and Medications

Several studies surveyed whether certain medical conditions predispose to ovarian cancer. Diabetes, hypertension, and thyroid diseases seem unrelated to risk. In line with a number of clinical studies showing simultaneous occurrences of endometriosis and ovarian cancer, epidemiologic studies have found that women with a diagnosis of endometriosis have elevated risks for developing ovarian cancer (66). In several of these studies, the relationship was shown to be especially pronounced for clear cell and endometrioid ovarian cancers, and more recently also for low-grade serous malignancies (66). As reviewed by Ness (67), the two conditions share a number of pathophysiologic processes, including estrogen excesses and progesterone deficits, immunologic responses, and inflammatory reactions. Pelvic inflammatory disease has also been found to be a possible risk factor for ovarian cancer (68), supporting the notion of a role for tubal inflammation and/or damage in ovarian carcinogenesis.

Findings have also suggested a reduced risk among women who use anti-inflammatory or other analgesic medications, and a recent pooled analysis reported a modest inverse association between aspirin use and ovarian cancer risk, with stronger risk reductions among daily aspirin users (69). However, chemoprevention via the use of these medications remains a premature concept.

Anthropometry and Physical Activity

Obesity has recently received increased scrutiny as a possible risk factor. Most individual studies fail to show an association, but pooling projects and meta-analyses are beginning to indicate increased risks associated with higher BMI (70). Some investigations have shown stronger relationships restricted to certain subgroups, including those who have never had children, premenopausal women, postmenopausal women, nonusers of menopausal estrogens, women without a

family history of ovarian cancer, and physically inactive women. Furthermore, some studies have suggested that obesity is a risk factor only for certain types of tumors, with most evidence pointing to increased risks for borderline serous and invasive endometrioid and mucinous tumors (71,72).

Height has also emerged as an independent risk factor for obesity (73). Additional studies have examined effects of physical activity levels on ovarian cancer risk, with one meta-analysis reporting a 19% risk reduction associated with high levels of recreational activity; however, the association was not statistically significant when only cohort investigations were considered (74). Sedentary behavior (6+ hours of sitting per day) was recently associated with increased ovarian cancer risk (75).

Cigarette Smoking

In general, cigarette smoking is not considered a major risk factor for ovarian cancer, although it may be related to increases in risk of mucinous tumors (76). In a systematic review, smoking doubled the risk for mucinous tumors, but did not increase risk for endometrioid or clear cell tumors (77). The risk of mucinous cancers increased with amount smoked but returned to that of never smokers within 20 to 30 years of stopping smoking.

Dietary Factors

Ecologic studies of dietary factors and ovarian cancer risk led to the hypothesis that high intake of fat, milk, and eggs may be related to an increased risk of ovarian cancer, while high intake of fruits and vegetables may be related to a decreased risk. However, the majority of the observational studies targeting food classes, lactose and dairy foods, fats, vitamins/nutrients, fiber, fruits, and vegetables provide conflicting results.

Lactose Consumption

Several early studies raised concern that higher consumption of yogurt, cottage cheese, and other lactose-rich dairy products might increase ovarian cancer risk given that galactose-related enzymes can influence gonadotropin levels. Although the majority of studies fail to show increases in risk with lactose consumption or galactose metabolism, results from the Nurses' Health Study suggest that further attention may be warranted regarding effects for serous tumors (78).

Fat Intake

The WHI Dietary Modification Randomized Control Trial evaluated the effects of a low-fat dietary pattern on chronic disease incidence and reported a decreased risk of ovarian cancer associated with the intervention (a 20% reduction in total fat intake) (24). A meta-analysis of 12 cohort studies found no overall association with fat, cholesterol, or egg intakes, but some suggestion that very high levels of saturated fat intake may increase risk (79). Additional meta-analyses reported no association between red meat and inconsistent results for high intake of processed meat (80).

Fruits and Vegetables and Micronutrient Intake

Although a number of studies have suggested that ovarian cancer risk might be reduced by higher consumption of fruits and vegetables or fiber, others, including a pooling project of 12 cohort studies, fail to support such relationships (81). Some studies have shown inverse associations with particular nutrients, such as vitamins A, C, and E, β-carotene, folate, or methionine, but results have been inconsistent across studies. Meta-analyses evaluating vitamin D or the major carotenoids and ovarian cancer risk report no substantial relationships (82). Further clarification of effects may require

evaluating associations according to other risk factors and within histologic subgroups.

Alcohol and Caffeine

A number of studies have examined ovarian cancer risk in relation to alcohol consumption. Most investigations, including pooling efforts (83), have not found any convincing relationships.

Caffeine and ovarian cancer risk has been evaluated in studies of coffee consumption, tea consumption, or studies of both. Although coffee consumption has been linked to an elevated risk of ovarian cancer in several studies, a recent investigation and updated meta-analysis failed to provide support for a relationship of risk with either coffee or tea consumption (84). Another meta-analysis reported reduced ovarian cancer risk with green tea consumption and no association with black tea consumption (85). Overall, there are no consistent patterns between caffeine consumption and ovarian cancer risk; however, it may be that more detailed information on type of caffeine and frequency and duration of consumption need to be evaluated.

Host Factors

A family history of ovarian cancer is the strongest risk factor identified to date. Which family member was affected is less important than the total number of affected relatives or their age at diagnosis (86). Women with two or more affected relatives or whose relative was diagnosed before 50 years of age experience the highest risks (87). Approximately 5% to 10% of ovarian cancer patients have a first-degree relative with ovarian cancer (86). Family histories of breast and colon cancer are also associated with increased ovarian cancer risk, but slightly less strongly than a family history of ovarian cancer.

Inherited mutations in two autosomal dominant genes—*BRCA1* and *BRCA2*—are strongly linked to familial ovarian cancer (and breast and other cancers) (88). Whereas the lifetime probability of developing ovarian cancer in most women is 2%, the probabilities in women with a family history or women with *BRCA1* and *BRCA2* mutations are 9.4% and 15% to 40%, respectively (89). Despite these increases, *BRCA1/2* mutations explain less than one third of the elevated risk in women with familial ovarian cancer (87). Lynch syndrome is reported to be associated with a 12% lifetime risk of ovarian cancer (90). High-penetrance genetic variation is associated with considerable disease heterogeneity; mutations in *BRCA1/2* lead to the development of serous cancers, whereas mutations of DNA mismatch repair genes are more frequently associated with mucinous and endometrioid tumors (91).

Common genetic variation and ovarian cancer risk in moderate- or low-penetrance susceptibility genes have been evaluated using candidate gene studies of single nucleotide polymorphisms (SNPs) and through GWAS. Candidate genes/SNPs have generally been selected from biologic pathways based on relevant hypotheses, and several candidate genes have been identified as possibly related to ovarian cancer risk, including *PGR, TP53*, and *CDKN2A*. GWAS have further identified susceptibility loci for ovarian cancer at 9p22.2, 8q24, 19p13, 2q31, 3q25, and 17q21 (91) and 1p36, 4q26, 9q34.2, and 17q11.2 (92). The underlying genetic basis of ovarian cancer contributes to disease heterogeneity with common low-penetrance genetic variation, with GWAS loci 9p22.2, 1p34.3, and 6p22.1 being more strongly associated with serous subtype than other subtypes (91,92). Identifying common genetic susceptibility alleles will lead to a greater understanding of disease etiology, potentially allowing the development of preventive approaches targeted toward women who have these genetic variants.

Talc

Over-the-counter talc, a silicate which chemically resembles asbestos, has been of concern with respect to ovarian cancer risk for some time. Although evaluated in many studies, results have been conflicting (93). One meta-analysis (94) indicated that exposure is associated with slight increases in risk of either all subtypes or of serous cancers, albeit with

inconsistent dose–response relations. However, the WHI Observational Study reported no associations overall or by area of application, duration of use, or histologic subtype (95). Thus, it is apparent that further evaluations of this exposure are needed to fully understand potential effects.

Environmental and Occupational Risk Factors

A variety of studies have focused on effects on ovarian cancer risk of certain professions (e.g., teachers, health care workers, bookkeepers), without definitive conclusions. Specifically, there has been concern regarding potential effects of occupational exposures to either hair dyes or triazine herbicides to ovarian cancer, although no clear patterns of risk have emerged. A Monographs Working Group of the International Agency for Research on Cancer (IARC) concluded that asbestos exposure is associated with ovarian cancer, with the association confirmed in a subsequent meta-analysis of occupational cohorts (96). Until additional data address the potential for inconsistent or chance findings and the challenge of finding large populations with sufficient data on other potential confounding variables, occupational exposures beyond asbestos will likely not be considered major risk factors for ovarian cancer.

Etiologic Heterogeneity

A unified ovarian cancer progression model has not yet been established, and growing evidence demonstrates that subtypes of ovarian carcinomas have different molecular, pathological, and clinical characteristics, suggesting that there may be several distinct disease entities. Specifically, ovarian cancer subtypes appear to molecularly and morphologically resemble cancers of other sites: fallopian tube (serous), endometrium (endometrioid), gastrointestinal tract (mucinous), and unspecified glycogenated epithelium (clear cell) (97).

As previously discussed, some risk factors have been shown to have distinctive effects for certain subtypes of ovarian cancer, but there have been inconsistent findings—most likely reflecting small numbers in the studies of some of the rarer subtypes. Probably one of the more consistent findings is the propensity of endometriosis to predispose to clear cell and endometrioid tumors (66). Tubal ligation may also be more strongly related to reductions in endometrioid cancers than to other ovarian subtypes (56). Mucinous tumors also show some distinctiveness with demonstrating increased risks related to cigarette smoking (77) and decreased risks with use of menopausal hormones (72). Obesity is beginning to emerge as an especially strong predictor for certain cancers, including endometrioid cancers (71), consistent with the link of obesity to endometrial cancer (13).

It is clear that further leads regarding the etiologic heterogeneity of ovarian cancer will depend on either large studies or more likely on consortial efforts, which bring together data from multiple epidemiologic studies. Such efforts are currently underway by several groups and should provide further insights as to possibly distinct origins of some of these tumor subtypes.

Conclusions

Much of the clinical and epidemiologic evidence concerning risk factors for ovarian cancer implicates ovulatory activity (**Table 1.2**). Conditions associated with reduced ovulation (e.g., pregnancy and oral contraceptive use) consistently reduce risk. Combining these and other menstrual factors into single “ovulatory age” or “lifetime ovulatory cycles” indexes has generally produced the expected associations with ovarian cancer risk; that is, older ovulatory ages or higher cycle counts increase risk. However, the misclassification inherent in these indexes is sufficient to generate different risk estimates, and the magnitude of risk reduction for short-term oral contraceptive use or a single pregnancy exceeds the proportional decrease in ovulatory cycles that would be expected to be associated with these exposures.

The putative mechanisms behind ovulatory inhibition and the risk associated with “increased ovulation” raise additional questions. An early report suggested, based on the associations with parity and infertility, that an unidentified endocrine

abnormality predisposed women to relative or absolute infertility and ovarian cancer. The protection associated with oral contraceptives seems unlikely to fit this hypothesis unless, in some improbable manner, their use induces an endocrine milieu similar to that underlying infertility.

A second popular unifying hypothesis is that ovarian cancer is the result of accumulated exposure to circulating pituitary gonadotropins. Although this is consistent with the parity, menopause, and oral contraceptive associations, there is no support for high gonadotropin levels being related to increased risk. This theory also fails to account for the risks associated with clinical infertility, and it predicts that menopausal hormone therapy use would decrease risk, because both exposures are associated with reduced gonadotropin levels.

TABLE 1.2 Risk Factors for Ovarian Cancer

Factors Influencing Risk	Estimated Relative Risk[a]
Older age	3.0
Female relative with ovarian cancer	3.0–4.0
Residency in North America, Northern Europe	2.0–5.0
Higher levels of education or income	1.5–2.0
White race	1.5
Nulliparity	2.0–3.0
History of infertility	2.0–5.0
Early age at menarche	1.5
Late age at natural menopause	1.5–2.0
History of hysterectomy or tubal ligation	0.5–0.7
Use of oral contraceptives	0.3–0.5
Long-term use of menopausal estrogens	3.0–5.0
Perineal talc exposure	1.5–2.0

[a]Relative risks depend on the study and referent group employed.

A third explanation points to a biologic effect of ovulation on ovarian surface epithelium. Ovulation prompts a cascade of epithelial events, including minor trauma, increased local concentrations of estrogen-rich follicular fluid, and increased epithelial proliferation, followed by local inflammation and wound repair. Such proliferation, particularly near the point of ovulation, can recruit inclusions into the ovarian parenchyma. Some or all of these “incessant ovulation” events may lie on the causal path to ovarian cancer. This is consistent with most of the endocrine-related risk factors except for the risks associated with clinical infertility.

Although it has been hypothesized that epithelial inclusion cysts give rise to ovarian tumors, cancer precursors of ovarian surface epithelium remain unclear, and progress in understanding ovarian carcinogenesis, as previously mentioned, is partly limited by this lack of clarity on tissue of origin of ovarian epithelial carcinomas. Nearly all other epithelial gynecologic cancers arise via a sequence of events whereby the normal epithelium undergoes conversion to a precursor lesion that can then become an invasive neoplasia. Cervical intraepithelial neoplasia (CIN), the precursor of cervical cancer, is probably the most well-known example. More recently, increasing evidence indicates that at least a subset of high-grade serous ovarian carcinomas arise from high-grade intraepithelial serous carcinomas in the fallopian tube and spread to the ovary (97). This could help explain the inconsistent reduced risks associated with tubal ligation and hysterectomy, given that the fallopian tubes would be removed only in a subset of these procedures.

No single theory adequately incorporates the available data. A unifying hypothesis may lie in a combination of ovulation, hormones, and local effects. Additional factors, such as genetic alterations; androgens, progestins, and other hormones;

inflammation; and endometriosis, also appear to be important.

Each hypothesis identifies testable possibilities. Discriminating between the roles of voluntary versus involuntary infertility could identify the mechanisms underlying the role of parity. Characterizing the specific reproductive abnormalities associated with clinical infertility could reveal new biologic mechanisms involved in ovarian carcinogenesis. Exploring the interactive contributions of the hormones along the hypothalamic–pituitary–gonadal axis could explain how specific hormones seem to influence risk at different time periods. In addition, verifying that inflammation or related conditions and pathways play an etiologic role in ovarian carcinogenesis could open new lines of inquiry.

Ovarian cancer epidemiology presents both simple and complex patterns. Rates have largely remained unchanged over the last 40 years. The highly penetrant genes account for only a small proportion (10%) of women who develop ovarian cancer, but a better understanding of the mechanisms behind those risks could introduce immediate benefits for high-risk women. A clear picture has emerged for some protective factors, such as oral contraceptives and parity, but risk associated with other important public health issues, such as smoking, obesity, and physical activity, remains uncertain. Although it is tempting to attribute the differences to histology-specific associations, such hypotheses will require substantially more epidemiologic, clinical, and genetic data before their acceptance is certain. Consistent risk factors for high-grade serous tumors, the most fatal subtype, also remain elusive. Continued attempts to account for the differences between studies should help delineate spurious associations from the etiologically relevant risk factors. Such efforts should help identify targets for improving detection, treatment, and prevention of this deadly tumor.

CERVICAL CANCER

Cervical cancer is a major source of morbidity and mortality globally. Evidence from basic biology and molecular epidemiology studies over the past three decades established the central causative role of chronic persistent infection, with carcinogenic genotypes of the HPVs in virtually all cases of cervical cancer (98). Cervical HPV infection is extremely common in all sexually active individuals, much more than the relatively rare development of precancer and the even rarer cases of cervical cancer, suggesting a role for additional etiologic factors that may modulate the HPV-induced cervical carcinogenic process. Other than intrinsic viral type-specific risk variations (HPV-16 being the most carcinogenic type, followed by HPV-18 and HPV-45 (99)) and variability in human host immunologic response, there are several cofactors, prominent among them being reproductive factors such as multiparity, hormonal influences (changes in endogenous hormonal milieu over the lifespan, as well as exogenous hormone exposures), smoking, coinfection with other infectious agents, and systemic immunosuppression.

Demographic Patterns: Global and United States

According to the latest global data from the IARC, cervical cancer is the fourth most common cancer (after breast, colorectal, and lung cancers) among women worldwide, with over 527,000 incident cases and over 265,000 deaths worldwide annually (**Fig. 1.7**) (3). The cancer burden (incidence and mortality) is disproportionately high in less developed regions of the world, which account for 85% of cases and deaths due to cervical cancer. The incidence and mortality rates are highly variable by global regions, reflective of difference in background HPV infection rates as well as disparities in access to prevention and clinical care services (**Fig. 1.8**) (3). Incidence and mortality rates of invasive cervical cancer have declined over the past six decades in a number of countries, mainly in countries that rank highly on the human development index (HDI), largely attributed to successes in screening programs for cervical cancer. However, rates remain high in most countries with low HDI, especially in countries in sub-Saharan Africa, largely reflecting lack of, or suboptimal, screening efforts, high HPV incidence, and more recent increases due to the heavy burden of human immunodeficiency virus (HIV)/acquired immune deficiency syndrome (AIDS) (100). Incidence rates are also high (over 15 per 100,000) in countries with low and medium HDI rankings, including in Latin America, Southern Asia, and parts of

Eastern Europe, also attributable to lack of widespread screening. In contrast, rates are lower in countries with medium HDI rankings including in Eastern Asia, Western Asia, and Northern Africa, despite suboptimal screening, likely attributable to lower HPV incidence.

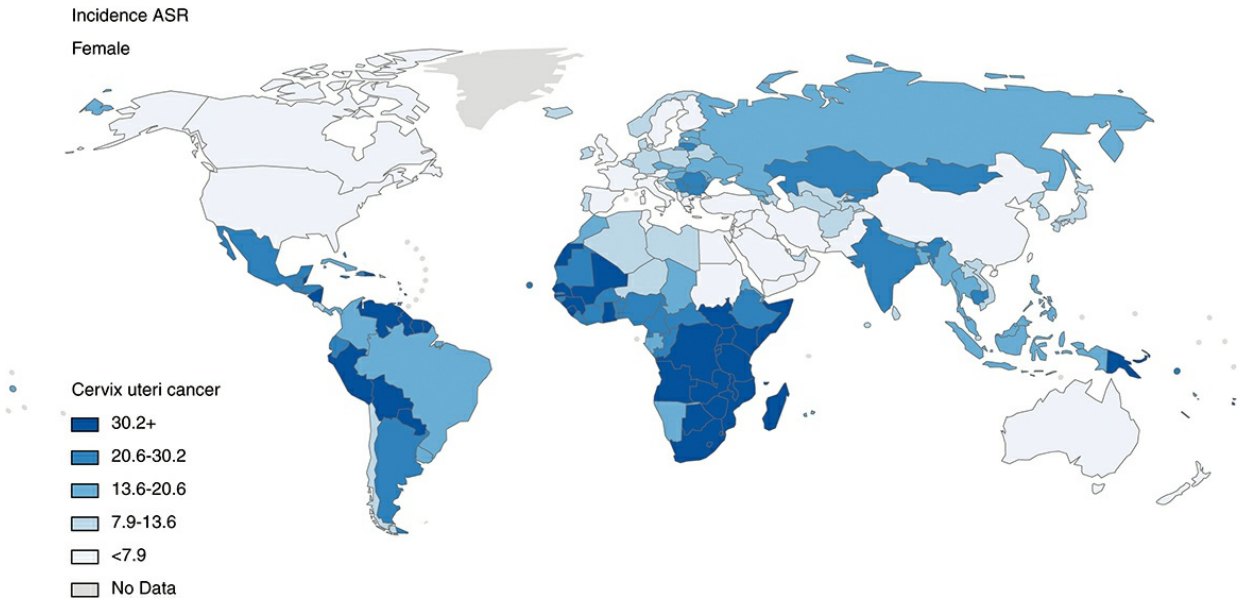

Figure 1.7 Age-standardized international incidence rates for cervical cancer. (GLOBOCAN, WHO, 2012 © WHO 2105. All rights reserved.)

The dramatic declines in incidence rates in countries with high HDI in the latter half of the 20th century are attributable to widespread and/or organized screening efforts (**Fig. 1.9**) (101). Despite lack of screening, several countries with medium HDI rankings have seen declines in incidence rates in the last quarter century as reflected by data from selected high-quality cancer registries in some of these countries (e.g., India, Thailand, Philippines). This is likely due to reductions in rates of multiparity, delayed ages at childbearing, and improvements in nutrition and hygiene (100). In several countries with high HDI rankings, despite general declines in incidence rates, risks by calendar period of diagnosis and birth cohorts have varied substantially, reflecting the duration and quality of screening programs over calendar time and changes in risk factors, notably sexual behaviors (e.g., earlier age at first sexual intercourse, multiple lifetime partners), over successive generations of women.

Of note, there are clear differences in incidence trends by histologic types of cervical carcinomas. While rates of squamous cell carcinomas, accounting for approximately 80% of invasive cervical cancers, have declined steadily since the introduction of Pap smear screening, adenocarcinomas (accounting for approximately 15%) have not (102). In fact, rates of cervical adenocarcinomas have risen in the past two to three decades in various countries including the United States, both relative to rates of squamous cell carcinoma and in absolute numbers.

It is estimated that 12,900 women were diagnosed with and 4,100 women died due to cervical cancer in the United States in 2015 (1). Geographic differences in incidence rates, with higher rates in underserved regions, are apparent (103). Substantial differences by race/ethnicity still persist; non-Hispanic Whites and Asian and Pacific Islanders have much lower rates compared with non-Hispanic Blacks, American Indians and Alaskan Natives, and Hispanic women.

Like other screening-preventable cancers, the age distribution of cervical cancer is affected by the availability and successes of screening. Studies prior to the introduction of screening have shown that cancer cases peak and then plateau around 45 years of age (104). It is unusual for cancer incidence rates to plateau or fall with increasing age; thus, this age structure reflects the origin and long natural history of cervical cancers from HPV infections acquired in early years of adolescence and adulthood, and is likely further influenced by several etiologic cofactors over the reproductive lifespan as well as perimenopausal hormonal changes.

Human Papillomavirus

For more than a century, epidemiologic studies have suggested an association between sexual activity and cervical cancer, but proof that HPV is the sexually transmitted agent responsible for this association was not achieved until sensitive methods for detecting HPV DNA were developed in the late 1980s. The recognition of the key etiologic role of HPV infection has profoundly altered the epidemiologic study of cervical cancer. The epidemiologic association between HPV infection and cervical cancer fulfills all of the established epidemiologic criteria for causality. As a result, HPV is now accepted to be the central, necessary causal factor for virtually all cases of cervical cancer globally (98).

Natural History of Cervical HPV Infection

Cervical HPV transmission, which is primarily sexual, is studied best at the molecular level, primarily because genotypic heterogeneity informs risk stratification. Moreover, before development of precancerous stages, most infections are not microscopically or macroscopically evident. The epidemiology of cervical cancer is most coherently understood in terms of the natural history of cervical carcinogenic HPV infection, which can be broadly categorized in the following stages: i) acquisition of HPV following sexual exposure, with clearance of infection in most cases, ii) persistence of HPV in a minority of women, with oncogenic cellular transformation progressively involving the entire thickness of the epithelium, leading to precancerous lesions, and iii) untreated precancerous lesions progressing to invasive cervical cancer. Terminologies for classifying precancerous lesions have evolved, and the most widely used CIN grading system uses increasing grades (CIN 1, CIN 2, and CIN 3) of increasing severity or extent of the squamous epithelial involvement on histopathology. Of note, CIN 1 is only an insensitive histopathological sign of HPV infection, CIN 2 includes a heterogeneous group of lesions which are equivocal in cancer potential, whereas CIN 3 represents the most clinically relevant lesion and is the best surrogate endpoint for efficacy against invasive cervical cancer in screening or vaccine trials (105).

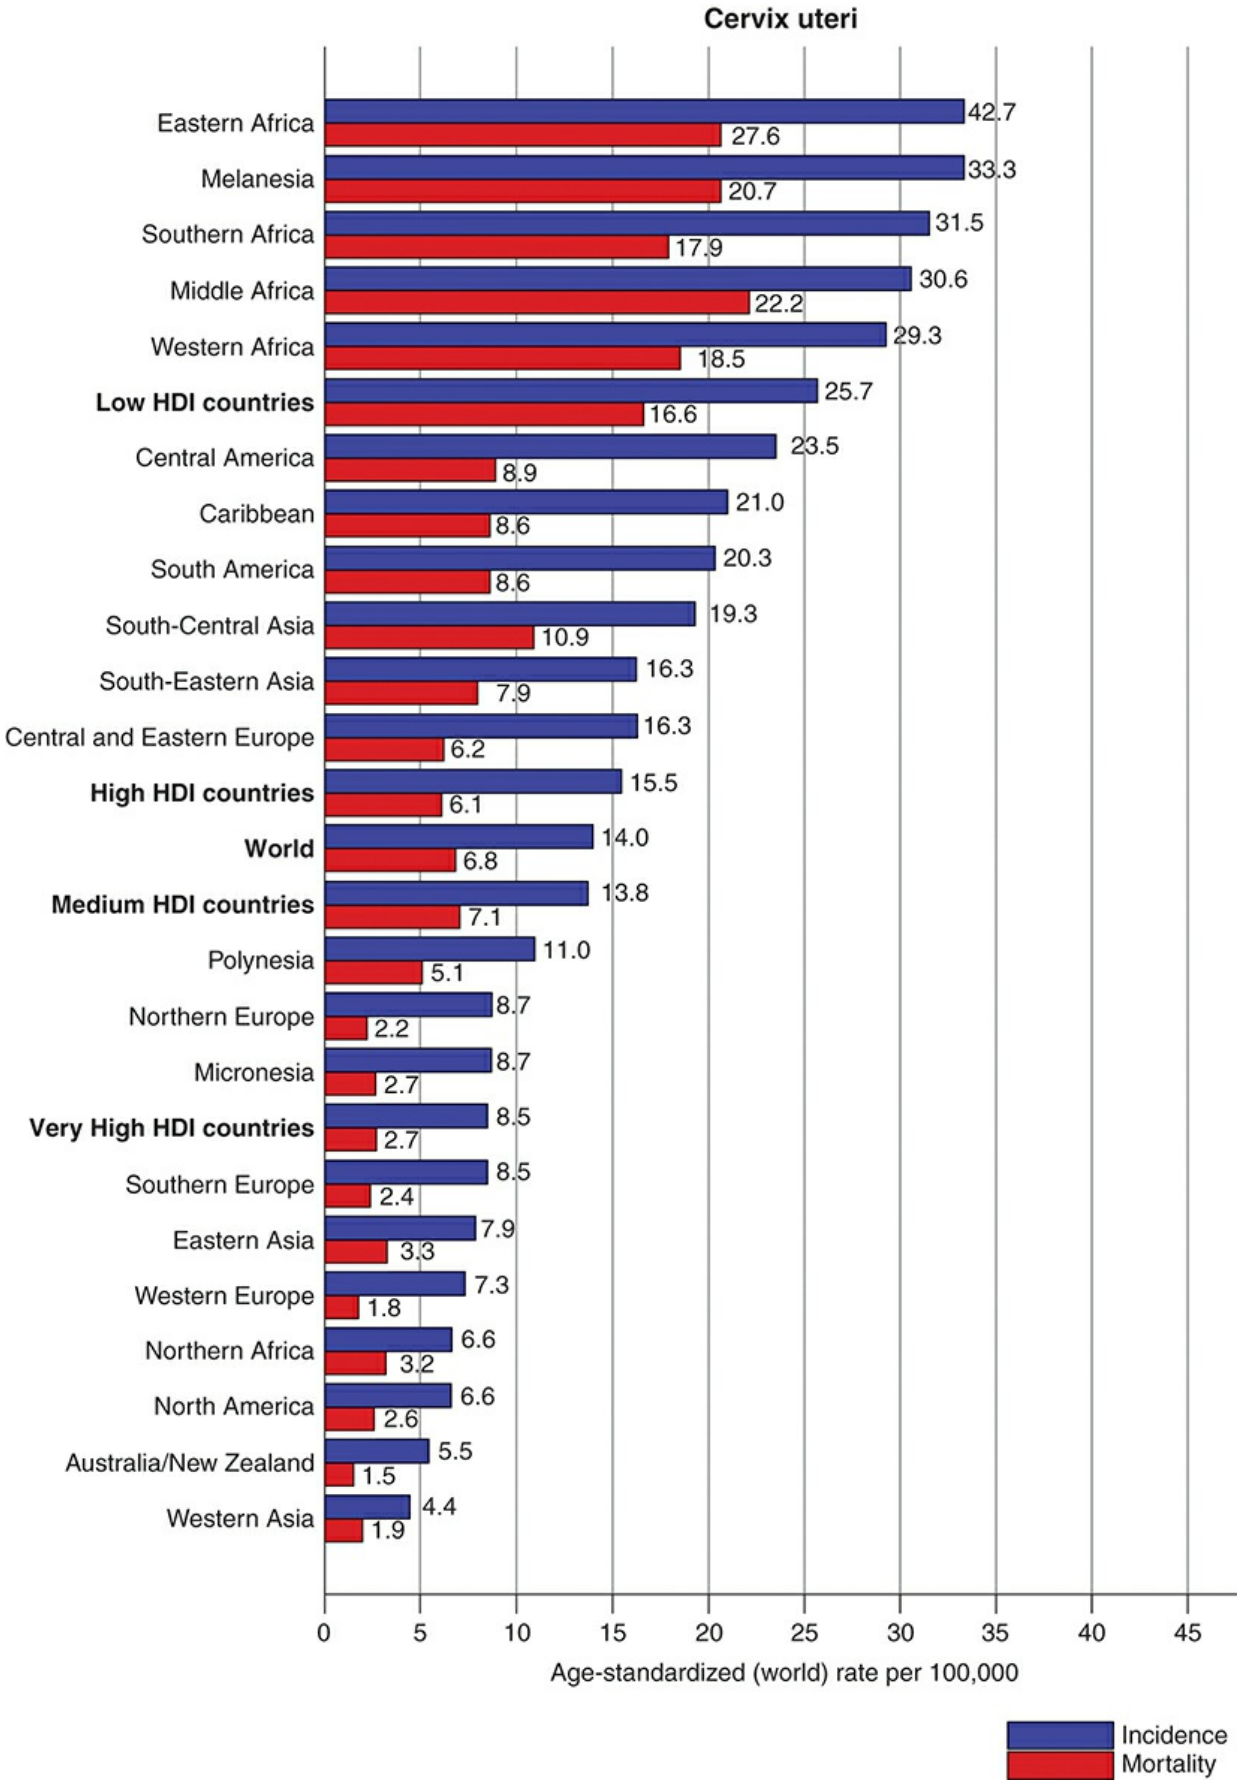

Figure 1.8 Age-standardized incidence and mortality rates for cervical cancer. HDI, human development index. (GLOBOCAN, 2012.)

As the most common sexually transmitted infection, HPV infection acquisition and transmission rates peak in the years following sexual initiation. Acquisition and clearance dynamically oppose each other, to produce the characteristic age distributions as infections are transmitted sexually when women have new partners and are then cleared (106). Transient HPV infections are ubiquitous among sexually active young women (and men), but progression to a cervical cancer precursor requires persistence of carcinogenic types. It is the overt persistence of one of the carcinogenic types that is strongly linked to precancerous lesions. Persistence of carcinogenic types of HPV and development of high-grade precancerous lesions are not identical, but thus far they are so closely linked that epidemiologists are only beginning to disentangle them. Part of the problem is that precancerous lesions begin as extremely small clonal lesions that may be below the limits of microscopic detection (107).

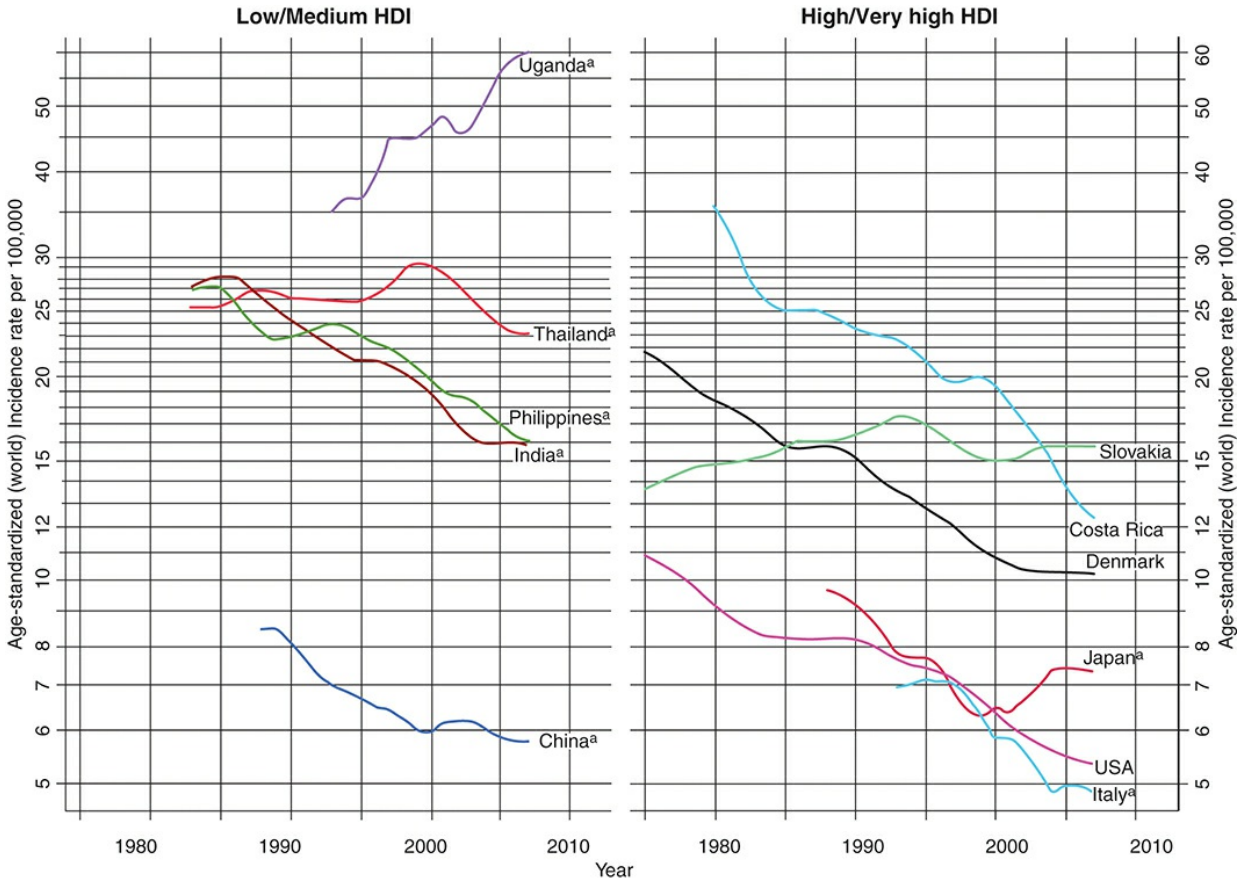

Figure 1.9 Time trends for cervical cancer incidence worldwide. [a][3]China (Hong Kong and Shanghai), India (Chennai and Mumbai), Italy (Ferrara, Modena, Parma, Ragusa, Torino, Sassari, Varese), Japan (Miyagi, Nagasaki, and Osaka), the Philippines (Manila), Thailand (Chiang Mai), Uganda (Kampala), the United States (SEER 9). HDI, human development index.

The recent discovery in the squamous-columnar junction of the cervix of a distinct population of cells of embryonic origin from which all cervical cancer may arise, that cannot be found elsewhere in the lower anogenital tract, may help explain the special vulnerability of the cervical transformation zone (108).

Behavioral Correlates of Cervical HPV Acquisition and Transmission

HPV is highly transmissible via sexual contact in both genders. Numerous epidemiologic studies have shown that markers of sexual activity, such as number of sexual partners (recent or lifetime), are among the most important correlates for HPV

detection and subsequent risk of cervical precancer and cancer (109). HPV infections are easily transmitted with few acts of sexual intercourse, and therefore, sexual frequency is not a major risk factor for cervical neoplasia. The age at sexual debut serves as an apparent proxy for the time of HPV infection in nonpreviously infected women, whereas there is no evidence for a special vulnerability of the cervix close to the time of menarche (104).

A protective effect against cervical cancer risk has been noted for careful, consistent condom use. Condom use affords modest protection against HPV infection and resultant external warts (HPV-6 and HPV-11) and cervical lesions caused by carcinogenic HPV types (110). Given that users of condoms may not report sporadic unprotected contacts, and that the entire skin and mucosal genital area at risk for infection is not protected with this contraceptive method, only modest protection against transmission would be expected (111).

HPV infection transmitted from a male partner to his female partner can be seen as "the male factor" for cervical cancer (112). Confirmed associations supporting this view include the geographic clustering of cervical and penile cancer, the increased risk of cervical cancer among wives of men who have penile cancer, the increased risk among partners of men who have had a previous partner who died of cervical cancer, and the increased risk among women whose partners travel (113). Circumcision is associated with a reduced risk of HPV detection in penile samples, and wives of men with a history of multiple partners are at lower risk of cervical cancer if the men had been circumcised (113,114). Circumcision is associated with reduced prevalent male HPV infection, and randomized clinical trial evidence from Africa has now shown that voluntary adult male circumcision reduces transmission between sexual partners (114,115).

HPV Types as Determinants of Cervical Risk

HPV type greatly affects both the absolute risk of viral persistence and of progression to precancer associated with viral persistence (116). The most common carcinogenic type, HPV-16, is also the most common type in the general population, linked to its greater propensity to persist (117). While certain noncarcinogenic types (e.g., HPV-61) can also be persistent and common, they do not cause malignant transformation (99). The average time of viral persistence that leads to diagnosable precancer is not clear. The average age at microscopic diagnosis of precancer is approximately 25 to 30 years, approximately 5 to 10 years after the average peak ages of carcinogenic HPV prevalence and associated minor cytologic abnormalities in screening populations (118). Biomarkers that predict persistence of cervical cancer and offer better discrimination of transforming versus transient HPV infections are increasingly available (119).

Noncarcinogenic HPV infections are capable of producing lesions falsely diagnosed as precancer, especially CIN 2, showing that this level of abnormality is not a perfect surrogate for cancer risk (120). Still, because of the emphasis on safety, particularly in US clinical practice, and concern over loss to follow-up, treating precancer (except as appropriate in very young women, etc.) is a valid clinical strategy to provide a margin of safety, given that it is not yet possible to know which lesions pose a threat. Eventually, better accuracy based on molecular profiling is the goal.

The distribution of HPV types in cervical cancer has been extensively studied in United States and international collaborative studies (121). The most common HPV types in descending order of frequency are HPV types 16, 18, 45, 31, 33, 52, 58, and 35, together responsible for approximately 90% of all cervical cancers worldwide. Persistent HPV-16 infection is an extremely strong risk factor for subsequent diagnoses of CIN 3 and invasive cancer, and has been classified as a Class 1 human carcinogen by IARC (89). HPV types are more predictive of risk than subtleties of minor and equivocal cytopathic effects, colposcopic findings, or behavioral cofactors such as smoking. Furthermore, intratypic sequence variants of HPV-16 and possibly other types have been associated with altered risk, although these risk modifications are weaker than the intertypic variation (122). The role of elevated viral load (i.e., HPV content in samples obtained from infected women) in predicting persistence and progression of infection is complicated and varies by HPV type and the detection of multiple infections (123). A clear trend of increasing prospective risk with increasing viral load has been demonstrated only for HPV-16, and viral load assessment is not useful clinically (124). Infection with one HPV type does not seem to influence the risk of persistence and development of precancer from another concurrent infection (116).

Host Factors Associated with HPV Persistence and Progression

Whereas humoral (antibody-mediated) immunity appears to play a central role in preventing HPV infection (leading to the prophylactic vaccines), elimination of HPV seems more closely related to mounting an effective cellular immune response. Impaired cellular immunity, attributable to HIV infection, transplantation, or immunosuppressive drugs, has been shown to increase HPV prevalence, persistence, warts, CIN, and cancer (125,126).

The immune response to HPV is an important determinant of viral clearance versus persistence and, by extension, a major determinant of cervical cancer risk (127). However, despite our growing understanding, many aspects of the interactions between HPV and the host immune system remain unknown (128). The key immune responses involved in the clearance of HPV infections are known to be cell mediated, although neutralizing antibodies are highly protective after immunization with HPV virus-like particle-based vaccines (129). A protective immune response to naturally acquired HPV infection develops in some women, but it has not been quantified adequately and is difficult to study, given the lack of site specificity and challenges in serological assay development and validation (130). Assays to measure HPV vaccine responses, on the other hand, have been extensively developed and are currently being standardized for facilitating international epidemiologic studies and future vaccine development and evaluation.

Polymorphisms in the human leukocyte antigen (HLA) genes have been implicated in the risk of HPV-associated diseases. HLAs are important determinants of the efficiency of antigen presentation to immune effector cells and, therefore, may influence the outcome of HPV infections (131). Both Class I HLA genes (those that encode HLA molecules that are present in all nucleated cells) and Class II HLA genes (those that encode HLA molecules that are present in lymphocytes and other immune-related cells) are involved in immune presentation (132). To date, HLA Class II genes have been more extensively studied than HLA Class I genes for their association with cervical cancer. A protective role for HLA DRB1*13 in cervical cancer has been consistently described in several populations. Activating combinations of HLA Class I alleles and the killer immunoglobulin-like receptor confer susceptibility to cervical cancer, whereas inhibitory combinations are associated with protection against the disease (131).

Although the biological basis is unknown, studies from nationwide tumor, twin, and other family registries in Scandinavian countries indicate that cervical cancer aggregates in families. In general, an approximate twofold increase in risk of precancer or invasive cervical cancer relative to the general population risk is observed in family members of cervical cancer patients. How much of this elevation in risk among relatives of individuals affected with cervical cancer can be attributed to shared environment versus genetic effects is not settled (133).

A major unresolved question of HPV natural history relates to the possibility of viral latency (134). In long-term studies, virtually all HPV infections become nondetectable by sensitive HPV DNA tests, usually within two years, except for those that lead to precancer. However, it is unknown if the nondetection reflects true virological clearance or a latent stage due to immunologic control that permits long-term presence (latency) below levels of detection. Indeed, the reemergence (reactivation) of viral types seen in immunocompromised individuals (e.g., immunosuppressed HIV-infected women) who have not been sexually active for a long time points to the existence of viral latency. The clinical significance of latency in terms of the fraction that can progress to precancers and cancers in immunocompetent women is unknown. In the era of HPV vaccination, many of these issues will acquire increased significance, especially with the emergence of HPV genotyping assays in clinical practice (135).

Cofactors Influencing Risk of Persistence of Carcinogenic HPV Infection and Progression of Cervical Precancer to Cancer

Since most women clear HPV spontaneously, and invasive cancer only affects a small minority of women who have

persistent infection, it is very likely that cofactors influence an individual woman's risk for viral persistence, development of precancerous lesions, and finally invasion (112–114). In particular, reproductive history and hormonal influences on carcinogenic risk have been substantively explored, given the characteristic age distribution seen in unscreened populations —increasing incidence seen during the reproductive years and a perimenopausal peak (around 45 years), a feature shared with estrogen-dependent cancers (104). Some of these cofactors and the evidence supporting them are discussed below.

Multiparity

HPV-infected women who have many live births are at increased risk of cervical cancer and precancer. There is a dose-dependent increase in risk with numbers of live births, most evident among women with many full-time live births (136). Although this epidemiologic association is firmly established, the explanatory mechanism is not clear. Mechanisms underlying the association between parity and cervical neoplasia include trauma during parturition, hormonal changes associated with pregnancy, immunosuppression, and possibly altered anatomy of the transformation zone, specifically eversion. Other menstrual and reproductive factors, including miscarriages, abortions, stillbirths, ectopic pregnancies, cesarean sections, age at first pregnancy, age at menarche, and age at menopause, are not independently associated with risk (113).

Hormonal Contraceptives

Use of oral hormonal contraceptives could plausibly potentiate the carcinogenicity of HPV infection, because transcriptional regulatory regions of HPV DNA contain hormone-recognition elements and transformation of cells *in vitro* with viral DNA is enhanced by hormones (137). Pooled analyses from multicenter case–control studies found an elevated risk of invasive cervical cancer among HPV-positive women who used oral contraceptives for more than 5 years after careful adjustment for other sexual and reproductive history, duration of HPV infection, and screening history (136). Shorter durations of use or use more than 5 years prior to cancer onset were not associated with elevated risk. Evidence linking oral contraceptives to cervical abnormalities has raised concern about long-acting steroid preparations, notably depot medroxyprogesterone acetate. Although these agents are widely used in many countries, studies evaluating their effects, particularly among HPV-infected women, are limited (138).

A pooled analysis of 10 case–control studies of cervical cancer and 16 HPV prevalence surveys from four continents showed that IUD use, a common contraception option in developing countries, was associated with a decreased risk of cervical cancer, regardless of duration of use (few months up to 9 years) and after adjustment for screening status (139). This evidence contradicts a widely held assumption that IUDs may increase risk of cervical cancer and might suggest their role as protective cofactors in cervical carcinogenesis, similar to the role they play in protecting against endometrial cancer. While the precise mechanisms are subject to future investigations, it has been suggested that local cellular immunity is triggered during the process of IUD insertion or by the device itself.

The relationship between endogenous hormones and cervical cancer risk is unclear and is a topic of ongoing investigation. Recent results point to the role of circulating levels of testosterone and estradiol in modulating cervical cancer risk in premenopausal women (140). Yet, mechanistic evidence to confirm these associations and exploration of signaling pathways suggests hormone–receptor modulation in cervical cancer likely differs from other estrogen-dependent cancers (such as breast cancer) (141). The relationship between cervical cancer risk and use of menopausal hormone therapy and overweight/obesity (as determinants of circulating estrogen levels in postmenopausal women) is not well understood (142).

Socioeconomic Status

In an international meta-analysis, women defined as belonging to a low socioeconomic class were found to have twice the

risk of cervical cancer compared with women defined as belonging to a high socioeconomic class (143). In the United States, a recent analysis of county-level incidence data indicated that poverty-associated infrequent screening leads to suboptimal stages at diagnosis, resulting in elevated incidence and mortality rates. Some of these affected areas included Appalachia, the southeastern Atlantic states, and the lower Mississippi Valley, as well as central counties of large metropolitan areas (103). A multicountry pooled analysis suggested that the excess of cervical cancer found in women with a low socioeconomic status in inadequately screened populations could not be explained by a concomitant excess of HPV prevalence, but rather by early events in a woman's sexually active life, that is, early sexual debut and early childbearing, that may modify the cancer-causing potential of HPV infection (144).

Cigarette Smoking

Several case–control and cohort studies, as well as collaborative pooled analyses and registry linkage studies, among groups of women infected with carcinogenic HPV have shown that smokers are at increased risk compared with infected women who do not smoke (145). Current smoking is the main risk factor, not past smoking, with no clear trend with time since stopping smoking. Among current smokers, evidence of increasing risk has been found with increasing intensity and duration (or early start) of smoking. Several investigations have attempted to define possible mechanisms by which smoking might alter the cervical epithelium (146). Some investigations have looked into measurement of tobacco-driven carcinogens such as polycyclic aromatic hydrocarbon–DNA adducts in cervical tissue of HPV-infected women (147). Tobacco-derived carcinogens are secreted into the cervix at levels higher than in serum, suggesting possible genotoxicity (147). The immunosuppressive effects of smoking may cause disturbance in the early immune responses or increase persistence through production of reactive oxygen species (148).

Nutrients

The influence of nutrient status on risk of cervical neoplasia has received substantial research attention. While dietary factors such as antioxidant micronutrient intake are likely important in cervical carcinogenesis, methodological difficulties prevent establishment of firm associations between a specific aspect of nutritional status and HPV infection or cervical cancer risk. A meta-analysis of case–control studies suggested preventive effects of micronutrients such as folic acid; vitamins B, C, and E; and β-carotene (149). However, lack of prospective studies and randomized trials preclude definitive evidence regarding the role of supplementation. The association of low folate levels and high homocysteine levels with risk of cervical cancer has led to interest in markers of one-carbon metabolism and DNA repair (119).

Infectious Agents Other Than HPV

HPV infection is known to be the central, necessary cause of cervical cancer, but other sexually transmitted agents could increase the risk of cervical cancer among HPV-infected women. Of the other agents examined, herpes simplex virus 2 was originally hypothesized to play a central role, but most attention now is focused on *Chlamydia trachomatis*. Although residual confounding by some aspect of HPV infection has not been completely ruled out, *C. trachomatis* seropositive women are at increased risk compared with seronegative women even after adjustment for HPV exposure using DNA tests and/or serology (150).

Women with HIV and AIDS have higher prevalence, incidence, and persistence of HPV infection and precancerous lesions, strongly associated with immunosuppression. It is also well established that the incidence of cervical cancer is increased severalfold in both women with HIV/AIDS and those who are iatrogenically immunosuppressed (e.g., organ transplant recipients), thus reinforcing the primary mediating role of immunosuppression in increasing this risk (151). The fraction of cancer attributable to HPV among HIV-infected women in the United States has been estimated to be 14.2%, compared with approximately 2.6% in the general female population (152). However, it is also hypothesized that interaction

between HPV and HIV in the affected cervical tissue leads to the persistence of HPV infection and cervical neoplasia by various other mechanisms including depletion of Langerhans cells (153), host immune response (154), or proinflammatory cytokine expression (155). An alternative explanation is at the cellular level; HIV-specific Tat protein upregulates expression of HPV E6 and E7 oncogenes and enhances their oncogenetic transformation efficacy (156). These two mechanisms are, however, not exclusive, and joint effects most likely take place at early precancerous stages.

Risk Factors for Cervical Adenocarcinoma

While infection with a carcinogenic HPV is a necessary cause of both squamous cell carcinomas and adenocarcinomas, the distribution of carcinogenic HPV types and variants detected in these two tumor types varies (157). Multiple studies suggest that HPV-18 accounts for a relatively higher percentage of adenocarcinomas as compared with squamous cell carcinomas, although more recent evidence points to an increasingly equitable role of HPV-18 as well as HPV-16 (121).

Interpreting rates for increased cervical adenocarcinomas over time pose challenges because of gradual improvements in clinical practices (including the use of devices to obtain better endocervical sampling), stricter criteria for adequate Pap tests, development of cytologic criteria for recognizing adenocarcinoma *in situ* (AIS), and, recently, formal inclusion of the AIS category in the new Bethesda System (158). In addition, proposed but unsubstantiated explanations for these upward trends include increased rates of HPV infection without improved cytologic detection of AIS, a specific increase in rates of HPV-18 infection, and increased exposure to HPV cofactors specific to adenocarcinoma.

Although our understanding of the etiology of cervical adenocarcinoma is incomplete, a picture is emerging in which adenocarcinoma seems to share most, if not all, risk factors with cervical squamous carcinomas (acquisition of HPV through sexual contact) and others with uterine carcinoma (more related to hormones). While adenocarcinoma has most risk factors in common with squamous cell carcinoma, an important exception is smoking, which does not seem to increase the risk for adenocarcinoma. In contrast, increased weight (or related measures) appears to be related to increases in the risk of cervical adenocarcinomas (159). Oral contraceptives and menopausal hormone therapy have been linked to an increased risk for AIS or adenocarcinoma. The increased risk of cervical adenocarcinoma associated with obesity and reduced risk with smoking resemble the epidemiology of endometrial adenocarcinoma. However, the relationship between cervical adenocarcinoma and oral contraceptives is more similar to reported results for squamous carcinomas of the cervix.

Conclusions

Knowledge of the epidemiology of HPV and its causal role in cervical carcinogenesis has been successfully translated into clinical practice (107,116), particularly to reduce rates of squamous lesions. In many developed countries, newer consensus guidelines now encourage cotesting with HPV DNA and cytology to improve screening performance and reduce screening intervals, since a negative result provides strong reassurance that immediate follow-up is not required and can reduce patient anxiety and health costs (107). Screening studies are underway to develop new optimized approaches that maximize resource utilization. New low-cost and point-of-care HPV tests are in the pipeline and may improve the feasibility and quality of cervical cancer screening in low-income countries. The management of HPV-positive women, however, remains a challenge. Finally, the increasing use of prophylactic HPV vaccines is expected to impact rates of cervical precancer in the coming years (even in the lowest income countries (160)), although reductions in cancer incidence will take longer. Epidemiologic research on HPV and cervical cancer will remain integral to clinical practice recommendations and to public health strategies that improve patient management and guide and monitor successes in cervical cancer prevention and control.

VULVAR CANCER

Demographic Patterns and the Importance of Pathologic Classifications

Carcinoma of the vulva accounts for 4% of gynecological malignancies worldwide. In the United States, the average annual age-adjusted incidence in all SEER areas during 2009 to 2013 was 2.4 per 100,000 women (2). During 2015, an estimated 5,150 women developed the disease and 1,080 died as a consequence of it in the United States (1). Contrary to cervical cancer, incidence rates for vulvar cancer are similar in all ethnicities, except in Asian women, who exhibit low rates (0.9 per 100,000). Slightly lower incidence rates than in the United States have been reported from several European countries, including Denmark, the United Kingdom, and Sweden, and in Australia (1.4 to 1.7 per 100,000, world standardized) (3). In other continents, vulvar cancer rates are generally equal to or lower than 1 per 100,000, and often below 0.3. Of note, very low rates are reported by cancer registries in Africa, Latin America, and India, where cervical cancer incidence and HPV prevalence are high (see section on Cervical Cancer). This unlikely discrepancy strongly suggests a substantial underreporting of vulvar cancer in low-resource countries.

Rates of vulvar cancer have remained relatively stable over the past three decades according to SEER data (2), but previously rare vulvar invasive and *in situ* carcinomas are now more common among younger women (161). Upward incidence trends in vulvar cancer among women below 50 or 60 years of age have also been observed in other countries, for example, Denmark (162).

HPV Infection

Vulvar cancer is etiologically heterogeneous (163). The majority of cases are squamous, with two subclassifications: basaloid and warty carcinomas, which are more frequently HPV-positive (~70%) than keratinizing (differentiated) squamous tumors (~13%) (164,165). Basaloid and warty carcinomas are also substantially more frequent in young women, particularly in North American studies. Carcinomas *in situ* of the vulvar are nearly always HPV-positive (~97%) (161) and so are vulvar intraepithelial neoplasias (VIN) grade 2 and 3 (165). HPV 16, in particular, is found in 48% of vulvar cancers and 81% of *in situ* carcinomas (161). HPV-positive VINs are often detected during cervical cancer screening (165). VIN 1 is considered condyloma and should be managed conservatively (166). Non-HPV-associated vulvar cancers are poorly understood but are often associated with chronic inflammatory states such as lichen sclerosus (167).

Risk Factors

Risk factors for vulvar cancer and VIN are mainly related to those linked to an increased probability of HPV infection, for example, number of sexual partners and immunosuppression. Cancer of the vulva, therefore, occurs significantly more frequently among women with primary cancers of the cervix (168), with the two diseases often detected simultaneously (169). Although the incidence of vulvar cancer was previously thought to be related to socioeconomic class, results from one case–control study indicated that control for sexual factors eliminated this effect (170). Several studies have suggested that a history of vulvar and anogenital warts is associated with an elevated risk of vulvar cancer (171). However, HPV-6 and HPV-11, the types that cause vulvar warts, are not genetically close to the major types found in vulvar cancers (predominantly HPV-16), so the exact relationship between warts and cancer is somewhat obscure. Genetic and local inflammatory factors may also be involved in the pathogenesis of VIN and vulvar cancer (172,173). Women living with HIV (151,174) or AIDS (151) have a strongly increased risk of vulvar cancer, and VIN 2 and VIN 3. The efficacy of HPV-6/11/16/18 vaccines against VIN 2/3 in HPV-naïve women (95%) or in by-intention-to-treat analyses (79%) (175) is similar to the efficacy against CIN 2 or worse lesions. In Costa Rica, equivalent protection of the HPV-16/18 vaccine was demonstrated against prevalent HPV-16/18 infection in the vulva and cervix (176).

Conclusions

Approximately half of vulvar cancer cases worldwide and 70% in the United States are caused by HPV infection, predominantly HPV-16. Despite similar etiology, vulvar cancer is much rarer than cervical cancer. While the epithelium of the entire anogenital tract can be infected by HPV, the transformation zone of the cervix is uniquely susceptible to HPV carcinogenesis (105). The recent discovery of a distinct population of cells of embryonic origin that cannot be found elsewhere in the lower anogenital tract may help explain the special vulnerability of the transformation zone (108). A favorable role of screening in vulvar cancer prevention is not clear, but prophylactic vaccines against HPV-16 and HPV-18 may prevent an even larger fraction of VIN 2/3 and HPV-related vulvar cancer than CIN 2/3 and cervical cancer.

VAGINAL CANCER

Demographic Patterns

Cancer of the vagina is rare, with an average annual age-adjusted incidence of 0.7 per 100,000 women in the SEER areas from 2009 to 2013 (2). During 2015, it was estimated that 4,070 women developed the disease and 910 died from it in the United States (1). The majority of vaginal cancers are squamous cell carcinomas and occur in the upper part of the vagina.

Only 15% of cases are found in women younger than 40 years and almost half of cases occur in women who are 70 years or older (177). The disease is twice as common in Black as in White women. Incidence rates similar to those in the United States are found in several European countries and some parts of sub-Saharan Africa, Brazil, India, and in indigenous populations in Canada and Australia (≥1 per 100,000). Rates of 0.1 per 100,000 or lower are reported by cancer registries in parts of China and the Middle East. Underreporting of vaginal cancer is likely to occur in low-resource countries; however, the international variation of the disease somewhat differs from that of vulvar cancer, probably because the disease is less frequently detected during cervical cancer screening (108).

Risk Factors

Vaginal cancer is frequently found as a synchronous or a metachronous neoplasm with cervical cancer, pointing to the role of HPV infection (178). An international meta-analysis reported HPV detection in 70% of vaginal cancers and 94% of vaginal intraepithelial neoplasias (VAIN) (165). A large study of archival tissue samples from the United States (179) showed 75% of vaginal cancers to be HPV-positive, with 55% HPV-16/18-positive. HPV-negative cancers were more frequent in women aged 65 years or older (39% vs. 19% below age 65) (179). While a vaccine targeting HPV-16/18 potentially could prevent the majority of vaginal cancers, direct information is not available, as VIN and less frequent VAIN lesions have been combined as efficacy endpoints in the available trials (180).

Diethylstilbestrol and Vaginal Clear Cell Adenocarcinomas

In the late 1960s, cases of clear cell carcinomas of the vagina, an uncommon cancer in any age group, began to be observed with much greater frequency than expected among women between 15 and 22 years of age. Most of these cases have been linked to prenatal exposure to diethylstilbestrol (DES) use, which was stopped in the United States in 1971 (181). A registry of clear cell cancers of the vagina and cervix was established, and many more cases have been reported (182), the vagina being affected about twice as frequently as the cervix. The rate for clear cell adenocarcinoma of the vagina and cervix through 39 years of age has been estimated to be 1.6 per 1,000 DES-exposed daughters (181), and an

increased risk of VAIN 3 and CIN 3 was also noted. When assessing a woman's cancer risk, whether her mother took DES in pregnancy might still be a relevant aspect of the medical history for women born during the period of DES use in pregnancy (181).

Conclusions

Less is known about risk factors for vaginal cancer than is known for vulvar cancer. It has recently been suggested that there may be two types of vaginal cancers with age-related etiology (183). In young patients, the etiology is strongly related to HPV infection, mainly HPV-16/18. HPV vaccination will therefore decrease the incidence of VAIN and vaginal cancer. The rare occurrence of vaginal adenocarcinoma in young women is distinctive in being essentially an iatrogenic disease related to *in utero* exposure to DES and other estrogens (181). A proposed mechanism involves nests of abnormal cells of Müllerian duct origin, which are stimulated by endogenous hormones during puberty and promoted into adenocarcinomas.

GESTATIONAL TROPHOBLASTIC DISEASES

Gestational trophoblastic diseases (GTDs) (which include hydatidiform moles, invasive moles, and choriocarcinoma) encompass a range of interrelated conditions characterized by abnormal growth of chorionic tissues with various propensities for local invasion and metastasis (184). Hydatidiform moles can be either complete or partial and have distinctive pathologies and etiologies. Complete moles have paternally derived nuclear DNA, but maternally derived cytoplasmic DNA. In contrast, partial moles generally have a triploid karyotype, with the extra haploid set of chromosomes being of paternal origin.

Demographic Patterns

Choriocarcinoma is a rare malignancy in the United States, with a reported incidence in all SEER areas of 0.1 per 100,000 women, or approximately 1 per 25,674 live births (185). Hydatidiform mole occurs about once in every 1,000 pregnancies, and approximately one of six occurrences results in invasive complications (either invasive mole or choriocarcinoma). Trophoblastic diseases have been reported to be more common in certain parts of the world, although some of the differences may be due to a variety of selection, detection, and reporting biases, including whether risk is expressed in relation to women at risk, conceptions, or live births. In the United States, incidence rates have declined over time, and survival has improved, but Blacks continue to have higher incidence and lower survival than women of other ethnicities.

The epidemiologic study of choriocarcinoma has been complicated by its relative infrequency. Most studies have, therefore, focused on defining risk factors for hydatidiform moles, but the extent to which these findings can be extrapolated to malignant trophoblastic disease is uncertain.

Host Factors

Trophoblastic disease rates are considerably higher in Asian and African countries, but the true extent of difference from rates in Western countries is difficult to decipher because of variations in reporting practices (184). In Europe and North America, the incidence of hydatidiform mole ranges from 0.57 to 1.1 per 1,000 pregnancies, whereas in Southeast Asia and Japan, the incidence is closer to 2.0 (186). Corresponding incidence rates in the two parts of the world for choriocarcinoma are 1 versus 9.3 per 40,000 pregnancies. These differences persist in migrants, with one study showing

that the incidence of GTDs in Asians was nearly twice as high as among non-Asians (187). One survey in the United States showed that, even after adjustment for age and birth distribution effects, Blacks had a 2.1-fold greater risk and other non-White races had a 1.8-fold greater risk than Whites (188). American Indians and Alaskan natives have also been shown to have high rates of GTDs (185).

One clearly established risk factor for choriocarcinoma and hydatidiform mole is maternal age. Women with extreme maternal ages (either very early or late) have nearly twofold elevated rates, with even further age differences noted for the occurrence of complete moles (187). The recent increase in incidence of GTDs in certain European countries has been attributed in large part to increases in maternal ages (189,190).

A history of hydatidiform mole is also a strong risk factor. The risk of another molar pregnancy in a subsequent conception is about 1% (184), and the risk appears to increase to about 15% to 20% in women who have had more than one previous hydatidiform mole. This risk does not appear to be altered with a change in male partners, suggesting an influence on oocyte defects of environmental factors (191). Familial clusters of biparental complete hydatidiform moles associated with novel missense *NLRP7* gene mutations on chromosome 19q have been identified (184). Hydatidiform mole is associated with a 1,000 to 2,000 times increased risk for development of subsequent choriocarcinoma, with an even further enhancement after a complete molar pregnancy (2,500 times higher than after a live birth).

Menstrual, Reproductive, and Anthropometric Risk Factors

In several studies that have adjusted for the effects of late maternal age, parous women have remained at a substantially reduced risk of GTD compared with nulliparous women, with some evidence of further reductions in risk with multiple births (192). A number of studies have found an increased risk associated with a prior spontaneous or induced abortion, although this has not been consistently observed (192). A history of infertility has also been suggested as a risk factor for GTD, although not confirmed in all studies (192). In one study, Chinese patients reporting the use of herbal medicines during the first trimester of a previous pregnancy were at elevated risk (192).

Low body mass, unrelated to dieting or exercise, has been reported as a risk factor for choriocarcinoma in one study (193). Patients also had later onset of menarche and lighter menstrual periods than controls, possibly reflecting lower estrogen levels.

Exogenous Hormones

Several studies have found an increased risk of trophoblastic diseases associated with long-term use of oral contraceptives (194). It has also been suggested that oral contraceptives may increase the risk of malignant sequelae after mole evacuation through a tumor-stimulating effect. However, more recent studies (as demonstrated by Costa and Doyle in a systemic review published in 2006) suggest no clear evidence for such an association, prompting the suggestion that practitioners should no longer avoid use of oral contraceptives during the postmolar follow-up period.

Conclusions

Although a genetic role in the development of hydatidiform mole is now certain, little is known about genotypes that predispose to hydatidiform mole or environmental factors that may increase the risk of defective ova. Except for the possible role of oral contraceptives, few potential environmental promoters have been examined.

The trophoblast plays an active role in pregnancy, including metabolizing and detoxifying xenobiotic substances, regulating nutrient and waste product transfer, synthesizing steroid and protein hormones, and controlling the immune response of the maternofetal unit. Injury to the trophoblast can occur in pregnancy as a result of environmental exposure

(e.g., heavy metals and polycyclic hydrocarbons), resulting in the breakdown of trophoblastic processes. When the trophoblast malfunctions, mutagenic, teratogenic, lethotoxic, and carcinogenic compounds gain access to the developing embryo, causing injury and death. The genotype of hydatidiform mole results in a trophoblast that malfunctions, and exposure to certain environmental agents during the molar pregnancy may promote choriocarcinoma. Before implantation, the trophoblast forms most of the embryonic tissue, which already metabolizes environmental agents. Even preimplanted moles, with their impaired metabolic capabilities, may increase the toxicity of environmental agents and promote carcinogenesis.

Recent advances in identifying genetic and molecular markers involved with partial versus complete moles (184) open a number of avenues for assessing the interaction of these markers with a variety of proposed environmental risk factors. This could include a focus on early stages in the disease process or on factors involved in the progression of molar pregnancies to more invasive complications.

SUMMARY

The goal of both medical practice and epidemiology is to reduce morbidity and mortality. For many diseases, the focus has turned to the ultimate aim of prevention. The link between identification of etiologic factors and possibilities for prevention is well illustrated for tobacco- and alcohol-related tumors and for those associated with specific pharmaceutical, radiogenic, and occupational exposures. Fortunately, for gynecologic cancers, there are a number of identified etiologic factors that are also amenable to preventive approaches.

Undoubtedly, the prospects for prevention are best for cervical cancer. For some time, secondary prevention in the form of screening for pathologic precursors of invasive disease has been the hallmark of the public health approach to this malignancy. The establishment of HPV as a central etiologic agent for the disease presents other avenues for prevention, including application of recently developed vaccines against the virus. Knowledge of when and how infection and other factors operate in the natural history of the disease has revolutionized screening strategies and shifted treatment from cell ablation to antiviral therapies. As always, combined laboratory, clinical, and epidemiologic research is needed to realize these propositions.

Many believe that more is known about the cause of endometrial carcinoma than for almost any other tumor. A unified theory of how all risk factors may operate through a final common estrogenic pathway is popular and well supported. A woman's hormonal milieu may prove to be favorable to modification at a practical level. There is substantial evidence that elimination of obesity and a reduction in fat in the diet—two interventions actively promoted for other reasons—should also reduce endometrial cancer risk. After the epidemic of endometrial cancer due to menopausal estrogen therapy, changes in the management of menopause occurred, resulting in a marked decline in the rates of endometrial cancer. More care is devoted to identifying women who truly need estrogen therapy, treatment of menopausal symptoms is for a much shorter period of time, the use of cyclic progestin in combination with estrogen is advised if indicated, and regular endometrial sampling is frequently practiced for long-term estrogen users.

Although past alterations in patient management led to a decline in endometrial cancer, current events make future patterns less clear. Previous enthusiasm for long-term treatment of large segments of the population of menopausal women with hormones to control symptoms and prevent osteoporosis and heart disease may have implications for endometrial cancer in the future. On the other hand, current patterns of use of oral contraceptives could lead to reductions in endometrial cancer rates in the general population. The impact of widespread oral contraceptive use at young ages on endometrial cancer risk at older ages is not well studied. However, if it is anywhere near the reduced risk seen at young ages, the resulting reduction in endometrial cancer overall could be substantial.

With further research, it is also possible that pharmacologic interventions aimed specifically at groups at high risk for endometrial cancer due to endogenous hormonal factors could be justified. More must be learned about the associations of risk for endometrial cancer and the quantitative levels of estrogens and other hormones and their relative proportions. Once

these factors are known, women with PCOS, diabetes, morbid obesity, or other predisposing conditions could be evaluated for unfavorable hormone profiles and appropriately targeted for treatment.

Although a substantial amount has been learned about ovarian cancer risks, the prospects for meaningful preventive measures aimed at this tumor are probably worse than for the other gynecologic malignancies. Although several ovarian cancer risk factors seem to indict ovulatory activity as a common pathway to increased risk, the mechanism by which this occurs is unknown. Even if some of the hypothesized mechanisms prove to be correct (e.g., levels of circulating gonadotropins), it is unclear how reasonable any interventions may be. However, if the long-term effect of oral contraceptive use on ovarian cancer risk is similar to its short-term effect, a substantial decline in ovarian cancer rates should result from pill use patterns of the past 40 years. Another reason for the limited prospects for prevention is that for several risk factors (e.g., protection associated with hysterectomy), no credible mechanism has been suggested. The associations promising the greatest opportunities for preventive actions are several recently suggested dietary relationships, specifically, decreased risks with consumption of diets high in fruits and vegetables and certain micronutrients. However, these observations need to be replicated in additional studies. Because of the preventive implications, attempts at confirmation should have high priority.

For cervical cancer, endometrial cancer, and ovarian cancer, much is known about the risk factors. Less is known about the precise biologic mechanisms through which the known risk factors operate. There is substantial enthusiasm for current interdisciplinary studies that incorporate state-of-the-art laboratory assays into robust epidemiologic research designs focused on answering these mechanistic questions. Even among some of the more conservative etiologists, there is a belief that the gynecologic oncologist may soon be able to intervene much earlier in the natural history of these diseases and, in some instances, engage in primary prevention.

CHAPTER 2 Molecular Pathogenesis of Gynecologic Cancers

Andrew Berchuck, Douglas A. Levine, Dariush Etemadmoghadam and David D. L. Bowtell

INTRODUCTION

An overview of the molecular pathogenesis of cancer is presented in the initial sections of this chapter. A more comprehensive discussion of this topic can be found in Part I of DeVita Hellman and Rosenberg's *Cancer: Principles and Practice of Oncology* (1). Genetic alterations involved in the development of gynecologic cancers are covered in more detail in the latter sections of this chapter.

The initiating events in human cancers are diverse, but malignant transformation is invariably caused by the development of genetic and epigenetic alterations that disrupt cell growth and death (**Table 2.1**). Several classes of genetic alterations are involved in carcinogenesis, including changes in the sequence of genes (mutations), gains (amplifications) or losses (deletions) in the number of copies of genes, and rearrangement and translocation of genes from their normal chromosomal locations that sometimes create new proteins by fusing the reading frames of genes. Mutations result in activation of genes that stimulate proliferation (oncogenes), inactivation of genes that inhibit proliferation (tumor suppressor genes), and impairment of programmed cell death (apoptosis). Disruption of DNA repair systems also often occurs in the process of malignant transformation and may lead to an accelerated accumulation of genetic alterations. Because repair of genetic damage inhibits carcinogenesis, many DNA repair genes are tumor suppressors, and some of the most notable inherited cancer susceptibility genes are involved in DNA repair.

TABLE 2.1 Molecular Alterations Involved in Cancer Pathogenesis

Genetic changes
Mutations
Mutations in oncogenes change a single amino acid and lead to gain of activity that stimulates proliferation. These mutations are dominant and not dependent on changes in the other copy of the gene
Mutations in tumor suppressor genes and DNA repair genes generally are small base insertions/deletions or single base changes that cause stop codons. These lead to truncated protein products that are nonfunctional. Loss of tumor suppressor activity is usually dependent on deletion of the other copy of the gene
Driver mutations play a critical role in the process of malignant transformation
DNA copy number changes

Deletion of one or both copies of a tumor suppressor gene due to genomic instability leads to loss of a gene product
Gain of additional copies of an oncogene leads to increased activity
Aneuploidy with gain or loss of complete chromosomes is common in many cancers
Gene rearrangements and translocations
When a gene is moved from its normal location to another chromosomal location, its expression may be increased due to proximity to a gene promoter or due to fusion of two genes
Clonal evolution
The genomic landscape of most cancers continues to evolve over time and space and the alterations observed in most cancers are often not present in all of the malignant cells
Other biologic processes
Epigenetic alterations
Hypermethylation of CpG islands in the promoter regions of tumor suppressor genes may lead to their inactivation
Loss of promoter methylation in genes that stimulate proliferation may provide an oncogenic stimulus
Changes in acetylation of histone proteins that coat DNA may play a role in carcinogenesis
Aberrant gene splicing
Alternative splice forms of genes may produce messenger RNAs and proteins with altered activity
Noncoding RNAs
Noncoding RNAs regulate gene expression, and their aberrant expression likely plays a role in the development and behavior of some cancers

Most transforming mutations in oncogenes alter a single amino acid at specific codons that produce overactive protein products (e.g., *KRAS*, *BRAF*), and only one allele needs to be mutated. In contrast, inactivation of tumor suppressors (e.g., *RB1*, *BRCA1*) requires loss of both copies of the gene (two hits). Mutations in tumor suppressors may occur throughout the gene and are usually small insertions, deletions, or base substitutions that alter the reading frame and thereby result in truncated protein products. Loss of the second nonmutated allele generally occurs due to chromosomal deletion, leading to abrogation of tumor suppressor activity. Some tumor suppressors are inactivated by methylation of their promoters, such as *MLH1*. Cancers may have many genetic alterations, but only a small fraction of these are “driver” mutations that are responsible for malignant transformation. The majority of mutations are “passenger” events, arising through carcinogen exposure and/or genetic instability, and do not contribute to tumor growth.

Changes in gene expression due to epigenetic alterations (DNA methylation and acetylation), aberrant gene splicing, noncoding regulatory RNAs, and other mechanisms also contribute to the malignant phenotype. The histopathologic progression through hyperplasia, dysplasia, carcinoma *in situ*, and invasive carcinoma reflects the multistep, multigenic nature of malignant transformation. While some mutational changes are sequential, it is now apparent that the evolution of most cancers follows a branching pattern, akin to speciation, resulting in the generation of clonally diverse, genetically distinct populations within the patient. Cancers may arise through the accumulation of acquired (somatic) alterations or through the inheritance of an alteration in the germline followed by the acquisition of additional somatic alterations. Hereditary cancers are discussed in detail in Chapter 3.

The techniques used to study genetic alterations have evolved dramatically. Advances in the 1980s and 1990s enabled the discovery of several genes that frequently play a role in the development of cancers, including the *KRAS* and HER-2/*neu* oncogenes and the *TP53* and *RB1* tumor suppressor genes. It became apparent that the spectrum of driver alterations varies considerably between cancer types, and among cancers of the same type (2). More recently, powerful new technologies have enabled comprehensive genomic studies. The Human Genome Project was completed in 2004 and provided a road map of the entire genome, including the approximately 18,000 protein-encoding genes. The HapMap project then catalogued the millions of common single nucleotide polymorphisms (SNPs) in the genome that vary at a single base in the DNA sequence between individuals. More recently, the 1000 Genomes Project has characterized rarer germline genetic variants. Large genome-wide association studies (GWAS), often involving thousands of cases and controls, have become a powerful approach for finding risk alleles that individually may have a small impact but that may interact additively or synergistically to increase an individual's genetic risk.

A road map of normal human genetic variation and the development of faster and cheaper "next generation" DNA sequencing have allowed mutational analysis of complete cancer genomes. Cancers typically have a mutation rate in the order of 1 to 10 (median of ~3) mutations per megabase (Mb), although the frequency varies over several orders of magnitude between tumor types (https://dcc.icgc.org/projects/summary). For example, mutation rates are generally high in lung cancer (median >10 mutations per Mb) and melanoma (median >60 mutations per Mb), due to exposure to tobacco smoke and UV light, respectively, whereas many pediatric tumors have few mutations (median <0.1 mutations per Mb in neuroblastoma). A small number of genes are mutated in a high fraction of cancers (e.g., *KRAS*, *TP53*), likely reflecting the strong selective advantage these alterations confer. A much larger number of genes are mutated at considerably lower frequencies. The terms "mountains" and "hills" have been used to describe genes that are commonly mutated versus rarely mutated in various types of cancers (2). Mutations in common cancers typically target multiple biological pathways, whereas some rare cancers have single dominant drivers in a majority of patients, such as ubiquitous *FOXL2* mutations in granulosa cell tumors. Several genes in a pathway may be mutated, but driver mutations in a pathway are often mutually exclusive when they involve the same pathway, as there may be little selective advantage to activating a given pathway multiple times (e.g., *KRAS* and *BRAF*).

The Cancer Genome Atlas (TCGA) Project, sponsored by the National Cancer Institute, has performed a comprehensive genomic characterization of common forms of human cancer and more recently initiated several rare tumor projects. Ovarian and endometrial cancers were among the first to be studied by TCGA and these findings have been incorporated into this chapter. The International Cancer Genome Consortium (ICGC) performed similar genomic analyses of human cancers. Both TCGA and ICGC have deposited their data online in the public domain to stimulate further research. The full spectrum and complexity of the genomic alterations in a single cancer can be best captured in a Circos plot (**Fig. 2.1**), which uses a circular ideogram layout to facilitate the display of changes across the genome.

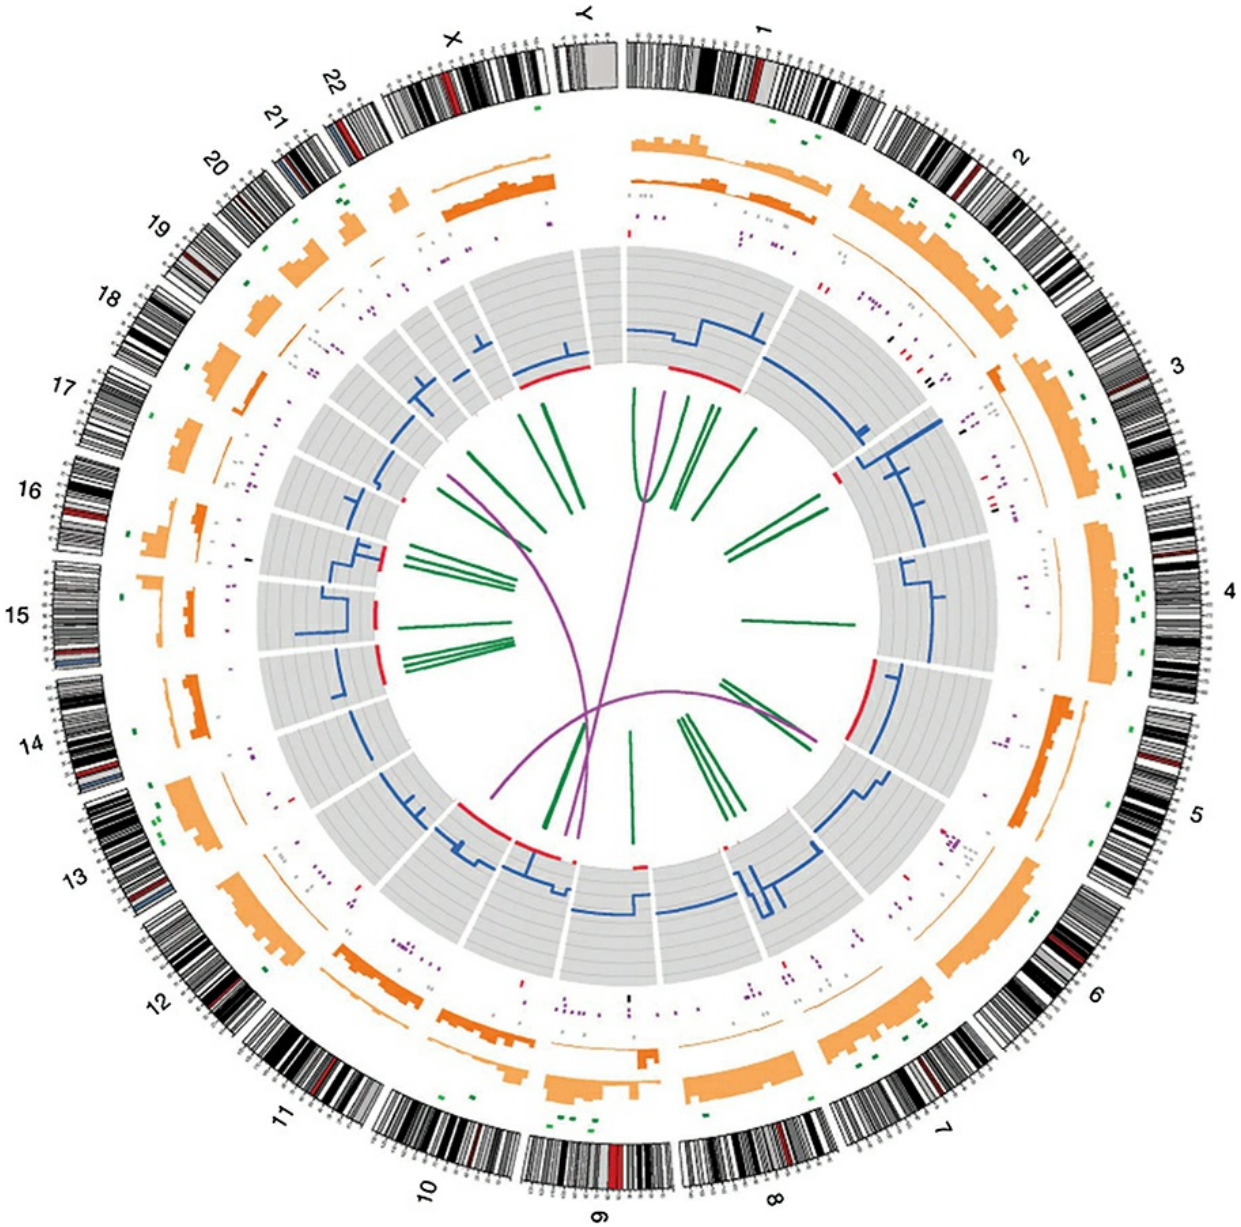

Figure 2.1 Circos plot of somatic mutations in COLO-829. Chromosome ideograms are shown around the outer ring and are oriented pter-qter in a clockwise direction with centromeres indicated in red. Other tracks contain somatic alterations (from outside to inside): validated insertions (light green rectangles); validated deletions (dark green rectangles); heterozygous (light orange bars) and homozygous (dark orange bars) substitutions shown by density per 10 Mb; coding substitutions (colored squares: silent in gray, missense in purple, nonsense in red, and splice site in black); copy number (blue lines); regions of loss of heterozygosity (LOH) (red lines); validated intrachromosomal rearrangements (green lines); validated interchromosomal rearrangements (purple lines). Reprinted by permission from Macmillan Publishers Ltd: Pleasance ED, Cheetham RK, Stephens PJ, et al. A comprehensive catalogue of somatic mutations from a human cancer genome. Nature. 2010;463(7278):191. [PMID: 20016485], copyright 2010.

Large-scale profiling studies provide the opportunity to perform Pan-Cancer (PANCAN) analyses to define common and distinct mutation events or patterns across cancer types (3,4). For example, analysis of base substitutions has revealed signatures associated with underlying oncogenic mutational processes. These studies have shown that the most common signature across cancer types is associated with older age at diagnosis and is characterized by a prominence of C>T substitutions at a specific trinucleotide context (NpCpG). Other signatures associated with specific mutagenic exposures

(e.g., UV radiation and smoking) have also been defined (5). Integrated sequence and copy number analysis have been used to characterize cancers driven by high levels of recurrent mutations (M-class), such as renal clear cell and colorectal cancers, in contrast to those characterized predominantly by copy number alterations (C-class), including breast and high-grade serous ovarian cancers (6). PANCAN analyses are further accelerating a reclassification of cancer, from one that is based on anatomy to a molecular description. These studies are highlighting unexpected molecular similarities between anatomically distinct tumors, such as the striking similarity between high-grade serous ovarian cancer and basal-like breast cancer.

An understanding of the molecular pathogenesis of cancer provides the opportunity to better define subgroups within a given type of cancer that may differ with respect to clinical behavior and survival (7). The identification of specific mutations has facilitated the development of therapies that target these alterations. In this regard, monoclonal antibodies and small molecules targeting aberrantly expressed cellular proteins that drive malignant growth have been successful in treating some cancers (2). The evolution of Food and Drug Administration–approved targeted therapies has been accompanied by the requirement for companion diagnostic tests that demonstrate the presence of the specific alteration being targeted (e.g., HER-2/*neu* amplification/overexpression guides use of trastuzumab in breast cancer, and *BRAF* V600E mutation guides use of vemurafenib in melanoma).

Unfortunately, most metastatic gynecologic cancers have not proven amenable to targeted therapy because their growth is not driven by a single altered gene or pathway. A notable recent exception is the development of polyADP ribose polymerase (PARP) inhibitors in *BRCA1/2*-mutated ovarian cancers. Germline genetic testing of *BRCA1/2* in high-grade epithelial ovarian cancers has been driven in the past by a strong family history of breast/ovarian cancer. However, with the advent of PARP inhibitor therapy for cancers with these mutations, it may become increasingly common to perform mutational analysis in tumor tissue with reflex germline testing in cases found to have a *BRCA1/2* mutation. This allows for the detection of both somatic and germline mutations in these genes. A similar paradigm shift may occur in other cancer types in which both somatic and germline alterations may have relevance for genetic risk assessment as well as therapy.

The utility of testing for common “druggable” driver mutations is now well accepted in many tumor types. With the evolution of genomic technologies, it is now feasible to test cancers for mutations in all of the genes that are potentially targetable. In a small fraction of cases, this approach will identify actionable mutations that are not frequent in that type of cancer. However, the clinical benefit of this approach in improving survival remains uncertain and must be balanced against the high cost of targeted therapies. The value of this new paradigm is presently being explored in the context of “match” or “basket trials” in which eligibility is based on the presence of the target rather than the anatomic origin of the cancer (8). Successful therapy may therefore require the use of multiple agents that target more than one gene or pathway. A more detailed description of targeted cancer therapies is provided in Chapter 12[1].

Resistance to targeted therapies often occurs due to mutational heterogeneity both within the primary tumor and in metastases as clonal evolution develops over time. Cancers are continually evolving due to genetic instability and contain subclones that differ with respect to their mutational profile. Intratumoral heterogeneity can vary across metastatic sites (spatial variation) and during treatment and disease progression (temporal variation). By analogy with the shape of a tree, mutations that occur early in the development of a cancer before metastasis occurs, such as *TP53*, are called “trunk” mutations and are found across metastases. In contrast, mutations that occur late in the development of a cancer, so-called “branch” mutations, are present in a minority of tumor sites. The presence of clonal and subclonal mutations in many patients has implications for the accuracy of molecular diagnostics that rely on biopsy and evaluation of single sites in the patient. Analysis of mutations in circulating tumor cells in the blood or in DNA released into the blood from dying tumor cells may provide a more accurate representation of the molecular events present in a patient than relying on a single metastatic site (9). The presence of intratumoral heterogeneity also has implications for personalized medicine approaches that match mutational events or “actionable mutations” to specific therapeutics. Heterogeneity between clones influences sensitivity to drugs and facilitates tumor adaptation through selection and outgrowth of resistant clones, ultimately leading to treatment failure. Strategies to monitor tumor cell evolution throughout treatment would further elucidate subclonal

variation, patterns of tumor evolution, and potentially improve clinical care using targeted therapies.

Finally, an increased understanding of the molecular pathogenesis of cancers provides the opportunity for early detection and prevention. This has been realized for cervical cancer with the identification of the human papillomavirus (HPV) leading to creation of a vaccine. In ovarian and endometrial cancers, identification of germline genetic alterations such as in *BRCA1* or *BRCA2* that dramatically increase risk facilitates the use of prophylactic surgery and/or screening. In addition, genetic changes that occur early in the development of cancers have the potential to serve as biomarkers for early detection and as surrogate endpoints in prevention studies. For example, it has been shown that common pathogenic mutations in endometrial and ovarian cancers can be detected in DNA from liquid Pap smears in a high fraction of cases (10). This may represent a promising step toward a broadly applicable screening methodology for the early detection of gynecologic malignancies.

CELLULAR GROWTH AND DEATH

Proliferation

The number of cells in normal tissues is tightly regulated by a balance between cellular proliferation and death. The final common pathway for cell division involves distinct molecular switches that control cell cycle progression from G1 to the S phase of DNA synthesis. These include the Rb and E2F proteins and their various regulatory cyclins, cyclin-dependent kinases (cdks), and cdk inhibitors. The events that facilitate progression from G2 to mitosis and cell division are regulated by other cyclins and cdks (**Fig. 2.2**), as well as by molecules involved in chromosomal segregation such as microtubules. When the chromosomes do not separate properly, aneuploidy may occur with gain or loss of complete chromosomes. Aneuploidy is a hallmark of many cancers and likely plays a role in their development and progression.

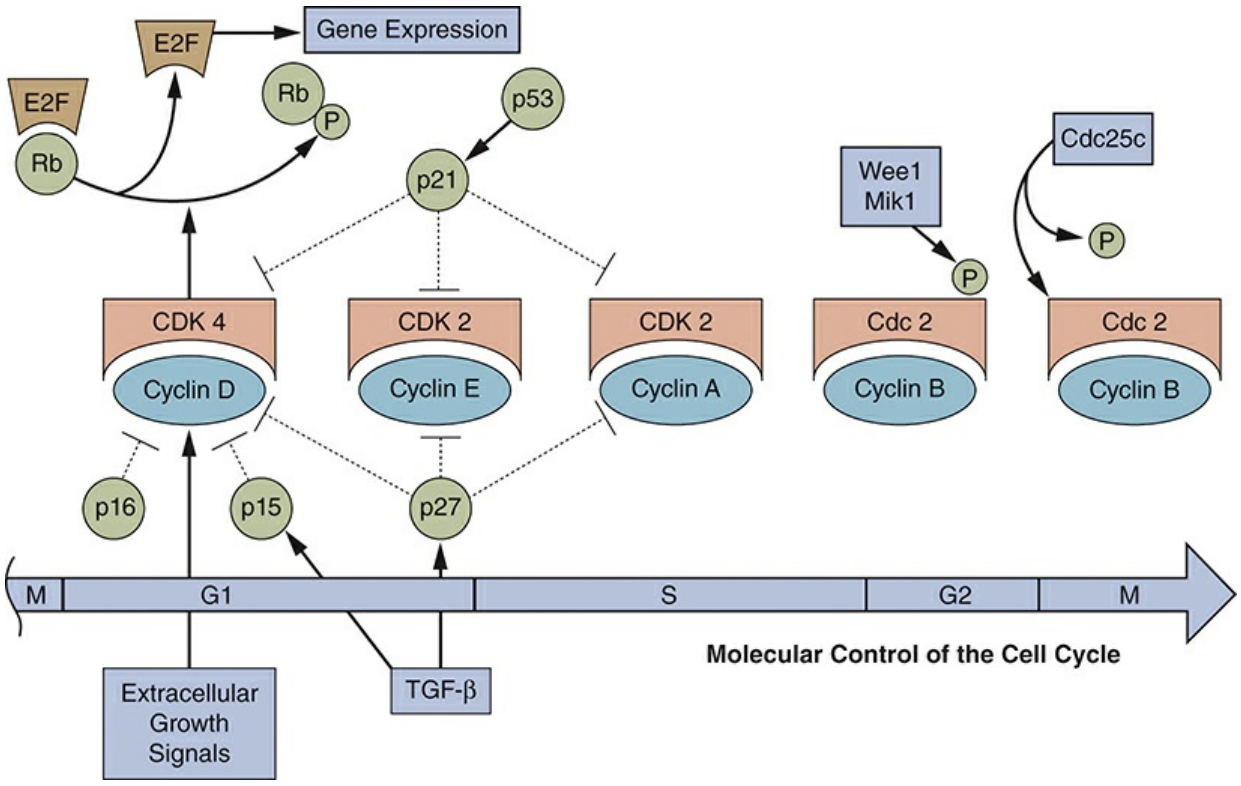

Figure 2.2 Molecular control of cell cycle progression. A linear version of the various stages of the cell cycle is shown with the various cyclin/cyclin-dependent kinase complexes corresponding to the stages that they control. CDK, cyclin-dependent

kinases.

Cell cycle progression is also dependent on ubiquitin-mediated proteolysis of molecules involved in cell cycle arrest. Ubiquitin is a 76 amino acid polypeptide that can be linked to lysine residues of proteins, and ubiquitination marks proteins for proteolysis and destruction by the proteasome complex. Proteasome inhibitors have been successfully employed to treat some hematologic malignancies, and the *FBXW7* (*CDC4*) ubiquitin ligase has been shown to be mutated in some uterine cancers.

In some tissues—such as the bone marrow, epidermis, and gastrointestinal tract—the life span of mature cells is relatively short and high rates of proliferation are required to maintain the population, whereas in other tissues—such as liver, muscle, and brain—cells are long lived and proliferation rarely occurs. Complex molecular mechanisms have evolved to closely regulate proliferation. These involve a finely tuned balance between growth stimulatory and inhibitory signals.

Increased proliferation is one of the hallmarks of cancer. There may be increased activity of genes involved in stimulating proliferation (oncogenes) and/or loss of growth inhibitory (tumor suppressor) genes. In the past, it was thought that cancer might arise solely because of more rapid proliferation or a higher fraction of cells proliferating. It is now clear that this was an overly simplistic view. Although increased proliferation is a characteristic of many cancers, the fraction of cancer cells actively dividing and the time required to transit the cell cycle is not always strikingly increased. Altered regulation of proliferation is only one of several factors that contribute to malignant transformation.

Cell Death

In addition to being driven by increased proliferation, growth of a cancer may be attributable to cellular resistance to death. At least three distinct types of cell death pathways have been characterized, including apoptosis, autophagy, and necrosis.

Apoptosis

The term “apoptosis” derives from Greek and alludes to a process akin to leaves dying and falling off a tree. Apoptosis is an active energy-dependent process that involves cleavage of the DNA by endonucleases and proteins by proteases called caspases. Morphologically, apoptosis is characterized by condensation of chromatin, nuclear and cytoplasmic blebbing, and cellular shrinkage, which is followed by phagocytic destruction. The molecular events that effect apoptosis in response to various stimuli are complex and have only been partially elucidated, but several reliable markers of apoptosis have been discovered including annexin V, caspase-3 activation, and DNA fragmentation.

External stimuli such as tumor necrosis factor (TNF), TNF-related apoptosis-inducing ligand (TRAIL), Fas, and other death ligands that interact with cell surface receptors can induce activation of caspases and lead to apoptosis via the extrinsic pathway. The intrinsic apoptosis pathway is activated in response to a wide range of stresses including DNA damage and deprivation of growth factors. The intrinsic apoptosis pathway is regulated by a complex interaction of pro- and antiapoptotic proteins in the mitochondrial membrane that affect its permeability. Proteins that increase permeability allow release of cytochrome *c*, which activates the apoptosome complex leading to activation of caspases that effect apoptosis. Conversely, proteins that stabilize mitochondrial membranes inhibit apoptosis. The first major insight that led to the understanding of the intrinsic apoptosis pathway was the finding that an activating translocation of the *BCL-2* gene in B-cell lymphomas results in essentially complete inhibition of apoptosis. Subsequent studies demonstrated that the antiapoptotic effect of *BCL-2* is attributable to stabilization of the mitochondrial membrane. Additional genes related to *BCL-2*, such as *BAD*, *BCL-XL*, and others, also block apoptosis by inhibiting membrane permeability. Other genes in the *BCL* family, such as *BAX* and *BAK*, increase membrane permeability and are proapoptotic. An understanding of the complex system of checks and balances involved in regulation of apoptosis provides opportunities for the development of targeted therapies.

Apoptosis is an ongoing process to balance the birth of new cells, thereby restraining the number of cells in normal

tissues. In addition, apoptosis serves an important role in preventing malignant transformation by allowing for elimination of cells that have incurred genetic damage. Following exposure of cells to mutagenic stimuli, including radiation and carcinogenic drugs, the cell cycle is arrested so that DNA damage may be repaired. If DNA repair is not sufficient, apoptosis occurs so that damaged cells do not survive. This serves as an anticancer surveillance mechanism by which mutated cells are eliminated before they proliferate or become fully transformed. The *TP53* tumor suppressor gene is a critical regulator of cell cycle arrest and apoptosis in response to DNA damage. Many of the molecules involved in apoptosis reside in the mitochondria and are encoded by mitochondrial DNA. Mutations in mitochondrial DNA have been shown to be frequent in cancer and may play a role in evasion of apoptosis.

Necrosis

Necrosis is a type of cell death that is distinct from apoptosis and is the result of bioenergetic compromise or external insult such as infection or trauma. Morphologic changes include swollen organelles and rupture of the cell membrane leading to loss of osmoregulation and cellular fragmentation. Necrosis is an unregulated process that leads to spillage of protein contents, and this may incite a brisk immune response. This is in contrast to the silent elimination of cells by apoptosis, which typically elicits a minimal immune response. There is evidence that some drugs may enhance necrotic death in tumors and this may stimulate a beneficial antitumor immune response.

Autophagy

Autophagy is a potentially reversible process in which a cell that is stressed eats itself. A wide range of stresses have been identified that may elicit autophagy (some of which may also elicit apoptosis), including growth factor deprivation and accumulation of reactive oxygen species. Unlike necrosis and apoptosis, in which loss of integrity of the cytoplasmic and nuclear membranes, respectively, are defining events, autophagy is characterized by the formation of cytoplasmic autophagic vesicles into which cellular proteins and organelles are sequestered. This may allow for cell survival if damaged organelles can be repaired. Conversely, the process may lead to cell death if these vesicles fuse with lysosomes with resultant degradation of their contents. Because autophagy may result in cell destruction or survival, it has both positive and negative effects on the development and treatment of cancers. For example, autophagy may result in the elimination of cancer cells, or conversely provide a survival mechanism for a cancer cell that has been damaged by chemotherapy or radiation.

Cellular Senescence

Normal cells are only capable of undergoing division a finite number of times before becoming senescent and this represents a barrier to immortality. Senescence can also be triggered by stresses such as oncogene activation. Induction of senescence is mediated by persistent p16 and p53 activation leading to permanent cell cycle arrest. Cellular senescence is regulated by a biological clock related to progressive shortening of repetitive DNA sequences (TTAGGG) called telomeres that cap the ends of chromosomes. Telomeres are involved in chromosome stabilization and in preventing recombination and chromosomal translocations and aneuploidy during mitosis. At birth, chromosomes have long telomeric sequences (150,000 bases) that become progressively shorter by 50 to 200 bases each time a cell divides. Telomerase is a ribonucleoprotein complex. The RNA component serves as a template for telomere extension, and the protein subunit acts to catalyze the synthesis of new telomeric repeats.

Replicative senescence serves as a defense against immortalization and malignant transformation by placing limits on proliferation of cells that have accumulated genetic damage. Reactivation of telomerase is critical to the emergence of cancers, but early in the process of malignant transformation, telomere shortening and dysfunction may promote the carcinogenic process through the generation of chromosomal rearrangements and aneuploidy. Progressive telomere

shortening during adulthood may explain the association between advancing age and increased cancer risk, particularly for epithelial malignancies. Cancer risk has been mainly attributed to progressive accumulation of mutations with aging, but this theory does not explain the marked aneuploidy of most epithelial cancers.

Telomerase activity is present in a high fraction of many cancers, including ovarian, cervical, and endometrial cancers. It has been suggested that detection of telomerase might be useful for early diagnosis of cancer, but it is also found in some normal adult tissues including endometrium. Perhaps this relates to the need for a large number of lifetime cell divisions because of rapid growth and shedding of endometrial tissue each month during the reproductive years. Therapeutic approaches to inhibiting telomerase are under development that would reverse the immortalized state of cancer cells and render them susceptible again to normal replicative senescence.

Stem Cells

Stem cells in normal tissues have the capacity to undergo asymmetric division to produce daughter cells that undergo differentiation and eventually senescence and can self-renew to produce more stem cells. Stem cells have been most easily identifiable in tissues that normally are highly proliferative, such as the bone marrow, skin, and intestine, in which a constant stream of cells are being born to replace those that are differentiating and dying. It has been theorized that stem cells exist in cancers and have the capacity for self-renewal and differentiation into populations of cells that recapitulate tumor heterogeneity. Stem cells are also referred to as tumorigenic cells because of their capacity to regenerate tumors. The stem cell theory suggests that less than 1% of cells in a cancer are stem cells and that by virtue of being dormant or quiescent, they may be relatively resistant to chemotherapy and radiation. It is postulated that cancer stem cells may persist as microscopic disease after eradication of most cancer cells and give rise to recurrent disease. There has been great interest in identifying and characterizing cancer stem cells, as this could facilitate the development of targeted therapies.

Several molecular markers have been identified that define cancer stem cells, including the cell membrane glycoprotein CD133 (Prominin). Expression of CD133 has been associated with greater proliferative potential and ability to form tumors in animal models. CD44 is the receptor for hyaluronic acid and has been identified as a stem cell marker in several cancer types. CD117, also known as c-kit, is another well-characterized stem cell marker that has been implicated in several solid tumors. CD24 is a mucin-like cell surface glycoprotein marker that has been identified as a stem cell marker, as has aldehyde dehydrogenase. The Notch, Sonic Hedgehog, and WNT pathways have also been implicated in stem cell behavior.

Although expression of the markers and pathways, described earlier, in cancers has been associated with stem cell characteristics, the existence of discrete cancer stem cell populations has not been definitively proven. It is possible that the genes and pathways involved in cellular renewal are simply more highly expressed in a fraction of cells within heterogeneous tumors (11). Cancer stem cells may exist in some malignancies but not others. In this regard, demonstration of progenitor stem cells has been more robust in leukemias than in solid tumors.

ORIGINS OF GENETIC ALTERATIONS

Human cancers arise due to a series of genetic alterations that lead to disruption of normal mechanisms that govern cell growth, death, and senescence. Genetic damage may be inherited or may arise after birth due to various exposures including those related to carcinogenic substances such as tobacco and asbestos, physical factors such as ultraviolet radiation, infections such as HPV, dietary factors, obesity, and inflammation. However, much of the acquired genetic damage that causes cancer is due to endogenous mutagenic processes within the cell (**Table 2.2**). The incidence of most cancers increases with aging because the longer one is alive, the higher the likelihood of a cell acquiring sufficient damage to become fully transformed. It is thought that at least three to six alterations are required to fully transform a cell.

TABLE 2.2 Origins of Genetic Damage in Human Cancers	
Type of Genetic Damage	**Examples**
Germline alterations	
High-penetrance genes	BRCA1, BRCA2 (breast, ovarian cancers) MLH1, MSH2 (Lynch syndrome)
Moderate-penetrance genes	RAD51C/D, BRIP1 (ovarian cancer)
Low-penetrance genes	SNPs associated with various cancers
Exogenous carcinogens	
Ultraviolet radiation	TP53 mutations in skin cancers
Tobacco	TP53 mutations in lung cancers
Viruses	HPV inactivation of RB and TP53 in cervical cancer
Endogenous DNA damage	
Cytosine methylation and deamination	TP53 mutations in many cancer types
DNA hydrolysis	Various genes
Spontaneous errors in DNA synthesis	Various genes
Free radical production due to oxidative stress	Various genes?

Inherited Cancer Susceptibility

Although most cancers arise sporadically due to acquired genetic damage, inherited mutations in cancer susceptibility genes are responsible for some familial cases. The age of cancer onset is younger in these families and it is not unusual for individuals to be affected with multiple primary cancers. Tumor suppressor genes and DNA repair genes have been implicated most frequently in hereditary cancer syndromes. The most common forms of hereditary cancer syndromes predispose to breast/ovarian (*BRCA1/2* genes) and colon/endometrial (DNA mismatch repair [MMR] genes) cancers. Although affected individuals carry the germline alteration in every cell of their bodies, paradoxically, cancer susceptibility genes are characterized by a limited repertoire of cancers. The penetrance of cancer susceptibility genes is incomplete, as all individuals who inherit a mutation do not develop cancer. The emergence of cancers is dependent on the occurrence of additional genetic alterations. Hereditary cancer syndromes are covered in detail in Chapter 3.

In addition to the high-penetrance mutations, noted earlier, that cause familial cancer syndromes, low-penetrance genetic variants may also affect cancer susceptibility, albeit less dramatically. There are over 10 million polymorphic genetic loci in the human genome. Most of these are SNPs, in which there is variation in the nucleotide at a chromosomal location (e.g., C vs. A). Many SNPs are relatively common, with the rarer of the two alleles occurring in more than 5% of individuals. GWAS have discovered over 20 SNPs that affect the risk of ovarian cancer by 10% to 50% per rare allele copy. The discovery of these common, low-penetrance-risk SNPs has been facilitated by the development of an international ovarian cancer association consortium (OCAC) that includes over 75 studies from around the world, with over 70,000 ovarian cancer cases and controls. These risk SNPs are not located within genes, but rather in regulatory regions of the genome where they are thought to play a role in regulating gene expression. A more complete understanding of the genetic factors that affect cancer susceptibility could facilitate implementation of screening and prevention approaches in subsets of the population at increased risk.

Acquired Genetic Damage

The etiology of acquired genetic damage in cancers has also been elucidated to some extent. For example, a strong causal link exists between cigarette smoke and cancers of the aerodigestive tract, between ultraviolet radiation and skin cancer, and between HPV and lower genital tract cancers (**Table 2.2**). For many common forms of cancer (e.g., colon, breast, prostate, endometrium, ovary), there is not a strong association with specific carcinogens. It is thought that the genetic alterations responsible for these cancers may arise mainly due to endogenous mutagenic processes. This includes methylation and deamination of cytosine residues leading to transition mutations to thymidine. In this regard, in most types of cancers that are not associated with a specific carcinogen, transition mutations from purine to purine (A/G) or pyrimidine to pyrimidine (C/T) are much more common than transversion mutations that change purine to pyrimidine (A/G to C/T) or pyrimidine to purine (C/T to A/G). An additional mechanism of endogenous damage includes spontaneous errors in DNA synthesis that frequently occur during the process of DNA replication associated with normal proliferation. Free radicals generated in response to inflammation and other cellular damage may also cause DNA damage. These endogenous processes are thought to produce mutations on an ongoing basis. Several networks of highly effective DNA damage surveillance and repair genes exist, but some mutations may elude them. The efficiency of these DNA damage response systems varies between individuals due to genetic and other factors and may affect susceptibility to cancer.

Epigenetic Changes

Epigenetics comprises heritable changes that are not due to alterations in DNA sequence. Methylation of cytosine residues that reside next to guanine residues (CpG dinucleotides) is the primary mechanism of epigenetic regulation, and this process is regulated by a family of DNA methyltransferases. CpG dinucleotides are asymmetrically distributed with about half of human genes containing CpG-rich regions termed “CpG islands” at their transcriptional start sites. Most genes are regulated without changing the methylation status of the CpG sites, but permanent silencing of genes associated with X-chromosome inactivation and genomic imprinting is due to heritable methylation of CpG islands.

Most cancers have globally reduced DNA methylation, hypomethylation, which may lead to activation of some genes. Conversely, selective hypermethylation of CpG islands in the promoter regions of tumor suppressor genes may lead to gene inactivation (e.g., *BRCA1*, *MLH1*). In addition, loss of silencing of imprinted genes that stimulate proliferation, such as *IGF2*, may provide an oncogenic stimulus. Acetylation and methylation of the histone proteins that coat DNA represent another level of epigenetic regulation that is altered in cancer. Alterations in activity of DNA methyltransferases are likely the underlying cause of epigenetic alterations in cancers.

Alterations in Signal Transduction Pathways in Malignant Transformation

Alterations in genes that stimulate cellular growth (oncogenes) can cause malignant transformation when they become overactive. Oncogenes may become overactive when affected by gain of function point mutations. In some cancers, amplification of oncogenes occurs with resultant overexpression of the corresponding protein. Instead of two copies of one of these genes, there may be many additional copies. Finally, oncogenes may be translocated from one chromosomal location to another and come under the influence of gene promoters that actuate overexpression. This latter mechanism frequently occurs as a driving event in the development of leukemias and lymphomas, but is much less frequent in gynecologic cancers. However, some other types of solid tumors may have translocations that represent significant driver events, such as those involving the *ALK* receptor gene in lung cancer. These cancers have been targeted successfully with the monoclonal antibody crizotinib.

Loss of tumor suppressor gene function also plays a role in the development of most cancers. This usually involves a two-step process in which both copies of a tumor suppressor gene are inactivated: mutation of one copy of a tumor suppressor gene and loss of the other copy due to deletion of a chromosome segment where the gene resides (e.g., *RB1*). There is also evidence that some tumor suppressor genes may be inactivated due to methylation of the promoter region of

the gene (e.g., *MLH1*, *BRCA1*). The promoter is an area proximal to the coding sequence that binds transcription factors that regulate whether or not the gene is transcribed from DNA to RNA. When the promoter is methylated, it is resistant to activation and the gene is essentially silenced despite remaining structurally intact. This two-hit paradigm of tumor suppressor gene inactivation is relevant to both hereditary cancer syndromes, in which one mutation is inherited and the second acquired, and to sporadic cancers, in which both hits are acquired.

The sections below will review the role of oncogenes and tumor suppressor genes in signal transduction pathways that regulate cellular growth and metabolism. These pathways are complex and have considerable overlap and redundancy, and an exhaustive discussion is beyond the scope of this book. Pathways for which there is less evidence of a role in driving the development of gynecologic cancers, such as the Hedgehog, Notch, and cytokine pathways, are not covered.

Peptide Growth Factors and Receptor Tyrosine Kinases

Peptide growth factors in the extracellular space, such as those of the epidermal growth factor (EGF), platelet-derived growth factor (PDGF), and fibroblast growth factor (FGF) families, stimulate a cascade of molecular events that leads to proliferation by binding to high-affinity cell membrane receptors (**Fig. 2.3**). Growth factors are involved in normal cellular processes such as stromal–epithelial communication, tissue regeneration, and wound healing. The concept that autocrine growth stimulation might be a key strategy by which cancer cell proliferation becomes autonomous has received considerable attention. In this model, it is postulated that cancers secrete stimulatory growth factors that then interact with receptors on the same cell. Although peptide growth factors provide a growth stimulatory signal, there is little evidence to suggest that overproduction of growth factors is a precipitating event in the development of most cancers. Increased expression of peptide growth factors likely facilitates, rather than drives, malignant transformation.

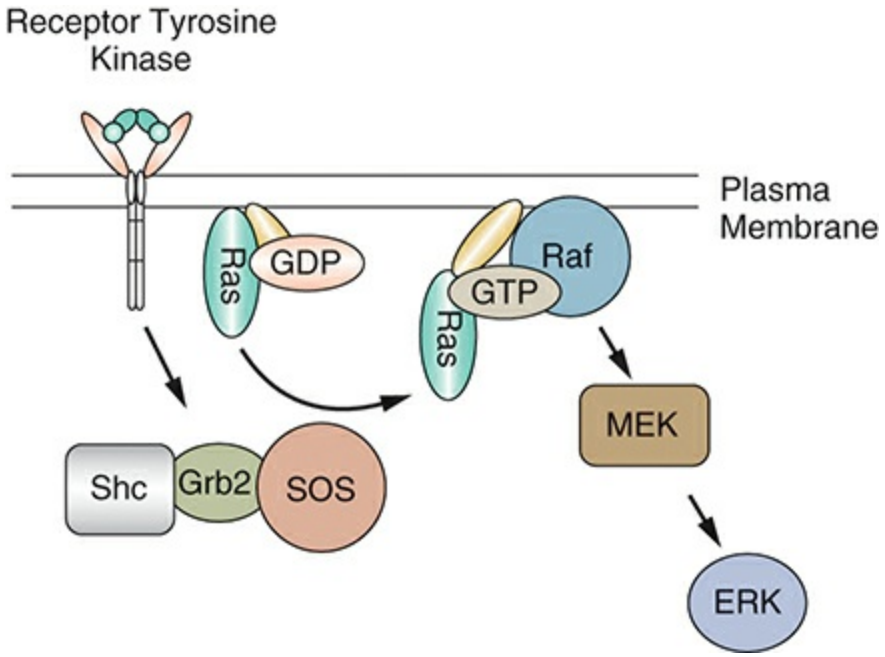

Figure 2.3 Receptor tyrosine kinase pathway. Most receptor tyrosine kinases stimulate the activity of the Ras guanine nucleotide exchange factor son of sevenless (SOS), which associates with the linker proteins Shc and Grb2. The activation of Ras by SOS stimulates a protein serine kinase cascade initiated by Raf, which stimulates MEK. MEK then activates the extracellular signaling-regulated kinases (ERKs). ERKs phosphorylate transcription factors to regulate gene expression. GDP, guanine-di-phosphate; GTP, guanine-tri-phosphate.

Cell membrane receptors that bind peptide growth factors are composed of an extracellular ligand–binding domain, a

membrane-spanning region, and a cytoplasmic tyrosine kinase domain. Binding of a growth factor to the extracellular domain results in dimerization and conformational shifts in the receptors and activation of the inner tyrosine kinase. The kinase transfers a phosphate group from ATP to specific tyrosine residues both on the growth factor receptor itself (autophosphorylation) and on molecular targets in the cell interior leading to activation of secondary signals that stimulate proliferation. Growth of some cancers is driven by overexpression of receptor tyrosine kinases. The epidermal growth factor receptor (EGFR) family of receptor tyrosine kinases plays a significant role in the development of several types of cancers and includes *ErbB-1* (EGFR), *ErbB-2* (HER-2/*neu*), *ErbB-3*, and *ErbB-4*. These receptors are activated by the binding of ligands, including EGF, transforming growth factor (TGF)-α, amphiregulin, and the neuregulins.

Because receptor tyrosine kinases are located on the cell surface, they are appealing therapeutic targets. A number of agents that target the EGFR family have been developed and translated into clinical practice. Trastuzumab is a monoclonal antibody that binds to HER-2/*neu*, blocking downstream signaling, and it is widely used in the treatment of breast cancers that overexpress this receptor (**Fig. 2.4A**). Cetuximab is a monoclonal antibody that targets the extracellular domain of EGFR, whereas gefitinib is a direct inhibitor of the EGFR tyrosine kinase (12). Lapatinib is a dual EGFR/HER-2 kinase inhibitor. Likewise, therapeutic approaches have been developed that target other receptor tyrosine kinases. Imatinib antagonizes the activity of the BCR-ABL, c-kit, and PDGF receptor tyrosine kinases and has proven highly effective in treatment of chronic myelogenous leukemias and gastrointestinal stromal tumors.

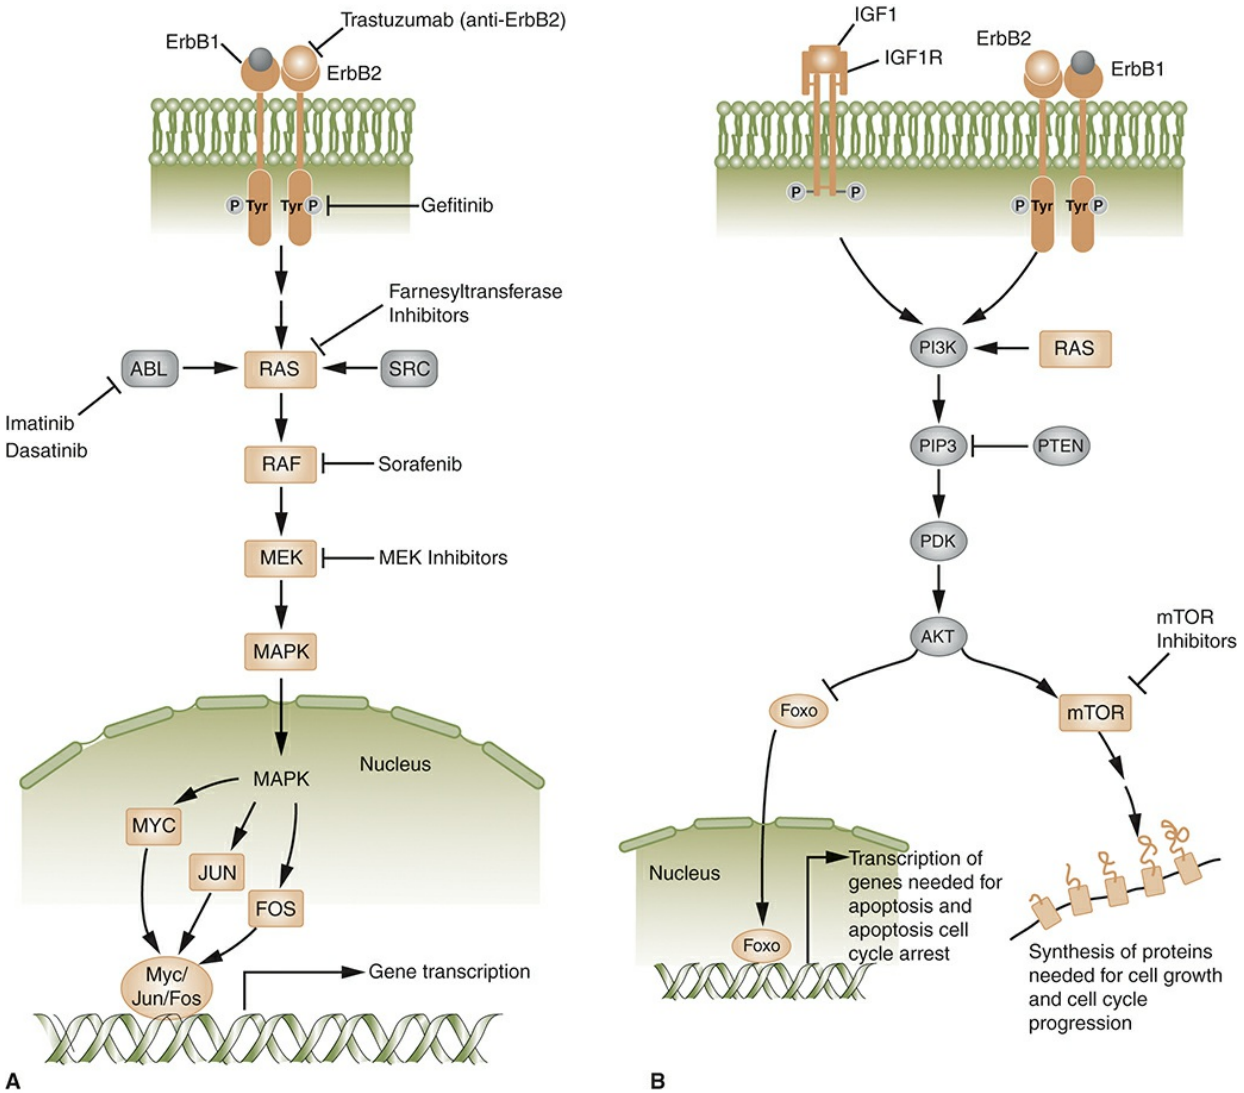

Figure 2.4A The ras/raf/MEK/MAPK pathway is activated by multiple growth factor receptors (here exemplified by ErbB1 and ErbB2) as well as several intracellular

tyrosine kinases such as SRC and ABL. Activated RAS stimulates a sequence of phosphorylation events mediated by RAF, MEK, and ERK (MAP) kinases. Activated MAP kinase (MAPK) translocates to the nucleus and activates proteins such as MYC, JUN, and FOS that promote the transcription of numerous genes involved in tumor growth. B: The phosphatidylinositol 3-kinase (PI3K) pathway is activated by RAS and by a number of growth factor receptors (here exemplified by IGF1R and the ErbB1/ErbB2 heterodimer). Activated PI3K generates phosphatidylinositol-3,4,5-triphosphate (PIP3), which activates phosphoinositide-dependent kinase-1 (PDK). In turn, PDK phosphorylates AKT. PTEN is an endogenous inhibitor of AKT activation. Phosphorylated AKT transduces multiple downstream signals, including activation of the mammalian target of rapamycin (mTOR) and inhibition of the FOXO family of transcription factors. mTOR activation promotes the synthesis of proteins required for cell growth and cell cycle progression.

Nonreceptor Kinases and Phosphatases

Following interaction of growth factors with cell membrane receptors, secondary molecular signals are generated to transmit the growth stimulus to the nucleus. This function is served by a multitude of complex and overlapping signal transduction pathways that occur in the inner cell membrane and cytoplasm. Many of these signals involve phosphorylation of proteins by enzymes known as nonreceptor kinases. The kinases that are involved in growth regulation are of two types, those that phosphorylate tyrosine residues of target proteins, including those of the *SRC* family, and others that are specific for serine and/or threonine residues such as the *AKT* family. The activity of kinases is opposed by phosphatases such as *PTEN*, which act in opposition to the kinases by removing phosphates from the target proteins. The *PTEN* gene is among the most frequently mutated tumor suppressor genes in human cancers.

RAS/RAF, Mitogen-Activated Protein Kinase (MAPK) Pathway

Guanosine-triphosphate–binding proteins (G proteins) such as RAS represent another class of molecules involved in transmission of growth signals (**Figs. 2.4** and **2.5**). They are located on the inner aspect of the cell membrane and are positively regulated by Grb and SOS in response to receptor tyrosine kinases and other signals. They have intrinsic GTPase activity that catalyzes the exchange of GTP (guanine-tri-phosphate) for GDP (guanine-di-phosphate). In their active GTP bound form, G proteins interact with kinases that are involved in relaying the mitogenic signal, such as those of the MAP kinase family. Conversely, hydrolysis of GTP to GDP, which is stimulated by GTPase activating proteins (GAPs), leads to inactivation of G proteins. The *RAS* family of G proteins (e.g., *KRAS*) is among the most frequently mutated oncogenes in human cancers. Activation of *RAS* genes usually involves point mutations that result in constitutively activated molecules.

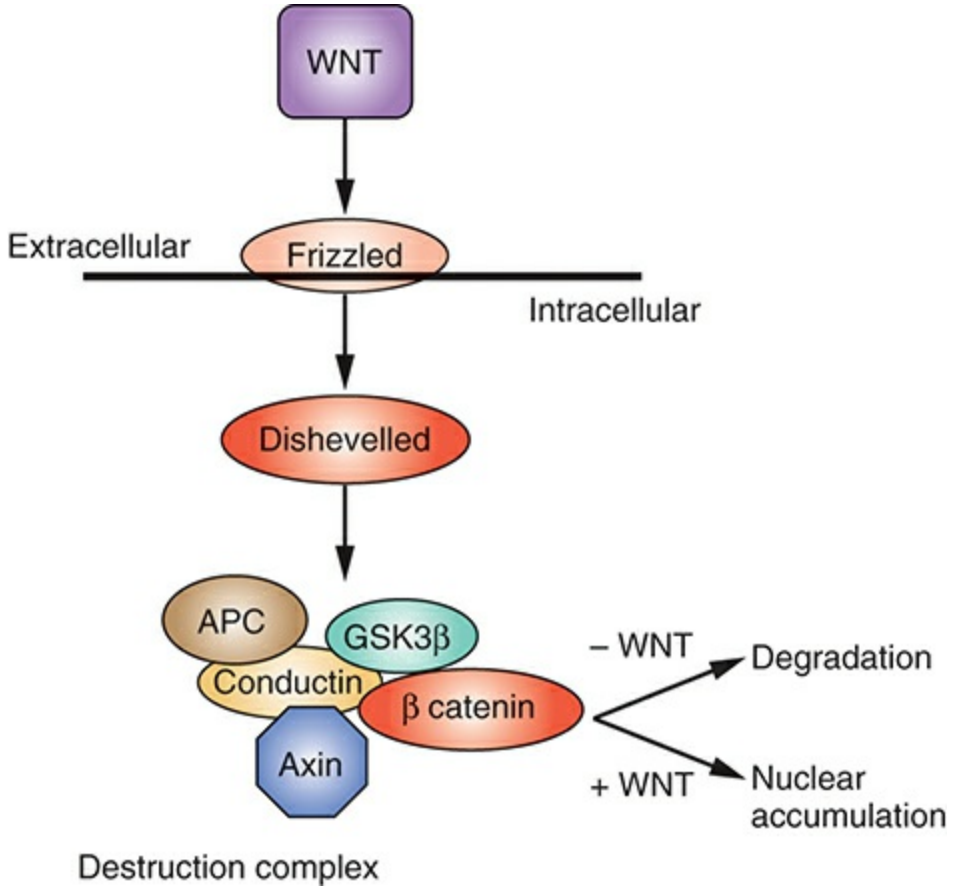

Figure 2.5 Wingless (WNT)/β-catenin signaling. WNT extracellular ligands bind Frizzled receptors and regulate the phosphorylation status of axin. Axin functions as part of the destruction complex that regulates the stability of β-catenin, a transcriptional regulator.

The *RAF* family of genes encodes serine–threonine kinases that interact with RAS proteins and propagate signaling by activating MAP kinases (MEK) which translocate to the nucleus. Mutations in the *BRAF* gene generally occur in cancers independently of *RAS* mutations (13). The mutual exclusivity of *KRAS* and *BRAF* mutations is consistent with the need to only activate one gene in a pathway. Melanomas often have mutations in codon 600 of *BRAF*. The BRAF kinase inhibitor vemurafenib has been shown to be highly active in these cancers as well as in other cancer types, including low-grade serous ovarian cancers.

The *RAF* serine/threonine kinase is downstream of *RAS*, and its activation leads to signaling via mitogen-activated protein kinase kinase (*MAPKK*), also called *MEK*, which activates MAP kinase or extracellular regulated kinase (*ERK*). MAP kinase activation results in phosphorylation and activation of nuclear factors such as ribosomal S6 kinase and transcription factors *JUN*, *MYC*, and *FOS*, resulting in the switching on of a number of genes associated with proliferation. Several MEK inhibitors have been developed and these appear to have activity in low-grade serous cancers, which are characterized by activation of this pathway.

PI3K/AKT/mTOR Pathway

Phosphatidyl-inositol 3-kinases (PI3Ks) are a class of lipid kinases that phosphorylate phosphoinositides (PIs) at position D3 of the inositol ring (14). Extracellular molecules such as growth factors are the main effectors for PI3K pathway activation through the interaction with receptor tyrosine kinases and G protein-coupled receptors (**Fig. 2.4B**). Phosphorylated PIs serve as plasma docking sites for the recruitment of pleckstrin homology domain-containing proteins such as AKT and its upstream activator PDK1. PI3K activation is one of the main causes of increased proliferation and

resistance to apoptosis. The *PIK3CA* gene is one of the most frequently mutated oncogenes in human cancers.

Alterations in PI3Ks and downstream effectors, including AKT and mammalian target of rapamycin (mTOR), frequently are involved in initiation and maintenance of the tumorigenic phenotype. The PI3K-AKT pathway promotes cell growth and survival and inhibits apoptosis and autophagy through several mechanisms: (1) AKT activates the mTOR pathway (**Fig. 2.4B**) and modulates genes that inhibit cell cycle progression (e.g., cdks, *CHK1* and *MDM2*). (2) *AKT* targets include the proapoptotic effectors *BAD* and *BAX*, resulting in inhibition of the apoptotic response. (3) *AKT* inhibits the expression of BH3-only proteins such as BAD and BIM through effects on transcription factors, such as Forkhead family proteins (e.g., FOXO3a) and p53. (4) AKT influences p53 activity through MDM2 phosphorylation at Ser166 and Ser186, which promotes its translocation to the nucleus with subsequent destabilization. (5) AKT can phosphorylate and activate IκB kinase-alpha, which in turn phosphorylates IκB, targeting it for degradation. This leads to nuclear translocation and activation of the transcription factor NF-κB and transcription of NF-κB–dependent prosurvival genes.

The PTEN tumor suppressor is the most important negative regulator of the PI3K signaling pathway. It is a lipid and protein phosphatase that removes phosphates in opposition to PI3K tyrosine kinases. Its ability to dephosphorylate phosphatidylinositol 3,4,5-trisphosphate (PIP3) resulting in phosphatidylinositol 4,5-bisphosphate (PIP2) inhibits oncogenic PI3K-dependent signaling. Although *PTEN* is a tumor suppressor and may be completely lost due to mutation and deletion of the two copies of the gene, mutational inactivation of one copy of the gene (haploinsufficiency) also appears to facilitate malignant transformation.

Both genetic and epigenetic alterations affect the activity of this pathway. Mutations in the *PIK3CA* gene that lead to increased activity frequently occur in human cancers, including ovarian and endometrial cancers. *PTEN* is frequently targeted by either germline or somatic mutation and is also among the most frequently mutated genes in human cancers. In addition, loss of heterozygosity (LOH) or promoter hypermethylation occurs in a broad range of cancers, including endometrioid ovarian and endometrial cancers. Inhibition of the PI3K/Akt/mTOR pathway represents an attractive therapeutic approach and a number of trials are ongoing.

WNT Pathway

β-Catenin (*CTNNB1*) is involved along with cadherins in cell–cell adhesion junctions and may play a role in inhibition of excessive growth when cells come in contact with each other. β-Catenin may also be translocated to the nucleus and may play a role in regulating transcription of genes involved in embryonic development, cell differentiation, and cell polarity (**Fig. 2.5**). β-Catenin activity is regulated by the WNT pathway. The WNT family of genes encodes secreted peptides that interact with Frizzled family cell surface receptors. Frizzled activates the intracellular Dishevelled protein resulting in an increase in the amount of β-catenin translocated to the nucleus. Dishevelled accomplishes this by inhibiting a complex of proteins that includes axin, GSK-3β, and APC that normally promote proteolytic degradation of β-catenin. This allows β-catenin to enter the nucleus and interact with T-cell factor (TCF)/lymphoid enhancing factor (LEF) family transcription factors to promote gene expression.

Genes encoding WNT signaling inhibitors are often downregulated during carcinogenesis and driver mutations in several of these genes (*APC, Axin, GSK-3b, CTNNB1*) occur frequently in human cancers, including endometrial cancers. Germline mutations in the APC gene are responsible for familial adenomatous polyposis of the colon, and it is the most commonly mutated gene in colorectal cancer.

Nuclear Oncogenes

If proliferation is to occur in response to signals generated in the cell membrane and cytoplasm, these events must lead to activation of nuclear transcription factors and other gene products responsible for stimulating DNA replication and cell division (**Fig. 2.4**). When inappropriately overexpressed, these transcription factors can act as oncogenes. The *MYC* family of nuclear transcription factors is often involved in the development of human cancers, including some ovarian

cancers, due to amplification/overexpression. Many of the nuclear regulatory genes such as *MYC* that control proliferation also impact the threshold for apoptosis. Thus, there is overlap in the molecular pathways that regulate the opposing processes of proliferation and apoptosis. In addition, genes that positively regulate cell cycle progression within the nucleus may be amplified and/or overexpressed in some cancers, leading to unrestrained proliferation (e.g., cyclin D1 [*CCND1*] and cyclin E1 [*CCNE1*]).

Nuclear Tumor Suppressor Genes

The retinoblastoma gene (*RB1*) was the first tumor suppressor gene discovered and is frequently mutated in human cancers. It was named based on its discovery in the context of a rare hereditary cancer syndrome, as have many other tumor suppressor genes. The *RB1* gene plays a key role in regulation of cell cycle progression. In the G1 phase of the cell cycle, RB protein binds to the E2F family of transcription factors and prevents it from activating transcription of other genes involved in DNA replication and cell cycle progression. This serves as an important restriction point that can protect genomic integrity if DNA damage is present. G1 arrest is maintained by cdk inhibitors such as p16, p21, and p27 that prevent phosphorylation of RB. When RB is phosphorylated by cyclin/cdk complexes, E2F is released and stimulates entry into the DNA synthesis phase of the cell cycle. Other cyclins and cdks are involved in progression from G2 to mitosis. Mutations in the *RB* gene have been noted primarily in retinoblastomas and sarcomas, but less frequently in other types of cancers. By maintaining G1 arrest, the cdk inhibitors p16, p21, p27 and others act as tumor suppressor genes. Loss of p16 (*CDKN2A*) tumor suppressor function due to genomic deletion or promoter methylation occurs in some cancers. Likewise, loss of p21 and p27 has been noted in some cancers as well.

Mutation of the *TP53* tumor suppressor gene is the most frequent genetic event described thus far in human cancers and is a ubiquitous feature of some tumor types, such as high-grade serous ovarian cancers (15). The *TP53* gene encodes a 393-amino acid protein that plays a central role in the regulation of both proliferation and apoptosis. In normal cells, p53 protein resides in the nucleus and exerts its tumor suppressor activity by binding to transcriptional regulatory elements of genes, such as the cdk inhibitor p21, that act to arrest cells in G1. The *MDM2* gene product degrades p53 protein when appropriate, whereas p14ARF downregulates *MDM2* when upregulation of p53 is needed to initiate cell cycle arrest.

Many cancers have missense mutations in one copy of the *TP53* gene that result in substitution of a single amino acid, most commonly in exons 5 through 8, which encode the DNA-binding domains that are involved in regulating transcription (**Fig. 2.6**). Although these mutant *TP53* genes encode full-length proteins, they are unable to bind to DNA and regulate transcription of other genes. Mutation of one copy of the *TP53* gene often is accompanied by deletion of the other copy, leaving the cancer cell with only mutant p53 protein. If the cancer cell retains one normal copy of the *TP53* gene, mutant p53 protein can complex with wild-type p53 protein and prevent it from oligomerizing and interacting with DNA. Because inactivation of both *TP53* alleles is not required for loss of p53 function, mutant p53 is said to act in a “dominant negative” fashion. While normal cells have low levels of p53 protein because it is rapidly degraded, missense mutations encode protein products that are resistant to degradation. The resultant overaccumulation of mutant p53 protein in the nucleus can be detected immunohistochemically. A smaller fraction of cancers have mutations in the *TP53* gene that encode truncated protein products. In these cases, loss of the other allele occurs as the second event as is seen with other tumor suppressor genes.

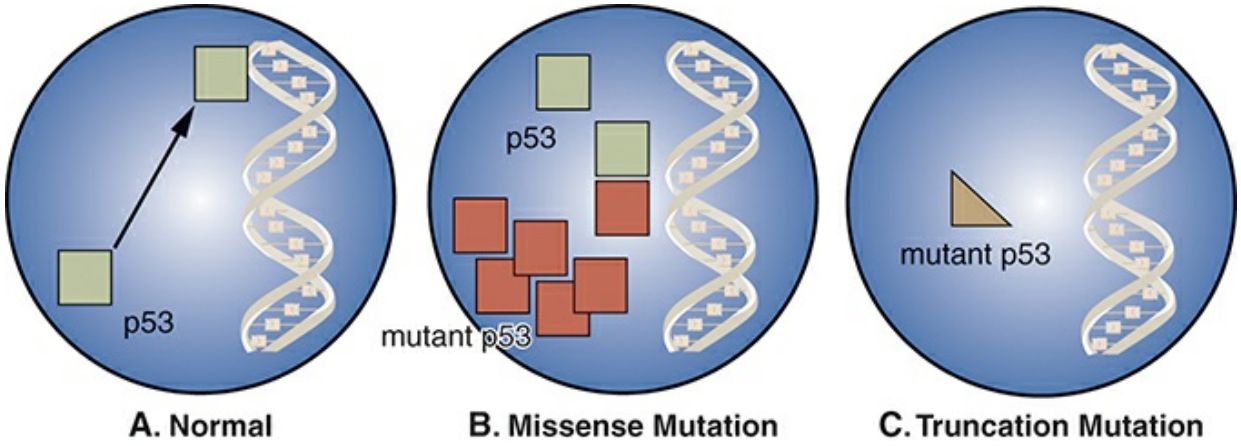

Figure 2.6 Inactivation of the p53 gene. A: Normal p53 protein binds to transcriptional regulatory elements in DNA. B: TP53 missense mutations encode proteins that no longer bind to DNA and the mutant protein complexes with and inactivates any remaining normal p53 in the nucleus. C: TP53 mutations that encode truncated protein products result in proteins that no longer bind to DNA, and these mutations usually are accompanied by deletion of the wild-type p53 allele.

Beyond simply inhibiting proliferation, normal p53 is thought to play a role in preventing cancer by stimulating apoptosis of cells that have undergone excessive genetic damage. In this regard, p53 has been described as the "guardian of the genome" because it delays entry into S phase until the genome has been cleansed of mutations. If DNA repair is inadequate, p53 may initiate apoptosis, thereby eliminating cells with genetic damage.

Finally, genes involved in chromatin remodeling in the context of the SWI/SNF complex in the nucleus also have been implicated as tumor suppressors (e.g., *ARID1A* in clear cell and endometrioid ovarian cancers).

TGF-a Pathway

The TGF-β family of growth factors inhibits proliferation. It is thought that TGF-β causes G1 arrest by inducing expression of cdk inhibitors such as p27. Three closely related forms of TGF-β have been discovered that are encoded by separate genes (*TGF-b1*, *TGF-b2*, *TGF-b3*). TGF-β is secreted in an inactive form bound to a portion of its precursor molecule from which it must be cleaved to release biologically active TGF-β. Active TGF-β interacts with type I and type II cell surface TGF-β receptors and initiates serine/threonine kinase activity. Prominent intracellular targets include a class of molecules called SMADs that translocate to the nucleus upon TGF-β receptor–mediated phosphorylation and act as transcriptional regulators. In the nucleus, the SMAD complex interacts with other DNA-binding transcription factors and cofactors to regulate the transcription of TGF-β target genes to initiate growth arrest. Typical events include the upregulation of cdk inhibitors (p16, p15, p21, and p27) and translation-inhibitory protein 4eBP1, as well as the downregulation of MYC. In addition to growth arrest, TGF-β also limits tumor progression through the induction of apoptosis.

Regulatory RNAs

Some RNAs that are transcribed from the genome are not translated into proteins, but rather affect various biological processes by regulating the activity of other genes. These noncoding RNAs include long noncoding RNAs (longer than 200 nucleotides) and smaller regulatory RNAs such as microRNAs (miRNAs), short interfering RNAs (siRNAs), and other species. miRNAs consist of single RNA strands of about 21 to 23 nucleotides that bind to messenger RNAs with complementary sequences and can block protein translation. Dysregulation of miRNA expression appears to play a role in the development and behavior of human cancers. miRNA production begins in the nucleus from several kilobase-long

primary miRNAs (pri-miRNA). These pri-miRNAs undergo cleavage to produce short hairpin-shaped intermediates known as precursor miRNAs (pre-miRNA), which are approximately 70 nucleotides in length. Drosha, an RNAse III enzyme, processes the precursors prior to translocation to the cytoplasm. Subsequently, pre-miRNAs are cleaved by Dicer, also an RNAse III enzyme, resulting in mature miRNAs. siRNA, an approximately 21-nucleotide single-stranded sequence, is derived within the cytoplasm and does not require processing by the Drosha-DGCR8 complex. Mature miRNAs and siRNAs are then activated through the RNA-induced silencing complex, which produces host mRNA degradation and/or translational repression upon binding to the target.

Noncoding RNAs can also be used as powerful experimental tools. Exogenous constructs of either siRNAs or short hairpin RNAs (shRNA) can also be introduced into cells experimentally. shRNAs are introduced through viral vectors (transduction) to produce stable gene silencing, whereas siRNA transfection through encapsulation in lipids is transient. More recently, the CRISPR-Cas9 system has been used to engineer mutations at specific target sequences to interrogate their biological significance (16). The cas9 nuclease generates double-strand breaks guided by small RNAs that are aberrantly repaired by nonhomologous end joining (NHEJ), resulting in insertion/deletion mutations and gene disruption. Alternatively, in the presence of an introduced repair template, homology-directed repair can be utilized to induce precise mutations at the target sequence. RNA interference (RNAi) and genome editing technologies have been used as research tools to study the effect of turning off various genes and also potentially have therapeutic applications.

Energy Metabolism

Cancer cells uptake increased amounts of glucose to satisfy their metabolic demands, and this is the basis of fluorodeoxyglucose (FDG)-positron emission tomography imaging. Normal tissues generate energy using mitochondrial oxidative phosphorylation and only switch to breaking down glucose to derive energy in the absence of oxygen, which leads to the accumulation of lactate. In contrast, glycolysis of glucose to lactate occurs in cancers even in the presence of oxygen, a phenomenon called “aerobic glycolysis.” This is referred to as the Warburg effect, in honor of its discoverer. Because cancers often outgrow their blood supply and become hypoxic, the ability to survive using aerobic glycolysis instead of oxidative phosphorylation may be selected for during malignant transformation. Lactate production by cancers may also promote invasion and metastasis by acidifying the microenvironment. Aerobic glycolysis also may serve the increased metabolic requirement for carbon atoms to produce the macromolecules needed to build new cancer cells. If glucose is completely broken down to carbon dioxide via the citric acid cycle, these carbon building blocks are lost.

The hypoxia-inducible transcription factor-1α (HIF-1α) plays an important role in the cellular response to decreased oxygen in the local environment. When oxygen is absent, HIF-1α accumulates and promotes transcription of proangiogenesis genes as well as those involved in glucose transport and glycolysis. HIF-1α accumulation may be a consequence of loss of the *VHL* tumor suppressor gene, providing a link between the loss of a tumor suppressor and the altered metabolic phenotype of malignant cells. Another link between glucose metabolism and cancer is the finding that isocitrate dehydrogenase (IDH), an enzyme involved in glycolysis, is frequently mutated in glioblastomas. The common amino acid-changing IDH mutations result in increased production of 2-hydroxyglutarate, which accumulates to high levels and plays a role in the development of these cancers. Activation of the PIK and RAS pathways also regulates glucose uptake and metabolism.

Differences in metabolism between normal and malignant cells represent an appealing therapeutic target. In this regard, there is a suggestion that the diabetic drug metformin may have efficacy in the treatment and prevention of cancer. This appears to be independent of blood glucose level, and the exact mechanism is unclear.

DNA REPAIR

It has been estimated that thousands of mutations occur in humans on a daily basis. Cells in many organs such as the skin,

gastrointestinal tract, and respiratory tract that are exposed most directly to the environment constantly undergo renewal with shedding of differentiated cells that may contain mutations. Mammalian cells also have highly evolved and complex DNA repair systems to maintain the integrity of the genome. A series of cell cycle checkpoints exist that allow the opportunity to pause for successful DNA repair, or alternatively for cell death if repair cannot be accomplished. DNA damage checkpoints occur at the boundaries between G1/S and G2/M and during S phase and mitotic spindle assembly. These checkpoints serve to protect against genetic damage that can lead to malignant transformation being fixed in the genome.

There are several repair mechanisms that operate on specific types of DNA damage during these checkpoints, including MMR, nucleotide excision repair (NER), base excision repair (BER), homologous recombination (HR) repair, and NHEJ. Loss of DNA repair activity increases the likelihood of mutations being fixed in the genome, and this is a hallmark of many cancers.

DNA Mismatch Repair

MMR excises nucleotides that are incorrectly paired with the correct nucleotide on the opposite DNA strand. It involves recognition of a base pair mismatch, recruitment of repair enzymes, excision of the incorrect sequence, and resynthesis by DNA polymerase using the parental strand as a template (**Fig. 2.7**). The recognition of small loops generated by insertion or deletion of nucleotides, as well as single base mismatches, is primarily accomplished by a complex called MUTSα, which is a heterodimer of MSH2 and MSH6. MLH1 and PMS2 are recruited to the site to initiate the subsequent steps of repair, including excision, DNA synthesis, and ligation.

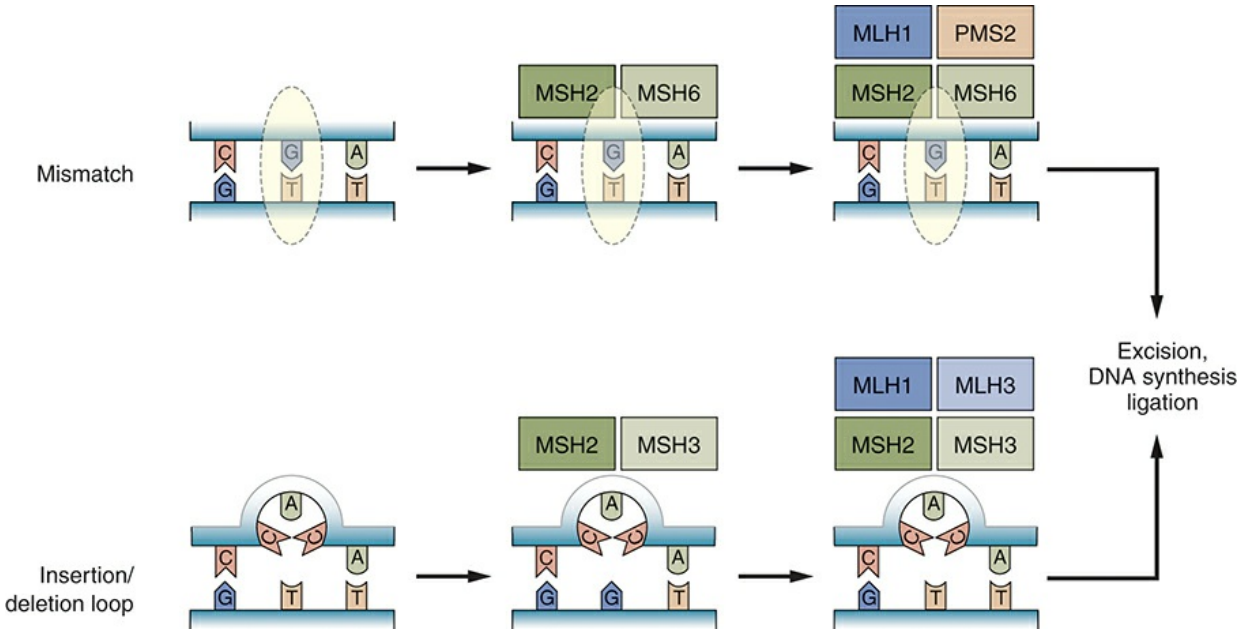

Figure 2.7 Mismatch repair pathways. Mispaired bases due to errors in DNA replication or other causes are recognized by the mismatch repair machinery. The initial step involves recognition of simple mismatches by MSH2 and MSH6 (upper panel), or recognition of insertion/deletion loops by MSH2 and MSH3 (lower panel). Subsequent steps involve recruitment of MLH1 and PMS2 to mismatch sites, or MLH1 and MLH3 to insertion/deletion loop sites. This is followed by excision of the respective lesions, DNA synthesis, and ligation to complete the repair.

Loss of MMR leads to a "mutator phenotype" in which there is accumulation of genetic mutations throughout the genome, particularly in repetitive DNA sequences called microsatellites. Examples of microsatellite sequences include mono (AAAA), di (CACACACA), and tri (CAGCAGCAGCAG) nucleotide repeats. Replication errors in these repetitive

sequences are common and their inefficient repair leads to the propensity to accumulate mutations, and this is referred to as microsatellite instability (MSI). Some microsatellite sequences are in noncoding areas of the genome, whereas others are within genes. It is thought that accumulation of mutations in microsatellite sequences of tumor suppressor genes may inactivate them and accelerate the process of malignant transformation.

About 3% of endometrial cancers arise due to inherited mutations in MMR genes in the context of Lynch syndrome (17,18). Most cases are due to alterations in *MSH2* and *MLH1*, but *MSH6* and *PMS1*, *PMS2*, and *MSH3* mutations also occur. Lynch syndrome is covered in depth in Chapter 3. More frequently, the *MLH1* MMR gene is inactivated due to promoter methylation in sporadic endometrioid cancers of the endometrium leading to MSI.

Nucleotide Excision Repair/Base Excision Repair

The MMR pathway functions primarily in the recognition and repair of replication errors, while the NER and BER pathways respond to damage caused by DNA damaging agents. NER is an important DNA repair mechanism, as evidenced by severe human diseases, including xeroderma pigmentosum, that result from hereditary defects of NER proteins. The NER genes recognize and repair bulky DNA damage caused by environmental carcinogens, ultraviolet light, and chemotherapeutic agents such as platinum compounds (**Fig. 2.8**). Defects in NER proteins predispose to various types of cancer, including skin cancer in xeroderma pigmentosum.

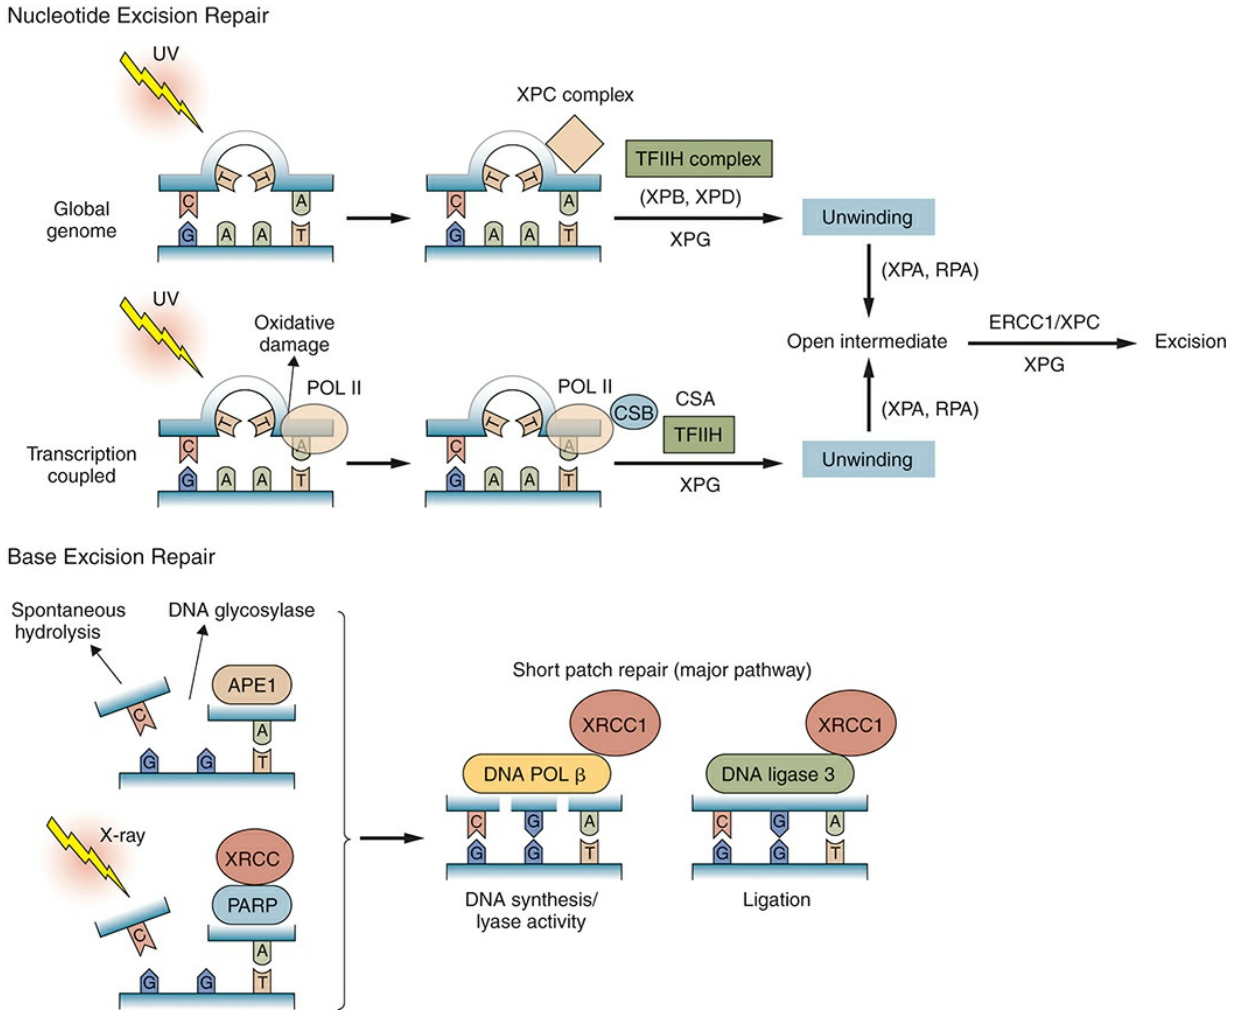

Figure 2.8 Nucleotide excision repair (NER) and base excision repair. NER is activated in response to bulky lesions that are generated, for example, by UV irradiation (upper panels). Global genome (GG) repair involves proteins identified by complementation groups in patients with xeroderma pigmentosa (XP proteins). Initial recognition of

lesions occurs by a complex containing xeroderma pigmentosa C (XPC). Transcription coupled repair (TCR) also involves proteins identified by mutation in Cockayne syndrome (CS proteins) and occurs when RNA polymerase II stalls at the site of lesions. Stalled RNA polymerase II recruits Cockayne syndrome B (CSB) to the site of damage. Subsequently, DNA is locally unwound around the injured site by a TFIIH complex containing XPB and XPD. This process also involves XPG, CSA, and other proteins for TCR. Once unwound, XPA and replication protein A (RPA) contribute to stabilization of an open intermediate and recruitment of the ERCC1 and XPF endonucleases that excise the lesion. Subsequent steps involve DNA synthesis and ligation to complete the repair. In base excision repair (BER) (lower panels), abasic sites generated by spontaneous hydrolysis, action of DNA glycosylases, or x-ray–induced single-strand breaks are recognized by the APE1 endonuclease, as well as PARP and XRCC1. Subsequent repair is influenced by PARP-mediated ADP ribosylation of histones and other proteins, while XRCC1 serves as a scaffold for recruitment of DNA polymerase β and DNA ligase 3. These latter enzymes catalyze nucleotide reinsertion and ligation into the injured strand as part of the short patch repair pathway (major BER pathway).

There are two NER pathways: one global pathway involved in scanning the entire genome and another that detects lesions that interfere with elongating RNA polymerases. The proteins required for NER assemble in an ordered stepwise fashion at sites of base damage. This assembly generates a large multiprotein complex, namely, the "repairosome." This repair complex can nick the DNA at precise distances on either side of the base damage, and these gaps are repaired using the opposite normal DNA strand as a template. There are several proteins involved in the NER process including *ERCC1, RPA, RAD23A, RAD23B XPA, XPB, XPC, XPD, XPE, XPF, XPG, CSA*, and *CSB*. *BRCA1* may also play a role in NER. *ERCC1* expression may be a marker of cisplatin resistance in cervical cancer, with low expression predicting superior 5-year disease-free survival (19).

BER is closely related to NER in that both repair lesions in DNA bases (**Fig. 2.8**). BER involves repair of small lesions due to chemicals and x-rays that do not distort the DNA helix. Single bases in DNA can be damaged by several mechanisms, the most common being deamination, oxidation, and alkylation. BER is initiated by DNA glycosylases that recognize a single or small set of altered or inappropriate bases. BER removes damaged bases that could otherwise cause mutations by mispairing or lead to breaks in DNA during replication. The BER system excises the inappropriate base from the genome as a free base, leaving a site of base loss in the DNA. These sites are further repaired and reconstructed by a series of biochemical events.

Deletion of BER genes increases mutation rates and contributes to the development of various cancers. In this regard, somatic mutations in the DNA polymerase Pol β have been found in some human cancers. Mutations in POLE have been found by TCGA in a subset of endometrial cancers with the highest mutation rates (20). Inherited mutations in the DNA glycosylase *MUTYH* increase susceptibility to colon cancer.

Double-Strand Break Repair: HR Repair, NHEJ

Double-stranded DNA damage can be caused by exogenous factors such as ionizing radiation, ultraviolet rays, alkylating agents, chemotherapeutic drugs, or by endogenous factors such as reactive oxygen species or errors in cellular DNA metabolism. Following double-stranded DNA damage, the ATM (ataxia telangiectasia mutated) and ATR kinases phosphorylate several proteins including CHK1 and CHK2 that initiate cell cycle arrest by way of p53, and this leads to DNA repair that restores genomic integrity or to apoptosis if DNA repair is inadequate.

HR is a process that provides high-fidelity, template-dependent repair of complex DNA damage such as DNA cross-links, double-strand breaks, single-strand DNA gaps, and DNA interstrand cross-links (**Fig. 2.9**). The HR pathway involves the following basic steps. Double-stranded breaks are recognized by the MRN complex and checkpoint proteins. A 5′-3, exonuclease generates 3′ overhangs, which are then coated with replication protein A (RPA). BRCA1–BRCA2–RAD51 forms a stable complex (21) and potentiates HR by promoting assembly of RAD51 onto single-stranded ends. A

homology search ensues, followed by strand invasion and DNA synthesis. The links between DNA strands (double Holliday junctions) can be resolved to produce exchange between chromosomes (crossovers) or no exchange (noncrossovers). This is a precise repair mechanism that restores the original sequence. If double-stranded breaks are not repaired precisely, this can cause deletions, translocations, and fusions in the DNA, producing genomic rearrangements.

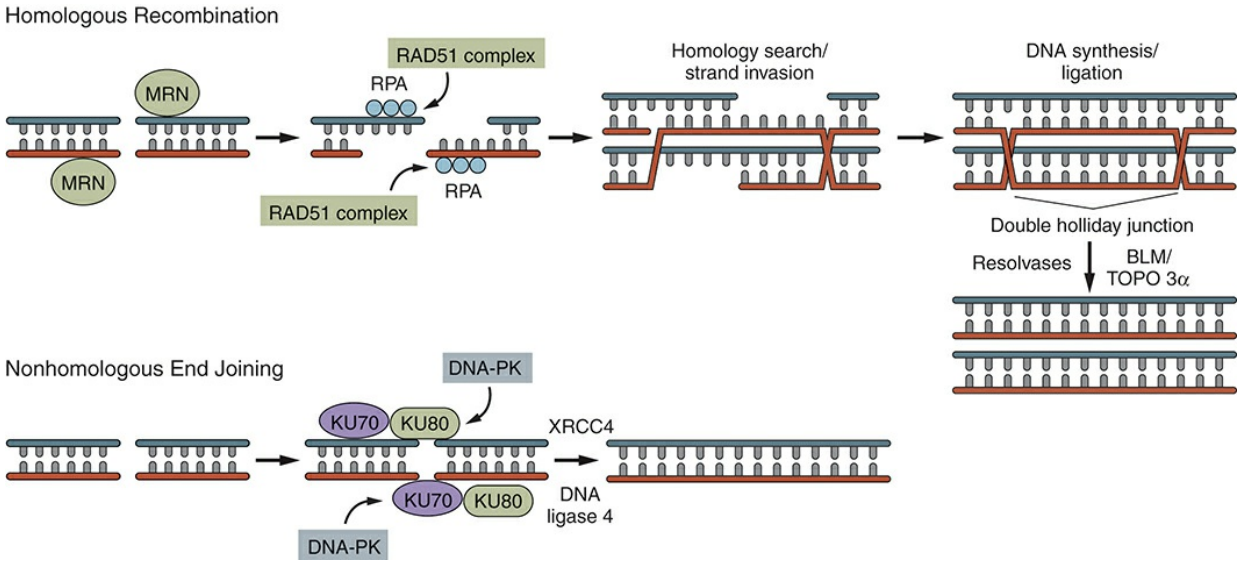

Figure 2.9 Double-strand break (DSB) repair by homologous recombination and nonhomologous end joining (NHEJ). In homologous recombination (HR), DSBs are recognized by the MRN (Mre11, Rad50 and Nbs1) complex, among other proteins. 5′-3′ exonuclease activity results in the generation of single-strand overhangs that are coated with RPA. Mediator proteins such as BRCA2 and RAD52 stimulate assembly of a RAD51 nucleoprotein filament complex that guides subsequent homology search and strand invasion into the homologous strand (e.g., the identical sister chromatid in late S/G2 phase and mitosis). Subsequent DNA synthesis and ligation result in the formation of recombination intermediates that contain double Holliday junctions. These are resolved by resolving enzymes such as the RecQ helicase BLM, in conjunction with topoisomerase 3α. The process of NHEJ involves recognition of DSB ends by the Ku70-Ku80 heterodimer, with subsequent recruitment of DNA-dependent protein kinase. DNA ends are then ligated following recruitment of XRCC4 and DNA ligase 4.

Fanconi anemia is an inherited disease characterized by hypersensitivity to DNA cross-linking agents and predisposition to cancer. There are over a dozen genes in the Fanconi anemia pathway that cooperate in HR repair of DNA cross-links. Mutations of several of these, including *BRCA1* and *BRCA2*, increase the risk of breast and ovarian cancer. Inherited mutations in other genes involved in HR are associated with predisposition to these cancers, including *RAD51C* (fivefold increase) and *RAD51D* (11-fold increase) (22). *PALB2* plays a critical role in HR repair through its ability to recruit BRCA2 and RAD51 to DNA breaks. This serves as the molecular scaffold in the formation of the BRCA1–PALB2–BRCA2 complex. *PALB2* mutations confer susceptibility to breast cancer, and less likely ovarian cancer. The *BRIP1* gene is involved in the repair of DNA double-strand breaks by HR in a manner that depends on its association with BRCA1. *BRIP1* germline mutations have also been associated with ovarian cancer risk by about 11-fold (23).

DNA double-strand breaks may also be repaired through an NHEJ repair mechanism, wherein the break ends are directly ligated without the need for a homologous template (**Fig. 2.9**). Proteins associated with NHEJ include DNA-PKcs, MRE11, RAD50, XRCC4, and DNA ligase IV.

GYNECOLOGIC MALIGNANCIES

Gynecologic cancers vary with respect to grade, histology, stage, response to treatment, and survival. It is now appreciated that this clinical heterogeneity is attributable to differences in underlying molecular pathogenesis. Some cancers arise in a setting of inherited mutations in cancer susceptibility genes, but most occur sporadically in the absence of a hereditary predisposition. The spectrum of genes that are mutated varies between cancer types. For each type of cancer, there are a few genes that are frequently mutated, while a wider spectrum is altered in a small fraction of cases. There also is significant variety with respect to the spectrum of genetic changes within a given type of cancer. Cancers with a similar microscopic appearance may differ considerably at the molecular level. In some instances, molecular features may be predictive of clinical phenotypes such as stage, histologic type, and survival. An understanding of the clinical phenotypes associated with various genetic alterations in gynecologic cancers has the potential to inform prognosis and prediction of response to therapy.

ENDOMETRIAL CANCER

Etiology

Epidemiologic and clinical studies of endometrial cancer have suggested that endometrial cancer can be broadly classified into two general types. “Type I” cases are associated with unopposed estrogen stimulation and often develop in a background of endometrial hyperplasia. Obesity is the most common cause of unopposed estrogen and is often part of a metabolic syndrome that also includes insulin resistance and overexpression of insulin-like growth factors that may also play a role in carcinogenesis. Type I cancers prototypically are well-differentiated, endometrioid, early-stage lesions and have a favorable outcome. In contrast, “Type II” cancers are poorly differentiated and/or nonendometrioid and more virulent. The spectrum of genetic alterations also has been found to differ between the two types (**Table 2.3**). Although this dichotomous classification system is a useful framework to organize endometrial cancers, it lumps widely different histologic subtypes such as carcinosarcoma, clear cell, and serous into one category, leading to an oversimplification of extensive heterogeneity, and fails to account for additional heterogeneity that exists within endometrioid tumors.

TABLE 2.3 Characteristics of Type 1 versus Type 2 Endometrial Adenocarcinomas

	Type 1	Type 2
Clinical features		
Risk factors	Obesity, unopposed estrogen	Older age
Precursor	Atypical endometrial hyperplasia	None or in situ carcinoma
Histology	Endometrioid	Serous/clear cell
Grade	1, 2	3
Stage	I/II	III/IV
Survival	Favorable	Poor
Molecular features[a]		
Ploidy	Diploid	Aneuploid
MSI	35%	Rare
Tumor suppressor genes		
TP53 mutation	15%	90%

HER-2/neu amplification	Rare	30%
FBXW7 mutation	10%	30%
PPP2R1A mutation	Rare	25%
ARID1A mutation	40%	10%
PTEN mutation	80%	Rare
MLH1 methylation	35%	None
POLE mutation	10%	Rare
CTCF mutation	25%	None
Oncogenes		
MYC amplification	Rare	25%
FGFR2 mutation	15%	10%
PIK3CA mutation	55%	40%
PIK3R1 mutation	40%	Rare
CTNNB1 (β-catenin) mutation	40%	None
KRAS mutation	25%	Rare

[a]Mutation frequencies obtained from TCGA data.

Similar to other human cancers, endometrial cancers are believed to arise due to a series of genetic alterations. For Type I cancers, it has long been thought that estrogens contribute to the development of endometrial cancer by virtue of their mitogenic effect on the endometrium. A higher rate of proliferation in response to estrogens may lead to an increased frequency of spontaneous mutations. In addition, when genetic damage occurs, regardless of the cause, the presence of estrogens may facilitate clonal expansion. It also has been postulated that estrogens may act as "complete carcinogens" that both promote carcinogenesis by stimulating proliferation and act as initiating agents by virtue of their carcinogenic metabolites. Unopposed menopausal estrogen replacement therapy was found in the 1970s to increase the risk of endometrial cancer by four- to five-fold. Estrogen has been listed as a known carcinogen by the U.S. Department of Health and Human Services since 1985 and may also play a role in the development of Type II cancers. In contrast, progestins oppose the action of estrogens both by downregulating estrogen receptor levels and by decreasing proliferation and increasing apoptosis.

Lynch Syndrome and MSI

About 3% of endometrial cancers occur in women with a strong hereditary predisposition due to germline mutations in DNA MMR genes in the context of Lynch syndrome. First described by Henry Lynch, this syndrome commonly includes malignancies of the colon, endometrium, stomach, and ovary. Less frequent malignancies that are part of this syndrome include those arising in the small bowel, upper urinary tract, brain, and biliary tract. Colorectal cancer is the most common malignancy in Lynch syndrome overall, which also is sometimes called hereditary nonpolyposis colorectal cancer syndrome. However, the risks of colorectal cancer and endometrial cancer in women are approximately equivalent (40% to 60%). Lynch syndrome is covered in more detail in Chapter 3.

Lynch syndrome is caused by inherited germline mutations in one of several DNA MMR genes—*MLH1*, *MSH2*, and, less often, *MSH6*, *MSH3*, *PMS1*, and *PMS2*. These defects lead to faulty DNA MMR. A hallmark of MMR deficiency is MSI. Microsatellites are short repetitive regions of DNA that become unstable during replication in the setting of defective MMR. In addition to germline mutations in the MMR genes, epigenetic silencing through promoter methylation, specifically in *MLH1*, is the most common mechanism of MSI in endometrial cancer (24). Methylation of *MLH1* is not a heritable

condition associated with Lynch syndrome. MSI is found in up to 35% of endometrial carcinomas and is generally restricted to endometrioid cases. Methylation of the *MLH1* promoter also has been noted in endometrial hyperplasia and normal endometrium adjacent to cancers, suggesting that this is an early event in the development of some cancers (25).

The Cancer Genome Atlas Project

In 2006, The Cancer Genome Atlas (TCGA) began with studies in glioblastoma and high-grade serous ovarian cancer. The National Institutes of Health committed major resources to TCGA to collect and characterize the genomic landscape of more than 20 cancer types. A national network of research and technology teams pooled the results of their efforts to create an economy of scale and develop an infrastructure for making the data publicly accessible (http://cancergenome.nih.gov). Each cancer underwent comprehensive genomic characterization and analysis. The data generated by TCGA are available and widely used by the cancer research community through the TCGA Data Portal. The analyses included sequencing of the entire coding regions (exomes) of each cancer. Additionally, levels of gene expression, including mRNA and microRNA, were measured either through microarray-based platforms or using second-generation sequencing techniques to sequence the RNA transcriptome. Copy number alterations and methylation events were also assessed through microarray platforms. Some tumors were also hybridized to reverse-phase protein arrays when sufficient biomaterial was available.

Inherent in the design of the TCGA program are methodological aspects to be considered when interpreting the data. Only serous and endometrioid subtypes were accrued in the endometrial cancer project. Furthermore, most of the frozen tumor specimens used were previously collected and banked. Thus, larger tumors undoubtedly are overrepresented, because smaller ones are less likely to be banked. There is also an overrepresentation of serous and high-grade endometrioid cancers, with underrepresentation of the more common low-grade cancers. This was to assure adequate numbers of the former groups.

TCGA has reclassified endometrioid and serous endometrial cancers in four broad categories using comprehensive genomic approaches (**Fig. 2.10**) (20). One third of the cancers is characterized by MSI and associated hypermutation. These cancers have a background mutation rate (BMR) that is approximately 10-fold greater than microsatellite stable (MSS) tumors. These tumors are exclusively endometrioid and have few DNA copy number alterations. The cancers without MSI can be further separated into two groups. Serous cases with extensive DNA copy number alterations and genomic instability (similar to that seen in high-grade serous ovarian carcinoma) comprise one group, and endometrioid cases with few or only focal copy number alterations comprise the other. A smaller fourth subgroup contains samples with very high mutation rates (~100-fold or more than MSS tumors) and is characterized by mutations in the exonuclease domain of *POLE*, a DNA polymerase involved with repairing errors in transcription. Molecular features can be distinctly overlaid onto these four subclassifications and are discussed below.

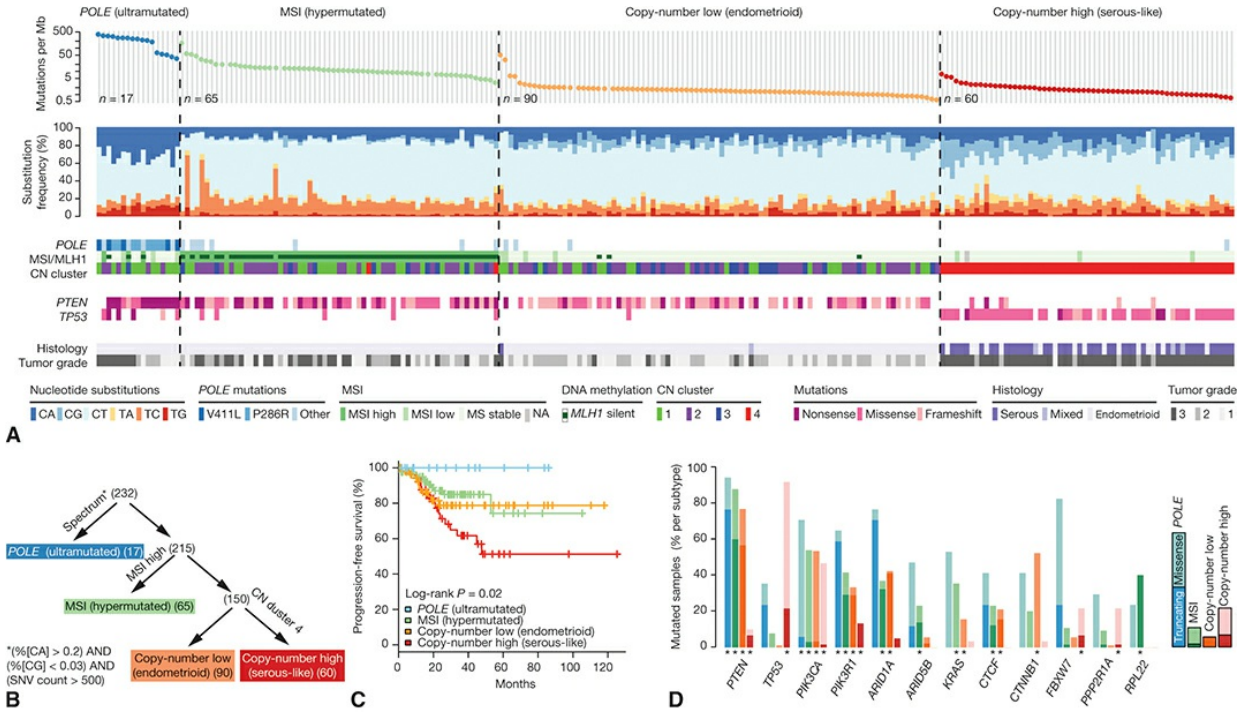

Figure 2.10 Mutation spectra across endometrial carcinomas. A: Mutation frequencies (vertical axis, top panel) plotted for each tumor (horizontal axis). Nucleotide substitutions are shown in the middle panel, with a high frequency of C-to-A transversions in the samples with POLE exonuclease mutations. B: Tumors were stratified into the four groups by (1) nucleotide substitution frequencies and patterns, (2) MSI status, and (3) copy number cluster. C: POLE-mutant tumors have significantly better progression-free survival, whereas copy number high tumors have the poorest outcome. D: Recurrently mutated genes are different between the four subgroups. Shown are the mutation frequencies of all genes that were significantly mutated in at least one of the four subgroups (MUSiC, asterisk denotes FDR < 0.05). CN, copy number; SNV, single-nucleotide variant. Reprinted by permission from Macmillan Publishers Ltd: The Cancer Genome Atlas Research Network. Integrated genomic characterization of endometrial carcinoma. Nature 2013;497:69; copyright 2013.

DNA Copy Number

Early cytogenetic studies described gross chromosomal alterations in endometrial cancers, including changes in the number of copies of specific chromosomes. Comparative genomic hybridization (CGH) studies have also demonstrated areas of chromosomal loss and gain in endometrial cancer and atypical hyperplasia (26,27). Uterine serous carcinomas are aneuploid and have copy number alterations in nearly every chromosomal arm. Endometrioid endometrial cancers with MSI have few copy number alterations. The endometrioid cases lacking MSI have some focal copy number alterations and can be subdivided into a group with absolutely no copy number alterations and a second group with focal copy number alterations. A subset of samples also has amplification of chromosome 1q. A more global and specific approach, called GISTIC, can be used to identify recurrent focal copy number alterations. TCGA data suggest that this approach identifies approximately 81 focal copy number events, including 38 amplifications and 43 deletions (20). Amplifications occur in many oncogenes, including *KRAS*, *PIK3CA*, *PAX8*, *ESR1*, *MYC*, *FGFR1*, *FGFR3*, *ERBB2*, *ERBB3*, and *CCNE1*. Deletions occur in tumor suppressors, including *PTEN*, *RB1*, *NF1*, *WWOX*, and *PARK2*.

Gene Expression

Microarray analysis and other techniques have been developed that allow analysis of mRNA expression of thousands of

genes in a tissue sample. Patterns of gene expression have been described using microarrays that distinguish between normal and malignant endometrium and between various histologic types of cancer (28,29). Global gene expression profiles associated with both lymph node metastasis and recurrence also have been identified in endometrial cancer.

TCGA identified three gene expression subtypes in endometrial cancer (20). One subtype contained most of the uterine serous cases and some grade 3 cases thought to be serous-like. One subtype was enriched for hormonally responsive genes and had higher expression of *ESR1* (estrogen receptor) and *PGR* (progesterone receptor). The third subtype was enriched for genes involved in immune regulation. Although these subgroups were associated with clinical outcome, at present it is unclear if they are independent of other known prognostic factors such as stage, grade, and histology. Studies to validate these biomarker panels and molecular-based prediction models are ongoing. These findings will further increase our understanding of the molecular pathogenesis of endometrial cancer and may help predict clinical phenotypes.

Tumor Suppressor Gene Alterations

TP53

Inactivation of the *TP53* tumor suppressor gene is among the most frequent genetic events in endometrial cancers. *TP53* mutation occurs in about 20% to 30% of all endometrial adenocarcinomas and is associated with several known prognostic factors, including advanced-stage, poor-grade, and nonendometrioid histology (30). *TP53* missense mutations are more common (~75%) and generally result in overexpression and accumulation of mutant p53 protein, whereas *TP53* truncating mutations (~25%; nonsense and frameshift) result in complete absence of p53 protein expression (31). Mutations in exons 5 through 8 are common and lead to loss of DNA-binding activity. Hotspots or areas of very frequent mutation exist at codons 248 and 273. Numerous studies have confirmed the strong association between p53 overexpression and poor prognostic factors and decreased survival (32). This is predominantly due to the disproportional frequency of *TP53* mutations in serous and high-grade endometrioid cancers. Most uterine serous carcinomas have *TP53* mutations as do one-quarter of high-grade endometrioid cases (20). Infrequent *TP53* mutation frequencies are found in grade 2 (~10%) and grade 1 (~5%) endometrioid cases.

PTEN

The *PTEN* tumor suppressor gene encodes a phosphatase that opposes the activity of cellular kinases that stimulate proliferation. *PTEN* is the most commonly mutated gene in endometrial carcinomas (33). Deletion of both copies of the gene had previously been thought to be a frequent event, resulting in complete loss of *PTEN* function. However, TCGA data suggest that homozygous deletion and mutation infrequently co-occur, as would be expected mechanistically, and homozygous deletion in the absence of mutation is also uncommon (20). More recent data suggest that single copy loss of *PTEN* is uncommon, and most tumors are diploid at this locus. *PTEN* mutations may be deletions, insertions, and nonsense mutations throughout the gene that lead to truncated protein products. In addition, missense mutations in the phosphatase domain can also inactivate PTEN function (**Fig. 2.11**). Loss of PTEN in endometrial cancers is associated with increased activity of the PI3 kinase, with resultant phosphorylation of its downstream substrate AKT (34). The PTEN/AKT pathway is frequently activated in many solid tumors, and endometrial cancer appears to be the tumor type with the greatest pathway activation.

Mutations in the *PTEN* gene are associated with endometrioid histology, early stage, and favorable clinical behavior (35). Well-differentiated, noninvasive cases have the highest frequency of *PTEN* mutations (>75%), which are uncommon in serous cases. In addition, *PTEN* mutations have been observed in endometrial hyperplasia, suggesting that this is an early event in the development of some endometrial cancers (36). It has been reported that loss of PTEN may occur in normal appearing endometrial glands, and it is proposed that this may represent the earliest event in endometrial

carcinogenesis (37).

Other Mutated Tumor Suppressor Genes

TP53 and *PTEN* were both found to be significantly mutated genes (SMGs) in the TCGA project, as evidenced by a statistically increased mutation rate compared with an expected BMR when corrected for the size of the coding region (20). Other noteworthy SMGs in endometrial cancer include *FBXW7*, *ARID1A*, and *PPP2R1A*.

FBXW7 (CDC4) mediates ubiquitin-dependent proteolysis of phosphorylation-dependent ubiquitination and ubiquitin-mediated degradation of CCNE1 and other putative oncogenes. FBXW7 has also been reported to regulate mTOR signaling, and depletion of FBXW7 results in increased levels of both mTOR and phospo-mTOR. Data from TCGA and other studies suggest that *FBXW7* is mutated in a substantial fraction (~30%) of uterine serous carcinomas.

ARID1A is a large nuclear protein that participates in chromatin remodeling with downstream effects on cellular growth and other processes. It was first reported to be mutated in ovarian endometrioid and clear cell tumors and subsequently in approximately 40% of endometrioid endometrial carcinomas. Functional studies have demonstrated that *ARID1A* is a tumor suppressor gene, and more recent data suggest that it also participates in DNA repair through interaction with the checkpoint kinase ATR.

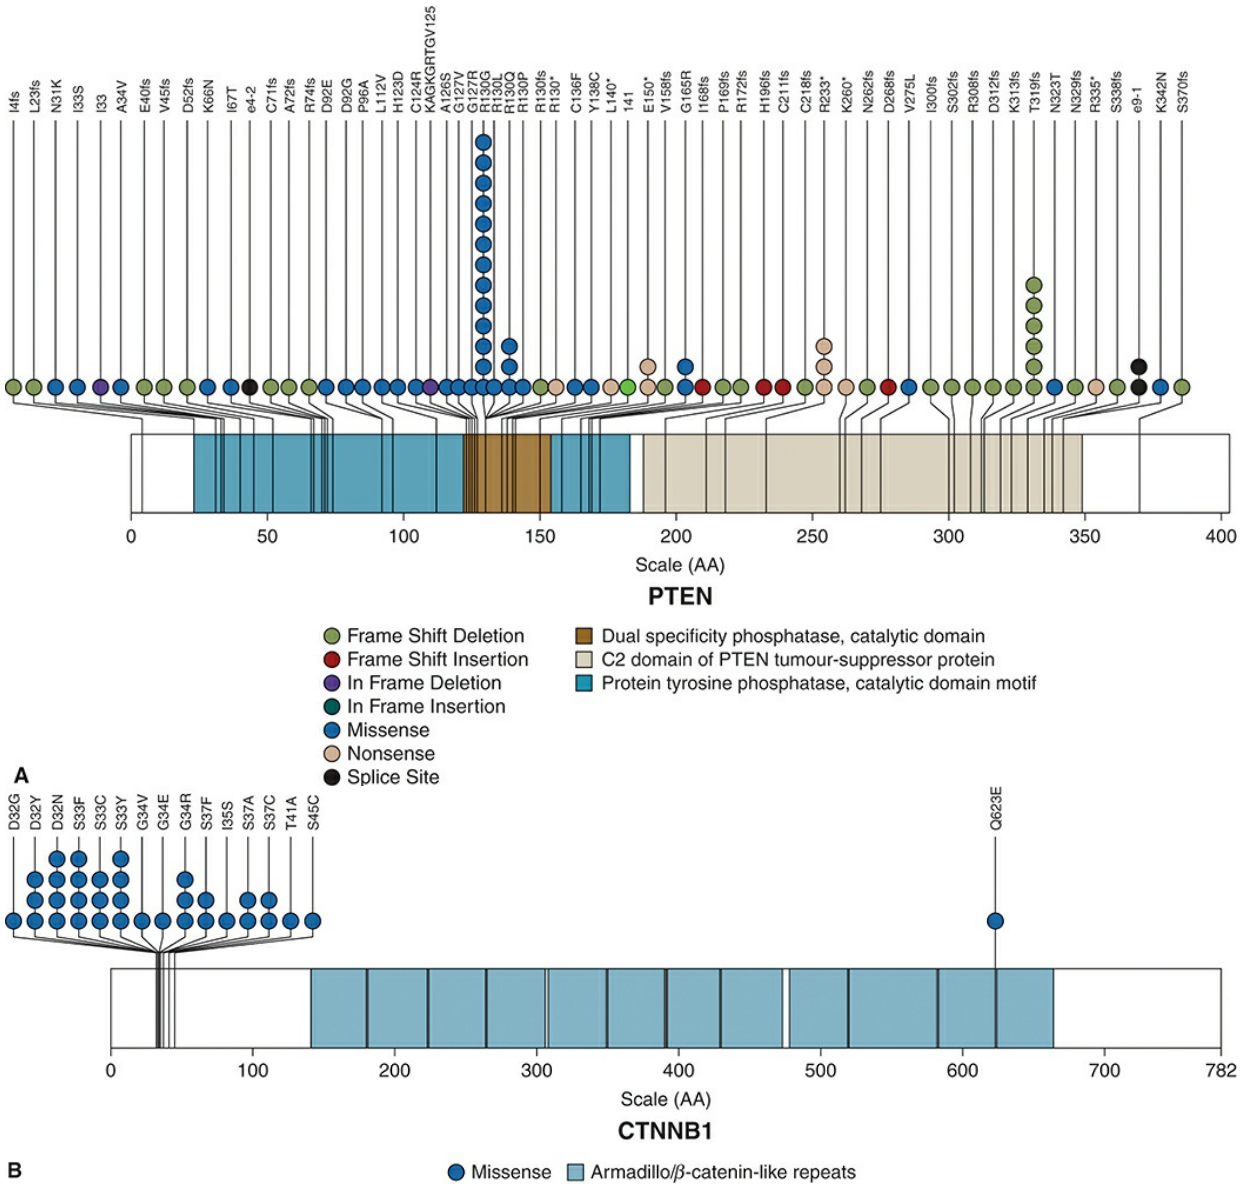

Figure 2.11 Mutational spectrum of the PTEN tumor suppressor gene and CTNNB1 (β-catenin) oncogene in 68 well-differentiated nonhypermutated endometrial cancers from TCGA. A: Mutations in the PTEN tumor suppressor occur throughout the gene. B: Mutations in the CTNN1B oncogene are missense changes in critical amino acids that result in increased activity. (Figures provided by Cyriac Kandoth and Li Ding, The Genome Institute, Washington University, St. Louis, Missouri).

PPP2R1A is the constant regulatory subunit of the protein phosphatase 2A (PP2A), a serine threonine/phosphatase, and functions in control of cell growth and division. It is mutated in 20% to 30% of uterine serous carcinomas, but not in ovarian serous carcinomas. *PPP2R1A* mutations are seen in uterine endometrioid tumors at relatively low frequency.

CTCF is a transcription factor that functions as a negative regulator of both MYC and IGF2, suggesting a role as a tumor suppressor. TCGA found *CTCF* to be mutated in nearly 25% of endometrioid cancers, but mutations were not seen in serous cases. These findings suggest varied regulation of MYC with direct amplification occurring in serous tumors and loss of inhibition through *CTCF* mutation occurring in endometrioid tumors.

Oncogene Alterations

ERBB2 (HER-2/neu)

Alterations in oncogenes have been demonstrated in endometrial cancers, but occur less frequently than inactivation of tumor suppressor genes (**Table 2.3**). Increased expression of the HER-2/*neu* receptor tyrosine kinase initially was noted in 10% of endometrial cancers (38) and was associated with advanced stage and poor outcome. HER-2/*neu* overexpression is most frequently noted in serous endometrial cancers (39). TCGA data indicate that HER-2/*neu* is amplified in ~25% of uterine serous carcinomas and only ~1% of endometrioid tumors, confirming a strong association with histologic subtype (20).

Therapies that target HER-2/*neu* may have a role in the treatment of some uterine serous carcinomas. However, the levels of HER-2/*neu* overexpression in endometrial cancers are much less striking than in breast cancers. The Gynecologic Oncology Group (GOG) studied trastuzumab in advanced or recurrent HER-2/*neu*-amplified endometrial cancers. They confirmed a higher rate of overexpression in serous tumors (28%) than endometrioid tumors (7%). However, there were no major responses to therapy (40). Presently, a study of trastuzumab in combination with chemotherapy is ongoing, and PIK3CA mutations may represent a mechanism of resistance to this therapy (41).

KRAS

The *RAS* oncogenes undergo point mutations in codons 12, 13, or 61 that result in constitutively activated molecules in many types of cancers. Initial studies of endometrial adenocarcinomas in the 1990s found codon 12 of *KRAS* mutations in about 10% of American cases and 20% of Japanese cases (42,43). TCGA data indicate that *KRAS* is mutated in ~25% of endometrioid cases and rarely in serous cases (20). There is a greater frequency of *KRAS* mutations among hypermutator endometrioid cases (35%) compared with other cases (15%). *KRAS* mutations also have been identified in some endometrial hyperplasias (44), which suggests that this may be a relatively early event in the development of some Type I cancers.

PI3K

The *PTEN* tumor suppressor gene, which negatively regulates phosphatidylinositide 3-kinase (PI3K) activity, is frequently mutated in endometrioid endometrial cancers. Conversely, the *PIK3CA* gene is oncogenically activated in many cases.

Activating mutations in the catalytic subunit of *PI3K* (*PIK3CA*) have been described in numerous cancer types. The p85-alpha regulatory subunit of PI3K (PIK3R1) has also been reported to be mutated and the p85-beta regulatory subunit of PI3K (PIK3R2) is mutated, although much less frequently, often in the setting of MSI.

In an initial study, *PIK3CA* mutations were seen in 36% of endometrial cancers, and 24% of cases had mutations in both *PTEN* and *PIK3CA* (45). In a subsequent study, 39% of endometrial cancers and 7% of atypical endometrial hyperplasias were found to harbor mutations in *PIK3CA* (46), implying that *PIK3CA* mutation occurs early in tumorigenesis. As in the initial study, a high fraction of cases had co-mutation in both *PTEN* and *PIK3CA*. These and other studies (47) confirm that *PIK3CA* activating mutations occur in both serous and endometrioid endometrial cancers.

TCGA identified *PIK3CA* mutations in ~50% of both serous and endometrioid tumors (20); however, *PIK3R1* mutations were generally restricted to endometrioid cases, occurring in ~40%. It has been suggested that one mechanism by which *PIK3R1* mutations are oncogenic is through the disruption of p85-alpha dimers that stabilize PTEN (48). Both inactivation of PTEN and activation of PIK3CA can lead to activation of AKT, which in turn leads to upregulation of the mTOR. Recent studies have suggested that inhibitors of the AKT/mTOR pathway such as temsirolimus may be useful in the management of endometrial cancer (49). Response to agents targeting this pathway may be enhanced by selection of patients with *PIK3CA* mutations (50).

CTNNB1 (β-catenin)

Alterations in the WNT pathway involving E-cadherin (CDH1), APC, and β-catenin (CTNNB1) have been noted in endometrial cancers. E-cadherin is a transmembrane glycoprotein involved in cell–cell adhesion, and decreased expression in cancer cells is associated with increased invasiveness and metastatic potential. E-cadherin mutations do not occur in uterine serous cancers, but occur more commonly (~7%) in endometrioid tumors with some predisposition to those cases with MSI. The cytoplasmic tail of E-cadherin exists as a macromolecular complex with the *b-catenin* and *APC* gene products, which link it to the cytoskeleton. It appears that a critical function of the *APC* tumor suppressor gene is to regulate GSK3B phosphorylation of serine and threonine residues (codons 33, 37, 41, 45) in exon 3 of β-catenin, which results in degradation of β-catenin. Mutational inactivation of APC allows accumulation of β-catenin, which translocates to the nucleus and acts as a transcription factor to induce expression of cyclin D1 and perhaps other genes involved in cell cycle progression.

Germline *APC* mutations are responsible for the adenomatous polyposis coli syndrome, and somatic mutations are common in sporadic colon cancers, but *APC* mutations have not been previously described in endometrial cancers. TCGA identified APC gene mutations, but these were mostly restricted to hypermutator cases and may be passenger rather than driver mutations. The *APC* gene may be inactivated in some endometrial cancers due to promoter methylation.

It has been shown that missense mutations in exon 3 of β-catenin lead to the same end result—namely, abrogation of the ability of APC and GSK3B to induce β-catenin degradation—which results in nuclear localization and increased transcriptional activity. β-Catenin mutations have been observed in several types of cancers, including hepatocellular, prostate, colon, and endometrial cancers. Nuclear accumulation of β-catenin protein due to mutation of the gene has been reported in about one-third of endometrioid endometrial cancers (51). Mutation of *β-catenin* has not been observed in uterine serous carcinomas. However, TCGA data indicate that the mutational frequency is ~50% in the MSS/nonhypermutator endometrioid cancers and only 15% to 20% in the MSI/hypermutator cases, suggesting that this is an important driver mutation in cases without MSI (20).

GFR2

Mutations have also been observed in the fibroblast growth factor receptor 2 (*FGFR2*) gene in about 10% of endometrial cancers (52). In TCGA, *FGFR2* mutations were found more commonly in endometrioid cancers, with a slight predilection for MSI cases. A recent report indicates that *FGFR2* and *KRAS* mutations occur in a near mutually exclusive pattern.

FGFR2 mutations were found to be associated with a worse outcome among early-stage endometrioid tumors (53). Further studies are needed to evaluate the significance of the identified mutations, as well as the potential clinical utility of drugs targeting the receptor (54).

Other Oncogenes

Among nuclear transcription factors involved in stimulating proliferation, amplification of members of the *MYC* family have most often been implicated in the development of human cancers. It has been shown that MYC is expressed in normal endometrium with higher expression in the proliferative phase. Several studies have suggested that *MYC* may be amplified in a fraction of endometrial cancers (55). TCGA has identified a low frequency of somatic mutations in *MYC*, but 25% of uterine serous cancers have high-level amplification of the gene (20). *CTCF* is a transcription factor that functions as a negative regulator of both *MYC* and *IGF2*, suggesting a role as a tumor suppressor. TCGA found *CTCF* to be mutated in nearly 25% of endometrioid cancers, but mutations were not seen in serous cases. These findings suggest varied regulation of *MYC*, with direct amplification occurring in serous tumors and loss of inhibition through *CTCF* mutation occurring in endometrioid tumors.

Uterine Sarcomas

Although little is known regarding molecular alterations in uterine sarcomas, a number of studies are being conducted to examine uterine carcinosarcomas, leiomyosarcomas, adenosarcomas, and endometrial stromal sarcomas. The rare tumor TCGA project on uterine carcinosarcoma has identified somatic *TP53* mutations in >90% of tumors, consistent with prior reports, but distinct from uterine adenosarcomas, which only rarely harbor TP53 mutations (56). Preliminary TCGA data from uterine leiomyosarcomas indicate that ~35% of cases have *TP53* mutations.

Endometrial stromal sarcomas are characterized by gene rearrangements that result in fusion of parts of two genes, and these are presumed to have the ability to stimulate malignant transformation. Low-grade endometrial stromal sarcomas usually present at an early stage and many have rearrangement of genes involved in chromatin binding. Most often, this is manifest in the form of t(7;17)(p15;q21), which results in a *JAZF1–SUZ12* fusion. In contrast, undifferentiated endometrial stromal sarcomas, which are more virulent and usually present at an advanced stage, frequently have t(10;17)(q22;p13) rearrangements that result in an in-frame fusion between *YWHAE* (exons 1 to 5) and one of the two highly homologous genes *FAM22A* and *FAM22B* (exons 2 to 7) (designated as *YWHAE-FAM22*) (57). Fluorescence *in situ* hybridization can be used to identify the gene fusions that differentiate low grade from undifferentiated endometrial stromal sarcomas.

OVARIAN CANCER

Etiology

About 20% of high-grade ovarian cancers arise in women who carry germline mutations in cancer susceptibility genes—predominantly *BRCA1* or *BRCA2* (58). Hereditary ovarian cancer is discussed in Chapter 3. The vast majority of ovarian cancer is sporadic and arises due to accumulation of somatic genetic damage. The causes of acquired genetic alterations remain uncertain, but exogenous carcinogens have not been strongly implicated. Cellular proliferation and oxidative stress with free radical formation with associated inflammation at the time of ovulation or in association with endometriosis or infection may also contribute to accumulation of DNA damage. Regardless of the molecular mechanisms involved, reproductive events that decrease lifetime ovulatory cycles (e.g., pregnancy and birth control pills) are protective against

ovarian cancer (see Chapter 1). The action of other reproductive hormones such as estrogens, androgens, and gonadotropins may also contribute to the development of ovarian cancers.

Epithelial ovarian cancers are heterogeneous with respect to behavior (borderline vs. invasive), grade, and histologic type. It has become increasingly clear that there are striking differences in the molecular pathogenesis of various disease subsets. It has been proposed that ovarian cancers can be classified as Type I or II based on histology, grade, stage, and molecular alterations (59). Type I tumors are generally confined to an ovarian mass at diagnosis and include low-grade serous, mucinous, and most endometrioid and clear cell carcinomas. They are genetically stable and are characterized by mutations in a number of genes including *KRAS*, *BRAF*, *PTEN*, *CTNNB1*, *ARID1A*, and *PPP2R1A*. Type II cancers typically present at an advanced stage and are predominantly high-grade serous lesions, but also include high-grade endometrioid, carcinosarcoma, and undifferentiated cancers. This group of tumors has a high level of genetic instability, with frequent chromosomal gains and losses and mutation of *TP53*.

There is now strong evidence to suggest that nearly all epithelial ovarian cancers have an extraovarian origin (59). High-grade serous cancers of the ovary, fallopian tube, and peritoneum are likely derived from epithelial cells of the distal fallopian tube and fimbria (60). In this regard, most early serous cancers discovered in *BRCA1/2* carriers undergoing prophylactic surgery have been found to originate in the fallopian tube fimbria and are associated with preinvasive serous tubal *intraepithelial* carcinomas (STICs) that overexpress mutant *TP53*. In contrast, most endometrioid and clear cell cancers are thought to develop in deposits of endometriosis on the ovary or other pelvic structures. The origin of mucinous ovarian cancers is less clear, and some may arise from preexisting dermoid cysts (teratomas). Historically, the majority of mucinous ovarian tumors represented unrecognized metastatic gastrointestinal cancers. It has also been postulated that some mucinous and Brenner tumors arise from embryonic rests near the ovary.

As our understanding of the molecular pathogenesis of ovarian cancer continues to mature, it is likely that the various ovarian cancer subsets will increasingly be thought of as distinct entities with respect to diagnosis, treatment, and prevention (7). In view of this, each of the subtypes is discussed separately below.

High-Grade Serous Ovarian Cancer

High-grade serous ovarian cancer was the second cancer analyzed by TCGA project (58). This comprehensive genomic analysis confirmed prior findings; most notably, these cancers are characterized by a high degree of genetic instability with many copy number alterations and inactivation of *TP53* and *BRCA1/2* and other genes in the HR DNA repair pathway. Some previously unreported alterations also were discovered. This section will put the TCGA data in perspective with prior studies.

DNA Copy Number Alterations

Most high-grade serous ovarian cancers are characterized by extensive genetic instability. Initially gains and losses of various segments of the genome were demonstrated using karyotyping and later at a finer level using CGH. Likewise, LOH, indicative of deletion of specific genetic loci, was also demonstrated to occur at a high frequency on many chromosomal arms. Most recently, it has been possible using next-generation sequencing to characterize chromosomal rearrangements at the level of the actual base sequence, which facilitates analysis of their functional significance (61). Large gene deletions have been reported as well as transcriptional fusions that impact on platinum resistance.

TCGA examined DNA copy number alterations in 489 cases using a variety of high-resolution platforms (58). There were 8 chromosomal regions with recurrent gains and 22 with losses, all of which had been described previously. There were 63 recurrent focal amplifications that encoded 8 or fewer genes. The most common focal amplifications included *CCNE1* (cyclin E), *MYC*, and *MECOM*, each of which was amplified in more than 20% of cancers.

It was already known prior to the TCGA study that increased activity of transcription factors such as MYC and various cyclins might stimulate malignant transformation. Amplification of MYC had been reported to occur in some

ovarian cancers (62), as had amplification and overexpression of cyclin E1 (63). In studies of advanced-stage ovarian cancers, high cyclin E1 expression was associated with poor outcome (64). Alterations of the PI3K pathway are frequent in ovarian cancer, and it also previously had been reported that the *AKT2* (65) and *PIK3CA* genes are amplified in some cases (66).

Cyclin E1 (*CCNE1*) amplification has been reported to occur independently of *BRCA1/2* mutation, and it is associated with reduced patient survival. Insensitivity of *CCNE1*-amplified tumors to platinum cross-linking agents may be partly because of an intact *BRCA1/2* pathway. These events may be mutually exclusive, because either change provides a path to tumor development, with no selective advantage to having both mutations. Using data from a genome-wide shRNA synthetic lethal screen, *BRCA1* and members of the ubiquitin pathway were shown to be selectively required in cancers that harbor *CCNE1* amplification (67). Furthermore, specific sensitivity of *CCNE1*-amplified tumor cells was shown to the proteasome inhibitor bortezomib. These findings provide an explanation for the observed mutual exclusivity of *CCNE1* amplification and *BRCA1/2* loss in high-grade serous cancers and suggest a unique therapeutic approach for treatment-resistant *CCNE1*-amplified tumors. In addition, *CDK2* was shown to be an effective therapeutic target in CCNE1-amplified cells *in vitro* (68).

TCGA identified 50 focal deletions, and the known tumor suppressor genes *PTEN*, *RB*, and *NF1* were deleted, albeit only in a small fraction of cases (58). The latter two genes also were targeted by mutations, consistent with the two-hit paradigm of tumor suppressor gene inactivation. Although mutations in the *RB1* tumor suppressor gene are not a common feature of ovarian cancers, evidence suggests that inactivation of *RB1* greatly enhances tumor formation in the presence of *TP53* mutations (69). A recent study identified frequent (~15%) gene breakage in *RB1* using whole-genome sequencing that had been previously overlooked through less robust sequencing approaches. A similar frequency of *NF1* loss due to gene breakage was also identified. A large number of other candidate genes are in regions that are recurrently amplified or deleted in high-grade serous ovarian cancers. Considerable effort will be required to elucidate which of these represent driver events in some cancers, as opposed to alterations of no consequence for tumorigenesis or progression.

About 30% of breast cancers express increased levels of the HER-2/*neu* (*ERBB2*) oncogene (70), usually due to gene amplification, and overexpression has been associated with poor survival. Expression of HER-2/*neu* is increased in a fraction of ovarian cancers, and overexpression has been associated with poor survival in some studies. However, ovarian cancers with HER-2/*neu* overexpression rarely have high-level gene amplification. Anti-HER-2/*neu* antibody therapy (trastuzumab) has demonstrated great efficacy in breast cancer and often is administered with chemotherapy in the context of both adjuvant therapy and treatment of metastatic disease (71). A study performed by the GOG found that only 11% of ovarian cancers exhibited significant HER-2/*neu* overexpression (72). The response rate to single-agent trastuzumab therapy was disappointingly low (7%), but there may be some benefit using it in regimens that also include cytotoxic or other biological agents.

The cdk inhibitors act as tumor suppressors by virtue of their inhibition of cell cycle progression from G1 to S phase. Expression of several cdk inhibitors appears to be decreased in some ovarian cancers. *CDKN2A* (p16) undergoes homozygous deletions in approximately 15% of ovarian cancers (73). There is evidence to suggest that *CDKN2A* (74) and *CDKN2B* (p15) (75) may be inactivated via transcriptional silencing due to promoter methylation rather than mutation and/or deletion. Likewise, decreased expression of the p21/*WAF1* cdk inhibitor has been noted in a significant fraction of ovarian cancers despite the absence of inactivating mutations (76). Loss of p27 (*CDKN1B*) also may occur and correlates with poor survival in some studies (77). It has been suggested that aberrant expression of p27 in the cytoplasm may be most associated with poor outcome (78).

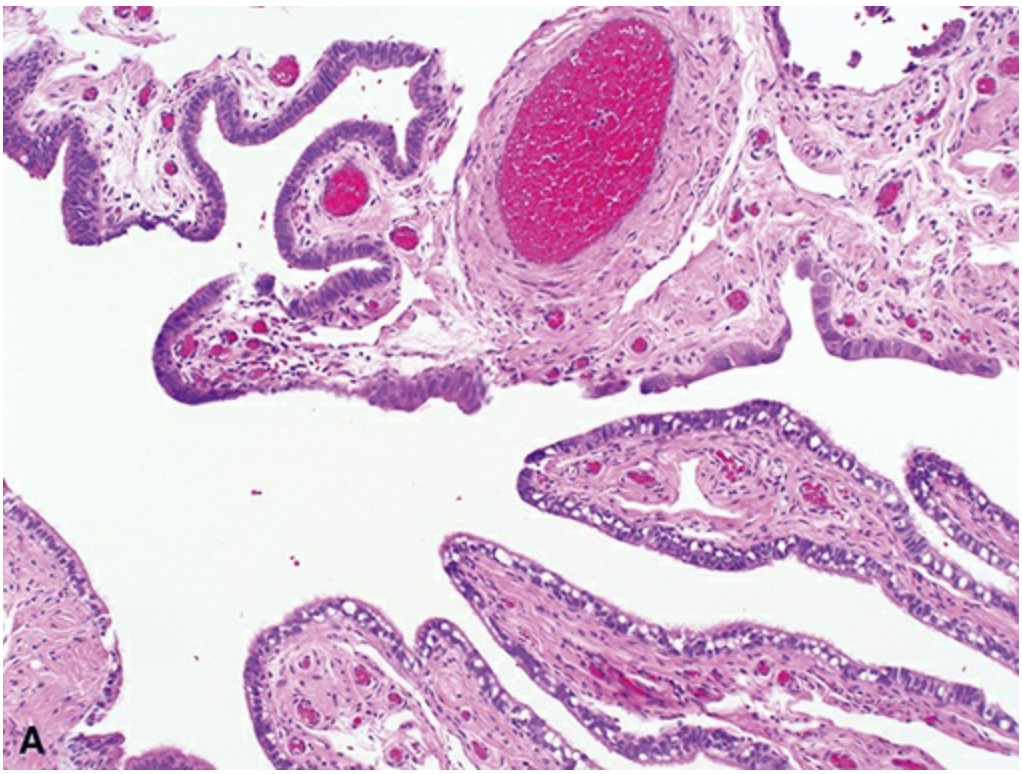
Mutations

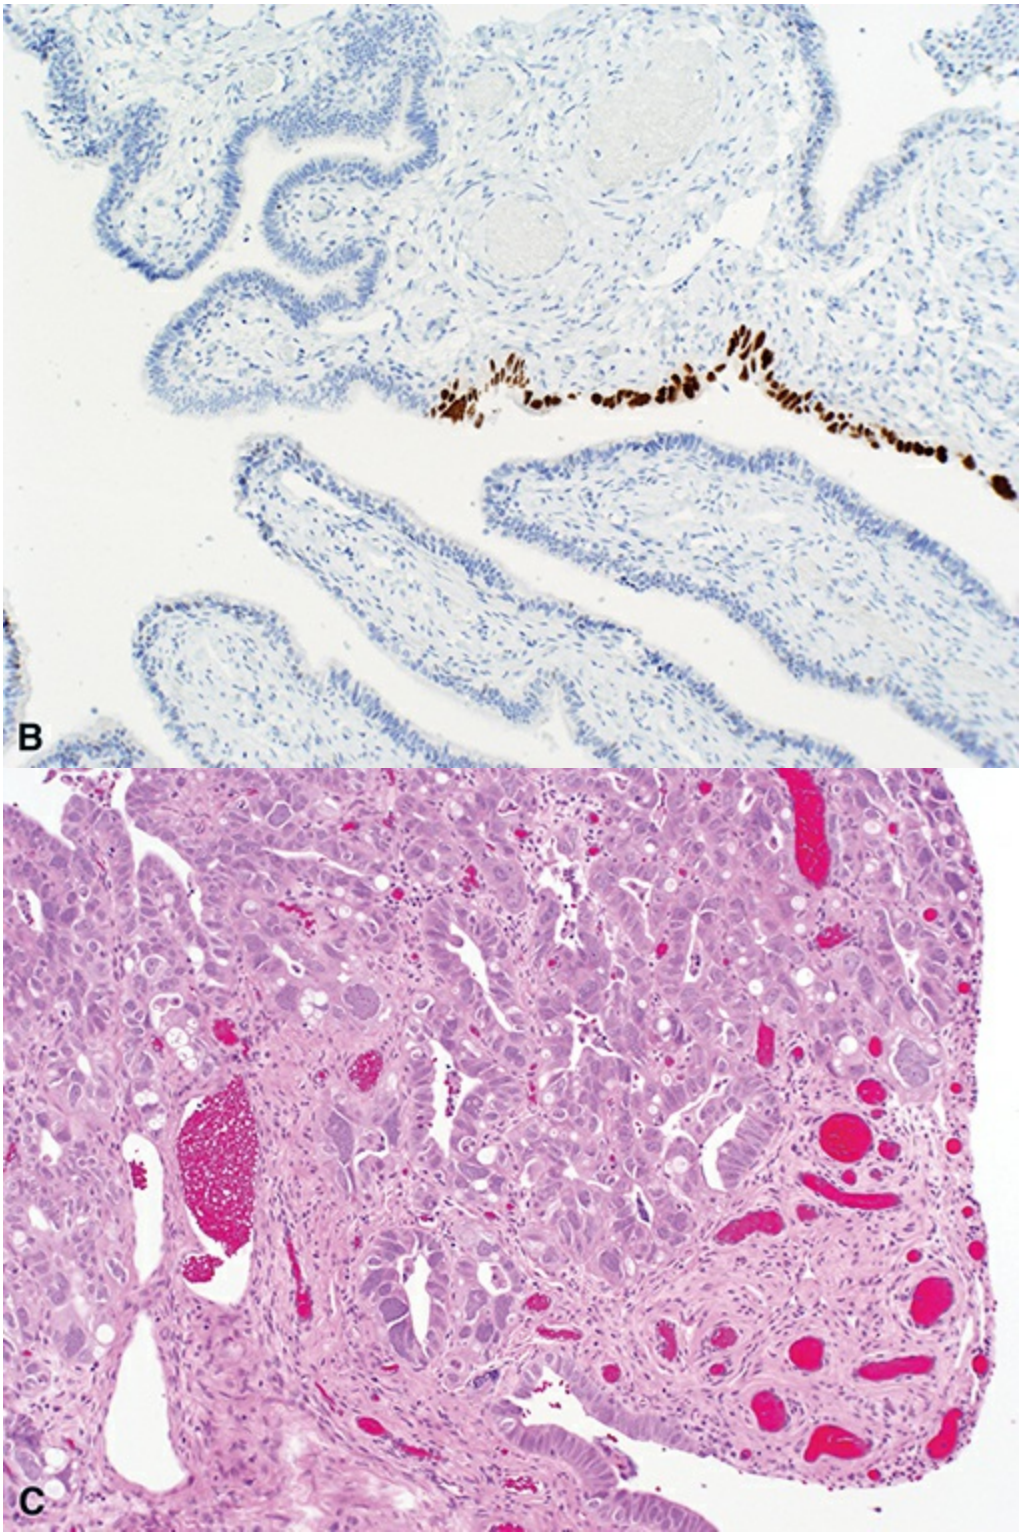
TCGA performed sequencing of the coding regions and splice sites of approximately 18,500 genes in DNA isolated initially from 316 high-grade serous ovarian cancers (58). The extent of this sequencing effort in ovarian cancer was unprecedented and would not have been possible without the recent development of massively parallel next-generation

sequencing technologies. Although several genes were identified that are mutated at low frequencies, *TP53*, *BRCA1*, and *BRCA2* were confirmed to be the most frequently mutated genes in high-grade ovarian cancers.

TP53.

The TCGA study validated the prior finding that mutation of the *TP53* tumor suppressor gene is the most frequent genetic event in high-grade serous ovarian cancers (**Table 2.4**). It is an early event that is found in STIC (**Fig. 2.12**) (60). About two-thirds of high-grade serous ovarian cancers have *TP53* missense mutations in the DNA-binding regions of exons 5 through 8 that result in p53 protein overexpression due to increased stability of the protein. Codons 175, 248, and 273 are mutational hot spots. These missense mutants act as dominant negative transforming genes due to their nonfunctional transcriptional activity. Loss of the other copy of the *TP53* gene is not required.





B
C

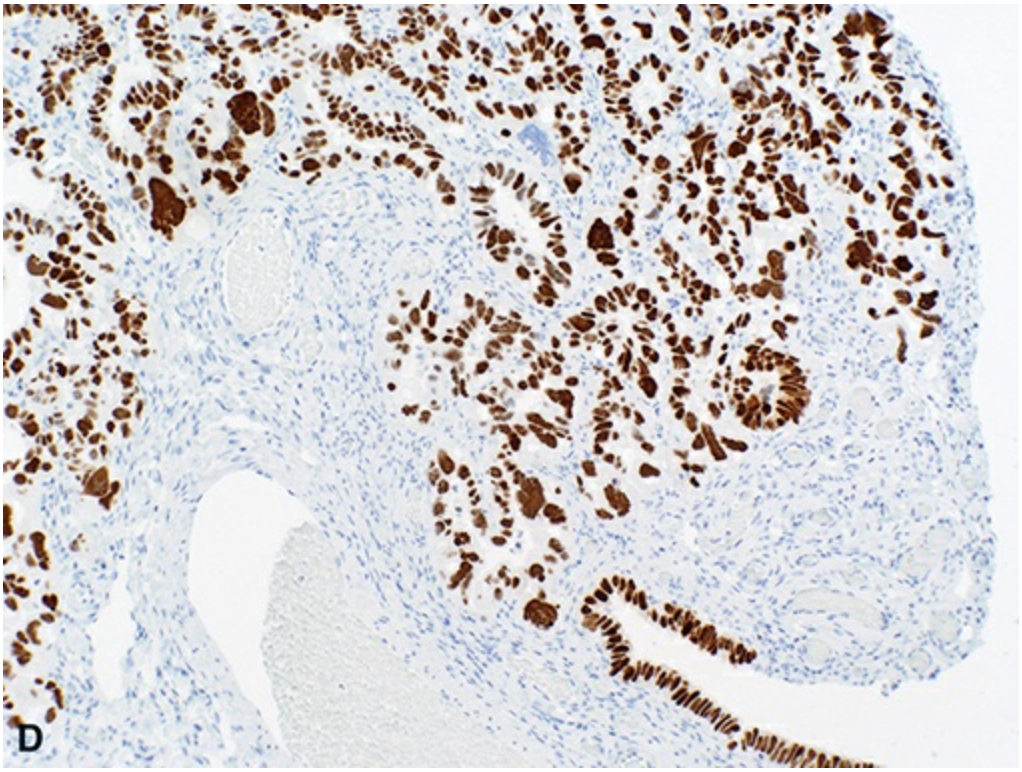


Figure 2.12 Overexpression of mutant TP53 in serous tubal carcinoma in situ (A, B) and in high-grade serous ovarian cancer (C, D).

TABLE 2.4 Characteristics of Common Invasive Epithelial Ovarian Carcinomas

	Mucinous	Endometrioid/Clear Cell	High-Grade Serous	Low-Grade Serous
Origin	Unclear	Endometriosis	Fallopian tube	Fallopian tube
Typical stage	Early	Early	Advanced	Advanced
Survival	Favorable	Favorable	Poor	Favorable
Commonly altered genes	KRAS	PTEN	TP53	KRAS
	HER-2/neu	PIK3CA	BRCA1	BRAF
	TP53, CDKN2A	CTNNB1(β-catenin) ARID1A PPP2R1A	BRCA2	

Most high-grade serous ovarian cancers that do not overexpress p53 protein have *TP53* mutations that result in truncated protein products. These are usually accompanied by loss of the other copy of the gene, consistent with the classic two-hit model of tumor suppressor gene inactivation. TCGA found *TP53* mutations in >95% of samples, suggesting that this is essentially a requisite event in the development of these cancers. Subsequent pathology review of the few cases lacking mutations found that these were probably not high-grade serous cancers (79).

BRCA1 and BRCA2.

BRCA1 and *BRCA2* germline mutations were found in 9% and 8% of high-grade serous cases, respectively, in the TCGA

study, and somatic mutations in each gene occurred in an additional 3% (58). Silencing of *BRCA1* due to promoter methylation was observed in 11% of cases. Defective HR repair of double-stranded DNA damage due to loss of *BRCA1/2* was predicted in 31% of high-grade serous ovarian cancers. Other genes in the HR pathway are inactivated in some cancers, and the HR pathway may be compromised in approximately half of all cases (**Fig. 2.13**). A subsequent analysis of germline and somatic alterations in 429 TCGA ovarian carcinoma cases and 557 controls suggests that truncation variants and large deletions exist across Fanconi pathway genes in 20% of cases (80).

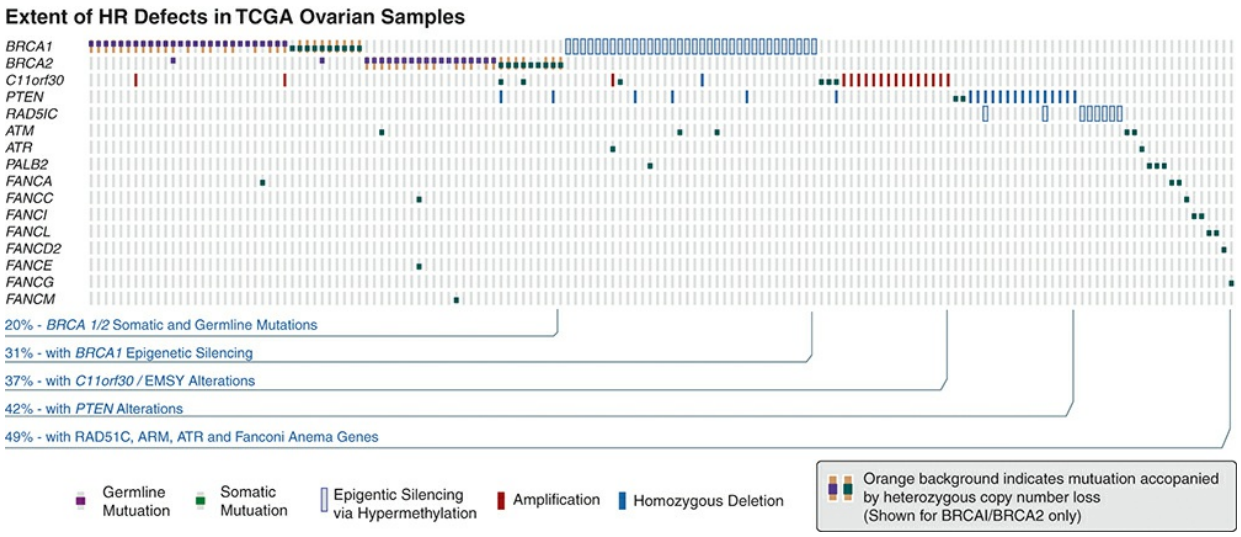

Figure 2.13 Genomic fingerprint of homologous recombination (HR) pathway alterations. Each column represents an individual case; each row represents a gene. Only cases with HR defects (N=154) are shown.

Patients with *BRCA1* or *BRCA2* mutations were initially noted to have increased sensitivity to platinum chemotherapy and favorable survival relative to sporadic cases (81,82). Conversely, the emergence of platinum resistance in these cancers may occur due to "revertant mutations" in which the normal *BRCA1* or *BRCA2* sequence is restored (83). More recently, studies have suggested that the initial favorable outcome seen in BRCA1/2 carriers does not persist with longer follow-up (84).

Cancers with defects in the double-stranded DNA HR repair pathway can be targeted effectively by inducing a second hit in the form of inhibition of the single-stranded DNA repair pathway. This concept of synthetic lethality—the combination of two genetic alterations, which on their own are nonlethal, but together result in a lethal phenotype—led to interest in inhibitors of enzymes such as PARP that are involved in single-stranded BER (85). Inhibition of PARP leads to the persistence of DNA lesions normally repaired by HR and makes HR-deficient cells particularly sensitive to chemotherapy-induced DNA injury. PARP inhibitors have been shown to be selective for cells with defects in the repair of double-strand DNA breaks by HR, particularly in the context of *BRCA1* or *BRCA2* mutation. While normal cells can repair the damage and survive, the BRCA-deficient cells cannot activate the HR system and therefore die (86). PARP inhibitors have demonstrated promising results in ongoing trials in ovarian cancer, and olaparib has been approved in the United States and Europe for treatment of *BRCA1/2*-mutated ovarian cancers.

While only a minority of high-grade serous ovarian cancers have germline *BRCA1* or *BRCA2* mutations, sporadic ovarian cancers can harbor acquired genetic and epigenetic defects in *BRCA1/2* and in other HR genes and proteins, such as *RAD51C/D* and *BRIP1*, that may contribute to a "BRCAness profile" (87). Given the shared role that *BRCA1* and *BRCA2* have with other DNA repair genes, defects in these could influence response to treatment, recurrence rates, and overall survival and increase sensitivity to platinum drugs and PARP inhibitors (88). In this regard, it was shown using the TCGA data that a DNA repair pathway score was predictive of outcome in ovarian cancer (89).

More recently, investigators with the Australian Ovarian Cancer Study performed whole-genome sequencing of tumor and germline DNA from 92 patients with primary refractory, resistant, sensitive, and matched acquired resistant disease

(90). It was shown that gene breakage commonly inactivates the tumor suppressors *RB1*, *NF1*, *RAD51B*, and *PTEN* and contributes to acquired chemotherapy resistance. *CCNE1* amplification was common in primary resistant and refractory disease. Several molecular events were associated with acquired resistance, including multiple independent reversions of germline *BRCA1* or *BRCA2* mutations in individual patients, loss of *BRCA1* promoter methylation, an alteration in molecular subtype, and recurrent promoter fusion associated with overexpression of the drug efflux pump *MDR1*. Clonal evolution also has the potential to affect responsiveness of high-grade serous cancers. In a genomic analysis of 31 tumor deposits from six patients, only 51.5% of mutations were present in every sample of a given case (range 10.2% to 91.4%), and *TP53* was the only mutation consistently present in all samples (91).

Other mutations.

Six other genes were found to be significantly mutated by TCGA, including *RB1*, *NF1*, *FAT3*, *CSMD3*, *GABRA6*, and *CDK12*, but none was mutated in more than 6% of cancers (58). *RB1* and *NF1* are known tumor suppressor genes, while *CDK12* has also been implicated in both the regulation of RNA splicing and HR DNA repair. *FAT3* and *GABRA6* are not expressed in serous ovarian cancers or in the fallopian tube, and the significance of these mutations is unclear. A number of other known oncogenic mutations were found in *KRAS*, *NRAS*, *PIK3CA*, and *BRAF*, but at low frequencies of less than 1%. These mutations have been shown to have transforming activity and probably represent important drivers of some cancers, but may highlight cases misdiagnosed as high-grade serous.

In subsequent analysis of the TCGA whole-exome sequencing data, mutations of eight members of the ADAMTS family were noted in 10.4% of cases and were associated with a significantly higher chemotherapy sensitivity and better overall survival (58.0 vs. 41.3 months) (92). ADAMTS family members are metalloproteases that play roles in cell adhesion, migration, blood clotting, inflammation, angiogenesis, and connective tissue modeling. ADAMTS-mutated cases exhibited a distinct mutation spectrum and were significantly associated with tumors with a higher genome-wide mutation rate (median mutations per sample, 121 vs. 69).

Gene Expression

Microarray chips that contain sequences complementary to thousands of genes have been created that allow global assessment of the level of expression of each gene. Many genes have been identified that appear to be up- or downregulated in the process of malignant transformation. In addition, microarrays have demonstrated patterns of gene expression that distinguish between histologic types (93), borderline versus invasive cases (94), and between early- and advanced-stage disease (95). Molecular signatures have also been identified that are predictive of survival (96). More recently, sequencing of RNA has become technically feasible at a reasonable cost and provides a more accurate and direct representation of gene expression. RNA sequencing appears to be replacing microarrays as the preferred method for gene expression quantification.

In the TCGA ovarian cancer project, a 193-gene expression signature predictive of survival was developed and validated in several other existing data sets (**Fig. 2.14**) (58). TCGA also identified four gene expression subtypes of high-grade serous ovarian cancer that confirmed prior studies (97). These were named mesenchymal or C1, immunoreactive or C2, differentiated or C4, and proliferative or C5 subtypes based on the genes that characterized each subtype (**Fig. 2.14**). Favorable outcome is associated with the immunoreactive (C2) type, consistent with earlier studies and a worse prognosis for the mesenchymal (C1) and proliferative (C5) types (98). Alterations in gene expression may be attributable to methylation of their promoters. The TCGA examined tumor methylation using arrays that include promoters of thousands of genes. They found 168 epigenetically altered genes compared with normal fallopian tube epithelium. Further validation of genomic signatures is needed, but genomic approaches hold the potential to guide selection of therapy in the future. Patients identified as having a “poor prognosis” molecular profile might be the best candidates for investigational trials of new therapies.

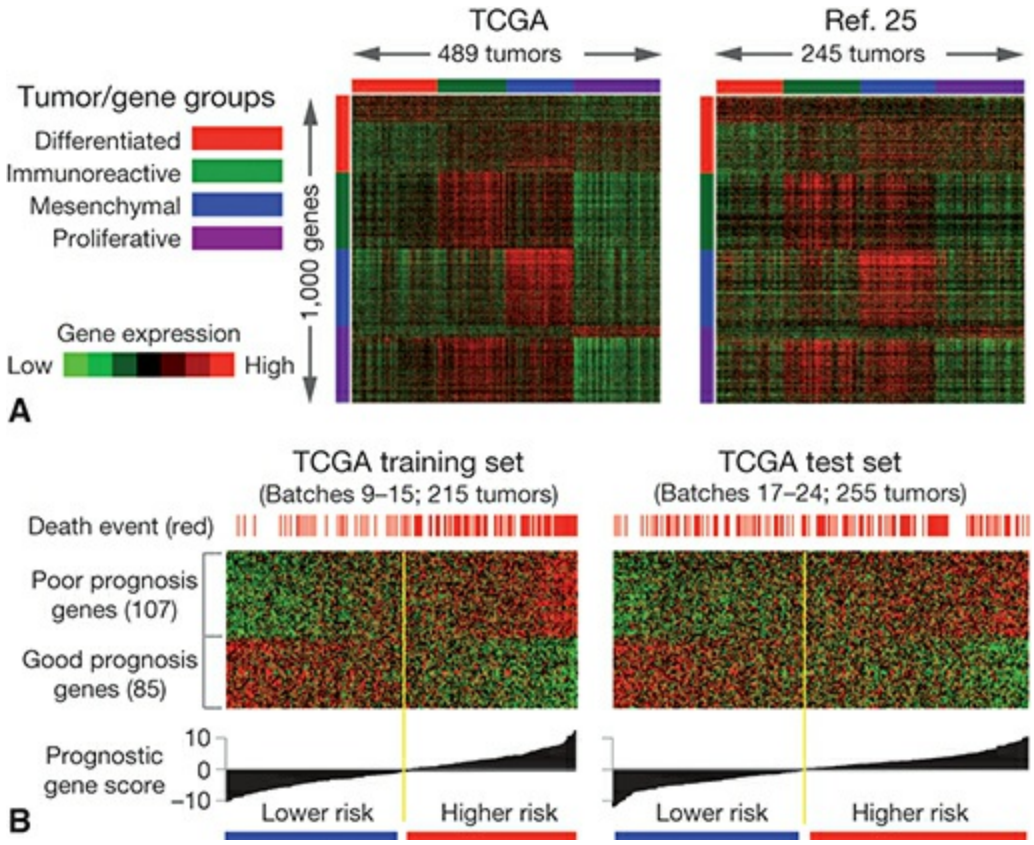

Figure 2.14 Gene expression patterns of molecular subtype and outcome prediction in high-grade serous ovarian cancers from TCGA and from reference 97. A: Cancers separated into four clusters on the basis of gene expression. B: Using a training data set, a prognostic gene signature was defined and applied to a test data set. Reprinted by permission from Macmillan Publishers Ltd: The Cancer Genome Atlas Research Network. Integrated genomic analyses of ovarian carcinoma. Nature 2011;474:612; copyright 2011.

With the evolving characterization of the genome, networks of molecular signals that regulate cellular proliferation and death have been identified—from receptor–ligand interactions at the cell membrane that transmit signals to the cytoplasm and then to the nucleus. The extensive genomic characterization of high-grade serous ovarian cancer by TCGA allowed for assessment of various signaling pathways. It was found that components of the RB and PI3K/RAS pathways were frequently altered, while the homologous DNA repair pathway was frequently inactivated.

Recently, 13 publicly available data sets totaling 1,525 subjects were used to develop gene expression signatures for predicting debulking status and survival in advanced-stage, serous ovarian cancer and debulking status (99). The survival signature stratified patients into high- and low-risk groups (hazard ratio = 2.19; 95% confidence interval [CI] = 1.84 to 2.61) significantly better than the TCGA signature. *POSTN*, *CXCL14*, *FAP*, *NUAK1*, *PTCH1*, and *TGFBR2* were validated by quantitative reverse transcription-polymerase chain reaction and POSTN, CXCL14, and phosphorylated Smad2/3 were validated by immunohistochemistry ($p < 0.001$) as independent predictors of debulking status. Immunohistochemistry for these three proteins classified 92.8% of samples correctly for suboptimal debulking, potentially allowing for stratification of patients for primary versus secondary cytoreduction.

Borderline and Invasive Low-Grade Serous Ovarian Cancers

Similar to high-grade serous cancers, it is thought that borderline and low-grade serous cancers likely arise from fallopian tube epithelium. However, the underlying genetic alterations in borderline and low-grade tumors are different from those of

high-grade cancers, suggesting that they are distinct entities rather than a single disease with varying degrees of differentiation.

Activating mutations in codons 12 and 13 of the *KRAS* oncogene are common in borderline serous ovarian tumors, occurring in about 25% to 50% of cases (100). In addition, the activating mutation V600E in the *BRAF* gene, which is a downstream effector of *KRAS*, occurs in about 20% of serous borderline tumors (101). Mutations in *KRAS* and *BRAF* have also been noted in benign epithelial cysts adjacent to serous borderline tumors, suggesting that this is an early event in their development (13). Specific inhibitors of V600E mutant BRAF protein have proven highly effective in melanomas. Mutations in these two genes are mutually exclusive and result in constitutive activation of the MAP kinase pathway.

Mutations in *KRAS*, and less frequently *BRAF*, also occur in some low-grade serous ovarian cancers (59). *KRAS* mutations are very common in recurrent cases, while *BRAF* mutations are rare (102). In another study, exome sequencing identified *BRAF*, *KRAS*, *NRAS*, *USP9X*, and *EIF1AX* as the most frequently mutated genes (103). *USP9X* and *EIF1AX* have both been linked to regulation of mTOR, suggesting that this pathway may be a candidate for targeted therapy trials (103), since metastatic low-grade serous and borderline cancers are generally resistant to platinum/taxane therapy. The MAP kinase pathway downstream from *KRAS/BRAF* also represents an appealing target. The MEK inhibitor trametinib and others have shown some minor activity in trials to date, but this does not correlate with *KRAS*/*BRAF* mutational status. In one patient who had an extraordinary response to a MEK inhibitor, genomic analysis identified a 21-base-pair deletion in the *MAP2K1* gene that encodes MEK1 (104).

Endometrioid and Clear Cell Ovarian Cancers

About 20% of epithelial ovarian cancers have endometrioid or clear cell histology, and these are thought to arise in pelvic endometriosis, on the ovary, or in the pelvic peritoneum. Clear cell cancers and low-grade endometrioid cancers have less genetic instability than high-grade serous cases. The most common alteration in clear cell cancers is mutations of the *ARID1A* tumor suppressor gene, which is involved in chromatin remodeling and occurs in approximately 50% of cases (105). The PI3K pathway is also frequently altered, and activating mutations of *PIK3CA* occur in approximately 50% of cases, and deletion of the *PTEN* tumor suppressor occurs in approximately 20% of cases (106). *PPP2R1A* encodes the α-isoform of the scaffolding subunit of the serine/threonine PP2A holoenzyme. This putative tumor suppressor complex is involved in growth and survival pathways. Missense mutations in this gene were noted in approximately 5% of clear cell carcinomas (107). Identical *ARID1A* and *PIK3CA* mutations have been observed in tumors and multiple accompanying deposits of benign and atypical endometriosis (108). This suggests that these mutations are an early event in the development of clear cell/endometrioid cancers.

Mutations of these same genes also occur in endometrioid cancers: *ARID1A* (30%), *PIK3CA* (20%) and *PTEN* (20%), *PPP2R1A* (10%) (109,110). In addition, approximately 30% of endometrioid cancers have mutations in the *CTNNB1* gene that encodes β-catenin, a nuclear transcription factor involved in the WNT pathway. These mutations occur in exon 3 at or adjacent to the serine/threonine phosphorylation sites and stabilize the protein product leading to nuclear overexpression and increased transcriptional activity. In some endometrioid ovarian cancers with abnormal nuclear accumulation of β-catenin that lack mutations in this gene, the *APC*, *AXIN1*, or *AXIN2* genes that regulate β-catenin activity are mutated (111). This suggests that in addition to the mutations that are also present in clear cell cancers, endometrioid cancers frequently have alterations in the WNT signaling pathway (**Table 2.4**). Mouse models in which the WNT and the PI3K/PTEN pathways are inactivated lead to the development of endometriosis and endometrioid cancers (112). Although endometrioid ovarian cancers are believed to arise from ectopic endometrium, and there is considerable overlap in pathogenic mutations, the frequency of mutations differs between endometrioid ovarian cancers and endometrioid endometrial cancers. In one comparative study (113), *PTEN* mutations were more frequent in low-grade endometrial endometrioid carcinomas (67%) compared with low-grade ovarian endometrioid carcinomas (17%). In contrast, *CTNNB1* mutations were significantly more common in low-grade ovarian endometrioid carcinomas (53%) compared with low-grade endometrial endometrioid carcinomas (28%). High-grade endometrioid ovarian cancers typically have molecular

features similar to high-grade serous ovarian cancers, including genetic instability and *TP53* mutations. These tumor types may be difficult to classify by pathologists based on light microscopy.

Synchronous Endometrioid Ovarian and Endometrial Cancers

Synchronous endometrioid cancers are sometimes encountered in the endometrium and ovary that are indistinguishable microscopically. In some of these cases, identical *PTEN* mutations have been identified, suggesting that the ovarian tumor represents a metastasis from the endometrium (114). In other cases, the *PTEN* mutation seen in the endometrial cancer was not found in the ovarian tumor, suggesting that these represent two distinct primary cancers. Mutational analysis of *PTEN*, *CTNNB1*, and other genes frequently mutated in endometrioid cancers is helpful when a mutation is present in both cancers or in one cancer and absent in the other, but this approach may often be uninformative. It has been reported that mitochondrial DNA mutations are fairly common in endometrial cancers (115), and mitochondrial DNA sequencing has been proposed as an alternative method of determining whether synchronous endometrioid cancers of the ovary and endometrium represent separate primary cancers. Two recent papers have strongly suggested that most endometriod ovarian cancers are likely metastases from endometrial primaries and are clonally related (116,117).

Mucinous Ovarian Cancer

Historically, mucinous ovarian cancers were often misdiagnosed as metastases from the gastrointestinal tract. However, some mucinous carcinomas clearly arise from the ovary, perhaps from mucinous cystadenomas, borderline tumors, or teratomas (dermoid cysts). Similar to mucinous colorectal cancers, mucinous ovarian cancers frequently have *KRAS* mutations (59). These mutations occur in 50% to 75% of mucinous ovarian cancers and are missense changes in the hotspot codons. Identical *KRAS* mutations have been found in mucinous carcinomas and adjacent mucinous cystadenomas and borderline tumors, suggesting that the latter lesions represent premalignant precursors (59). Amplification/overexpression of HER-2/neu has been found in 19% of 154 mucinous ovarian cancers and 6% of 176 (6.2%) mucinous borderline tumors (118). Exhaustive exome sequencing analysis of these tumors revealed mutations in known drivers, such as *KRAS*, *BRAF*, and *CDKN2A* (119). In addition, a high percentage of mucinous ovarian carcinomas had *TP53* mutations (52%), and recurrent mutations were found in *RNF43*, *ELF3*, *GNAS*, *ERBB3*, and *KLF5*. Another targeted sequencing study in mucinous tumors found similar results with mutations in *KRAS*, *TP53*, *CDKN2A*, *PIK3CA*, *PTEN*, *BRAF*, *FGFR2*, *STK11*, *CTNNB1*, *SRC*, *SMAD4*, *GNA11*, and *ERBB2* (120). Proven and potential RAS pathway activating changes were observed in all but one case, suggesting the potential of targeting this pathway.

Stromal Ovarian Tumors

The genetic alterations driving stromal tumors of the ovary were unknown until recently when it became possible to screen the entire genome using next-generation sequencing. Essentially all adult granulosa tumors were found to have missense mutations in codon 134 of *FOXL2*, a gene encoding a transcription factor known to be critical for granulosa cell development (121). This mutation was also found in approximately 20% of thecomas and 10% of juvenile granulosa cell tumors, but not in other types of sex cord stromal tumors.

DICER1 mutations in the RNase IIIb domain were found in approximately 30% of nonepithelial ovarian tumors, predominantly in Sertoli-Leydig cell tumors (60%) (122). These mutations were restricted to codons encoding metal-binding sites within the RNase IIIb catalytic centers, which are critical for microRNA interaction and cleavage. More recently, mutations in this part of the *DICER1* gene also have been found in approximately 2% of endometrial cancers

(123). In addition, high expression of these two genes has been shown to be associated with increased survival in ovarian cancer (>11 vs. 2.7 years) (124).

CERVICAL CANCER

Etiology

Although the incidence of cervical cancer has fallen by over 80% in developed countries due to widespread implementation of cervical screening, in developing areas of the world it is still the most common cancer in women. Almost all cervical cancers are caused by sexually transmitted HPV infection, as are many vaginal and vulvar cancers. The epidemiology and biology of HPV infection and its role in screening and prevention are discussed in Chapters 1 (Epidemiology) and 7 (Preinvasive Lower Genital Tract Disease).

Unlike most other types of human cancers that occur due to mutations in oncogenes and/or tumor suppressor genes that disrupt their normal genetic sequence, cervical cancers arise as a consequence of viral inactivation of the *TP53* and *RB* tumor suppressors by the HPV E6 and E7 oncoproteins, respectively (**Fig. 2.15**). Variations in oncogenic potential between HPV subtypes may be related in part to differences in the efficiency with which E6 and E7 bind to and inactivate these tumor suppressors (125,126). In some studies, the levels of E6 and E7 in invasive cervical cancers have been found to predict outcome, whereas HPV viral load does not (127). There is also evidence that HPV E6/E7 may interact directly with other proteins such as telomerase that enhance growth and inhibit apoptosis. In addition, the cdk inhibitor p16 is strikingly upregulated in most cervical dysplasias and cancers (128). p16 detection may represent a useful adjunct to improve the positive predictive value of high-risk HPV testing for detection of cervical dysplasia.

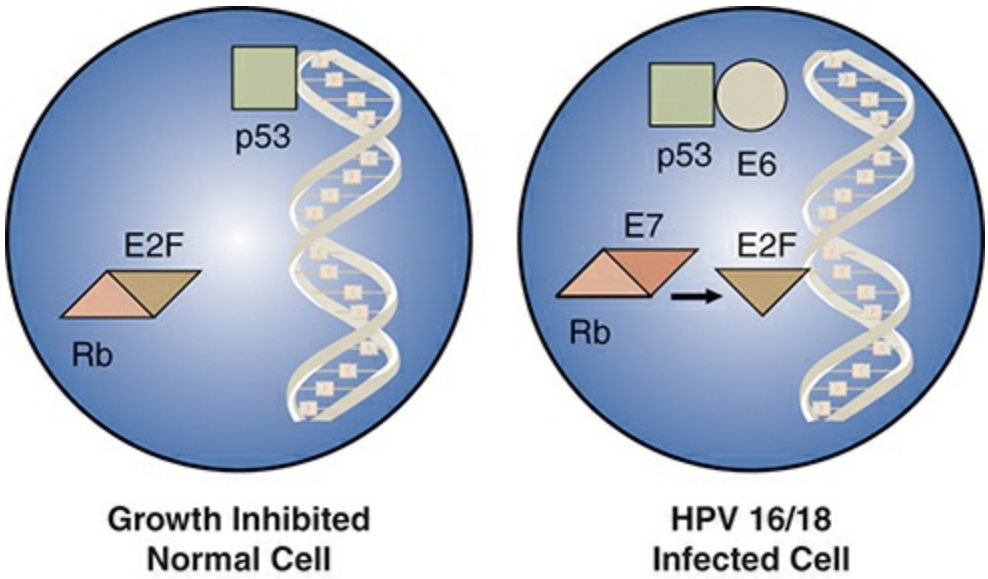

Figure 2.15 Role of TP53 and RB genes in cervical carcinogenesis. The HPV-16/18 E6 and E7 proteins inactivate the TP53 and RB genes, respectively.

HPV-negative cervical cancers are uncommon, but have been reported to exhibit overexpression of mutant p53 protein (129). This suggests that inactivation of *TP53* is a requisite event in cervical carcinogenesis. The biology of HPV-related transformation, including the role of E6/E7, is discussed in greater detail in Chapter 7. This chapter will focus on the secondary genetic alterations that have been observed in invasive cervical cancers.

Secondary Genomic Changes

HPV-associated cervical carcinogenesis with inactivation of the *TP53* tumor suppressor gene leads to genomic instability that results in secondary genetic alterations that play a role in the development and phenotype of these cancers. Over time, this ongoing instability leads to significant intratumoral heterogeneity as genetic damage continues to accumulate. Most cervical cancers are aneuploid, and CGH studies have shown that areas of DNA copy number gain or loss are common. A strikingly consistent finding of various studies is the high frequency of gains on chromosome 3q in both squamous cancers (130,131) and adenocarcinomas (132). Other chromosomes that exhibit frequent gains include 1q and 11q. The most common areas of chromosomal loss include chromosomes 3p, 2q and 13q (133). The frequency of gains and losses at various genomic locations may be random to a certain extent, but there are areas of the genome that are more susceptible to breakage leading to translocations or loss/gain. Abnormalities seen in invasive cancers using CGH have also been identified in high-grade dysplasias, suggesting that these are early and perhaps requisite events in cervical carcinogenesis (131,134,135).

Alterations in gene dosage due to chromosomal gains or losses have the potential to lead to changes in expression of genes involved in the regulation of processes central to malignant transformation such as growth, differentiation, and apoptosis. Cervical carcinogenesis is also accompanied by changes in DNA methylation that affect gene expression. Regardless of the cause, some changes in gene dosage likely represent collateral damage and have no effect on development and evolution of the malignant phenotype. However, it is likely that over time there is selection for clones that exhibit enhanced growth and invasive potential. It is possible that genetic instability may also enhance the emergence of resistance to radiation and chemotherapy.

A study of gene dosage in locally advanced cervical cancers using microarrays found frequent alterations, including 14 regions with recurrent gains and 14 with recurrent losses. The most common alterations were gain on 1q, 3q, 5p, 20q, and Xq and loss on 2q, 3p, 4p, 11q, and 13q, each involving 44% to 76% of the patients. Four genes on 3p (*RYBP*, *GBE1*) and 13q (*FAM48A*, *MED4*) correlated with outcome at both the gene dosage and expression level and were validated in the independent cohort. Despite circumstantial evidence provided by studies such as this, with the exception of the fragile histidine triad (*FHIT*) gene on chromosome 3p14, it has been difficult to prove that genomic gains and losses result in alterations in specific oncogenes or tumor suppressor genes that are directly involved in tumor development. The *FHIT* gene is frequently deleted in many different cancers, including cervical cancer (136). In one study, FHIT protein expression was markedly reduced or absent in 71% of invasive cancers, 52% of high-grade squamous intraepithelial lesions (HSILs) associated with invasive cancer, and 21% of HSILs without associated invasive cancer (137). In addition, reduced expression is associated with poor prognosis in advanced cervical cancers (138).

The role of several oncogenes has been examined in cervical carcinomas including most prominently the *RAS* and *MYC* genes. Mutant *RAS* genes are capable of cooperating with HPV in transforming cells *in vitro*. There is some evidence that mutations in either *KRAS* or *HRAS* may play a role in a subset of cervical cancers. *MYC* amplification and overexpression may be an early event in the development of some cervical cancers. Overexpression of *MYC* has been demonstrated in one-third of early invasive carcinomas and some cervical intraepithelial neoplasia (CIN) 3 lesions. In some studies, amplification correlated with poor prognosis in early stage cases (139).

A comprehensive genomic analysis of 115 cervical carcinomas found previously unknown somatic mutations in 79 primary squamous cell carcinomas including recurrent E322K substitutions in the *MAPK1* gene (8%), inactivating mutations in the *HLA-B* gene (9%), and mutations in *EP300* (16%), *FBXW7* (15%), *NFE2L2* (4%), *TP53* (5%), and *ERBB2* (6%) (140). Somatic mutations in *ELF3* (13%) and *CBFB* (8%) were noted in 24 adenocarcinomas. Squamous cell carcinomas have higher frequencies of somatic nucleotide substitutions occurring at cytosines preceded by thymines than adenocarcinomas. Gene expression levels at HPV integration sites were statistically significantly higher in tumors with HPV integration compared with the same genes in tumors without viral integration at the same site.

Gene silencing due to promoter hypermethylation also may play a role in cervical carcinogenesis (141). In this regard, expression of the *RASSF1A* gene on chromosome 3p21 is frequently lost in cervical cancers, particularly

adenocarcinomas (142). The function of this gene is not completely understood, but is thought to be involved in *ras*-mediated signal transduction pathways. Hypermethylation of genes associated with programmed cell death (apoptosis) and tumor suppressor genes has also been described in cervical cancers.

GESTATIONAL TROPHOBLASTIC DISEASE

The genetic alterations that underlie gestational trophoblastic disease have been elucidated to a great extent. The most prominent feature of these tumors is an imbalance of parental chromosomes. In partial moles, this involves an extra haploid copy of one set of paternal chromosomes (XXY, XXX, or XYY). Complete moles generally are characterized by two pairs of one paternal haploid set of chromosomes (XX) and an absence of maternal chromosomes, while a minority are (XY) due to dispermy. Although the risk of repeat molar pregnancy is only about 1%, women who have had two molar pregnancies have about a 25% risk of developing another mole. Although this suggests a hereditary defect that affects gametogenesis, this remains speculative. Thus far, there is no convincing evidence that damage to specific tumor suppressor genes or oncogenes contributes to the development of gestational trophoblastic disease. However, the presence of two identical copies of each chromosome in most complete moles could facilitate transformation due to increased or decreased expression of imprinted genes involved in growth regulatory pathways. In addition, inactivation of a tumor suppressor gene on a paternal chromosome that might not normally be manifest because of the presence of a wild-type allele on the maternal chromosome could become significant in cells with two copies of the same haploid paternal genome.

The occurrence of recurrent molar pregnancy and familial aggregation in some reports suggests that genetic predisposition plays a role in some cases. Genetic mapping studies in families with multiple affected individuals identified a locus on chromosome 19q13.4, and subsequently causative mutations in the NLRP7 gene were identified (143). The mutations segregated in the studied families and each patient had two defective alleles, each inherited from one parent as expected for an autosomal recessive disease. About 42 different mutations have been described, and about 65% are truncating and 35% missense. NLRP7 and other genes in the NLRP family may also be associated with other forms of recurrent pregnancy loss in addition to molar pregnancies.

It is hypothesized that oocytes from patients with loss of NLRP7 function may be defective at several levels and are not able to sustain early embryonic development (144). Consequently, the embryos stop developing very early in these conceptions. Because these patients also have decreased cytokine secretion due to loss of NLRP7, they may fail to mount an appropriate inflammatory response to reject these arrested pregnancies as normal women would. As a result, the retention of these dead pregnancies with no embryos to later gestational stages leads to the hydropic degeneration of chorionic villi. This, combined with the potential role of NLRP7 mutations in enhancing proliferation, may lead to the three fundamental aspects of moles: aberrant human pregnancies with no embryo, abnormal excessive trophoblastic proliferation, and hydropic degeneration of CV. Discovery of NLRP7 facilitates the potential for genetic testing and counseling in patients with familial or recurrent molar pregnancies.

Microarray studies have identified several genes that are differentially expressed compared with normal villi, particularly genes associated with cellular apoptosis, immune suppression, and cell invasion (145,146). In one study in which genomic techniques were used to compare gene expression between moles that spontaneously regressed and those that subsequently developed, metastatic gestational trophoblastic neoplasia (GTN) identified 16 differentially expressed transcripts (146). Downregulation of ferritin light polypeptide (*FTL*) and insulin-like growth factor–binding protein 1 (*IGFBP1*) was confirmed in cases that subsequently developed GTN compared with those that regressed. Studies have also suggested that changes in expression of genes involved in apoptosis, such as greater expression of the antiapoptotic gene *Mcl-1*, may be involved in progression of a molar pregnancy requiring chemotherapy (147).

CHAPTER 3 Hereditary Gynecologic Cancers

Noah D. Kauff, Andrew Berchuck and Karen H. Lu

INTRODUCTION

Identifying a woman with gynecologic cancer as having a hereditary cancer syndrome has tremendous implications for both the patient and her family members. Hereditary breast and ovarian cancer syndrome, caused by germline mutations in *BRCA1* or *BRCA2*, and Lynch syndrome, caused by germline mutations in *MLH1*, *MSH2*, *MSH6*, *PMS2*, *or EPCAM*, are the most common high-penetrance hereditary syndromes that include gynecologic manifestations as part of their tumor spectrum. Other well-characterized high-penetrance syndromes that include gynecologic cancers are Cowden syndrome (*PTEN* germline mutation), Peutz–Jeghers syndrome (*STK11* germline mutation), and Li–Fraumeni syndrome (*TP53* germline mutation) (**Table 3.1**). These high-penetrance syndromes are generally associated with as much as a 6- to 60-fold increased risk of cancer compared to women in the general population. Recently, a number of additional genes, including *BRIP1*, *RAD51C*, *RAD51D*, *PALB2*, *ATM*, *CHEK2*, and *NBN*, have been associated with a moderately increased risk (generally on the order of a 2- to 6-fold increased risk) of breast, gynecologic, and in some cases other cancers.

TABLE 3.1 Selected Hereditary Cancer Syndromes with Gynecologic Manifestations

Syndrome	Gene	Chromosome	Predominant Cancers
Hereditary breast/ovarian cancer	BRCA1	17q21	Breast, ovary
	BRCA2	13q12	
Lynch syndrome	MLH1	3p22.2	Colon, endometrium, ovary, and urinary tract
	MSH2	2p21–16	
	MSH6	2p16	
	PMS2	7p22	
	EPCAM	2p21	
Cowden syndrome	PTEN	10q23	Breast, thyroid, and endometrial
Li–Fraumeni syndrome	TP53	17p13	Breast, sarcomas, leukemias, and brain
Peutz–Jeghers syndrome	STK11	19p13	Colon, breast, gastric,

		and ovarian SCTAT
Hereditary small cell carcinoma of the ovary, hypercalcemic type	SMARCA4 19p13	SCCOHT

SCTAT, sex cord tumor with annular tubules; SCCOHT, small cell carcinoma of the ovary, hypercalcemic type.

The vast majority of both the high- and moderate-penetrance cancer susceptibility syndromes are caused by mutations in tumor suppressor genes. In order for an individual to develop a cancer associated with one of these syndromes, both the maternally and paternally inherited copy of the relevant gene must be inactivated as described by Knudson's two-hit hypothesis (1). Women with hereditary cancer syndromes have inherited, from either their mother or their father, a nonworking copy of one of the relevant genes and this defect is present in all of their cells. Therefore, in order for cancer to develop in a susceptible tissue through defects in a specific pathway, only the second working copy of the relevant gene needs to be lost. This is why the cancers occur earlier and more frequently than in the general population. This also partly explains why not all individuals with an inherited predisposition develop cancer, as it is possible that the second working copy of the relevant tumor suppressor gene is never lost in a susceptible tissue. Importantly, particularly for the moderate-penetrance cancer susceptibility genes, these genetic changes do not happen in isolation. Rather there is a genetic and environmental background which also clearly plays a role in whether or not an individual who has lost the second working copy of a relevant tumor suppressor gene in a susceptible tissue actually develops cancer.

In recent years, prognostic and therapeutic implications relevant to cancer patients with hereditary cancer syndromes have been discovered, and recommendations for prevention of hereditary cancer have been refined. Given this, there has been increasing emphasis placed on developing guidelines to assist physicians in recognizing those patients for whom genetic counseling and testing may be helpful. These developments will be reviewed in this chapter.

HEREDITARY BREAST OVARIAN CANCER SYNDROME

Epidemiology

Of all common solid tumors, ovarian, fallopian tube, and primary peritoneal cancers have the highest proportion caused by heritable germline mutations, with mutations in *BRCA1* and *BRCA2* accounting for the vast majority. When pelvic serous cancer alone is examined, 16% to 18% of unselected patients with high-grade disease reportedly have a deleterious *BRCA1* or *BRCA2* mutation (2,3). In 2011, Zhang and colleagues reported a population-based series of 1,342 invasive ovarian cancers identified in Ontario, Canada, from 1995 to 1999 and from 2002 to 2004. In this series, 135 (18.0%) of 751 patients with serous ovarian cancer had a deleterious *BRCA1* or *BRCA2* mutation (2). Of note, 6.1% of the non-founder mutations identified in this study were large genomic rearrangements not detected on sequencing and discerned only on multiplex ligation-dependent probe amplification (MLPA) testing. Similarly, in 2012, Alsop and colleagues found 118 (16.6%) *BRCA1* and *BRCA2* mutations in 709 patients with incident pelvic serous cancers identified as part of the Australia Ovarian Cancer Study from 2002 to 2006. Notably, 62 (8.3%) of 749 patients without a significant family history had a germline *BRCA* mutation, and 44% of all the mutations identified in the study occurred in the absence of a family history (3).

Given this substantial frequency of mutations in women with pelvic serous cancer irrespective of family history, both the American College of Obstetricians and Gynecologists (ACOG) and the National Comprehensive Cancer Network (NCCN) recommend consideration of testing for *BRCA* mutations in any woman with high-grade serous ovarian cancer if it will impact the care of either the woman or her close family members (4,5).

As noted above, recently, several additional genes have recently been implicated in an inherited predisposition to breast cancer, ovarian cancer, or both. Many of these genes are in the *BRCA1*- and *BRCA2*-dependent homologous recombination (HR) repair pathway. Early studies suggest that these may be associated with as much as a 2- to 6-fold

increased risk of cancer compared to women in the general population. In a series from University of Washington and the Gynecologic Oncology Group, of 1,498 patients undergoing primary therapy for high-grade serous epithelial ovarian, fallopian tube, or primary peritoneal cancer, 240 (16.0%) patients had a deleterious mutation in either *BRCA1* or *BRCA2*. Fifty-three (3.5%) patients had deleterious mutations in other tumor suppressor genes potentially associated with ovarian cancer including 22 (1.4%) in *BRIP1, 9* (0.6%) in *PALB2, 7* (0.5%) in *RAD51C*, 7 (0.5%) in *RAD51D*, 4 (0.3%) in *PMS2*, 3 (0.2%) in *BARD1*, and 1 (0.1%) in *MSH6*. While the authors also found mutations in a number of other genes, including *CHEK2*, *ATM*, *NBM*, *TP53*, and *RAD50*, none of these were seen to occur more frequently than in unaffected individuals genotyped as part of either the National Heart, Lung, and Blood Exome Sequencing Project or the Exome Aggregation Consortium (6). In a series of two reports evaluating frequency of non-*BRCA* mutations in 3,226 and 3,429 women with invasive epithelial ovarian, and 3,431 and 2,772 population controls, respectively, mutations in *BRIP1, RAD 51C*, and *RAD51D* were confirmed to be more frequent in cases than in controls. There was also a suggestion that mutations in *PALB2* were more frequent, but this did not reach statistical significance (7,8). Taken together, there is evidence that *BRIP1*, *RAD51C*, *RAD51D*, and perhaps *PALB2* may be associated with an approximately 2- to 6-fold increased risk of ovarian cancer, though wide confidence intervals for these estimates remain. Similarly, several other studies have examined breast cancer risks associated with genes in the HR repair and related pathways and have found that *ATM*, *CHEK2*, *NBN*, and *PALB2* may be associated with a 3- to 6-fold increased risk of breast cancer (9). To put these risks in perspective, *BRCA1* mutations are associated with an 18- to 36-fold increased risk of developing breast cancer prior to age 50 years and a 30- to 60-fold increased risk of developing ovarian cancer by age 70. Similarly, women with *BRCA2* mutations have a 10- to 19-fold increased risk of early-onset breast cancer and a 6- to 20-fold increased risk of ovarian cancer at any age (10). Given the generally lower relative risk of cancer associated with mutations in these genes compared to *BRCA1* and *BRCA2*, it is not yet known if risks associated with mutations in these other genes are great enough to be considered causative or if loss of function mutations in these genes act more as modifiers of cancer risk.

Pathology

BRCA1- and *BRCA2*-associated cancers appear to be preferentially associated with specific histologic subtypes of ovarian and fallopian tube cancer. In the 2011 report from Zhang et al., *BRCA* mutations were identified in 135 (18.0%) of 751 serous cancers, 26 (9.1%) of 287 endometrioid cancers, and 2 (2.2%) of 91 clear cell cancers (2). Similarly, Norquist et al. found *BRCA* mutations in 240 (16.0%) of 1,498 high-grade serous cancers, 7 (10.9%) of 64 high-grade endometrioid cancers, 4 (6.9%) of 58 clear cell cancers, and 4 (5.7%) of 70 low-grade serous cancers. No *BRCA* mutations were identified in low-grade endometrioid cancers or mucinous tumors (6).

It should be noted that the proportion of non–high-grade serous cancers associated with *BRCA* mutations may be overrepresented in these studies. Reportedly, *BRCA*-associated serous ovarian cancers frequently have a somewhat atypical histologic appearance, in some cases appearing to be “pseudo-endometrioid,” or “pseudo-transitional.” This can result in misclassification unless serous-specific immunohistochemical (IHC) markers are used (11). This was seen in the 2012 report from Alsop et al. In this population-based series from Australia, *BRCA1* or *BRCA2* mutations were identified in 10 (8.9%) of 119 cancers initially diagnosed as endometrioid. However, 8 of these cancers were subsequently reclassified after immunohistopathology review as serous or unspecified carcinomas, suggesting that the actual rate of *BRCA* mutations in endometrioid ovarian cancer is only 1.7%. Similarly, of the 4 (6.3%) of 63 clear cell cancers shown to have a *BRCA* mutation, 3 were reclassified as high-grade serous with focal clear cell differentiation, suggesting that the actual prevalence of *BRCA* mutations in clear cell ovarian cancer is approximately 1.6% (3).

Natural History of BRCA-Associated Ovarian Cancer

Over a dozen studies have reported on differences in outcome between *BRCA*-associated and sporadic ovarian and fallopian tube cancers (12). In one of the first large studies to examine this issue, Chetrit and colleagues reported on an

Israeli population-based series including data from 779 Jewish women with invasive epithelial ovarian cancer genotyped for the three Ashkenazi founder mutations. In this series, *BRCA* mutation status was associated with an increase in survival from 37.9 to 53.7 months (13). More recently, investigators from The Cancer Genome Atlas (TCGA) project reported that patients with stage II to IV high-grade serous ovarian or fallopian tube cancer and germline or sporadic mutations in *BRCA1* or *BRCA2* had improved outcome compared to patients without evidence of *BRCA* deficiency (median overall survival 66.5 vs. 41.9 months, $p = 0.0003$) (14). Interestingly, in this series tumors associated with mutations in *BRCA1* or *BRCA2* also had improved outcomes compared to patients with silencing of *BRCA1* due to methylation of the *BRCA1* promoter, suggesting that the mechanism of loss of *BRCA* function may be relevant to the biology and clinical behavior of these tumors.

Until recently, most studies examining the impact of *BRCA* mutations on outcome have analyzed carriers of *BRCA1* mutations and carriers of *BRCA2* mutations together. However, mutations in *BRCA1* and *BRCA2* cause related, but distinct, cancer susceptibility syndromes. Given this, it is possible that response to therapy and clinical outcome may differ between carriers of *BRCA1* mutations and carriers of *BRCA2* mutations. In one of the first studies to examine this issue, Yang et al. reexamined data from the TCGA ovarian project. In this report, patients with *BRCA2*-associated ovarian cancer had markedly better outcome than those with *BRCA* wild-type tumors (HR = 0.33; 95% CI, 0.16 to 0.69). *BRCA1*-associated tumors also appeared to have a somewhat better outcome than *BRCA* wild-type tumors (HR = 0.76; 95% CI, 0.43 to 1.35), but this result did not reach statistical significance (15). More recently, Bolton et al. reported on a pooled series of 3,879 invasive epithelial ovarian cancers genotyped for *BRCA* mutations and found that in a model adjusted for age at diagnosis, stage, grade, and histology, both *BRCA2* (HR = 0.49; 95% CI, 0.39 to 0.61) and *BRCA1* (HR = 0.73; 95% CI, 0.64 to 0.84) had improved outcome compared to *BRCA* wild-type tumors. Tests of heterogeneity also demonstrated that hazard ratio for *BRCA2* mutation carriers was significantly different from the HR for *BRCA1* mutation carriers (16).

Similarly, ovarian cancers associated with mutations in moderate-penetrance genes in the HR pathway may be associated with different natural history depending upon the specific mutated gene. In the recent series from Norquist, ovarian cancer patients with a mutation in a non-*BRCA*-associated HR gene had an intermediate prognosis compared to *BRCA2*-associated ovarian cancers and *BRCA* wild-type ovarian cancers (6).

Given the clear differences in the outcome between *BRCA* mutated and *BRCA* wild-type tumors, several authors have recommended that, at least for participants on clinical trials, we should obtain germline *BRCA* mutation status and stratify outcomes for the presence or absence of mutations (17,18). It also makes sense to stratify outcomes depending upon whether other newly identified moderate-penetrance ovarian cancer–associated genes are also mutated.

Therapeutic Implications

BRCA1 and *BRCA2* are known to be necessary for repair of double strand DNA breaks through HR (19,20). Therefore, tumor cells from *BRCA*-associated ovarian cancers that have no working copy of either *BRCA1* or *BRCA2* are believed to be exquisitely sensitive to agents that induce double strand DNA breaks, such as platinum-based chemotherapy. While this mechanism likely explains at least some of the survival advantage seen in *BRCA*-associated ovarian cancer, until recently knowledge of this information did not provide a new therapeutic opportunity because almost all patients with serous ovarian cancer receive platinum-based chemotherapeutics as part of first-line therapy. In 2005, however, two independent groups hypothesized that the *BRCA*-dependent HR pathway could be stressed by inhibiting poly (ADP-ribose) polymerase (PARP), an enzyme necessary for the repair of single strand DNA breaks (21,22). If this enzyme (and repair of single strand DNA breaks) is inhibited during DNA replication, the advancing replication fork converts single strand DNA breaks into double strand breaks to be repaired by HR. In patients with a germline mutation in *BRCA1* or *BRCA2*, the single nonmutant allele is sufficient to allow repair in non–tumor-associated cells. However, tumor-associated cells have lost both working alleles of either *BRCA1* or *BRCA2* and therefore cannot utilize HR, forcing the cell to use error-prone nonhomologous end joining, which frequently leads to complex rearrangements and eventual apoptosis (23).

The first clinical data supporting the potential utility of PARP inhibitors in *BRCA*-associated tumors were published in 2009 (24). In this Phase I trial, 60 patients, including 22 with either a documented *BRCA1* or *BRCA2* mutation, received increasing doses of a novel PARP inhibitor, olaparib. Radiologic response or stable disease was observed in 11 (9 ovarian and 2 breast cancer) of 19 patients with heavily pretreated *BRCA*-associated ovarian, breast, or prostate cancer. Following this, a large Phase II trial of olaparib in *BRCA*-associated, platinum-resistant ovarian cancer demonstrated tumor response in 60 (31.1%) of 193 participants. Stable disease for ≥8 weeks was also noted in 78 (40%) participants (25). This data, in December 2014, led to accelerated approval in the United States of olaparib monotherapy for women with advanced ovarian cancer with a deleterious germline *BRCA* mutation who have been treated with three or more prior lines of chemotherapy. Olaparib has also been evaluated in the maintenance setting. In 2014, Ledermann et al. (26) published a preplanned analysis to examine the impact of *BRCA* mutation on the results of a randomized Phase II trial evaluating olaparib maintenance versus placebo in the setting of platinum-sensitive recurrent ovarian cancer. In this study, women with *BRCA*-associated ovarian cancer treated with olaparib maintenance after achieving clinical remission following two or more lines of platinum chemotherapy had an improved PFS compared to women treated with placebo (11.2 vs. 4.3 months; HR, 0.18; 95% CI, 0.10 to 0.31). Of note, there was a smaller but still significant difference in PFS between olaparib- and placebo- treated women who were *BRCA* wild type (7.4 vs. 5.5 months; HR, 0.54; 95% CI, 0.34 to 0.85). There was also a suggestion that *BRCA* mutant patients who received olaparib had increased overall survival, but this did not reach statistical significance (HR, 0.73; 95% CI, 0.45 to 1.17). Given the promising results of these trials, there are over half a dozen ongoing or planned Phase III trials of PARP inhibitors in *BRCA*-associated pelvic serous cancer (27). Furthermore, given the substantial frequency in pelvic serous cancer of either: (a) somatic mutations in *BRCA1* or *BRCA2*; (b) germline mutations in other genes associated with HR; or (c) epigenetic silencing of *BRCA1* through methylation of the *BRCA1* promoter (14), PARP inhibitors are also being actively investigated for treatment of ovarian cancer without germline *BRCA* mutations (28).

GENETIC COUNSELING FOR HEREDITARY BREAST AND OVARIAN CANCER SYNDROME

Approximately 1 in 345 to 1 in 800 women have a *BRCA1* or *BRCA2* mutation associated with hereditary breast and ovarian cancer (29,30). Hereditary breast and ovarian cancer syndrome is seen in all racial and ethnic groups. However, due to the phenomenon of genetic drift, several racial and ethnic groups have experienced a marked increase in the population frequency of specific mutations, known as founder mutations. Best known of the founder mutations are the 185delAG and 5382insC mutations in *BRCA1* and the 6174delT mutation in *BRCA2* that are collectively found in 1 of 40 individuals of Eastern European Jewish (Ashkenazi) heritage. Increased incidence of *BRCA* mutations has also been seen in individuals of Icelandic, Swedish, Dutch, Polish, French Canadian, and Hungarian descent.

The vast majority of deleterious mutations in *BRCA1* and *BRCA2* are nonsense mutations that lead to a premature stop codon and a truncated protein. While the majority of protein-truncating mutations are detectable by direct sequencing of *BRCA1* and *BRCA2*, approximately 6% to 18% of deleterious mutations are caused by large genomic deletions or rearrangements that will not be identified on direct sequencing and must instead be screened for by methods such as MLPA (31–33). Additionally, depending on ethnicity, as many as 6% to 17% of individuals undergoing direct sequencing of *BRCA1* or *BRCA2* will have a missense mutation that causes a single amino acid substitution in the protein (34). These missense mutations are termed variants of uncertain significance, as it is frequently not possible to ascertain whether the protein can tolerate the resulting amino acid substitution or if the substitution will cause abrogation of protein function.

Several recent developments have fundamentally changed the manner in which genetic testing for breast and ovarian cancer is offered. The first of these developments was the Supreme Court of the United States ruling in June 2013 that: (a) segments of DNA that make up human genes were “products of nature” and not patentable under section 101 of the Patent

Act; and (b) comparing a patient's isolated DNA sequence to a reference sequence was not a patentable method (35). Until this time the vast majority of commercial sequencing of *BRCA1* and *BRCA2* was performed by a single commercial lab that owned patents on both the sequence and interpretation of the genes. Within days of the Supreme Court decision, multiple molecular diagnostic companies began offering commercial testing for mutations in *BRCA1* and *BRCA2* using a variety of different methodologies and processes. However, at this time there is little standardization with respect to how individual labs assure analytic and clinical validity of sequencing results. This creates difficulties for providers in choosing labs and interpreting results (36).

The other development causing profound changes in genetic testing for hereditary breast and ovarian cancer is the advent of massively parallel sequencing technology, frequently termed next-generation sequencing. This sequencing technology allows for testing of multiple putative tumor suppressive genes at the same time that *BRCA1* and *BRCA2* are sequenced. With this development, multiple genes potentially associated with cancer risk are increasingly being added to commercial multiplex panels. While early data has suggested that some genes, including *BRIP1*, *RAD51C*, *RAD51D*, and perhaps *PALB2* may be associated with an increased risk of ovarian cancer (6–8), the actual magnitude and timing of those risks remain unclear. Furthermore, while it is hypothesized that ovarian cancer associated with non-*BRCA* HR genes may be preferentially sensitive to treatment with either platinum agents or PARP inhibitors (6), definitive studies proving or refuting this hypothesis have not yet been completed.

An additional issue with multiplex cancer susceptibility testing is that many panels include genes based on molecular pathway inference, as opposed to actual clinical data (37). However, as the cancer risks for many of these genes is uncertain, testing for them may increase the potential for false alarms and inappropriate clinical action without benefitting the patient (38). Given these issues, caution should be exercised in deciding which genes putatively associated with ovarian cancer risk should be examined in an individual undergoing genetic testing for inherited predispositions to breast and ovarian cancer.

Lastly, a number of genome-wide association studies have also identified single nucleotide polymorphisms (SNPs) that modify breast and/or gynecologic cancer risk in the setting of a *BRCA1* or *BRCA2* mutation (39). However, to date, none of these markers, either alone or in combination, have been shown to alter *BRCA*-associated cancer risk at a magnitude necessary to appreciably guide recommendations for risk-reduction strategies (40). Given the rapidly changing nature of the field, genetic counselors and other appropriately trained genetic professionals can assist in determining the most appropriate genetic tests for an individual patient. In addition, they can assist in interpreting the results in the context of the family history. Furthermore, the genetic professional can assist in identifying the most appropriate individuals for genetic testing, as in many families, it may be more informative to initiate testing in a relative of the patient, rather than in the patient herself. Importantly, genetic professionals can help identify other relatives who should be informed of a potential inherited risk (41) and can assist patients in planning such communication.

Cancer Risks Associated with a BRCA1 or BRCA2 Mutation

For women with mutations in *BRCA1*, lifetime risks, through age 70, of pelvic (ovarian, fallopian tube, or primary peritoneal) cancer are on the order of 39% to 46%. For women with mutations in *BRCA2*, the risk through age 70 of pelvic cancer is 12% to 20% (10,42). The average age of diagnosis of *BRCA1*-associated pelvic cancers is 53, which is approximately 10 years earlier than the average age of diagnosis of sporadic ovarian or fallopian tube cancer. Interestingly, the average age of *BRCA2*-associated pelvic cancer is 60 to 62 years, no earlier than is seen with sporadic disease (3,43). When considering the timing of approach to risk-reduction, it is also important to evaluate the risks of cancer based on the patient's approximate age of menopause. For women with *BRCA1* mutations, 10% to 21% will develop pelvic cancer by age 50, but only 2% to 3% of women with *BRCA2* mutations will develop pelvic cancer by the same age (42,44).

Breast cancer risks are also markedly elevated for women with mutations in these genes, with risks of breast cancer approaching 65% to 74% by age 70 for both carriers of *BRCA1* and *BRCA2* mutations (10,42). Breast cancer also occurs

substantially earlier than is seen in the general population, with 26% to 34% of carriers of either *BRCA1* or *BRCA2* mutations developing breast cancer by age 50 (10,42,45).

For other ovarian cancer–associated genes in the HR pathway, the magnitude and timing of ovarian cancer risks are less clear. Early studies have suggested that RAD51C and RAD51D are associated with risks through age 70 of approximately 2.9% and 6.6%, respectively. BRIP1 has also been associated with a risk through age 70 of 2.5% to 6.1% (46). At present it is not clear if mutations in any of these three ovarian cancer susceptibility genes are also associated with clinically meaningful modification of breast cancer risk (9).

Guidelines for Offering Genetic Risk Assessment for Hereditary Breast and Ovarian Cancer Syndrome Caused by Mutations in BRCA1 and BRCA2

Several organizations have proposed guidelines for offering genetic risk assessment for hereditary breast and ovarian cancer syndrome. For the gynecologic oncologist, the most relevant guidelines are those published by the ACOG (4), the Society of Gynecologic Oncology (SGO) (47), and the NCCN (5). Briefly, all of these guidelines state that hereditary cancer risk assessment is a process that: (a) should include assessment of risk, education, and counseling; (b) should be conducted by a physician, genetic counselor, or other provider with experience in cancer genetics; and (c) may include genetic testing after appropriate counseling and consent is obtained.

Specifically, ACOG states that it is reasonable to offer genetic risk assessment to any woman who has greater than a 5% to 10% chance of having a *BRCA1* or *BRCA2* mutation. Specific constellations of personal and family history that meet this threshold are outlined in **Table 3.2**. Given that 16% to 18% of high-grade serous ovarian and fallopian tube cancers (including 8% to 10% of patients with no significant family history) and a significant proportion of other high-grade epithelial ovarian and fallopian tube cancers segregate a *BRCA1* or *BRCA2* mutation, both SGO and NCCN recommend genetic risk assessment and testing for *BRCA1* and *BRCA2* mutation in all women with high-grade epithelial ovarian cancer, irrespective of age of diagnosis or family history. There are also several risk-prediction models, such as BRCAPRO, BOADICEA, and IBIS, that can assist in predicting the likelihood of a patient having a mutation in *BRCA1* or *BRCA2*. Each of these models, however, has unique advantages and limitations, and selecting the appropriate model is generally best done with the assistance of a genetics professional.

TABLE 3.2 The ACOG Criteria for Offering Genetic Risk Assessment for Hereditary Breast and Ovarian Cancer Syndrome

Patients with greater than an approximate 5%–10% chance of having an inherited predisposition to breast and ovarian cancer, and for whom genetic risk assessment may be helpful:

- Women with breast cancer at age 40 y or younger
- Women with ovarian cancer, primary peritoneal cancer, or fallopian tube cancer of high-grade, serous histology at any age
- Women with bilateral breast cancer (particularly if the first case of breast cancer was diagnosed at age 50 y or younger)
- Women with breast cancer at age 50 y or younger and a close relative[a] with breast cancer at age 50 y or younger
- Women with breast cancer at age 50 y or younger and a close relative[a] with male breast cancer at any age
- Women of Ashkenazi Jewish ancestry with breast cancer at age 50 y or younger
- Women with breast cancer at any age and two or more close relatives[a] with breast cancer at any age (particularly if at least one case of breast cancer was diagnosed at age 50 y or younger)
- Unaffected women with a close relative[a] who meets one of the above criteria
- Unaffected women with a close relative[a] with a known BRCA1 or BRCA2 mutation

[a]Close relative is defined as a first-degree relative (mother, sister, daughter) or second-degree relative

(grandmother, granddaughter, aunt, niece).

Source: Adapted from ACOG Practice Bulletin No. 103: Hereditary breast and ovarian cancer syndrome. Obstet Gynecol. 2009;113:957–966.

As noted above, the role of testing for mutations in other cancer susceptibility genes that may be associated with an inherited predisposition to breast and ovarian cancer is less clear. While genes such as *BRIP1*, *RAD51C*, and *RAD51D* almost certainly confer some risk of ovarian cancer, there is currently limited data to guide management of either affected or unaffected women with mutations in any of these genes. Additional tools for assessment knowledge will, however, evolve rapidly over the next several years, and physicians offering genetic risk assessment within their practice are encouraged to regularly collaborate with genetic professionals to determine the most appropriate genes to examine.

Screening and Prevention

Unaffected patients with a deleterious mutation in *BRCA1* or *BRCA2*, have several options for reducing the risk of both gynecologic and breast cancer (**Table 3.3**).

TABLE 3.3 Risk-Reduction Recommendations for Carriers of BRCA1 and BRCA2 Mutations

Breast • Annual breast MRI age 25–29 y • Annual mammography and annual breast MRI age 30–75 y • Breast screening considered on an individual basis for women older than 75 y • RRSO to reduce breast cancer risk between age 35 and 40 y and when childbearing is complete. (For women with BRCA2 mutations who have already undergone bilateral mastectomy, it may be reasonable to defer RRSO until age 40–45 y.) • Consider chemoprevention with tamoxifen, raloxifene, or an aromatase inhibitor (particularly in the setting of a BRCA2 mutation) • Consider RRM
Ovary/fallopian tube • RRSO to reduce ovarian and fallopian tube cancer risk once a woman has entered the risk period for gynecologic cancers (age 35–40 y for BRCA1, age 40–45 y for BRCA2) and after childbearing is complete • Consider chemoprevention with oral contraceptives

Screening

Ovarian/fallopian tube **cancer**. Screening for ovarian and fallopian tube cancer in the general population is not recommended. Recently, two large randomized trials of ovarian cancer screening in women not known to be at inherited risk have been reported. In 2011, the Prostate, Lung, Colorectal, and Ovarian Cancer Screening Randomized Trial reported the results of the ovarian cancer screening aim (48). In this trial, 78,216 women were randomized to either ovarian cancer screening with annual transvaginal ultrasound for 4 years and annual CA-125 determination for 6 years or usual care. After a median 12.4 years of follow-up, there was no difference in ovarian cancer mortality between the screened women and women participating in usual care

(risk ratio [RR], 1.18; 95% CI, 0.82 to 1.71). Furthermore, 3,285 (8.4%) of 39,105 screened women had a false-positive result during the course of the study, with 1,080 (2.8%) undergoing surgical follow-up. In 2015, Jacobs et al. (49) reported the results of the UK Collaborative Trial of Ovarian Cancer Screening. In this trial, 202,638 women were randomized to one of three strategies: 50,640 participants were randomized to a multimodal screening strategy utilizing annual CA125 determinations analyzed by the Risk of Ovarian Cancer Algorithm (ROCA); 50,639 were randomized to annual transvaginal ultrasound; 101,299 were randomized to no screening. After a median 11.1 years of follow-up, a 15% (95% CI, –3% to 30%; $p = 0.10$) mortality reduction was seen with multimodal screening compared to no screening and an 11% (95% CI, –7% to 27%; $p = 0.21$) mortality reduction was seen with ultrasound screening compared to no screening, though neither of these reached statistical significance.

Two prospective trials specifically targeting women at familial/inherited risk have also been completed. In 2013, the results from Phase I of the UK Familial Ovarian Cancer Screening Study (UK FOCSS) were reported. In this study, 3,563 women with a greater than 10% lifetime risk of ovarian cancer were followed with annual transvaginal ultrasound and annual CA-125 blood tests (50). The results suggested a stage shift, with only 6 (26%) of 23 cancers not associated with Lynch syndrome in women screened according to protocol diagnosed at stage IIIc or higher. This was in contrast to 6 (86%) of 7 cancers being of advanced stage in women with delayed screening. This research group has now completed Phase II of the study, in which participants were followed with annual transvaginal ultrasound and every 4-month CA125 determinations, interpreted by the ROCA algorithm. Unfortunately the preliminary results, presented in abstract form, have not suggested that increasing the frequency of screening further improves the stage distribution.

The Gynecologic Oncology Group recently completed Study 0199, a prospective study of risk-reducing salpingo-oophorectomy (RRSO) and longitudinal CA-125 screening in women at increased genetic risk of ovarian cancer (51). In this study, participants at increased risk of breast and ovarian cancer elected either RRSO or surveillance with annual transvaginal ultrasound and every 3-month CA-125 interrogated with ROCA. All participants in the study were genotyped, and just under 400 of the approximately 1,600 women who elected surveillance had a *BRCA* mutation. The study has completed data collection and is currently in analysis.

Until final results are available from UK FOCSS and GOG 0199, given the lack of evidence with respect to benefit, transvaginal ultrasound and CA-125 determinations likely cannot be recommended as an alternative to RRSO in a woman with a mutation in *BRCA1* or *BRCA2* once she enters the risk period for ovarian cancer (5).

Breast cancer. For patients with a deleterious mutation in *BRCA1* or *BRCA2*, annual mammography beginning at age 30 is recommended (5,52). However, several studies have suggested that mammography alone in women with *BRCA* mutations is inadequate. In 2001, Brekelmans and colleagues (53) reported that 4 of 9 invasive breast cancers in 128 *BRCA* mutation carriers presented as palpable masses in the interval between screens. Similarly, in 2002, Scheuer et al. (54) reported that 7 of 12 invasive breast cancers diagnosed in 251 *BRCA* mutation carriers undergoing mammographic screening presented as interval cancers. Due to the relatively low sensitivity of mammography, breast MRI has been investigated as a complimentary imaging modality. Three of the largest studies to date have shown a 71% to 78% sensitivity of breast MRI for *BRCA*-associated cancers compared to a 36% to 40% sensitivity for mammography (55). Furthermore, in 2011, Warner and colleagues (56) demonstrated that the addition of annual MRI to annual mammography led to a down staging of *BRCA*-associated breast cancers (adjusted hazard ratio for the development of stage II to IV breast cancer associated with MRI screening = 0.30; 95% CI, 0.12 to 0.72). Currently, both the NCCN and the American Cancer Society recommend the combination of annual mammography and annual breast MRI, beginning by age 30, for screening in women with *BRCA* mutations (5,52).

Chemoprevention

Ovarian/fallopian tube cancer.

Multiple studies have suggested that use of oral contraceptives in the general population is associated with a substantial and long-lasting reduction in the risk of ovarian cancer (57). Given this, several authors have examined the impact of oral contraceptives on ovarian cancer risk in the setting of *BRCA1* or *BRCA2* mutations. In a recent meta-analysis of five case–control and retrospective cohort studies, Iodice and colleague (58) found that ever use of oral contraceptives was associated with a significant reduction in ovarian cancer risk in both *BRCA1* (summary relative risk = 0.51; 95% CI, 0.40 to 0.65) and *BRCA2* (summary relative risk = 0.52; 95% CI, 0.31 to 0.87) mutation carriers. Further, longer use was associated with a greater risk-reduction, with a 36% risk reduction seen for each 10 years of use (summary relative risk = 0.64; 95% CI, 0.53 to 0.78).

When caring for women with *BRCA1* or *BRCA2* mutations, it is important, however, to consider both breast and ovarian cancer risk, and the data regarding breast cancer risk has been somewhat more conflicting. Of five published studies addressing the impact of oral contraceptives on breast cancer risk in *BRCA1* mutation carriers, three suggested an increased risk of breast cancer with oral contraceptive use and two showed no increase in risk. Similarly, in the three studies reporting on breast cancer risk with oral contraceptive use in *BRCA2* mutation carries, two studies suggested an increased risk, and one study showed no increase in risk (58). After meta-analysis, neither *BRCA1* (summary relative risk = 1.09; 95% CI, 0.77 to 1.54) nor *BRCA2* (summary relative risk = 1.15; 95% CI, 0.61 to 2.18) mutation carriers demonstrated a statistically significant increased risk of breast cancer with oral contraceptive use. However, oral contraceptive formulations used before 1975 were associated with an increased risk of breast cancer (summary relative risk = 1.47; 95% CI, 1.06 to 2.04) (58). Given the data currently available, it likely makes sense to counsel patients that oral contraceptives may be associated with some adverse impact on breast cancer risk. This potential risk, however, needs to be balanced against the risk of unintended pregnancy and the benefit of oral contraceptives on ovarian cancer risk.

Breast cancer. The selective estrogen receptor (ER) modulators, tamoxifen and raloxifene, and to the aromatase inhibitor exemestane have been studied in the general population as chemoprevention for breast cancer. Tamoxifen is the only one of these agents that has been studied in women with *BRCA* mutations. King and colleagues (59), in a reanalysis of the NSABP P-1 trial, found a suggestion that tamoxifen was associated with protection against *BRCA2*-associated breast cancer (RR, 0.38; 95% CI, 0.06 to 1.56) but not *BRCA1*-associated breast cancer (RR, 1.67; 95% CI, 0.32 to 10.70), though neither of these results reached statistical significance. It was speculated that the reason for this possible differential effect was the different ER phenotypes of breast cancer seen between *BRCA1* and *BRCA2* mutations carriers. Sixty-five percent to 80% of *BRCA2*-associated breast cancers are ER positive, as opposed to only 10% to 25% of *BRCA1*-associated breast cancers (60,61). In 2000, Narod and colleagues examined the impact of therapeutic tamoxifen on contralateral breast cancer risk. In this study, tamoxifen appeared to be associated with a reduction of contralateral breast cancer risk in both *BRCA1* (odds ratio 0.38; 95% CI, 0.19 to 0.74) and *BRCA2* (odds ratio 0.63; 95% CI, 0.20 to 1.50) mutation carriers (62). Of potential significance, *BRCA1* mutation carriers who received tamoxifen in this study likely had ER-positive disease. Weitzel et al. (63) demonstrated that, in women with *BRCA* mutations who develop contralateral breast cancer, the ER status of the second breast cancer is highly concordant with the ER status of the first breast cancer, suggesting that women with ER-positive *BRCA1*-associated breast cancer are more likely to develop a second ER-positive cancer and therefore may be more likely to benefit from hormonal chemoprevention.

Risk-Reducing Surgery

Salpingo-Oophorectomy

Impact on ovarian cancer risk. Two of the earliest studies to examine the impact of RRSO on ovarian cancer risk were published in 2002. The first of these was a prospective cohort study from Memorial Sloan-Kettering Cancer Center. In this study, 170 women with a documented deleterious mutation in *BRCA1* or *BRCA2* elected either surveillance or RRSO. In this series, RRSO was associated with a 75% reduction in the subsequent risk of breast or *BRCA*-associated gynecologic cancer (HR = 0.25; 95% CI, 0.08 to 0.74) (64). When the impact of RRSO on gynecologic risk alone was examined, there was a an approximately 85% reduction in gynecologic cancer risk (HR = 0.15; 95% CI, 0.02 to 1.31). At the same time, a retrospective study from the University of Pennsylvania found that RRSO was associated with an approximately 96% reduction in gynecologic cancer risk (HR = 0.04; 95% CI, 0.01 to 0.16) (65). However, a commentary from Klaren et al. (66) pointed out that the retrospective study may have overestimated the conferred risk-reduction. Since that time, several other studies have suggested that RRSO is associated with a 71% to 89% reduction in gynecologic cancer risk (67), and a 2009 meta-analysis concluded that RRSO was associated with approximately 79% reduction in risk of *BRCA*-associated gynecologic cancer (HR = 0.21; 95% CI, 0.12 to 0.39) (68).

The origin of peritoneal cancers after RRSO is not entirely clear. Some of these may represent recurrence of occult ovarian or tubal malignancies that were not recognized on initial pathologic evaluation, emphasizing the need for careful pathologic evaluation of the entire ovary and fallopian tube at the time of RRSO. It has also been speculated that peritoneal cancer can arise from exfoliated tubal cells (endosalpingiosis) that implant on the peritoneum and undergo malignant transformation in that location. Lastly, some authors have suggested that peritoneal malignancies can arise exclusively in the peritoneum through Müllerian metaplasia (69). Irrespective of the origin, it is important that patients undergoing RRSO be informed of the small possibility of primary peritoneal cancer occurring after the procedure.

Impact on breast cancer risk. In the first study examining the impact of RRSO on breast cancer risk, Rebbeck and colleagues (70) found that RRSO in women with a *BRCA1* mutation was associated with a 47% reduction in *BRCA1*-associated breast cancer risk (HR = 0.53; 95% CI, 0.33 to 0.84). In a prospective study by Kauff et al. (64) reported in 2002, which examined both *BRCA1* and *BRCA2* mutation carriers, RRSO appeared to be associated with an approximately 68% reduction in breast cancer risk (HR = 0.32; 95% CI, 0.08 to 1.20). In 2008, Kauff, Rebbeck, and colleagues (71) pooled their updated prospective data and reported on 597 women with breast tissue at risk who had RRSO or surveillance and were prospectively followed for 2.8 years. When women with *BRCA1* and *BRCA2* mutations were examined together, RRSO was associated with a 47% reduction in breast cancer risk (HR = 0.53; 95% CI, 0.29 to 0.96). However, when *BRCA1* and *BRCA2* mutation carriers were examined separately, women with *BRCA2* mutations had a 72% reduction in breast cancer risk compared to women whose ovaries had been left *in situ* (HR = 0.28; 95% CI, 0.08 to 0.92). Women with *BRCA1* mutations appeared to have a 39% reduction in breast cancer risk (HR = 0.61; 95% CI, 0.30 to 1.22). However, despite this being the largest prospective study to date, these results did not reach statistical significance. An exploratory analysis examining the impact of RRSO on breast cancer stratified for ER status was also performed. In this analysis, RRSO appeared to be highly protective against ER-positive breast cancer (HR = 0.22; 95% CI, 0.05 to 1.05). However, no impact against ER-negative breast cancer was noted (HR = 1.10; 95% CI, 0.48 to 2.51).

Of note, a recent analysis from Heemskerk-Gerritsen et al. (72) has suggested that the design of several studies evaluating the impact of RRSO on breast cancer risk may have resulted in an overestimation of the risk-reduction conferred by RRSO against breast cancer. However, a reanalysis of data from Kauff et al. and Domcheck et al. according to the recommendations of Heemskerk-Gerritsen et al. suggests that, while there may be some change in the magnitude of risk-reduction conferred, the protective effect against breast cancer remains (73).

Impact on life expectancy. Domchek and colleagues (74) reported the results of a prospective cohort study concluding that RRSO in *BRCA* mutation carriers was associated with reduction in breast cancer–specific (HR = 0.44; 95% CI, 0.26 to 0.76), ovarian cancer–specific (HR = 0.21; 95% CI, 0.06 to 0.80), and all-cause mortality (HR = 0.40; 95% CI, 0.26 to 0.61). Similarly, Finch et al. (75) reported a 77% reduction in all-cause mortality (HR = 0.23; 95% CI, 0.13 to 0.39) following RRSO. While the effect of RRSO on mortality demonstrated by both Domchek et al. and Finch et al. is almost certainly present, there is a fair amount of instability in the estimates of the actual magnitude of this effect due to potential

biases introduced by the respective study designs. In the Domcheck study, participants could be identified as many as 20 years prior to the identification of *BRCA1* and *BRCA2*, but in many cases only underwent genotyping (and inclusion in the final analysis) if: (a) they lived long enough for clinical testing to become available or (b) they developed a cancer of interest. Similarly, in the Finch study, participants with breast cancer, including presumably those with advanced or metastatic disease diagnosed prior to study entry, were included in the analysis of mortality. In light of this, there may have been a selective survival bias in women who ultimately elected RRSO.

Even given the limitations of the available studies evaluating the efficacy of RRSO on subsequent cancer risk and mortality, for carriers of *BRCA1* and *BRCA2* mutations, RRSO remains the best available protection against pelvic serous cancer. It should be strongly considered after childbearing is complete, once a woman has entered the risk period for *BRCA*-associated gynecologic cancer.

Technical considerations. Given that the ovaries and fallopian tubes are both at risk for malignant transformation, it is imperative that the entire ovary and distal fallopian tube are removed at the time of RRSO. To do this, it is necessary that the surgeon be able to enter the retroperitoneal space and ligate the infundibulopelvic ligament at least 2 cm from its insertion into the ovary. Malignant cells leading to upstaging of disease have also been found in peritoneal cytology specimens from a number of women undergoing RRSO (76). Given these findings, washing should probably be performed at the time of peritoneal entry in all women undergoing RRSO.

Additionally, as 2% to 10% of RRSO specimens obtained from *BRCA* mutation carriers are determined to have an occult malignancy at the time of pathologic review (77), it is essential that the entire ovary and fallopian tube be serially sectioned to minimize the possibility of a small invasive cancer going undetected (4). The fimbrial ends of the fallopian tubes are the most frequent site of occult invasive serous carcinomas (78–80), and these lesions are best visualized using the SEE-FIM (sectioning and extensively examining the fimbriated end) method (81). Briefly, SEE-FIM entails lengthwise sectioning (sagitally) of the fimbriated portion of the fallopian tube in multiple planes to maximize exposure of the tubal plicae. When this method is utilized, serous tubal intraepithelial carcinoma (STIC), a putative precursor to invasive serous carcinoma, is also identified in as many as 5% to 8% of specimens obtained at the time of RRSO in women with mutations in *BRCA1* or *BRCA2* (82,83). Patients in whom small high-grade invasive serous cancers are found incidentally at RRSO generally receive adjuvant chemotherapy. The role of adjuvant therapy in the management of STIC is less clear (76).

Recently, Wethington et al. (84) evaluated the clinical outcome of patients found to have STIC at RRSO. Of 593 patients in this study, isolated STIC was diagnosed in 12 patients (2%). Seven patients subsequently underwent hysterectomy and omentectomy, six patients had pelvic node dissections, and five patients had para-aortic node dissections. With the exception of positive peritoneal washings in one patient, no invasive or metastatic disease was identified. None of the patients received adjuvant chemotherapy. At median follow-up of 28 months (range, 16 to 44 months), no recurrences were identified. The authors concluded that the yield of surgical staging is low in patients with STICs, and short-term clinical outcomes are favorable.

Timing of procedure. For most women with mutations in either *BRCA1* or *BRCA2*, RRSO should generally be considered between age 35 and 40, and when childbearing is complete (4,5). For women with *BRCA1* mutations, this is recommended because only 2% to 3% of women with mutations in *BRCA1* gene will develop pelvic serous cancer by age 40, but 10% to 21% of *BRCA1* mutation carriers will develop pelvic serous cancer by age 50 (10,42,85). For women with *BRCA2* mutations, the risk of pelvic serous cancer by age 50 is only 2% to 3%. However, women with *BRCA2* mutations who defer RRSO until the age of natural menopause likely lose the significant protection against *BRCA2*-associated breast cancer conferred by RRSO (77). For women with *BRCA2* mutations who have already had bilateral mastectomy and ovarian ablation is not being utilized as part of adjuvant therapy for a prior breast cancer, RRSO likely can be reasonably deferred until the mid-40s.

Role of hysterectomy. While RRSO is now part of standard management for women with *BRCA1* and *BRCA2* mutations, the role of concomitant hysterectomy is controversial, as it is not clear if women with *BRCA* mutations are at increased risk of uterine cancer (4,77). Recently, Shu et al. (86) reported the results of a multicenter prospective study in which

1,083 women with deleterious *BRCA1* or *BRCA2* mutation were followed for a median 5.1 years after RRSO. Eight incident uterine cancers were observed (4.3 expected; O/E = 1.9, $p = 0.09$). Stratifying by subtype, the authors found no increased risk of endometrioid endometrial carcinoma or sarcoma. Five serous/serous-like endometrial carcinomas were observed (4 *BRCA1*+; 1 *BRCA2*+) 7.2 to 12.9 years after RRSO (*BRCA1*: 0.18 expected; O/E = 22.2, $p < 0.001$; *BRCA2*: 0.16 expected; O/E = 6.4, $p = 0.15$). Using these data, the authors estimated that a *BRCA1* mutation carrier undergoing RRSO at age 45 had a 2.6% to 4.7% risk of serous uterine cancer through age 70. They concluded that, if these results are confirmed by future studies, hysterectomy with bilateral salpingo-oophorectomy may become the preferred risk-reducing surgical approach for women with *BRCA1* mutations, unless there are strong reasons for uterine retention.

Role of salpingectomy. With evidence suggesting the distal fallopian tube epithelium is the cell of origin for pelvic serous cancer, several authors have suggested a role for risk-reducing salpingectomy with delayed oophorectomy as a bridging strategy for women with *BRCA1* and *BRCA2* mutation who are not ready to proceed with oophorectomy (87). However, caution is warranted with this approach, for several reasons (88). First, while the hypothesis that fallopian tube epithelium is the cell of origin, in at least a portion of pelvic serous cancers is compelling, it is not known what proportion of pelvic serous cancers are explained by this hypothesis. Even if the distal fallopian tube is the site of origin of the vast majority of pelvic serous cancers, it is probably not the location of neoplastic transformation in a least a fraction of pelvic serous cancers. There is no evidence of fallopian tube neoplasm in 30% to 60% of serially sectioned fallopian tubes, in the setting of a coexisting ovarian serous malignancy. Lastly, if oophorectomy is deferred until the time of natural menopause, women with *BRCA* mutation will lose the significant benefit of oophorectomy in the prevention of *BRCA*-associated breast cancer. Given this, until clear data becomes available demonstrating that salpingectomy with delayed oophorectomy reduces the risk of pelvic serous cancer, once a woman with BRCA mutation enters the risk period for gynecologic cancer RRSO remains the recommended risk-reduction strategy.

Mastectomy.

Several studies have demonstrated that risk-reducing mastectomy (RRM) in women with *BRCA1* or *BRCA2* mutation is associated with at least a 90% reduction in the risk of new breast cancer (89,90). Importantly, the impact on life expectancy may be markedly less, as the majority of these cancers in women undergoing both mammography and breast MRI will be diagnosed at a curable stage. In a decision analysis by Kurian et al. (91) RRM at age 40 (in addition to RRSO at age 40 and breast screening starting at age 25) only increased the probability of survival to age 70 from 74% to 77% in carriers of *BRCA1* mutations and from 80% to 82% in carriers of *BRCA2* mutations. Given these relatively small absolute improvements in survival, intensive breast screening or RRM are likely reasonable options for a woman with a *BRCA1* or *BRCA2* mutation.

RISK-REDUCTION STRATEGIES FOR WOMEN WITH MUTATIONS IN NON-BRCA HR GENES

As noted above, recent advances in massively parallel sequencing have led to increased identification of individuals with germline mutations in moderate-penetrance cancer susceptibility genes that may be associated with increased risks of breast and ovarian cancer. It appears that *BRIP1*, *RAD51C*, *RAD51D*, and perhaps *PALB2* may be associated with increased risk of serous ovarian cancer. On the basis of early data from relatively small series, the lifetime risk of ovarian cancer (through age 70) associated with protein-truncating mutations in these genes is approximately 2.5% to 6.6% (46). Similarly, protein-truncating mutations in *ATM*, *NBM*, *CHEK2*, and *PALB2* may be associated with a breast cancer risk of 21% to 35% through age 70 (46). Tung et al. recently proposed a framework for counseling patients with mutations in these moderate-penetrance genes about risk-reducing strategies. Briefly, Tung et al. (46) suggested that we do not consider

incremental screening or risk-reducing surgery in women with a mutation in one of these moderate-penetrance genes until the age-specific cumulative risk of cancer at least exceeds the lifetime risk of breast and gynecologic cancer in the general population. For example, the authors estimate the cumulative risk of developing ovarian cancer through age 49 in the setting of an *RAD51C* or *RAD51D* mutation is 0.6% and 1.4%, respectively. As the lifetime risk of ovarian cancer in the United States is 1.3%, the authors suggest that women with mutations in *RAD51C* or *RAD51D* do not consider RRSO until after approximately age 50. Until further data becomes available, this appears to be a reasonable starting point for discussion of risk-reduction strategies in women with mutations in moderate-penetrance cancer susceptibility genes. However, given the rapid pace of changes in our understanding of the cancer risks associated with these genes, it is recommended that patients have an ongoing discussion with clinical genetics professionals, to determine if changes in management are warranted.

LYNCH SYNDROME

Epidemiology

Approximately 3% to 5% of endometrial cancer cases may be attributed to an inherited predisposition (92). Lynch syndrome, or hereditary nonpolyposis colorectal cancer (HNPCC) syndrome, accounts for the majority of these cases. Individuals with Lynch syndrome have a germline mutation in one of four genes in the DNA mismatch repair family: *MLH1*, *MSH2*, *MSH6*, or *PMS2 or* a heritable deletion in the *EPCM* gene that leads to silencing of *MSH2*. While Lynch syndrome has historically been characterized by an increased risk for colorectal cancer, women with Lynch syndrome also have a substantial risk for endometrial cancer. The estimated lifetime risk for colon cancer in women is 40% to 60%, and in men as high as 80% (93,94). In women, the lifetime endometrial cancer risk is approximately 40% to 60%. In a study focusing specifically on individuals with *MSH6* mutations, risk for endometrial cancer was 26% by age 70 and as high as 44% by age 80, and lifetime risk of colon cancer was 10% by age 70 and 20% by age 80 (95). Women with Lynch syndrome also have an approximate 5% to 10% lifetime risk for developing ovarian cancer. Other cancers associated with Lynch syndrome include cancers of the stomach, small bowel, renal pelvis and ureter, and brain.

In the general population, Lynch syndrome occurs in about 1 in 600 to 1 in 3,000 individuals (96,97). In a population-based study of endometrial cancer patients, the incidence of Lynch syndrome was 2.3%, which is similar to the 2.2% incidence of Lynch syndrome among colon cancer patients (98). For women with endometrial cancer under the age of 50, the proportion with Lynch syndrome increases to 5% to 9% (99–101). The mean age of diagnosis for endometrial cancer in women with Lynch syndrome is 47 years, which is substantially lower than the mean age of diagnosis of endometrial cancer in the general population. Women with Lynch syndrome are also at increased risk of developing synchronous or metachronous cancers. In a study examining 101 women with Lynch syndrome who had developed both gastrointestinal (GI) cancer and gynecologic cancer, 51% presented first with gynecologic cancer at a median age of 44 and 49% presented with GI cancer first (102).

Pathology

Unlike the ovarian cancers associated with *BRCA1* and *BRCA2* mutations, the endometrial cancers associated with Lynch syndrome span a broader spectrum of histologies. In a study by Broaddus et al. (103), 43 of 50 (86%) endometrial cancers were endometrioid histology, with the remainder being papillary serous carcinoma, clear cell carcinoma, and malignant mixed Mullërian tumors. Interestingly, all of the nonendometrioid tumors in this study occurred in patients with *MSH2* mutations. Among all of the patients with Lynch syndrome, 78% were diagnosed at stage I, 10% at stage II, and 12% at stage III or IV. Lymphovascular space involvement was noted in 24% of the cases, and 26% had deep myometrial

involvement that was defined as invasion greater than 50%. Endometrial cancers that arise in the lower uterine segment are relatively rare in the general population, but are seen more frequently in women with Lynch syndrome. In a study by Westin et al. (104), almost one-third of patients with endometrial cancers arising in the lower uterine segment were suspected to be associated with Lynch syndrome, based on tumor studies or germline testing. This characteristic phenotype is similar to the increased proportion of right-sided colon cancers seen in individuals with Lynch syndrome. Other pathologic features that have been seen more frequently in Lynch syndrome–associated colon cancers, including poor tumor differentiation and tumor-infiltrating lymphocytes, have not been seen consistently in Lynch syndrome–associated endometrial cancers.

The ovarian cancers seen in Lynch syndrome also have a different stage and histology spectrum from that seen in women with sporadic disease. In a recent series, 22 (47%) of 47 Lynch-associated epithelial ovarian cancers presented at stage I. Furthermore, serous cancers were underrepresented in this series, accounting for only 28% of tumors. Endometrioid, clear cell, and mucinous histologies were seen in 35%, 17%, and 5%, respectively (105).

Genetic Risk Assessment for Lynch Syndrome

For gynecologic oncologists, identifying Lynch syndrome in a patient with endometrial cancer has important implications for both the patient and her family members. Individuals with Lynch syndrome are at significant lifetime risk of developing a second primary malignancy. Therefore, when an endometrial cancer patient is identified as having Lynch syndrome, appropriate colon cancer screening can be initiated. Additionally, if a specific mutation in one of the DNA mismatch repair genes is identified in the endometrial cancer patient, her family members can undergo targeted predictive genetic testing for the same mutation.

Historically, guidelines to assist physicians in identifying individuals with Lynch syndrome have focused on colon cancer patients. Prior to the discovery of the genes responsible for Lynch syndrome, the Amsterdam I criteria were formulated to identify families with Lynch syndrome for research studies (106). These initial criteria only considered colon cancer as a sentinel diagnosis. The criteria were subsequently revised into the Amsterdam II criteria, to include extracolonic Lynch syndrome–associated cancers as sentinel diagnoses (107). To meet the Amsterdam II criteria, four factors must be present in a family: (a) three or more relatives have been diagnosed with Lynch syndrome–associated cancers, (b) two affected relatives are in successive generations, (c) one affected relative is a first-degree relative of the other two, and (d) one of the Lynch syndrome–associated cancers must have been diagnosed before the age of 50. While the Amsterdam criteria are quite specific, they are not sensitive enough for routine clinical use, as they only detect 13% to 36% of individuals with molecularly proven Lynch syndrome in population series (108,109).

Given the limited sensitivity of the Amsterdam I and II criteria, the Bethesda criteria were developed in 1997 and revised in 2004, to provide a more sensitive set of guidelines in order to identify patients with colorectal cancer who should be assessed further for the possibility of Lynch syndrome (110,111). However, the 2004 Bethesda criteria did not specify which patients with endometrial cancer should undergo further evaluation for Lynch syndrome. As it has become increasingly clear that female Lynch syndrome patients often present with endometrial or ovarian cancer as their first cancer, several authors have suggested modification to the 2004 Bethesda criteria to include endometrial cancer as a sentinel diagnosis (112). (**Table 3.4**)

TABLE 3.4 The 2004 Bethesda Guidelines (Modified to Include Endometrial Cancer as a Sentinel Cancer) to Identify Individuals with Colorectal or Endometrial Cancer for Whom Genetic Risk Assessment Is Recommended

- Patients with endometrial or colorectal cancer diagnosed before age 50 y
- Patient with endometrial or ovarian cancer with a synchronous or metachronous colon or other Lynch/HNPCC-associated tumor[a] at any age
- Patients with colorectal cancer with tumor-infiltrating lymphocytes, peritumoral

lymphocytes, Crohn-like lymphocytic reaction, mucinous/signet-ring differentiation, or medullary growth pattern diagnosed before age 60 y • Patients with endometrial or colorectal cancer and a first-degree relative[b] with a Lynch/HNPCC-associated tumor[a] diagnosed before age 50 y • Patients with colorectal or endometrial cancer diagnosed at any age with two or more first-degree or second-degree relatives[b] with Lynch/HNPCC-associated tumors[a], regardless of age

HNPCC, hereditary nonpolyposis colorectal cancer.

[a]Lynch/HNPCC-related tumors include colorectal, endometrial, stomach, ovarian, pancreas, ureter and renal pelvis, biliary tract, and brain tumors (usually glioblastoma as seen in Turcot syndrome), sebaceous gland adenomas, and keratoacanthomas in Muir–Torre syndrome, and carcinoma of the small bowel.

[b]First-degree relatives are parents, siblings, and children. Second-degree relatives are aunts, uncles, nieces, nephews, grandparents, and grandchildren.

Source: Adapted from Lancaster JM, Powell CB, Kauff ND, et al. Society of Gynecologic Oncologists Education Committee statement on risk assessment for inherited gynecologic cancer predispositions. Gynecol Oncol. 2007;107(2):159–162.

While family history remains an important component in identifying individuals who may benefit from genetic risk assessment for Lynch syndrome, tumor testing for evidence of mismatch repair defects is increasingly being used to triage patients who may be at risk for a germline DNA mismatch repair mutation (113,114). These tumor tests include immunohistochemistry for one of the four mismatch repair proteins (MLH1, MSH2, MSH6, and PMS2) and microsatellite instability (MSI) analysis. Both of these studies can be performed on formalin-fixed, paraffin-embedded tissues and can be a first step in the evaluation of Lynch syndrome in a patient with endometrial cancer.

For immunohistochemistry-based triage, the absence of a specific mismatch repair protein in the tumor is considered abnormal. For example, a tumor may demonstrate loss of staining of the MSH2 protein, with normal staining of the MLH1, MSH6, and PMS2 proteins. The loss of staining of the MSH2 protein in the tumor indicates that both copies of the gene are nonfunctional and suggests that the woman may have an *MSH2* germline mutation.

For MSI-based triage, both tumor and normal tissues are required. MSI testing reflects the tumor phenotype of deficient DNA repair. When a tumor has deficient DNA repair capability, multiple mistakes occur in the DNA in both coding and noncoding regions. These mistakes are especially common in regions of mononucleotide and dinucleotide repeats, such as CCCCCC or CGCGCG. The National Cancer Institute has identified seven regions in the genome that can be examined for MSI testing (BAT25, BAT26, BAT40, D2S123, D5S346, D173250, and TGF-BR2). Tumors with allelic shift in two or more microsatellites in this panel are considered MSI-high. Tumors with allelic shift in only one microsatellite are considered MSI-low. Tumors with no allelic shift in all seven microsatellites are considered microsatellite-stable. For MSI-high tumors with loss of MLH1 protein expression by IHC, methylation-specific PCR for *MLH1* proximal promoter region −248 to −178 is performed to detect possible methylation of the *MLH1* promoter. When methylation is present, the patient most likely has a sporadic carcinoma rather than a Lynch syndrome–associated cancer (*MLH1* promoter methylation is discussed in more detail in Chapter 2).

Immunohistochemistry (IHC) can also direct which of the four DNA mismatch repair genes should be sequenced. This can be performed in most pathology labs, and it has become the preferred approach for initial assessment of the mismatch repair pathway in endometrial cancers. In 2014, the ACOG published a practice bulletin, including an IHC-based algorithm, for assessing the possibility of Lynch syndrome in endometrial tumors (113) (**Fig. 3.1**). Additionally, they recommend that practices taking care of women with endometrial cancer adopt one of three approaches to determine which patients should be assessed for Lynch syndrome. Briefly, they recommend that any of the following is reasonable: (a) assessing all endometrial cancer patients diagnosed prior to age 60; (b) assess all endometrial cancer patients regardless of age of diagnosis; or (c) utilize a systematic clinical screen that includes a focused personal and family medical history, to determine which endometrial cancers should be further assessed. A study from the Australian endometrial cancer study has suggested that assessing all endometrial cancer patients who present prior to age 60 with an IHC-based approach is the most cost-effective strategy for triage (115). However, local resources and limitations will clearly influence the choice of approach in individual practices.

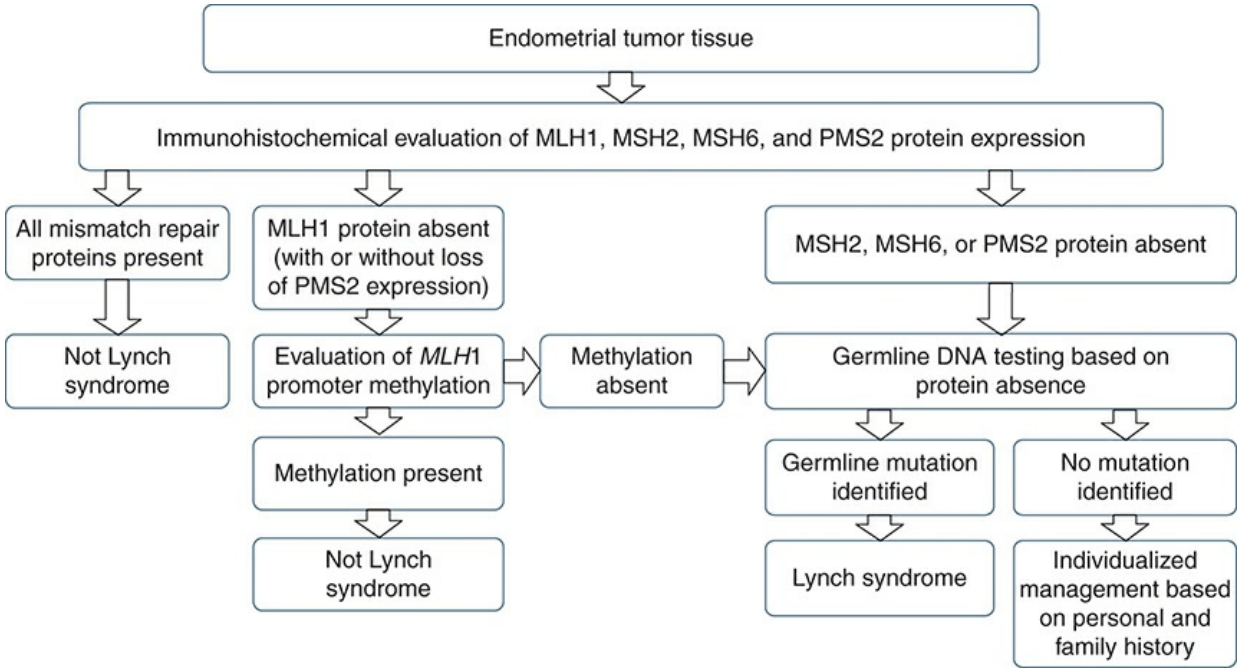

Figure 3.1 Algorithm for using IHC evaluation of mismatch repair protein expression to triage endometrial tumors for the possibility of Lynch Syndrome.
Source: Adapted from ACOG Practice Bulletin No. 147: Lynch syndrome. Obstet Gynecol. 2014;124:1042–1054.

An important limitation of IHC-based triage is that 10% to 15% of tumors with loss of either the MLH1 or PMS2 protein and 35% to 40% of tumors with loss of the MSH2 or MSH6 protein remain unexplained after comprehensive genetic evaluation, leading to counseling and management challenges. Recent data has suggested a fraction of these may be caused by biallelic somatic mutations (116), but clinical testing for this possibility is not widely available.

Given these challenges and rapid advances in next-generation sequencing technology, several authors have suggested proceeding immediately to direct germline testing of patients with a potential Lynch-associated endometrial cancer. However, while this may be a more efficient strategy in some cases, it may lead to increased genetic counseling demands due to higher rates of detection of variants of uncertain significance and potential detection of mutations in off-target genes. Furthermore, while direct germline testing may confirm the diagnosis of Lynch syndrome, only tumor testing can conclusively rule out the diagnosis.

Screening and Prevention

Screening

Guidelines for screening and prevention of Lynch syndrome–associated cancers have been published, and should be reviewed with patients when the diagnosis of Lynch syndrome is made (113,117,118) (**Table 3.5**). Colon cancer screening is recommended for individuals with Lynch syndrome every 1 to 2 years, starting at the age of 20 to 25 (or 30 years in patients with known *MSH6* mutations). This first evidence in support of this approach came from Jarvinen et al. (119), who demonstrated both a reduction in the incidence of invasive colorectal cancer from 16% to 6% (p = 0.014), and a relative risk of death of 0.34 (95% CI, 0.17 to 0.68) in individuals with Lynch syndrome who underwent colonoscopy or sigmoidoscopy and barium enema every 3 years, compared to those who received no routine screening. More recently, Vasen et al. (120) demonstrated an even lower risk of colorectal cancer in individuals having colonoscopy every 1 to 2 years versus every 2 to 3 years.

TABLE 3.5 Risk-Reduction Recommendations for Women with Lynch Syndrome

GI • Colonoscopy every 1–2 y beginning at age 20–25 (or 2–5 y before the earliest colorectal cancer diagnosis in the family, whichever is earlier) • Consider esophagogastroduodenoscopy every 3–5 y beginning at age 30–35 y, if Asian descent or family history of gastric or duodenal cancer • Consider chemoprevention with aspirin (though optimal dose and duration are uncertain)
Gynecologic • Endometrial biopsy every 1–2 y beginning at age 30–35 y • Women should keep menstrual calendar, and abnormal uterine bleeding should be evaluated • Consider chemoprevention with progestin-based contraception, including oral contraceptivesConsider risk-reducing hysterectomy with bilateral salpingo-oophorectomy after completion of childbearing. In general, this procedure should be discussed with a patient by their early to mid-40s
Urologic • Consider annual urinalysis starting at age 30–35 y

Source: Adapted from ACOG Practice Bulletin No. 147: Lynch syndrome. Obstet Gynecol. 2014;124:1042–1054 and National Comprehensive Cancer Network: NCCN Clinical Practice Guidelines in Oncology—Genetic/Familial High-Risk Assessment: Colorectal. 2016. Version 1.2016. http://www.nccn.org

In contrast to colon cancer screening, there are no proven screening strategies for the early detection of endometrial or ovarian cancer in women with Lynch syndrome. Two European studies reported a high false-positive rate and poor efficacy of using measurement of endometrial stripe by transvaginal ultrasound as an endometrial cancer screening tool (121,122). Two more promising studies have reported identification of premalignant lesions and endometrial cancers in asymptomatic women with Lynch syndrome using office endometrial biopsy as a screening strategy (123,124). One of these studies, including 175 women with known *MLH1*, *MSH2*, or *MSH6* gene mutations, reported a stage migration, with 7% of women in the surveillance group presenting with stage III/IV disease versus 17% of women who presented symptomatically (123). The second study reported on 100 women from Lynch kindreds and demonstrated that routine endometrial sampling resulted in a significantly higher rate of malignancies and premalignancies, compared with prior historical controls in which routine endometrial sampling was not performed (6.3% vs. 1.4%, $p = 0.026$) (124). Importantly, no study to date has examined the mortality impact of routine endometrial sampling in women with Lynch syndrome. ACOG guidelines currently recommend uterine cancer surveillance with endometrial biopsy every 1 to 2 years, beginning at age 30 to 35, and keeping of a menstrual calendar, with evaluation of abnormal uterine bleeding (113). Given that endometrial biopsy is an invasive and uncomfortable procedure, a study by Huang et al. (125) demonstrated the feasibility and acceptability of performing surveillance endometrial biopsies in women with Lynch syndrome, while the patient is sedated for a screening colonoscopy. They also concluded that there was a substantial reduction in reported pain when the procedures were done concurrently under sedation.

Chemoprevention

In the general population, multiple studies have demonstrated that combination oral contraceptives reproducibly decrease endometrial and ovarian cancer risk (57,126). Progestin therapy is also effective in reversing complex atypical hyperplasia and early endometrial cancer (127). While there are no epidemiologic data that have evaluated the role of progestins or progestin-based oral contraceptives as chemoprevention in women known to have Lynch syndrome, a short-term biomarker study demonstrated a significant decrease in endometrial proliferation using either 150-mg depo medroxyprogesterone acetate or a 30-*m*g ethinyl estradiol/0.3 mg norgestrel oral contraceptive pill (128). An ongoing trial is examining the use of the levonorgestrel intrauterine device as a chemopreventive in women with Lynch syndrome.

Risk-Reducing Surgery

Risk-reducing hysterectomy and salpingo-oophorectomy are reasonable options for prevention of endometrial and ovarian cancer in women with Lynch syndrome. A multi-institutional retrospective study of women with Lynch syndrome demonstrated that the incidence of endometrial cancer fell from 33% to 0% in women who underwent hysterectomy, and the incidence of ovarian cancer fell from 5.4% to 0% in women who underwent salpingo-oophorectomy (129). The risk of primary peritoneal cancer after oophorectomy in women with Lynch syndrome is unclear, although one case report has been published (130). It is also important to note that occult endometrial cancers have been found in asymptomatic women at the time of risk-reducing hysterectomy and salpingo-oophorectomy (131,132).

Women with Lynch syndrome should be counseled that the estimated risk for endometrial cancer by age 40 does not exceed 2% and the estimated risk of ovarian cancer by age 40 does not exceed 1% (94). Therefore, women with Lynch syndrome can likely complete childbearing prior to consideration of risk-reducing surgery. In addition, there does not appear to be a contraindication to estrogen replacement therapy after risk-reducing surgery. Two studies have performed cost-effectiveness analyses of options for gynecologic risk reduction in women with Lynch syndrome (133,134). Both studies found that risk-reducing hysterectomy and salpingo-oophorectomy led to the lowest cost and the greatest increase in quality-adjusted life years.

For patients undergoing colonic resection for a Lynch-associated colorectal cancer, it may be reasonable to discuss concomitant hysterectomy with BSO. However, for premenopausal patients who are diagnosed with Lynch syndrome at the same time as their colorectal cancer, substantial fertility and psychosocial issues may be associated with this approach.

OTHER INHERITED SYNDROMES WITH A GYNECOLOGIC CANCER COMPONENT

Cowden Syndrome

Cowden syndrome is caused by germline mutations in the *PTEN* gene. Individuals with Cowden syndrome are at increased risk for both benign and malignant processes. These include GI polyps, thyroid disease, and mucocutaneous lesions, as well as breast, thyroid, and endometrial cancer (135). The lifetime risk of endometrial cancer in a woman with Cowden syndrome has been estimated to be 19% to 28% (136,137). Current NCCN guidelines recommend observation for and prompt evaluation of abnormal uterine bleeding (5). Screening with endometrial biopsies and/or ultrasound measurement of the endometrial stripe is being evaluated in the context of ongoing research studies.

Li-Fraumeni Syndrome

Li–Fraumeni syndrome is caused by germline mutations in *TP53* and is characterized by early-onset breast cancer, soft tissue and bone sarcomas, adrenal cortical tumors, and brain tumors (138). Although it is not a major cancer risk in individuals with Li–Fraumeni syndrome, cases of ovarian cancer have been reported. While screening breast MRI is recommended beginning at age 20 to 25, there are no current screening recommendations for gynecologic cancers in women with Li–Fraumeni syndrome (5,139).

Peutz-Jeghers Syndrome

Peutz–Jeghers syndrome is caused by germline mutations in *STK11*. Peutz–Jeghers is generally characterized by multiple GI polyps and pigmented lesions on the lips and buccal mucosa. Women with this syndrome also have a markedly

increased risk for GI and breast malignancies (140). Gynecologic cancers associated with this syndrome include sex cord–stromal tumors with annular tubules (SCTAT) of the ovary and adenoma malignum of the cervix (141). SCTATs are typically benign and bilateral. Adenoma malignum of the cervix is a rare, though aggressive, neoplasm that can also be seen in Peutz–Jeghers syndrome. It is often difficult to diagnose clinically and histologically. On imaging, the tumor appears as a multicystic endocervical mass. Histologically, the tumor appears well differentiated, but the natural history can be aggressive. Due to the rarity of both this syndrome and the associated gynecologic cancers, it is unclear whether women with Peutz–Jeghers should be screened. Regular pap smears using liquid-based cytology, beginning at age 25, have been recommended. However, the role of pelvic imaging is unclear (142).

Hereditary Small Cell Carcinoma of the Ovary, Hypercalcemic Type

Small cell carcinoma of the ovary, hypercalcemic type (SCCOHT), is a highly lethal ovarian malignancy that presents primarily in adolescents and young adults (median age of diagnosis is 25) (143). These tumors are caused by mutations in *SMARCA4* (144–146), with as many as 43% caused by germline mutations (143). For patients with suspected SCCOHT, immunostaining of tumor for the BRG1 protein, which is encoded by *SMARCA4,*is recommended. If BRG1 protein expression is absent, genetic counseling is recommended to assist with management decisions regarding the contralateral ovary and allow predictive testing of at-risk relatives. While the risk for developing SCCOHT associated with *SMARCA4* mutations is not entirely known, presymptomatic risk-reducing oophorectomy has been performed in this setting (147).

CHAPTER 4 Invasion, Metastasis, and Angiogenesis

Angeles A. Secord, Charlie Gourley and Elise C. Kohn

INTRODUCTION

Gynecologic cancers are potentially curable if diagnosed at an early stage, when the tumor remains confined to the primary organ; survival is compromised by dissemination or metastasis of the disease into, around, or adjacent to vital organs. The process of this dissemination and the result of metastasis require activation of key elements of invasive and angiogenic processes early in disease. Invasion requires activation of adhesion and deadhesion, migration, migration stimulation, and proteolytic and glycolytic events. These are activated in the early precursor cell and continue progressively along the continuum of cancer development (Fig. 4.1). We now know the sites of origin for all major epithelial gynecologic cancers and can map at least roughly how and when they may acquire the attributes that make them lethal cancers.

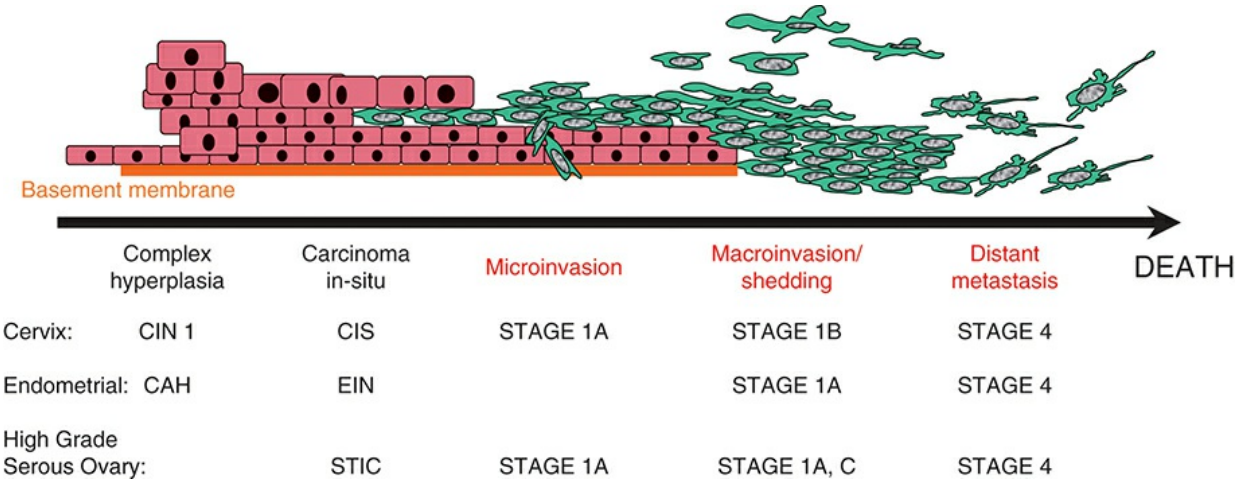

Figure 4.1 Paradigm of cancer progression. Progression from the earliest detectable event of complex hyperplasia to overt invasive and metastatic malignancy is believed to take over a decade for endometrial and cervical cancers. The tubal epithelium is now believed to be the source for type 2 high-grade serous ovarian cancer; the time frame from acquisition of p53 mutation (p53 signature) to STIC is unclear, as is the subsequent time to dissemination. Tubal epithelium can shed at an early and microscopic stage. When identified early, each of these cancers has a high cure rate and long OS. However, when identified at or beyond the stage of microinvasion, progressive disease and death from disease is common. STIC, serous tubal intra-epithelial carcinoma.

Cervical and endometrial cancers follow the classically recognized development from dysplasia/hyperplasia/metaplasia to carcinoma *in situ* to invasive cancer. Local dissemination occurs predominantly by local invasion into lymphovascular

structures, allowing stepwise and generally anatomically direct progression. This permits the success of local interventions of surgery and radiotherapy that are the mainstay of treatment. The general tenet of invasion and metastasis, lymphatic and hematogenous spread to the first capillary beds, fits the common patterns of progression of these cancers. This appears to be consistent with most of the histologic types, although the process is faster for the more aggressive types of clear cell, small cell, and serous cancers, where systemic spread is rapid and necessitates systemic therapeutic intervention.

Ovarian cancer is different in several ways. As described in depth elsewhere in this text, it is now recognized that epithelial ovarian cancer comprises different types, for which there are histopathologic, demographic, and molecular differences (1). The most prevalent and most deadly is the high-grade serous and endometrioid type (HGS/ epithelial ovarian cancer), generally sheets of malignant cells, with early shedding into the peritoneal cavity, causing carcinomatosis, rendering nearly all p53 dysfunctional, and initiating from fallopian tube epithelium (2,3). Clear cell and low-grade endometrioid types appear to have common endometriotic precursors, and up to 40% have somatic *ARlDla* mutations (4). Both are more frequent and have a better outcome when presenting in early-stage disease, although clear cell cancers have the highest recurrence rate of early-stage disease at ~40%. Low-grade serous cancers appear to progress from the normal surface epithelium or included surface epithelium, through serous borderline tumor, to invasive disease. They often have *RAS* and *BRAF* mutations, although data suggest that these may not be drivers of malignant or invasive behaviors (5). All types have metastatic potential and angiogenic activity and thus are potentially targetable with this broadening direction of therapeutics.

The ovary is an “inside-out” organ, where the epithelium faces the peritoneal cavity and sits on its basement membrane, the capsule of the ovary. It is a vascular organ, with further cyclical vascular changes occurring during the patient’s reproductive years. This angiogenic capacity of the pelvic microenvironment makes the ovaries excellent *soil* for the *seed* of malignancy, primary or metastatic (6,7). Likewise, the fallopian tube is “inside-out,” also with its epithelium facing the peritoneal cavity. This orientation facilitates shedding of premalignant and malignant cells, a process that can occur as early as the point of microscopic malignant disease. The first stop for such shed malignant tubal cells is the prime soil of the vascular and dynamic ovary (Fig. 4.2; note epithelium on the outside of the basal membrane).

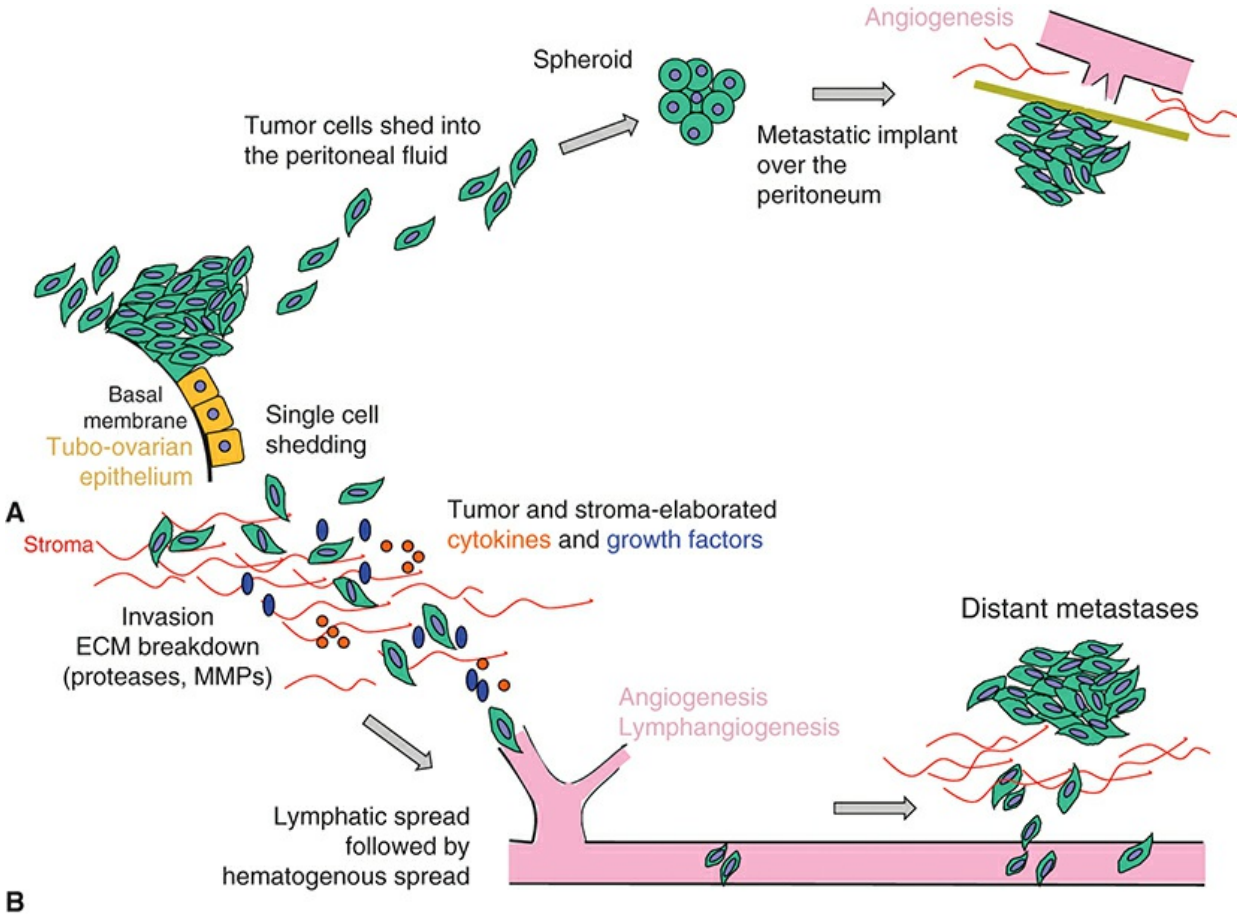

Figure 4.2 Tubo-ovarian cancer: shedding and spreading. The primary tubo-ovarian tumor metastasizes in two different ways. The first mechanism (A), occurring early, is shedding of single cancer cells from the surface of the tube or ovary into the peritoneal cavity; the second mechanism (B), occurring later, is invasion into surrounding and distant tissues. Cells shed in the peritoneal fluid form spheroids that have acquired mechanisms to resist anoikis. These spheroids implant on peritoneal mesothelial surfaces; cause stromal activation with desmoplasia, inflammation, and angiogenesis; and grow into metastatic deposits. ECM, extracellular matrix; MMPs, matrix metalloproteinases.

The progress in understanding ovarian cancer has uncovered an unexpected migratory behavior of endometrial contents along the fallopian tubes. Here, the tubes function as retrograde conduits for endometrial materials to leave the uterus (8). This happens during endometriosis and can result in endometrial materials enclosed in follicular cysts within the ovary and other forms of ovarian endometriosis. Such occurrences are now presumed to be precursors to clear cell and low-grade endometrioid ovarian cancers, in which *ARIDla* mutations are shared (4). The ovary is the first site reached, the most permissive and the most common site of endometriosis. The seminal processes of invasion and metastases—adhesion, migration, local microenvironmental remodeling, and angiogenesis—are pathologic processes in both benign and malignant pelvic diseases (6).

THE TUMOR ENVIRONMENT AND METASTASIS

The genotypic and phenotypic make-up of a tumor is a major determinant of its metastatic efficiency, and a receptive microenvironment is a prerequisite for successful tumor growth (9,10). In 1889, Sir James Paget stated that the microenvironment of each organ, *the soil,* influences the survival and growth of tumor cells, *the seed.* Multiple overlapping

signal and adhesion networks cooperate to enable molecular and structural remodeling of tissues that support tumor invasion, growth, and metastatic dissemination. Cellular behavior and activation or inactivation of genes are influenced heavily by the local tumor environment. This reinforces the idea that a complex interplay of molecules and signals is needed for tumor sustainability. The tumor environment has a plasticity that allows participating elements, such as the harsh environment of hypoxia, acidosis, metabolic stress, inflammation, and cellular interactions, to vary throughout the events of cancer progression (10,11).

The tumor environment consists of its microenvironment, or proximate cellular and acellular locale, and the macroenvironment, the local perfused organ milieu. The macroenvironment changes within and between the pelvis and local region of the ovaries and the abdominal cavity and, in part, dictates the local microenvironment. The omentum, for example, has a rich background of pluripotent adipocytes and other cells that interactively promotes generation and release of enzymes and cytokines. These soluble molecules modify the local extracellular matrix (ECM), promoting invasion, proliferation, angiogenesis, and metastasis (11-14).

The microenvironment is governed by the immediate cellular and ambient regional surroundings. The ovary is the first microenvironment for tubal epithelium. The outside-in setting for the epithelium means that any growth factors, cytokines, and ECM components released by the ovarian epithelium may reach the apical or outer margin. The microenvironments of the abdominopelvic serosa, peritoneal mesothelium, and omentum are similarly favorable, though more distant, sites. The mesothelial cell, the single-cell layer of the peritoneum and outer serosal layer of organs, is a pluripotent mesenchymal cell that responds to changes in its surroundings. Such responses may be production and secretion of entities that attract and/or nurture shed tumor as well as vascular precursor cells and immune infiltrates. The omentum is a very advantageous site. Adipose tissue contains adipose stem cells that have shown the ability to differentiate into many different end cells, from bone and connective tissue cells, to vascular endothelium; this has been shown in both ovarian cancer and in endometrial cancer (13,15).

The microenvironment of the primary tumor and metastatic sites has a high metabolic demand requiring adequate blood supply for nutrients, removal of waste, influx of immune and stromal cells, and ultimately as a conduit for hematogenous spread (1,6,11,12). Tumors have developed mechanisms to sustain themselves in nutrient-poor environments, with both activation of internal pathways and manipulation of their locale through events such as autophagy, internal protein degradation and recycling, and producing and secreting factors to attract vascular sprouts and support cells (16). Angiogenesis, the formation of new vessels, occurs by multiple mechanisms, from within the organ milieu in which the tumor is growing (6,17). Angioregulatory factors are secreted into and by elements of the tumor microenvironment, leading to new vasculature that supports tumor survival and progression (11). Invasion, angiogenesis, and metastasis are thus orchestrated within the tumor microenvironment through a dynamic interaction between the tumor cells, the ECM, stromal and immune cells, and secreted chemokines and growth factors (6,11,12). Tumor cells adapt in response to environmental and cellular stress, and upregulate different mechanisms including cell migration, angiogenesis, autophagy, and apoptosis for their survival.

Inflammation

The endometrium, tube, and ovaries are dynamic cyclic organs with cycles of growth, remodeling, differentiation, and angiogenesis. Estrogen drives these changes by facilitating the release of inflammatory mediators from the epithelial, stromal, and vascular cells of the endometrium. These are further modified by exogenous elements such as pharmaceutical hormones, hormonal changes related to obesity, diet, and stress (18,19). For example, the menstrual cycle is a physiologic inflammatory process. There is a strong parallel between the immune regulation and requirements for immune tolerance in the reproductive tract and the findings that support tumor invasion and dissemination due to immune tolerance in gynecologic cancer.

Local activation of select components of the immune response promotes angiogenesis and dissemination, while others interact within the tumor microenvironment to create a potent immunosuppressive effect (20). Inflammatory mechanisms

include but are not limited to the recruitment of activated CD8 T cells, production of reactive oxygen species and free radicals that directly damage DNA and proteins, and production of proinflammatory/proangiogenic molecules, such as cytokines, tumor necrosis factor-a, and interleukins (IL)-6, -8, and -10, and tumor growth factor (TGF)-β, promoting local activation and migration of proangiogenic stromal and immune components, and tumor-associated macrophages. Immunosuppressive events that may also occur in the tumor microenvironment to inhibit immune recognition of malignancy include upregulation of regulatory T cells (Tregs), T_H2 cells unable to support a cytolytic response, dysfunctional dendritic cells unable to present antigen, and M20-differentiated macrophages expressing IL-12. These events can collectively upregulate immune checkpoint inhibitors on tumor, endothelial, and immune cells, such as programmed death-1 (PD-1) and PD-ligand 1 and 2 (PDL-1 and -2) (20–23).

Cellular interactions within the tumor microenvironment are a dynamic process and can shift from an immune tolerant to an immune active antitumor mode, with changes in the local environment or with selected therapeutics (22,23). TGF-β, long recognized to be a promoter of tumorigenesis, invasion, and dissemination, also plays a role in promoting immune tolerance. Hypoxia with induction of VEGF, IL-6, and IL-8, among other cytokines and factors, promotes angiogenesis, which provides support for invasion and metastasis while also promoting recruitment and suppression of immune cell types including myeloid-derived suppressor cells, inhibitory macrophages, and Tregs (20,24). The growing understanding of the activity between immune, stromal, and tumor components is helping to guide application of novel immunotherapeutics that can modulate invasion, angiogenesis, and metastatic dissemination.

THE INVASIVE PROCESS

Mechanisms and Patterns of Dissemination

Shedding, spreading, and hematogenous and lymphatic metastasis all lead to dissemination of premalignant and malignant cells from primary malignant or premalignant neoplasms to secondary sites (6,12). They require one of two major processes. In the first, cells detach from their primary site, then the shed cells transport to a secondary site, for example, into the peritoneal cavity, and attach at a new location; tumor cells interact with the mesothelial cells to which they have attached, creating a cross-talk that results in the production of factors to enhance the immediate locale and promote growth at the secondary site (9,14,15,25). The more common mechanism, and the one that explains lymph node and parenchymal organ involvement, is true invasion where cells locally proteolyze the basement membrane through which they invade into the local stroma. This commonly requires metalloproteinases, such as matrix metalloproteinases (MMP)-2 and -9 (6). Invasive cells then travel to a secondary site via the lymphatic and/or the vascular system, and again disrupt the local basement membrane barriers to create a rent through which they extravasate into the secondary site (6,26). A recent study using parabiotic mice, mice anatomically connected by the skin, though without abdominal or peritoneal connections, demonstrated that subcutaneous inoculation on one mouse could ultimately result in intraperitoneal disease in the attached mouse, implicating an invasive method of dissemination (26).

Tumor cells must interact closely with elements in their microenvironment, such as vascular cells, stromal cells, and immune components, to achieve successful metastasis (9,12). The peritoneum, omentum, and mesenteric serosa are permissive environments to which tumor cells can attach and grow, co-opting support cells and vasculature to sustain their survival and growth. Recent preclinical studies have shown active and dynamic interactions between endometrial or ovarian cancer cells with pluripotential omental adipose cells (15,25). These data suggest that peritoneal dissemination seen in ovarian cancer may reflect the process used by endometrial and other cancers at later stages in their dissemination. Many events within the tumor cell support these outcomes.

Epithelial–Mesenchymal Transition

Epithelial–mesenchymal transition (EMT) describes a series of molecular, biochemical, and functional events that occur at a cellular level in response to local changes such as local growth factor and cytokine presence, changes, and/or exposure to the ECM (10,27). These changes progress the epithelial tumor cell along a mesenchymal-like continuum and upregulate survival and invasion signals, promoting single-cell autonomy. The tumor cells of most gynecologic cancers are epithelial in origin and nature, transforming from polarized basement membrane-bound normal cells into freely moving single cells or small groups of cells. Events occurring during EMT include downregulation of proteins that promote the homotypic cell attachment that maintains order and polarization, such as E-cadherin, and upregulation of proteins that promote heterotypic cell adhesion, such as P- and N-cadherin. These are induced by upregulation of key transcription factors, including *slug* and *snail* that inhibit transcription and expression of CDHl/E-cadherin, and upregulation of elements of the TGF-β pathway. Such changes occur in response to endogenous and exogenous stimuli along the EMT continuum (10,27,28). These gene expression changes were also described in the transcriptional and genomic analyses of ovarian cancers, leading to a subcategory of an aggressive subset of mesenchymal-like ovarian cancers, where patient outcome is poorest (29,30) (Fig. 4.3).

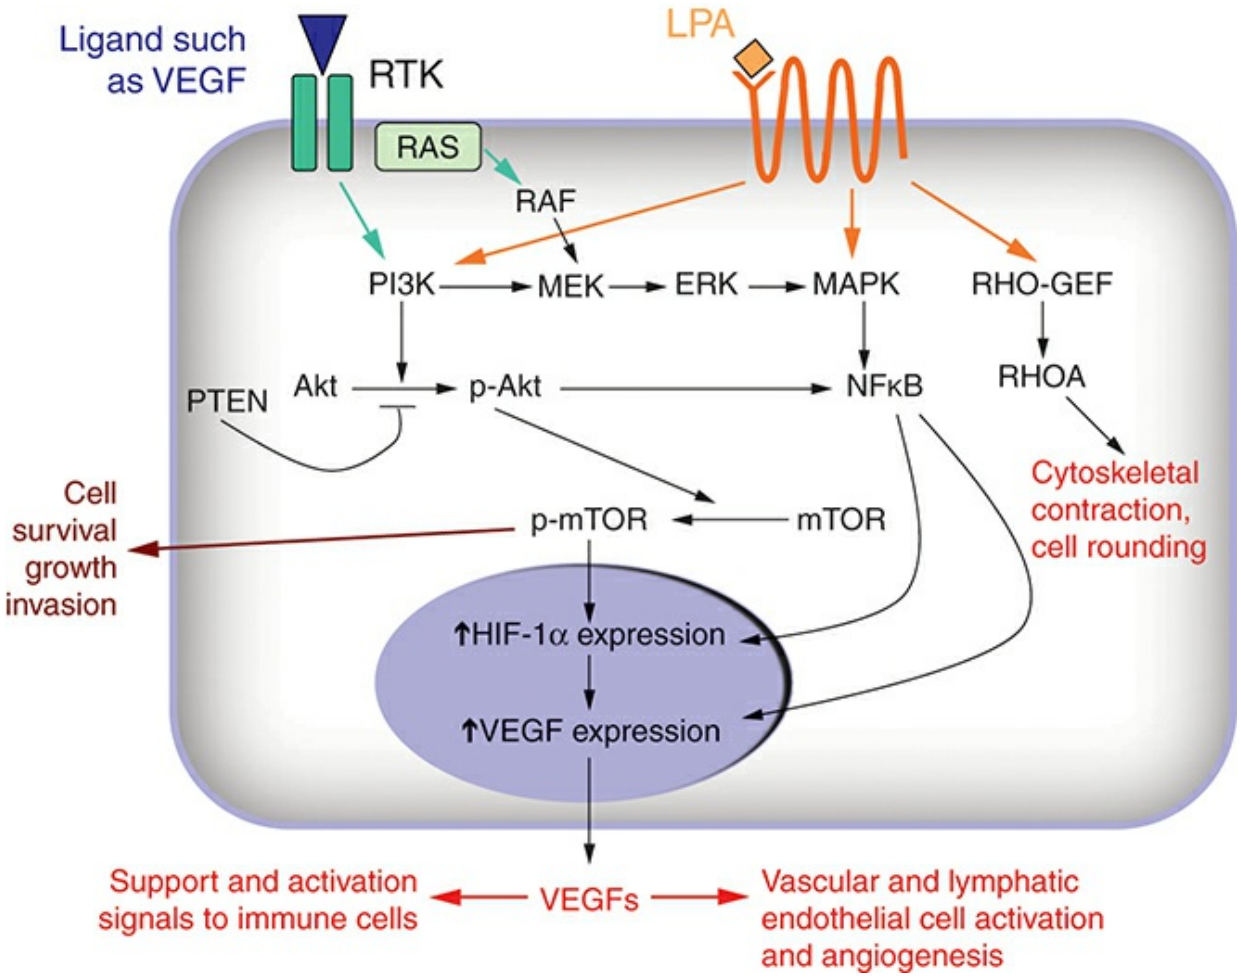

Figure 4-3 Molecular pathways. Activation of AKT is a well-recognized and potent prosurvival and proangiogenic pathway activated by LPA and growth factors and cytokines that activate RTKs. Many of these ligands are produced and secreted by gynecologic cancers, and often by mesothelial, stromal, immune, and/or vascular cells as well. LPA signals through the LPA receptor, a 7-pass transmembrane G-protein-coupled receptor. LPA promotes expression of VEGF for angiogenesis and cell survival through the PI3K/AKT, NF-κB, and MAPK signaling pathways. RTK activation also promotes cell survival, invasion, angiogenesis, and proliferation through the PI3K/AKT, NF-κB, and MAPK pathways. ERK, extracellular regulated kinase; LPA, lysophosphatidic acid; MAPK, mitogen-activated protein kinase; MEK, MAP-ERK kinase; mTOR, mammalian target of rapamycin; NF-κB,

nuclear factor KB; PTEN, phosphatase and tensin homolog; Rho-GEF and RHO A are Rho family GTPases; RTK, receptor tyrosine kinases; VEGF, vascular endothelial growth factor.

Anoikis is a specific apoptotic process triggered by loss of cell–cell or cell–substratum survival signals (28). It is a physiologic phenomenon that maintains cell and tissue homeostasis and is disrupted in physiologic events such as immune response and pregnancy, and pathologically in cancer. Resistance to anoikis allows cancer cells to avoid apoptosis during the metastatic process, when single or small clusters of cells invade and migrate within and out of the ECM. Similarly, tumor cells require prosurvival signals when within effusions where there may be cell-bound or soluble matrix molecules, but not the classical adherent prosurvival behavior of normal epithelial cells. Anoikis resistance is thus critical in the development of carcinomatosis and ascites, creating a permissive survival signal for cancer cells shed into the peritoneal space. These viable clusters then adhere to and invade into serosal mesothelium. The mechanism by which the apoptosis of anoikis is triggered relies on the loss of prosurvival signals induced by the binding between the cell and its scaffolding. The phosphatidyl inositol-3′ kinase (PI3K)/AKT and phosphatase and tensin homolog (PTEN)/AKT pathways produce major prosurvival signals and anoikis resistance. This convergent pathway has been shown to be important in all gynecologic cancers. PI3K activation and/or PTEN loss is prevalent in endometrioid endometrial and ovarian cancers, and promotes the AKT prosurvival signaling pathway (29,31) (Fig. 4.4).

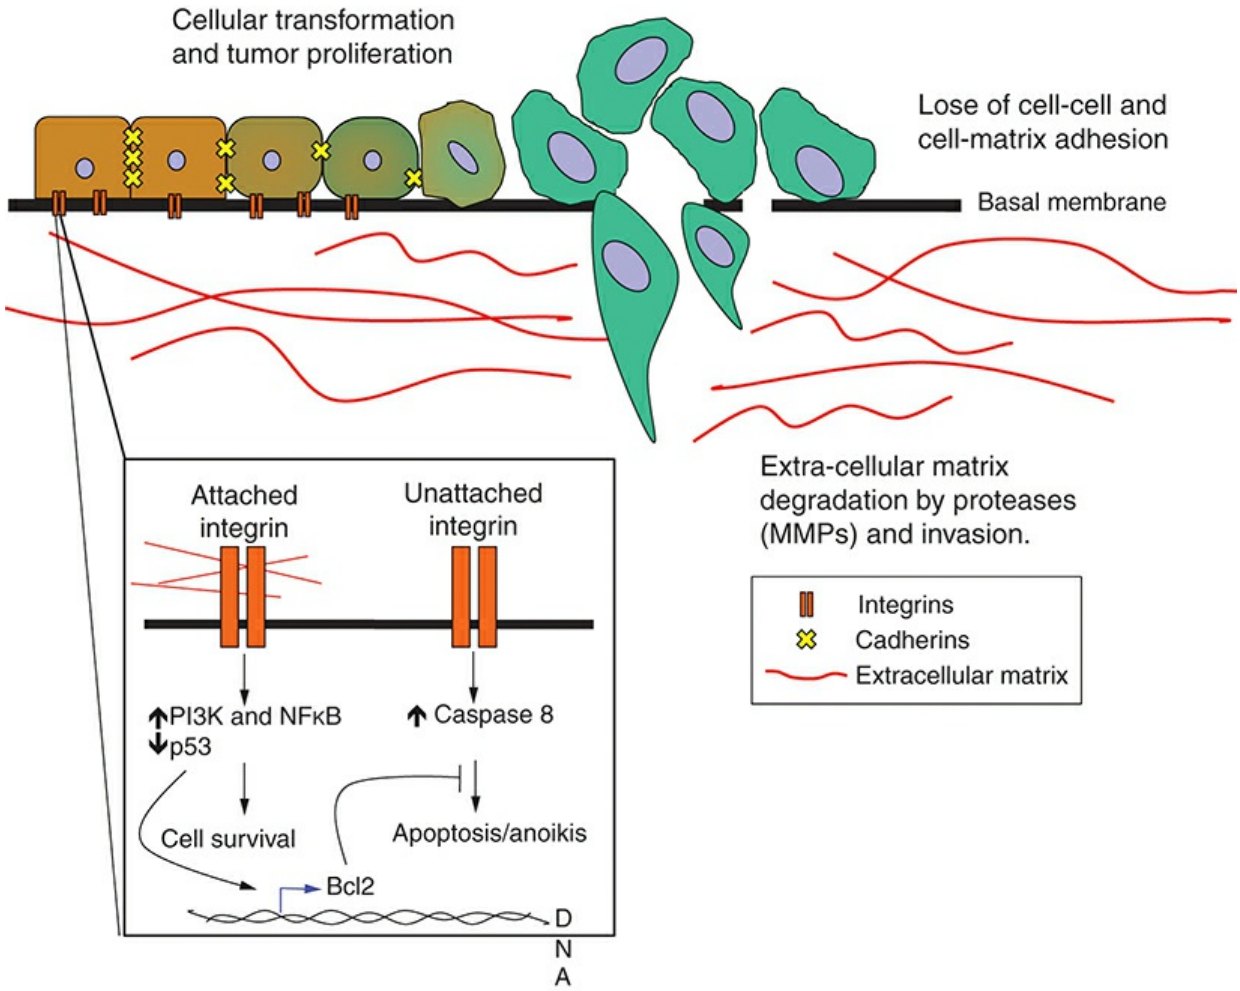

Figure 4.4 Invasion. Cancer cells lose their cell-to-cell (cadherin) and cell-to-matrix (integrin) attachment, releasing single cells and permitting cell migration. The production and secretion of proteases (MMPs, serine proteases) promotes ECM degradation forming tracks through which cancer cells migrate and invade surrounding tissues. Metastatic cancer cells have acquired mechanisms to resist anoikis. ECM, extracellular

matrix; MMP, matrix metalloproteinase.

Extracellular Matrix

The ECM is the complex glycoproteinaceous structure surrounding and supporting cells. It comprises three major classes of biomolecules: proteoglycans, structural proteins such as collagens and elastins, and specialized matrix proteins such as fibronectin and laminins (6). The ECM serves many functions, including providing cellular scaffolding support, acting as a binding site for growth factors and cofactors, and acting as a modulator of intercellular communication. Integrins are heterodimeric transmembrane receptors that integrate microenvironment and cell signaling as mediators of bidirectional signaling, incorporating cross-talk with a variety of cell surface receptors and intracellular signaling proteins (32). The tripeptide sequence, Asp–Gly–Arg (RGD), is the important ligand recognition site for integrins. The actin cytoskeleton is connected to the cytoplasmic integrin tail through the ERM proteins, ezrin, radixin, and moesin. Ligand binding also initiates intracellular signaling cascades that provide the machinery needed for cell motility and invasion, and to support survival (28).

Adhesion

Cell attachment to other cells or to basement membrane is a requirement for normal epithelial cells. Loss of adhesion in normal epithelial cells is associated with anoikis-associated apoptosis, overruled by malignant transformation, where autologous survival stimulation occurs (10,27,28). Tumor cells interact with the local acellular microenvironment through adhesion molecules and integrins. All of these interactions can stimulate cell survival messages, or cell death messages, as may be seen in some immune interactions. There are four categories of adhesion molecules: integrins, cadherins, immunoglobulin superfamily cell adhesion molecules (CAMs), and selectins. They participate in cell–cell and/or cell–substratum binding, yielding a complexity of adherence and signaling possibilities. When expression or function of adhesion molecules becomes altered by tumor progression, new signals that can promote tumor growth, survival, and metastasis are propagated. Such adhesion interactions between tumor cells and normal cells, such as endothelial or immune cells, or fibroblasts, can result in activation of angiogenesis or the immune response, or augmentation of immune tolerance, drug resistance, and metastasis (10,11,21,26,33). Adhesion of circulating tumor cells to platelets, macrophages, or endothelial cells or matrix molecules via integrin engagement is critical to overcoming the anoikis of single-cell circulation.

ANGIOGENESIS

All cells need a supply of nutrients and oxygen with which to sustain survival. This requires that they be located within 100 μm of a blood vessel (6,11,17). This also applies to tumor cells. They require de novo blood vessel formation to support cell cluster growth beyond 1 mm in diameter. Such new blood vessel formation is regulated by a network of pro- and antiangiogenic factors produced as a result of interaction between tumor cells, endothelial cells, and the stromal and immune macro- and microenvironments (11,17). This neovascularization occurs via a number of mechanisms, including recruitment of endothelial progenitors, vessel co-optation, vascular mimicry, sprouting angiogenesis, intussusceptive angiogenesis, and lymphangiogenesis (17).

Types of Angiogenesis

Human endothelial progenitor cells can be recruited locally or from the bone marrow in response to hypoxia or tumor-

derived growth factors such as vascular endothelial growth factors (VEGFs) and fibroblast growth factors (FGFs). Response of endothelial progenitor cells to these growth factors as well as circulating ECM factors facilitates vasculogenesis by both induction of paracrine factor secretion and differentiation to form the vascular tube (34) (Fig. 4.5). Sprouting angiogenesis starts with the creation of a tip cell from a resting endothelial cell, and the concomitant degradation of the surrounding ECM by activated proteases. The tip cell then roams away from the parent vessel as the stalk divides under the control of the vascular endothelial growth factor receptor-2 (VEGFR-2), induction of Notch, angiopoietins (Angs), glycolysis, protein kinase A activation, and induction of the TGF-β/bone morphogenetic protein signaling pathways (35–37).

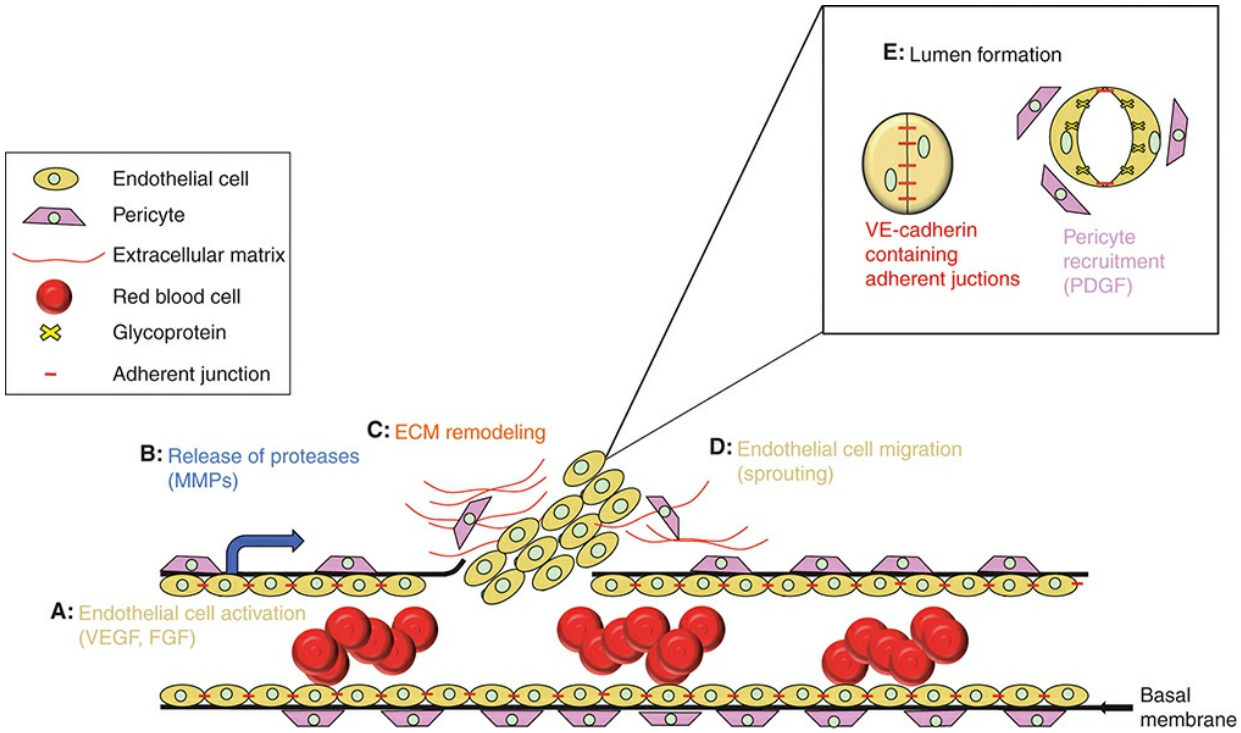

Figure 4.5 Angiogenesis sprouting. A: Endothelial cells are activated by multiple angiogenic factors secreted by tumor cells and cells of the tumor microenvironment. B, C: Proteases are released with the resulting remodeling of the ECM. D: Activated endothelial cells migrate into the stroma forming endothelial cords in the sprouting and other angiogenic and lymphangiogenic processes. E: After cellular polarization, negatively charged glycoproteins and the cytoskeleton retract, forming a vascular lumen. Pericytes are recruited for maturation of the blood vessel, mainly through the action of PDGF. ECM, extracellular matrix; FGF, fibroblast growth factors; VEGF, vascular endothelial growth factor.

Intussusceptive angiogenesis involves the folding of the parental capillary wall into the vascular lumen, the formation of a so-called intraluminal pillar, a perforation in the core of the pillar, and subsequent splitting into two new capillaries. Factors that regulate intussusceptive angiogenesis include angiopoietins, TIE2, FGF2, and platelet-derived growth factor B (PDGFB) (38–40). It is believed that intussusceptive angiogenesis is increased in hypoxic conditions, a process that may be regulated through hypoxia-inducible factor 2a (HIF-2a) and erythropoietin.

Vascular co-option is a process whereby tumor cells grow and migrate along host blood vessels, allowing them to proliferate and metastasize without deriving their own independent blood supply. It has been proposed that this process is most frequently utilized by tumors growing in highly vascular organs such as the brain, liver, and lung (41). Information regarding the factors that specifically facilitate vascular co-option is more limited; *in vitro* models suggest that VEGF and angiopoietins are important (42). In vascular mimicry, highly dedifferentiated tumor cells, themselves, form vessel-like structures. The signaling pathways involved are well summarized (43). Key pathways include vascular-endothelial (VE)-

cadherin, without which tumor cells cannot form the vascular mimicry tube. Ephrin A2, focal adhesion kinase, laminin 5γ2 chain, and HIF-2a are all additionally important in this unique process.

Lymphangiogenesis

The lymphatic system comprises the lymphatic vessels, lined by lymphatic endothelial cells, and lymphoid tissue. Two of its three primary physiologic functions are also involved in cancer progression and metastasis: maintenance of the blood volume through reabsorption of interstitial fluid and immunological surveillance. It was previously believed that the role of lymphatic vessels in tumor metastatic spread was a passive one. It now appears that this is an active process, stimulated by the tumor, and involves both lymphangiogenesis and hyperplasia of collecting lymphatics (44). These processes are analogous to vascular angiogenesis, with recruitment and proliferation of lymphatic endothelial vessels, sprouting, and tube formation.

The signaling pathways of lymphangiogenesis remain under evaluation. They include activation of the angiogenic VEGFs/VEGFRs and of the lymphangiogenic VEGFR-3 by VEGF-C and VEGF-D (44). Lymphangiogenic VEGFs are induced by hypoxia and angiogenic signals, tumor cells, infiltrating inflammatory cells, and stromal cells. Lymph vessels are low-pressure vessels with limited basement membrane and no stromal components; they are permissive to entry and exit of tumor cells, immune cells, and pathogens; therefore, they are a ready route for metastasis. High expression of VEGF-D in epithelial ovarian tumor has been associated with higher FIGO stage, intratumoral lymphatic vessels, tumor lymphatic invasion, and lymph node metastasis. VEGF-D, intratumoral lymphatics, and lymphatic invasion have been suggested as independent prognostic factors for overall survival (OS) and disease-free survival in patients with epithelial ovarian carcinoma.

VEGFs and Receptors

It is clear from the role of vascular and lymphatic angiogenic processes that VEGFs are central factors in tumor maintenance and dissemination. VEGFs and their receptors are the focus of many of the targeted agents now being deployed for the treatment of gynecological malignancy. VEGF, first isolated from cancer xenograft ascites, was identified as a causative factor in blood vessel permeability and development (45). The VEGF family comprises seven glycoproteins, VEGF-A–E and placental growth factors-1 and -2, secreted by tumor cells, endothelial cells, stromal cells, leukocytes, and platelets. VEGF-A, the best characterized, has four in-frame isoforms determined by RNA splicing. There are three transmembrane VEGF receptor tyrosine kinases. VEGF-A, -B, and -E stimulate angiogenesis via VEGFR-1 (VEGFs-A and -B) or VEGFR2 (-A and -E). VEGFRs are predominantly found in endothelial cells and bone marrow–derived cells, though they can be expressed in other cells, including ovarian cancer cells (17,45).

Upregulation of VEGFs is mediated by many events, with tissue hypoxia, hypoglycemia, and growth factors and cytokines being the most prominent and well studied. The tumor microenvironment is hypoxic and acidic, both of which stimulate angiogenesis by induction of HIF-1a. VEGF and VEGFR-1 are under transcriptional regulation by HIF-1a, which is overexpressed in several solid tumors, including ovarian carcinomas. TGF signaling cascades, such as lysophosphatidic acid (LPA), nuclear factor (NF)-κB, and PI3K pathways, are activated by tumor and stromal-induced growth factors and can result in induction of VEGFs in gynecologic cancers. High expression of VEGF or high circulating concentrations of VEGF have been correlated with shorter OS in ovarian cancer. VEGF secreted into malignant ascites by ovarian cancer cells contributes to the increasing ascites burden and carcinomatosis through its effects on vascular permeability, modulation of the immune microenvironment, and prosurvival signals.

SOLUBLE FACTORS AFFECTING THE TUMOR

MICROENVIRONMENT

Chemotactic cytokines, known as chemokines, are small secreted proteins or peptides that help regulate motility of a variety of cells. They are subdivided according to cysteine residue position into four groups: C, CC, CXC, and CX_3C (46). Their primary function is chemoattraction and activation of leukocytes that then recruit other immune and/or inflammatory cells from the blood to an affected site. Cancer cells and many other cells in the malignant microenvironment produce and/or respond to chemokines in an autocrine or paracrine manner via chemotaxis—migration up a concentration gradient—or chemokinesis—migration within a chemoattractant milieu (6,11). Chemokines and their receptors act at many stages of tumor progression, ranging from cell transformation to angiogenesis promotion, leading to tumor growth and supporting cell growth. Tumor cell passage through the ECM, the vasculature, and/or lymphatics can be mediated by chemokines. Growth factors, differentiated from chemokines by their initial definition as growth promoters for epithelial and not inflammatory cells, also play a role in tumor ascites formation, motility, invasion, and migration.

The major proangiogenic chemokines are CCL2 (MCP-1), CXCL1 (GRO-a), and CXCL8/IL-8. These bind to the CXCR1 and CXCR2 endothelial cell receptors, promoting angiogenesis. Ovarian cancer patients have elevated serum IL-8 (47), with particularly high levels associated with an adverse outcome (48). IL-8 and IL-6 are multifunctional chemokines, secreted by multiple cell types, including monocytes, neutrophils, endothelial and mesothelial cells, and tumor cells. They are usually activated during an inflammatory response and function to recruit other immune cells to the affected site. Recent studies have shown that tumor progression, metastasis, and angiogenesis are associated with overexpression of these chemokines. Ovarian cyst fluid, effusions, blood, and tumor tissue have elevated IL-8 and IL-6 concentrations; these have demonstrated correlation with poor OS (47). Similarly, elevated circulating IL-6 concentrations have been associated with an aggressive and chemotherapy-resistant behavior in endometrial cancer. Preclinical data suggest that IL-8 and IL-6 increase resistance to chemotherapeutic treatments in ovarian cancer cells (33). Collectively, these observations provide a rationale for targeting these chemokines therapeutically in gynecological cancers (49).

Another of the many important chemokine pairs is the receptor CXCR4 and its ligand CXCL12. Together, they activate signaling pathways that enhance proliferation, migration, angiogenesis, and invasion of gynecologic cancers. Whereas normal ovaries express very little CXCR4, in approximately 60% of ovarian cancers it is expressed with specific gene amplification in the high-grade serous histological subtype (29,50). CXCL12 is expressed in more than 90% of ovarian cancers. The CXCL12/CXCR4 pathway also controls expression of proteolytic enzymes such as urinary plasminogen activator (uPA) and MMP-9 (51) that promote local tumor and endothelial cell migration. AMD3100, a CXCR4 inhibitor, blocked CXCL12-stimulated migration of ovarian cancer cells *in vitro*. Blockade of CXCR4/CXCL12 activation led to reduced tumor growth and prolonged survival in ovarian cancer xenografts.

A fundamental requirement for successful tumorigenesis and tumor dissemination is the capacity for tumor cells to suppress host immunity (52). Ovarian cancer cells and their tumor-associated macrophages produce CCL22; CCL22 binds to CCR4 on immunosuppressive $FOXP3^+$ regulatory Tregs. This results in accumulation of Tregs at the tumor site, facilitating immune tolerance (52). Release of CXCL10 at the site of ovarian tumors causes accumulation of a second population of $FOXP3^+$ Tregs. These differ by expression of CXCR3, the CXCL10 receptor. This causes suppression of effector T-cell proliferation, again facilitating immune tolerance of the tumor (53). New data continue to emerge describing the interaction of these many types of cells in the tumor microenvironment and how, as a community, they promote tumor stability and reduce tumor susceptibility to treatment (33).

THERAPEUTICS THAT TARGET INVASION AND THE TUMOR MICROENVIRONMENT

Development of novel agents and agent combinations to advance successful interdiction of gynecologic cancers is an ongoing need and challenge. The last decade has brought about great progress with many new classes of agents and multiple agents within classes. Progress has been observed with new drug registrations internationally for ovarian and cervical cancers. Validated predictive biomarkers are needed to assist practitioners with agent and regimen selection.

Clinical Application: Therapies Directed Against Invasion, Angiogenesis, and Metastasis

There is a strong rationale for targeting angiogenesis, invasion, and metastasis in gynecologic cancers. Several completed studies have evaluated antiangiogenic agents in combination with chemotherapy, demonstrating significantly improved progression-free survival (PFS), and in some cases improved OS, in women with epithelial ovarian cancer (54–56) and enhanced OS in women with cervical cancer (57,58). Suggestions that angiogenesis and metastasis inhibitors may benefit women with endometrial cancer have been reported in abstract form. A meta-analysis including 12 randomized trials evaluating several different classes of antiangiogenic agents in women with ovarian cancer (bevacizumab, n = 4; VEGFR tyrosine kinase inhibitors (TKIs), n = 6; trebananib, n = 2) revealed improved PFS (hazard ratio [HR], 0.61; confidence interval (CI), 0.48 to 0.79; $p < 0.001$) for bevacizumab, VEGFR TKIs (HR, 0.71; CI, 0.59 to 0.87; $p = 0.001$), and trebananib (HR, 0.67; CI, 0.62 to 0.72; $p < 0.001$). However, no significant improvement in OS was noted (59).

Several critical questions that remain in the clinical arena include the following: (a) the value of specific rather than promiscuous inhibitors; (b) whether therapeutic antibodies that cause antibody-directed cellular cytotoxicity are more active than simple neutralizing antibodies; (c) what is the best strategy for combination development with other targeted agents and/or chemotherapy; (d) whether therapy is best in treatment and/or in maintenance of response; and (e) identification of biomarkers that can accurately direct therapy. Validation and illustration of mechanism, with demonstration that the activated target is present, affected by the therapeutic, and that modulation of the target by the therapeutic is correlated with outcome, are necessary attributes of reliable biomarkers and targeted inhibitors of angiogenesis, invasion, and tumor dissemination (60,61) (Fig. 4.6; Table 4.1).

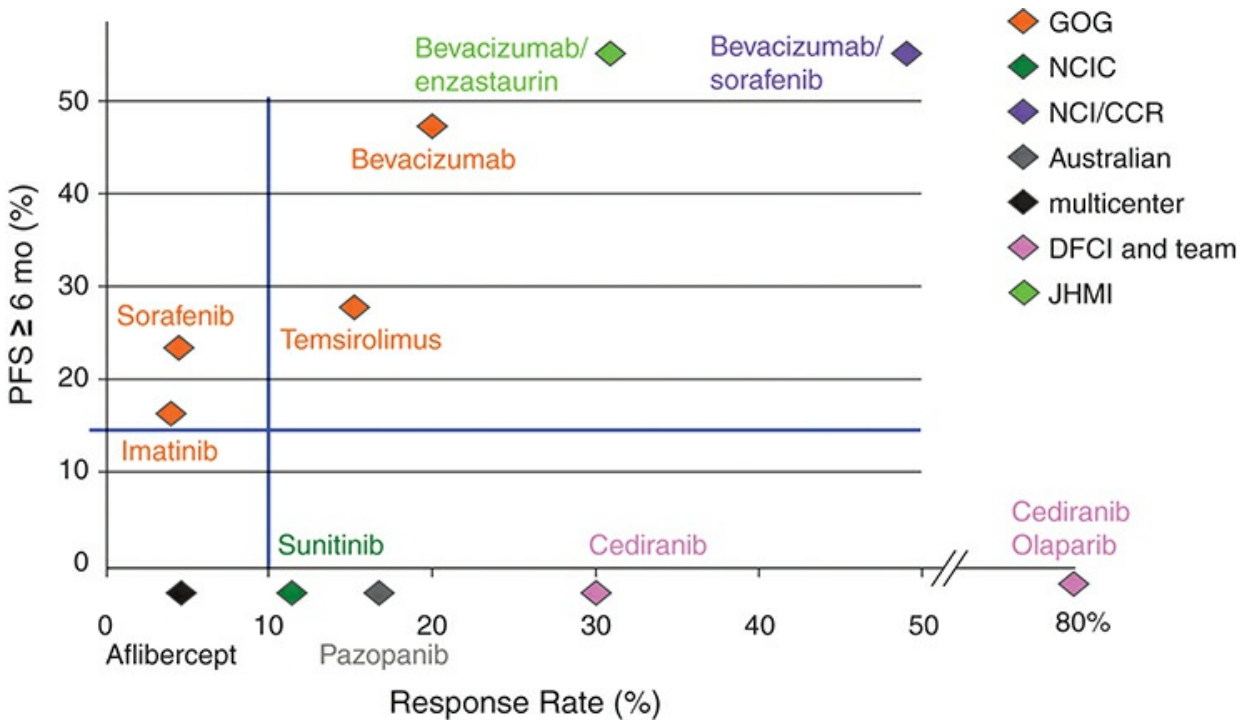

Figure 4.6 Angiogenic agents and combinations in ovarian cancer. Results of phase I–III trials of antiangiogenic agents, alone and in combinations, are plotted. Response

rate and frequency of 6-month PFS are shown. PFS, progression-free survival.

TABLE 4.1 Select Phase II/III Clinical Trials of Targeted Antiangiogenic Agents in Uterine and Cervical Malignancies

Agent	Target	Disease Type	Phase (N)	Description of Study	PFS	OS
Bevacizumab GOG-0086P/NCT00977574 (ASCO 2015)	VEGF	Advanced (Stage III–IV) or Recurrent Endometrial Cancer	II (349)	A) Carboplatin AUC6 + paclitaxel 175 mg/m^2 + BEV 15 mg/kg q3 wk x 6 cycles + BEV 15 mg/kg	A) HR = 0.81; CI = 0.63–1.02	A) HR = 0.71; CI = 0.55–0.91
				B) Carboplatin AUC5 + paclitaxel 175 mg/m^2 + TEM 25 mg days 1/8 q 3 wk x 6 cycles + TEM 25 mg IV q wk days 1/8/15 q3 weeks	B) HR = 1.22; CI = 0.96–1.55	B) HR = 0.99; CI = 0.78–1.26
				Carboplatin AUC 6 + ixabepilone 30 mg/m^2 + BEV 15 mg/kg q 3 weeks x 6 cycles + BEV 15 mg/kg	C) HR = 0.87; CI = 0.68–1.11	C) HR = 0.97; CI = 0.77–1.23
Bevacizumab MITO END-2/ NCT01770171 (ASCO 2015)	VEGF	Advanced (Stage III–IV) or Recurrent Endometrial Cancer	II (108)	Carboplatin AUC5 + paclitaxel 175 mg/m^2 + BEV 15 mg/kg q 3 wk for 6–8 cycles + BEV 15 mg/kg	13.0 vs. 8.7 mo HR = 0.57; CI = 0.34–0.96; p = 0.036	
Bevacizumab GOG240/ NCT00803062 (58)	VEGF	Recurrent, persistent, or metastatic cervical cancer	III (452)	Cisplatin 50 mg/m^2 + paclitaxel 135 or 175 mg/m^2 every 3 wk or topotecan 0.75 mg/m^2 days 1-3 + paclitaxel 175 mg/m^2 every 3 wk + BEV 15 mg/kg every 3 wk	8.2 vs. 5.9 mo HR = 0.67; CI = 0.54–0.82; p = 0.002	17. vs. 13.3 mo HR = 0.71; CI = 0.54–0.95; p = 0.004
Bevacizumab RTOG0417/ NCT00369122 PMID: 24331655	VEGF	Locally advanced cervical cancer	II (49)	BEV 10 mg/kg every 2 wk × 3 cycles during chemoradiation (WPRT + brachytherapy + weekly cisplatin 40 mg/m^2)	3-year DFS: 68.7% LRF: 23.2%	3-year OS: 81.3%

Pazopanib NCT00430781 PMID:20606083	VEGFR-1/2/3, PDGFR-α/β, FGFR-1/3, and c-Kit	Stage IVb, persistent or recurrent cervical cancer	II (152)	A) Lapatinib 1500 mg po qd B) Pazopanib 800 mg po qd C) Lapatinib + pazopanib (Arm C closed for futility)	17.1 wk vs. 18.1wk HR = 0.66; CI = 0.48-0.91; p = 0.013	39.1 wk vs. 50.7 wk HR = 0.67; CI = 0.46-0.99; p = 0.045
Pazopanib PALETTE/ NCT00753688 PMID:22595799	Uterine LMS	III (369)	Pazopanib 800 mg po qd	4.6 vs. 1.6 mo HR = 0.35; CI = 0.26-0.48; p< 0.001 LMS Subgroup Analysis HR = 0.37 - CI = 0.23-0.60	12.6 vs. 10.7 mo HR = 0.87; CI = 0.67-1.12; p = 0-25	
Cediranib CIRCCa/ NCT01229930 (62)	VEGFR-1/2/3	Metastatic or recurrent cervical cancer not amendable to surgery	II (69)	Paclitaxel 175 mg/m^2 + carboplatin AUC5 every 3 wk for up to 6 cycles + either cediranib 20 mg or placebo po qd	8-1 vs. 6-7 mo HR = 0-58; CI = 0-40-0-85; p = 0-032	13.6 vs. 14.8 mo HR = 0-94; CI = 0-65-1.36; p = 0-42

AEs, adverse events; AUC, area under the curve; BEV, bevacizumab; CI, confidence interval; DFS, disease-free survival; EOC, epithelial ovarian cancer; FGFR, fibroblast growth factor receptor; GIP, gastrointestinal perforation; GOG, Gynecologic Oncology Group; HR, hazard ratio; HTN, hypertension; LMS, leiomyosarcoma; LRF, locoregional failure; MITO, Multicenter Italian Trials in Ovarian cancer and gynecologic malignancies; OS, overall survival; PDGFR, platelet-derived growth factor receptor; RTOG, Radiation Therapy Oncology Group; TEM, temsirolimus; VEGF, vascular endothelial growth factor; VEGFR, vascular endothelial growth factor receptor; WPRT, whole pelvic radiation therapy.

Inhibitors of Angiogenesis

Bevacizumab is a recombinant humanized neutralizing antihuman VEGF-A monoclonal antibody. Blocking VEGF reduces angiogenesis and related tumor growth, limits invasion and dissemination, and may alter immune function. The U.S. FDA has approved bevacizumab for use in cervical cancer and recurrent platinum-resistant ovarian cancer. Bevacizumab in combination with paclitaxel and either cisplatin or topotecan is licensed for the treatment of persistent, recurrent, or metastatic cervical cancer. It is approved in ovarian cancer in combination with paclitaxel, pegylated liposomal doxorubicin, or topotecan for the treatment of patients with platinum-resistant recurrent cancers of the ovary, fallopian tube, and primary peritoneal cancer who have received no more than two prior chemotherapy regimens. Bevacizumab has also received European Medicines Agency (EMA) approval for these gynecologic indications, as well as for the treatment of advanced newly diagnosed ovarian cancer, and (in combination with chemotherapy) for platinum-sensitive recurrent ovarian cancer.

The addition of bevacizumab to front-line chemotherapy and in maintenance therapy for epithelial ovarian cancer was evaluated in two pivotal phase III trials, GOG 218 and ICON 7. GOG 218 was a three-arm, placebo-controlled trial of front-line paclitaxel and carboplatin to which either concurrent bevacizumab or concurrent and maintenance bevacizumab were added. A PFS benefit was seen in women who received both concurrent and maintenance bevaci- zumab at 15 mg/kg (14.1 vs. 10.3 months; HR, 0.717; $p < 0.0001$) (55). No significant difference in OS was demonstrated (39.7 vs. 39.3 months; $p = 0.45$). ICON 7 evaluated first-line paclitaxel/ carboplatin alone or in combination with bevacizumab followed by bevacizumab maintenance, using a 7.5 mg/kg dose (56). PFS was enhanced in the bevacizumab arm (HR, 0.81; 95% CI, 0.70 to 0.94; $p = 0.0041$), and interim analysis revealed no significant OS improvement. A post hoc exploratory subgroup analysis found an OS benefit for patients with stage IV or stage IIIC disease with >1 cm residual tumor (HR, 0.64; 95% CI, 0.48 to 0.85; $p = 0.002$). The optimal duration of bevacizumab treatment is controversial, with some advocating for continuing maintenance bevacizumab until disease progression. Two different fixed bevacizumab maintenance schedules are being evaluated in the BOOST trial (15 vs. 30 months bevacizumab; NCT01462890).

Combination chemotherapy and bevacizumab have been evaluated in women with platinum-sensitive and -resistant recurrent ovarian cancers. Two phase III trials have demonstrated survival benefit with the addition of bevacizumab to chemotherapy in women with platinum-sensitive disease. In the OCEANS trial, the bevacizumab with concurrent gemcitabine and carboplatin with maintenance bevacizumab arm showed an improved response rate (RR; 78.5% vs. 57.4%, $p < 0.0001$) and a 4-month improvement in PFS (12.4 vs. 8.4 months; HR, 0.484; $p < 0.0001$) with no difference in OS (54). GOG 213, presented as an abstract, demonstrated that bevacizumab plus platinum-based chemotherapy resulted in a 5-month improvement in OS compared with chemotherapy alone for women with first recurrence platinum-sensitive ovarian cancer (42.2 vs. 37.3 months; HR, 0.83; $p = 0.056$; abstract). The phase III AURELIA trial examined the role of the addition of bevacizumab to standard of care nonplatinum-based chemotherapy in women with recurrent platinum- resistant ovarian cancer. It reported an enhanced median PFS (6.7 vs. 3.4 months; HR, 0.48;$p < 0.001$), improved RR (27.3% vs. 11.8%; $p = 0.001$), and decreased frequency of paracentesis (17% vs. 2%) (63). Bevacizumab treatment improved patient-reported outcomes, with an increased proportion of patients achieving improvement in abdominal symptoms (21.9% vs. 9.3%; $p = 0.002$). The results of the AURELIA trial led to FDA and EMA approval of bevacizumab in women with platinum-resistant ovarian cancer.

The regulatory agencies have also approved bevacizumab for women with advanced and recurrent cervical cancer. The phase III GOG 240 trial compared taxane-based doublets (paclitaxel and cisplatin vs. paclitaxel and topotecan) in a two-by-two factorial design against use of placebo or bevacizumab with chemotherapy (58). The combination of bevacizumab and chemotherapy significantly improved RR (48% vs. 36%; $p = 0.008$), median PFS (8.2 vs. 5.9 months; HR, 0.67; $p = 0.002$), and median OS (HR, 0.71; $p = 0.004$) compared to chemotherapy alone. The addition of bevacizumab also increased toxicity, most notably demonstrating increased frequency of gastrointestinal perforations and/or genitourinary fistulas (6% vs. 0%; $p = 0.002$).

Despite suggestions of activity, no definitive role for bevacizumab has been demonstrated in endometrial cancer. Several recent studies have been presented in abstract form and await peer review. The randomized phase II GOG 86P study evaluated three experimental arms, two of which incorporated bevacizumab and one with temsirolimus, each with combination chemotherapy, in women with chemo-naïve advanced or recurrent endometrial cancer. The experimental arms were compared against historical control data. OS was statistically significantly increased with bevacizumab, paclitaxel, and carboplatin (34 vs. historical control of 22.7 months; HR, 0.71; $p < 0.039$) relative to the historical control. The randomized phase II trial, MITO END-2, compared paclitaxel and carboplatin with and without bevacizumab in women with advanced or recurrent endometrial cancer. The addition of bevacizumab significantly increased PFS (13 vs. 9.7 months; HR, 0.59; $p = 0.036$) and was associated with nonsignificant increased RR (72.7 vs. 54.3%; $p = 0.065$) and OS (23.5 vs. 18 months; $p = 0.24$).

Other Angiogenesis and Metastasis Inhibitors

Cediranib is an oral TKI that selectively targets all three VEGFRs with less potency against c-kit. Single-agent studies in recurrent ovarian cancer yielded limited RRs of 13% to 17%, with hypertension and fatigue being the most common grade 3 adverse events. Cediranib was evaluated in combination with carboplatin and paclitaxel followed by maintenance cediranib in a three-arm randomized placebo-controlled phase III trial (ICON6) in women with first recurrence platinum-sensitive disease (64). PFS was improved (8.7 vs. 11.0 months; HR, 0.56; $p < 0.001$), and preliminary OS was encouraging (17.6 vs. 20.3 months; HR, 0.70; $p = 0.04$), all favoring the concurrent/maintenance cediranib arm (NCT00532194). Adverse events were significantly more common in the cediranib maintenance arm and included hypertension, diarrhea, hypothyroidism, hoarseness, bleeding, proteinuria, and fatigue. The polyADPribose polymerase (PARP) inhibitor, olaparib, is being added to the combination for ICON9, a phase III trial under development.

Several mixed kinase inhibitors, all of which include inhibition of VEGFRs, have been examined in gynecologic cancers. *Nintedanib*/ BIBF1120 inhibits VEGFRs 1, 2, and 3; PDGFR-α and -β; and FGF receptors 1 to 3. A phase III randomized placebo-controlled trial of nintedanib in combination with carboplatin and paclitaxel followed by maintenance nintedanib or placebo (AGO-OVAR12/LUME-Ovar1) in first-line treatment of ovarian cancer revealed a statistically significant PFS, but of minimal difference (17.3 vs. 16.6 months; HR, 0.84; $p = 0.0239$) (65). The most common significant adverse effects in the nintedanib arm included elevated transaminases and diarrhea. A randomized phase II trial of carboplatin and paclitaxel with or without nintedanib is ongoing in cervix cancer (NCT02009579).

Pazopanib is a kinase inhibitor that targets all three VEGFRs, both PDGFRs, and c-kit. Pazopanib is FDA approved for the treatment of patients with advanced soft tissue sarcoma who have received prior chemotherapy, including those with uterine leiomyosarcoma (LMS), based on the randomized placebo-controlled PALETTE trial (NCT00753688). Patients who received pazopanib had a statistically significant improvement in PFS compared with placebo (4.6 vs. 1.6 months; HR, 0.35; CI, 0.26 to 0.48; $p < 0.001$), with no difference in OS (66). The PazoDoble trial is currently evaluating the combination of gemcitabine and pazopanib in patients with recurrent or metastatic uterine LMS or carcinosarcoma (NCT02203760). Pazopanib also has potential value in ovarian cancer. The phase III randomized placebo-controlled maintenance trial of pazopanib 600/800 mg daily after front-line platin/taxane-based chemotherapy (AGO-OVAR16) revealed significantly longer PFS in the pazopanib group (17.9 vs. 12.3 months; HR, 0.766; CI, 0.64 to 0.91; $p = 0.002$), with no difference in OS (67). However, the benefit of pazopanib on PFS effect was not seen in East Asian women with ovarian cancer. A further exploration combined a subset of East Asian patients on the AGO-OVAR16 trial with those who participated in a separate East Asian pazopanib maintenance study. Maintenance pazopanib in this subgroup was associated with worse survival (OS HR, 1.71; CI 1.01 to 2.88; $p = 0.05$), with no identifiable factors to explain the differential findings. Weekly paclitaxel combined with pazopanib has been studied in women with recurrent platinum-resistant ovarian cancer (MITO11; NCT01644825), yielding an improved PFS (6.4 vs. 3.5 months; HR, 0.42; CI, 0·25 to 0·69; $p = 0·0002$) and a trend toward improved OS (19.1 vs.13·7 months; HR, 0.60; CI, 0.32 to 1.13; $p = 0·056$) (68). However, a similarly designed randomized phase II trial demonstrated conflicting results, reporting that the combination of paclitaxel and pazopanib was not superior to paclitaxel alone in women with recurrent ovarian cancer (NCT01468909; abstract).

Cabozantinib is an oral kinase inhibitor that targets c-MET, ALK, and VEGFR-2, and been shown to reduce tumor growth, invasion, and angiogenesis (69). Simultaneous targeting of the MET and VEGF signaling pathways may be a promising strategy to improve antitumor activity by blocking complementary stimulatory pathways. Cabozantinib is showing preliminary activity in a single-arm phase II trial in women with recurrent or metastatic advanced endometrioid or serous endometrial cancer and endometrial carcinosarcomas (NCT01935934). These preliminary results will be further examined in a randomized trial.

Trebananib (AMG 386) is a peptide-Fc fusion protein that inhibits angiogenesis by binding angiopoietin-1 and -2 and blocking their interaction with the Tie2 receptor. The phase III trial of weekly paclitaxel with trebananib or placebo for patients with recurrent ovarian cancers resulted in an improved PFS (7.2 vs. 5.4 months; HR 0.66; $p < 0.0001$), but no difference in OS (70).

COMBINATION THERAPY OPPORTUNITIES AGAINST ANGIOGENESIS AND METASTASIS

Further refinement of targeted therapy is focused on the hypothesis that inhibiting biologic targets in combination may be more effective than alone. Studies have been initiated exploring the activity of targeted agents in combination with cytotoxic chemotherapy, multitargeted agent combinations, and combinations with immunomodulators. Antiangiogenic agents in combination with PARP inhibitors have been reported with promising results. It is recognized that inhibition of angiogenesis with induction of local hypoxia causes downregulation of genes involved in DNA repair (71).

Clinical successes of combination antiangiogenesis therapy, in which the microenvironmental context is synergized with other interventions, are now being reported. A randomized open-label phase II study examined the PARP inhibitor, olaparib, alone or in combination with cediranib in women with platinum-sensitive high-grade serous or endometrioid epithelial ovarian cancer or those with germline BRCA1/2 mutations (72). The median PFS was significantly longer for combination therapy compared to olaparib alone (17.7 vs. 9.0 months; $p = 0.005$). Unplanned post hoc subset analysis evaluating the interaction against deleterious germline *BRCA1* or *2* mutation carriers showed that women with no mutation or unknown status had a nearly threefold greater PFS over single-agent olaparib. Pilot biomarker studies suggest that markers indicating hypoxic injury such as induction of IL-8 and release of circulating endothelial cells may be a mechanism for synergy (73). Recent data implicate hypoxia in downregulation of BRCA1 and BRCA2 expression, creating a BRCA-like tumor phenotype. These findings suggest that understanding the myriad of potential pathway and microenvironmental interactions can be leveraged for clinical benefit. Success will be enhanced further by development and validation of predictive and/ or patient selection biomarkers.

Biomarkers

Biomarkers are important tools with which to guide treatment and patient care decisions, in order to maximize benefit, as well as minimize cost and toxicity. It is important to differentiate predictive from prognostic markers. Predictive biomarkers differentiate patient outcome as a function of treatment intervention, such as therapy or radiation, whereas prognostic biomarkers are independent of treatment (60) (Table 4.2). Identification and validation of predictive biomarkers require demonstration of a treatment outcome interaction and thus cannot be evaluated on single-arm studies. Prognostic biomarkers differentiate overall outcome, such as PFS and OS, within a population and have little application to individual patients. The biology of invasion, angiogenesis, and metastasis has yielded many biomarkers of prognostic utility in gynecologic cancers, including CAMs, MMP-s, angiogenic and immune growth factors and cytokines, and their receptors.

TABLE 4.2 Biomarkers Predictive of Outcome to Antiangiogenic Therapy

Agent	Biomarker	Study	Results
Bevacizumab (ASCO 2014)	Molecularly defined proangiogenic vs. immune subgroup	ICON7	Immune subgroup had worse PFS (HR = 1.73; CI = 1.12 – 2.68) and OS (HR = 2.00; CI = 1.11 – 3.61) when treated with BEV compared to chemotherapy alone. Proangiogenic group had a nonsignificant trend to improved PFS with the addition of BEV (median 17.4 vs. 12.3 mo)
Bevacizumab (ASCO 2014)	Molecularly defined subgroups: proliferative and mesenchymal subtypes compared with	ICON7	Patients with serous proliferative subtype serous ovarian cancers had greatest benefit from BEV with an improvement of median PFS of 12.8 mo (p = 0.032). Median PFS with BEV was not significantly greater in the differentiated, immunoreactive, and mesenchymal subtypes. Patients with mesenchymal serous cancers had improvement in median OS with BEV (HR = 0.27, CI = 0.08 – 0.96, p = 0.03)

	immunoreactive or differentiated subtypes		
Bevacizumab (62)	Serum VEGFR-3, α_1,-acid glycoprotein, and mesothelin combined with CA125	ICON7	The signature-positive group demonstrated improved median PFS in the BEV arm compared with the control arm (17.9 vs. 12.4 mo; p = 0.04). The signature-negative group had an improved median PFS in the standard chemotherapy arm compared with the BEV arm (36.3 vs. 20 mo; p = 0.006)
Bevacizumab (74)	Serum Ang1 and Tie2	ICON7	Patients with high Ang1 and low Tie2 levels had improved PFS with BEV (23.0 vs. 16.2 mo, p = 0.006). Patients with high Ang1 and Tie2 levels had lower median PFS for BEV arm (12.8 vs. 28.5 mo, p = 0.007); patients with low Ang1 levels had no significant PFS differences associated with treatment regardless of Tie2 levels
Bevacizumab (ASCO 2015)	Tumor CD31 MVD, VEGF, VEGFR-2, NRP-1 or MET	GOG218	Higher CD31 MVD counts in BEV/BEV arm had predictive value for PFS (>Q3 MVD, HR = 0.38, CI = 0.25 - 0.58; ≤03 MVD, HR = 0.68, CI = 0.54 - 0.86; p = 0.018) and OS (>Q3 MVD, HR = 0.57, CI = 0.39 - 0.83; ≤Q3 MVD, HR = 1.03, CI = 0.83 - 1.27; p = 0.0069). Tumor VEGF showed potential predictive value in BEV throughout vs. control for OS (>Q3 tumor VEGF, HR = 0.62, CI = 0.43 - 0.91; ≤Q3 tumor VEGF, HR = 1.01, CI = 0.82 - 1.25; p = 0.023). No prognostic or predictive association was seen for plasma VEGF or VEGFR2; or tumor VEGFR-2, NRP-1, or MET
Bevacizumab (75)	Ascites	GOG218	Patients with ascites treated with BEV had improved PFS (HR = 0.72, CI = 0.63 - 0.83; p < 0.001) and OS (HR = 0.82, CI = 0.7 - 0.96; p = 0.01). Patients without ascites did not demonstrate a difference in PFS or OS
Bevacizumab (ASCO 2016)	Plasma IL-6, Ang-2, OPN, SDF-1, and VEGF-D	GOG218	IL-6 was predictive of BEV advantage for PFS and OS. Pts with high IL-6 levels treated with BEV had longer PFS (14.2 vs. 8.7 mo) and OS (39.6 vs. 33.3 mo). Both IL6 and OPN were found to be negative prognostic markers for PFS and OS

Ang, angiopoietin; BEV, bevacizumab; CI, confidence interval; GOG, Gynecologic Oncology Group; HR, hazard ratio; ICON, International Collaborative Ovarian Neoplasm; MET, MNNG HOS transforming gene also known as hepatocyte growth factor receptor; MVD, microvessel density; NRP, neuropilin; OPN, osteopontin; OS, overall survival; PFS, progression-free survival; SDF-1, stromal cell-derived factor-1; VEGF, vascular endothelial growth factor; VEGFR, vascular endothelial growth factor receptor.

Biomarkers can be clinical findings or measured events, such as tumor or blood factors. Ascites is known to be related to overexpression of VEGF and its associated vascular permeability (45). The presence of ascites was shown to be a positive prognostic finding in a bevacizumab trial. Several studies, reported in abstract form, have suggested that higher tumor CD31 microvessel density, higher tumor VEGF, and presence of ascites may be predictive and/or prognostic of benefit with bevacizumab treatment. In contrast, no prognostic or predictive association was seen for circulating VEGF or VEGFR-2 concentrations. Exploratory retrospective findings must be validated prospectively prior to application for patient selection or trial design as reliable predictive biomarkers.

Several promising biomarker candidates have come from retrospective exploration of serum samples. Combined serum VEGFR-3, $a_r$acid glycoprotein, mesothelin, and CA125, together were denoted an as yet not validated predictive signature. The signature-positive group in the bevacizumab arm of ICON7 had improved median PFS compared with the control arm (17.9 vs. 12.4 months; $p = 0.04$) (73). The signature-negative group did not benefit from added bevacizumab. Other preliminary biomarker data suggest that serum Ang1 and Tie2 concentrations may differentiate women who may benefit or

be harmed by bevacizumab. High Ang1 and low serum Tie2 levels signified benefit from bevacizumab (PFS, 23.0 vs. 16.2 months, $p = 0.006$), while both high Ang1 and Tie2 levels were associated with lower median PFS with bevacizumab (12.8 vs. 28.5 months, $p = 0.007$) (74). A further study, published in abstract form only, demonstrated that a molecular subgroup characterized by high expression of immune response genes was associated with improved PFS and OS in patients treated with primary debulking and standard first-line chemotherapy. However, in a translational subgroup study of patients from the ICON7 study, patients in this immune subgroup who received bevacizumab appeared to have an inferior outcome compared to patients on the control arm. Validated predictive markers should help to optimize the use of our therapeutic opportunities to improve quality and quantity of life by predicting clinical benefit or lack thereof.

CONCLUSIONS

Continued scientific, epidemiologic, and clinical advances are critically needed until such time as successful, reproducible, and accurate early detection of gynecologic tumors becomes routine. Understanding the biology, regulation, and implications of the process of invasion and angiogenesis will continue to drive new biomarker and therapeutic target identification and intervention. The similarity between dys- regulated invasion and angiogenesis and unregulated motility of metastasis allows the potential for a dual-purpose intervention. The tumor's interaction with its microenvironment becomes the focus for scientific dissection and therapeutic application. Here, the process of autocrine and paracrine regulation, signal pathway activation, and cell-cell conversation is critical. The use of the newer and high-throughput technologies to identify collections of biologic targets rather than one gene or protein at a time can make the process more streamlined and provide a broader view of the interaction of events. In addition, it is clear that there are numerous convergent and divergent angiogenic processes. New targets are emerging that may overcome angiogenesis escape, including novel endothelial cell and pericyte targets. Several new approaches including novel pathway inhibitors, immune modulators, and signaling pathway combinations are in clinical trials or presently under development. Improved understanding, study of events in the patient populations, and cooperative and collaborative progress will allow us to overcome invasion and metastasis, the major causes of morbidity and mortality in gynecologic cancers.

CHAPTER 5 Development and Identification of Tumor Serum Markers

Aleksandra Gentry-Maharaj and Usha Menon

Tumor markers are defined as molecules or substances produced by malignant tumors that enter the circulation in detectable amounts. They indicate the likely presence of cancer or provide information about its behavior. In the management of cancer, the most useful biochemical markers are the macromolecular tumor antigens, including enzymes, hormones, receptors, growth factors, biologic response modifiers, and glycoconjugates. A substantial number of substances have been investigated as potential tumor markers over the past decade and the list is continually growing owing to new technology employed in biomarker discovery.

Tumor markers can be used for risk stratification, screening, differential diagnosis, prognosis, predicting and monitoring response to therapy, and detecting recurrence (**Table 5.1**). The performance of a tumor marker depends on its sensitivity (percentage of patients with cancer correctly identified as a result of a positive test) and specificity (percentage of the population without cancer correctly identified as a result of a negative test) and positive predictive value (PPV, percentage of patients with positive test that have the cancer, true positives) (**Table 5.2**). An ideal tumor marker should have a 100% sensitivity, specificity, and PPV. However, in practice such a marker does not exist. As the majority of markers are tumor-associated rather than tumor-specific, and are elevated in multiple cancers, benign and physiologic conditions, they lack specificity. In addition, if sensitivity is low, a normal result may not exclude malignancy. Tumor markers discovered thus far contribute to differential diagnosis but are not themselves diagnostic. This restricts their use, with few exceptions, to monitoring therapeutic response and follow-up.

TABLE 5.1 Tumor Markers and Their Potential Uses

1. Risk stratification
Adjusting risk categorization for an individual without the disease. The marker could then be used in screening or prevention if these are proven to be effective.
2. Screening
Screening to detect cancer earlier than it would have been using clinical signs and symptoms.
3. Differential diagnosis
Use of serum and tissue tumor markers to establish the tissue of origin of a newly diagnosed cancer by differentiating between the cancer and benign conditions.
4. Prognosis
Markers used to determine prognosis in a patient, i.e., risk of invasion and metastasis in the absence of therapy.
5. Prediction

Ability of a marker to determine the likelihood of sensitivity or resistance to specific therapy.
6. Monitoring
Monitoring patients either during or after therapy to determine the status of the cancer. Patients are usually monitored during primary therapy but also during therapy for metastatic disease to determine if the patient is responding to the treatment or if an alternative therapy is needed.

TABLE 5.2 Parameters of Tumor Marker Assays

	Tumor Marker Result	
True Tumor Status	Positive	Negative
Positive	a (True positives)	b (False positives)
Negative	c (False negatives)	d (True negatives)

Sensitivity = True positives/All with tumor = a/a + c

Specificity = True negatives/All tumor-free = d/d + b

Positive predictive value (PPV) = True positives/All with positive tumor marker result = a/a + b

Tumor markers currently used in nongynecologic malignancies include:

1. Carcinoembryonic antigen (CEA), the most commonly elevated marker in colorectal cancer. Preoperative assessment is recommended by the American Society of Clinical Oncology (ASCO) as it may complement surgical staging and help in choosing the most appropriate surgical treatment. Abnormal preoperative levels may also indicate higher risk of recurrence, but there is no concrete evidence as to whether patients with colorectal cancer would benefit from adjuvant therapy based on preoperative CEA alone (1). Carcinoembryonic antigen is, however, not used in screening or early diagnosis.
2. CA15-3 measurements have been advocated (ASCO) in monitoring response to treatment in breast cancer when the disease is not measurable.
3. Prostate-specific antigen (PSA) is used in screening for prostate cancer but its use as a stand-alone marker is not recommended. Most guidelines recommend a PSA test followed by digital rectal examination, with definitive diagnosis always requiring a biopsy. PSA may have a role in detecting disease recurrence and monitoring treatment in patients with prostate cancer (2).

This chapter focuses on those markers that are clinically relevant to female genital tract malignancies.

OVARIAN AND FALLOPIAN TUBE CANCERS

Women have approximately a 1% to 2% lifetime risk of developing ovarian cancer (OC). OC accounts for 4% of cancers diagnosed in women, with over 239,000 new cases diagnosed worldwide each year (3). Incidence rates are highest in the United States and Northern Europe and lowest in Africa and Asia. It is associated with the highest mortality rates of all female genital tract malignancies. Around 85% of cases occur over the age of 50 years and 80% to 85% are epithelial in origin. It is now widely accepted that epithelial ovarian cancer (EOC) is a heterogeneous disease and consists of five main histologic subtypes: high-grade serous, low-grade serous, endometrioid, clear cell, and mucinous cancers, each associated with a unique origin, pathogenesis, and prognosis (4). In addition, women previously diagnosed with primary peritoneal cancers would likely be re-classified as ovarian cancers in view of the new WHO (2014) classification which states that

any ovarian/tubal involvement would results in a diagnosis of ovarian cancer. The most common histologic subtype of EOC is serous OC, which usually presents at advanced stages and has the poorest outcomes (5). However, in those of reproductive age, germ cell tumors, granulosa cell/sex cord tumors, mucinous, and endometrioid tumors are more common. High-grade serous cancer which accounts for most of the OC mortality is thought to originate mainly in the fallopian tube and involve the ovaries secondarily. Given the growing evidence to support these origins as well as the notion that epithelial OC is a heterogeneous disease, it is unlikely that one marker/strategy would be equally effective in diagnosis of each subtype. Cancer antigen 125 (CA125) has been the only marker used clinically in diagnosis and management of OC. Despite decades of research to identify a better biomarker than CA125, no single marker with superior performance has been found; however, there is some encouraging data on markers that can improve the performance of CA125, and these will be discussed later in this chapter.

CA125

CA125 was first described by Bast *et al.* (6) in 1981. It is a 200 kD glycoprotein recognized by the OC-125 murine monoclonal antibody. CA125 carries two major antigenic domains: domain A (binds monoclonal antibody OC-125) and domain B (binds monoclonal antibody M11). The current second-generation heterologous CA125-II assay incorporates M11 and OC125 antibodies, while the original homologous assay was with OC125 alone. Currently there are a number of CA125 assays that correlate well with each other (7).

CA125 is expressed by amniotic and coelomic epithelium during fetal development. It is widely distributed in adult tissues (mesothelial cells of the pleura, pericardium, and peritoneum, tubal, endometrial, and endocervical epithelium); however, it is not expressed by the surface epithelium of normal fetal and adult ovaries with the exception of inclusion cysts, areas of metaplasia, and papillary excrescences (8). It therefore lacks complete specificity for OC.

The level of CA125 in body fluids or ovarian cysts does not correlate well with serum levels. This is probably due to the serum concentration being reflective not only of the production of the antigen by the tumor but also other factors that affect its release into the circulation. The widely adopted cutoff at 35 kU/L routinely used in clinical practice is based upon the distribution of values in 99% of 888 healthy men and women (9). However, as levels of CA125 tend to be lower in postmenopausal women or in patients who have undergone hysterectomy, levels of 20 kU/L and 26 kU/L have been suggested (10). Approximately 85% of patients with EOC have CA125 levels of >35 kU/L. Raised serum levels are found in 50% Stage I and >90% Stage II–IV cancers (11) (**Table 5.3**). CA125 levels are more frequently elevated in serous invasive compared to mucinous, clear cell, and borderline tumors (11,12). CA125 can be elevated in other malignancies (pancreas, breast, colon, and lung cancers) (**Table 5.4**), in benign conditions (**Table 5.3**), and in physiologic states such as pregnancy, endometriosis, and menstruation (11). In postmenopausal women, the diagnostic accuracy of raised CA125 is improved by absence of many of these nonmalignant conditions (**Table 5.3**). It is possible that specificity could be improved by posttranslationally modified glycosylated forms of CA125 (13).

TABLE 5.3 CA-125 Elevations in Benign Disorders and Ovarian Cancer

Cutoff		
Healthy women	Premenopausal[a]	35 kU/L
	Postmenopausal[b]	20 kU/L
Disease	Condition	CA125 elevations over 35 kU/L (%)
Benign ovarian disease	Overall (all benign tumors)[c]	29
	Ovarian cysts[c]	14

Screening

Screening is the identification of unrecognized disease in apparently asymptomatic population by use of tests, examinations, or other procedures that allow earlier diagnosis of the disease than if it had presented clinically. The main goal of cancer screening is to reduce mortality from the disease by either preventing it (if a premalignant condition exists) or diagnosing it earlier when treatment is more effective. Detection of the cancer of interest alone before it is symptomatic cannot justify screening.

There are cancer-specific criteria detailing which cancers could most benefit from screening that build on the WHO criteria for all diseases (**Table 5.5**) (14). To be effective and applicable to the population at large, screening must achieve high sensitivity/specificity, PPV, and negative predictive value (NPV) (**Table 5.6**), and it must be acceptable to the populations being tested. The PPV depends on the prevalence of the disease within the population, with more false positives detected if disease prevalence is low. Well-organized national screening programmes, such as cervical cancer screening, are required to realise the true potential of screening in reducing disease-specific mortality.

TABLE 5.5 World Health Organization Criteria for a Screening Program

1. The condition sought should be an important health problem
2. There should be accepted treatment for patients with recognized disease
3. Facilities for diagnosis and treatment should be available
4. There should be a recognizable latent or early symptomatic stage
5. There should be a suitable test or examination
6. The test should be acceptable to the population
7. The natural history of the condition, including development from latent to declared disease, should be adequately understood
8. There should be an agreed policy on whom to treat as patients
9. The cost of case finding (including diagnosis and treatment of patients diagnosed) should be economically balanced in relation to possible expenditure on medical care as a whole
10. Case finding should be a continuing process and not a “once and for all” project

From Wilson J, Jungner G. WHO Principles and Practice of Screening for Disease. Geneva, Switzerland: World Health Organization; 1968:66–67.

TABLE 5.6 Parameters Crucial When Evaluating Screening Tests

1. Test validity
Accuracy/Validity of the screening test is evaluated by its sensitivity and specificity. Sensitivity is the correct identification of the individuals with disease out of all with positive screening results, whereas specificity is the proportion of those with negative screening results who do not have the disease.
2. Measuring test performance
Easier to measure in research setting than in a screening program. The proportion of the population with detectable preclinical disease is an important factor in judging the effectiveness of a screening strategy. An ideal test would detect the disease early; tests that can only detect advanced disease indicate a long screening interval or poor test sensitivity.

3. PPV
Proportion of individuals with a positive screening test that will have the disease. A PPV of 10% means that only 1 out of 10 individuals investigated had the disease, the other 9 were investigated unnecessarily.
4. NPV
Proportion of individuals with a negative test result who are correctly diagnosed as not having the disease. In clinical setting, high NPV means that the test only rarely misclassifies a sick person as being healthy.
5. Test sensitivity versus program sensitivity
Test sensitivity (screening test applied once) can be different from program sensitivity (screening test applied multiple times to the same population). Program sensitivity is higher in cases where population adherence to screening is high, because if the cancer was missed in the first round of screening, it is very likely to be detected on the second round. However, if adherence to screening is poor, some cancers will be missed and diagnosed only when symptomatic.
6. Validity
RCT is the gold standard for evaluating effectiveness of a screening strategy but needs a large number of participants and takes a long time to complete (at least 15 years). Case-control studies have been used to evaluate screening tests but suffer due to potential selection bias.
7. Lead-time bias
Screening advances the time of diagnosis; therefore, the duration of time between when a cancer is detected by screening and when it would have been detected due to symptoms is referred to as lead time. However, if there is no effect on survival, i.e., the cancer is diagnosed through screening but the individual dies at the same time as if the cancer were symptomatic at the time of detection, it would appear that survival is longer in the screened population when, in fact, it is not. This is called lead-time bias.
8. Length-bias sampling
Screening tends to pick up less aggressive, slow-growing cancers and is less likely to pick up more aggressive, faster-growing cancers. Length-time bias refers to the greater likelihood of screen-detected cancers to be slow-growing—this would give the false impression of improved survival of screen-detected cancers.
9. Overdiagnosis
Screening can result in overdiagnosis, detection of the cancer that would not have been detected during that person's lifetime if not for screening. These lesions are not easy to distinguish from those that become clinically significant. There may be serious consequences for these patients, although it is unclear what proportion of them are at risk. However, any harm caused by overdiagnosis is probably miniscule when compared to the benefits of screening.
10. Selection bias
Individuals who participate in screening programs are usually more health conscious, healthier, more aware of signs and symptoms of the disease, have better access to treatment and are more likely to adhere to treatment. Hence they might have better outcomes if they develop cancer than the unscreened population. Selection bias is higher in clinical trials than in screening programs that are associated with high uptake.

NPV, Negative Predictive Value; PPV, Positive Predictive Value.

In a national screening programme, issues that must be considered include: frequency of screening, age of the population to be screened, well-defined mechanisms for referral and treatment of screen-detected abnormalities, comprehensive information systems that not only send invitations at predefined intervals but also recall those with abnormalities for assessment and schedule follow-up of those treated, and quality assurance protocols to monitor and

evaluate the efficacy of the screening programme. Furthermore, for a screening strategy to be successful, uptake and compliance with screening has to be high.

The established population cancer screening programmes include breast, bowel, and cervical cancer, with ongoing debates on the risks and benefits of lung and prostate cancer screening. A survey in the United Kingdom of 2,024 men and women aged 50 to 80 years demonstrated that there is a positive view of and widespread enthusiasm for cancer screening without a full appreciation of its limitations (15).

Screening for OC has been investigated in the research setting with CA125 being the only tumor marker explored in large trials. When it is interpreted using a cutoff, 2.9% of healthy postmenopausal women will have elevated CA125 levels, limiting its use as a stand-alone test (16). In the multimodal screening strategy, this is overcome by use of transvaginal ultrasound (TVS) as a second-line test in women with elevated CA125 levels, so that high specificity (99.9%) and four or fewer operations for each OC detected can be achieved (17,18). Over the last two decades, there has been a move to use CA125 profile over time rather than as a single value. A statistical algorithm (Risk of Ovarian Cancer Algorithm, ROCA), based on the age-specific risk of the disease and the behavior of CA125 over time in women with OC versus normal controls, has significantly improved both the sensitivity (19) and specificity of CA125 interpretation (19–21) for primary invasive EOC. Algorithms such as the ROCA rely on modeling the behavior of a biomarker from disease onset to clinical presentation, and use data accumulated in large trials over many years.

The first suggestion of a survival benefit with screening came from the Bart's pilot RCT of 22,000 women carried out in the 1980s, which used sequential CA125 and TVS. The trial reported improved median survival in women with ovarian/tubal cancer in the screened (72.9 months) group when compared to control (41.8 months) group (17).

Since then, four large trials on OC screening (OCS) have reported in the general population. Aside from the Kentucky Screening Study (22), which was a single-arm annual ultrasound screening study of 25,327 women, the other three were randomized controlled trials (RCTs) and used the tumor marker CA125 together with pelvic ultrasound. The Japanese Shizuoka Cohort Study of Ovarian Cancer Screening (23) was an RCT of 82,487 low-risk postmenopausal women who were screened using an annual ultrasound and CA125 using a cutoff. Sensitivity of 77.1% and specificity of 99.9% were reported with the proportion of Stage I OCs higher in the screened group (63%) than in the control group (38%). However, it did not reach statistical significance (23) and the impact on mortality has not yet been reported.

The U.S. Prostate, Lung, Colorectal and Ovarian (PLCO) Cancer Screening Trial enrolled 78,237 women aged 55 to 74 years, with 34,202 women randomized to OCS. Women were screened using serum CA125 using a cutoff of 35 kU/L and TVS for 3 years followed by CA125 alone for a further 2 years. Evaluation and management of positive screening tests was at the discretion of participants' clinicians. The sensitivity, specificity, and PPV of this strategy for detection of primary invasive ovarian, tubal, and primary peritoneal cancers were 68.2%, 98.9%, and 7.7% (24). At a median follow-up of 12.4 years (25th to 75th centile, 10.9 to 13.0), PLCO showed no mortality benefit with OCS, with 118 and 100 deaths in the screening and control arm, respectively (mortality rate ratio of 1.18, 95% CI, 0.91 to 1.54) (**Fig. 5.1**). Moreover, excess morbidity was reported as a result of false-positive surgery with major complication rate of 15% (25).

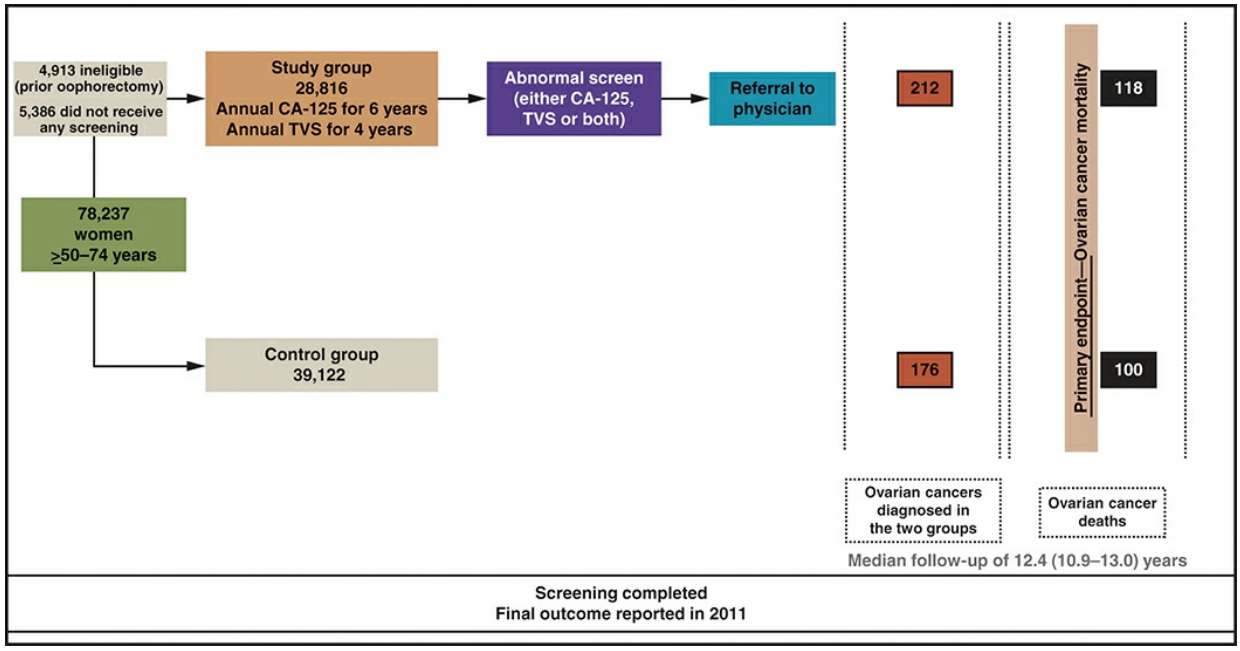

Figure 5.1 Cancer Screening Trial. Women in the trial underwent four annual screens with CA125 (interpreted using a cutoff of 35 kU/L) and TVS and two further screens with CA125 alone. If an abnormality was detected on screening, the women were referred to their physician. Final outcome (OC mortality) was reported in 2011. TVS, transvaginal ultrasound.

In the UK Collaborative Trial of Ovarian Cancer Screening (UKCTOCS), 202,638 postmenopausal women aged 50 to 74 years were randomized to either control or annual screening with ultrasound (USS) or a multimodal strategy (MMS) in a 2:1:1 fashion (26,27) (**Fig. 5.2**). In the MMS group, CA125 was interpreted using the ROCA (which takes into account the absolute value of CA125 and serial levels over time) to triage the women into low, intermediate, and elevated risk. Those at intermediate risk had a repeat CA125 in 12 weeks, whereas those with elevated risk were referred for a TVS and repeat CA125 in 6 weeks. The prevalence screen suggested that MMS strategy has superior sensitivity (89.4%) and specificity (99.8%) to USS screening alone (sensitivity 84.9%; specificity 98.2%) for primary OC. High sensitivity and specificity (89.5%/99.8%) for detection of primary invasive epithelial ovarian/tubal cancers (iEOCs) were reported in the MMS group, which were lower (75.0%/98.2%) in the USS group (27). During incidence screening in the MMS group, 46,237 women underwent 296,911 annual incidence screens with 133 of the 640 women who underwent surgery being diagnosed with primary iEOCs. Sensitivity and specificity of the MMS strategy for iEOC diagnosed within 1 year of screen were 85.8% and 99.8%, respectively, with five operations/iEOC. Of note, using ROCA alone, 86.5% (134/155) of iEOCs were detected compared with 41%, 48%, and 66.5% of the iEOCs if a fixed CA125 cutoff at last annual screen of >35, >30, or >22 U/mL was used, respectively. The area under curve (AUC) for ROCA (0.915) was significantly (p = 0.0027) higher than for a single threshold rule (0.869) with screening using ROCA doubling the number of screen-detected iEOCs compared to a fixed cutoff. The benefit of using serial profile rather than a predefined cutoff is probably also applicable to screening for other cancers (21). Other serial algorithms include the parametric empirical Bayes (PEB) longitudinal screening algorithm, which when applied to the annual samples from 44 women who developed OC in the PLCO trial, was able to identify 20% of cases earlier than a single threshold rule (>35 kU/L) (28). A method of mean trends (MMT) algorithm has also been described that measures biomarker dynamics over time by assigning weights to sample importance to trends (changes in) marker values and include additional trend indices.

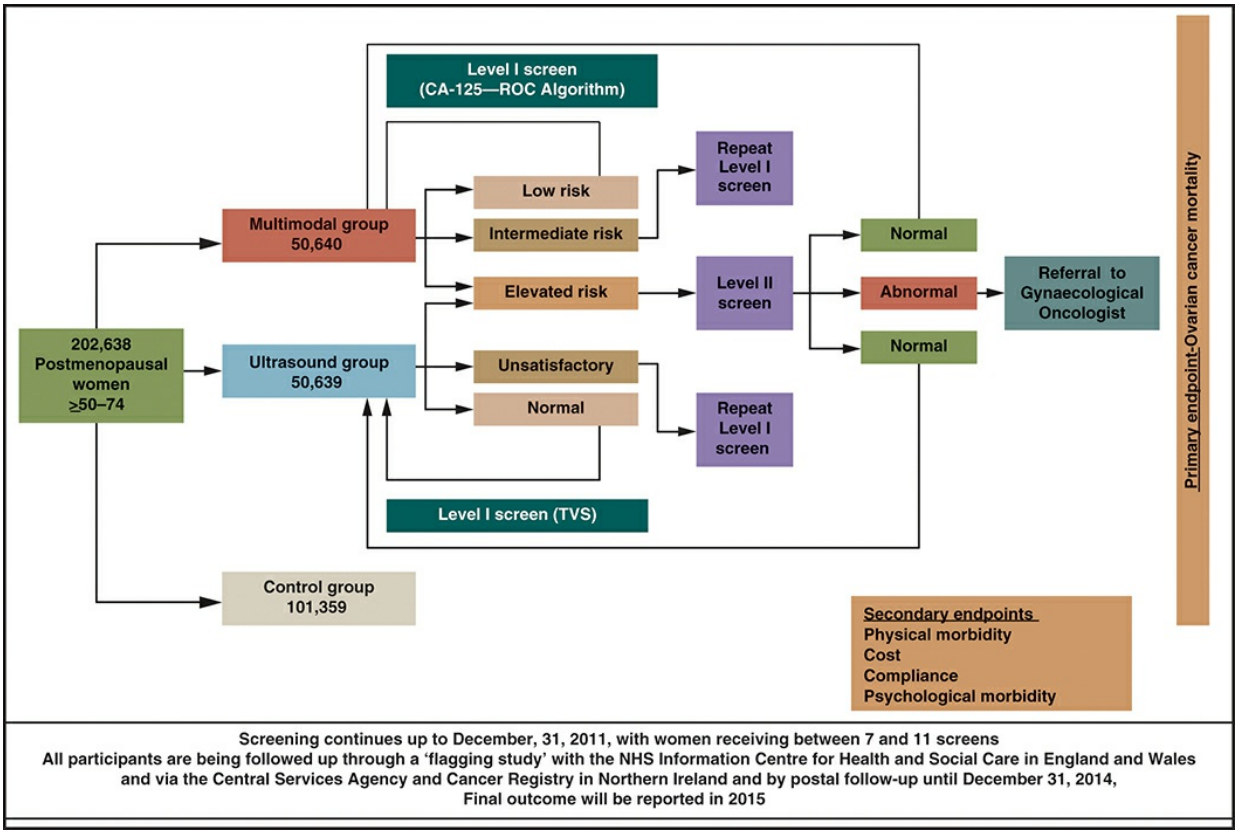

Figure 5.2 The United Kingdom Collaborative Trial of Ovarian Cancer Screening (UKCTOCS). Women in the trial, based on the Risk of Ovarian Cancer (ROC) value, are triaged into low risk (ROC < 1/3,500), and returned to annual screening with the next blood test in 1 year; intermediate risk (<1/1,000 and <1/3,500) with a repeat CA125 in 12 weeks; and elevated risk (>1/1,000) with Level II screen (CA125 and TVS) scheduled in 6 to 8 weeks, with earlier screens arranged if there is a high index of suspicion. Those with persistent abnormalities on Level II screen are referred to a gynecological oncologist. The screening protocol has been described in detail elsewhere. Final outcome (OC mortality) was reported in 2015. TVS, transvaginal ultrasound.

More recently, mortality outcome data has become available from UKCTOCS, the largest OCS trial undertaken to date (29). During the course of the trial 673,765 annual screens were performed and accrued 2.2 million women years of follow-up (median 11.1 years per woman). On censorship at 14 years from start of trial (31st December, 2014), compared to the control arm, there was a significant stage shift of iEOC and primary peritoneal cancers in the MMS arm (119/299, 40.0% vs. 149/574, 26.0%; $p < 0.0001$) but not in the USS arm (62/259, 24% vs. 149/574, 26.0%; $p = 0.57$). However, the average reduction (15% MMS, 11% USS) over 14 years was not significant on the primary analysis using the Cox model. As noted in other screening trials, the mortality effect was delayed and was only apparent 7 years after women joined the trial, with reductions of 8% in the first 7 years and 23% in years 7 to 14 in the MMS group, and 2% and 21%, respectively, in the USS group. At censorship, the control group ovarian/tubal/peritoneal cancer death rate continued to rise, whereas the rates in MMS and USS groups appeared to be plateauing. While the data are encouraging, further follow-up is planned until the end of 2018 to definitively ascertain that the stage shift translates into a mortality benefit in the MMS arm and to determine the size of the reduction in deaths (29). With regard to harms, 14 women in the MMS arm and 50 in the USS arm per 10,000 screens underwent trial surgery as a result of positive screen results and were then found to have only benign ovarian lesions or normal ovaries (29). The major surgical complication rate (3.1% MMS and 3.5% USS) in the latter were similar to those reported for such surgery in the gynecologic oncology departments in the United Kingdom (30). Although there was an increase in anxiety following intense repeat testing after abnormal annual screening and in those undergoing surgery for OC, overall, screening within UKCTOCS did not appear to raise anxiety (31).

There are ongoing efforts to identify women who may be at a substantially lower or higher risk than the general population risk of 1.37% based on genetic and epidemiologic factors to maximize benefit from screening. Data from the Ovarian Cancer Association Consortium (OCAC) suggests that there are currently over 30 low-penetrance single nucleotide polymorphisms (SNPs) that predispose women to OC, each individually increasing the relative risk by 10% to 20% (32). A combination of these genetic risk factors together with lifestyle and reproductive factors have been estimated to confer lifetime risk of OC ranging from 0.35% (95% CI, 0.29 to 0.42) to 8.8% (95% CI, 7.10 to 10.9). Of the women in the 4% to 9% risk category, 73% had no family history of OC (33). A number of new as well as refined versions of existing risk-prediction models such as the Breast and Ovarian Analysis of Disease Incidence and Carrier Estimation Algorithm (BOADICEA) model should be available in the future for risk stratification.

A second target population for screening are women who have a strong family history of OC. These women (from families with multiple first-degree relatives affected by ovarian, breast and ovarian cancer, or Lynch syndrome) have a greater than 10% lifetime risk of developing OC and are considered to be high-risk. Most of this risk is attributable to mutations in the *BRCA1*, *BRCA2*, and *MMR* genes with cumulative risks by the age of 70 years for OC of 40% (35% to 46%) in *BRCA1*-mutation carriers, 18% (13% to 23%) in *BRCA2* mutation carriers (34), and 10% to 12% in women with mutations in the *MMR* genes (35). Recent efforts have also reported that mutations in moderate-penetrance genes such as RAD51C, RAD51D (36), and BRIP1 (37) are associated with lifetime risk of OC ranging from 5% to 15%. It is likely that many more women who are at increased risk of OC would be identified in the near future, in view of the increasing availability of genetic testing and falling costs of these tests. This in turn drives the continued effort to develop effective screening strategies for high-risk women to detect the disease early without causing significant harm. In these women, the primary recommendation is risk-reducing salpingo-oophorectomy (RRSO) (38). In the United States, the National Comprehensive Cancer Network (NCCN) recommends RRSO in those with BRCA1, BRCA2, and Lynch syndrome, while there is currently insufficient evidence for such an approach in those with RAD51C, RAD51D, BRIP1, PALB2, and BARD1 mutations. Surgery is associated with reduction in breast and OC risk in BRCA carriers but accompanied by the issue of surgically induced premature menopause (39). A number of studies have shown that irrespective of family history, the prevalence of BRCA1/2 mutations may be as high as 22% in women with triple-negative breast cancer and high-grade serous OC (40,41). Germline BRCA1/2 testing for all patients with invasive non-mucinous EOC, irrespective of their age or family history, is being rolled out in many countries.

To those who choose not to avail themselves of RRSO, screening is usually offered in the context of trials from the age of 35, with a number of studies evaluating OCS in these high-risk women. There is now conclusive evidence that a strategy based on annual screening is not effective in detecting early-stage disease in this population. An approach based on 3- to 4-month screenings using CA125, interpreted using the ROCA, was evaluated in prospective screening studies in the United Kingdom (UK Familial Ovarian Cancer Screening Study [UKFOCSS Phase II]) (42) and in US trials under the auspices of the Cancer Genetics Network and Gynecological Oncology Group (43) and the US-based Cancer Genetics Network (CGN) (44). The latter used the ROCA to screen 2,343 high-risk women at 3-month intervals. Thirty-eight women underwent surgery following 6,284 screens. Five OCs were detected, two prevalent (one early, one late stage) and three incident (all early) cases, resulting in a PPV of 13%. Three further occult cancers were detected at RRSO and one woman developed an interval (late stage) cancer (45). During 4-month screening involving 14,263 women screen years and 4,531 women in UKFOCSS Phase II, there were 12 screen-detected ovarian/tubal cancers and 6 occult cancers at RRSO. There were no interval cancers. Of the screen-detected iEOCs, only 42% were Stage I/II. This is probably a reflection of the natural history of high-grade serous OCs, for which modeling suggests that the median diameter of tumor is about 3 cm when it progresses to Stage III or IV (46). Encouragingly, complete cytoreduction was achieved in over 90% of the women with ovarian/tubal cancers in UKFOCSS (47). Despite the intensive screening in UKFOCSS leading to women being recalled for abnormal results, only transient cancer-specific distress and no significant effect on general anxiety/depression or overall reassurance was reported (48). The final results of the UK trial are anticipated in 2016, but this preliminary data seems to suggest that in high-risk women who decide to defer/not avail of surgery, a programme of intensive screening with ROCA and second-line TVS, together with regular discussions about RRSO, might be an option.

The importance of serial monitoring of CA125 rather than using absolute cutoff is further illustrated by a case report of an asymptomatic woman seen in a familial clinic who had rising levels of CA125 within the normal range, was managed conservatively, and then went on to present with Stage IIIc OC (49).

Monitoring CA125 levels post-RRSO (although performed occasionally in high-risk women due to the small residual risk of primary peritoneal cancer [PPC]) is a contentious issue. In a recent series of 207 BRCA1/2 carriers monitored with annual CA125 between 1990 and 2008, only one woman with Stage III PPC (whose baseline CA125 before RRSO was 19.5 kU/L but 14 months after the procedure rose to 143 kU/L) was detected, supporting the majority view that CA125 monitoring post-RRSO is not effective (50).

In a 1980s biobank study, CA125 was found to be raised in 59 out of 236 (25%) stored serum samples collected from women with OC 5 years before diagnosis (51). Data from the Japanese OCS study indicate that, in serous-type OC, first elevation of CA125 to diagnosis has a shorter interval compared with those with non-serous disease (1.4 vs. 3.8 years; $p = 0.011$). Furthermore, a higher proportion (75%) of serous OCs developed following a normal CA125 (<35 kU/L) compared to 47% of non-serous OCs that developed from slightly elevated CA125 levels (35 to 65 kU/L) (52). A model of natural history of OC developed by Brown and Palmer suggests that on average it takes over 4 years for *in situ* Stage I or Stage II cancers to become clinically apparent and approximately 1 year to progress to Stage III/IV cancers (46). Serous cancers are less than 1 cm in diameter during the occult period. The model suggests that for a screening strategy to be able to detect 50% of the cancers before they progress to Stage III, an annual screen would have to detect tumors 1.3 cm in diameter, whereas to detect 80% of the cancers, the strategy would have to pick these tumors up when only 0.4 cm (53). The current tests are imprecise as they are unable to detect OCs when this small, thus the continued search for more precise markers.

Whether a raised CA125 in asymptomatic postmenopausal women is a predictor of non-gynecologic cancer is not yet clear. Data from the Bart's RCT of 22,000 postmenopausal women (17) reported that elevated serum CA125 was not a predictor of a nongynecologic malignancy on mean follow-up of 6.2 years (54). However, it was associated with significantly increased risk of death from all causes in the next 5 years (55). In contrast, data from the Norwegian OCS trial of 5,500 women showed that breast and lung cancer were overrepresented among women with elevated CA125 (56). Both trials indicate that elevated CA125 is a risk factor for death from malignant disease. This data indicates that steps should be taken to rule out other malignancies such as breast, lung, and pancreas in asymptomatic postmenopausal women with rising CA125 levels and no evidence of gynecologic malignancy.

Differential Diagnosis of an Adnexal Mass

There are certain criteria a tumor marker must fulfill to be incorporated into clinical practice (**Table 5.7**). Serum CA125 is used routinely in clinical practice in differential diagnosis of benign and malignant adnexal masses, especially in postmenopausal women. Using an upper limit of 35 kU/L, sensitivity of 78%, specificity of 95%, and PPV of 82% could be achieved for malignant disease in women with palpable adnexal masses (57). Despite further improvements in specificity being achieved by using a panel of markers (CA125 II, CA 72-4, CA 15-3, and lipid-associated sialic acid) and an artificial neural network approach to differentiate malignant from benign pelvic masses (58), these are not used in clinical practice.

The risk of malignancy index (RMI) has been the most valuable clinical tool used in the past two-and-a-half decades. It combines serum CA125 values with ultrasound findings and menopausal status. The initial study (1990) demonstrated a sensitivity of 85% and a specificity of 97%. Patients with an elevated RMI score had on average a 42-fold increase in the background risk of OC (59). Since then, the RMI has been validated extensively. A 2009 systematic review of 109 eligible studies assessing accuracy of models for predicting malignancy in ovarian masses showed that while all models had acceptable sensitivity and specificity, RMI was the best predictor. Using a value of 200 as the cutoff, the pooled estimate for sensitivity for preoperative assessment of an adnexal mass was 78%, for a specificity of 87% (60). Varying the RMI cutoff (from 25 to 1,000) in combination with specialist ultrasound (US), magnetic resonance imaging (MRI), and

radioimmunoscintigraphy (RS) can achieve a higher sensitivity (94%) and specificity (90%), thus suggesting that using this approach may improve the correct referral of cancer patients to a cancer center (61). More recently, RMI-I cutoff of 200 was shown to have a higher sensitivity (92%), but a slightly lower specificity (82%) (62). However, despite many modifications of the RMI since 1990 (by varying the cutoff levels, incorporating CA19-9), the performance between RMI-IV is comparable (63). Despite the lower accuracy of the RMI in borderline, Stage I invasive and nonepithelial OCs, the RMI is a simple, easily applicable method in the primary evaluation of patients with adnexal masses that identifies OCs more accurately than any other criterion used in diagnosis of this disease (64).

TABLE 5.7 Criteria for Incorporating Tumor Marker into Clinical Practice

1. The intended use of the tumor marker must be clearly outlined
2. The difference between "positive" and "negative" populations must be sufficient to guide change in clinical management
3. The estimate of difference must be reliable and validated
Assay must be technically stable, reproducible, and accurate
Clinical study must have been suitably designed and have sufficient power to address the utility of intended use
Statistical analysis must be rigorous

Hayes DF. Biomarkers. In: DeVita VT Jr, Lawrence TS, Rosenberg SA, DePinho RA, Weinberg RA, eds. Cancer: Principles and Practice of Oncology. Philadelphia, PA: Wolters Kluwer Health; Lippincott, Williams & Wilkins; 2011:694–701.

In further efforts to improve the specificity of CA125, a cancer-specific glycoform of CA125 (O-glycosylated CA125) was identified that was able to discriminate between primary iEOCs from benign ovarian neoplasms in women with moderate elevations of CA125 (30 to 500 kU/L), with a specificity of 60% and a sensitivity of 90% (13).

The International Ovarian Tumor Analysis (IOTA) group has led the effort in identifying ultrasound features that could distinguish between benign and malignant adnexal masses. Despite many studies relying on ultrasound alone, more recently, CA125 was introduced into their Assessment of Different NEoplasias in the adneXa (ADNEX) model, which achieved an AUC of 0.85 for benign versus borderline, 0.92 for benign versus Stage I cancer, 0.99 for benign versus Stage II–IV cancer, and 0.95 for benign versus secondary metastatic cancer (65), with suggestions on how this model could be applied to clinical practice (66). However, the model performed similarly to subjective assessment in predicting whether a pelvic tumor is metastatic and of non-ovarian origin (67). The latest IOTA study of 5,200 women with a pelvic mass recently reported an encouraging performance of 10 simple ultrasound rules (5 features indicative of a benign tumor and 5 indicative of malignancy) if 30% risk cutoff was used (sensitivity of 89.0%, specificity of 84.7%). The authors suggest that such an algorithm is applicable in both oncology as well as non-oncology centers and can be easily used clinically in the management of patients as well as triage to a gynecologic oncologist (68). Of all the models thus described in the literature, RMI-I and the IOTA Logistic Regression 2 (LR2) model perform best for preoperative characterization of adnexal masses in postmenopausal women. In those of reproductive age, the two best-performing models are LR2 and simple rules (63).

Prognosis

The role of CA125 (pre-, postoperative, and during treatment) in prognosis is well established (69). Single measurement of CA125 has limited value in predicting prognosis compared with a change in CA125. Preoperative serum CA125 levels are related to tumor stage, tumor volume, and histologic grade of OC and may be of value in those with localized/early-stage disease (70). Lower preoperative serum CA125 (<65 kU/L) levels indicate a significantly longer survival in those with Stage I EOC (71). These findings have been further confirmed by an international study in which those with CA125 of

≤30 kU/L (regardless of histologic subtype, substage or grade) had a good prognosis and survival and could possibly be spared from adjuvant chemotherapy (72). Additional parameters, such as cyclooxygenase-2 overexpression, in combination with preoperative CA125 <30 kU/L are independent predictors of survival (73). However, CA125 does not appear to be an independent prognostic factor in advanced OC (70).

Postoperative CA125 levels have been found to be significant prognostic factors (74). Patients with a low "CA125 prognostic score" (composed of two CA125 values, one taken preoperatively and the other taken 1 month after surgery because levels can be elevated 4 weeks post-surgery), have significantly better prognosis than patients with high scores (75). In advanced EOC, serum CA125 half-life is another way of measuring treatment response, with a half-life of 20 days most commonly used. Overall, all studies to date indicate that prolonged half-life reflects the persistent production of CA125 in OC patients and is a poor prognostic indicator (76). In patients with CA125-positive tumors, other useful prognostic indicators of survival are the serum CA125 levels prior to third course of chemotherapy (77) and the slope of the CA125 exponential regression curve. In patients treated on maintenance chemotherapy and achieving a clinically defined complete response to primary chemotherapy, with a baseline CA125 level of ≤35 kU/L, the baseline CA125 level before initiation of maintenance chemotherapy strongly predicts the risk of subsequent relapse. Patients with pre-maintenance baseline CA125 values ≤10 kU/L have a superior progression-free survival (PFS) compared to those with higher levels, even if in the normal CA125 range (78).

Serum CA125 continues to be of prognostic significance when OC recurs; patients with normal serum CA125 levels (≤35 kU/L) at relapse have a better prognosis than patients with elevated levels (79).

Monitoring Response to Treatment

It is now established that serum CA125 levels reflect progression or regression of disease in over 90% of OC patients with elevated preoperative levels (**Fig. 5.3**). Despite the widespread use of serum CA125 levels to monitor the clinical course of OC and its response to chemotherapy, CA125 should not be used as the sole criterion to determine clinical response. Studies involving second-look laparotomy have confirmed that CA125 values of <35 U/mL do not exclude active disease (80). Serial measurements are more informative than a cutoff. Rustin (81) has proposed using at least a 50% decrease in CA125 or a 75% response from pretreatment levels to define response. Response has been defined and incorporated into the RECIST criteria (82). A multicenter French study showed that pre-chemotherapy CA125, its half-life, nadir concentration, and time to nadir have a univariate prognostic value for disease-free and overall survival (OS) (83). Following first-line therapy, shorter rate of rise of CA125 (measured by CA125 doubling time) carries a worse prognosis (84). In addition to CA125 half-life, other kinetic variables have been described to assess response to therapy (85).

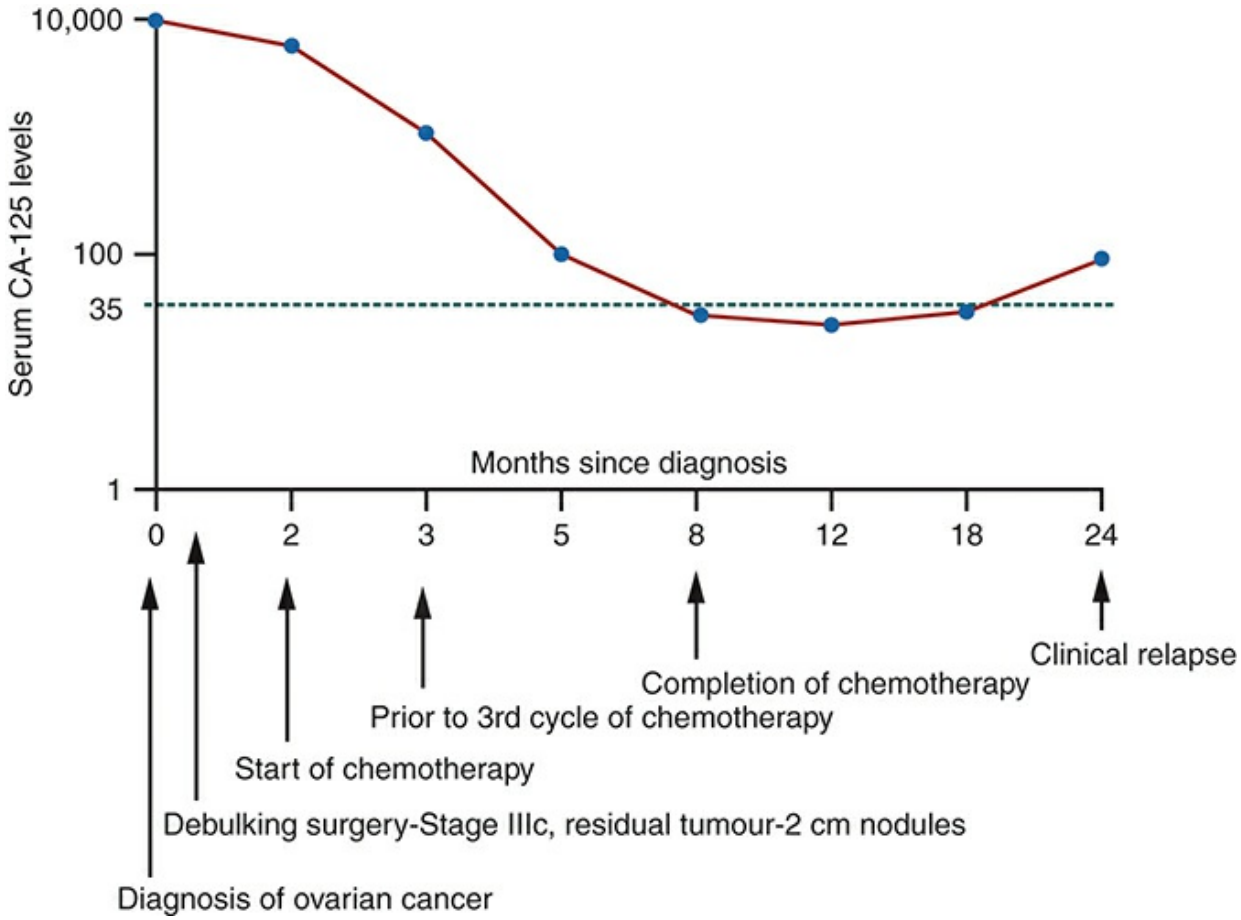

Figure 5.3 Correlation between serum CA-125 and clinical course in ovarian cancer.

Detecting Recurrence

Among patients with elevated CA125 levels at diagnosis, serial monitoring following initial chemotherapy can lead to the early detection of recurrent disease. A risk of recurrence is increased in those with either a relative increase in CA125 of 100% (OR = 23.7; 95% CI, 2.9 to 192.5), or an absolute increase of 5 kU/L (OR = 8.4; 95% CI, 2.2 to 32.6) or 10 kU/L (OR = 71.2; 95% CI, 4.8 to >999.9), thus suggesting that progressive low-level increase in serum CA125 levels is strongly predictive of disease recurrence (86).

In the follow-up of OC patients, thin-section computed tomography (CT) does not aid physical examination and CA125 with ultrasound (87).

Whether to use CA125 in follow-up or wait for a symptomatic presentation of disease has been a subject of much debate. The MRC OVO5/EORTC55955 trial led by Rustin showed no benefit in CA125 monitoring in the follow-up of OC patients, as those randomized to immediate (based on CA125 levels) or delayed chemotherapy (the latter when signs and symptoms of recurrence were present) did not demonstrate a difference in survival (early arm: median 25.7 months, 95% CI, 23.0 to 27.9; delayed arm: median 27.1, 95% CI, 22.8 to 30.9; HR 0.98, 95% CI, 0.80 to 1.20; $p = 0.85$). The trial therefore suggested that CA125 should only be measured if there is a suspicion of relapse or at patient's request (88). However, in view of the potential biases/challenges of this trial, the European Society of Gynaecological Oncology (ESGO) did not support the notion of unanimously abandoning CA125 monitoring during follow-up, as certain patient groups may benefit from such monitoring (e.g., those treated as part of a clinical trial following complete response to primary treatment, those that are not undergoing routine follow-up, those eligible for secondary surgery at recurrence, those eligible to take part in a clinical trial on second-line treatment) (89).

The usual pattern of CA125 throughout a clinical course of the disease is presented in **Figure 5.3.** CA125, remains the

best-performing biomarker for OC when tumors of mucinous origin are excluded (89). However, some encouraging markers/technologies discussed below have emerged in recent years.

Human Epididymis Protein 4 (HE4)

Despite three-and-a-half decades passing since the identification of CA125, and many international efforts to find a better-performing marker or one complementing CA125, only more recently has another promising marker, Human epididymis protein 4 (HE4), been identified. HE4 is a glycoprotein in the epithelial cells of the epididymis with increased serum levels observed in OC patients.

Screening

There is as yet no clear evidence whether HE4 performs better than CA125 as a first or second-line test in screening. A case -control set (using preclinical samples collected 6 months prior to diagnosis) nested within PLCO showed that CA125 remained the single best biomarker for OC (sensitivity of 86%) followed closely by HE4 (73%) (90). Urban et al demonstrated that HE4 outperforms TVS both as a first-line (sensitivity of 35.7% vs. 28.6%) and second-line test (91). Using HE4 as a second-line test when CA125 levels are raised (>35 kU/L) was able to detect 27 out of 39 cancers (69.2%) compared with only 17 OCs detected by TVS alone (43.6%). Compared with TVS, HE4 was better at detecting Type II cancers (40% vs. 20%) than Type I cancers (18.8% vs. 56.2%). In terms of outcome, however, there is no clear advantage in diagnosing HE4-associated rather than TVS-associated tumors (91). In another nested case-control study within PLCO, none of the five predictive models, each containing six to eight biomarkers, nor a model derived from all of the 28 markers evaluated in the PLCO set, showed improvement over CA125 alone (92). A limitation of these studies was that CA125 was used in "real time" for triaging women for diagnostic workup for OC (93). There are two possibilities why studies have thus far failed to show improvement over CA125: either the current technologies are unable to identify biomarkers with greater or complementary potential for screening; or the available technologies, powerful as they are, have not yet been applied appropriately in either discovery or validation, with one of the main obstacles being use of clinical as opposed to prediagnostic/preclinical samples (94). Carotene and Retinol Efficacy Trial showed that a panel including CA125, HE4, and mesothelin may provide signal for OC 3 years before diagnosis (95) but this has not been subsequently confirmed.

Differential Diagnosis

Mean serum HE4 in patients with malignant ovarian lesions (248.7 pM) is much higher than in controls (34.1 pM) or in women with benign lesions (39.1 pM) (**Table 5.8**). HE4 levels are decreased in pregnancy (median levels of 30.5 pmol/L) (96) and levels around 50 and 60 have been demonstrated in pre- and postmenopausal women, respectively, (97) which increase with age (median 109.5 pmol/L in women over 80 years). HE4 levels are lower in many of the benign conditions that usually elevate CA125 levels (**Table 5.9**), especially in women with endometriosis.

TABLE 5.8 Mean Levels of Serum HE4 in Normal Controls, Benign and Malignant Lesions

Condition	Serum HE4 Level (Mean)
Normal Controls	34.1 pM
Benign Lesions	39.1 pM
Malignant Lesions	248.7 pM

	Mucinous	43.8	68.8
	Other histologies	57.9	68.5

[a]Moore RG, Miller MC, Steinhoff MM, et al. Serum HE4 levels are less frequently elevated than CA125 in women with benign gynecologic disorders. Am J Obstet Gynecol. 2012;206:351.e351－358.

[b]Escudero JM, Auge JM, Filella X, et al. Comparison of serum human epididymis protein 4 with cancer antigen 125 as a tumor marker in patients with malignant and nonmalignant diseases. Clin Chem. 2011;57(11):1534－1544.

HE4 can also be elevated in other cancers (**Table 5.10**). Initial reports stated that its specificity is superior to CA125 and of particular value for early-stage disease (98). There are conflicting reports, with some studies indicating that combining CA125 with HE4 increases sensitivity for detection of OC while maintaining high specificity (98), while others

do not support this (99). An Italian multicenter study of 405 patients including 82 OCs recently demonstrated that HE4 was more specific than CA125 in ruling out patients with OCs (100).

The performance of HE4 can be improved by being incorporated into an algorithm that includes CA125 and menopausal status (Risk of Malignancy, ROMA index). The ROMA gives a risk of OC with a value >13.1% predicting a high risk of EOC in premenopausal women, and a value >27.7% used in the postmenopausal population (101). In a single-center prospective cohort study of 432 women with a pelvic mass who were scheduled to have surgery, RMI combined with subjective ultrasound was shown to be superior to ROMA (102).

An index that uses age rather than menopausal status (as used in ROMA) has been described and evaluated in an international setting. The Copenhagen Index (CPH-I) based on serum HE4, serum CA125, and patient age was derived in a set of 809 patients with benign ovarian disease and 246 with OC. On validation in further eight international studies of 1,060 patients with benign ovarian masses and 550 patients with OC, CPH-I was able to discriminate benign from malignant ovarian disease with a sensitivity and specificity of 95.0% and 78.4%, respectively, in the training cohort, and 82.0% and 88.4% in the validation cohort (using a predefined cutoff of 0.070). It had similar AUC and specificity (at 95% sensitivity) as ROMA and RMI. Therefore, a simple index independent of US findings and menopausal status may optimize referral of women with suspected OC (103).

When evaluating new biomarkers/combinations of markers, it is important to establish the normal range in healthy individuals, especially if the marker has been shown to be very promising, such as HE4. The normal range for HE4 has been established in serum samples from 1,101 healthy women and 67 pregnant women. HE4 concentration increased with advancing age (>40 years). Median serum HE4 levels in premenopausal women (46.6 pmol/L) were significantly lower than in postmenopausal women (57.6 pmol/L; $p < 0.001$). The upper 95th percentile for HE4 levels was 89 pmol/L for premenopausal women, 128 pmol/L for postmenopausal women, and 115 pmol/L for all women. In pregnant women, median HE4 concentrations are significantly lower than their premenopausal counterparts ($p < 0.001$) (104). HE4 levels appear to be lower in the Asian population (HE4 of 33.2 pmol/L) (105). These values are important in the clinical application of the test in different populations. A recent study of 756 patients with pelvic mass (275 OCs, 53 borderline tumors, and 428 benign masses) from South China demonstrated a superior performance of HE4 and ROMA to that of CA125 in detecting borderline tumors and early-stage EOC. The authors also suggest a 70 pmol/L as the optimal cutoff in both pre- and postmenopausal women (106). Despite many studies evaluating the role of HE4 in differential diagnosis of malignant from benign adnexal masses, there is currently no consensus as to whether HE4 outperforms CA125 in this setting.

Detecting Recurrence

Schummer *et al.* (107) demonstrated that in patients who go on to develop a recurrence, HE4 rises earlier than CA125, with a lead time of up to 4.5 months. It can also be elevated in patients who do not express CA125 at sufficient levels to make a clinical decision. However, as HE4 levels fail to normalize at the end of treatment, it is possible that it can be used as a marker predicting poor prognosis.

TABLE 5.10 Elevations of HE4 in Women with Cancers other than Ovarian

	Cancer Group	HE4 > 140 pmol/L (%)
Nongynecologic malignancies	Breast	5.6
	Digestive tract malignancy	11.3
	Lung	

	Small cell lung cancer (SCLC)	26.90
	Non-small cell lung cancer (NSCLC)	29.30
	Liver	16.3
	Melanoma	11.1
	Urologic malignancies	21.5
	Hematologic malignancies	10.0
	Mesenchymal tumors	0.0
	Non-ovarian/endometrial/NSCLC malignancies (without effusion or liver metastases)	6.5
	Non-ovarian/endometrial/NSCLC malignancies (with effusion or liver metastases)	18.5
Nonovarian gynecologic malignancies	Endometrial cancer	28
	Cervical cancer	0

Escudero JM, Auge JM, Filella X, et al. Comparison of serum human epididymis protein 4 with cancer antigen 125 as a tumor marker in patients with malignant and nonmalignant diseases. Clin Chem. 2011;57(11):1534–1544.

Prognosis

Elevated HE4 levels are strong and independent factors of worse prognosis in EOC patients compared to CA125 (108). High preoperative HE4 levels are poor prognostic factors, with levels over 394 pmol/L being predictors of death (HR = 1.67; 95% CI, 1.08 to 2.59) (109).

Additional Markers

In the past few years, major efforts have been made to identify either a better marker or a panel of markers that would improve the performance of CA125 in the context of screening. However, most of the studies used clinical samples (rather than preclinical samples), making their findings more relevant to differential diagnosis of benign from malignant masses, in order to avoid unnecessary operations in women with benign lesions. The latter ensures that where there is high suspicion of OC, surgery is undertaken by trained gynecologic oncologists in tertiary-care centers (110). A significant effort had been made over the years to identify other markers for OC: Interleukin-6 (IL-6), interleukin-7 (IL-7), soluble interleukin-2 receptor (sIL-2R), tumor necrosis factor (TNF), soluble receptors of TNF (sTNF-R), macrophage colony-stimulating factor (M-CSF), CA15-3, CA72-4 or TAG-72, CA19-9, OVX1, CASA/OSA, growth factors, tetranectin, tumor-associated trypsin inhibitor (TATI), galactosyltransferase associated with tumor (GAT), lipid-associated sialic acid (LASA), vascular endothelial growth factor (VEGF), immunosuppressive acid protein (IAP), lysophosphatidic acid (LPA), autoantibodies to MUC1 (111), prostasin, cadherin, shed glycans, dipeptase 1. Despite a plethora of studies, none of these markers have been shown to be useful in clinical practice. Limited sensitivities and specificities constrain their use in screening.

Apart from HE4, glycodelin is the only other marker that has shown encouraging performance (as part of multimarker panels) (112) but only improves the performance of CA125 in the screening scenario marginally (113).

Other markers such as soluble MUC1 and serum MUC1-specific antibodies have been evaluated both in early detection and as prognostic markers. Antibodies to anti-MUC1 glycopeptides are of no value in screening for OC (111) but have been shown to be prognostic for poor clinical response and reduced OS in both platinum-resistant as well as platinum-refractory OC treated with interleukin 2 (IL-2) (114).

Survivin is another marker which has shown promise as a prognostic marker for OC, as its levels positively correlated with age, advanced stage, and poor disease-free survival (DFS) (115).

Cancer-Specific Biomarkers and Novel Biospecimens

Cell-Free DNA as a Novel Biomarker

Cell-free DNA is increasingly been investigated as a potential biomarker, as it reflects the release of both normal and tumor-derived DNA (ctDNA) into the circulation through cellular necrosis and apoptosis. Cell-free DNA levels are much higher in iEOC patients (median preoperative level of 10,113 GE/mL) compared with those with benign ovarian neoplasms (median, 2,365 GE/mL; $p < 0.0001$) and controls (median, 1,912 GE/mL, $p < 0.0001$). In iEOC patients, elevated levels of cell-free DNA (>22,000 GE/mL) are associated with decreased patient survival ($p < 0.001$) and a 2.83-fold increased risk of death from disease ($p < 0.001$) (116).

The modeling of the natural history of high-grade serous OC (46) suggests that lesions would have to be detected at 1.3 cm in diameter (53) for a screening strategy to be able to detect 50% of these cancers. This suggests that early detection of low-volume rather than early-stage disease may be a more realistic target for screening in the short term, with a longer term goal of detection of the premalignant serous tubal in situ carcinoma (STIC) lesion. Over 95% of high-grade serous cancers harbor p53 mutations. A significant effort has been made to develop more sensitive assays to detect cancer-specific tumor DNA, based on mutations in TP53 and other cancer-related genes, such as *EGFR*, *BRAF*, and *KRAS*. BEAMing is one of these new technologies that is able to detect small amounts of mutant alleles in cell-free body fluids and can be quantified with unprecedented sensitivity (117). Using tagged-amplicon deep sequencing (TAm-Seq), Rosenfeld *et al.* were able to identify TP53 mutations in plasma of patients with advanced OC who had high levels of circulating tumor DNA (ctDNA). The technique was able to identify these mutations with allelic frequencies of 2% to 65%, but despite the inability of TAm-Seq to achieve a more sensitive detection limit (<2% allele frequency) so as to identify mutations in the plasma of patients with less advanced cancers, the noninvasive nature of the test holds much promise as a low-cost, high-throughput "liquid biopsy" approach for early detection of small tumors (118). This approach could also complement CA125 in women with elevated CA125 but negative imaging. A recent study of 44 ovarian/uterine cancer cases with samples collected at time of surgery demonstrated that ctDNA was detectable in women with positive CA125 and CT imaging but also in six patients with negative imaging (119).

In addition to serum and plasma, liquid cytology cervical samples provide another source of sample in which cancer-specific mutations could be detected. Using a sensitive massively parallel sequencing method to detect mutations in a panel of 12 genes, Kinde *et al.* reported that they were able to identify these expected tumor-specific mutations in 14 liquid cytology cervical samples from women with OC. These results, albeit restricted to a small study, are encouraging in that they suggest that tumor DNA could be detected in a proportion of OCs in a standard liquid-based cervical cytology specimen obtained during routine pelvic examination (120). The technique, however, needs further improvement; increasing the number of potential gene targets would increase the technical sensitivity of the test, while endometrial aspirates may help enrich the sample with cells of tubal and ovarian origin. An additional study assessing the feasibility of uterine cavity lavage in detecting shed cancer cells and its ability to provide sufficient amounts of DNA demonstrated that mutations could be identified in 80% (24/30) of patients with OC by using massive parallel sequencing and singleplex analysis (121).

In addition to its role in early detection, ctDNA holds promise as a prognostic marker in gynecologic cancers. Undetectable levels of ctDNA at 6 months following initial treatment was associated with improved progression-free and OS in a series of 44 patients with ovarian and uterine cancers (119).

DNA Methylation Profile

As changes in DNA methylation are one of the most common alterations in cancer, circulating methylated DNA may represent a new generation of tumor marker (122). Despite many studies showing hypermethylation of tumor-derived DNA in serum and plasma of cancer patients, no definitive clinically useful such marker had been described in OC patients

as yet. However, encouraging data from colorectal cancer suggests that a methylated septin 9 (SEPT9) marker can increase the sensitivity of screening (to 77%) (123), and this has already been marketed as the Epi proColon commercial test.

DNA methylation profiles have been extensively studied in OC. The findings suggest that up to 21% of the CpG islands are hypomethylated, with a different panel of genes displaying hypo/hypermethylated pattern according to histologic subtype (124). Despite some encouraging data that DNA methylation profile could predict active disease (125), response to treatment (126) and OS (127), profiling is yet to be used in clinical practice.

Salivary Transcriptomes as Novel Markers

In an effort to derive tests that are not only noninvasive (such as a blood test) but would require no visit to a clinic, saliva has been proposed as a suitable alternative. Many groups are now focusing on this approach, and a strategy examining salivary transcriptomes has identified that a combination of five biomarkers (AGPAT1, B2M, BASP2, IER3, and ILI1) yielded an encouraging sensitivity (85.7%) and specificity (91.4%) for early detection of the disease (128). However, the study only included 32 OC patients, so would need validation in further studies.

Proteomics

Since the initial report by Petricoin in 2002 about the promise of proteomics in the search for OC biomarkers (129), the race has yet to abate. Surface-enhanced laser desorption ionization time-of-flight (SELDI-TOF) analysis and matrix-associated laser desorption ionization time-of-flight (MALDI-TOF) technologies have been employed over the past few years to identify patterns or changes in protein profile between those with and without cancer. However, the lack of markers identified may not be due to the issues with the technologies as much as the way the samples had been collected and processed. The biomarkers identified through the proteomics approaches include apolipoprotein A1, a truncated form of transthyretin, and elevated levels of a cleavage fragment of inter-alpha-trypsin inhibitor heavy chain H4 (ITIH4), all of which have been independently validated (130). Apolipoprotein A1, truncated transthyretin, and connective tissue–activating protein III (CTAP III) when combined with CA125 can improve the sensitivity of CA125 alone from 68% to 88% (131). A test called OVA1, which includes these markers, is marketed in the United States as part of the diagnostic workup and determination to refer to a gynecologic oncologist (132). The complexity of mass-spectrometry data requires use of algorithms to identify the most informative “common” peaks. This may be one of the reasons why despite years of proteomics biomarker discovery, a limited number of markers for OC have been identified. A proteomics study using preclinical samples from UKCTOCS identified CTAPIII and putative platelet factor 4 (PF4) as markers that could discriminate cases from controls up to 15 and 11 months before diagnosis, respectively, but, more importantly, earlier than CA125 alone (133).

In contrast, in a nested case–control study from the PLCO trial with samples collected <12 months before cancer diagnosis, a panel of markers (CA125 and apolipoprotein A1, truncated transthyretin, transferrin, hepcidin, β-2 microglobulin, connective tissue–activating protein III, and interalpha-trypsin inhibitor heavy chain 4) did not improve the sensitivity of CA125 alone (61.5%) (134).

In a case–control study nested within UKCTOCS, using isobaric tags (iTRAQ), Russell *et al.* were able to identify Protein Z as a novel early-detection biomarker, which can discriminate between Type I and Type II OC. Unlike CA125, Protein Z was significantly downregulated up to 2 years prediagnosis in Type I; whereas in Type II, it was significantly upregulated up to 4 years before diagnosis ($p = 0.01$). There was a statistically significant increase in the AUC for CA125 and CA125 combined with protein Z, from 77% to 81% for Type I and 76% to 82% for Type II. This new data suggest that Protein Z could add to CA125 and potentially ROCA in screening (135).

A more promising approach has been put forward with the use of Serial Window Acquisition of Theoretical Spectra-Mass Spectrometry (SWATH-MS), which would allow creation of a permanent OC profiling map and data mining for

years to come.

Metabolite Profiling

Metabolites are the end products of cellular regulatory processes. Alterations in their levels can be regarded as response to genetic or environmental changes. In a study of 66 invasive OCs and 9 borderline ovarian tumors by gas chromatography/time-of-flight mass spectrometry (GC-TOF MS), 291 metabolites were detected, of whom 114 were already annotated compounds. Principal component analysis as well as additional supervised predictive models allowed a separation of 88% of the borderline tumors from the carcinomas. This suggests that metabolomics is a promising high-throughput, automated approach in addition to functional genomics and proteomics for analyses of molecular changes in malignant tumors (136).

Encouraging data from a U.S. study of 50 patients with serous OC and 50 with serous benign tumors indicate that plasma metabolite/lipidomics biomarkers identified by liquid chromatography–mass spectrometry could distinguish between malignant and benign serous tumors, with the performance of the top four lipid metabolites (0.85, SD = 0.07) being similar to that of CA125 alone (AUC = 0.87, SD = 0.07); however, they performed best in combination with CA125 (AUC = 0.91, SD = 0.05) (137).

MICRORNA-BASED OVARIAN CANCER BIOMARKERS

MicroRNAs (miRNAs) are small noncoding RNAs that regulate gene expression by translational inhibition or mRNA degradation. They are involved in diverse biologic processes including development, proliferation, differentiation, and apoptosis. In recent years, several unique OC miRNA signatures have been described (miR-200 family, miR-199/214 cluster, let-7 paralogs) due to their potential role as therapeutic targets in advanced disease or chemoresistant tumors. Initial studies examining tissue profiling of OCs and normal ovaries showed upregulation (miR-200a, miR-200b, miR-200c, miR-141) or downregulation (miR-199a, miR-140, miR-145 or miR-125b1) of certain miRNAs (138). One advantage of using miRNAs as biomarkers is that they are generally stable and can be detected in serum and plasma. More recently, eight miRNAs extracted from serum (e.g., miR-21, miR-141, miR-200a, miR-200b, miR-200c, miR-203, miR-205, or miR-214) were compared in exosomes isolated from sera from women with benign disease and OC, demonstrating that exosomal microRNA profile in OC patients is distinct from those with benign disease (139). Resnick *et al.* (140) have shown other miRNAs being up- (miR-21, miR-92, miR-93, miR-126, miR-29a) or down- (miR-155, miR-127, miR-99b) regulated, but more encouragingly, they have demonstrated upregulation of miR-21, miR-92 and miR-93 in three cancer patients with normal CA125 levels. Although miRNA signature/profile is not of established value in diagnosis, prognosis, or response to treatment, further understanding of the role of miRNAs in OC is warranted.

Carcinoembryonic Antigen (CEA)

CEA was first identified in 1965 in the serum of rabbits immunized with colon carcinoma (141). It is an oncofetal antigen which is found in small amounts in the adult colon. Elevated levels are associated with colon and pancreatic cancer but CEA levels are also raised in benign diseases of the liver, gastrointestinal tract, and lung, and in smokers. In OC, CEA is expressed by most endometrioid and Brenner tumors and in areas of intestinal differentiation in mucinous tumors. In contrast to CA125, this marker is not expressed in normal and inflammatory conditions of the adnexa. Around 25% to 50% of OC patients have elevated levels of CEA and the correlation with OC is not as well established as with the other markers (142,143).

Serum CEA is more informative in borderline ovarian tumors (Stage IB-IV) (144) and more frequently overexpressed at

the tissue level (18% LMP vs. 4% OC), in which using a 30% overexpression cutoff carries a worse disease-specific survival (145). Despite an encouraging sensitivity of preoperative CEA and CA-125 serum levels of 82% to 85% (146), CEA is not routinely used in the clinic in diagnostic workup.

Alpha-Fetoprotein

Alpha-Fetoprotein (AFP) is an oncofetal protein produced by the fetal yolk sac, liver, and upper gastrointestinal tract. Elevated levels of AFP occur in pregnancy and benign liver disease. Serum levels are raised in most patients with liver tumors and in some patients with gastric, pancreatic, colon, and bronchogenic malignancies (142). AFP is rarely raised in iEOC but is elevated in patients with the rarer germ cell tumors (endodermal sinus tumors, or immature teratomas, or dysgerminomas) that present in younger women and adolescents (147). Alpha-Fetoprotein also accurately predicts the presence of yolk sac elements in mixed germ cell tumors (148).

In women with endodermal sinus tumors, AFP is a reliable marker for monitoring therapeutic response and detecting recurrence (149,150). Levels of over 1,000 ng/mL, age over 22 and histology are main prognostic factors in patients with ovarian and extragonadal germ cell tumors (151).

In postmenopausal women, yolk sac tumors are aggressive tumors (requiring adjuvant platinum-based chemotherapy) with poor outcome (152,153).

Simultaneous detection of multiple markers has not shown much promise; however, a sensitive chemiluminescence (CL) imaging immunoassay method for detection of multiple tumor markers with high throughput, easy operation, and low cost has been developed. The proof of concept study included four markers (AFP, CA125, CA-153, and CEA) to screen patients with liver, breast, or ovarian cancers. The method showed very good reproducibility, accuracy, and wide detection range, thus making it an ideal platform to study the performance of the panel in clinical and preclinical sets of samples from OC patients accumulated over the past decade (154).

Human Chorionic Gonadotropin

Human chorionic gonadotropin (hCG) is synthesized in pregnancy by the syncytiotrophoblast. It is a glycoprotein hormone made up of two dissimilar covalently linked subunits α and β, which could be released into the circulation and therefore routinely measured. hCG is elevated in virtually all cases of gestational trophoblastic disease (hydatidiform mole, invasive mole, and choriocarcinoma) and serves as an ideal tumor marker. There is a close correlation between hCG levels and tumor burden, and hCG levels are used in staging and clinical management. Serum hCG can also be detected in patients with non-trophoblastic cancers. Although gynecologic cancers are prominent in this group, the sensitivity of using hCG is lower than for other markers in current use, except in germ cell tumors with a chorionic component (155).

Elevated levels of serum hCG-β and AFP are significant predictors of OS in patients with Stage IC to IV malignant ovarian germ cell tumors; age at diagnosis is of no prognostic value (156).

In pediatric patients (mean age 12.5 years), elevated hCG-β, AFP, and CA125 are observed in over half of the cases (54%). However, the best indicators of malignancy in these young patients are complaints of a mass or precocious puberty, a mass exceeding 8 cm or a mass with solid imaging characteristics (157).

hCG levels are elevated in 67% of OCs (mainly in Stage II mucinous tumors) compared with 26.7% of benign ovarian tumors ($p = 0.000$). hCG tissue expression is positive in 68% of OCs and carries a favorable outcome (when also LH-R positive/FSH-R negative) (158) suggesting that hCG and LH-R may be useful targets in novel cancer therapies.

In gynecologic malignancies, serum-free β-subunit or its urinary degradation product β-core fragment is produced by 68% of ovarian, 51% of endometrial, and 46% of cervical cancers. The free β-subunit enhances growth and invasion in all these malignancies and is therefore associated with poor prognosis. In clinical practice, confusion arises when a patient presents with persistently low positive hCG in absence of pregnancy and no obvious malignancies (159). The first aim is to rule out a tumor in these patients, then consider a false-positive test by assaying hCG in the urine. A further possibility in

women aged over 35 with oligomenorrhea, amenorrhea, or following bilateral salpingo-oophorectomy is pituitary hCG.

Inhibin and Related Peptides

Inhibin is a heterodimeric glycoprotein (composed of a common α-subunit and one of two β-subunits), resulting in either inhibin A (αβA) and inhibin B (αβB). There are other forms (α subunit not attached to the β subunit, pro-αC, and pro-αN-αC). The original Monash assay detected immunoreactive inhibin that included a range of inhibin-related peptides in addition to biologically active inhibin dimers.

Inhibin is elevated in women with granulosa cell tumors and is clinically used in differential diagnosis and surveillance of these malignancies. In the clinic, in addition to inhibin A and B, measurement of anti-Müllerian hormone (Müllerian inhibitory factor, AMH) levels is of value in the diagnosis of granulosa cell tumors. Elevated AMH and inhibin B are significantly elevated in patients with primary adult-type granulosa tumors and recurrent disease, and the combination of two markers is superior to inhibin B alone (160). The role of the inhibin peptides in EOC is less clear. Although there is encouraging data suggesting elevated serum inhibin levels in EOCs using either the original Monash assay (25% to 90%) or the total inhibin assay described in 2004 (93% of serous, 94% of mucinous tumors) (161), assays that measure inhibin A alone did not confirm this, as only 5% to 31% of patients with EOC had elevated levels (162). Use of pro-αC alone is not of use, but in combination with CA125 improves sensitivity for detection of EOC (163). Inhibin B is the main form secreted by granulosa cell tumors and reflects disease progression much better than inhibin A, and thus may be of value in the follow-up of these patients (164). As inhibin is rarely elevated in serous compared to mucinous tumors, it is used sparsely in the clinical setting.

The elevations of inhibin in patients with ovarian malignancies are presented in **Table 5.11**.

Activin is a dimer of the two β subunits of inhibin and exists as activin A (βAβA), activin B (βB βB), and activin AB (βA βB). Although serum activin A has been shown to be significantly elevated in EOC (165), with highest levels detected in undifferentiated tumors, the role of activin in OC requires further investigation. There is a suggestion that high concentrations of activin A in the peritoneal fluid of women with serous ovarian carcinoma can distinguish it from cystadenoma (166).

Kallikreins

The human kallikrein gene family currently consists of 15 members. There is accumulating evidence that in addition to prostate-specific antigen (PSA, hK3) and human glandular kallikrein (hK2) (both prostate cancer biomarkers), many other members of the human kallikrein gene family are differentially regulated in breast, ovarian, and testicular cancers. The malignant phenotype of ovarian cancer cells can be enhanced by overexpression of the human tissue kallikrein genes 4, 5, 6, and 7 (167). Potential biomarkers for OC include kallikreins 5, 6, 7, 8, 10, 11, and 14. Some kallikreins (e.g., K4) are upregulated in effusions from EOC patients (168) and may differentiate ascites between OC and non-OC patients (169). Kallikrein-related peptidase, KLK5, was found to be significantly elevated in the serum and ascitic fluid (41/41) of OC patients (42/52), with increased levels associated with poor patient outcome (170).

Of the kallikreins either expressed by ovarian cancer cells (KLKs 2 to 11 and 13 to 15) or elevated in serum (KLKs 5 to 8, 10, and 13), kallikrein-related peptidase 6 (KLK6) has been the most promising OC biomarker (171), and a specific ELISA serum assay has been developed. Kallikreins are key components of OVSCORE, an algorithm to predict surgical outcome in OC patients based on volume of ascites on ultrasound, tumor grade (laparoscopy/CT-guided biopsy), and KLK tissue expression, with KLK7 being an independent marker of OS. The hope is that OVSCORE, if independently validated, could aid in identification of patients who are unlikely to benefit from primary surgery (172). These findings are in keeping with the role of kallikrein-related peptidases in metastasis in OC (173).

Osteopontin

Despite encouraging data on the performance of osteopontin and mesothelin in OC, neither has been validated for any clinical use.

TABLE 5.11 Elevations in Inhibin or CA125 Levels in Women with Ovarian Cancer

	Cancer Group	Elevations in Inhibin[a] Levels (%)	CA125 > 35k U/L (%)	Inhibin + CA125 (%)
Malignant ovarian tumors	Serous	18	94	97
	Mucinous	84	71	94
	Endometrioid	54	91	90
	Other ovarian cancers	33 - 44	78 - 100	89 - 100
	Granulosa cell tumor	100	30	100
	All ovarian cancers	50	82	95

[a]Total inhibin.

Robertson DM, Pruysers E, Jobling T. Inhibin as a diagnostic marker for ovarian cancer. Cancer Lett. 2007;249(1):14 - 17.

Osteopontin is a biomarker that has been identified using gene expression profiling techniques. Its tissue expression is weak or absent in 93% of OCs compared with positive expression in 81.5% in borderline tumors and 50% in omental and lymph node implants. Its expression does not correlate with histologic type, grade, or clinical stage (174). A 2015 systematic review and meta-analysis that included 13 studies (839 OC patients and 1,439 controls) reported a sensitivity of 66% (95% CI, 51 to 78) and a specificity of 88% (95% CI, 78 to 93). Despite encouraging AUC of 0.85 (95% CI, 0.81 to 0.88), use of osteopontin is not recommended because the eligible studies were subject to selection bias (175). Osteopontin levels have been shown to correlate with the presence of ascites, bulky disease, and recurrence (176), and may be of value in detecting recurrent OC, as levels rise in 90% of these patients (177). Statins can inhibit OC proliferation by up to 50% with the effect being mediated by changes in osteopontin gene expression. Simvastatin-treated mice survive significantly longer compared to the controls. These findings need further exploration as a possible new drug therapy in OC (178).

Mesothelin

Mesothelin is a marker initially identified in mesotheliomas and OCs in 1996 (179). Serum levels are higher in OC patients when compared with women with benign ovarian tumors or healthy women. The levels increase significantly from early to advanced stages. Elevated mesothelin levels before therapy are associated with poor OS both in patients with optimal debulking surgery and in those with advanced disease (180). Mesothelin and MMP7 have both been assessed as part of multimarker panels but cannot add to the performance of CA125 and HE4 in predicting recurrence (107). Although it is possible that mesothelin may prove to be a useful tumor marker in the future, both for differential diagnosis of EOC as well as for prognosis, there is currently little data to suggest its significance.

Cytokines

Cytokines are soluble mediator substances produced by cells that exercise a specific effect on other target cells. Their importance in tumor biology has increased since it was shown that many cytokines are produced by cancer cells and can influence the malignant process in a positive or a negative manner (181). However, cytokines do not fulfill the classic criteria for tumor markers, as they may be elevated in a number of pathologic conditions, are invariably produced by nonmalignant surrounding tissue rather than the tumor itself, and are not specific for one cell type. Despite this, their measurement in malignant conditions may provide valuable clinical information regarding prognosis and response to treatment.

The role of cytokines as biomarkers in OC is limited. A majority are at an early stage of evaluation and conflicting reports are associated with some. The one studied the most, serum M-CSF (or CSF-1), was shown to have a high specificity for OC in the initial reports, with elevation being related to stage (182,183). It has been investigated in combination with other markers (CA125II, CA 72-4 and M-CSF) and was shown to have encouraging sensitivity for detecting early-stage disease compared to CA125II alone (70% vs. 45%), while maintaining high specificity (98%) (184). Elevated serum levels are associated with poor outcome (185). When combined with CA125 and HE4, M-CSF has an encouraging sensitivity for detecting serous OC, early-stage disease, and distinguishing OCs from benign lesions (186).

Interleukins have also been studied in OC. Although IL-6 is elevated in 50% of OCs, combination of IL-6 and CA125 does not improve the sensitivity of CA125 alone (187). More encouragingly, a combination of IL-7 and CA125 was found to accurately predict 69% of OC patients, without falsely classifying patients with benign pelvic mass (188).

Cytokeratins

Cytokeratins are intermediate filaments that are part of the cytoskeleton of all epithelial cells. They are specific markers of epithelial differentiation and continue to be expressed by epithelial cells following malignant transformation. Fragments of cytokeratins, in contrast to cytokeratins themselves, are soluble in serum and can be detected and measured using monoclonal antibodies. Their role as tumor markers in various malignancies has been investigated.

Tissue polypeptide-specific antigen (TPS) and CYFRA 21-1 (fragment of cytokeratin 19), although showing an encouraging sensitivity of around 50% in the original reports, have not shown further promise; some more recent studies suggest that CYFRA 21-1 is elevated in only 19.6% of OC patients (189).

Other Markers

Other serum markers have been assessed in isolation or as part of biomarker panels in women with OC, both in the context of screening and differential diagnosis, as well as in assessing prognosis, monitoring response to treatment, and detecting recurrence. **Table 5.12** details their current role in OC.

It is important to note that in women with OC, no single marker or combination of markers has emerged with a clear clinical advantage over CA125, except in specific tumor subtypes such as germ cell tumors with yolk sac and chorionic elements, and granulosa cell tumors. Few markers (TATI, CA19-9, CA 72-4, CEA combined with CA125) may be of value in non-mucinous OC (190). The results of the new approaches such as SWATH in proteomics and ctDNA are eagerly awaited. The consensus is that these new approaches are most likely to identify novel markers or marker panels that, in combination with CA125, will improve biomarker accuracy in OC.

With the ongoing efforts to detect OC using noninvasive approaches, saliva, liquid cytology, and more recently urine autofluorescence (191) may prove promising sources of novel biomarkers for OC.

ENDOMETRIAL CANCERS

A majority of women with endometrial cancer present symptomatically with abnormal vaginal bleeding, and are usually investigated using pipelle biopsy or hysteroscopy. Therefore, the role of serum markers has not been investigated with as much enthusiasm as in OC. Currently, there are no serum markers with an established role in the clinical management of endometrial cancer. Serum CA125 is elevated in 10% to 31% of patients, with elevated levels detected in 63% to 67% of patients with advanced stage compared with only 10% to 19% of those with early-stage disease (192). Preoperative assessment of serum CA125 may be useful in predicting the presence of extrauterine and metastatic disease, and to a lesser extent myometrial invasion, but it is not of benefit in the follow-up of these patients (193). Levels over 40 kU/L are correlated with higher stage, higher grade, increased depth of myometrial invasion, lymph node metastases, and the presence of lymphovascular space involvement, compared with lower levels (CA125 <40 kU/L) denoting a longer OS and recurrence-free survival (194). Despite some encouraging data on elevated CA125 and CA15-3 being poor prognostic factors, these markers are not used in the clinic.

Since the 1990s, a number of serum markers have been explored in endometrial cancer (CYFRA 21-1, urinary β-core or UGF levels, SCC and CA15-3, CA19-9, amino-terminal propeptide of type III procollagen, placental protein 4, CA72-4, OVX1 antigen, soluble interleukin-2 receptor, M-CSF, kallikrein 6, inhibinβB, matrix metalloproteinase 2 [MMP-2], survivin, p53, p21, polipoprotein A1, prealbumin, transferrin, Cathepsin-B, and serum amyloid A). However, none proved very useful, as evidenced by the lack of further publications.

Endogenous estrogens have a major role in endometrial carcinogenesis. Women with high circulating estradiol are at increased risk of endometrial cancer (RR 2.1 to 4.1) (195–197). Apart from estradiol levels, elevated estrogen metabolites (4-hydroxyestradiol (4-OHE2) may indicate risk of estrogen-induced endometrial cancer (198). Alongside estrogens and androgens, a number of other biomarkers associated with adiposity have been investigated in endometrial cancer such as insulin, glucose, IGF-1, SHBG, adiponectin, leptin, prolactin, and TSH (199). A 2014 review suggested that a routine measurement of adiponectin in patients with lifestyle-related diseases such as endometrial cancer may be recommended (200). Circulating adiponectin levels are inversely associated with risk of endometrial cancer (independent of BMI), suggesting that insulin and estrogen pathways are working in parallel in predisposing women to endometrial cancer (201).

TABLE 5.12 Status of Current Tumor Markers in Ovarian Cancer

Screening		Differential Diagnosis of an Adnexal Mass	Prognostic Indicator	Monitoring Response to Therapy	Monitoring Disease and Recurrence
Epithelial cancers					
Clinical practice		CA125 is the main marker—when combined with menopausal status and ultrasound features in the risk of malignancy index (RMI), a sensitivity of 71%–85% and specificity of 96%–97% is achieved. CEA	CA125 levels post surgery and during chemotherapy are independent prognostic indicators. Various criteria are used based on CA125 half-life.	Serial CA125 levels reflect clinical course in 90% of positive tumors and are used routinely for monitoring patients. HE4	CA125 detects recurrence with a sensitivity of 84%–94% and a false-positive rate of <2%. Median lead time compared with clinical diagnosis of recurrence is 60–99 days. HE4

Sex cord stromal tumors				
Clinical practice	Inhibin in granulosa cell tumors		Inhibin in granulosa cell tumors	

Proteomic markers for endometrial cancer have recently been identified in the serum (HSPA8) (202) and urine (N-glycopeptides) (203). Distinct miRNA profiles (miR-26a, let-7g, miR-21, miR-181b, mir-199c, miR-200c, miR-192, miR-215, miR-200c, and miR-205) have also been described in endometrial cancer patients. Further work in elucidating their role in these patients is warranted.

HE4 is also elevated in endometrial cancer. HE4, included as one of a panel of biomarkers, may be of use in risk stratification in endometrial cancer at an early stage in patients at high risk (204). Preoperative serum HE4 levels over 8 mfi (median fluorescence intensity units) was shown to be superior in detecting advanced stage disease compared with CA125. Median HE4 levels were significantly elevated in both Type I (>50% myometrial invasion and >2 cm tumor diameter) and Type II endometrial cancer. HE4 may therefore be of value in preoperative prediction of high-risk disease and guide the need for definitive surgical staging (205), and it may be of value in identifying high-risk patients within low-grade endometrioid endometrial cancer who may benefit from lymphadenectomy (206).

L1CAM (L1 Cell Adhesion Molecule) overexpression can identify low/intermediate risk patients with endometrial

cancer at high risk of recurrence. More recently, its role in prognosis of high-risk endometrial cancer was investigated in a study of 116 endometrial cancers (86 endometrioid, 30 non-endometrioid subtype) with high-risk features (such as high tumor grade and deep myometrial invasion). Use of a much higher threshold (50% positive staining compared to 10% in lower risk groups) identified women with L1CAM and p53 expression, which in combination may be useful prognostic markers (207). As a third of high-risk endometrial cancers overexpress L1CAM, it may be a potential novel therapeutic target in this subgroup of patients.

DNA methylation profile (ADCYAP1, ASCL2, HS3ST2, HTR1B, MME, NPY, SOX1) can discriminate carcinoma from benign endometrium with an AUC of 0.93 (208).

The last 5 years have seen promise in identification of novel biomarkers for endometrial cancer for risk stratification and early detection. With rising rates of obesity across the world combined with prolonged life expectancy, it is very likely that endometrial cancer incidence will increase within the next decade. Novel biomarkers/approaches may demonstrate a clinical utility for risk stratification and early detection in the future.

CERVICAL CANCERS

Screening for cervical cancer is one of the most prevalent and successful public health measures for cancer prevention. The screening strategy is based on exfoliative cytology, liquid-based cytology, and high-risk HPV DNA detection in cervical specimens. Currently no serologic markers have been identified that are sensitive or specific enough for screening purposes. However, a variety of serum markers have been investigated in assessing prognosis, monitoring response to treatment, and detecting recurrence.

Squamous Cell Carcinoma Antigen (SCCA)

Squamous cell carcinoma antigen (SCCA) is one of 14 subfractions of tumor antigen TA-4. Elevated levels of SCCA are found in 57% to 70% of women with primary squamous cell carcinoma (SCC) of the cervix (209). SCCA is not specific for cervical SCC; elevated levels are found in other SCCs of the head and neck, esophagus and lung, and in adenocarcinoma of the uterus, ovary, and lung. SCCA is probably a marker of cellular differentiation of squamous cells, as the incidence of elevated serum levels is higher in women with well-differentiated (78%) and moderately differentiated carcinoma (67%) than in those with poorly differentiated tumors (38%) (210). Its levels before treatment indicate poor response to chemotherapy and indicate a high risk of recurrence (211).

Similar to the other gynecologic cancers, the ability of a marker to detect the disease/recurrence early works in tandem with optimal treatment being delivered. In cervical cancer, rising levels of SCCA precede clinical detection of recurrent disease and can therefore be used in its earlier diagnosis. However, SCCA monitoring is not implemented routinely because adequate curative strategies are currently not available (212). There is no evidence that earlier detection of recurrent disease influences treatment outcome or prognosis after primary treatment.

SCCA may be of value in individualizing treatment, but no randomized trials have yet been conducted to confirm this hypothesis. There is no evidence that more aggressive treatment improves pelvic control and survival in patients with elevated SCCA levels (213).

Preliminary studies suggest that SCCA isoforms (free SCCA2, total SCCA2, total SCCA1, and total SCCA) may provide additional clinical information when compared to total SCC antigen. Roijer *et al.* evaluated specific serum immunoassays for the different isoforms of SCCA. Patients with recurrence or progressive disease have rising levels of SCCA1 and SCCA2, with elevations in SCCA2 being more prominent than that in SCCA1 (214).

In a more recent series of 138 patients with Stage I-IVA cervical cancer, SCCA was shown to be the only independent prognostic factor for DFS, with the combination of IL-6 and SCCA being prognostic for OS. In women with early-stage disease (of whom 45% recurred), VEGF was of prognostic value for DFS while IL-6 and CYFRA 21-1 was of prognostic

value for OS. The findings indicate that these markers measured prior to diagnosis may be useful prognostic indicators (215).

In conclusion, SCCA may prove useful in the pretreatment identification of squamous cervical cancer patients at high risk of lymph node metastasis, and in pretreatment prediction of prognosis, monitoring response to treatment, and detecting recurrence. However, further studies are needed before clinical recommendations can be made.

CYFRA 21-1, CA125, CEA

Elevated CYFRA 21-1 levels are observed in squamous cell carcinoma (SCC) (35% Stage IB-IIA, 64% Stage IIB-IV disease) (216) and 63% of patients with cervical adenocarcinoma (217). Despite some data suggesting it has a role in follow-up and predicting residual tumor post-chemoradiation (218), the evidence available so far does not justify its routine measurements.

Serum CA125 has a limited value in cervical cancer. It is more frequently elevated in cervical adenocarcinoma compared with SCC. (219). CA125 levels rise with advancing stage of cervical cancer akin to SCCA levels (220). Falling CA125 levels are observed in those who respond to chemotherapy (221). Serum CEA alone is less useful in cervical cancers, with an overall sensitivity of 15% (at a 90% specificity) (222).

Other Markers

Methylation markers (DNA methyltransferase, tyrosine phosphatase receptor type R promoter) have been evaluated in cervical cancer and may play a role in cancer development and metastasis (223). As p16(INK4a) is overexpressed in virtually all HPV-transformed cells, it can improve the accuracy of cytology-based cancer early-detection programs (224). It is anticipated that the introduction of prophylactic HPV vaccines will reduce the incidence of cervical cancer and its malignant precursors, thus focusing effort on identifying women at high risk who would then require treatment, as well as improve the triage of the HPV-positive tests. It is believed that biomarkers will also serve an important role in the optimization of this alternative screening algorithm; therefore, the efforts continue to identify the biomarkers best-suited for this purpose.

As in OC, ctDNA has been explored as a biomarker in cervical cancer, with circulating Bmi-1 mRNA shown as an independent prognostic factor for DFS and OS (225).

Programmed death ligand 1 (PD L1) expression has been shown in many cancers and anti-PD L1 therapy has shown significant promise in recent years. In cervical cancer, PDL1 expression has not been shown in normal cervical epithelia even when adjacent to CIN or cancer but increased expression was reported in 95% of CIN and 80% of cervical squamous cell cancers suggesting a potential role for anti-PD L1 therapy in cervical cancer. In contrast, only 19% of endometrial and 13% of ovarian cancers expressed PD L1 (226).

Efforts of the past 5 years have focused on noninvasive samples that women could easily collect themselves. Cervicovaginal fluid captured on tampons is one way of testing that could, in principle, identify precancerous lesions. A multicenter randomized controlled trial of 14,041 women demonstrated that mailing of a self-collection kit to the woman's home resulted in a higher participation in a screening programme compared to a clinic visit, even in those having HPV as the primary screening test (227).

VULVAR AND VAGINAL CANCER

Tumors of the vulva and the vagina are rare and there are relatively few studies on circulating markers in these conditions. Few markers have been evaluated; TPS being elevated in 80% of patients with vulvar or vaginal cancer (228), SCC in 43%

(229), urinary core fragment of the β-subunit of hCG in 38% (230). The latter is a poor prognostic factor (90% of patients with elevated levels die within 24 months vs. 32% of those with normal levels). Very few markers have been explored in vulvar cancer, with data from a small study suggesting that loss of Rho-associated coiled-coil-containing protein kinase 1 (ROCK1) expression at a tissue level is associated with poorer survival (231). Whether this translates into a role for circulating ROCK1 in vulvar cancer is not known.

In view of the recent advances in sequencing technology, there has been a wealth of data gathered on biomarkers for gynecologic cancers. However, it will be some time before we are able to unravel the complexities of these molecular changes in a way that translates into therapeutic benefit (232).

CHAPTER 6 Cancer Prevention Strategies

Mary B. Daly and Gina M. Mantia-Smaldone

INTRODUCTION

As our knowledge of the genetic, physiologic, environmental, and lifestyle factors associated with the carcinogenic process grows, the prevention of cancer is increasingly becoming a reality and being incorporated into oncology practice. Options for the primary prevention of cancer are expanding and include avoidance of carcinogens (e.g., smoking cessation, sun avoidance, removal of asbestos), diet modification, exercise and weight loss, use of cancer vaccines, prophylactic surgery, and chemoprevention. Avoidance of tobacco and sun exposure and elimination of obesity could have a major public health impact on cancer incidence, as well as other chronic conditions (1,2). Options for secondary prevention through screening for occult disease when treatment may be more effective are also becoming more sophisticated. Great strides have been made in the prevention of many of the most common cancers.

The most common risk factor for lung cancer, which is the largest cause of death from cancer for both men and women, is tobacco use. Primary prevention strategies, including tax increases on tobacco products, mass media campaigns, restrictions on smoking in public places, and the physiologic and psychological treatment of nicotine addiction, have all contributed to the reduction in smoking prevalence rates and the decrease in the incidence of lung cancer (3,4). Recently, low-dose spiral CT (LDCT) scans have been shown to detect earlier-stage lung cancer, resulting in a reduction in lung cancer mortality (5). This has led to the recommendation of LDCT screening in at-risk populations by the United States Preventive Services Task Force (6).

Nonsteroidal anti-inflammatory drugs (NSAIDs) reduce the risk of adenomatous polyps and invasive cancer among individuals with very high risks of colon cancer due to hereditary syndromes (7). Their use for primary prevention among individuals at average risk, however, is not recommended due to potential side effects. A moderate risk reduction has been seen among individuals at population risk for colorectal cancer who use long-term aspirin prophylaxis (8). There is also evidence that alteration of lifestyle factors, including adoption of a healthy diet and avoidance of obesity, smoking, and heavy alcohol use, would have a significant impact on colon cancer incidence (9). Perhaps the greatest contribution to the prevention of colorectal cancer is the increasing adoption of screening colonoscopy to identify and remove premalignant polyps (10).

Alcohol consumption and obesity in postmenopausal women are associated with an increased risk of breast cancer, suggesting that changes in dietary patterns would have a protective effect on breast cancer incidence (11). Large randomized trials have established the efficacy of both tamoxifen and raloxifene to prevent estrogen receptor–positive breast cancer (12–14). More recently, the aromatase inhibitors anastrozole and exemestane have been shown to confer a similar risk reduction in the incidence of breast cancer among high-risk women (15,16). With the demonstration of the increased risk in breast cancer associated with combined estrogen and progesterone hormone replacement therapy (HRT) by the Women's Health Initiative, the use of these products has declined significantly, and the decline is thought to be

associated with a subsequent decrease in breast cancer incidence (17,18). Both prophylactic mastectomy and prophylactic oophorectomy reduce the risk of breast cancer and are considered options for women with hereditary syndromes that convey high rates of breast and ovarian cancer (19,20). There have been several advances in screening modalities for breast cancer. The recent addition of breast tomosynthesis to digital mammography has been shown to reduce the recall rate and increase cancer detection rate among women at population risk of breast cancer (21). The use of screening breast MRI in selected high-risk individuals has improved the detection of early-stage occult cancers and has led to a downstaging of disease (22,23).

A large randomized trial of finasteride, which reduces the androgenic stimulation of the prostate, produced a 30% reduction in prostate cancer incidence (24). Several other agents targeting inflammatory, antioxidant, and other pathways have been proposed as chemopreventive agents for prostate cancer, but so far none have proven efficacy (25). The role of prostate cancer screening with digital rectal examination and serum prostate-specific antigen (PSA) levels among average-risk men has recently been challenged on the basis of high rates of detection of indolent disease (26). The role of screening high-risk men, African American men, and those with a family history of this cancer is the subject of ongoing studies.

The prevention of gynecologic cancer is becoming a reality due to the recognition that the initiation and progression of gynecologic cancers is a multistep process characterized by distinct molecular genetic events that provide opportunities to intervene in the carcinogenic process at several steps and reverse its early stages. The concept of preventing gynecologic cancer is based on an understanding of causally related risk factors, their role in carcinogenesis, and opportunities for their avoidance and/or reversal of their effect. There are three distinct models that can be applied to gynecologic cancer prevention: (a) *risk avoidance and adoption of protective practices*, which includes the identification of key risk factors and the development of strategies for their avoidance. Included in risk avoidance are the avoidance of exogenous and endogenous exposures (chemical, hormonal, infectious, etc.) and the avoidance of risky health behaviors. The adoption of protective practices, such as vaccination with the human papillomavirus (HPV) vaccine, a healthy diet, and exercise, may forestall early premalignant events; (b) the use of *chemopreventive agents*, both natural and synthetic, to reverse early, premalignant changes; and (c) *surgical prophylaxis* to remove either healthy at-risk organs or tissues with premalignant changes.

In addition to establishing valid interventions for cancer prevention, it is important to identify optimal target populations for their application and to tailor the interventions to the level of risk. Interventions for use in the general population at average risk must be highly effective, safe, inexpensive, and socially acceptable. Population groups with high risks may tolerate interventions that confer more risk and higher costs. All prevention efforts are greatly enhanced by public and professional education about their use and by a health care system that values, promotes, and invests in prevention activities.

The avoidance of environmental, occupational, and lifestyle risk factors through public education and social policies has the potential to prevent a large proportion of human cancer. The epidemiologic literature has provided a wealth of information about the risks associated with cancers of the cervix, uterus, and ovary, which allows us to devise risk avoidance and risk reduction strategies. This chapter focuses on the opportunities for primary prevention of these three cancers and directions for the future.

CERVICAL CANCER

Risk Factors

Approximately 13,000 new cases of cervical cancer are diagnosed per year in the United States, and over 4,000 women die of the disease. The disease burden is not distributed equally but is overrepresented among African American, Hispanic/Latina, and American Indian women (27). However, the greatest burden of cervical cancer is in the developing countries (**Fig. 6.1**), which account for 86% of the cases and 88% of deaths (28). Traditionally, the most significant

factors associated with the risk of cervical cancer have been the number of sexual partners and early onset of sexual activity. This observation has led to the discovery that the primary cause of cervical cancer, and its precursor, intraepithelial lesions, is persistent infection with HPV, which is sexually transmitted. The HPVs comprise a large (over 100 types) family of viruses that infect skin and mucosa (**Fig. 6.2**). Of the approximately 40 HPV types that infect the genital tract, about one-half are associated with anogenital warts that are nononcogenic or are considered to pose a low risk of malignancy. The other half may give rise to a range of anogenital cancers, including cancers of the cervix, vulva, and anus in women, and penis and anus in men, and are referred to as high risk or oncogenic (29). HPV types 16 and 18 alone account for >70% (**Fig. 6.3**) of all cervical cancers. Similarly, HPV types 6 and 11 account for >90% of all anogenital warts. In the United States, where the median age of sexual debut is 17 years, close to 20% of girls are sexually active by age 15 years and close to 60% are sexually active at age 18 years. As a result, the infection rate of HPV among the general population is high, peaking in the second and third decades of life when infection rates range from 27% to 46% (30). The median length of infection is 8 to 12 months, and most individuals have cleared the virus by 2 years. A small proportion, 10% to 13%, however, develop chronic persistent HPV infection, which can lead to genital warts, cervical dysplasia, carcinoma *in situ*(CIS), and invasive cancer (**Fig. 6.4**). Persistence of HPV infection is likely to be related to modifying factors, including immune status, the use of oral contraceptives (OCPs), smoking, and infection with other sexually transmitted diseases (31). Prolonged duration of OCP use is thought to function as a promoter of HPV-related carcinogenesis, not as a facilitator of HPV infection, although the mechanisms are uncertain (32). Tobacco carcinogens have been found in cervical secretions, and it is postulated that smoking constituents may interact with HPV to induce immunologic changes leading to cervical dysplasia, or may produce genomic damage via genotoxins (33,34).

Prevention

Risk Reduction and/or Adoption of Healthy Practices

Cervical cancer prevention requires decreasing the risk of infection with oncogenic strains of HPV. Few sexual partners and the use of condoms have been associated with a reduced risk for cervical cancer (35). Avoidance of factors that enhance the persistence of HPV infection, viz. smoking and OCP use, has the potential to reduce the rate of malignant change. OCPs, however, are the most effective means of contraception, and their avoidance overall is not a wise public health strategy. Safe and effective vaccines now offer the best option for cervical cancer prevention. Early studies in animal models provided the proof of principle that neutralizing antibodies, directed to determinants on the major viral capsid protein, were generated by infection with HPV and could be detected in the serum. In the early 1990s, it was found that the L1 protein, when expressed in recombinant vectors, self-assembled into virus-like particles (VLPs), which closely resemble the antigenic characteristics of the wild-type virions. VLPs formulated on aluminum adjuvants were shown to induce a strong virus-neutralizing antibody response in nonhuman primates (36,37), leading to their development for human populations. A series of phase 1 trials in humans tested the immunogenicity and safety of monovalent VLP-based vaccines and found that they generated levels of neutralizing antibodies that far exceeded those seen in natural infections, and were sustained at long-term follow-up. The predominant antibody responses are of the immunoglobulin G1 (IgG1) subclass (29). In these early trials, vaccine efficacy against infection with HPV-16/18 and against cervical intraepithelial neoplasia (CIN) 2+ at 6.4 years of follow-up was 100% (38).

Subsequently, three vaccines have been developed for use in humans: Gardasil (Merck), a quadrivalent vaccine that includes HPV-16, -18, -6, and -11 and is formulated with aluminum adjuvant; Gardasil 9, which includes five additional oncogenic HPV types; and a bivalent vaccine Cervarix (GlaxoSmithKline), which includes HPV-16 and -18 and is formulated with a proprietary adjuvant, AS04, which contains aluminum and a bacterial lipid. Data from several clinical trials of the quadrivalent vaccine Gardasil reported vaccine efficacy of 99% against CIN grade II–III or adenocarcinoma *in*

situ. Protection remains evident 8 years after completion of a three-dose protocol (39). Combined analysis of the FUTURE I and FUTURE II randomized double-blind trials has also demonstrated protection against low-grade HPV-related lesions. At 42 months of follow-up, efficacy in the HPV naïve population was 96% for CIN grade I, 99% for condyloma, and 100% for vulvar and vaginal intraepithelial neoplasia (40).

A recent international randomized, double-blind clinical trial compared the immunogenicity, efficacy, and safety of a new nine-valent HPV vaccine, which includes the original quadrivalent HPV types and five additional oncogenic types, 31, 33, 45, 52, and 58, with the quadrivalent vaccine. The incidence of disease associated with HPV types 6, 11, 16, and 18 was similar in the two groups. There was a 96% reduction in incidence of high-grade cervical, vulvar, and vaginal lesions associated with HPV types 31, 33, 45, 52, and 58 in the nine-valent arm. Nearly 100% of women in the nine-valent arm underwent seroconversion within 1 month of vaccination. The rate of mild to moderate injection-site adverse events was higher in the nine-valent vaccine, and is attributed to an increase in the amount of HPV VLP antigens compared with the quadrivalent vaccine. As the nine types of HPV included in the new vaccine account for 90% of all cervical cancer, the introduction of this vaccine is likely to represent an important advance in the elimination of cervical cancer (41,42).

In June 2006, Gardasil received Food and Drug Administration (FDA) approval for the vaccination of females aged 9 to 26 years, followed closely by approval for its use in children and adults aged 9 to 26 years by the European Commission.

Early studies of the bivalent vaccine Cervarix established its immunogenicity, efficacy, and safety. In the large double-blind randomized trial, the Papilloma Trial against Cancer In young Adults (PATRICIA), high vaccine efficacy for Cervarix was shown among women aged 15 to 25 years against persistent infection and high-grade CIN associated with HPV-16 and -18, with some cross-reactivity with other HPV types. In the final event-driven analysis of PATRICIA, vaccine efficacy was 50%, 70%, and 87% against CIN 1+, CIN 2+, and CIN 3+, respectively, among women negative for evidence of HPV infection at baseline. Among the total vaccinated cohort, which included some women with evidence of previous or current HPV infection, the vaccine prevented 30% and 33% of CIN 2+ and CIN 3+, respectively. Immunogenicity persisted through 36 months of follow-up (43).

The demonstrated efficacy of the HPV vaccines in young women led to similar trials of vaccine efficacy in males, in whom HPV is associated with a significant proportion of anal, penile, and oropharyngeal cancers, as well as anogenital warts. In a randomized, double-blinded, placebo-controlled trial, the quadrivalent HPV vaccine resulted in seroconversion for HPV-6, 11, 16, and 18 in over 97% of vaccinated subjects. Efficacy against external genital lesions associated with these HPV types was 90.4%, and an 85.6% reduction in persistent infection was observed (44). The vaccine is currently recommended for males aged 9 through 26 years.

The Advisory Committee on Immunization Practices (ACIP) of the Centers for Disease Control and Prevention (CDC) recommends routine vaccination for HPV of girls aged 11 to 12 (range, 9 to 26 years) and has added Gardasil to its Vaccines for Children Program (45,46). Similarly, the American Academy of Pediatrics recommends that all girls should be vaccinated against HPV at age 11 to 12 years (47). The more recent data on vaccine efficacy in males have expanded the indication for HPV vaccination to include males. Currently, the CDC recommends a three-dose series of four-valent and nine-valent HPV vaccine for boys and men aged 9 to 26 years.

There are several questions remaining regarding the use of HPV vaccines. The duration of protection afforded by HPV vaccines is not fully known, although data from the large efficacy trials report continuing protection 8 years after completion of the vaccination protocol (39). The need for a booster dose and the degree of cross-reactivity are also unknown. Despite official recommendations for vaccination, and improving insurance coverage for the cost of the vaccine, uptake of at least one dose of HPV vaccine among females in the United States was only 57% in 2013 (48), and rates are even lower among males. One of the factors most strongly related to vaccine uptake is recommendation by a provider. However, surveys have found that only a minority of providers routinely recommends HPV vaccine and the recommendation is often inconsistent, behind schedule, and without urgency (49).

Much work remains to be done to educate the public about HPV and cervical cancer. Recent studies have shown that the majority of women are unaware of the link between HPV and cervical cancer. Awareness of HPV is increased among

young women, more educated women, and those with more access to the health care system (50,51). Public health efforts to introduce the vaccine should clearly be accompanied by vigorous educational programs directed at both young women and their parents to increase acceptability and the success of the HPV vaccine program. Since the introduction of Gardasil into clinical care, there has been vigorous debate about the issue of compulsory HPV vaccination. Concerns raised include the lack of long-term safety data, the expense of the vaccine, and resistance to governmental coercion (52). Another concern that parents and other groups have expressed is the fear that vaccination against HPV may lead to a sense of invulnerability, would undermine abstinence-based messages, and may increase high-risk sexual behavior. There is no data, however, to suggest that fear of HPV is an important deterrent from sexual activity in young men or women. Several states have considered legislation to mandate HPV vaccination, although few have actually enacted such laws. All of the proposed laws have opt-out provisions for parents who object. However, they do not address the potential financial burdens imposed by the mandate. Mandating HPV vaccination would certainly boost vaccine coverage rates but at a price of loss of parental autonomy.

These and other vaccine-related concerns will need to be addressed by primary care providers as well as public health officials. Vaccine delivery by primary care practitioners in the United States is approximately 32% among 13- to 17-year-old girls. In contrast, rates of vaccination completion in the UK and Australia, where vaccine programs are school-based, are much higher (ő84% and ≥72%, respectively) (53).

The most significant unresolved issue pertains to the application of HPV vaccines to underdeveloped nations, where the greatest burden of disease attributable to HPV is found (**Fig. 6.5**). Contributing to this burden is a lack of understanding of the dimensions of the disease, weak infrastructures and insufficient funds for population-wide vaccination programs, and lack of political will to address the behavioral and public health issues pertinent to a sexually transmitted disease. The delivery of a new vaccine to a nonpediatric population is particularly problematic in countries with limited public health resources. Yet it is precisely in these countries that the potential benefit for a widespread vaccination program is greatest. Administering the vaccine in infancy along with other basic childhood vaccines may be the best choice, even though the duration of protection is at this time unknown. Clearly, the support of the international community will be required to make HPV vaccination a reality in the third world.

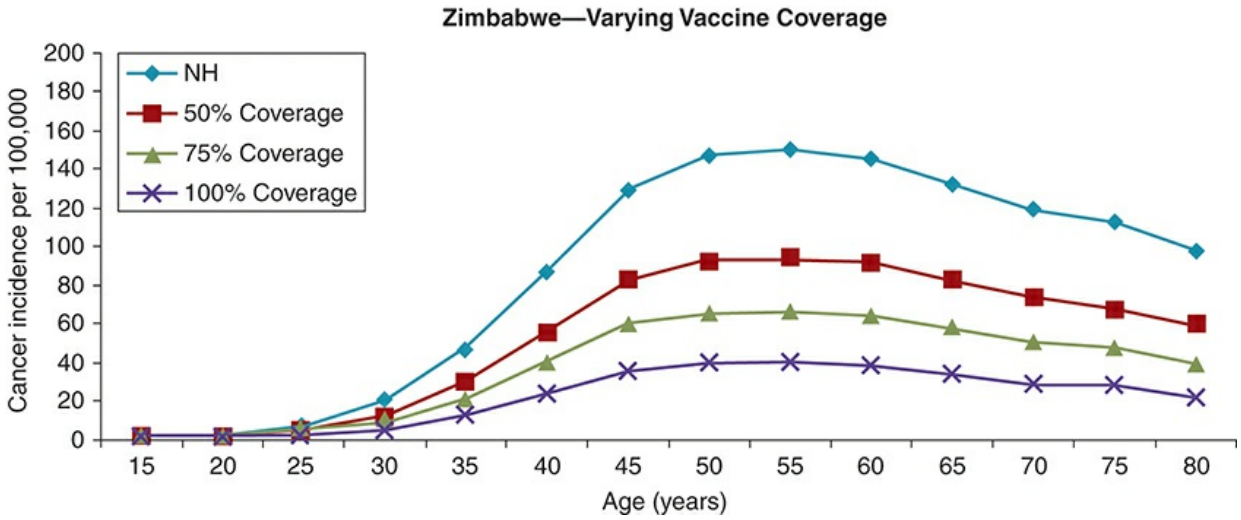

Figure 6.5 Impact of HPV-16/18 vaccines on incidence of cervical cancer.

Chemoprevention

Several promising targets for the chemoprevention of cervical cancer have been identified, including topical retinoids, carotenoids, prostaglandins, indole-3-carbinol, green tea, folic acid, and immune modulators (54–56). In phase 1 and 2 trials, topical retinoids applied directly to the cervix resulted in significant complete histologic regression of CIN 2 lesions

compared to placebo (57). None of the proposed agents, however, have been subject to definitive phase 3 randomized trials.

Surgical Prophylaxis

The introduction of widespread cervical cancer screening using the Papanicolaou (Pap) smear has dramatically reduced the incidence of invasive cervical cancer through the detection of treatable, premalignant lesions, referred to as CIN. Recently, the detection and quantification of oncogenic HPV DNA in cervical epithelial cells has been added to routine Pap screening in selected situations, with demonstrated improvement in sensitivity. Co-testing with HPV DNA detects high-grade lesions earlier, thus providing a subsequent longer low-risk period. HPV screening is recommended in women with atypical squamous cells of undetermined significance (ASCUS) on cytology, co-testing with cytology in asymptomatic women aged 30 years and older, among whom a positive HPV screen is thought to represent persistent infection, and in the follow-up of treated individuals for more aggressive detection and management of persistent HPV infection (30). Its use in asymptomatic women under the age of 30 leads to overdiagnosis because of the transient nature of infection in this age group. Studies of cost-effectiveness of co-testing with HPV DNA and cytology offer a cost saving by allowing for a reduction in the frequency of screening (58). Primary high-risk HPV (hrHPV) screening is being evaluated as an alternative to cytology-based testing (59).

Transient HPV infections are associated with low-grade lesions (CIN 1). When oncogenic HPV infections persist, the viral genome is integrated into the host genome and cervical lesions progress to more advanced lesions (CIN 2 and VIN 3) (60). Because of the high rate of spontaneous regression, management of women with CIN 1 and satisfactory colposcopy (visualization of the entire squamocolumnar junction) is repeat cytology at 6 and 12 months or DNA testing for oncogenic types of HPV at 12 months. Alternatively, ablative (cryotherapy, electrocoagulation, or laser vaporization) or excisional (cold-knife conization or loop electrosurgical excision procedure [LEEP]) treatment may be offered. If the entire squamocolumnar junction cannot be visualized, an excisional procedure is the preferred approach. Treatment of CIN 2–3 lesions with satisfactory colposcopy involves excision or ablation of the entire transformation zone rather than just the colposcopically identified lesion (61). Cryotherapy, laser vaporization, and LEEP all appear to be effective modalities, although over time LEEP has become the procedure most widely chosen. When colposcopy is not satisfactory, a diagnostic excisional procedure is recommended. A variety of posttreatment surveillance protocols utilizing cervical cytology with or without colposcopy and HPV testing at frequent intervals have been proposed. Hysterectomy is reserved for recurrent or persistent biopsy-confirmed CIN 2–3, for positive margins when repeat diagnostic excision is not possible, or for women with persistent CIS who have been previously treated and who no longer desire fertility (62). This approach to cervical cancer prevention based on large-scale cytologic screening programs is not feasible, however, in countries in the developing world, due to lack of infrastructure, funding, and public health education (**Tables 6.1** and **6.2**).

TABLE 6.1 Cervical Cancer—Major Points

Widespread screening using Pap smear has dramatically reduced the incidence of invasive cervical cancer.
Virtually all cervical cancer is related to persistent infection with HPV.
HPV infection is common, affects up to 50% of women, and peaks in the second and third decades of life.
Altered immune status, smoking, and the use of OCPs affect the rate of persistent HPV infection.
Cervical cancer is a leading cause of cancer morbidity and mortality among women in the underdeveloped world.
Three HPV vaccines have shown high efficacy in eliminating persistent HPV infection and cervical lesions in previously uninfected women.

HPV, human papillomavirus; OCPs, oral contraceptives.

TABLE 6.2 Cervical Cancer—Remaining Questions
What is the duration of protection of HPV vaccines?
What is the extent of cross-vaccination with the current HPV vaccines?
What is the sociocultural acceptability of vaccinating adolescent girls?
What is the added benefit of vaccinating males?
What is the impact of effective vaccination on subsequent screening practices and screening performance?
Which methods will best educate the public about HPV vaccines?
How should HPV vaccines be made available to underdeveloped nations?
What are the best cervical cancer screening approaches for use in underdeveloped countries?

HPV, human papillomavirus.

OVARIAN CANCER

Risk Factors

Ovarian cancer is the most common cause of death from a gynecologic cancer in the United States and accounts for approximately 14,180 deaths per year (63). Worldwide there are 238,700 new cases (64) and 157,800 deaths per year (65). Ovarian cancers are categorized as serous, endometrioid, clear cell, and mucinous. These categories are further divided into high grade and low grade. High-grade serous cancer represents the majority of epithelial ovarian cancers (66). Due to a lack of effective screening tools to identify ovarian cancer at early, highly curable stages, the majority of ovarian cancers are diagnosed at advanced stages when survival is poor. Historically, the origin of epithelial ovarian cancer was believed to be from the invagination of ovarian surface epithelium (OSE) into the ovarian stroma forming inclusion cysts, which had the potential to undergo malignant transformation (67). The recent adoption of prophylactic salpingo-oophorectomy for women with deleterious mutations in *BRCA1* and *BRCA2*, however, has challenged that theory. Careful examination of the fallopian tubes obtained at the time of prophylactic surgery has identified a high prevalence of occult primary serous carcinomas and serous tubal intraepithelial carcinomas (STIC) in the fimbrial end of the fallopian tube. Up to 15% of women with *BRCA1/2* mutations who undergo prophylactic bilateral salpingo-oophorectomy (BSO) harbor these lesions in the fallopian tubes (68,69). Both lesions are often accompanied by p53 mutations, also at the fimbriated end of the fallopian tube (70,71), suggesting that STIC is the precursor lesion for invasive ovarian carcinoma. While these changes were originally thought to be present only in women with *BRCA1* or *BRCA2* mutations, there is growing evidence pointing to the existence of these precursor lesions among women who develop sporadic serous ovarian cancer (72). Up to 60% of women with sporadic ovarian cancer may also have STICs or early invasive fallopian tube cancers identified (68). The distal fallopian tube, therefore, is increasingly being seen as the origin of tubal, ovarian, and peritoneal serous ovarian cancer. The fallopian tube is also implicated in the presentation of endometrioid and clear cell ovarian cancers, which are attributed to the passage of endometriosis tissue from the uterus through the fallopian tube to implant on the surface of the ovary or the peritoneum where it can undergo malignant transformation (73).

While our understanding of the biology of epithelial ovarian cancer is rapidly advancing, most of our current knowledge regarding risks for ovarian cancer has emerged from the epidemiologic literature. Advancing age, reproductive factors (specifically, nulliparity), and heredity are established risk factors for the disease. The majority of ovarian cancers are diagnosed after menopause. Rates are higher in nulliparous women, while parity has been found to offer protection. The risk of ovarian cancer is increased twofold in women who are infertile, and the risk appears to be independent of fertility

drug treatment (74). Chronic inflammation, with its attendant increase in cell proliferation and potential for DNA disruption, has been proposed as a precursor for many cancers, including ovarian cancer. Endometriosis and pelvic inflammatory disease, both of which induce chronic inflammatory states, and possibly talc are associated with ovarian cancer (75,76).

Although the majority of cases of ovarian cancer are sporadic, up to 20% are thought to fit a hereditary pattern of autosomal dominant inheritance (77). Epidemiologic studies have estimated a two- to fourfold increase in risk among first-degree relatives of women with ovarian cancer. Recently, a number of genes have been identified that account for a large percentage of hereditary ovarian cancer and that allow more precise estimates of risk. Since the identification of *BRCA1* on chromosome 17q in 1994, and *BRCA2* on chromosome 13q in 1995, several hundred mutations in these genes have been characterized, many of which lead to premature truncation of protein transcription and, therefore, presumably defective gene products. Ovarian cancer in these families is characterized by multiple cases of ovarian and breast cancer in successive generations, earlier age of onset, and evidence of both maternal and paternal transmission (**Fig. 6.6**). The penetrance of *BRCA1/2*, that is, the likelihood that a mutation will actually result in ovarian cancer, is estimated to range anywhere from 36% to 46% for *BRCA1* mutation carriers, and from 10% to 27% for *BRCA2* mutation carriers (20). Some mutations may be more specifically related to ovarian cancer risk than others. Ovarian cancer cluster regions have been identified within the *BRCA1* gene from c.1380 to c.4062 (within exon 11) and within the *BRCA2* gene from c.3249 to c.5681 (near c.5946 dekT) and from c.6645 to c.7471, which carry a higher risk of ovarian cancer than breast cancer (78). The wide variation in penetrance observed may also reflect the interaction of the genetic mutation with other genetic and/or environmental factors, and suggests that these genes may function as "gatekeepers" and, when lost, allow other genetic alterations to accumulate. Ovarian cancer is also included in the phenotype of the mismatch repair genes (*MSH2*, *MSH6*, *MLH1,* and *PMS1*) associated with the hereditary nonpolyposis colon cancer, or Lynch syndrome, in which the lifetime risk for ovarian cancer is estimated to be approximately 12%, and the median age at diagnosis 42.7 years (**Fig. 6.7**). The risk may be highest for women with *MLH1* or *MSH2* mutations, with up to 24% lifetime risk compared with 11% for women for *MSH6* and <10% for *PMS2* (79–81).

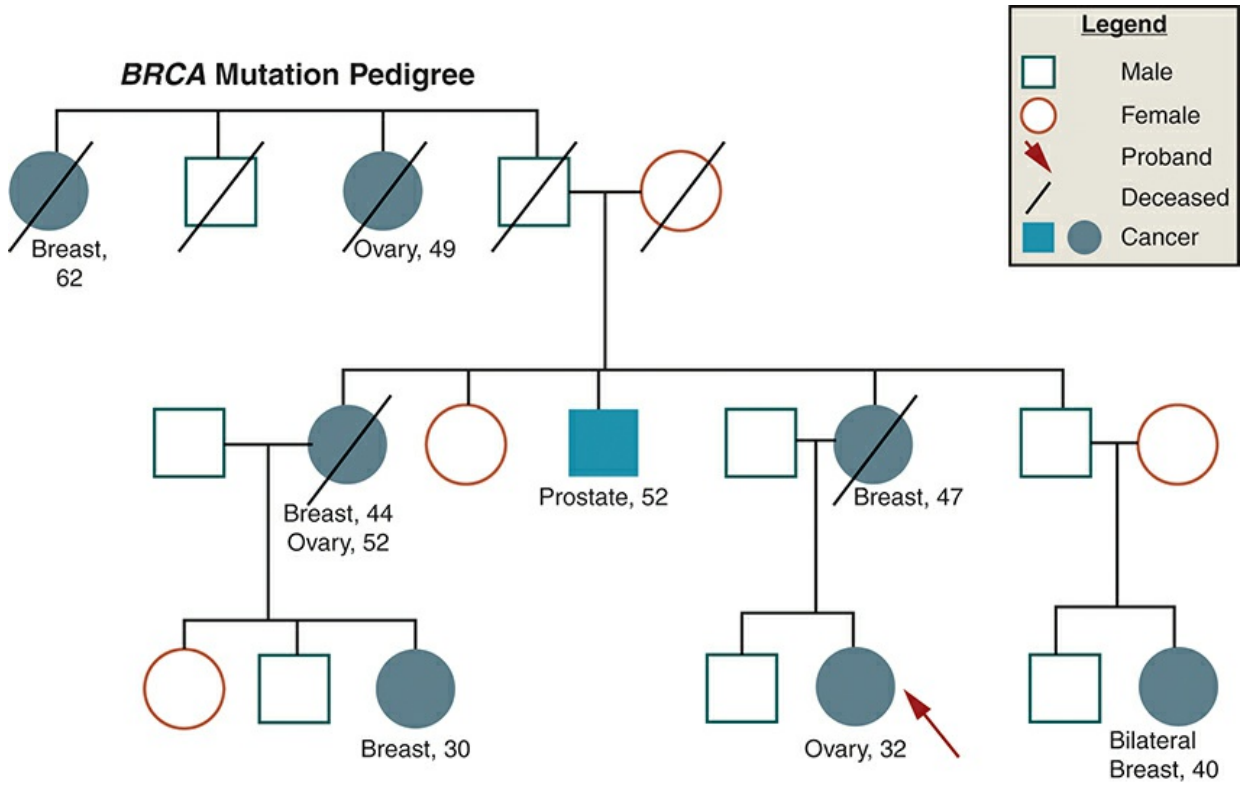

Figure 6.6 Family pedigree illustrating BRCA mutation.

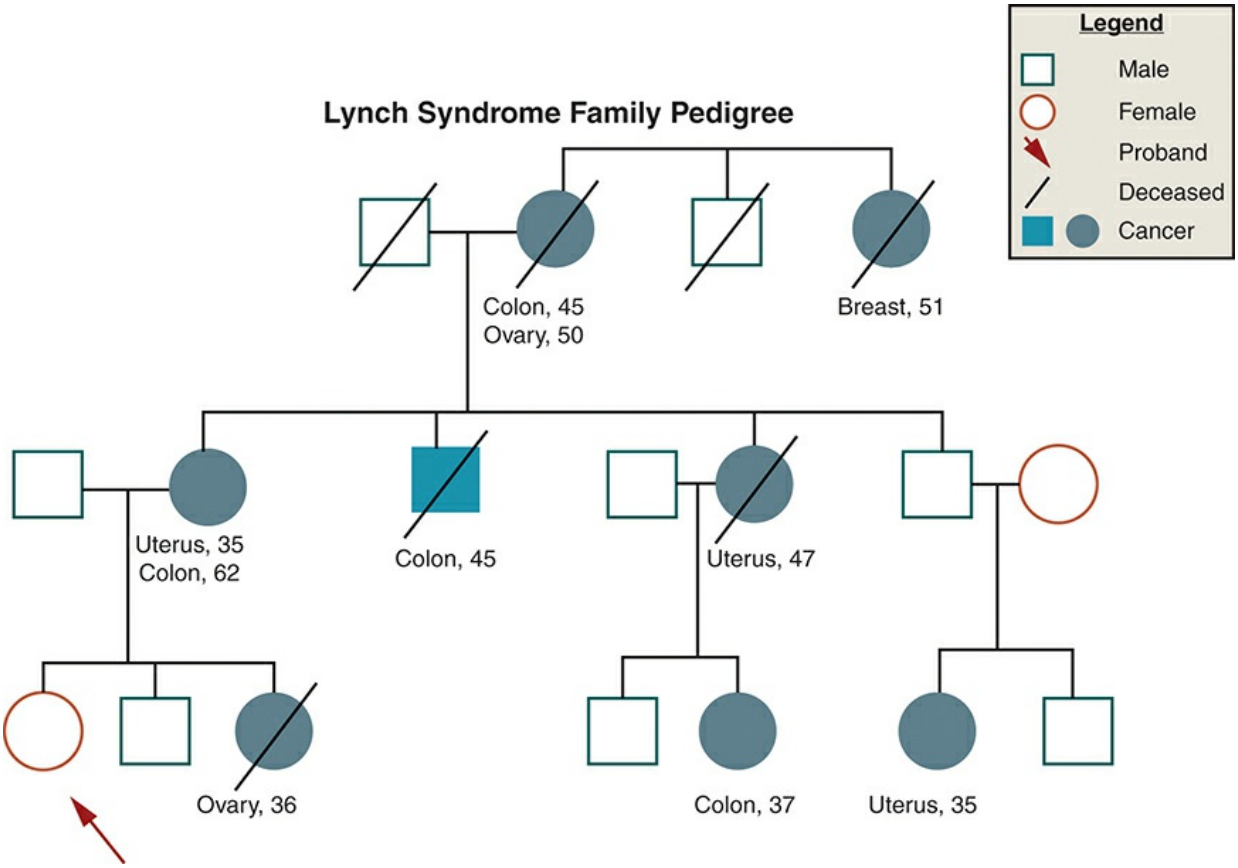

Figure 6.7 Family pedigree illustrating Lynch syndrome.

With the expansion of next-generation sequencing platforms and commercialization of numerous multigene panels, additional gene mutations have been identified, which may account for an increase of ovarian cancer among women who test negative for *BRCA1/2* and Lynch syndrome. Panel screening affords the opportunity to simultaneously screen for numerous genetic mutations in a single setting and may uncover mutations in less common ovarian cancer susceptibility genes, permitting use of preventive strategies for ovarian cancer. Multigene panel testing, however, may also uncover genetic variants of uncertain significance that can contribute to distress among patients and confusion among providers regarding their true pathogenic potential, and may result in inappropriate use of interventions (82).

A multigene sequencing panel for cancer risk assessment was assessed in a cohort of 198 women referred for clinical *BRCA1/2* testing in the Stanford Clinical Center Genetics program (83). Among 141 who tested negative for *BRCA1/2* mutations, pathogenic variants were identified in *ATM*, *BLM*, *CDH1*, *CDKN2A*, *MLH1*, *NBN*, *PRSS1* and *SLX4*, suggesting that selected patients may benefit from multiple-gene sequencing. Lincoln and colleagues examined a 29-gene panel in 1,105 patients and found pathogenic variants, most commonly in *ATM*, *PALB2*, *CHEK2*, *MLHI*, *MSH2*, *MSH6*, and *PMS2* in approximately 4% of *BRCA*-negative ovarian cancer cases (84).

Early data from studies among *BRCA1/2*-negative women suggest that upon retesting with multigene panels, approximately 3% to 5% will have a pathogenic mutation in other genes thought to be associated with breast/ovarian cancer (83,84). Mutations in genes belonging to the BRCA-Fanconi anemia pathway, including *RAD51C*, *RAD51D*, *PALB3*, and *BRIP1,* have been identified in *BRCA*-negative patients, and up to 3.5% of unselected ovarian cancers may have a loss of function mutation on one of these four genes. Similar to *BRCA1/2*, these genes are critical for DNA repair of double-stranded breaks via homologous recombination. Odds ratios for all ovarian subtypes were 5.2 (95% CI, 1.1 to 24) for *RAD51C* and 12 (95% CI, 1.5 to 90) for *RAD51D* (85).

BRIP1 mutations are associated with an eightfold increased risk of ovarian cancers and can be found in 1.4% of unselected ovarian cancer cases. The average age at diagnosis is 61.6 years in mutation carriers (86).

The identification of these additional hereditary syndromes of ovarian cancer provides new opportunities to understand

the biology of the disease and to devise novel preventive strategies.

Prevention

Risk Avoidance and/or Adoption of Protective Practices

The available evidence regarding factors that lower ovarian cancer risk has been based primarily on the results of case–control studies retrospectively comparing the reproductive, hormonal, or behavioral characteristics of ovarian cancer cases with matched controls, not on prospective randomized trials. These studies have consistently shown an inverse association of ovarian cancer with increasing parity, with the first birth conferring significantly more protection (35%) than subsequent births (15%). The protective effect of pregnancy occurs regardless of fertility history and is not age-dependent (87). Pregnancy is characterized by a prolonged period of anovulation as well as high levels of circulating progesterone, which may cause terminal differentiation of premalignant cells (88,89).

The evidence supporting a protective effect of breast-feeding against epithelial ovarian cancer risk is weak and inconsistent. Some studies suggest a 10% to 20% decrease in ovarian cancer risk associated with breast-feeding. In the studies that are positive, the impact of breast-feeding on ovarian cancer risk appears to be greatest for the first 6 months of lactation, with longer-term lactation conferring no apparent increase in protective effect (90,91).

Several studies have examined the association of HRT with ovarian cancer risk. While the majority find a modest increase in risk, most lack statistical significance. The strongest association is seen in endometrioid histologies, where relative risks range from 1.2 to 5.5 (92).

Several retrospective and prospective studies have examined associations between dietary factors and ovarian cancer risk. Modest levels of protection have been reported for fruits and vegetables in general, and for vitamin A and β-carotene in particular, although findings are inconsistent. While there is some case–control data that invasive ovarian cancer is reduced among women who report frequent high-intensity exercise, the relationship between physical activity and ovarian cancer risk is inconsistent, and may differ by histologic type (74,93–95).

Chemoprevention

The majority of theoretical models of ovarian cancer chemoprevention have been based on the assumption that the origin of ovarian cancer is the OSE. As the paradigm has shifted to identifying the epithelial surface of the fallopian tube as the site of origin, it is not clear how to interpret the previous theories. Prior research has explored the presence of receptors for most members of the steroid hormone superfamily, including receptors for progestins, retinoids, androgens, and vitamin D. Progestins, retinoids, and vitamin D have been shown to exert a broad range of common biologic effects in epithelial cells, including induction of apoptosis, upregulation of transforming growth factor-β (TGF-β), cellular differentiation, and inhibition of proliferation. In addition to hormonal agents, there is growing evidence that NSAIDs may have ovarian cancer preventive effects (96).*It is yet to be demonstrated that these agents are active in the fallopian tube epithelium.*

To date, only OCP use has been consistently shown to be protective against ovarian cancer. OCPs were first introduced in the United States in the 1960s. Most formulations include estrogen, progesterone, or a combination of the two. In addition to suppressing ovulation, OCPs also reduce pituitary secretion of gonadotropins and protect against chronic inflammation associated with pelvic inflammatory disease (97). In addition to these potential mechanisms, a 3-year study on primates demonstrated that the progestin component of an OCP had a potent effect on apoptotic and TGF-β signaling pathways in the ovarian epithelium, raising the possibility that progestin-mediated biologic effects may underlie the protective effects of OCPs (98). The use of OCPs appears to decrease a woman's risk for ovarian cancer by 30% to

60%. Risk reduction is apparent with as little as 3 months of use, increases in magnitude with increased duration of use, and persists for as long as 10 years after discontinuation of use. The risk reduction applies to nulliparous as well as parous women; to all histologic subtypes, including tumors of low malignant potential; to women with a hereditary risk for ovarian cancer; is consistent across races; and is independent of age at use or menopausal status (72,89,99). Although there has never been a randomized clinical trial to demonstrate the protective effect of OCPs on ovarian cancer risk, it is often recommended empirically to women at high risk for ovarian cancer to reduce their risk.

Epidemiologic and laboratory evidence suggest a potential role for retinoids as preventive agents for ovarian cancer (73). Retinoids are natural and synthetic derivatives of vitamin A. They have great potential for cancer prevention due to a broad range of important biologic effects on epithelial cells, including inhibition of cellular proliferation, induction of cellular differentiation, induction of apoptosis, cytostatic activity, and induction of TGF-β. The most significant evidence supporting a rationale for retinoids as chemopreventive agents for ovarian cancer is that of a chemoprevention study in Italy, which suggested an ovarian cancer preventive effect from the retinoid 4-HPR. Among women randomized to receive either 4-HPR or placebo in a trial designed to evaluate 4-HPR as a chemopreventive for breast carcinoma, significantly fewer ovarian cancer cases were noted in the 4-HPR group as compared to controls (100).

Vitamin D is a fat-soluble vitamin that is essential as a positive regulator of calcium homeostasis. The vitamin D receptor and the retinoic acid receptors share strong homology and readily dimerize, making it likely that vitamin D and retinoids have common signaling pathways in the cell (101). Vitamin D has been shown to have diverse biologic effects in epithelial cells relevant to cancer prevention, including retardation of growth, induction of cellular differentiation, induction of apoptosis, and upregulation of TGF-β (102). With regard to ovarian cancer, a recent study has correlated population-based data regarding ovarian cancer mortality in large cities across the United States with geographically based long-term sunlight data reported by the National Oceanic and Atmospheric Administration. The study demonstrated a statistically significant inverse correlation between regional sunlight exposure and ovarian mortality risk suggesting that sunlight induces production of native vitamin D in the skin (103). However, a systematic review of 20 ecologic and case–control studies failed to find consistent evidence for a relationship between vitamin D exposure and ovarian cancer incidence or mortality (104).

Epidemiologic studies have suggested that use of NSAIDs may lower ovarian cancer risk (105). Several biologic mechanisms have been proposed to account for the chemopreventive effects of NSAIDs, including inhibition of ovulation, inhibition of COX, and downregulation of prostaglandins, enhancement of the immune response, and induction of apoptosis (89,106,107). Similarly, dietary antioxidants have shown an inverse association with ovarian cancer (108). The role of β-blockers has recently been examined in ovarian cancer patients as a means to decreased adrenergic activation and thus decrease ovarian cancer growth and metastasis and has been associated with a significant improvement in overall survival (109). The role of β-blockers for chemoprevention of ovarian cancer has yet to be defined. Despite a growing body of preclinical data indicating chemopreventive effects of several agents, clinical research exploring their efficacy to reduce rates of ovarian cancer is hindered by the relatively low incidence of the disease, insufficient understanding of the preclinical course of ovarian cancer, the lack of validated preclinical biomarkers, and inadequate screening strategies.

Surgical Prophylaxis

For women with a family history of ovarian cancer, or a hereditary pattern of breast cancer, BSO has been shown to lower the risk of subsequent epithelial ovarian cancer by 80% to 95% (20,110). Prospective follow-up of a large international cohort of 2,482 *BRCA* carriers found not only a lower risk of ovarian cancer, but also a significantly lower all-cause mortality (HR 0.40; 95% CI, 0.26–0.61) and ovarian cancer–specific mortality (HR 0.21; 95% CI, 0.06–0.76). There is also a 50% reduction in rates of breast cancer in women who undergo prophylactic BSO (111). Occult invasive and *in situ* tumors have been found at the time of BSO in 2% to 10% of *BRCA1/2* mutation carriers (112), a large proportion of which occur in the fimbrial end of the fallopian tube (97,113), emphasizing the need for both deliberate removal of the fallopian tubes at the time of prophylactic surgery and of careful pathologic examination of the surgical

specimen (114). The incidence of primary peritoneal cancer following BSO is reported to be approximately 2% to 5% (115). Because the median age of diagnosis of ovarian cancer among women with a hereditary risk is 50 years for *BRCA1* carriers and 60 years for *BRCA2* carriers, the recommended age for prophylactic surgery is at the completion of childbearing, or between age 35 and 40 years for *BRCA1* carriers and 40 and 45 years for *BRCA2* carriers (116). Although the incidence of premenopausal ovarian cancer is higher in *BRCA1* carriers than *BRCA2* carriers, removal of the ovaries before menopause is recommended for both groups given the added benefit of breast cancer risk reduction, which is highest for women who undergo the surgery before natural menopause (28). In addition, because there is an approximate 15% risk of ovarian cancer after age 60 years among *BRCA* carriers, BSO is also justified at older ages for women who still have intact ovaries (117). Women undergoing prophylactic hysterectomy for a deleterious mutation related to Lynch syndrome are also counseled to remove their ovaries because of the approximate 10% to 12% incidence of ovarian cancer (118).

In addition to the significant reduction in ovarian cancer incidence associated with BSO, several studies have found a significant decline in ovarian cancer worry and anxiety following the procedure (119). These potential benefits of prophylactic oophorectomy must, however, be weighed against its adverse consequences, including the short- and long-term surgical risks, the physical and psychological impact of early menopause, and the potential subsequent risks of cardiovascular disease and osteoporosis related to early estrogen/progesterone depletion (120). Although the use of combined estrogen/progesterone HRT has been associated with an increased risk for breast cancer among postmenopausal women in the general population, one study with short follow-up found no increased risk of breast cancer among *BRCA1/2* mutation carriers who took HRT following BSO (121). Also, data from the Mayo Clinic showed that there was no increase in breast cancer among women under the age of 50 years undergoing BSO (122). Women seeking information regarding prophylactic oophorectomy should be counseled about the practical short- and long-term sequelae of the surgery, the risks and benefits of postoperative HRT, and the small potential for primary peritoneal cancer.

Given the recent evidence that a majority of ovarian cancers arise in the fimbrial end of the fallopian tube, alternative surgical procedures, including radical fimbriectomy as well as bilateral salpingectomy with delayed oophorectomy have been introduced. The principle is that complete removal of both fallopian tubes will remove the source of the premalignant changes in the fallopian tube, which give rise to serous ovarian cancer. In addition, removing the tubes will prevent any endometrial tissue from reaching the ovary or peritoneal cavity. These surgical procedures have been proposed as a temporary solution which will prolong the production of ovarian hormone for *BRCA1/2* carriers, thus postponing the onset of premature menopause (123,124). Because prospective data to establish the efficacy of this approach are lacking, and because there is still a proportion of ovarian cancer that may arise out of inclusion cysts in the ovary, radical fimbriectomy or salpingectomy alone are not considered standard of care and are discouraged outside of a clinical trial by current National Comprehensive Cancer Network (NCCN) guidelines. However, salpingectomy could be considered in place of tubal ligation among those women desiring permanent sterilization or among those undergoing hysterectomy for benign indications. This is referred to as opportunistic salpingectomy by some. Tubal ligation has been associated with lower ovarian cancer risk in both case–control and cohort studies. A strong inverse association was observed between tubal ligation and ovarian cancer risk in the Nurses Health Study, with a relative risk (RR) of 0.33 (CI, 0.16–0.64) after controlling for age, OCP use, and parity (125). A recent meta-analysis of 13 case–control, retrospective, and prospective studies found that tubal ligation reduced the risk of invasive epithelial ovarian cancer by 34% (RR, 0.66; 95% CI, 0.60–0.73) (126). The International *BRCA1/2* Carrier Cohort Study found a 52% reduction in ovarian cancer among *BRCA1* carriers who had undergone tubal ligation (72). Proposed mechanisms include changes in local or circulating hormones, reduced access of carcinogens to the ovary, or a reduction in inflammatory processes. As it appears that a significant proportion of ovarian cancers arise in the fallopian tube, tubal ligation may reduce the risk by compromising the blood supply to the fimbrial end of the fallopian tube. Although the protective effect of tubal ligation appears to be substantial, the ability to perform BSO using a laparoscopic approach would seem to make this procedure a preferable choice among women with an increased risk of ovarian cancer (**Tables 6.3** and **6.4**).

TABLE 6.3 Ovarian Cancer—Major Points

Several risk factors, including age, nulliparity, and family history, have been identified for ovarian cancer.
Germ-line mutations in the BRCA1/2 genes and the DNA mismatch repair genes associated with Lynch syndrome significantly increase the risk of ovarian cancer
The fimbrial end of the fallopian tube, not the OSE, has been identified as the source of most serous ovarian cancers.
OCPs confer significant protection from ovarian cancer, and the level of protection is related to the duration of use.
Tubal ligation also confers significant protection from ovarian cancer, although the physiologic mechanism is unknown.
Prophylactic BSO is the most effective method of preventing ovarian cancer in women with a hereditary pattern of ovarian cancer.
Radical fimbriectomy has been proposed as a temporary alternative to BSO in high-risk women to forestall surgical menopause.
Opportunistic salpingectomy has been proposed as a reasonable prophylactic measure among women undergoing tubal ligation or hysterectomy for benign conditions.

OCPs, oral contraceptives.

TABLE 6.4 Ovarian Cancer—Remaining Questions

What is the duration of latent, preclinical ovarian cancer?
Can effective screening strategies, using biomarkers and/or imaging studies, be identified?
Are there effective chemopreventive agents that will reduce the risk of ovarian cancer?
What degree of protection from ovarian cancer does radical fimbriectomy confer?

Because of the risk reduction associated with BSO among high-risk women, some have advocated the routine removal of the ovaries among all women undergoing hysterectomy for benign conditions. However, data do not support the removal of the ovaries at the time of hysterectomy for benign disease in women at average risk of ovarian cancer, among whom the negative cardiovascular and metabolic impact of early surgical menopause outweighs any potential benefit (127,128). However, opportunistic salpingectomy is reasonable in this population.

ENDOMETRIAL CANCER

Risk Factors

Endometrial cancer is the most common gynecologic cancer in the United States. Over 54,870 new cases are diagnosed each year, and there are 10,170 deaths annually (27). Unlike many other tumors, the incidence and mortality from endometrial cancer is increasing, with a lifetime risk of 2.7% and a 16% risk of death (129–131). The increasing incidence of endometrial cancer is thought by some to be related to an overall increased life expectancy and the increased prevalence of obesity (132). Globally, endometrial cancer is more common in more developed countries than less developed countries (64). The relatively low-case fatality rate is due to early detection and treatment of early-stage disease. The majority of risk factors associated with type 1 (endometrioid) endometrial cancer, increased age, nulliparity, early age at menarche, late age at menopause, obesity, long-term use of unopposed estrogen replacement therapy, polycystic ovary syndrome, and the use of tamoxifen are all thought to exert their effect through estrogen-induced endometrial proliferation leading to hyperplasia and malignant transformation. The increased risk associated with diabetes, hypertension, and thyroid disease also suggests

a role for altered growth hormone pathways in addition to the steroid hormone pathways (**Fig. 6.8**). Genetic syndromes account for approximately 5% of all endometrial cancer cases. Women with germ-line mutations in the DNA repair genes associated with the HNPCC or Lynch syndrome have a 40% to 60% risk of endometrial cancer. The mean age at diagnosis in this group is approximately 50 years (81). Epigenetic silencing of the Lynch syndrome genes by hypermethylation is also thought to contribute to endometrial cancer risk (133). Recently, universal screening of endometrial cancers using immunohistochemical staining and/or microsatellite instability staining has been adopted by many centers to identify women at risk for Lynch syndrome. Endometrial cancer is also a component of Cowden syndrome, in which it is estimated that mutations in the *PTEN* gene confer a lifetime risk for endometrial cancer of approximately 19% to 28%, with the increased risk occurring mainly before the age of 50 (134). Type 2 serous endometrial cancer is uncommon and is not related to unopposed estrogen exposure.

Prevention

Risk Avoidance and Uptake of Protective Behaviors

It has been estimated that approximately 40% of endometrial cancers are attributable to excess body weight of many patients in developed countries (132) (**Fig. 6.9**). Maintenance of ideal body weight, regular physical activity, and control of diseases associated with endometrial cancer (diabetes, hypertension, and thyroid disease) are prudent approaches to reduce disease risk. Vigorous physical activity helps to control, prevent, or reverse weight gain; improve insulin sensitivity; and reduce circulating estrogen levels, thus leading to a 22% reduction in endometrial cancer (135). Tamoxifen is a proven chemotherapeutic strategy to reduce the incidence of breast cancer in women at increased risk. While acting as an estrogen antagonist in the glandular epithelium of the breast, tamoxifen acts as an agonist in the endometrium, increasing the risk of postmenopausal bleeding, endometrial hyperplasia, endometrial polyps, and endometrial cancer. Although the absolute numbers were small, the RRs for endometrial cancer in the National Surgical Adjuvant Breast and Bowel Project (NSABP) Breast Cancer Prevention Trial (BCPT) for women on the tamoxifen arm compared to placebo were 2.53 (95% CI, 1.35–4.97) for all women, and 4.01 (95% CI, 1.70–10.90) for women aged 50 years and older (136). Women considering the use of tamoxifen for breast cancer risk reduction should carefully weigh the greater-than-twofold risk of endometrial cancer with the benefits as they make their decision (137). Women experiencing abnormal uterine bleeding while taking tamoxifen for chemoprevention of breast cancer should be instructed to seek immediate gynecologic evaluation to exclude endometrial hyperplasia or malignancy.

Chemoprevention

The addition of a progestin to the estrogen component of HRT has been shown to eliminate the increased risk of endometrial cancer. Progesterone controls many pathways resulting in growth inhibition and tissue homeostasis, and reverses the estrogen effect on the endometrium, thus preventing the development of hyperplasia. The use of combined estrogen and progesterone OCP decreases the risk of endometrial cancer by 50%, although their effectiveness in obese women is not clear (138). For every 5 years of OCP use, the risk of endometrial cancer may decrease by 24%, and this risk reduction may persist for more than 30 years after OCP use (139). Women with Lynch syndrome can experience greater than 60% risk reduction in endometrial cancer with use of OCP for ő1 year (140). Oral progestins have long been used to reverse premalignant hyperplasia and to prevent the development of endometrial carcinoma (130). Progestin-releasing intrauterine devices, which deliver local therapy to the endometrium and spare some of the systemic effects, have been studied as an alternative to oral progestins both for women with early-stage endometrial cancer who desire to preserve fertility and among those taking adjuvant tamoxifen following breast cancer treatment (141,142).

Daily aspirin use has recently been investigated as a chemopreventive agent in Lynch syndrome carriers in a large

international randomized trial (7). In the CAPP2 trial, Lynch syndrome carriers who were randomized to aspirin (600 mg daily) experienced a 30% risk reduction in extracolonic tumors. While these results are promising, there is currently not sufficient data to recommend regular use of aspirin for chemoprevention in Lynch syndrome carriers.

Surgical Prophylaxis

It is thought that the majority of invasive endometrial cancers progress through a series of premalignant stages, simple hyperplasia, complex hyperplasia, simple atypical hyperplasia, and complex atypical hyperplasia, all of which may present with abnormal vaginal bleeding (143). Conservative management of these conditions involves the use of progestational agents, which results in a complete regression of atypical hyperplasia in 50% to 94% of cases. Even in complete responders, however, there is a high rate of recurrence, and definitive therapy of atypical hyperplasia is hysterectomy (54). Among women with documented germ-line mutations associated with the Lynch syndrome, a retrospective study found that prophylactic hysterectomy conferred 100% protection from subsequent endometrial cancer (144). Because of the high success rate for endometrial cancer treatment, however, it is not clear if this protection would translate into a significant survival benefit. This study also found 100% protection from ovarian cancer, which may warrant the consideration of prophylactic total abdominal hysterectomy (TAH)–bilateral salpingo-oophorectomy (BSO) in this population. Alternatively, transvaginal ultrasound along with annual endometrial biopsies starting at age 30 to 35 years may be suggested in women with Lynch syndrome to detect early, premalignant endometrial lesions (145) (**Tables 6.5** and **6.6**). Any episodes of abnormal uterine bleeding should prompt evaluation in women at increased risk for endometrial cancer.

TABLE 6.5 Endometrial Cancer—Major Points

The major risk factors for type 1 endometrial cancer exert their effect through estrogen stimulation of the endometrial surface epithelium.
Altered growth hormone pathways may also be involved in endometrial carcinogenesis.
Endometrial cancer rates are correlated with obesity, which explains the increase in rates in the United States and globally.
Hereditary forms of endometrial cancer have been associated with Lynch syndrome and Cowden syndrome.
Endometrial cancer screening is not recommended for the general population, although women with a hereditary risk are recommended to undergo annual endometrial biopsy.
Prophylactic hysterectomy in high-risk women has been shown to protect women from subsequent endometrial cancer.

TABLE 6.6 Endometrial Cancer—Remaining Questions

Can interventions targeting weight control and physical activity impact the incidence of endometrial cancer?
What are the most effective forms of progesterone-containing contraceptive preparations for reducing the incidence of endometrial cancer?
Does prophylactic hysterectomy in hereditary cases translate into a survival benefit?

FUTURE DIRECTIONS

The prevention of gynecologic malignancies involves many disciplines and requires the collaboration of basic scientists, clinicians, behavioral scientists, and policy makers. The successful development of the HPV vaccines is a major

breakthrough in the prevention of cervical cancer and will likely undergo further improvements and refinements. Advances in molecular genetics, molecular pathology, and molecular imaging will contribute to the early identification of specific markers of premalignant change associated with gynecologic malignancies. The identification of safe and effective chemopreventive agents will provide additional strategies for prevention. Accompanying this progress will be the need to address the psychosocial and cultural barriers to the adoption of preventive strategies.

CHAPTER 7 Preinvasive Disease of the Lower Genital Tract

Britt K. Erickson, Mark H. Einstein and Warner K. Huh

INTRODUCTION

Human papillomavirus (HPV) is central to any discussion of preinvasive and invasive lesions of the lower genital tract. Infection with HPV is necessary for the development of almost all preinvasive cervical and vaginal lesions, and it is present in roughly half of preinvasive vulvar disease. It is also highly associated with anal cancer and implicated in the development of carcinoma of the penis and oropharynx. HPV is the most commonly diagnosed sexually transmitted infection in the United States, with a point prevalence in young women of over 40% and an estimated lifetime probability of infection of almost 85% (1,2). Our knowledge surrounding HPV biology and epidemiology has increased exponentially in the past three decades, leading to improved screening modalities and strategies as well as development of prophylactic vaccination.

In this chapter, we will discuss the biology and epidemiology of HPV infections as they relate to cervical, vaginal, and vulvar carcinogenesis. Additionally, we will review the clinical and HPV-associated risk factors for the development of disease and the pathology of preinvasive lesions including cytology and histology and discuss the efficacy and impact of prophylactic HPV vaccination.

SECTION 1: HUMAN PAPILLOMAVIRUS

Evidence for Causal Relationship

HPV was first proposed as a causative agent in the development of cervical cancer in the 1970s when Dr. Harald zur Hausen, a German physician and virologist, suggested that the same viral particles noted in genital warts may also be responsible for genital tract malignancies (3). This was a departure from the prevailing theory that a herpes simplex virus might be the causative agent. In 1983, he isolated HPV type 16 and implicated it in the development of cervical cancer (4). One year later, he had isolated HPV-18, thus discovering the two HPV types that cause approximately 70% of cervical cancers worldwide (5). For this body of important work, zur Hausen was awarded the Nobel Prize in Medicine in 2008.

In 1991, the International Agency for Research on Cancer (IARC) and the World Health Organization (WHO) concluded beyond a reasonable doubt that there is an association between HPV and cervical cancer (6). Though factors such as tobacco use, parity, contraceptive use, and sexual history may increase one's risk for development of the disease, persistent high-risk HPV infection is indisputably the most important risk factor.

Classification of HPV

Papillomaviruses are double-stranded DNA viruses that are members of the *Alpha* genus of the family Papovaviridae. Papillomaviruses are highly species-specific and infect a wide range of vertebrate hosts. All papillomaviruses have regulatory, early (E), and late (L) genomic regions. Within a given host species, many types of papillomaviruses exist and this phylogenetic subdivision is determined by the extent of DNA relatedness.

HPVs are epitheliotropic-infecting epithelial cells of the skin and mucous membranes and cause epithelial proliferation at the site of infection. HPV is currently divided into 120 distinct genotypes, and this list continues to expand (**Fig. 7.1**) (7). Over 40 types of HPV infect the anogenital tract (8). Traditionally, specific HPV types have been classified as high-risk types based on their potential to cause preinvasive and invasive disease. The most recent meeting of the IARC described 12 α-1 HPV types as high risk. These include HPV-16, -18, -31, -33, -35, -39, -45, -51, -52, -56, -58, and -59. Additionally, HPV-68, in the group α-2A, is categorized as probably carcinogenic (9).

Biology of HPV

HPV is a nonenveloped virus with a proteinaceous coat, which encases and protects the viral DNA. More specifically, the particle is composed of 72 capsomeres made of the viral proteins L1 and L2, also known as the major and minor capsid proteins, respectively. In addition to providing protection for the viral nucleic acid, the capsomeres also serve as the initial interaction site of the viral particle with the host cell.

The HPV genome is circular and double stranded and contains nearly 8,000 base pairs (**Fig. 7.2**). The overall organization of various HPV types is similar. The genome contains eight open reading frames, which are transcribed as a single polycistronic messenger RNA (mRNA), and through alternative splicing mechanisms and ribosomal scanning, this mRNA is translated into the eight proteins E1, E2, E4, E5, E6, E7, L1, and L2.

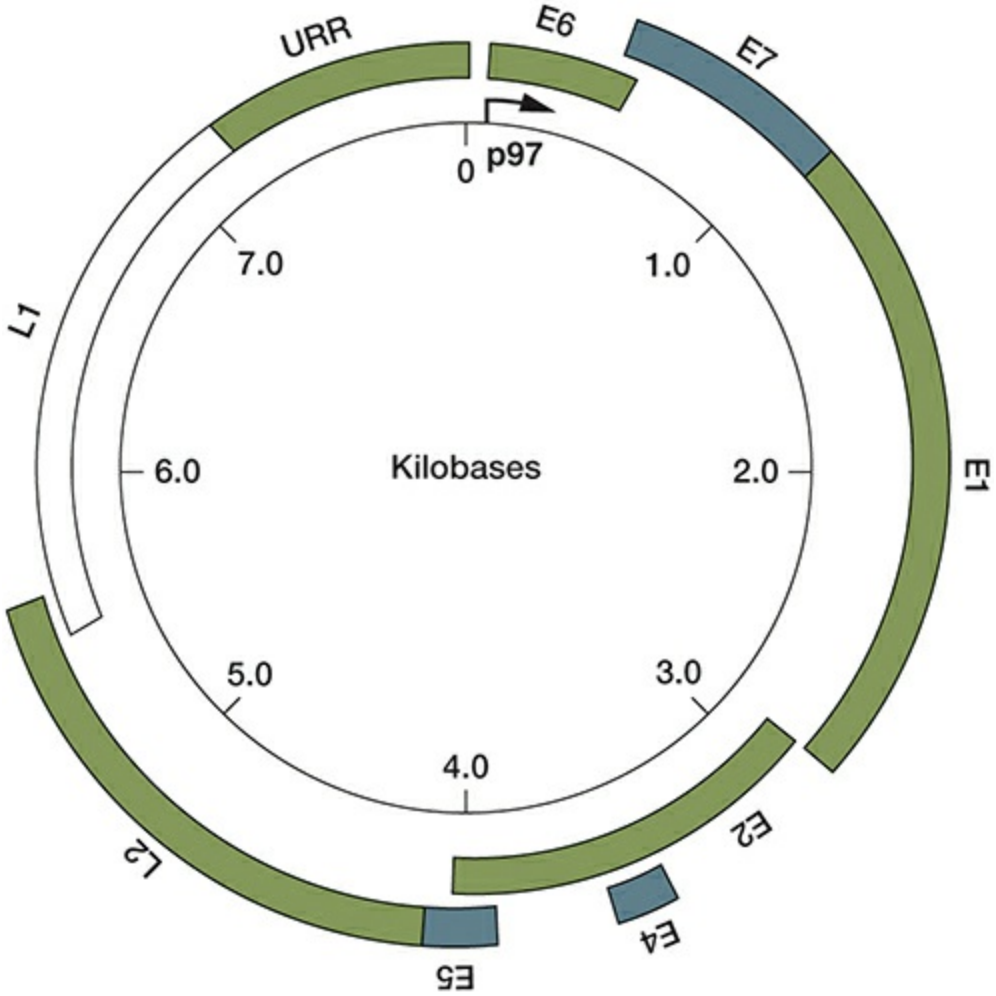

Figure 7.2 Schematic of genomic organization of HPV.

The HPV genome can be divided into three regions. The first region is the upstream regulatory region (URR), composed of nearly 1,000 base pairs. The URR does not code for proteins but contains binding sites for different cellular transcriptional activators and repressors, which then regulate the expression of the early viral genes (10). This region also contains binding sites for the viral proteins E1 and E2, which initiate viral replication and transcription (11). The URR is necessary for the regulation of gene expression, replication of the genome, and packaging of virus particles.

The URR primarily regulates the transcription of proteins in early infection including proteins E6, E7, E1, and E2. The late promoter is activated during the productive phase of the viral life cycle and results in transcription of the capsid proteins (L1 and L2) as well as E1, E2, E4, and E5.

HPV Life Cycle

Like other viruses, HPV must deliver its genome to the host cell and subsequently exploit the cellular machinery for its own purposes. HPV infects the host at sites of epithelial microtrauma, where the HPV particle can gain access to the actively proliferating basal cells of the epithelium (**Fig. 7.3**). The mechanisms of cell entry are complex and continue to be better elucidated (12). The HPV particle interacts with the cell surface via its major and minor capsid proteins (L1 and L2). α-6-Integrin had initially been suggested as a receptor; however, controversies exist regarding its interaction with HPV (13,14). Attachment receptors for HPV particles are likely heparan sulfate proteoglycans (HSPGs), specifically syndecan-

1, which is found in the extracellular matrix of epithelial cells (13). Laminin-5 may be another specific extracellular matrix receptor involved in binding and cell entry (15). Although the main target of HPV is the keratinocytes of the epithelium, HPV virus-like particles (VLPs) have also been shown to attach to cells important in immune function such as dendritic cells and Langerhans cells (16).

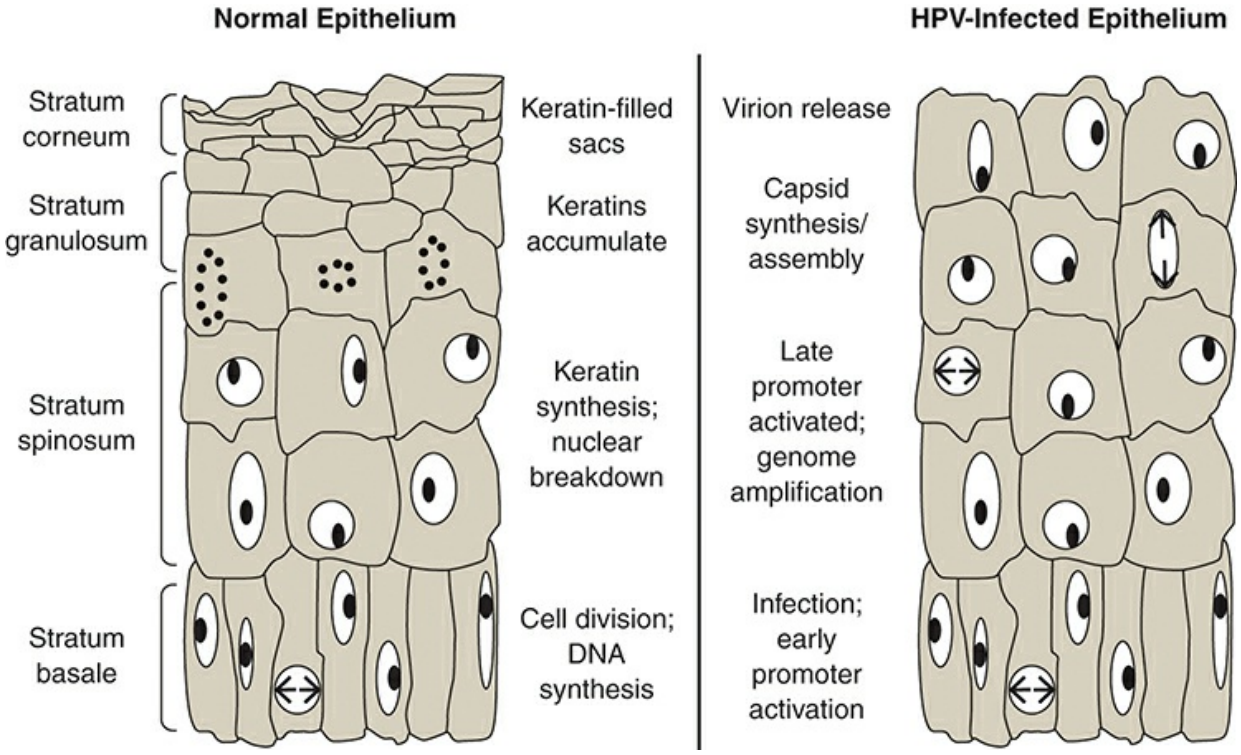

Figure 7.3 Diagram of normal epithelium and HPV-infected epithelium.
Source: Reprinted with permission from Hebner CM, Laimins LA. Human papillomaviruses: basic mechanisms of pathogenesis and oncogenicity. Rev Med Virol. 2006;16(2):83–97.

The binding of HPV to cell surface receptors in the basal cells over the basement membrane then initiates conformational changes in L2, which exposes additional binding sites (17,18). HPV then enters the cells via endocytosis. Most studies suggest clathrin- or caveolin-dependent endocytosis (19), although internalization independent of these proteins has also been described (20).

Once inside the basal epithelial cells, the viral genome begins to replicate. The life cycle of HPV is closely linked to the state of differentiation of the squamous epithelium of the host tissue. In normal squamous human epithelium, the basal layers (stratum basale) are the areas of active cell division. After division, the daughter cells migrate away from the basal cells (stratum spinosum) and no longer progress through the cell cycle. Instead, these terminally differentiated cells produce high-molecular-weight keratins until eventually the nuclear envelope breaks down and the cells become empty keratin-filled sacs (stratum corneum).

HPV-infected cells migrate away from the basal layer, and as the cells reach higher epithelial layers, the late promoter is activated and late gene transcription and translation occur. There is high-level amplification of the viral genome in these layers, and in the uppermost layer DNA is packaged into capsids and the infectious virions are assembled. Typical HPV-associated cytopathic changes such as koilocytosis, multinucleation, and nuclear enlargement are due to the assembly of the viral particles in the upper epithelial layers. The epithelium is then shed and HPV particles are released, which can then infect a new host.

Oncogenic Proteins

The oncogenic potential of high-risk HPV is primarily attributed to the E6 and E7 proteins. E6 and E7 proteins differ in high-risk and low-risk types. These proteins do not have intrinsic enzymatic activities, but instead interact directly and indirectly with other cellular proteins affecting cell cycle regulation. In addition to their individual effects, their combined effects are likely synergistic.

HPV E7

The E7 protein is responsible for immortalizing cells infected with HPV, primarily by affecting the cell's transition from G1 into S-phase. E7 has a variety of targets, including the retinoblastoma (Rb) protein family, histone deacetylases (HDACs), cyclins, cyclin-dependent kinases (cdks), and cdk inhibitors (21).

Rb proteins regulate the cell cycle by controlling the transition at the G1/S-phase. Rb is hypophosphorylated and bound to E2F, a cellular transcription factor. In its bound state, Rb and E2F inhibit cellular proliferation. In normal proliferating cells, cyclin–kinase complexes phosphorylate Rb, E2F is then released, and transcription of S-phase genes occurs. E7 competes for Rb binding, thereby freeing E2F, which results in expression of S-phase genes and uncontrolled cell cycle proliferation (22,23).

The zinc finger region of E7 can interact with the class I HDACs. Through deacetylation of histones, HDACs induce chromatin remodeling (24). E7 binding to HDACs causes progression into S-phase, thereby lengthening the life of the cell.

Independent of these effects, continuous activity of the E7 protein leads to increasing genomic instability, which leads to more dysregulated cell growth and eventually cancer. It has been observed that cells expressing E7 show irregularities in numerous centrosomes leading to aberrant mitotic spindle poles, thereby affecting chromosome number during replication (25). E7 expression is a late event in malignant transformation.

HPV E6

Like E7, E6 is a small 151 amino acid protein that induces important changes in the host cell. It also lacks endogenous enzymatic activity and binds to cell cycle regulatory proteins, affecting life cycle and immortalization.

E6's most notable effect is its ability to bind to p53. p53 is a transcriptional activator and is an important tumor suppressor gene. p53 induces expression of genes involved in apoptosis and cell cycle arrest. p53 levels typically increase in response to stress, DNA damage, or abnormal cellular proliferation (e.g., radiation exposure, hypoxia, and infection). This increase in p53 corresponds to arrest in the G1-phase of the cell cycle, thereby allowing for repair of DNA damage or progression to apoptosis. In HPV-infected cells, E6 binds to p53 and causes degradation of the protein through a ubiquitin-dependent pathway. Thus, less apoptosis and growth arrest occurs, leading to cellular proliferation (26).

E6 has also been shown to interact with other proteins that are involved in a variety of cellular functions. E6 binds to transcriptional coactivators CREB-binding protein/p300, further downregulating p53-mediated transcription (27). E6 also interacts with the PDZ proteins, which are involved in cell signaling and cell-to-cell adhesions, which ultimately affects the life cycle and carcinogenesis (28).

In addition to its inhibition of apoptosis through p53 interaction, E6 also upregulates the cellular telomerase complex. By synthesizing new DNA, telomerase maintains the length of the telomeric DNA at each end of a chromosome. Without this, the telomeres shorten with each cell division until they reach a critically short length and can no longer replicate. Therefore, by upregulating the cellular telomerase complex, E6 further immortalizes the host cell (29). E6 expression is a late event in malignant transformation.

HPV E1/E2

Both E1 and E2 are proteins necessary for HPV DNA replication. E1 first initiates viral replication by binding near the start site of transcription. E1 complexes with the E2 protein, then binds to the viral genome, which initiates helicase activity

(30). E1 also binds various other nuclear proteins for further replication of the viral DNA (31).

E2 is involved with DNA replication as well as genome transcription. In addition to forming a complex with E1 to assist in replication, E2 also works on the upper regulatory region to affect transcription of early genes (32). High concentrations of E2 repress transcription and low levels activate transcription. E2 therefore regulates E6 and E7 and loss of E2 expression can lead to carcinoma due to the unrestricted effects of E6 and E7. Like E1, other interactions have been noted between E2 and various proteins involved with transcription as well as mitosis and cell division. E1 and E2 expressions are early events in the natural history of cervical dysplasia.

Viral Integration and Transformation to Malignancy

HPV genomes infect the cell via circular extrachromosomal copies; however, over time, its viral genome can become inserted into host cell DNA, a process called integration. In low-grade cervical intraepithelial neoplasia (CIN), the HPV DNA is maintained in its closed, circular, episomal shape. However, in most high-grade CIN and cancers, the HPV DNA becomes integrated in the host chromosomal DNA (33,34). Many believe that this is a necessary event in cervical carcinogenesis. Integrated HPV has been found to be present in 83% of invasive cervical cancers, as compared with 8% of low-grade CIN, suggesting that integration is highly associated with the transition of low-grade to high-grade lesions (35,36).

SECTION 2: EPIDEMIOLOGY OF HPV INFECTIONS

Prevalence

HPV is the most common of all sexually transmitted infections; while age, race, geographic region, and other modifiable risk factors correlate with new infections, age and sexual behaviors are most clearly linked to new HPV infections. Early studies likely underestimated the prevalence of HPV infections. As newer molecular technologies have been developed, detection of viral infection improved, even at low levels. In addition to variability surrounding detection methods, HPV positivity may be episodic, corresponding to times of viral shedding.

Utilizing polymerase chain reactions on self-collected cervicovaginal specimens from over 4,000 US females, aged 14 to 49, the prevalence of HPV infection was estimated as part of the 2011 National Health and Nutrition Examination Survey (NHANES) (1) (**Fig. 7.4**). The overall prevalence of the 37 separate types was 42.5%. Prevalence was lower among females aged 14 to 19 (32.9%) and highest among females 20 to 24 years (53.8%), which is the peak age of new exposures. In that study, prevalence varied by race, with non-Hispanic Blacks having the highest prevalence (59.2%) followed by Mexican Americans (44.2%) and non-Hispanic Whites (39.2%). HPV positivity was significantly associated with poverty, sexual activity (including number of partners, age, and first encounter), and history of genital warts. In the United States, it is estimated that almost 85% to 90% of men and women will acquire HPV at some point in their lifetime (2).

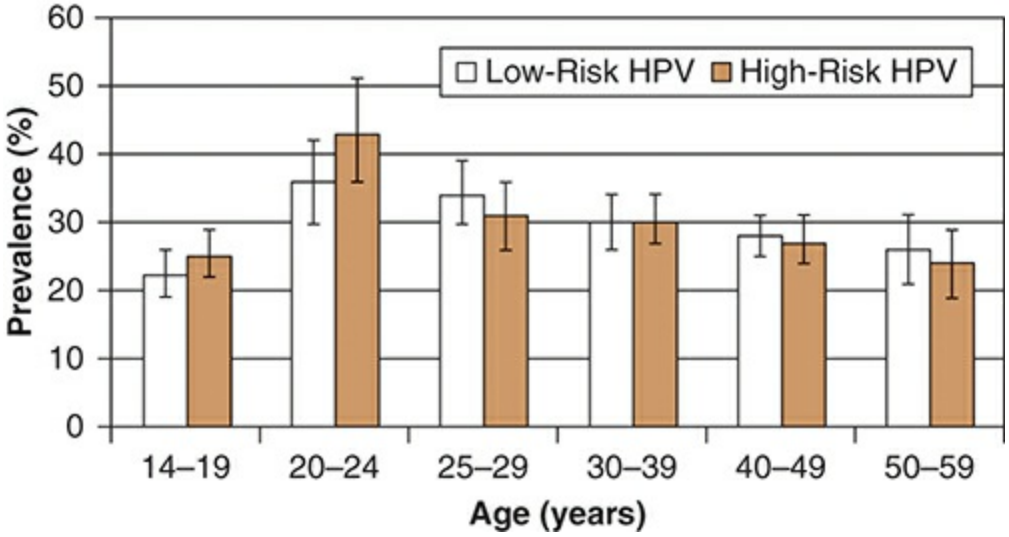

Figure 7.4 US prevalence of HPV infections in women.
Source: Reprinted with permission from Hariri S, Unger ER, Sternberg M, et al. Prevalence of genital human papillomavirus among females in the United States, the National Health and Nutrition Examination Survey, 2003–2006. J Infect Dis. 2011;204:566–573.

HPV Prevalence Worldwide

Worldwide age-related trends are similar to US cohorts. Women less than 25 years of age have the highest prevalence of HPV infection. In most regions of the world, there is a decrease in prevalence with increasing age. In Africa, prevalence ranges from 12% to 55%, although most studies consisted of cohorts of younger women. In Central and South America, prevalence has been reported to be as high as 64%, and interestingly, many studies showed an overall decrease in

prevalence with age followed by an upward trend in women over age 50. Canadian prevalence was lower than that in the United States, with a peak incidence of 25%. Chinese trials showed a range of 6% to 53%, while Japanese trials generally reported prevalence of less than 15%. Studies of Indian women show ranges from 0% to 45%. European prevalence was almost consistently lower than in the United States, with a peak of approximately 20% in young women (37).

HPV Prevalence in Men

The trends in prevalence and clearance in men are inextricably linked to the epidemiology of HPV infections in women. HPV testing in men has limited yield when compared with HPV testing in women, because of the generally keratinized genital surfaces where HPV infection is present in men. A large population-based trial investigating HPV infection in American, Mexican, and Brazilian men demonstrated a 50% prevalence of any type of HPV infection. Specifically, high-risk HPV infections were found in 30%, with HPV 16 (7%) and HPV 51 (6%) being the most common (38,39). Additional data from the NHANES survey showed that men have a higher incidence of oral HPV infection of 10% versus 4% (40). In contrast to trends in women, prevalence of any HPV infection was not affected by age. Clearance of HPV infections seems to occur quicker in men, with an average clearance time of any HPV infection of approximately 6 months. In one study, nearly two-thirds of HPV infections in men were cleared within 1 year, and 90% within 2 years. Clearance was slowest in men aged 18 to 30 (38). Male circumcision significantly reduces genital HPV prevalence in men, which has led some to suggest circumcision as a method to reduce HPV-related disease burden in endemic communities where vaccination and screening is not yet feasible (41). In contrast to squamous cell carcinomas (SCC) of the female genital tract, HPV has only been detected in half of invasive penile SCC (42).

Natural History of HPV Infection (Rates of Abnormal Cytology, CIN, Cancer)

Despite its high prevalence, the majority of HPV infections are cleared by the body's immune system. Only a minority of persistent high-risk HPV infections result in CIN, and an even smaller subset progresses to invasive cancer.

Determining the exact rate of HPV clearance is complex. Some trials examine existing infections (prevalence trials), while others follow women who develop new infections (incident trials). Even within incidence-based trials, methods vary and any subject may have a combination of low-risk, high-risk, preexisting, or incident HPV infections. It is important to also note that though a negative HPV test likely represents clearance of infection, it may also represent a latent, subclinical infection. This concept is derived from a number of sources including data examining HIV positive women who became HPV positive in the absence of new sexual exposures, suggesting a reactivation of viral shedding during periods of immunodeficiency (43). Also, in long-term cohort studies, recurrent infections are often HPV types that the patient has previously had, suggesting reactivation (44,45). However, once cleared, very few HPV type-specific infections reappear and far fewer lead to clinically relevant disease such as high-grade CIN or cervical cancer (46).

The 1-year clearance rate of incident HPV infection ranges from 40% to 70%. Two- to 5-year clearance rates are as high as 70% to 100% in young women (47–50). This rate may be significantly lower in older women; one Chilean trial showed no clearance of high-risk HPV infections in women over the age of 70 (47). Young women are more likely to clear infections than older women, and low-risk HPV infections clear more quickly than high-risk HPV infections (49). The longest course of persistent infection is seen with HPV types 16, 31, 53, and 54 (49) (**Table 7.1**).

TABLE 7.1 HPV Persistence

Study	Year	Average Age	Type of Infection	HPV Persistence at 1 Year	HPV Persistence at 2 Years
Richardson	2003	23	Incident, high	61%	x

et al.			risk		
Ho et al.	1998	20	Incident, high and low risk	30%	9%
Dalstein et al.	2003	32	Prevalent, high risk	60%	50%
Bae et al.	2009	48	Prevalent, high risk	X	41%

The majority of women who acquire HPV infections do not develop CIN or invasive cancer. Of women who have persistent high-risk HPV infections, trials report variable rates of progression to CIN 2/3 from 8% to 28% (51–53).

Transmission

HPV infections are almost exclusively acquired during sexual exposure. Areas of microtrauma within the skin and mucosal surfaces are the likely sites of initial infection. Many natural history studies of HPV negative women at baseline who initiated intercourse confirm precedent sexual activity with new HPV infections (54). HPV has been detected in the oral mucosa and genital tract of young women who have not reported a history of vaginal intercourse. This may be the result of underreporting of sexual activity or noncoital sexual behaviors as a route for HPV transmission (55,56).

The rate of HPV acquisition correlates with increasing number of sexual partners (57). Transmission may occur more readily from women to men than from men to women, although data are conflicting (58,59). Data regarding concordance and HPV transmission efficacy among couples are also conflicting. In studies of young women and their male partners, HPV concordance ranged from 40% to 60%. Specific mechanisms that determine the efficiency of HPV transmission and concordance are poorly understood, although it appears that length of sexual activity may increase concordance (60–62). In addition to cervical, vaginal, and penile detection, HPV has been detected on areas of unprotected genital skin such as the vulva and scrotum, providing an explanation as to why condoms offer some but not complete protection against HPV infection (63).

Section 3: Additional Risk Factors for Development of Preinvasive Lesions of the Lower Genital Tract

Although HPV has been implicated as the most important and necessary risk factor for the development of preinvasive lesions of the lower genital tract, other risk factors have been identified that either increase the risk of HPV infection or potentiate the progression of HPV infection to malignant transformation.

Sexual History

Even before data convincingly linked HPV to the development of cervical cancer, it was well recognized that various aspects of a patient's sexual history put women at increased risk for developing preinvasive and subsequent invasive lesions of the cervix, vagina, and vulva.

Sexual history and behaviors strongly correlate with risk of acquiring HPV infection and developing preinvasive lesions (54). Overall, the number of recent and total lifetime male partners increases the rate of HPV infection, particularly high-risk HPV infection (64,65).

Early onset of sexual activity has also been shown as an independent risk factor for HPV infection in some studies (65). Some studies suggest that frequency of intercourse with one's partner may also play a role (54). Characteristics of the partner, including number of lifetime partners and multiple coincidental partners, have all been implicated in risk of HPV acquisition (54,64). The rate of having new partners and having known a new partner for shorter periods of time before having vaginal intercourse are also associated with increased risk of HPV infection (64).

Additionally, coinfection with other sexually transmitted diseases and vaginal infections has been associated with increased susceptibility to HPV infection. Both bacterial vaginosis and trichomoniasis are associated with HPV infection, although the correlation is not as strong with development of CIN (66,67). A history of herpes simplex virus infection and vulvar warts also increase the incidence of HPV infection (50). A history of previous chlamydial infection has long been implicated in the development of invasive SCC of the cervix (68,69). Hypotheses regarding pathogenesis include induction of squamous metaplasia at the transformation zone, increase in microabrasions, as well as interference with immune surveillance (68,70). More recent cohort studies have found that the role of chlamydia in carcinogenesis is likely related to both in promoting the acquisition and persistence of HPV infections (71,72).

Tobacco

In 2004, the IARC added cervical cancer to the list of cancers causally related to smoking based on analysis of numerous studies in the prior decade (73). As more epidemiologic and natural history studies were performed, conflicting data emerged on the association between cigarette smoking and HPV acquisition, persistence, and progression. Confounding variables have also been a factor; women who smoke are less likely to be compliant with screening guidelines (74) and more likely to have social stressors (75).

Most studies confirm that current smoking increases the prevalence and persistence of HPV infection, particularly of high-risk types (76–78). Additionally, most studies suggest delayed clearance of HPV infection in women who smoke (79,80). Compared with nonsmokers and former smokers, current smokers have higher high-risk HPV viral loads (81).

The effects of smoking on the development of lower genital tract neoplasia are multifactorial. Nicotine and other by-products of cigarette smoke have been readily identified in the cervical mucus of smokers (82). Benzo-a-pyrene, a known

human carcinogen, has been found in cervical mucus and has been specifically noted to potentiate the HPV-16 and HPV-18 viral life cycle (83). It has long been known that smoking causes a local immunological effect whereby the function of Langerhans cells is significantly decreased, thus affecting the innate immune system (84). Studies of women with preinvasive and invasive disease have shown that compared with nonsmokers, smokers show aberrant methylation of p16, a tumor suppressor (85). Other recently identified tumor markers in smokers with CIN include overexpression of cyclooxygenase-2 and Ki-67 and underexpression of p53, interleukin-10, and fragile histidine triad (86).

Oral Contraceptive Pills

The association between oral contraceptive pills (OCPs) and preinvasive and invasive diseases of the lower genital tract has been conflicting and controversial. The largest population-based study, which pooled data from trials involving over 50,000 women worldwide, showed an increased risk of preinvasive and invasive disease in current users of OCPs, although this risk was eliminated when OCP use was discontinued (87). This study is criticized for heterogeneity between trials and the possible confounding effects of sexual behavior in women on OCPs—thus, many have questioned the conclusions. More recent large trials have shown that OCP use is not an independent risk factor for development of abnormal cytology, CIN, adenocarcinoma *in situ* (AIS), or invasive disease (88,89).

HIV and Immunosuppression

HIV infection is strongly associated with HPV infection and with more severe preinvasive and invasive disease (90). Additionally, HIV coinfection in one partner impacts the prevalence of HPV infection in the other partner (91). Higher incidence and prevalence as well as prolonged persistence of HPV are all more frequent in women who are HIV positive (92,93). CD4 count and HIV RNA levels correlate with high-risk HPV positivity (43). Although highly active antiretroviral therapy (HAART) has not been shown definitively to affect the incidence or persistence of HPV infections, it has been associated with better CIN outcomes and improves overall life expectancy of HIV positive women (94).

In a large prospective US-based study that followed more than 3,000 HIV-infected women and HIV-uninfected controls, high rates of HPV positivity were found in both HIV+ and HIV− women (92% vs. 66%, $p < 0.001$). CIN 3 or worse was found in 5% of HIV+ women compared with 2% of HIV− women ($p < 0.001$). Detection rate fell after 2 years of study, suggesting that although HIV+ women have higher rates of CIN 3+, it is still uncommon, especially after the initiation of regular cervical cancer screening and HAART (92,95).

In addition to its effect on prevalence of HPV infection, other mechanisms related to coinfection of HPV and HIV have been proposed. Primarily, it is noted that a functional immune system is required to keep HPV in a latent and subclinical state. Thus, HIV infection, in addition to other forms of immunosuppression, predisposes to progression and reactivation of HPV infection (43). Additionally, different molecular pathways have been proposed for HIV-related preinvasive lesions including a higher frequency of microsatellite instability as well as promotion of viral oncogenesis in HIV-associated CIN (96). Based on patterns of local pro-inflammatory immune markers, it appears that persistent HPV infection might make someone more susceptible to HIV infection as well.

Another group of women known to be at high risk for preinvasive HPV-associated lesions is transplant recipients and other patients on chronic immunosuppressive therapy such as those with systemic lupus erythematosus. Small, early studies noted a higher incidence of HPV infections and up to 16 times the rate of invasive cervical cancer in women with a history of renal transplant compared with controls (97). However, these data are limited by less effective methods of HPV testing and lack of control for covariates. In a recent prospective 10-year study of 48 Italian women with renal transplants, no increased risk of HPV infection, high-grade cytology, or preinvasive lesions was observed (98). A large Swedish cohort study found that the rate of vulvar malignancy in women who had undergone solid organ transplant was 26 times higher than the general population. Additionally, the rate of vaginal cancer was 16 times higher. Rates of cervical cancer were not statistically higher, and preinvasive lesions were only marginally increased (99). A US cohort of transplant

recipients was analyzed, and only vulvar carcinoma demonstrated a statistically significant higher incidence in transplant recipients. In fact, the incidence of vulvar carcinoma following a solid organ transplant was higher than the incidence of cervical cancer (7.5 vs. 5.8 per 100,000 person years) (100). This may reflect improved cervical cancer surveillance in this population. However, it may also reflect the different pathology of vulvar lesions in immunocompromised women. Smaller studies suggest rates of 90% to 100% HPV positivity in preinvasive and invasive vulvar lesions in women with transplants (101,102).

Racial Disparities

For reasons not well understood, there are higher rates of cervical cancer as well as worse prognosis in both the primary and recurrent setting in African American women compared with non–African American women. Emerging data suggest there may be racial differences in the immunologic response to HPV infection. In one of the HPV vaccine trials, African American women were more likely to have non–HPV-16– or HPV-18–related infections (specifically, they were more likely to be infected with subtypes 35 and 58) (103). In another trial of HPV clearance in college-aged women, African American women were less likely to clear high-risk HPV infection compared with White women. Specifically, it took 601 days versus 316 days for 50% of women to clear their infection (104).

SECTION 4: PATHOLOGY OF PREINVASIVE LESIONS

Cervix

The nomenclature of preinvasive lesions has undergone many changes. Formerly known as cervical dysplasia and carcinoma *in situ* (CIS), preinvasive squamous cell lesions of the cervix were then categorized as various levels of CIN. More specifically, mild, moderate, and severe dysplasia/CIS were termed *CIN 1*, *CIN 2*, and *CIN 3*, respectively. In 2012, the College of American Pathologists and the American Society for Colposcopy and Cervical Pathology (ASCCP) convened and recommended a new standard nomenclature: the Lower Anogenital Squamous Terminology (LAST) (105). A single set of diagnostic terms is now recommended for all HPV-related preinvasive lesions of the lower genital tract. Lesions should be low-grade squamous intraepithelial lesions (LGSIL) or high-grade squamous intraepithelial lesions (HGSIL). When it cannot be determined based on routine stains if a lesion is high grade or low grade, biomarkers such as p16 should be used (105). Presence of p16 positivity on immunohistochemistry confirms that an indeterminate lesion is likely high grade (**Fig. 7.5**).

CIN Localization

The vast majority of CIN/SIL develop in the transformation zone of the cervix, located at the squamocolumnar junction between the columnar epithelium of the endocervix and the squamous epithelium of the ectocervix. This area has been

"transformed" due to the process of metaplasia (**Fig. 7.6**). Prior to menarche, the transformation zone does not exist. The squamocolumnar junction occurs exactly at the level of the external cervical os. During menarche (as well as during pregnancy), the columnar epithelium of the endocervix appears on the ectocervix and is termed an "ectropion" or "cervical ectopy." This columnar epithelium gradually becomes replaced by stratified squamous epithelium due to a variety of factors including alterations in pH and other hormonal changes. This area of former columnar, now squamous, epithelium that lies between the original squamocolumnar junction and the new squamocolumnar junction is termed the *transformation zone*. The transformation zone is the primary site for inducing cell-mediated immunity in the lower genital tract, and its role in the acquisition of not only HPV infections, but also HIV infections, is still being elucidated (106,107).

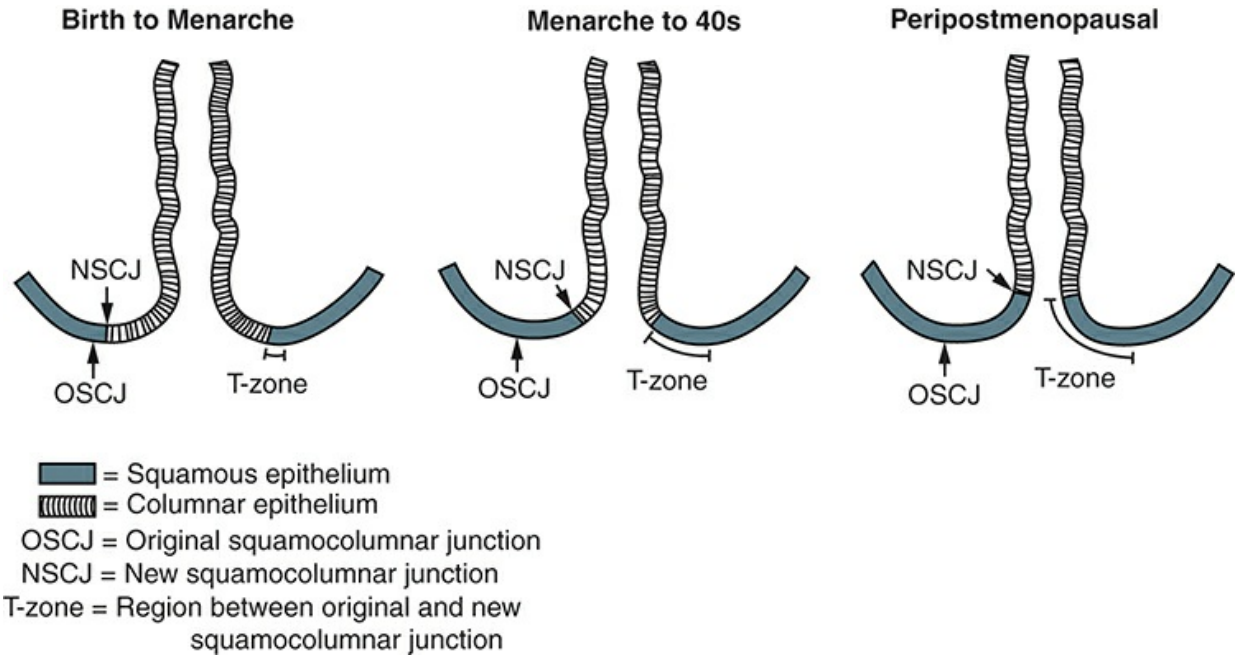

Figure 7.6 Impact of age on the location of the squamocolumnar junction. As females age, the location of the squamocolumnar junction on the cervix moves. The movement of the squamocolumnar junction defines the transformation zone.

Microscopic Appearance of CIN/SIL

Nuclear atypia is a prominent feature of CIN/SIL, which can occur at any level of dysplastic severity. It occurs as a result of enhanced proliferation, replication, and intracellular assembly of viral particles in HPV-infected cells. The nuclei are hyperchromatic and frequently multinucleated; additionally, the nuclear outline is often irregular rather than round. The swollen appearance of the cells is a result of viral particles present in the episomal area of the cell.

In addition to nuclear atypia, CIN 1 to 3 (low-grade to high-grade SIL) histology shows aberrant cytoplasmic differentiation. The basaloid cells, which are normally found as a single layer in contact with the basement membrane, replace the normal epithelium. These cells display nuclear crowding, loss of normal cell polarity, pleomorphism, and abnormal mitotic figures. The extent of these abnormal basaloid cells determines the grade of CIN/SIL.

This classification system was developed when all of CIN was thought to be a spectrum of disease. Now we understand that CIN 1/low-grade CIN 1/LGSIL usually represents a benign process that is merely a cytomorphologic representation of an active HPV infection, whereas high-grade SIL (formerly CIN 2 or 3) is truly premalignant. CIN 2 was traditionally a poorly reproducible category, with high levels of interobserver variability (108). In one trial, agreement between pathologists was as low as 13% in the category of CIN 2 compared with 81% agreement with CIN 3 lesions (109). Because of limitations surrounding reproducibility, it is now recommended that lesions be dichotomously classified as either low-grade or high-grade SIL, with the addition of molecular markers to improve clinically relevant disease

ascertainment (105) (**Fig. 7.5**).

In CIN 1/LGSIL, the lower portion of the epithelium displays nuclear atypia of immature basaloid cells, while the remainder of the epithelium often shows additional cytopathic effects, termed *koilocytosis*, which are directly related to an active HPV infection. Koilocytes are cells with atypical nuclei and perinuclear clearing, also known as vacuolization. The large, perinuclear vacuole is often a result of activation of viral E5 and E6 proteins (110).

Natural History of CIN

CIN 1/LGSIL is the most common histologic diagnosis after colposcopic biopsy. Fortunately, very few of these lesions actually progress to a higher-grade lesion. Most will remain persistent or regress spontaneously as the HPV infection is cleared. In both prospective and retrospective trials, the incidence of CIN 2/3 18 to 24 months after diagnosis of CIN 1 ranges from 4% to 10% (111,112). A retrospective analysis of the ASCUS-LSIL Triage Study (ALTS) found that a diagnosis of CIN 1 on pathology (compared with a negative biopsy, or no biopsy taken) was not a risk factor for developing CIN 3 (113). Therefore, CIN 1/LGSIL is considered a non-neoplastic lesion and is not a disease that should require any extirpative treatment.

Without treatment, HGSIL has at least a 30% probability of becoming invasive cancer. This was shown in an unfortunate prospective study of a cohort of women with untreated CIN 3 followed over a 30-year period beginning in the 1960s in New Zealand. If adequately treated, however, very few women with HGSIL will recur or develop invasive cancer (114).

Glandular Dysplasia and AIS

Although the majority of preinvasive cervical lesions are of squamous cell histology, approximately 3% represent precursors to invasive adenocarcinoma (115). While HPV-16 is the most commonly identified subtype in glandular lesions, HPV-18 causes a greater proportion of glandular as compared with squamous lesions (116). Contrary to popular conceptions regarding preinvasive glandular lesions, the majority are solitary. Multifocal (or “skip lesions”) do occur, but only in 10% to 15% of cases. Though glandular lesions can be found higher in the endocervical canal, the majority occur at the squamocolumnar junction (117).

Preinvasive glandular lesions can be divided into the categories of endocervical glandular dysplasia and AIS. These categories differ by degree of nuclear stratification, nuclear atypia, and numbers of mitosis and apoptosis. Additionally, immunohistochemistry, such as staining for a proliferative marker, Ki-67, may also be used to help differentiate between the two categories (118). An additional category, termed glandular atypia, encompasses nonpremalignant lesions with atypia associated with inflammation or previous radiotherapy. Rare variants of AIS have been described including endometrioid, intestinal, serous, and clear cell histologies.

Histologically, AIS is characterized by enlarged glandular cells with large, hyperchromatic nuclei (**Fig. 7.7**). Unlike the cytopathic effect of koilocytosis seen in HPV-infected squamous cells, endocervical cells show decreased cytoplasm and minimal intracellular mucin. Structurally, glandular cells are crowded with pseudostratification. Unlike squamous lesions, apoptosis is a common feature in glandular lesions and is seen in higher frequency in AIS compared with invasive adenocarcinoma (119).

Source: Images courtesy of the University of Alabama at Birmingham.

Diagnosing early invasive endocervical adenocarcinoma is sometimes more challenging than diagnosing squamous lesions due to the complex growth patterns of endocervical glands. Atypical glands that extend greater than 5 mm from the uninvolved glands are usually termed invasive, whereas lesions within 5 mm are considered early invasive disease. Other features distinguish invasion from *in situ* lesions, including stromal reaction (desmoplasia, inflammation), confluence of glands, and solid components.

Vulva

Vulvar intraepithelial neoplasia (VIN) is increasing in incidence in the United States, with a 400% increase in preinvasive lesions and a 20% increase in invasive lesions between 1973 and 2000 (120). Classification of preinvasive vulvar disease has undergone many changes. In 2003, the WHO classified VIN in a three-grade system. Then, in 2004, the International Society for the Study of Vulvovaginal Disease (ISSVD) reclassified VIN into two categories: usual-type VIN, which is associated with HPV infection; and differentiated VIN, which is usually not associated with HPV infection (121). VIN 1 was abandoned in terminology primarily due to its high rate of misclassification into clinically relevant disease. Usual-type VIN includes only high-grade VIN and is composed of warty, basaloid, and mixed histologies. In addition to being an HPV-associated lesion, usual-type VIN shares the same risk factors as those for CIN including tobacco use and immunodeficiency. Differentiated VIN, sometimes referred to as “keratinizing type,” occurs most commonly in older women and is often associated with lichen sclerosis. p53 mutations and microsatellite instability have been implicated in its pathogenesis. Five percent of women with lichen sclerosis develop invasive SCC with an average interval of 10 years (122). Differentiated VIN has a greater propensity to progress to invasive disease, and time to progression is shorter than that of usual-type VIN.

The differential diagnosis for vulvar lesions is broad and diverse. Distinguishing benign from preinvasive lesions can be difficult by visual inspection alone and thus biopsy is usually necessary to establish diagnosis. Usual-type VIN appears as a

sharply demarcated lesion that can exhibit various colorations, including white, gray, red, and black. VIN is most commonly found at the introitus, on the labia minora, and around the anus. When the disease spreads beyond the anal verge, it is referred to as anal intraepithelial neoplasia and lesions are frequently multifocal (123). Microscopically, VIN resembles cervical SIL and displays nuclear atypia and cytoplasmic differentiation.

Natural History of VIN

Based on retrospective reviews, an estimated 10% to 15% of untreated VIN will progress to invasive SCC over many years (124,125). Additionally, up to 20% of women with high-grade VIN will have occult invasive disease at the time of surgery for preinvasive disease (126). Unlike CIN, regression of VIN is rare; one review noted only a 1% complete regression of VIN 3 (125).

Vagina

Vaginal intraepithelial neoplasia (VAIN) is another lesion that is part of the HPV spectrum in the lower genital tract. Its occurrence is less common and represents only 0.5% of all lower genital tract intraepithelial neoplasias. VAIN is most often found in the upper vagina and is most often multifocal. Many cases occur after hysterectomy, and occult vaginal malignancy is uncommon (127). Recurrence is more common with multifocal disease and ranges from 20% to 60% after treatment with laser or 5-fluorouracil (127). Recurrence is uncommon after partial vaginectomy (128). HPV infection is implicated in the pathogenesis of over half of VAIN (129). The histologic features of VAIN are similar to those of CIN and VIN. Because of its infrequency, there are no current recommendations for vaginal cancer screening in low-risk populations. Most screening recommendations do not recommend performing vaginal cuff cytology after a hysterectomy unless the hysterectomy was for CIN or cervical cancer (130).

SECTION 5: SCREENING

With the advent of successful screening for preinvasive disease of the lower genital tract, effective treatments of precancerous lesions have also emerged, subsequently affecting the overall disease burden of invasive lower genital tract malignancies.

Cervical cancer screening is hailed as one of the major public health advances in the 20th century. Initially seeking determinants of the ovulation cycle in guinea pigs, Dr. George Papanicolaou evaluated the vaginal smear as an indicator of hormone status. Eventually, he studied human subjects and incidentally found a malignancy on a vaginal smear. More than a decade later, Dr. Papanicolaou and his colleague Dr. Herbert Traut published *The Diagnostic Value of Vaginal Smears in Carcinoma of the Uterus*, which forever changed the landscape of cancer screening for women (131). The Papanicolaou, or Pap smear, is now used worldwide for cervical and vaginal cancer screening, and its utility and efficacy continue to be validated as newer molecular technologies emerge, particularly testing for HPV DNA.

It should be noted that the utility of the Pap smear as a screening test has not been based on randomized, controlled trials. Being the first such screening test in the modern era, the Pap smear never had to prove its clinical benefit through an evidence-based approach, as many modern screening tests are evaluated today.

Despite a lack of level I evidence, international epidemiologic data are quite convincing (132–135). In developed countries, the incidence of cervical cancer has declined dramatically since the acceptance and utilization of cervical cytology–based screening. In the United States, rates declined from 36.3 per 100,000 in the 1930s to 7.2 per 100,000 in the beginning of the 21st century—a reduction of over 80%. The greatest rate of decline occurred from the 1950s to the 1970s when rates dropped by over 3% per year (136). This correlates with the widespread adoption of routine cervical cancer cytology–based screening programs in the United States.

However, despite the widespread acceptance of cervical cancer screening tests, it is estimated that there are still over 12,000 new cases of cervical cancer diagnosed in the United States annually (137). Reports estimate that 20% to 30% of cases will be in women who have had proper screening (137,138). Thus, as effective as the Pap smear may be, it is evident that some cases of cervical cancer and premalignant lesions are not detected, suggesting that it can be further optimized.

There are elements inherent to cytology that may inhibit its success as a screening test. This includes poor cellularity due to collection or transfer. Also, Pap smears may be read as unsatisfactory due to inflammation, scant cellularity, or obscuring blood, thereby limiting diagnostic ability. The rate of unsatisfactory Pap smears ranges from 1% to 8% (139,140), and on reevaluation, a significant number of these show cytologic atypia, including high-grade lesions and carcinoma (139). This is usually overcome with liquid-based cytology, which is the more commonly used cervical cytology platform due to the ability to also perform molecular testing for pathogens like HPV from the same collection vial. One of the suggested approaches to overcoming human error in the analysis of Pap smears is HPV testing, which is highly sensitive and is not dependent on any subjective evaluation.

Despite rigorous international standards, the interpretation of cytology is subject to interobserver variability. Discrepancies between low- and high-grade lesions among various laboratories and personnel may be as high as 15% (141). Moreover, it is well established that the category of atypical squamous cells of undetermined significance (ASC-US) remains a poorly reproducible category. Attempts have been made to improve its low positive predictive value including HPV triage testing, but nonetheless, much variability exists regarding cytologic interpretation (108).

Even under the best circumstances when sampling is adequate, and interpretation is performed by experienced cytologists, the sensitivity and specificity of the Pap smear at baseline limit its functionality as a screening test. A pooled analysis of European and Canadian studies noted that though the specificity of the Pap smear in detecting high-grade dysplasia (CIN 2 or greater) was 96%, the sensitivity was only 53% (142). In another systematic review, the sensitivity of the Pap smear ranged from 30% to 87% and specificity ranged from 86% to 100% (143).

Currently, the American Cancer Society (ACS), the ASCCP, and the American Society of Clinical Pathology (ASCP) recommend that women should begin cytology screening starting at age 21, regardless of risk factors (**Table 7.2**). Cytology should be performed every 3 years until age 30 (130). Based on modeling studies in this age group, and taking into consideration the natural history of the disease (including high rates of regression and long periods required before invasion), there is no increased risk of death due to cervical cancer associated with screening every 3 years versus every 2 years. Moreover, there is a 40% increase in the rate of colposcopy when screening is performed every 2 years compared with every 3 years, with no increase in cancer detection with more testing (144).

TABLE 7.2 Cervical Cancer Screening Recommendations

Age	Screening Method	Comments
<21 years	No screening recommended	HPV testing is not recommended in this age group
21–29 years	Cytology alone every 3 years	HPV testing is not recommended in this age group
30–65 years	Preferred = "Cotesting" (HPV and cytology) or Acceptable = Cytology alone every 3 years	
>65 years	No screening following adequate negative prior screening	If history of CIN 2+, continue screening for 20 years
After hysterectomy	No screening	Applies only to women with no cervix and no history of CIN 2+
HPV vaccinated	Follow age-specific recommendations (same as unvaccinated women)

American Cancer Society, American Society for Colposcopy and Cervical Pathology, and American Society for Clinical Pathology screening guidelines for the prevention and early detection of cervical cancer. J Low Genit Tract Dis. 2012;16(3):175–204, with permission.

At age 30, combined concurrent testing (or cotesting) with cytology and HPV testing is the preferred method of screening. If both tests are negative, screening can occur every 5 years (130). Cotesting improves sensitivity of detection of CIN 2/3 and lowers the false-negative rate of cytology alone (145,146). HPV testing also improves the detection of glandular lesions, which often go undetected with conventional cytology alone (147). If no HPV testing is performed, cytology alone every 3 years is acceptable. Women older than 65 and women with a previous hysterectomy for benign indications no longer need screening for cervical or vaginal cancer.

Cervical Cytology

Figure 7.8 shows the distribution of abnormal cervical cytology. ASC-US is the most common cytologic abnormality but the most poorly reproducible category. Other cytologic results include low-grade squamous epithelial lesion, high-grade squamous epithelial lesion, atypical squamous cells that cannot exclude high-grade SIL (ASC-H), and atypical glandular cells. Management algorithms will not be reviewed here, but can be referenced from society websites such as the ASCCP (http://www.asccp.org/guidelines).

Detection Methods

Molecular technologies for HPV detection have developed rapidly and been widely implemented clinically. The U.S. Food and Drug Administration (FDA) has approved five tests for detecting HPV. The first, Hybrid Capture II (HCII) assay (Qiagen, Germantown, MD), was approved in 2003; it detects 13 high-risk HPV types through nucleic acid hybridization assays using signal amplification and chemiluminescence. In 2009, the FDA approved two additional HPV DNA tests: Cervista HPV HR (Hologic, Bedford, MA), which detects 14 high-risk types, and Cervista HPV-16/18 (Hologic, Bedford, MA), which detects HPV types 16 and 18. In 2011, the Cobas HPV test (Roche Molecular Systems, Pleasanton, CA) was approved for the identification of HPV-16 and -18 while concurrently detecting 12 other high-risk HPV types. Most recently, the APTIMA HPV assay (GenProbe, San Diego, CA) was approved for cytology triage and cotesting. This assay detects the messenger RNA of the oncogenic E6 and E7 proteins of 14 high-risk HPV types (**Table 7.3**).

After over 60 years of cervical cancer screening with the Pap smear alone, guidelines have been modified to reflect an improved understanding of the role of high-risk HPV in the development of cervical cancer and the role of HPV testing in cervical cancer screening. The ASCCP recommends HPV testing in a variety of specific situations (130,148).

Primary HPV testing as the sole screening modality has been investigated in multiple international trials and shows promise in upfront screening strategies (146,149,150). In general, it has demonstrated improved sensitivity compared with cytology, although specificity may be lower. The ATHENA trial (Addressing the Need for Advanced HPV Diagnostics) was the first US-based prospective study to evaluate HPV testing as an upfront screening strategy. The objective of this trial was to evaluate various screening strategies with endpoints including detection of CIN2+, number of screening tests required, and number of colposcopies required. Over 40,000 women aged 25 and over were enrolled. Primary HPV testing with triage to colposcopy if the patient was specifically HPV-16 or HPV-18 positive had the highest sensitivity of CIN 2+ detection (80%), but required more colposcopic exams. Cotesting with both upfront cytology and high-risk HPV testing had similar sensitivity, but required many more screening tests (150). These data support primary HPV screening (with colposcopy based on HPV subtype analysis) for women aged 25 and over (151).

Additional Screening Strategies

In addition to cervical cytology and HPV testing from liquid-based cytologic specimens, other innovative techniques are being used in populations with limited access to standard screening approaches. In an attempt to make high-risk HPV testing more efficient, less invasive, and less costly, self-HPV testing has developed. Self-sampling demonstrates high concordance with physician collected samples (152). Prospective trials involving women who did not attend routine cervical screening programs in the Netherlands showed that, because of higher participation rates, the detection rate of CIN was higher than in the regularly screened population (153,154).

In developing nations where the cost of frequent follow-up exams and testing is prohibitive, visual inspection tests have emerged as an important method of screening and treatment. With a bright halogen lamp, visual inspection with acetic acid (VIA) or Lugol's iodine (VILI) is performed and positive lesions are referred to colposcopy with directed biopsy.

Additionally, positive lesions can be treated immediately, bypassing the need for follow-up colposcopy. This is an efficient method of screening and treatment, and health care providers can be trained easily in visual inspection, further improving its feasibility (155). Although significant verification bias exists in a see-and-treat strategy, pooled analysis of trials utilizing visual inspection in developing nations revealed a sensitivity of 62% to 80% and specificity of 77% to 84% in detecting high-grade CIN (156).

VIA and VILI with see-and-treat strategies appear to be cost-effective. A study that modeled screening strategies in India, Kenya, Peru, South Africa, and Thailand showed that screening women once per lifetime with visual inspection effectively reduced cervical cancer mortality by over 25% at an acceptably low cost in relation to each nation's gross domestic product (157). Population-based studies on VIA have yielded mixed results. In a South Indian population, cervical cancer mortality was reduced by 25% with VIA compared to no screening (158). In the largest prospective trial enrolling over 130,000 women in rural India, one-time screening methods of HPV testing, cytology, and VIA were compared. Compared with a control group, only HPV testing reduced the rate of cervical cancer (159). Thus, once per lifetime HPV testing in women over 30 has been proposed as an effective method of cervical cancer reduction in low-resource settings.

SECTION 6: HPV VACCINATION

With an improved understanding of the role of HPV infection in the natural history of preinvasive and invasive lesions of the lower genital tract, prophylactic vaccination has emerged as an important element in cervical cancer prevention (Table 7.4).

[a]Merck Sharp & Dohme Corp., Inc., Whitehouse Station, NJ, USA.

[b]GlaxoSmithKline, Rixenstart, Belgium.

The L1 capsid protein, which is one of two viral capsid proteins of the HPV virus, is the primary target for prophylactic vaccination. Vaccines consist of recombinant L1 proteins that form VLPs, which are combined with different adjuvants. Adjuvants stimulate the immune system and increase the response to vaccination and are aluminum based. VLPs primarily induce a humoral response with neutralizing antibodies, but they also induce cell-mediated immune responses. Neutralizing antibody responses are logs higher than that generated from a response to a new HPV infection.

Currently, three vaccines are approved in the United States for the prevention of cervical cancer. The quadrivalent vaccine (Merck & Co., Inc., Whitehouse Station, NJ, USA) contains VLPs to HPV types 6, 11, 16, and 18, and the bivalent vaccine (GlaxoSmithKline, Rixenstart, Belgium) contains VLPs to HPV types 16 and 18. In addition to the types covered in the quadrivalent vaccine, the newest 9-valent vaccine (Gardasil 9, Merck & Co., Inc., Whitehouse Station, NJ, USA) contains additional VLPs to the HPV types 31, 33, 45, 52, and 58, which combined account for about 20% of cervical cancers.

The FDA originally approved the quadrivalent vaccine in 2006 for girls and women aged between 15 and 25 years for the prevention of cervical cancer caused by HPV types 16 and 18; precancerous genital lesions caused by HPV types 6, 11, 16, and 18; and genital warts caused by HPV types 6 and 11. The federal Advisory Committee on Immunization Practices (ACIP) recommended routine vaccination of all 11- and 12-year-old girls. The three-shot vaccination series can begin as young as age 9 and can be given to women up to age 26. In 2008, the quadrivalent vaccine was also approved for the prevention of vaginal and vulvar cancer in this same population. The following year, its use was expanded to the prevention of genital warts due to HPV type 6 and 11 in boys and men aged between 15 and 25. In 2010, the FDA further expanded the indications to include the prevention of anal cancer and associated premalignant lesions caused by these same HPV types. In 2011, the ACIP recommended routine vaccination of all boys. The vaccine series can be given to boys as young as age 9 and up through age 22 for most men. The FDA approved the bivalent vaccine in 2009 for the prevention of cervical cancer and precancerous lesions caused by HPV-16 and -18 in women from 15 to 25 years of age. The ACIP recommendations for the bivalent vaccine mirror those for the quadrivalent vaccine, except that the bivalent vaccine is not approved for use in males. The 9-valent was approved in December 2014 for females aged 9 to 26 and males aged 9 to 15 for the prevention of cervical, vulvar, vaginal, and anal cancers and genital warts caused by the nine HPV types.

Multiple phase III trials have been conducted to evaluate the efficacy of these vaccines (160–162). These trials were blinded, placebo-controlled trials with endpoints that included development of CIN as well as external genital lesions for the quadrivalent vaccine. In an international trial that enrolled over 17,000 women aged between 16 and 26, the quadrivalent vaccine was 99% effective in preventing HPV-16 and -18 preinvasive or invasive lesions in a 3-year follow-up period in women who were HPV-naive at baseline. In an intent-to-treat analysis including women with preexisting infections, there was considerably less efficacy against incidence of CIN 2/3 or AIS due to any HPV type, thus proving that it works primarily as a prophylactic vaccine (161). This trial also showed that the quadrivalent vaccine was effective in preventing 96% of CIN 1, 100% of VIN 1, and 99% of condyloma in HPV-naive women (160).

The 4-year follow-up of a bivalent HPV vaccine trial, which enrolled over 18,000 young women, showed similar efficacy against development of CIN 3 and AIS. Specifically, efficacy against HPV-16– and HPV-18–mediated CIN 3 lesions was 100% in women who were HPV negative at the time of vaccination. The vaccine was also effective against other lesions caused by HPV types 31, 33, and 45, which are closely related to HPV-16 and -18 (163).

An international trial compared the efficacy of the quadrivalent vaccine with the 9-valent vaccine in women aged 16 to 26 years old (164). The rate of high-grade preinvasive genital tract disease was the same in both arms (14 per 1,000 person years), although there was a significant reduction in disease related to the five additional HPV types in the 9-valent arm. Antibody responses to HPV types 6, 11, 16, and 18 were noninferior in the 9-valent arm compared with the quadrivalent arm.

HPV vaccination has not been shown to be therapeutic against preexisting HPV infections. Therefore, HPV vaccine is most effective if it is administered prior to the onset of sexual activity. Additionally, the vaccine is not infectious, does not contain anything that would be teratogenic, and is considered teratogenicity category B. Routine pregnancy testing prior to administration is not necessary and lactating women can safely receive the vaccine (165). Based on the natural history of HPV infection and development of preinvasive and invasive disease, it may take at least 15 years before there is a significant impact on the incidence of high-grade SIL and perhaps 30 years before there is a change in cervical cancer incidence.

HPV vaccination programs are being instituted worldwide. HPV vaccination presents unique challenges in both high- and low-resource settings, including an older age of vaccination, a three-dose regimen at a high cost relative to other childhood vaccines, and potential sociocultural concerns about HPV being a sexually transmitted disease. Uptake of vaccination seems to be most affected by coverage of the vaccine at the state or national level. In the United States, it is estimated that almost 50% of adolescents received at least one dose and only 32% received all three. Vaccine uptake varies significantly by state, likely a reflection of variability of state funding (166). Worldwide, rates are slightly higher in other high-resource settings. In Manchester, United Kingdom, the uptake of two doses was reported at 55%; three-dose coverage in southern Australia was 69% and in Denmark, 62% (167–169). Despite many barriers to HPV vaccination, it is

apparent that when communities make a focused effort to promote vaccination through financial coverage or public health awareness, high levels of vaccine uptake are noted.

Over 85% of cervical cancer cases occur in the developing world (170), yet patients in these nations are less likely to receive HPV vaccination. Despite its high cost relative to other childhood vaccines, in nations with high incidence, emerging models suggest that vaccination is cost-effective (171). Moreover, HPV vaccination has recently been made more affordable at a subsidized price of 5 US dollars per dose (166). This has prompted research into the most effective strategies for large-scale vaccination. In a large international trial of developing nations, HPV vaccination programs were integrated into preexisting health center-based and school-based vaccination programs in communities in India, Peru, Uganda, and Vietnam. Remarkably, complete vaccination (i.e., all three doses) was achieved in 68% to 96% of eligible girls (166). This study confirmed that a range of HPV vaccine delivery strategies were effective in achieving HPV immunization among eligible girls.

SECTION II
Diagnostic and Therapeutic Modalities

CHAPTER 8 Perioperative and Critical Care

James J. Burke II, Scott C. Purinton and Heather MacNew

INTRODUCTION

Surgery remains the mainstay of treatment for women with gynecologic malignancies regardless of whether an open or minimally invasive approach is utilized. Ultimately, outcomes of the surgical intervention rest with the gynecologic oncologist in concert with anesthesiologists, nursing staff, stomal therapists, physical therapists, pharmacists, social workers, and the social network/support of the patient, as well as others. Careful assessment of the patient prior to surgery can lead to improved outcomes and minimize surprises in the postoperative period. Should the need arise, prudent consultation with other medical specialists prior to or following surgery can further enhance patient care and result in better outcomes.

The chapter has been divided into two sections: preoperative care/risk recognition and postoperative care/critical care. Within each section, clinical information has been arranged by organ system, and recommendations are based on evidence (when available). As has become the norm with hospitals in the United States, most intensive care units (ICUs) have become "closed," meaning that when a patient is admitted to the ICU, the patient is cared for by a team led by a critical care specialist/intensivist. Thus, the critical care section provides basic yet practical information for the reader so that comanagement of the critically ill gynecologic oncology patient with an intensivist may be seamless.

PREOPERATIVE RISK ASSESSMENT

Initial Preoperative Evaluation

At the initial consultation for patients with known or suspected gynecologic malignancies, the gynecologic oncologist should take a thorough history, assessing for comorbid conditions, which may impact perioperative risk (1). Similarly, a thorough physical examination, looking for signs of diseases of which the patient is unaware, will aid in finding diseases that can impact surgical outcome. Review of accompanying medical records and radiographs is important. Ultimately, patients who will benefit from surgery are identified and will be deemed operable, operable but requiring further evaluation from specialists prior to surgery, or inoperable.

Subsequent discussions should focus on the course of treatment. If surgical, the planned operative procedure should be described to the patient in nonmedical terminology. Attendant risks of the procedure, as well as alternatives for therapy (if they exist), should be described to the patient. The length of time for the operation and length of anticipated hospital stay should be estimated for the patient and her family. Further time to recovery from the planned operative procedure should be estimated for the patient. Ideally, this information should be given in oral and written form for the patient. These

elements of the treatment plan constitute *informed consent* and should be documented in the medical record by the physician at the initial consultation. Preferably, this "consenting" should be done before the patient is in the preoperative holding area on the day of her surgery. Should further evaluation be needed from a specialist (e.g., a cardiologist or a pulmonologist), a letter outlining the proposed surgical intervention should be sent to the consultant. However, the impact of these consultations, or "preoperative clearances," on perioperative outcomes is unclear (2–4).

If the patient's condition is such that a stoma(s) (ileostomy, colostomy, or urostomy) may be required, consultation with an enterostomal therapist for marking of the planned stoma(s) should be considered. During this visit, the therapist will take into account the location of the patient's waist, abdominal creases, how she wears her clothing, the types of clothing she wears, and the location of the future stoma when she stands or sits. In addition, the therapist can initiate education on the function and care of the stoma(s).

Should the proposed surgery result in a marked change of body image or possible sexual dysfunction (e.g., exenteration, radical vulvectomy, or vaginal reconstruction), consultation with prior patients who have successfully recovered from similar operations may be warranted. In addition, these patients may benefit from psychological counseling prior to their surgery. ***Best practice: Although quality evidence is lacking, most studies show that counseling provides beneficial effects with no evidence of harm. It is recommended that patients should routinely receive dedicated preoperative counseling.***

Ideally, preoperative laboratory testing will be dictated by findings from the history and physical examination. Unfortunately, unnecessary and inappropriate preoperative testing has been done in an effort to reduce poor perioperative outcomes, whereas evidence to support this practice is lacking and the cost to complete these unnecessary tests has been estimated to be over $3 billion (5). In order to standardize preoperative testing, evidence-based guidelines have been developed (6). The National Institute for Health and Care Excellence [formally known as the Institute for Health and Clinical Excellence] (NICE), an independent organization in the United Kingdom that produces evidence-based guidelines for the promotion of good health and treatment of disease, developed guidelines for preoperative testing. These guidelines take into account the patient's age, type of surgery, associated comorbidities, and the American Society of Anesthesiologists (ASA) grade for anesthesia risk (7) (Table 8.1). St. Clair et al. performed a retrospective study assessing adherence to the NICE guidelines for preoperative testing in patients having gynecologic surgery between 2005 and 2007. The authors found that among 1,402 patients evaluated, inappropriate preoperative testing resulted in costs over $418,000 (8).

TABLE 8.1 National Institute for Health and Clinical Excellence Recommendations for Preoperative Testing

Study	Age (years)	Recommendation
Chest X-ray	Any age	Cardiovascular surgery
	60 or older	Grade 4 surgery and ASA 3 or greater with cardiovascular disease
Electrocardiogram	16 – 39	ASA 2 or greater with cardiovascular disease or cardiovascular surgery
	40 – 59	As above, plus grade 4 surgery if ASA 2 or greater with renal disease, or ASA 3 with respiratory disease
	60 – 79	As above, plus grade 2 surgery if ASA 2 or greater with renal disease, or ASA 3+ with respiratory disease or grade 3 surgery or greater
	80 or older	Consider deferring if grade 1 surgery
Full blood count	16 – 59	ASA 3 with renal disease, or grade 3 or greater surgery

	60 or older	As above, plus grade 2 or greater surgery
Hemostasis	16 or older	Never recommend, may be considered
Renal function	15–59	ASA 2 or greater with renal disease, ASA 3 or greater with cardiovascular disease, ASA 2 or greater with cardiovascular disease, with grade 3 or greater surgery, ASA 3 or greater with respiratory disease, with grade 3 or greater surgery
	60 or older	As above, plus ASA 2 with cardiovascular disease, with grade 2 or greater surgery, or any grade 3 surgery
Urinalysis	16 or older	Never recommended, may be considered

ASA, American Society of Anesthesiologists.

ASA grade: ASA 1, normal/healthy; ASA 2, mild systemic disease; ASA 3, severe systemic disease.

Surgery grade: grade 1, minor surgery; grade 2, intermediate surgery; grade 3, major surgery; grade 4, extensive surgery.

CARDIAC RISK ASSESSMENT

Any gynecologic oncologist must be aware of the significance of cardiac disease in women when evaluating cardiac risk preoperatively. In 1999, the American Heart Association (AHA) published the first women-specific recommendations on the prevention of cardiovascular disease (CVD) (9). These recommendations were updated in 2011 (10). Over the past 15 years, significant improvements have been made in the recognition and treatment of CVD in women; however, in recent years, the rate of death from coronary heart disease in women aged 35 to 54 years has been increasing. This increase is thought to be secondary to the alarming rise of obesity in the United States (11). Because of hormonal differences related to pregnancy and hormonal therapy, women are at higher risks for cerebrovascular events. The recently updated guidelines classify women in one of three groups: at high risk, at risk, or at ideal cardiovascular health. Preventative measures focus on normalization of cholesterol levels, treatment of hypertension, maintenance of a normal body mass index (BMI), smoking cessation, and consistent physical activity.

Cardiac risk factors are certainly one of the top concerns for surgeons when assessing perioperative risk. There are numerous reviews and systems that have been created for the purpose of evaluating cardiac risk among patients undergoing noncardiac surgery (12–16). The first large, prospective, multivariate analysis of patients undergoing noncardiac surgery was published by Goldman et al. in 1977 (17). They used definite endpoints of cardiac death, ventricular tachycardia, pulmonary edema, and myocardial infarction (MI). The assessment involves nine independent risk factors to create a point risk index and predict morbidity and mortality (Tables 8.2 and 8.3). One weakness of this index is that it underestimates risk in vascular surgery patients. To overcome this, newer cardiac risk assessment tools have been created. These include the Revised Cardiac Risk Index (RCRI) and the American College of Surgeons' National Surgical Quality Improvement Program (NSQIP) (18,19). The RCRI is a validated tool that assesses the risk of major cardiac complications in the perioperative period using six predictors of risk. The American College of Surgeons' NSQIP tool is different in that it adjusts risks depending on the type of surgery.

TABLE 8.2 Multifactorial Index of Cardiac Risk

Risk Factor	Points

S3 gallop or increased jugular venous pressure	11
Myocardial infarction in previous 6 months	10
More than five premature ventricular ectopic beats per minute	7
Rhythm other than sinus or premature atrial contractions	7
Age > 70 years	5
Emergency noncardiac operative procedure	4
Significant aortic stenosis	3
Poor general health status	3
Abdominal or thoracic surgery	3
Possible total	53

TABLE 8.3 Multifactorial Index of Cardiac Risk, Cardiac Risk Class, Morbidity, and Mortality

Cardiac Risk	Total Points	Morbidity (%)	Mortality
Class I	0–5	0.7	0.2
Class II	6–12	5.0	1.6
Class III	12–25	11.5	2.3
Class IV	>26	22.2	55.6

Source: Adapted from Goldman L, Caldera DL, Nussbaum SR, et al. Multifactorial index of cardiac risk in noncardiac surgical procedures. N Engl J Med. 1977;297:845–850, with permission.

In response to a shift in the literature from calculation of risk with indices to clinical decision making, especially in regard to the need for preoperative evaluation, the American College of Cardiology/American Heart Association (ACC/AHA) guidelines for the prevention of CVD in women were developed (20). This document provides risk classification of CVD, based on clinical criteria and/or the Framingham 10-year global risk score (Table 8.4). This CVD risk stratification has not been assessed specifically for preoperative risk assessment, but provides classification of women who may need further (noninvasive or invasive) evaluation. The updated 2011 guidelines change the definition of a high-risk patient to include one who is at 10% or higher risk for a CVD event within 10 years (10).

TABLE 8.4 Classification of CVD Risk in Women

Risk Status	Criteria
High risk	Established coronary heart disease
	Cerebrovascular disease
	Peripheral arterial disease
	Abdominal aortic aneurysm
	End-stage or chronic renal disease
	Diabetes mellitus
	10-year Framingham global risk >20%[a]
At risk	≤1 major risk factors for CVD, including:

	Cigarette smoking
	Poor diet
	Physical inactivity
	Obesity, especially central adiposity
	Family history of premature CVD (CVD at <55 years of age in male relative and <65 years of age in female relative)
	Evidence of subclinical vascular disease (e.g., coronary calcification)
	Metabolic syndrome
	Poor exercise capacity on treadmill test and/or abnormal heart rate recovery after stopping exercise
Optimal risk	Framingham global risk <10% and a healthy lifestyle, with no risk factors

CVD, coronary vascular disease.

[a]OR at high risk on the basis of another population-adapted tool used to assess global risk.

Source: Adapted from Mosca L, Banka CL, Benjamin EJ, et al. Evidence-based guidelines for cardiovascular disease prevention in women: 2007 update. Circulation. 2007;115:1481–1501, with permission.

Clearly, the approach to the patient must include a careful history and physical examination. Some risk calculators determine that age alone is an independent risk factor for perioperative morbidity secondary to major adverse coronary events (19). Age greater than 62 years is an independent risk factor for perioperative stroke (21). Any prior history of cardiac disease such as angina, MI, arrhythmia, congestive heart failure (CHF), or valvular disease must be evaluated. Patients with unstable angina, recent MI, class III–IV heart failure, decompensated congestive failure, or aortic stenosis (AS) present the highest risk. These patients will likely require further invasive testing. Severe AS must be identified preoperatively because the risk of perioperative morbidity is as high as 30% (22).

In patients without overt cardiac risks, other factors, such as insulin-dependent diabetes mellitus, elevated preoperative serum creatinine, and history of cerebrovascular disease, need to be considered for uncovering subclinical disease. These risk factors are identified in the risk prediction models (18,19).

In 2014, the ACC/AHA published revised guidelines to direct invasive or interventional evaluations (16). The guidelines utilize functional capacity in terms of metabolic equivalents, with a level <4 being considered poor. An example would be a patient's ability to climb one flight of stairs or walk up a hill, which would classify the patient in the >4 group.

Testing available for further evaluation includes both invasive and noninvasive methods. The routine resting electrocardiogram (ECG) is a valuable screening tool for patients in whom history of coronary artery disease is unknown (23). It can potentially identify a prior MI, which may prompt further evaluation of coronary artery disease. Echocardiography can predict postoperative CHF in patients with ejection fractions (EFs) less than 35% (24). Although echocardiography cannot reliably predict ischemia, it may be quite useful in the evaluation of valvular diseases or for follow-up of patients with known left ventricular (LV) dysfunction. Additionally, elevated preoperative brain natriuretic peptide is an independent predictor of 30-day adverse cardiovascular outcomes after noncardiac surgery (25). Exercise or pharmacologic stress testing provides valuable information for perioperative ischemic risk. Nuclear scintigraphy with evaluation of perfusion defects has shown a positive predictive value of 12% to 16% and a negative predictive value of 99% (26). Dobutamine stress echocardiography has shown similar predictive values.

The ACC/AHA recommendations provide a mechanism to segregate patients whose surgery must be delayed for further cardiac evaluation because of a recent MI; those who should have their CHF optimized; or those who should have optimized control of dysrhythmias. In selected patients, coronary revascularization, angioplasty, stent placement, or valve replacement may be prudent before the planned noncardiac surgery (16).

The risk of reinfarction after a recent MI is directly related to the interval between the MI and an event which could precipitate an MI. However, these rates have been declining due to improved perioperative care. Reinfarction rates have

dropped from 37% in patients undergoing noncardiac surgery within 3 months following MI to 5% to 10% more recently. Reinfarction rates continue to decline as the interval from the original MI increases, with rates of reinfarction being 2% to 3% and 1% to 2%, 4 to 6 months and greater than 6 months, respectively, following the acute event (27). Elective surgery should be postponed for 6 months following an acute MI; however, an urgent operation may be performed 4 to 6 weeks after infarction if stress testing is favorable and the patient receives cardiac monitoring in the perioperative period.

Perioperative β-Blockade

In 1996, a multicenter, randomized, placebo-controlled trial was published that evaluated the use of β-blockade with atenolol versus placebo in patients undergoing noncardiac surgery. Although no difference in perioperative mortality or MI was seen, the atenolol group had significantly fewer ischemic episodes (24% vs. 39%). Furthermore, at 6 and 24 months, the atenolol group had decreased mortality (9 vs. 21 deaths) and decreased number of cardiac events (16 vs. 32) (28). The Perioperative ISchemic Evaluation (POISE) trial showed that the use of β-blockers in the perioperative period reduces the risk of the composite outcome of cardiovascular death, nonfatal MI, and nonfatal cardiac arrest at 30 days. However, it also showed that bradycardic episodes and clinically significant hypotensive events resulted in an increased rate of strokes and death (29). The current recommendations from the ACC/AHA are that perioperative β-blockers should be continued on patients who are on β-blockers chronically. It may be reasonable to begin β-blockers on patients with intermediate- or high-risk myocardial ischemia; however, this must be guided by clinical circumstances (16).

PULMONARY RISK ASSESSMENT

Postoperative pulmonary complications (PPCs) represent a significant cause for morbidity and mortality in patients undergoing elective surgery. Additionally, they are one of the costliest of major postoperative complications (30). The incidence of pulmonary complications after nonthoracic surgery ranges from 2% to 19% (31). Laparotomy results in a 45% decrease in vital capacity and a 30% reduction in functional residual capacity (FRC) (32,33). When the patient is in the supine position, FRC is reduced below alveolar closing volume (i.e., the volume at which point alveoli start closing), which results in atelectasis (34).

When examining risk factors for postoperative pulmonary problems, a number of issues surface. General medical status (e.g., functional status, obesity, nutrition) is related to PPCs. A history of CHF, renal failure, poor mental status, and immunosuppression is associated with a higher PPC rate (35). Surgical issues such as the type of procedure (open or minimally invasive), the type of incision (thoracic and upper abdominal being worse than midline or lower abdominal), duration of anesthetic (>2 hours), the use of a nasogastric tube (NGT; increased risk), and the use of parenteral (increased risk) versus epidural (decreased risk) analgesics are all correlated with PPC incidence (36,37). All patients undergoing noncardiothoracic surgery should be evaluated for the presence of the following risk factors for PPCs to receive pre- and postoperative interventions to reduce risk: chronic obstructive pulmonary disease (COPD), CHF, ASA class of II or greater, functional dependence, and age older than 60 years. In terms of direct pulmonary risk factors, the most common preexisting pulmonary disease is COPD (38). These patients retain carbon dioxide, have poor gas exchange, and have an increased residual volume. Smoking and history of dyspnea, pneumonia, and sleep apnea are other risk categories (36).

When interpreting the usual preoperative radiographic and laboratory values, several caveats must be kept in mind. A preoperative chest radiograph in normal adults has no predictive value other than providing essential baseline data for an at-risk patient. Arterial blood gas analysis has not been shown to be useful in providing risk stratification (39). A low serum albumin is a powerful marker of increased risk and should be considered in patients with one or more risk factors for PPCs (40). Preoperative pulmonary function tests (PFTs) are rarely useful for risk stratification and are not indicated prior to surgery. A consensus statement from the American College of Physicians in 2006 recommended that preoperative PFTs or chest radiography may be appropriate in patients with a previous diagnosis of COPD or asthma (38). Such testing may

provide valuable baseline data and aid in risk stratification for patients with moderate to severe COPD who are undergoing major abdominal surgery.

Perioperative strategies for reducing the risk of PPCs include lung expansion techniques, smoking cessation, and optimization of gas exchange. Although preoperative and postoperative incentive spirometry has shown mixed results in reducing the rate of PPCs, it continues to be widely recommended (41), and it should be considered as a preventive strategy for any patient undergoing laparotomy. In order to maximize patient compliance, preoperative counseling and education are necessary. Clearly, COPD must be managed by controlling infection and optimizing medical regimens. Reactive airway disease should be prevented with the use of perioperative inhalation therapy such as β agonists. Steroid therapy is generally reserved for patients already utilizing these drugs as part of their medical regimen. These steroid-dependent patients will need stress-dose steroids to prevent insufficiency (see "Adrenal Suppression" section). Prophylactic antibiotics are not indicated in COPD patients to prevent pulmonary infections.

Smokers have significantly more postoperative complications, including pneumonia, surgical site infections, and death (42). Smoking-cessation programs have had an unclear effect on PPCs (43). Although data from poorly controlled trials have shown that short-term abstinence (<8 weeks from the time of surgery) may actually increase the complication rate, these results are controversial (44). However, abstinence for greater than 10 weeks demonstrated complication rates similar to those for nonsmokers (45). Unfortunately, the long-term success rate of smoking-cessation programs is low, and in the case of malignancy, the gynecologic oncologist rarely has the opportunity to delay the operation for 8 to 10 weeks.

Risk prediction tools for PPCs are available and can be useful in guiding the clinician's perioperative care (35,46–48).

ENDOCRINOLOGIC RISK ASSESSMENT

Diabetes

The prevalence of diabetes has reached epidemic proportions in the United States. In 2011, the Centers for Disease Control and Prevention reported that 25.8 million people or 8.3% of the population have diabetes (49). Diabetes accounts for the fourth leading comorbid condition among hospital discharges (50). One-fifth of surgical patients will have diabetes and people with known diabetes have a 50% risk of undergoing surgery at some point in their lifetime (51). Interestingly, one-third to one-half of patients hospitalized are unaware that they have diabetes and are currently receiving no treatment. It is only during preoperative evaluation for elective surgery or acute hospitalization that these patients will be diagnosed (52). Because of this prevalence, some authors have suggested that all surgical patients be regarded as dysglycemic until proven otherwise (53). Understanding the basic physiology of diabetes and how it impacts perioperative risk is crucial for the surgeon.

There are two types of diabetes. Type 1 diabetes occurs as a result of insulinopenia, with all type 1 diabetics being insulin dependent. In the absence of sufficient insulin, these patients develop ketoacidosis. Type 1 diabetics account for approximately 10% of all diabetics. Type 2 diabetes occurs as a result of insulin resistance and impaired insulin secretion. Type 2 diabetics may be treated with diet alone, oral hypoglycemic agents, noninsulin injectable medications, or insulin. These patients account for approximately 90% of all diabetics (54). However, approximately 30% of hospitalized patients will have a prediabetic condition consisting of impaired fasting glucose levels or impaired glucose tolerance (52). Thus, perioperative glycemic control will be dictated by known (or newly discovered) diabetic status.

When evaluating patients with known diabetes for surgery, attention should be directed toward the patient's diabetic status (i.e., type of glucose control; number of hypoglycemic events, etc.) and the long-term complications caused by diabetes, since this end organ damage can impact perioperative outcome. Most complications of diabetes are related to microvascular changes, such as diabetic retinopathy, neuropathy, nephropathy, and CVD (55). In addition to a thorough history and physical examination, preoperative studies should include an ECG to rule out a prior "silent" MI (especially in

patients with diabetes for more than 10 years), serum creatinine, blood urea nitrogen, urinary analyses to assess renal function, and glycosylated hemoglobin (HbA_{1C}) to evaluate recent glycemic control. HbA_{1C} levels reflect the level of hyperglycemia that red blood cells (RBC) have been exposed to. Because the average lifespan of an RBC is 120 days, HbA_{1C} is an indicator of glycemic control over that period of time (54). As mentioned earlier, because of the prevalence of dysglycemia among hospitalized adults in the United States, measurement of HbA_{1C}, as a screening for diabetes, may identify patients with undiagnosed diabetes or impaired glucose metabolism (53). HbA_{1C} levels ≤6.5% are associated with good long-term glucose control and have been associated with decreased rates of infectious complications across a variety of surgical procedures (56,57). However, HbA_{1C} levels >6.5% are diagnostic for diabetes and evidence of poor glycemic control in known diabetics (58,59). Ultimately, the type of diabetes, preoperative glycemic control, the extent and magnitude of the intended surgery, the elective or emergent nature of said surgery, and other comorbid medical conditions will affect the metabolic changes these patients face intra- and postoperatively (53).

Another entity that has come to light in the last decade among hospitalized patients is that of stress-induced hyperglycemia (SIH). This disease is defined as an inpatient fasting glucose measurement ≥126 mg/dL or a random glucose measurement of more than 200 mg/dL, which returns to normal after discharge (51,60). A growing body of evidence suggests that SIH and diabetic hyperglycemia are different diseases (61), and SIH confers a higher risk of adverse outcomes, such as an increased risk of in-hospital mortality (59,62,63) and longer lengths of stay compared with nondiabetic or hyperglycemic diabetic patients (60).

The armamentarium available for treatment of diabetes has expanded over the last decade. Type 1 diabetics will most likely be using a combination of insulin therapies for glycemic control, whereas type 2 diabetics may be on oral therapy alone, insulin therapy alone, injectable noninsulin therapy alone, or some combination therapy of all the aforementioned agents. Table 8.5 outlines some of these drugs and the timing for stopping these medications prior to surgical procedures because of their pharmacologic half-lives (64).

TABLE 8.5 Management of Diabetes Medications before Surgery in Patients Who Must Be NPO

Medication Type	Night before Surgery	Morning of Surgery
Oral agents		
Sulfonyl-urea		Hold
Glyburide	Give with meal	
Glipizide		
Glimepiride		
Metformin (contraindicated in women with creatinine levels >1.4)	Hold	Hold; can induce lactic acidosis and should be held in procedures that require IV contrast
Thiazolidinediones	Hold	Hold; Can cause fluid retention in the postoperative period
Rosiglitazone		
Pioglitazone		
Meglitinides	Give with meal	Hold
Repaglinide		
Nateglinide		

α-Glucosidase inhibitors	Give with meal	Hold
Acarbose		
Miglitol		
Dipeptidal peptidase-IV inhibitor	Give with meal	Hold
Sitagliptin		
Noninsulin injectable		
Incretin mimetics	Give 30–60 minutes before meal	Hold
Exenatide		
Amylin analog	Give immediately before meal	Hold
Pramlintide		
Insulin		
Regular insulin	Give full dose	Give half dose
Humulin R		
Novolin R		
ReliOn R		
NPH insulin	Give full dose	Give half dose
Humulin N		
Novolin N		
ReliOn N		
Premixed insulins	Give full dose	Give half dose
Humulin 70/30		
Novolin 70/30		
Humalog 75/25		
Novolog 70/30		
Rapid-acting insulin	Give full dose with meals	Hold
Aspart		
Glulisine		
Lispro		
Inhaled insulin		
Basal insulin (long-acting)	If patient is on basal insulin and rapid-acting insulin, give full dose. If patient is on oral diabetes medication plus basal insulin or basal insulin only, give half dose	If patient is on basal insulin and rapid-acting insulin, give full dose. If patient is on oral diabetes medication plus basal insulin or basal insulin only, give half dose
Glargine		
Detemir		

Continuous subcutaneous insulin pump	Continue current settings	Switch to continuous insulin infusion and titrate

Perioperative management of diabetes mellitus. Physicians' Information and Education Resources. American College of Physicians, 31 Aug. 2009. 26 Apr. 2012. http://pier.acponline.org/physicians/public/periopr879/tables/periopr879-tl.html, with permission.

The physiologic changes that diabetic patients encounter during surgery result in a hyperglycemic state due to insulin resistance. The stress of surgery increases secretion of epinephrine, norepinephrine, cortisol, and growth hormone, all of which directly antagonize insulin action (53–55). In addition, gluconeogenesis and lipolysis are increased with mobilization of glucose precursors, and a net protein catabolism ensues. Glycemic control perioperatively will depend on the type of diabetes or impaired glucose tolerance the patient has, as well as the medications that have/have not been utilized to control such disease states. Recently, the Clinical Guidelines Subcommittee of The Endocrinology Society published treatment guidelines for noncritically ill patients hospitalized and subsequently found to be hyperglycemic (known diabetes vs. unknown). The authors would direct the reader to review these guidelines, and recommendations from this group, for perioperative care of patients with hyperglycemia undergoing surgical interventions, are listed in Table 8.6 (65).

TABLE 8.6 Perioperative Blood Glucose Control: An Endocrine Society Clinical Practice Guideline

Recommendation Number	
5.3.1	All patients with type 1 diabetes who undergo minor or major surgical procedures receive either continuous insulin infusion or subcutaneous basal insulin with bolus insulin as required to prevent hyperglycemia during the perioperative period
5.3.2	Patients with diabetes should discontinue oral and noninsulin injectable antidiabetic agents before surgery with initiation of insulin therapy in those patients that develop hyperglycemia during the perioperative period
5.3.3	When instituting subcutaneous insulin therapy in the postsurgical setting, basal (for patients who are NPO) or basal bolus (for patients who are eating) insulin therapy is the preferred approach. Sliding scale insulin (SSI) should not be used

Source: Umpierrez GE, Hellman R, Korytkoski MT, et al. Management of hyperglycemia in hospitalized patients in non-critical care setting: an Endocrine Society Clinical Practice Guideline. J Clin Endocrinol Metab. 2012;97:16–38.

There are several case–control studies that demonstrate an increased risk for adverse outcomes in patients undergoing elective noncardiac surgery who have either preoperative or postoperative hyperglycemia (66–70). Postoperative glucose levels greater than 200 mg/dL are associated with prolonged hospital stays and increased risk of postoperative complications including wound infections and cardiac arrhythmias (67–69). Although diabetic patients with vascular disease are at risk of silent postoperative MI and acute renal failure (ARF), postoperative infections (respiratory, urinary, wound infections, etc.) account for about two-thirds of all postoperative complications and 20% of all postoperative deaths among diabetics undergoing surgery (56). Hyperglycemia has been shown to impair phagocytic function and chemotaxis of granulocytes when glucose levels are higher than 250 mg/dL (71).

Although glycemic control is important, the jury is still out on when control should be achieved (pre-, intra-, or postoperatively or throughout the entire perioperative period), what glucose levels should be achieved for maximum benefit, and which insulin regimen is most effective (53). The landmark publication by Van den Berghe et al. in 2001 showed, in a randomized, prospective fashion, that aggressive glycemic control through intensive insulin therapy (IIT) (maintaining glucose levels between 80 and 110 mg/dL) versus conventional insulin therapy (glucose levels between 180

and 200 mg/dL) in critically ill postoperative patients (more than 60% were cardiac surgery patients) reduced episodes of septicemia and in-hospital mortality by 46% and 34%, respectively (72). Despite the enthusiasm for tighter glucose control, subsequent studies over the last decade, with a heterogeneous population of acutely ill patients, have failed to confirm the results of Van den Berghe's work (53,60). In fact, the multinational, multidisciplinary **N**ormoglycemia in **I**ntensive **C**are **E**valuation and **S**urvival **U**sing **G**lucose **A**lgorithm **R**egulation (NICE-SUGAR) trial in 6,104 ICU patients reported increased mortality rates (27.5% [IIT] vs. 24.9% [control]) in patients who were kept at blood glucose levels of 81 to 108 mg/dL versus <180 mg/dL. The increased mortality was driven by increased rates of hypoglycemia (blood glucose <40 mg/dL) among patients with the tightest blood glucose control (6.8% [IIT] vs. 0.5% [control]) (73). Because of the NICE-SUGAR study, and others (60), recommendations for blood glucose targets have relaxed somewhat depending upon the condition of the patient.

Intravenous (IV) insulin therapy should be instituted in critically ill patients when blood glucose levels exceed 180 mg/dL, with the goal of maintaining glucose control between 140 and 180 mg/dL. For noncritically ill patients, the preprandial goal for glucose level is less than 140 mg/dL (74), with maintenance of blood glucose at these levels while minimizing hypoglycemia. Attaining these levels of glycemic control will depend upon the patient's type of diabetes, her medical condition, and her oral intake status.

Individual institutional policy will vary as to where patients may receive IV insulin therapy (ICU vs. step-down units vs. routine hospital floors). If the patient is receiving IV insulin, then transition to a subcutaneous route must be started before discontinuing the IV route. Most patients can be converted to long-acting basal insulin, with the dose usually being 50% to 80% of the prior day's IV insulin dose. An insulin regimen utilizing a subcutaneous basal/bolus approach outperforms traditional sliding scale regular insulin regimens. Umpierrez et al. expanded their previous work (75) by conducting a prospective randomized trial comparing subcutaneous basal/bolus insulin replacement to traditional subcutaneous sliding scale insulin (SSI) replacement for patients with type 2 diabetes undergoing general surgery, not expected to be admitted to the ICU, and whose glucose levels exceeded 140 mg/dL. In the group randomized to the basal/bolus insulin, the starting daily dose was 0.5 U/kg/day, with half of the dose being given as basal insulin (insulin glargine) once daily and half given as rapid-acting insulin analog (insulin glulisine) in fixed doses prior to meals. If the patient was nil per os (NPO), then the insulin glargine dose was given and the insulin glulisine was held until meals were resumed. For supplementation, the rapid-acting analog was used. Among the 211 patients studied, those in the basal/bolus group received higher daily doses of insulin, had lower daily mean blood glucose levels (27 mg/dL), had the same risk of hypoglycemic episodes (blood glucose levels <40 mg/dL), and more often achieved the glycemic goal of <140 mg/dL. In addition, the basal/bolus group had fewer wound infections, pneumonias, episodes of bacteremia, respiratory failure, and ARF as compared with the SSI group. There also was a nonsignificant trend toward fewer postsurgical ICU admissions and shorter ICU stays than in the SSI group (76). Table 8.7 demonstrates the basal/bolus method to control hyperglycemia in type 2 diabetics postoperatively. Use of oral diabetic agents in hospitalized patients is not recommended (77). ***Best Practice: Perioperative maintenance of blood glucose levels (<180 to 200 mg/dL) results in improved perioperative outcomes. Glucose levels above this range should be treated with insulin infusions and regular blood glucose monitoring to avoid the risk of hypoglycemia.***

TABLE 8.7 Basal/Bolus Insulin Treatment Protocol

Starting Insulin Doses (Insulin Glargine)	Supplemental Insulin (Insulin Glulisine)	Insulin Adjustment
Discontinue all oral antidiabetic and noninsulin injectable medications	Give supplemental insulin glulisine according to the sliding scale (below) for blood glucose >140 mg/dL	If the fasting and predinner BG is between 100 and 140 mg/dL and no hypoglycemia

<table>

Thyroid Disorders

When patients give a history of hypothyroidism or hyperthyroidism during evaluation for surgery, thyroid-stimulating hormone (TSH) and thyroxine (T4) levels should be obtained. The primary objective is to determine whether the patient is

euthyroid or not, prior to surgical intervention, so as to avoid the complications of myxedema or thyroid storm in the postoperative period.

Hypothyroidism is a common condition in the United States, affecting approximately 1% of all patients and 5% of the population over the age of 50, and it develops 10 times more often in women than in men (78). Decision to operate on patients with hypothyroidism will depend upon the level of hypothyroidism and the urgency of the surgery. Hypothyroidism can influence many physiologic functions, such as myocardial function, respiration, gastrointestinal (GI) motility, hemostasis, and free water balance (53,79). Although there have been no prospective, randomized studies looking at the surgical outcome of hypothyroid patients versus controls, several retrospective case-matched control studies have evaluated hypothyroid patients undergoing surgery. A study by Weinberg et al. demonstrated no differences between hypothyroid and euthyroid controls for perioperative complications. In addition, no differences in outcome were seen when hypothyroidism was stratified by T4 levels. The investigators concluded that patients with mild to moderate hypothyroidism should not be denied needed surgery in order to correct the metabolic problem. They further stated that insufficient numbers of patients with severe hypothyroidism precluded recommendations for perioperative care of these patients (80). In another retrospective study, Ladenson et al. reviewed perioperative complications among hypothyroid patients undergoing surgery, finding more intraoperative hypotension in noncardiac surgery, more heart failure in cardiac surgery, and more GI and neuropsychiatric complications. They also noted that patients were unable to mount fever in the face of infection, although infection rates were not different. Further more, no differences were found in the duration of hospitalization, perioperative arrhythmias, delayed anesthesia recovery, pulmonary complications, or mortality (81).

Patients with mild to moderate hypothyroidism requiring urgent surgery may have it without delay. These patients may have more minor complications of ileus, postoperative delirium, or infection without fever. Patients with severe hypothyroidism (myxedema coma, decreased mentation, pericardial effusions, heart failure, or very low levels of T4) who are to undergo urgent/emergent surgery will need IV levothyroxine (200 to 500 μg given during 30 minutes) followed by daily doses of 50 to 100 μg IV. These patients will likely need stress-dose glucocorticoids (see "Adrenal Suppression" section) started prior to, during, and continued after surgery due to coexisting adrenal insufficiency (AI; or due to the fact that IV replacement with levothyroxine may precipitate AI) (53,81,82).

Myxedema coma is a rare condition, with an incidence of 0.22 per million patients per year. Most of the cases (80%) occur among hospitalized, elderly (older than 60 years) women with long-standing hypothyroidism, but it can occur at any age (83). A majority of the cases will occur in the postoperative period due to inciting causes such as infections, cold exposure, sedatives, analgesics, and other medications. The mortality from this disease is high (80%), but has been decreasing in recent years due to increased awareness, testing, and improved perioperative care (84–86). Myxedema coma is characterized by severely depressed mental status, seizure, hypothermia, bradycardia, hyponatremia, heart failure, and hypopnea. Although maintenance of normothermia by warming is tempting, the resulting vasodilation may cause cardiovascular collapse in patients with intravascular volume depletion, cardiac insufficiency, and pericardial effusion/tamponade and should be performed carefully if at all (84). Myxedema coma is a medical emergency and necessitates urgent administration of levothyroxine. An initial IV bolus of 200 to 500 μg should be given, followed by 50 to 100 μg IV daily. Dehydration is frequently present and aggressive volume resuscitation with dextrose and normal saline should be instituted. IV glucocorticoids should be administered (50 mg hydrocortisone IV, four times daily) because of frequent AI. Resolution of symptoms, if properly treated, should begin within 24 hours.

Patients using thyroid replacement preparations can have their doses held during the immediate postoperative period until they are able to tolerate oral intake, as the half-life of these drugs is 5 to 9 days (79).

The causes of hyperthyroidism are many, but the most common cause is Graves disease. This autoimmune disorder, caused by an antibody directed to TSH receptors, results in increased thyroid hormone production. The clinical signs of hyperthyroidism include tachycardia, atrial fibrillation, fever, tremor, goiter, and ophthalmopathy (54). Most complications occurring in hyperthyroid patients undergoing surgery involve cardiac function, as T4 and T3 have direct inotropic and chronotropic effect on the heart and a vasodilatory effect on peripheral vasculature, resulting in the activation of the renin–angiotensin–aldosterone system. All of these events result in a high cardiac output state, which increases cardiac work and

oxygen requirements and can result in MI (83). Arrhythmias are very common in the face of hyperthyroidism, with atrial fibrillation occurring in 10% to 20% of patients (87–90). Again, level of control prior to the operation will determine the perioperative outcome for the patient. Patients with controlled hyperthyroidism should be instructed to take their antithyroid medications in the morning of the day of surgery. Patients with mild hyperthyroidism may have surgery with preoperative β-blockers. However, patients with moderate or severe disease should have surgery canceled until a euthyroid state is attained (91).

The greatest perioperative risk for patients who have undiagnosed hyperthyroidism or who are inadequately treated is a rare, yet life-threatening condition known as thyroid storm. This "thyroid emergency" usually occurs intraoperatively or 48 hours postoperatively. The mortality of thyroid storm is 10% to 75% and requires treatment in a critical care environment (78). Symptoms are nonspecific and include hyperpyrexia, tachycardia, delirium, nausea and vomiting, and diarrhea (92). Treatment of thyroid storm is aimed at stopping production of thyroid hormone and treating the systemic effects of the decompensated patient. Antithyroid medications such as carbimazole, methimazole, and propylthiouracil (PTU) are used to inhibit the new synthesis of thyroid hormones. Unfortunately, there are no IV preparations for these compounds, so they must be administered enterally or per rectum as retention enemas or suppositories. Recent guidelines from the American Thyroid Association and the Association of Clinical Endocrinologists recommend that PTU be started with a loading dose of 500 to 1,000 mg followed by 250 mg every 4 hours, and methimazole should be administered at daily doses of 60 to 80 mg (93). Administering these drugs in this sequence will provide more rapid clinical improvement because PTU has the added advantage of inhibiting conversion of T4 to T3, which methimazole does not do. These drugs prevent synthesis of new thyroid hormone, but will not stop release of stored thyroid hormone. Either inorganic iodine or lithium carbonate (for patients who are allergic to iodine; 300 mg orally every 6 hours) must be given. Lugol's solution or a saturated solution of potassium iodide (3 to 5 drops orally, every 6 hours) may be used, but must not be given sooner than 1 hour after the administration of the thionamide dosage; otherwise thyroid hormone synthesis will be enhanced by the iodine treatment. In severe cases of thyroid storm, plasmapheresis and therapeutic plasma exchange may be needed. β-Blockade is critical to ameliorate the manifestations of thyroid excess and does so by correcting the heart rate, reducing cardiac oxygen demand, and decreasing agitation, convulsions, psychotic behavior, and tremors. Propranolol is the most commonly used agent and dosages of 60 to 80 mg given orally every 4 hours or 0.5 to 1 mg IV followed by subsequent doses of 2 to 3 mg every several hours are recommended. Another theoretic benefit of β-blockade is the inhibition of conversion of T4 to T3. One other medication that has a high therapeutic benefit is the administration of corticosteroids, which not only inhibits the conversion of T4 to T3, but also treats AI, which may have occurred due to the rapid turnover of cortisol. Acetaminophen is preferred to salicylates, as the latter may exacerbate thyrotoxicosis by decreasing thyroid protein binding and increasing free T3 and T4. Finally, a thorough search for the precipitating cause of the thyroid storm should be undertaken immediately, with the most common cause in the perioperative period being infection (83).

Adrenal Suppression

How patients respond to stress is directly related to the hypothalamic-pituitary axis (HPA), and any defect in this cycle can have dramatic effects in the perioperative period. The most common cause of primary AI is autoimmune adrenalitis, where the adrenal cortex is destroyed and the patient's endogenous production of glucocorticoid steroids is reduced or ceases. Secondary AI is characterized by atrophy of the adrenal cortex as a result of deficient adrenocorticotrophic hormone (ACTH) stimulation. The most common cause of secondary AI is administration of exogenous corticosteroids, which feeds back to cause a decrease in hypothalamic corticotropin-releasing hormone and subsequent decreased pituitary ACTH secretion. Although there is remarkable variability in individual response to a particular dose and length of treatment with steroids, in general, any patient who received the equivalent of 20 mg per day of prednisone for more than 5 days is at risk for HPA suppression. If the duration of steroid treatment is 1 month or longer, the patient will have HPA suppression, which can last for 6 to 12 months after stopping therapy, whereas an equivalent dose of prednisone 5 mg (or less) for any period of time will not usually suppress the HPA axis (94–96). Assessment of adrenal function (ACTH stimulation tests) in

the perioperative period has not been shown to be sensitive or specific in identifying patients who are at risk for AI and who might respond to supplemental corticosteroids (97–100).

Recently, Marik and Varon performed a meta-analysis of the world literature concerning perioperative stress doses of corticosteroids for patients who take corticosteroids chronically. Their search revealed two randomized controlled trials (RCTs) and seven cohort studies, for a total of 315 patients. Although the number of patients is small, the two RCTs showed no differences in the hemodynamic profiles of patients receiving stress doses of corticosteroids, compared with patients receiving only their usual daily dose of corticosteroid. Similarly, in five of the seven cohort studies, patients who continued to receive their usual daily doses of corticosteroids without additional stress doses did not develop unexplained hypotension or adrenal crisis perioperatively. The remaining two cohort studies each had one patient who stopped his or her usual daily dose of corticosteroid preoperatively, and each developed unexplained postoperative hypotension, which responded to hydrocortisone and fluid therapy. The authors recommend that patients receiving therapeutic doses of corticosteroids, who undergo surgery, do not routinely need stress doses of corticosteroids as long as their usual daily dose is continued. In addition, adrenal function testing is not recommended for these patients because the test is overly sensitive and does not predict which patient will develop adrenal crisis. Further more, patients who have primary AI and who are taking physiologic replacement doses of corticosteroids will require supplemental stress doses of corticosteroids in the perioperative period (101).

Figure 8.1 outlines an algorithm that may be helpful in guiding clinicians in their decision-making about stress-dose steroids for patients who take them chronically. Giving stress-dose glucocorticoids needs to be weighed against the potential side effects of the drug (such as poor wound healing, fluid retention, and increased risk of infection) versus the benefits of supporting the HPA axis in a surgically stressed patient.

Primary adrenal insufficiency (AI)

Hyponatremia

Hyperkalemia

Hypotension

Eosinophilia

OR

Secondary adrenal insufficiency (AI)

Patients taking 20 mg prednisone (or equivalent) for 5 days

Procedure	Emergent Surgery	Urgent or Elective Surgery
Minor Procedures performed under local anesthesia or less than 1 hour	25 mg IV Hydrocortisone (or equivalent)	1)No stress dose corticosteroids 2)Continue usual daily dose 3)If signs and symptoms of AI intraoperatively, 25 mg IV hydrocortisone (or equivalent)
Moderate Most vascular and orthopedic procedures	50 mg IV Hydrocortisone (or equivalent)	Preoperative short ACTH stim test[a] a)If appropriate response, no stress dose steroids. Continue usual daily dose b)If inappropriate response or suspected AI intraoperatively, 50 mg IV hydrocortisone (or equivalent)
Major Extensive procedures which last more than 2 hours and any procedure using cardiopulmonary bypass	100 mg IV Hydrocortisone (or equivalent)	Preoperative short ACTH stim test[a] a)If appropriate response, no stress dose steroids. Continue usual daily dose b)If inappropriate response or suspected AI intraoperatively, 100 mg IV hydrocortisone (or equivalent)

Figure 8.1 Algorithm for adrenal insufficiency. ACTH, adrenocorticotrophic hormone.
[a]The short ACTH stimulation involves IV administration of 250 μg synthetic ACTH (Cortrosyn, cosyntropin) followed by plasma cortisol collection 30 minutes later. Normal cortisol levels after stimulation greater than 18 μg/dL.
When given intraoperatively, steroid doses are continued every 8 hours for 48 hours.

RENAL RISK ASSESSMENT

Chronic kidney disease (CKD) affects over 13 million Americans (20 years and older; CKD stage 2 or worse) (102), with most having a glomerular filtration rate (GFR) of less than 60 mL/min/1.73 m^2 (103). The most common form of renal failure facing the surgeon is acute kidney injury (AKI) occurring during the postoperative period, which will be discussed in the section on postoperative/critical care. Since 2002, a uniform classification system for CKD was introduced, stratifying CKD into five stages based on estimation of GFR and documentation of renal injury (103). Class 5 CKD, or end-stage renal disease (ESRD), includes patients who require renal replacement therapy (usually dialysis) for treatment (102). With the aging population, increasing prevalence of diabetes and hypertension, and advances in dialytic therapy, the number of patients living with CKD is increasing (102). Therefore, surgeons must be cognizant of the potential perioperative risks associated with these patients.

The predominant causes of CKD are diabetes and hypertension, accounting for 71% of all patients who are dialysis dependent (102). Patients with these underlying diseases tend to have other comorbid conditions such as coronary artery disease and peripheral vascular disease. Evaluation of CKD patients undergoing surgery should focus on four areas: cardiac evaluation, fluid and electrolyte management, anemia, and bleeding diatheses. Of course, glycemic control for diabetics and blood pressure control for hypertensive patients is obvious.

CVD has long been recognized as the leading cause of death among ESRD patients, which occurs in 50% of patients (102,104,105). However, patients with other stages of CKD, even minor derangements, have an increased risk of CVD. A recent study correlated the stage of CKD with odds ratios (ORs) for cardiovascular risk, demonstrating a graded increase in risk with increasing stage of CKD (OR 15 for stage I to OR 20 to 1,000 for stage V) (105). The disease factors which contribute to CVD among CKD patients include microalbuminuria/proteinuria, hypertension, diabetes, dsylipidemia, and smoking (106). In addition, many CKD patients will have coronary artery disease (23% to 40%) (107–109), and many ESRD patients (70% to 80%) will develop ventricular hypertrophy due to hypertension and severe anemia. This hypertrophy results in a decreased myocardial capillary density and diastolic and systolic dysfunction, all of which leads to disturbances in intraventricular conduction, electrical excitability, and ventricular arrhythmias (110). Therefore, these patients may benefit from a formal cardiac clearance from a cardiologist prior to surgical intervention.

The capacity of the failing kidney to maintain volume and electrolyte homeostasis is achieved through adaptive processes, which are limited in their ability to respond to physiologic stresses, placing well-compensated patients, in the premorbid state, at increased risk of fluid and electrolyte disturbances during the perioperative period (111). Intraoperative and perioperative fluid management in patients with CKD must therefore take into account the reduced capacity for both water excretion and conservation. Excessive free water administration must be avoided to prevent iatrogenic hypotonicity, while providing sufficient free water to prevent hypertonicity. Electrolyte status should be monitored frequently and water administration adjusted if hypo- or hypernatremia ensues (112). ESRD patients who are dependent upon dialysis will need to be euvolemic prior to surgery. Thus, communication with the patient's nephrologist is paramount. Details about the operation should be discussed, with planned preoperative dialysis (without heparin 24 hours prior to surgery) and postoperative dialysis on the day of surgery for large intraoperative fluid loads. Electrolytes should be monitored in the immediate postoperative period, with hyperkalemia being aggressively managed with dialysis, or medically if necessary. Acute hyperkalemia may be treated with glucose and insulin, which will drive the Na/K-ATPase pump resulting in an increase of intracellular potassium and lowering of extracellular potassium. Ten milliliters of calcium gluconate can afford cardioprotection and membrane stabilization in patients with abnormal ECGs (113). Decreasing total body potassium is the final step in the treatment of hyperkalemia. In nonoliguric patients, renal potassium excretion may be enhanced with loop-acting diuretics. Sodium polystyrene sulfonate (Kionex, Kayexalate) may be used as an exchange resin in the GI tract. Forty grams dissolved in 80 mL of sorbitol (or more to promote elimination) and given orally will bind one millimole of potassium for each gram given. Alternatively, 50 to 100 g of sodium polystyrene sulfonate may be dissolved in 200 mL of water and given rectally as a retention enema by inserting a Foley catheter into the rectum and filling the balloon (112). These administrations should be repeated every 2 to 4 hours until the potassium level is in a normal range (see section on potassium derangements). Caution with the use of this resin in postoperative patients is urged, as intestinal necrosis has been reported (114).

Most patients with CKD have or will develop anemia due to erythropoietin deficiency during the course of their disease and, prior to the introduction of erythropoietin stimulating agents (ESAs), were transfusion dependent. In recent years, the use of ESAs has come under scrutiny. Recent reviews have demonstrated that raising the hemoglobin levels above 11 g/dL in patients with CKD resulted in a 1.14-fold increase in OR deaths. These results highlight the need to carefully manage hemoglobin levels with ESAs within a recommended range of 9 to 11 g/dL (115,116). In urgent situations, transfusion of blood is necessary to maintain hemoglobin prior to and during surgery.

CKD patients have an increased risk of bleeding complications. Platelet dysfunction caused by renal failure is multifactorial, with retained uremic toxins, abnormal binding of von Willebrand factor, abnormal platelet arachidonic acid metabolism, and excess vascular prostacyclin and nitric oxide production all being implicated (117). The bleeding time provides the best correlation with risk of clinical bleeding in CKD patients. If a patient has demonstrated prior bleeding because of uremic platelet dysfunction, these patients must be treated with 1-deamino-8-D-arginine vasopressin IV, or intranasally, and with cryoprecipitate to prevent bleeding during surgery (118). In addition, patients may be treated with IV conjugated estrogens (0.6 mg/kg) if they are given 4 to 5 days prior to surgery (112,119).

Furthermore, with reduced or absent renal function, these patients metabolize drugs such as antibiotics, anesthetics, and analgesics poorly. Drug administration in ESRD must be done judiciously, with careful attention to the pharmacokinetics of particular drugs. Multiple guidelines exist that can direct drug dose reductions for patients with ESRD (120,121).

HEPATIC RISK ASSESSMENT

An increasing number of patients with chronic liver disease (CLD), advanced or end stage, will require nonliver transplant surgery (122). Reasons for this increase are an aging population, better long-term survival of patients with liver cirrhosis, and continuously improving outcomes after surgery and critical care medicine (123). Historically, liver dysfunction was related to chronic viral or alcoholic hepatitis. While the incidence of these conditions has not changed dramatically in recent years, the rising rate of obesity has led to nonalcoholic fatty liver disease, which is increasingly recognized as the most common cause of CLD in the United States (124).

As mentioned earlier, thorough preoperative evaluation of patients includes a comprehensive history and physical examination, with laboratory testing based upon historical and physical findings. Routine testing of liver function or coagulation in asymptomatic patients rarely yields abnormal results or changes in perioperative management (7). However, patients with a history of liver disease, jaundice, blood transfusions, the use of alcohol or other recreational drugs, hepatitis, or physical findings of icterus, hepatosplenomegaly, palmar erythema, or spider nevi should be tested to rule out occult or active liver diseases (123).

Patients with acute hepatitis (viral or alcohol induced) should have their surgery delayed until the acute phase of the disease process has passed and liver function tests have returned to normal. Mortality rates among these patients can range from 10% to 58% if surgery is pursued. Patients with acute liver failure/fulminant liver failure, defined as the development of jaundice, coagulopathy, and hepatic encephalopathy within 26 weeks in a patient with acute liver injury and without preexisting liver disease, are critically ill, and all surgery other than liver transplantation is contraindicated in these patients (125). Contrarily, patients with chronic infectious hepatitis, which is stable, tolerate surgery with minimal mortality (122,126,127). Of course the operator should practice universal precautions with all surgical interventions, regardless of the patient's known infectivity status.

Assessing the severity of the underlying liver disease is important to determine the perioperative outcome, which has been correlated with two classification systems: the Child-Turcotte-Pugh (CTP) classification and the model of end-stage liver disease (MELD) score. The CTP score was the first predictor of surgical risk/mortality for patients undergoing surgical intervention, specifically, patients having portacaval shunts. The system was modified by Pugh and colleagues to include prothrombin time in place of the subjective assessment of nutritional status, for use in patients undergoing

esophageal transections for bleeding varices (128,129). Although widely known for classifying liver disease, this system has been criticized for utilizing subjective variables (ascites and encephalopathy) in developing a score. However, the CTP score correlates with mortality in patients undergoing differing types of surgery (123,130) (Table 8.8). The MELD score was originally devised as a prognostic measure of short-term mortality in patients with cirrhosis undergoing placement of a transjugular intrahepatic portosystemic shunt (131). The MELD score is derived from a complex formula which incorporates three biochemical variables (serum total bilirubin, serum creatinine, and the international normalized ratio [INR]) and assigns the patient a score of 8 to 40 (Table 8.9). The risk of morbidity and mortality in patients with liver disease depends upon the type of surgery and has been correlated to the aforementioned classification systems

TABLE 8.8 Child-Turcotte-Pugh (CTP) Classification of Liver Disease and Operative Mortality

	Score		
Component	1 Point	2 Points	3 Points
Ascites	None	Controlled with medication	Treatment refractory
Encephalopathy	Absent	Grade I–II; controlled with medication	Grade III–IV; treatment refractory
Albumin, g/L	>3.5	2.8–3.5	<2.8
Bilirubin, mg/dL	<2	2–3	>3
INR	<1.7	1.7–2.3	>2.3
CTP Classification	Class A (5–6 points)	Class B (7–9 points)	Class C (10–15 points)
90-day mortality risk (abdominal surgery)	2%–10%	2%–30%	12%–76%

(Tables 8.8 **and** 8.9) (130). However, it is likely that over the last two decades, mortality rates have decreased, despite the absence of large studies confirming this assumption (123).

TABLE 8.9 Model for End-Stage Liver Disease (MELD) Score

MELD Score = $(9.6 \times \log_e[\text{Creatinine}]) + (3.8 \times \log_e[\text{Bilirubin}]) + (11.2 \times \log_e[\text{INR}]) + 6.4$			
Creatinine levels above 4.0 mg/dL are assigned 4.0 mg/dL. Levels under 1.0 mg/dL are assigned 1.0 mg/dL. If the patient has had dialysis twice in the previous week, the value is assigned 4.0 mg/dL			
Bilirubin levels below 1.0 mg/dL are assigned 1.0 mg/dL			
INR levels below 1.0 are assigned 1.0			
The maximum score is 40. Scores calculated greater than 40 are assigned a value of 40			
MELD Score	Less than 10	10–15	Greater than 15
	Low Risk	Intermediate Risk	1. High Risk
30-Day Mortality (Abdominal/cardiac/orthopedic surgery)	5%–5.7%	10%	2. >50%

Patients with cirrhosis of the liver also have coagulopathies, which need to be corrected prior to surgery. Vitamin K, fresh frozen plasma, or cryoprecipitate may be administered to correct the prothrombin time to within 3 seconds of normal. Figure 8.2 presents an algorithm for patients with liver disease facing surgery.

Finally, selection of medications in patients with hepatic dysfunction needs to be done carefully, from types of perioperative antibiotics to anesthetic agents and analgesics. Patients with liver dysfunction are particularly susceptible to anesthetic effects such as changes in hepatic metabolism of medications and changes in hepatic blood flow. Alterations of the type and the dose of an agent are necessary to avoid postoperative hepatic dysfunction and hepatitis. Postoperative pain management with narcotic agents needs to be reduced by as much as 50% to account for the altered hepatic metabolism in these patients (132).

PREOPERATIVE NUTRITIONAL ASSESSMENT

There is a clear correlation between degree of malnutrition and increased risk of perioperative complications in cancer

patients undergoing surgery (133). The broader consideration of nutrition in the gynecologic cancer patient is discussed in Chapter 32. The intent of this section is to present the concepts of preoperative nutritional evaluation and support of the gynecologic oncology patient undergoing surgery. Early refeeding and enteral and parenteral nutritional support in the postoperative patient will be discussed later.

The incidence of malnutrition among cancer patients has been estimated to be 20% to 80%, with the prevalence among gynecologic oncology patients being approximately 20%. For example, ovarian cancer patients are 19 times more likely to have moderate malnutrition when compared with patients with other gynecologic malignancies or benign conditions (134,135). Malnourished gynecologic oncology patients have been found to have an increased risk of postoperative complications, longer lengths of stay, hospital readmissions, reoperations, earlier cancer recurrences, and residual tumor after initial surgery (135–137). The methods for assessing malnutrition have varied among investigators and have included weight loss over a given time, various objective anthropometric parameters (e.g., weight loss, BMI, triceps skinfold thickness, and arm circumference), biochemical testing (e.g., serum albumin, prealbumin, total protein, transferrin, hemoglobin, and vitamins), and immunologic testing (skin sensitivity tests) (Table 8.10) (138).

TABLE 8.10 Measurement of Nutritional Depletion

	Depletion		
Parameters	Mild	Moderate	Severe
Triceps skin fold (TSF) % Standard	50 - 90	30 - 50	>30
Mid-arm muscle circumference (MAMC) % Standard	80 - 90	70 - 80	>70
Albumin, g/dL	3.0 - 3.4	2.1 - 3.0	>2.1
Total lymphocyte count (TLC), cmm	1,200 - 1,500	800 - 1,200	>800
Weight loss, % initial			
In 1 week	>1	1 - 2	<2
In 1 month	>2	2 - 5	<5
In 3 months	>5	5.0 - 7.5	<7.5
In 6 months	>7.5	7.5 - 10.0	<10.0

Nutrition screening refers to the initial clinical evaluation that can quickly identify patients at high risk for malnutrition and who, later, may undergo a more formal and extensive nutritional assessment. Such instruments are the Malnutrition Screening Tool and the Malnutrition Universal Screening Tool, which have been used in oncology patients (Table 8.11). Logically, identifying patients at nutritional risk, by screening, will mark them for subsequent formal nutrition assessment and identify opportunities for medical nutrition therapy, which ultimately should improve patient outcomes. Unfortunately, this sequence of assumptions has never been subjected to prospective confirmation in clinical trials (139).

TABLE 8.11 Nutritional Screening and Assessment Tools

Tool	Components
Screening Instruments	
Malnutrition Screening Tool (MST)	3 items: weight, percentage weight loss, appetite
Malnutrition Universal Screening Tool (MUST)	3 items: BMI, percentage weight loss, acute disease effect
Nutritional Risk Screening 2002 (NRS	4 items: reduced BMI, percentage weight loss, decreased dietary intake, acute disease effect

2002)

Assessment Instruments	
Patient-Generated Subjective Global Assessment (PG-SGA)	Patient (4 questions): weight history, symptoms, food intake, activity level; Health care provider: metabolic demand, diagnosis and comorbidities, physical examination
Subjective Global Assessment (SGA)	History and physical examination to assign nutrition score
Prognostic Nutritional Index (PNI)	Equation: PNI Score (%) = 158 − 16.6 (albumin level in g/dL) − 0.78 (triceps skin fold in mm) − 0.2 (transferrin level in mg/dL) − 5.8 (Grade of delayed hypersensitivity)
Nutrition Risk Index (NRI)	Equation: NRI = 1.519 (serum albumin; g/dL) + 41.7 (current weight/usual weight) × 100
Mini Nutritional Assessment (MNA)	18 items: Screening portion (6 questions): food intake, weight loss, mobility stress, BMI; Assessment (12 questions): medical history, eating habits, anthropometric measurements

Source: Adapted from Huhmann MB, August DA. Review of American Society for Parenteral and Enteral Nutrition (ASPEN) clinical guidelines for nutrition support in cancer patients: nutrition screening and assessment. Nutr Clin Pract. 2008;23:182–188, with permission.

Many nutrition assessment tools have been developed, including subjective and objective data to assign risk, and some have been validated in cancer patients, including gynecologic cancer patients. Those instruments that have been used in cancer patients include the Subjective Global Assessment (SGA), the Patient-Generated Subjective Global Assessment (PG-SGA), Nutrition Risk Index (NRI), the Mini Nutritional Assessment (MNA), Prognostic Nutritional Index (PNI), and the Nutritional Risk Screening 2002 (NRS 2002) (Table 8.11). Although these are just examples of the many assessment tools available, none has emerged as the “gold standard” for nutritional screening and/or nutritional assessment among cancer patients, and their use depends upon which organization endorses a particular tool.

The SGA tool, originally described by Detsky in 1987, uses history and physical examination to assign a nutrition risk score. The PG-SGA was adapted from the SGA by Ottery, and later modified by McCallum and Polisena to give a numerical score of 0 to 47, specifically for the oncology population (140–143). It consists of two sections, one of which is done by the patient. This portion elicits information related to weight history, symptoms, food intake, and activity level. The other section, completed by a health care professional, includes an evaluation of metabolic demand, diagnosis, and comorbidities in relation to nutrition requirements and elements of physical examination. Every portion of the tool is given a numeric score, including the patient’s portion, which is used to triage intervention. Laky and colleagues in 2007 showed, in a prospective fashion, that the PG-SGA could be easily administered to identify gynecologic cancer patients at risk for malnutrition. Their work established a prevalence of malnutrition among their patients in Brisbane, Australia. Among 145 patients with known or suspected gynecologic cancer, 116 patients were classified as well nourished (PG-SGA A), 29 patients were moderately malnourished (PG-SGA B), and none of the patients were severely malnourished (PG-SGA C). These investigators found that ovarian cancer patients were 19 times more likely to be malnourished, compared with patients with other gynecologic malignancies or benign conditions. In addition, they found that preoperative serum albumin levels correlated with the PG-SGA B score among ovarian cancer patients, similar to other previous reports (136,137,143), and may be a good indicator of malnutrition among gynecologic cancer patients in the absence of a full nutritional assessment (134). In 2008, Laky found that the scored PG-SGA, albumin level, triceps skinfold thickness, and total body potassium could predict the SGA better than chance. The authors concluded that the scored PG-SGA is the most appropriate tool for identifying malnutrition in gynecologic cancer patients.

The NRI was used to stratify nutrition risk in the Veterans Affairs Total Parenteral Nutrition Cooperative Study Group trial of perioperative parenteral nutrition. It is a simple equation that uses albumin and weight to classify individuals as either well nourished or malnourished. The equation:

$$\text{NRI} = 1.519\,(\text{serum albumin; g/dL}) + 41.7\,(\text{current weight/usual weight}) \times 100$$

A score less than 100 is considered malnourished (144). This particular tool has not been studied in gynecologic oncology patients.

The MNA is an 18-item tool that is divided into two sections: screening and assessment. The screening segment contains six questions related to food intake, weight loss, mobility, stress, and BMI. If this score is 11 or less, then a health care provider will complete the remaining 12-item assessment. A total score of <17 indicates malnutrition and a score between 17 and 23.5 indicates risk for malnutrition. This instrument has been validated in the elderly population, but its use among cancer patients is limited, and nonexistent among gynecologic cancer patients.

The PNI is an objective evaluation of nutritional status that includes anthropometric measurements and laboratory testing and an assessment of cell-mediated immunity by testing for mumps, tuberculin, and *Candida* (the grade of response is 0—nonreactive; 1—<5 mm induration; 2—≥5 mm induration) (145). The information gathered is put into the formula below:

$$\begin{aligned}\text{PNI Score (\%)} = {} & 158 - 16.6\,(\text{albumin level in g/dL}) - \\ & 0.78\,(\text{triceps skin fold in mm}) - \\ & 0.2\,(\text{transferrin level in mg/dL}) - \\ & 5.8\,(\text{Grade of delayed hypersensitivity})\end{aligned}$$

If the PNI is <40%, then the patient is determined to have normal nutritional status; PNI 40% to 49% indicates mild malnutrition; PNI >50% is severe malnutrition. Santoso et al. compared this objective, yet cumbersome and expensive, method with the SGA for gynecologic malignancies. They found that agreement between the two methods was only fair to moderate, with the SGA methodology trending toward underreporting when compared with the objective method (146).

The NRS 2002 was developed to include measures of current malnutrition and disease severity. This scoring system assesses current malnutrition by scoring the amount and duration of weight loss, reduced BMI, and recent decrease in dietary intake. In addition, the severity of illness is graded as a reflection of increased nutritional requirements. A score is calculated for each part of the assessment and added together for the final score. A score ≥3 indicates the need to start nutritional support. This NRS 2002 is recommended by the European Society for Clinical Nutrition and Metabolism (ESPEN) for the screening of hospitalized patients and has been widely accepted in Europe. It is important to note that this tool is useful in identifying patients who will benefit from nutrition intervention, but does not categorize the risk of malnutrition. This tool has not been evaluated among patients with gynecologic malignancies undergoing surgery (147).

Currently, the American Society of Parenteral and Enteral Nutrition (ASPEN) and the ESPEN do not recommend routine nutrition support therapy (NST-parenteral or enteral) in patients undergoing major cancer operations. The risks and costs of routine perioperative NST outweigh benefits in terms of surgical outcomes in cancer patients (133,147,148).

Several RCTs have been conducted to evaluate NST in cancer patients undergoing surgery. The largest trial, the Veterans Affairs Cooperative Study, randomized 395 surgical (abdominal or noncardiac thoracic surgeries) patients, mostly male, to receive at least 7 days of preoperative and 3 days of postoperative total parenteral nutrition (TPN) or to receive no perioperative nutritional supplementation. The TPN group had a greater number of infectious complications, mostly among patients classified as borderline or mildly malnourished compared with the unfed patients (14.1% vs. 6.4%). However, a subset of severely malnourished patients derived benefit from lower operative complication rates (5% vs. 43%, $p = 0.03$) without incurring an increase in infectious complications. The overall 30- and 90-day mortality rates were not different between the groups (144). Meijerink et al. completed a trial of preoperative nutrition among 151 patients undergoing surgery for gastric or colorectal cancer and randomized to preoperative TPN versus enteral nutrition (EN) versus standard oral diet (SOD). The authors found that there was no difference in mortality among the groups. However, patients who were severely malnourished and received either TPN or EN had fewer intra-abdominal abscesses than the SOD, but there was a difference in infectious morbidity between the TPN and EN groups (149). A similar study by Bozzetti et al. randomized severely malnourished patients undergoing resection of gastric or colonic malignancies to 10 days of preoperative and 9 days of postoperative TPN or SOD with hypocaloric TPN postoperatively only. The TPN only group

showed lower noninfectious postoperative complication rates and mortality (150). And finally, Wu et al. randomized 468 patients to pre- and postoperative TPN/EN versus postoperative hypocaloric PN among moderately to severely malnourished patients undergoing surgery for GI cancers. The investigators found fewer complications, lower mortality, and shorter lengths of stay among the full nutrition support group (151). Because of the findings of these trials, ASPEN and ESPEN suggest that perioperative NST may be beneficial in moderately or severely malnourished patients if administered for 7 to 14 days preoperatively. The potential benefits of NST must be weighed against the potential risks of the NST itself and of delaying the operation. The authors direct the reader to reviews of these recommendations, which have been done by Huhman and August (for ASPEN) (133) and Braga et al. (for ESPEN) (148).

PREPARATION FOR SURGERY

Enhanced Recovery Pathway

In the last decade, enhanced recovery pathways (ERPs) or enhanced recovery after surgery (ERAS) protocols have been developed and implemented. These have improved surgical outcomes as well as realized significant cost savings in colorectal surgery, among other surgical specialties (152–155). These approaches were founded by European surgeons who challenged traditional surgical paradigms such as preoperative bowel preparation, the overnight fasting rule, and delayed postoperative feeding. The researchers found that most of these practices lacked scientific evidence and actually interfered with patients' preoperative preparation and recovery. Recent reviews of these protocols in colorectal surgery have demonstrated a reduction in length of stay of 2.5 days, a decrease in complications by as much as 50%, and a mean savings of $2,245 per patient (156–158). The basic principles of ERP are to attenuate the stress response to surgery by omitting bowel preparation, maintaining euvolemia, starting early postoperative feeding, and avoiding IV opioids (152,159,160) (Fig. 8.3). These programs are protocols that must be followed to obtain the greatest benefit, without omitting any of the steps along the way. The barriers to implementation come from long-held biases, based on lack of evidence, and the fact that the patient will encounter multiple people from various specialties (preoperative nursing, anesthesia, residents, postoperative nursing, etc.) through her journey of surgery. Critical to the success of these programs is auditing of the process to identify areas where protocol deviations occur, and to identify areas for improvement.

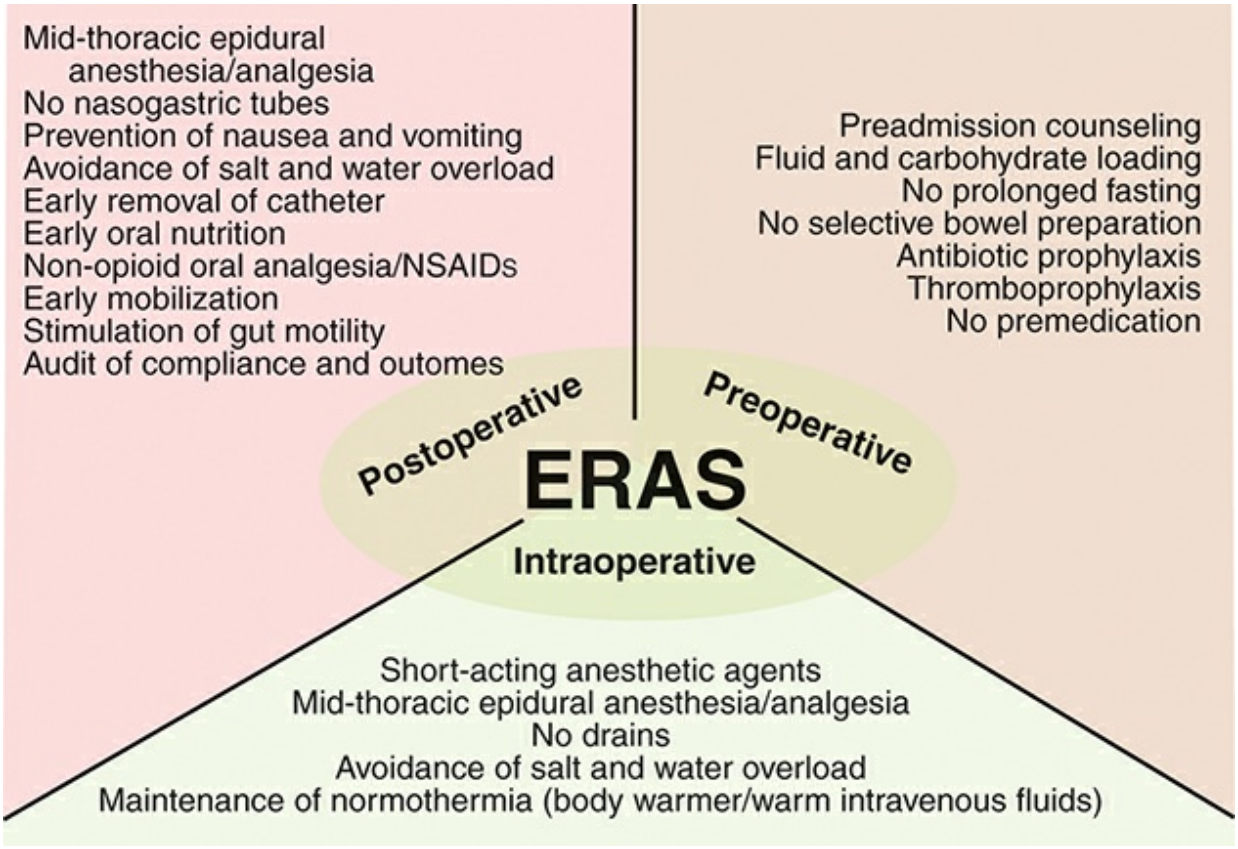

Figure 8.3 The elements of enhanced recovery after surgery (ERAS) pathways. For maximum benefit, all the elements must be followed. NSAID, nonsteroidal anti-inflammatory drug
Source: ERAS Protocol (EP). http://eras.org.in/eras-protocol/. Published 2010. Accessed April 2, 2016.

Although literature about ERP in gynecologic oncology is sparse, and mostly retrospective, interest in implementing such programs is growing. One such study done at the Mayo Clinic in Rochester, MN, by Kalogera et al. demonstrated that the use of patient-controlled anesthesia decreased over 60%, with an 80% reduction of opioid use in the first 48 hours, without change of pain scores among enhanced recovery patients as compared with historic controls. In addition, the authors showed a 4-day reduction in length of hospital stay, with stable readmission rates and a 30-day cost saving of more than $7,600 per patient on the ERP. Further more, there were no differences in the rate of or complexity of postoperative complications among the enhanced recovery patients (160). With the adoption and success of such ERP programs in colorectal surgery, and with the likelihood that these programs would yield similar benefits in other surgical specialties, the ERAS Society was founded in 2010 in an effort to reach other surgical specialists and subspecialists and publish guidelines. As a result, the Society recently published a two-part series on ERAS in *Gynecologic Oncology*. The authors direct readers to these guidelines for further details (161,162). In this chapter, we will point out best practice for ERAS.

Medication Management

In preparation for surgery, patients may need to decrease or stop taking certain medications, especially those associated with higher incidence of anticoagulation risks. Appropriate notice and clear instructions should be given to patients in this case, as some medications require several days of cessation to produce the desired results. For patients with INR levels between 2.0 and 3.0, it will take approximately 4 days after warfarin therapy is discontinued for the INR to reach 1.5. Many patients on warfarin do not need to be covered with heparin therapy preoperatively. Administration of treatment-dose

IV heparin or low-molecular-weight heparin (LMWH) while the INR is subtherapeutic is recommended for patients with a history of mechanical mitral valve, ball and cage valve, acute venous or arterial thromboembolism within 3 months of surgery, or atrial fibrillation with a history of thromboembolic stroke (163). A thorough discussion pertaining to usage of over-the-counter medications and herbal supplements is crucial in presurgery medication management. Patients should be counseled on the use of nonprescription medications, such as aspirin, nonsteroidal anti-inflammatories, ginkgo biloba, saw palmetto, garlic, ginseng, and vitamin E, as they have antiplatelet components and may enhance bleeding risk (164,165). If possible, anemia should be corrected preoperatively. The use of recombinant human erythropoietin with concurrent iron and folic acid supplementation 2 to 3 weeks preoperatively has been shown to reduce allogeneic blood transfusions in patients undergoing elective surgery (166). It has been estimated that 60% of all blood transfused in the United States is given to surgical patients.

Numerous studies have shown the benefit of starting medications, such as statins and β-blockers, in the preoperative setting to reduce cardiac risk (167). The perioperative use of β-blockers has been shown to reduce the incidence of postoperative myocardial ischemia, MI, and cardiac mortality by decreasing myocardial oxygen consumption and workload, although this has not been studied specifically in the morbidly obese population (167). Current ACC/AHA guidelines recommend that β-blockers should be continued in patients undergoing surgery who are receiving β-blockers to treat angina, symptomatic arrhythmias, hypertension, or other ACC/AHA class I guideline indications (168). For high-risk patients not receiving β-blockade, therapy should start before elective surgery, with the dose titrated to achieve a heart rate at rest of 50 to 60 beats/min (169). The perioperative use of β-blockers in high-risk patients undergoing major noncardiac surgery is supported by published data. However, studies have questioned the benefits of this approach in moderate-risk patients and report that the potential harm in low-risk groups might outweigh the benefit, highlighting the importance of patient selection (170).

Statins have also been shown to be effective cardioprotective drugs in the perioperative setting (167). Statins have been shown to act as plaque stabilizers and therefore possibly decrease the risk of thromboembolic events (167,171). With their low side effect profile and well-documented benefits, statins should be strongly considered for all obese patients with elevated serum cholesterol or triglycerides (172).

Close to 2 million patients undergo coronary angioplasty each year in Western countries, and >90% of these patients will have coronary stents placed as part of their intervention (173,174). Patients with bare metal stents are normally taking low-dose aspirin 81 mg. It is recommended that they stop taking aspirin 7 days before surgery (175,176).

Patients with drug-eluting stents take oral aspirin 81 mg, or even aspirin 325 mg, and, for the first 12 months after stent placement, daily oral clopidogrel 75 mg (176,177). Ideally, these patients should not undergo elective surgery, within the first 12 months after stenting. After the first 12 months, both medications are recommended to be stopped 7 days before surgery to reduce the risk of intra- and postoperative bleeding (175).

It is not uncommon for gynecologic oncology patients to undergo neoadjuvant chemotherapy. Most gynecologic oncologists would agree that the timing of surgery in relation to chemotherapy is crucial. In most cases, the surgical intervention should replace a cycle of chemotherapy. With regard to bevacizumab, special considerations should be taken into account since there is the added risk of bowel perforation and poor wound healing. The incidence, type, and timing of postsurgical bleeding events and wound healing complications were assessed in surgical patients in the AVastin And DOcetaxel (AVADO) and Avastin THErapy for advaNced breAst cancer (ATHENA) trials. Both study protocols followed recommendations to withhold bevacizumab for at least 6 weeks before elective surgery, and to wait 28 days (or until the wound was fully healed) after major surgery before recommencing bevacizumab therapy (178). Another study by Erinjeri et al. investigated how the timing of administration of bevacizumab affected the risk of wound healing in patients undergoing chest wall port placement. They concluded that the risk of a wound dehiscence requiring a chest wall port explant in patients treated with bevacizumab was inversely proportional to the interval between bevacizumab administration and port placement, with significantly higher risk seen when the interval is less than 14 days (179). Scappaticci et al. assessed postoperative wound healing complications in two randomized trials of 5 mg/kg bevacizumab in colorectal cancer treatment. Bevacizumab administered in combination with 5-fluorouracil/leucovorin-based chemotherapy 28 to 60 days

after primary cancer surgery caused no increased risk of wound healing complications compared with chemotherapy alone. While wound healing complications were increased in patients who had major surgery during bevacizumab therapy, the majority of bevacizumab-treated patients experienced no complications (180).

Blood Banking

Patients and their families are taking a more proactive role in their health care and thereby are entering into surgeries knowledgeable of risks and expecting alternative options. Preoperative counseling should include discussion of the potential for blood transfusions and associated risks. Transfusion rates of approximately 5% have been reported for patients undergoing abdominal hysterectomy for benign disease (181). Radical procedures performed for the treatment of gynecologic malignancies are associated with an estimated blood loss of 1,000 mL or greater. Transfusion rates for patients undergoing radical hysterectomy have been reported as high as 80% (182), but rates of 10% to 20% are more typical in the recent literature. The risk of transfusion-transmitted infection of human immunodeficiency virus, hepatitis B virus, and hepatitis C virus from RBC transfusion is estimated at 1:2.1 million units, 1:250,000 units, and 1:1.9 million units, respectively (183). Although these rates have significantly decreased in the last decade with the introduction of new screening technologies, transmission of other agents, bacterial contamination, transfusion reactions, increased infection complications, and immunosuppression remain risks of allogeneic blood transfusion (184,185). One alternative both physicians and patients have turned to is the use of donor blood in the perioperative period.

Since the mid-1980s, preoperative autologous blood donation (PABD) has been utilized in order to avoid allogeneic blood transfusion in patients undergoing elective surgery where excessive blood loss is anticipated. Although this practice decreases homologous blood use, 15% of autologous donors will still receive allogeneic transfusions, and 50% of units collected are not used and must be discarded (186). Furthermore, PABD greatly increases the likelihood of any transfusion being necessary and is not without medical risks. Severe reactions during autologous donation occurred at a rate of 0.32% per unit collected and 0.75% per donor. Serious incidents during blood collection that required hospitalization were 12 times more likely in PABD compared with allogeneic donors (187). Transfusions to the wrong recipient, bacterial contamination, febrile nonhemolytic reactions, and allergic reactions have also been reported with autologous transfusion. The cost-effectiveness of PABD has been found to be extremely poor and has steadily deteriorated over the decade (186–189).

Acute normovolemic hemodilution (ANH) is an autologous blood-procurement strategy that is equivalent to PABD in reducing allogeneic transfusion needs. Its clinical utility has been extensively studied in patients undergoing radical prostatectomy, total joint replacement, and, more recently, major colorectal surgery. During ANH, blood is procured in the holding or operating room and replaced simultaneously with colloid and crystalloid until a target hematocrit level of 28% is reached or blood volume of 1,500 mL is removed (190). The patient's blood becomes diluted and the amount of actual red cell mass lost during surgery is reduced. ANH obviates the costs of blood testing, storage, or wastage because all blood collected during ANH is kept in the operating room and returned to the patient before the end of surgery. It is simple to perform and more convenient for the patient. Since the blood is collected at point-of-care, there is no possibility for clerical error or contamination. ANH has been shown to be a cost-effective yet underutilized strategy to reduce allogeneic blood transfusions (190–192). ANH in which the blood is kept in a continuous circuit with the patient is often a workable alternative for a Jehovah's Witness patient (190,193).

The utilization of erythropoietin in oncology patients should be on a case-by-case basis due to recent evidence of adverse effects in oncology patients (194).

Bowel Preparation and Preoperative Fasting

Older thinking had been that in anticipation of colorectal surgery, bowel preparation would decrease the risks of infection and anastomotic leaks. In gynecology, it was thought that mechanical bowel preparation would make the bowel easier to

handle, improve visualization, especially with laparoscopic surgery, and decrease postoperative complications. Recent studies have demonstrated that these views are not true and actually may impede the preparation of patients for surgery. The process of cleansing the bowel with liters of fluid is distressing to patients, causing nausea and vomiting, physical discomfort, dehydration, electrolyte abnormalities, and prolonged fasting, all of which increase insulin resistance and catabolism, increasing the stress of the surgical process.

A recent meta-analysis of mechanical bowel preparation for gynecologic surgery (including laparoscopic surgery) showed no benefit of an improved operative field, better handling of the bowel, or decreased operative time. However, the analysis did show that the rates of patient dissatisfaction and discomfort were high with such practices. The authors concluded that mechanical bowel preparation was not necessary for gynecologic surgery (195). A systematic review of 18 RCTs of mechanical bowel preparation or rectal enemas versus no preparation prior to elective colorectal surgery showed that the infection and anastomotic leak rates were similar between the groups (with mechanical bowel prep—9.6% and 4.4%; without prep—8.5% and 4%, respectively) (196). Several recent retrospective studies have suggested that oral antibiotic bowel preparation may be associated with decreased infection rates with elective colorectal surgery. However, this finding has not been confirmed with randomized trials (161,197). Finally, a recent RCT assessing the benefit of mechanical bowel preparation versus no prep for patients undergoing low anterior resections for rectal carcinoma demonstrated higher infectious morbidity for the no prep group, but no difference in anastomotic leaks (198). Clearly, further study of this topic will be needed. ***Best Practice: Routine oral mechanical bowel preparation should not be used in gynecologic/oncologic surgery, including patients with planned enteric resection.***

Fear of aspiration drove "dogma" within the specialties of anesthesiology and surgery to instruct patients to fast for 12 or more hours before surgery. The thinking was that a prolonged fast prior to surgery would reduce the amount of acid and gastric contents in the stomach, thus preventing aspiration at the time of induction (199). A Cochrane review of 22 randomized clinical trials has shown that shortened fasting periods did not increase the risk of aspiration, regurgitation, or related morbidity (200). Thus, the ASA recommends a fast of 6 hours preoperatively for solid foods and that clear liquids be consumed for up to 2 hours prior to surgery (201). A prolonged preoperative fast for up to 12 hours will cause the patient to deplete her glycogen stores, which leads to insulin resistance and hyperglycemia, which can increase postoperative complications and morbidity. Carbohydrate loading drinks given to patients 2 to 3 hours prior to surgery can prevent insulin resistance, decrease hyperglycemia, and attenuate the stress response to surgery. These complex carbohydrate solutions are emptied by the stomach within 30 to 90 minutes and have been shown to reduce patient anxiety, thirst, and hunger (199). An RCT of carbohydrate loading versus no loading in patients undergoing colorectal surgery showed a significant reduction in length of stay (202). ***Best Practice: Patients should be permitted to drink clear liquids until 2 hours before anesthesia and surgery. Patients should abstain from oral intake of solids 6 hours prior to induction of anesthesia. Oral carbohydrate loading reduces postoperative insulin resistance, improves preoperative well-being, and should be used routinely in nondiabetic patients.***

Infection Prophylaxis

The use of prophylactic antimicrobials plays a large role in reducing the rates of surgical site infections (SSIs) and should be used in clean or clean-contaminated operations, which include most procedures performed by gynecologic oncologists. Radical pelvic surgery introduces women to a higher risk of postoperative infection secondary to several potential factors: lengthened operating time, average age of patient requiring this specific surgery, increased blood loss, anemia, potential hypothermia, probable poor nutritional status, the presence of tumor, prior pelvic irradiation, diabetes, obesity, peripheral vascular disease, and a history of postsurgical infection (203,204). Prophylactic antibiotics should provide coverage consistent with the microbial milieu most likely to be encountered. In gynecologic oncology surgery, the most common infecting organisms are coliforms, enterococci, streptococci, clostridia, and bacteroides.

Several guidelines for antibiotic prophylaxis in surgery have been published (203,205–207). Most reports recommend cefazolin for gynecologic procedures. Although no longer available, cefotetan had been the preferred antibiotic for

prophylaxis in longer radical gynecologic operations, as well as for prophylaxis prior to colorectal surgery, due to longer half-life and broad-spectrum coverage (208). An appropriate alternative for surgical procedures with a higher chance of bowel resection or injury is cefazolin plus metronidazole or ampicillin-sulbactam (207). Cefoxitin is another option, but availability has been limited. Most patients with a penicillin allergy can be treated with cefazolin; however, when allergy prohibits the administration of a cephalosporin, alternative regimens are clindamycin with gentamicin, a fluoroquinolone, or aztreonam (205). Itani et al. reported on a randomized, double-blinded trial in patients undergoing elective colorectal surgery that suggested ertapenem as an effective alternative to cefotetan (209). Ertapenem has received the Food and Drug Administration approval for prophylaxis for elective colon resection; however, the 2006 Medical Letter guidelines caution against the routine use of ertapenem for surgical prophylaxis due to cost and concerns that this practice may result in increased rates of antibiotic resistance (207).

When considering dosing orders to achieve and maintain effective tissue levels, parenteral antibiotics should be given within 1 hour (between 1 and 2 hours for fluoroquinolones and vancomycin) prior to skin incision as a loading dose (205). For patients weighing >70 kg, the dosage should be doubled (i.e., cefazolin 2 g IV) or weight-based dosing should be used. Repeat doses should be given intraoperatively for surgeries lasting longer than 3 to 4 hours or when blood loss exceeds 1,000 mL (207,208). Guidelines from the National Surgical Site Infection Project recommend that prophylactic antibiotic use for abdominal or vaginal procedures end within 24 hours of the operation (205). The majority of the published evidence supports the use of an appropriately timed administration of a single dose of antibiotic and indicates that repeat doses postoperatively are unnecessary and subject the patient to the potential emergence of resistant organisms (203,205–207).

The American College of Surgeons and the National Surgical Quality Improvement Plan employ a prospective, peer-reviewed database to quantify 30-day risk-adjusted surgical outcomes that encompass such variables as preoperative risk factors and postoperative mortality and morbidity, allowing comparison of outcomes among all hospitals in the program. Enrolled hospitals abstract case data into the database, the data are quantified, and the database generates comprehensive semiannual reports to the hospitals as well as real-time, continuously updated, online benchmarking reports (210).

SSIs account for nearly 40% of nosocomial infections in surgical patients and occur in up to 20% of patients undergoing abdominal surgery (203,205). They are a significant source of postoperative morbidity, resulting in longer hospital stays, increased rates of ICU admissions, hospital readmissions, and subsequently increased costs. Mortality rates increase two to three times for patients with an SSI as compared with patients who do not develop an SSI (211,212). In addition to the administration of preoperative antimicrobial prophylaxis, preoperative skin preparation is used to reduce the risk of SSI by decreasing the microbial count at the projected site of incision. A meta-analysis of six trials concluded that although whole-body scrubs or showers with antiseptic agents such as chlorhexidine or povidone-iodine prior to surgery reduce bacterial counts on the skin, this practice did not reduce wound infection rates (213). Surgical infection occurrences are noted to be influenced by both patient and operative environmental factors. Therefore, patients undergoing surgery should be instructed to bathe or shower normally the night or morning prior to surgery, removing any debris from the skin surface and decreasing environmental contaminants.

Inappropriate hair removal techniques can traumatize the skin and provide an opportunity for colonization of microorganisms. There is no evidence that hair removal prior to surgery will prevent or reduce SSI. To the contrary, meta-analysis evaluating hair removal techniques demonstrated a twofold increase in SSI when patients underwent hair removal by shaving versus clipping (214). Hair is generally sterile and therefore does not need to be removed unless the hair around the incision will interfere with the operation. When hair removal is necessary, the simplest and least irritating method of hair removal is an electric or battery-powered clipper with a disposable head (203,214). Some infection control experts advocate removing all razors from hospitals and operating rooms (215). ***Best Practice: IV antibiotics should be administered routinely within 60 minutes before skin incision. The dose should be repeated in the case of a prolonged operation or severe blood loss; the dose should be increased in obese patients. Hair clipping is preferred if hair removal is mandatory. Chlorhexidine-alcohol is preferred to aqueous povidone-iodine solution for skin cleansing.***

Special Considerations for Obese Patients

A heightened awareness of potential comorbidities should be extended when preparing morbidly obese patients for surgery. Coexisting disorders, such as coronary artery disease, hypertension, obesity-hypoventilation syndrome, obstructive sleep apnea, adult-onset diabetes mellitus, pulmonary hypertension, gastroesophageal reflux, impaired cardiac function, and hypercoagulability are common in morbidly obese patients and may be undiagnosed at the time of surgery. Certain symptoms of such comorbidities may not manifest themselves until the patient undergoes physiologic stress related to surgery thereby increasing perioperative morbidity and mortality. For example, baseline pulmonary function studies of markedly obese patients demonstrate mild hypoxemia; decreased vital capacity, tidal volume, and expiratory reserve volume; increased resistance; and ventilation-perfusion inequalities (216). During the postoperative period, severe hypoxemia may occur secondary to sedation, pain, immobility, atelectasis, and anemia, leading to cardiac arrhythmia or ischemia. A thorough preoperative medical history and physical examination should be performed to increase the findings of coexisting disease and minimize surgical risk. A comprehensive review of the pathophysiology associated with morbid obesity is beyond the scope of this chapter, and we direct the reader elsewhere for a thorough review (217).

Surgery in morbidly obese patients poses many challenges for teams on both sides of the surgical drape. The primary concern of the anesthesiologist is gaining adequate control of the airway. The combined problems of increased aspiration risk, rapid oxygen desaturation caused by decreased FRC, baseline hypoxemia, and increased oxygen demand, in addition to technical difficulties due to anatomic fat deposits, make intubation a high-risk procedure. An awake, fiberoptic-assisted intubation is often the technique of choice for obtaining an airway. Extubation should be delayed until the patient is fully awake and ideally sitting upright (218). There are technical operating room and instrumentation issues, which need to be addressed as well. Standard operating tables, stretchers, and hospital beds have weight limits, which have prompted specifically designed wider and sturdier models for the obese patient. Staff and patient safety during transfer of the patient from the operating table to the bed or gurney is also a concern in the extremely obese patient and must be taken into consideration. Proper retractors and extra-long instruments are essential and may not be available in all hospitals. Although these practical considerations are ostensibly mundane, failure to prepare may prevent a successful outcome, cause frustration to all involved, and possibly put the patient at risk.

Recent reports in the gynecologic oncology literature suggest performing panniculectomy to improve exposure of the peritoneal cavity and pelvic structures (219–221). Although this is a relatively straightforward procedure, it does require some experience and planning for optimal results. Hospital credentialing of surgical privileges may require the involvement of a plastic surgeon or proctoring until proficiency is demonstrated. In addition, since panniculectomy is considered a cosmetic procedure, many insurers may require prior authorization with documentation of medical necessity, or they may deny any reimbursement.

CRITICAL CARE AND POSTOPERATIVE MANAGEMENT

Cardiovascular Issues

Monitoring Issues

There are many tools at the hands of the modern-day clinician when it comes to monitoring the cardiovascular function of the patient. Clinical examination, heart rate, blood pressure measurement, and ECG are a few. In the critical care setting, the addition of the arterial catheter, central venous pressure (CVP), and pulmonary artery (PA) catheter increases sophistication. Most patients in the ICU can be managed with simple clinical parameters. Fluid status can be assessed by daily weights, pulse rate, blood pressure, and urine output. Continuous ECG monitoring is helpful for detecting

arrhythmias and ischemia. CVP is often used for assessment of volume status and a crude estimation of cardiac function. If a patient has a central line, one of the ports can be continuously transduced for CVP. It is a common mistake among novices to evaluate a single reading of CVP rather than reviewing the trend. When the CVP is correlated with volume status, the resulting graph is a scatter graph (i.e., no correlation). There is correlation over time and in response to fluid challenges, blood transfusion, or medical therapy. One must remember that the CVP is a pressure measurement and not the desired measurement of volume (preload). Therefore, only crude estimations of fluid status can be made with results from this instrumentation. When the status of a patient's cardiac output or fluid state is unclear, a minimally invasive hemodynamic monitor or an invasive PA catheter (e.g., Swan-Ganz catheter) may be helpful. A minimally invasive hemodynamic monitor connects to an existing arterial catheter and performs continuous self-calibration. The sensor provides information on stroke volume, stroke volume variation, and cardiac output (222).

PA catheters are placed via a central vein (subclavian or jugular) as a central line. The catheter has a balloon-tipped transducer and is "floated" into the PA. Waveforms of the right ventricle, PA, and pulmonary capillary wedge pressure (PCWP) are directly visualized as the catheter progresses through the heart (Fig. 8.4), and confirmed placement is verified by chest radiograph (Fig. 8.5). Complications of placement include pneumothorax, arrhythmia, line sepsis, and rarely PA rupture. The PA catheter allows the measurement of cardiac output and oxygen delivery and estimation of preload by obtaining the pulmonary artery occlusive pressure (PAOP) or PCWP, the "wedge."

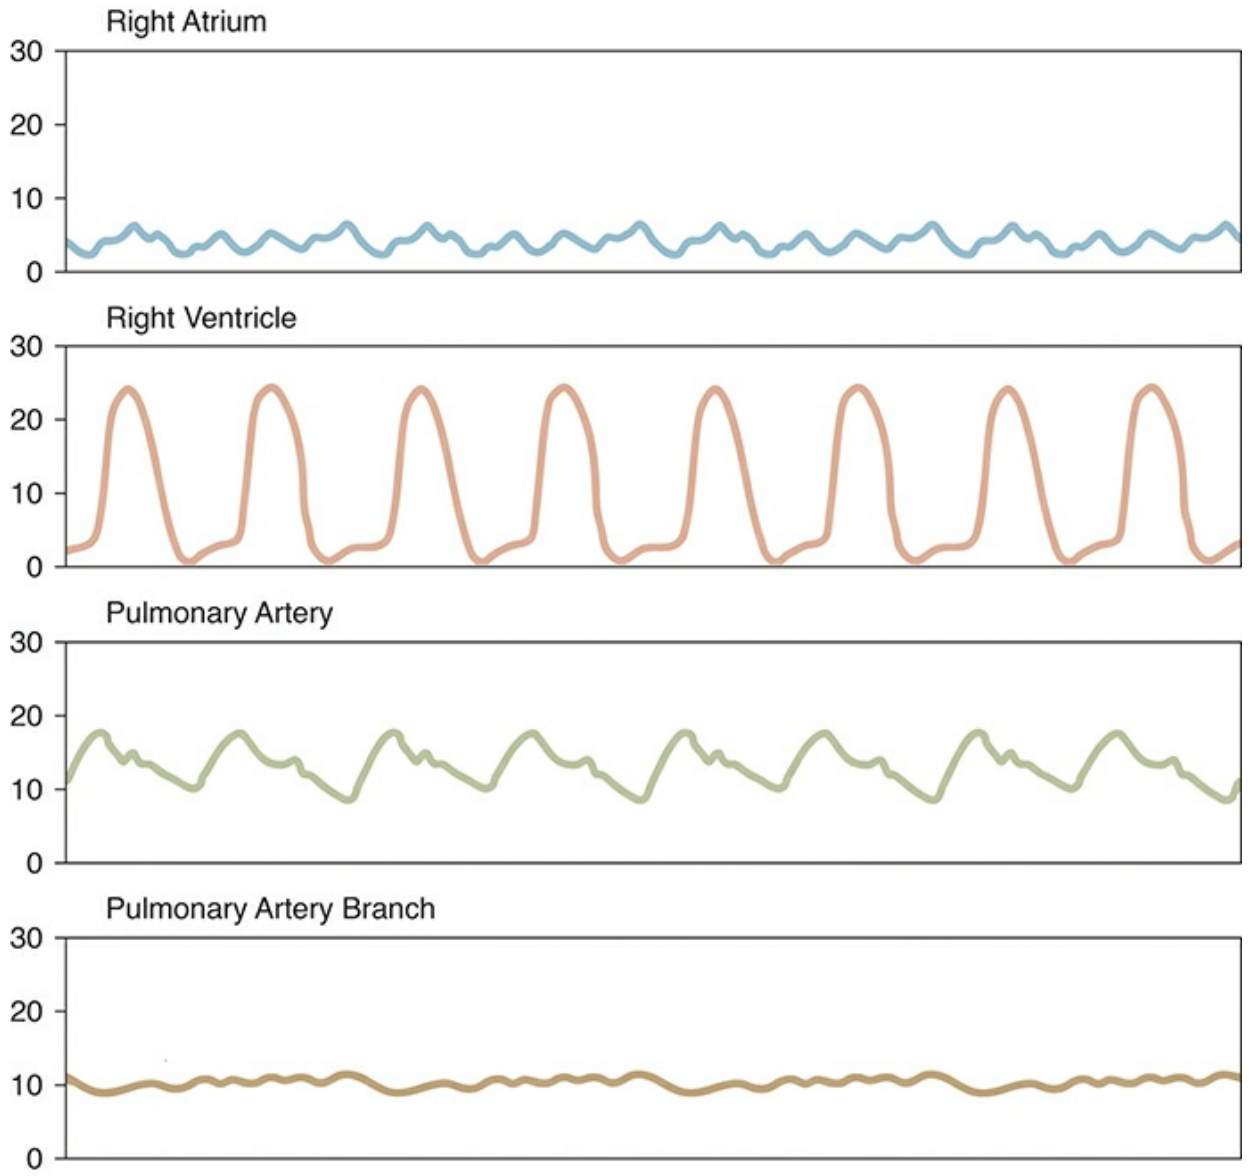

Figure 8.4 Pulmonary artery catheter waveform readings as the catheter passes through the heart into the pulmonary artery. Y-axis is reading in millimeters of mercury (mm Hg).

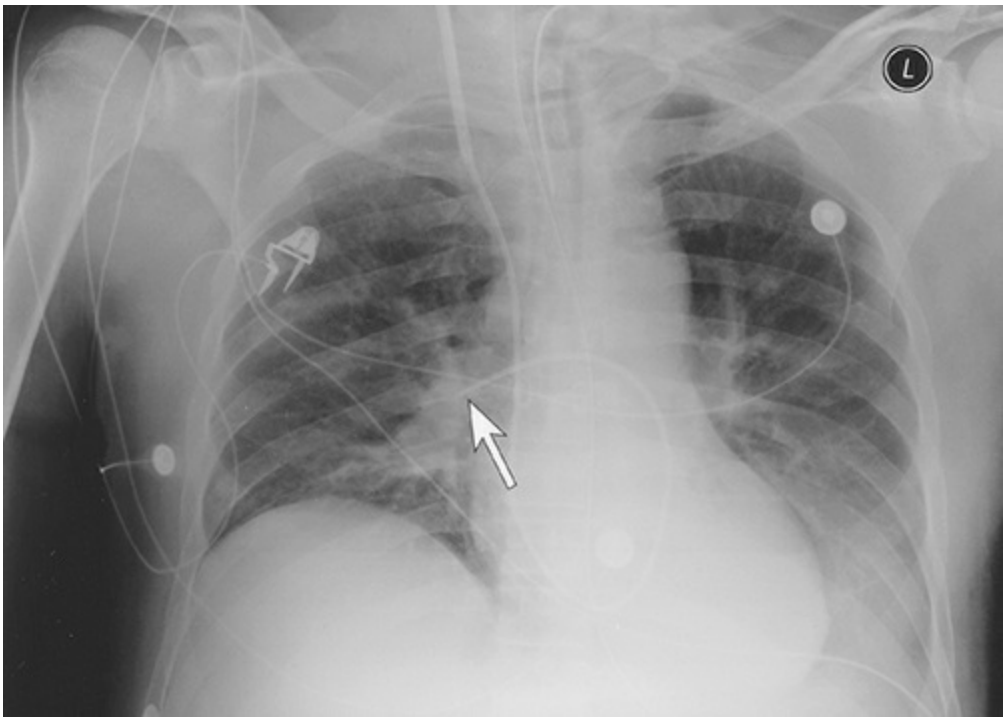

Figure 8.5 Chest radiograph showing proper placement of pulmonary artery catheter in the pulmonary artery (arrow shows tip of pulmonary catheter).

A number of formulas for calculation of hemodynamic parameters are crucial in utilizing the PA catheter for the care of the critically ill patient (Table 8.12). Assessment of preload is desirable for determining fluid administration or diuretic requirements for patients. The ideal measure of preload would be LV end-diastolic volume; however, this value is unobtainable with current technology and intensivists settle for "the wedge" as an estimation. By inflating the balloon placed in the PA, a direct column of standing fluid exists between the left atrium, through the pulmonary vasculature, and back to the balloon (transducer). The PAOP can be measured and is a crude reflection of left atrial pressure. If the PAOP is elevated, the preload is adequate (or excessive). If the measurement is low, the patient may be volume depleted. These measurements, as previously mentioned with CVP, are dynamic and trend is important. For example, if the PAOP is low and a fluid bolus is given, the PAOP should increase if the diagnosis of volume depletion was correct.

TABLE 8.12 Hemodynamic Formulas

Cardiac output (CO) = stroke volume (SV) × heart rate (HR) [4–8 L/min]
Cardiac index (CI) = CO/body surface area (BSA)
Systemic vascular resistance (SVR) = Mean arterial pressure (MAP) − Central venous pressure (CVP) × 80/CO [800–1,200 dynes − sec/cm^{-5}/m^2]
Arterial O_2 content (CaO_2) = (1.36) (hemoglobin) (oxygen saturation) + 0.003 (partial pressure of oxygen) [20 mL O_2/dL]
O_2 delivery (DO_2) = CO × CaO_2 × 10 [600–1,000 mL O_2/min]
O_2 availability (O_2AVI) = CI × CaO_2 × 10 [500–600 mL/min/m^2]
O_2 extraction ratio = (CaO_2 − CvO_2)/CaO_2 [25%]

Values in brackets are normal values.

Thermodilution techniques are used to calculate cardiac output by injecting saline via a proximal port in the PA catheter and measuring the thermal changes at the distal tip of the PA catheter. By combining the preload assessment provided by the PAOP and the calculated cardiac output, differentiation between volume depletion and cardiogenic disease states can be made (see section on shock). Currently, there are PA catheters that can calculate right ventricular EF.

Taking a blood sample from the tip of the PA catheter, the most desaturated blood in the body is retrieved. In normal circulation, the blood from the superior and inferior vena cava mix and the blood from the coronary sinus is added to give a sample known as the mixed venous blood. By evaluating the oxygen saturation of this blood, oxygen delivery can be calculated (Table 8.12). This measurement is perhaps the most important function of the PA catheter. Current technology allows this function to be continuous via an infrared sensor at the tip of the PA catheter. For example, if oxygen delivery is determined to be low, there are only three situations that the clinician can influence: increase cardiac output (with fluid, chronotropes, or inotropes), increase the hemoglobin, or increase the oxygen saturation. In a patient with multiple medical comorbidities and following a major abdominal operation, the measurement of a normal oxygen delivery provides reassurance to the clinician that end organs are being perfused.

Calculation of the systemic vascular resistance (SVR) is also possible with a PA catheter. Because the SVR is a calculated value and not directly measured, inaccuracies are inherent and overinterpretation of this value is cautioned. Rather than relying on the calculated SVR, the clinician should have a complete understanding of the measured blood pressure and cardiac output (SVR combines the two previously mentioned measured variables).

In one study of ovarian cancer patients undergoing cytoreductive surgery, 18% of patients had indications for PA catheter use (223). Because of the issues of volume status in these patients, PA catheter placement for postoperative fluid management may be especially helpful.

Recently, the use of PA catheters has become less common (224). Continuous dynamic measurements are possible with analysis of arterial and plethysmographic waveforms. Stroke volume variation can be used for goal-directed therapy (225). Other noninvasive or minimally invasive monitors have been developed, which include carbon dioxide rebreathing techniques to calculate cardiac output, esophageal Doppler among others (226).

Acute Postoperative MI

MI usually manifests with acute chest discomfort, elevated cardiac enzymes (troponin, creatinine phosphokinase, etc.), and ECG changes. Dyspnea, diaphoresis, nausea, and anxiety may also be associated. The MI definition is based on a rise of cardiac enzymes (troponin) in the setting of myocardial ischemia as evidenced by clinical symptoms, imaging findings, or ECG changes (227). Treatment includes ICU monitoring with continuous ECG monitoring, supplemental oxygen, immediate oral aspirin 325 mg administration, sublingual nitroglycerin, and morphine sulfate as needed until pain resolves. Beta-blocker therapy has been shown to decrease mortality by decreasing fatal arrhythmias, and their administration is part of the early treatment regimen for MI (228). An evaluation for heparin therapy, thrombolytics, or cardiac catheterization intervention can be made in consultation with a cardiologist.

Congestive Heart Failure

Patients with known CHF will be risk-stratified, as previously mentioned, before major elective surgery. However, in the postoperative setting, CHF will present in a number of ways. Patients with CHF are in a continuous hypervolemic state, and issues of fluid balance (strict “ins” and “outs”) will be paramount during the perioperative period. In difficult cases, insertion of a PA catheter can be very helpful. Judicious fluid administration guided by the PAOP as well as selective use of inotropic support to augment cardiac output will aid the clinician in a successful outcome of these difficult patients (229).

Inotropes and Vasopressors

A variety of hemodynamically active drugs are available to support the cardiovascular function of patients in the perioperative period (230). In the broadest sense, these drugs can be categorized as vasopressors, which elevate blood pressure, and inotropes, which enhance cardiac output (231). When it has been determined that oxygen delivery is low and increased cardiac output is desired, inotropes such as dopamine or dobutamine should be used. Dopamine, at lower doses, activates dopaminergic receptors and increases circulation in mesenteric, cerebral, and renal vascular beds. At intermediate doses, dopamine stimulates β-receptors in the heart and peripheral circulation. This activation causes tachycardia, increased stroke volume, and increased cardiac output. Increasing cardiac output in this fashion also increases demands for myocardial oxygen and could precipitate angina or MI (232). At high doses, dopamine acts as an α-agonist, causing vasoconstriction. Dobutamine is a β-1 agonist with much greater inotropic effect than dopamine and causes peripheral arterial vasodilation, decreasing afterload (this dilation can be abrupt and cause hypotension in some patients). Dobutamine is the drug of choice for severe heart failure.

Epinephrine is a potent sympathomimetic with β-mimetic effects at lower doses and α-mimetic effects at higher doses. This drug causes an acute increase in myocardial oxygen demand and is used in the setting of cardiac arrest or severe circulatory failure. Norepinephrine and phenylephrine are pure α-mimetic agents, utilized for vasoconstriction (neurogenic shock). In most situations of shock, fluid resuscitation is preferred to administration of α-agents. Although these agents will give a false sense of security that the blood pressure is normal, one must remember that the vasoconstriction underperfuses capillary beds and leads to renal hypoperfusion (acute renal injury), splanchnic hypoperfusion (resulting in translocation of gut flora), as well as a myriad of other problems (231,232).

Vasopressin is an option similar to epinephrine, with some important differences. This antidiuretic hormone (ADH) in high doses provides potent vasoconstriction and leads to improved cerebral and coronary blood flow in shock states. Unlike epinephrine, there is less myocardial oxygen demand and less propensity for inducing arrhythmias (233).

Amrinone (or inamrinone) and milrinone are phosphodiesterase inhibitors that provide a positive inotropic effect on cardiac musculature while causing systemic vasodilation. They are used in refractory cardiac failure (234).

Valvular Disease

AS is an independent risk factor for poor operative outcome from cardiac complications following noncardiac surgery. The risk depends on the severity of AS (235). Important considerations in perioperative management are directed at patients with AS and the level of ventricular failure. Patients with severe AS need valve replacement before elective surgery, whereas patients with mild to moderate AS need careful anesthetic control of blood pressure. The presence of ejection systolic murmurs requires assessment of LV function for the presence of CHF with echocardiography (236). Treatment and support will be related to maintenance of ventricular function. Avoidance of systemic hypotension in the perioperative period is essential. The AHA recommends no routine prophylactic antibiotic administration to prevent endocarditis in patients with valvular disease, with artificial valves, or who have had surgical correction of congenital defects undergoing GI or genitourinary (GU) procedures. However, if patients have active GU or GI infections, then the surgery should be delayed, if possible, to allow eradication of the infection with antibiotic treatment. Any antibiotic regimen should include agents that are active against enterococci, such as ampicillin or vancomycin, and should be administered 30 minutes before to 2 hours after the procedure (237,238). Antibiotic prophylaxis may be reasonable for patients with prosthetic cardiac valves if the valves have been placed within the previous 6 months; previous history of infective endocarditis; or certain congenital heart diseases (CHD) such as unrepaired cyanotic CHD, any repaired CHD with prosthetic material within the previous six months, and any repaired CHD with residual defect adjacent to a prosthetic patch or device (which prevents endothelialization) (239).

Arrhythmias

Postoperative arrhythmias are often secondary to noncardiac problems such as iatrogenic fluid overload, hypotension,

electrolyte abnormalities, hypoxia, or infection. Whenever an arrhythmia occurs in the postoperative setting, myocardial ischemia must first be ruled out (240). If ECG and cardiac enzyme measurements are normal, the arrhythmia is not likely to be due to myocardial ischemia. Fortunately, most arrhythmias in the postoperative period are transient and self-resolving. Asymptomatic arrhythmias, except in the preoperative period, are generally of little clinical significance. Hypercapnia, hypoxemia, hypokalemia, acidosis, inadequate analgesia, and anemia can all promote cardiac arrhythmias. Supraventricular tachycardia is the most common rhythm disturbance seen in the postoperative period (241). Treatment with calcium channel blockers (such as diltiazem) or a β-blocker is usually the first-line recommended treatment for atrial fibrillation (242).

Pulmonary Issues

Ventilator Management

The ability to provide ventilatory support to the surgical patient has been a tremendous advance in postoperative care. Mechanical ventilators have enabled oncologic surgeons to perform major operations for aggressive control of lesions that were once considered to be unresectable. Although preemptive preoperative therapies attempt to avoid postoperative mechanical ventilation, some patients will require this therapy. Mechanical ventilation must be thought of as providing two functions: ventilation and oxygenation. However, these two functions must be separated and applied independently to each particular situation. A more difficult concept for residents and fellows to understand is that ventilation has nothing to do with oxygenation. Many patients decompensate on the ward despite supplemental oxygen and 100% oxygen saturation because tidal volumes were low and the patient was not ventilating.

When contemplating mechanical ventilation, one must ask two questions: is the patient able to oxygenate her tissues adequately, and can she ventilate adequately to maintain normal partial pressure of carbon dioxide (P_{CO_2}) and acid–base function? Adequate oxygenation can be determined by measurement of oxygen saturation and arterial partial pressure of oxygen (P_{O_2}). Targets are generally an O_2 saturation >92% or P_{O_2} greater than 65 mm Hg. Poor oxygenation may be caused by fluid overload, depressed mental status, underlying pulmonary disease, or shunt. Evaluation of the arterial blood gas will also give a pH and P_{CO_2} measurement. Patients may hypoventilate for a number of reasons. Postoperative pain may prohibit deep inspiration and the overuse of pain medication may depress the level of consciousness, leading to fewer and poorer respirations. Atelectasis, pneumonia, and poor pulmonary compliance all lead to difficulties in ventilation. Finally, a bronchial mucous plug or a pneumothorax will lead to life-threatening ventilatory compromise. A respiratory rate greater than 35 per minute or a P_{CO_2} greater than 55 mm Hg are accepted indications for intubation and mechanical ventilation.

When intubating patients, the size of the endotracheal tube must be considered, as this may impact removal and discontinuation of mechanical ventilation later. The larger the tube, the less resistance and the easier it will be for the patient to participate in “weaning” trials for discontinuing ventilatory support (243). Typical recommendations are a 7.5-mm tube for women and an 8.0-mm tube for men.

Traditionally, there are pressure-cycled ventilators and volume-cycled ventilators. Pressure-cycled ventilators are used routinely in neonatal ICU patients because overinflation can be dangerous to neonates. In the adult ICU, most ventilators are volume cycled, meaning that the clinician sets the tidal volume, and regardless of the pressures necessary to give the volume, the volume will be delivered. In patients in whom pulmonary compliance is reduced (i.e., due to a stiff lung or acute respiratory distress syndrome [ARDS]), efforts at controlling pressure are important. When setting the ventilator, a number of decisions must be made. The mode of delivery, tidal volume, and rate will determine ventilation, whereas the fraction of inspired oxygen (F_{IO_2}) and positive end-expiratory pressure (PEEP) will determine oxygenation.

Mode

There are a number of ventilator modes. The first developed was controlled mechanical ventilation, where the tidal volume and rate are set and that is exactly what the patient receives—no more and no less. This mode is very good for patients under general anesthesia or who are paralyzed. However, this mode is very disturbing to the patient who wishes to participate, however slightly, in her own ventilation. This mode has evolved into the current assist/control (AC) mode, whereby the patient is guaranteed the fixed rate and tidal volume but can also trigger breaths in between with a similar tidal volume. In addition, the machine will synchronize the breath when the patient triggers such a breath. This mode provides complete rest for the patient by performing all the work of breathing and is generally used for patients in the immediate postoperative period or for patients who have critical illnesses such as organ failure or sepsis.

Intermittent mandatory ventilation (IMV) is a mode whereby the clinician sets a rate and a tidal volume, which the machine delivers. Any breath initiated by the patient is delivered in relation to the amount of effort the patient puts forth, meaning a strong effort gives the patient a large breath and a meager effort a smaller one. This is sometimes called a weaning mode. The patient is given full support with rate and tidal volume until she is stronger. The rate is slowly turned down, allowing the patient more frequent, spontaneous breaths until extubation. Synchronized IMV (SIMV) ensures that a machine-delivered breath does not stack onto a patient-initiated breath.

Pressure support ventilation (PSV) is a mode where patient-initiated breaths are given support from the ventilator only during the beginning of ventilation (inspiratory phase). The support is meant to help the patient overcome the large amount of resistance present in the valves of the machine, the ventilator circuit, and the endotracheal tube. By titrating PSV to the spontaneous tidal volume produced by the patient, one can fully or partially support patient breathing and overcome the work of breathing. This mode of ventilation is important during the “weaning” process.

Work of Breathing

When conceptualizing the job of the ventilator, the different types of work must be defined (243). In addition to the physiologic work of breathing that all humans do on a daily basis, huge workloads are imposed from the resistance of the ventilator equipment (e.g., breathing through a straw analogy). Finally, there is the pathologic work of breathing from pneumonia, the incision, etc. The intent of mechanical ventilation during disease states is to assume the last two types of “work” so that the patient may convalesce. As a patient improves and the pathologic work has been removed, the patient should be able to resume normal, physiologic work.

More Advanced Modes of Ventilation

With advanced circuitry and computer microprocessors, newer ventilator modes have been developed. Pressure-regulated volume control (PRVC) has largely replaced AC ventilation. PRVC provides the same function as AC while preventing overinflation. Recent data have shown that preventing overinflation (or stretch) of alveoli prevents trauma and decreases the incidence of ARDS (244). PRVC delivers the same tidal volume but changes the flow rate to prevent high pressures by measuring the pressure on a breath-to-breath basis. Volume control ventilation is a mode whereby a tidal volume target is set and the ventilator continually titrates the amount of PSV to provide this volume. This mode has been termed “autowean” or “weekend” mode because as the patient gets stronger, he or she will be able to meet the tidal volume setting. In situations where difficulties in ventilation are encountered, such as ARDS, hypercarbia, and acidosis, pressure control is used. This mode is similar to the neonatal pressure-cycled ventilator where the maximum pressure is set and the flow rate is decreased but the inspiratory time is lengthened to achieve proper ventilation. Airway pressure release ventilation, high-frequency jet ventilation, and inverse ratio ventilation are other advanced modes, the discussion of which is beyond the scope of this chapter.

Setting the Ventilator

Initial ventilator settings require a rate of 12 to 14 breaths per minute, with a tidal volume of 6 to 8 cc/kg. This is a departure from the traditional 12 cc/kg, which has been determined to result in greater alveolar trauma and increased risk for the development of ARDS (245). After initial setting of the ventilator, measurements of pH, P_{O_2}, and P_{CO_2} from arterial blood gas are used to make further ventilator adjustments.

Oxygenation

Oxygenation is controlled by two settings: F_{IO_2} and PEEP. The inspired oxygen content can easily be controlled with the ventilator, to keep blood oxygen saturation greater than 92%. Inspired oxygen concentration greater than 60% is considered to be potentially toxic and may be the etiologic reason for pathologic changes similar to ARDS. In patients with normal lung function, studies have shown that higher concentrations of inspired oxygen can cause acute inflammation and fibroproliferative changes, resulting in toxic effects to lung tissue. Similar studies in patients with underlying lung disease are lacking (246,247). If it is necessary to have oxygen concentrations above 60%, the recommendation is to wean these levels as soon as possible. PEEP is another mechanism for improving oxygenation. In normal physiology, the glottis closes before full expiration, creating a PEEP of approximately 4 cm H_2O, and is termed physiologic PEEP. When ventilating patients, the addition of 5 cm H_2O PEEP is used as a baseline and is increased if added oxygen delivery is required. Increasing PEEP is the preferred method for improving oxygenation in postsurgical patients as opposed to increasing the F_{IO_2}. Postsurgical patients have atelectasis and shunting secondary to operative pain and anesthesia. The addition of PEEP recruits collapsed alveoli, improving oxygenation and lung compliance. However, the use of PEEP must be balanced by potential adverse effects, which include decreased cardiac output and the risk for barotrauma.

Weaning from Ventilator

Multiple opinions exist on the techniques of weaning patients from mechanical ventilation. T-piece trials, spontaneous breathing trials, SIMV, and PSV are just a few. The best method of weaning is a pathway agreed upon by clinicians, nurses, and respiratory therapists. Before discontinuing mechanical ventilation, the disease process that required ventilation should have resolved and patients should have proper mental status and the ability to generate a cough. Copious secretions are often an initial reason not to consider weaning or extubation. Criteria for extubation, whether on T-piece or minimal PSV, have traditionally included a respiratory rate less than 35, a P_{CO_2} less than 50 mm Hg, and a negative inspiratory force greater than –20 cm H_2O. Rapid shallow breathing, defined as the respiratory frequency divided by the tidal volume in liters over a minute, is the most accurate predictor of failure in weaning patients from mechanical ventilation (248).

Acute Respiratory Distress Syndrome

ARDS is a condition that has been well recognized and extensively studied (249–251). This disease is a form of refractory hypoxemia that is caused by a variety of insults, which incites an inflammatory response consisting of increased production of cytokines, leukotrienes, endothelial adhesion molecules, and interleukins. These molecules, which are useful in the defense of the host organism, are particularly detrimental to pulmonary endothelium. ARDS is the result of some inciting cause and does not arise *de novo* as a primary problem. A study of patients who develop multiple organ dysfunction syndrome (MODS), a state where sequential organ failure leads to patient death, has shown that the lung may be the first organ system susceptible to these circulating inflammatory mediators (252). In addition to supportive treatment for ARDS, operative injuries or postoperative complications (e.g., intra-abdominal abscess, anastomotic leak) must be sought and ruled out.

In 1994, a consensus of American and European intensivists defined the criteria for ARDS and a lesser form of the disease described as acute lung injury (ALI) (250). Criteria include (a) acute onset after defined insult; (b) bilateral diffuse infiltrates on chest radiograph; (c) no evidence of left atrial hypertension, CHF, or a PAOP ≤ 18 mm Hg; and, most importantly, (d) impaired oxygenation. Impaired oxygenation was classified as ALI if the partial pressure of arterial oxygen (Pa_{O_2})/F_{IO_2} ratio was ≥300 mm Hg and ARDS if the Pa_{O_2}/F_{IO_2} ratio was ≤200 mm Hg. The Berlin definition of ARDS replaced the 1994 definition by removing the term ALI and removing the PAOP criteria (253). Postmortem examination of lungs with ARDS shows atelectasis, edema, inflammation, hyaline membrane deposition, and fibrosis. The mortality of ARDS is 30% to 40%. Treatment of these severely hypoxemic patients consists of mechanical ventilatory support with F_{IO_2} and PEEP. Because of alveolar damage, ventilation/perfusion mismatch occurs, resulting in a worsening shunt fraction and increasing dead space. As ALI/ARDS progresses, ventilation, due to decreased pulmonary compliance, becomes difficult and oxygenation progressively worsens. The end result is a hypercapnic state and respiratory acidosis.

The ARDS NET trial comparing high tidal volume, in order to maintain normocapnia, to low tidal volume, to prevent barotrauma, showed significantly improved survival among patients in the low tidal volume group (250). Current strategies employ tidal volumes of 6 cc/kg, while accepting elevated P_{CO_2} levels (permissive hypercapnia) (254).

Pneumonia

Pneumonia is a significant complication in postsurgical patients. Patients requiring mechanical ventilation are particularly susceptible to pneumonia (ventilator-acquired pneumonia [VAP]), with rates as high as 30% after 72 hours of ventilation. The mortality rate from VAP ranges from 25% to 50%. The pathogens are often gram-negative bacteria and are resistant to multiple antibiotics. High clinical suspicion and aggressive treatment of VAP are crucial. A review of this complicated topic by Chastre and Fagon is recommended for further reading (255).

Pulmonary Embolism and Deep Venous Thrombosis Prophylaxis

The prevention of venous thromboembolism is an important component of perioperative management of the gynecologic oncology patient. The American College of Chest Physicians consensus statement published in 2012 reviews the data extensively and provides recommendations (256). Patients undergoing major gynecologic surgery without venous thromboembolism prophylaxis have a risk of deep vein thrombosis (DVT) between 17% and 40% (257). Surgery for cancer, advanced age, previous VTE, prior pelvic radiation therapy, and abdominal resection (in contrast to vaginal resection) appears to increase the thromboembolic risk after gynecologic surgery (258). The incidence of pulmonary embolism (PE) is 1.6%, with the rate of fatal PE being 0.9%. In trials comparing low-dose unfractionated heparin (LDUH) with no therapy in general surgical patients, the DVT rate decreased from 25% to 8%. These studies also produced a 50% decrease in the rate of fatal PE (259). Comparisons of LMWH versus LDUH have shown equal efficacy. LMWH may have fewer complications (mostly wound hematomas) and greater ease of use with once-daily dosing.

Sequential pneumatic compression devices (PCDs) are attractive for patients at risk for bleeding complications. In trials comparing PCD with LDUH, both have shown efficacy. Elastic stockings T.E.D. hose and aspirin usage are not currently recommended for DVT prophylaxis. Studies have shown that the presence of D-dimer positivity in the face of DVT and/or PE, but the presence of any released blood or hematoma (i.e., in any postoperative patient) makes the D-dimer positivity nonspecific. In the surgical patient, a negative D-dimer makes DVT or PE highly unlikely; however, a positive test is essentially useless.

Patients at low risk (age less than 40 years, no risk factors, and minor surgery) need no prophylaxis, but early ambulation is encouraged. Moderate-risk patients (minor surgery in a patient with risk factors, major surgery with no risk factors) should receive PCD, LMWH, or LDUH, with equal results. High-risk patients require LWMH in addition to PCD.

Recently, the American College of Chest Physicians updated their recommendations for antithrombotic therapy for VTE disease (260). Diagnosis of DVT is performed by duplex ultrasonography, and treatment is with either heparinization to 1.5 times control prothrombin time or therapeutic doses of LMWH. Diagnosis of PE was traditionally made by pulmonary arteriogram. This practice has been abandoned because dynamic contrast-enhanced computerized tomography has better sensitivity. Once diagnosis is confirmed, the patient is anticoagulated with IV heparin or LMWH. Ultimately, since most of these patients have cancer, the updated recommendation is that these patients be treated with LMWH over warfarin (Coumadin) or any of the non–vitamin K oral anticoagulants (dabigatran, rivaroxaban, apixaban, or edoxaban) for at least 3 months in the case of DVT and PE (260). ***Best Practice: All gynecologic oncology patients with a major surgery > 30 minutes should receive VTE prophylaxis with either LMWH or heparin, with prophylaxis being started preoperatively and continued intra- and postoperatively in combination PCD. Extended prophylaxis with LMWH heparin should be continued for 28 days after laparotomy in patients with abdominal or pelvic malignancies.***

Fluid and Electrolyte Issues

Understanding fluid and electrolyte physiology in gynecologic oncology is paramount because of the underlying disease processes that face the gynecologic oncologist and the ultimate, radical surgical interventions that are needed to treat them. These treatments result in great fluid shifts perioperatively, requiring careful attention to input of fluids (volume and content/type) as well as output from renal and GI sources, insensible sources, and drains. Since extensive discussions of these topics can be found elsewhere, this section presents a brief review of normal fluid and electrolyte physiology and discusses strategies for fluid resuscitation and correction of electrolyte deficiencies.

Total body water (TBW) can be calculated by a variety of methods and varies directly with the amount of adipose or lean tissue present in an individual patient. TBW estimates, therefore, must be adjusted based on the adiposity of the patients. In women, TBW accounts for approximately 60% of a patient's weight. TBW is distributed into extracellular fluid (ECF) and intracellular fluid (ICF), with the ECF being further divided into intravascular (one-quarter of the ECF) and interstitial (three quarters of the ECF) compartments. The ECF accounts for approximately one-third of the TBW, whereas ICF accounts for two-thirds (261,262). Direct measurement of the ECF and TBW is possible, with the resulting difference being an estimated ICF. Table 8.13 describes the body fluid compartments and their contributions to body weight. Despite these arbitrary compartments (and electrolyte concentration differences between compartments, which are discussed in the paragraph below), water flows freely across all compartments. Thus, a derangement in one compartment will result in a compensatory change in another (263).

TABLE 8.13 Body Fluid Compartments

Total Body Water	Body Weight (%)	Total Body Water (%)
Total	60	100
Intracellular	40	67
Extracellular	20	33
Intravascular	5	8
Interstitial	15	25

The electrolyte composition of the various compartments is different. Sodium is the predominant cation in the ECF and potassium is the predominant cation of the ICF. Table 8.14 describes the various concentrations of electrolytes in the various fluid compartments. Because of the Donnan principle of equilibration, the content of cations and anions in the interstitial compartment is slightly higher than that in the intravascular compartment. This principle describes the unique

relation between solutions of permeable and impermeable complex anions when these anions are unevenly distributed across a semipermeable membrane. Water, on the other hand, as mentioned earlier, freely equilibrates between the compartments (263).

TABLE 8.14 Electrolyte Concentrations in the Various Fluid Compartments

Effective circulating volume (ECV) is a term used to describe the portion of the ECF that perfuses the organs of the body and affects baroreceptors (see next paragraph). In healthy patients, the ECV equates to the intravascular volume/compartment. But in disease states that increase "third spacing" such as sepsis (leaky capillaries), ascites due to intra-abdominal metastasis, or bowel obstruction with resulting edema and transudation, the interstitial compartment increases at the expense of the intravascular compartment, decreasing the ECV (261).

The osmotic activity of a fluid compartment is affected by the component ions and is described in milliosmoles (mOsm). Normal serum osmolality (in the ECF, of course) averages 290 mOsm/kg of H_2O. Osmoreceptors in the hypothalamus respond to small changes in serum osmolality, increasing or decreasing secretion of ADH and modifying the thirst response. These receptors are responsible for the day-to-day fine-tuning of fluid balance. Baroreceptors, on the other hand, in the intrathoracic vena cava, the atria, the aortic arch, the carotid arteries, and the renal parenchyma, sense volume changes by changes in pressure. These receptors begin a cascade of mediators such as aldosterone, atrial natriuretic peptide (ANP), prostaglandins, and the renin–angiotensin system, which ultimately result in changes of water and sodium balance mediated through the kidneys. These baroreceptors have little to do with the day-to-day fluid management and require intravascular losses of 10% to 20% to initiate activity (263).

The goal of fluid resuscitation is to maintain the ECV and keep or return the patient to euvolemia. Many gynecologic oncology procedures are lengthy and can result in large blood losses requiring immediate intraoperative replacement. In addition, following procedures where evacuation of large amounts of ascites has occurred and/or "peritoneal stripping" has left denuded surfaces, these patients may have large fluid shifts into the interstitial compartment, requiring large volumes of fluid to maintain the ECV. Finally, losses are not water alone and include electrolytes and clotting factors, which may

need repletion. Selecting fluids to administer to a given patient is akin to selecting the correct IV medication to give; not *all* fluids are for *all* patients. The physician should understand the amount of daily maintenance fluid and electrolytes required by patients, calculate losses (fluid and electrolytes), determine ongoing fluid and electrolyte losses, and replace them with the appropriate fluid and electrolyte combinations and volumes. It is easy to fall into the trap of giving all patients an 8-hour rate (125 mL/hour) of maintenance fluid. However, an octogenarian, even with normal cardiac and renal function, weighing 50 kg, does not need that much maintenance fluid. "Formulas" for calculating appropriate maintenance fluid requirements exist (263).

With new enhanced recovery protocols in colorectal surgery, restricting fluids intraoperatively and postoperatively has been shown to reduce cardiopulmonary complications (7% vs. 24%;$p < 0.001$) and overall morbidity (OR 0.41; $p = 0.005$) (264,265). It is important to note that these improvements in morbidity were not seen if the fluid restrictions were instituted postoperatively. However, extreme restriction of fluids can lead to increased morbidity and mortality. So a fine line must be walked in an effort to keep the patient normovolemic during the surgical procedure. If, however, the surgical procedure planned will result in large blood loss or the patient has SIRS, advanced hemodynamic monitoring may be helpful in managing fluid resuscitation to maintain euvolemia (net zero sum: fluids out = fluids in). Extrapolation to gynecologic oncologic surgery would be expected to have these same results.

In general, the normal maintenance requirement of sodium is 1 to 2 mEq/kg/day and for potassium 0.5 to 1.0 mEq/kg/day. Table 8.15 lists the various IV fluid preparations available for fluid resuscitation. Which fluid to be used is controversial and driven, in more instances, by "dogma," varying from physician to physician and institution to institution, rather than by evidence. Controversy over which fluid type to use in fluid resuscitation continues to this day. Several meta-analyses have shown no advantage of colloid over crystalloid for resuscitation in surgical patients (266–273). The use of colloid has been shown to be advantageous in conditions of hypoproteinemia, or in malnourished states where patients require plasma volume expansion and cannot tolerate large amounts of fluid (273).

TABLE 8.15 Electrolyte Content of Commonly Used Intravenous Electrolyte Solutions

	Electrolyte Concentration (mEq/L)					
Solution	Na^+	K^+	Ca_2^+	Mg_2^+	Cl^-	HCO_3^-
Lactated Ringer's solution	130	4	4	—	109	28
0.2% NaCl	34	—	—	—	34	—
0.33% NaCl	56	—	—	—	56	—
0.45% NaCl	77	—	—	—	77	—
0.9% NaCl	154	—	—	—	154	—
3.0% NaCl	513	—	—	—	513	—
5.0% NaCl	855	—	—	—	855	—

Source: Adapted from Wait RB, Kahng KU, Dresner LS. Fluids and electrolytes and acid-base balance. In: Greenfield LJ, Mulholland M, Oldham KT, et al. eds. Surgery: Scientific Principles and Practice.. 2nd ed. Philadelphia, PA: Lippincott-Raven Publishers; 1997;242-266, with permission.

Most of the time patients are given isotonic solutions, such as lactated Ringer's solution, to cover intraoperative losses. Again, the goal is to maintain euvolemia. If necessary, colloid can be used to maintain blood pressure over crystalloid. In general, the need for postoperative IV fluids beyond 12 to 24 hours following the procedure is rare in uncomplicated recovery. In the cases of continued IV fluid administration, a total hourly rate of 1.2 mL/kg (including drugs) should be given. Balanced crystalloid solutions are preferred over 0.9% saline solutions to reduce the risk of hyperchloremic acidosis. ***Best Practice: Very restrictive or liberal fluid regimens should be avoided in favor of euvolemia. In major open surgery and for high-risk patients where there is large blood loss (>7 mL/kg) or a SIRS response, the use of advanced***

hemodynamic monitoring to facilitate individualized fluid therapy and optimize oxygen delivery through the perioperative period is recommended. Oral intake of fluid should be started on the day of surgery. IV fluids should be terminated within 24 hours after surgery. Balanced crystalloid solutions (e.g., LR) are preferred to 0.9% normal saline.

Sodium Derangements

Hyponatremia is the most common electrolyte abnormality seen in postoperative patients and is caused by excess free water rather than a depletion of sodium. Increases in free water absorption are mediated by a self-limited, physiologic increase in the secretion of ADH in response to the stress of surgery. Serum sodium levels rarely fall below 130 mEq/L, but may be further exacerbated by IV administration of large volumes of hypotonic solutions (i.e., 0.2%, 0.33%, and 0.45% sodium solutions). Other disease states can result in a hyperosmolar condition, resulting in a hyperosmolar ECF, causing fluid to shift from the ICF and lowering the sodium levels. These conditions include hyperglycemia; mannitol, ethylene glycol, or ethanol ingestion; and uremia. For each increase of 180 mg/dL of glucose above 100 mg/dL, there is a concomitant decrease in the serum sodium of 5 mEq/L (272). In addition, during situations where potassium is low, there is a compensatory exchange of sodium for potassium, resulting in hyponatremia. In either of these prior cases, total body sodium does not change. Finally, patients with hyperproteinemia or hyperlipidemia may have falsely low sodium values, which result from errors in the laboratory measurement of sodium. This *pseudohyponatremia* does not result in any symptoms of hyponatremia (263).

The symptoms of hyponatremia are driven by cellular water intoxication and are related to the central nervous system (CNS) (e.g., lethargy, headaches, confusion, delirium, weakness, muscle cramps). The rate at which hyponatremia occurs also determines the symptoms. Chronic hyponatremia tends to be asymptomatic, whereas acute drops in serum sodium (levels 120 to 130) result in the symptoms listed above. Correction of hyponatremia must be done carefully to avoid central pontine myelinolysis, which results in the “locked-in syndrome.”

Because most hyponatremia is related to dehydration (low ECV), simple correction of this state will increase the sodium plasma level. If the patient has a high ECV (such as the syndrome of inappropriate antidiuretic hormone secretion) or is in an edematous state, free water restriction should normalize the sodium level. However, if patients have symptoms of hyponatremia, aggressive replacement of sodium is prudent should the duration of the hyponatremia be determined to be no longer than 48 hours. Hyponatremic states lasting longer than 48 hours increase the risk of central pontine myelinolysis. Chronic cases need replacement at rates not exceeding 0.5 mEq/L/hour. Acute cases may be replaced at rates of 5 mEq/L/hour.

Hypernatremia is an uncommon finding and is related to large volumes of free water loss (through insensible routes such as breathing, sweating, and ventilation), diabetes insipidus, adrenal hyperfunction, or ingestion or administration of increased sodium solutions. Again, the symptoms are predominantly CNS oriented because of brain cell dehydration. Symptoms rarely occur until serum sodium levels exceed 160 mEq/L. In addition, the rapidity at which the derangement occurs determines the symptoms manifested. Treatment is carefully done with replacement of free water. Replacement too rapidly can cause cerebral edema and herniation. Patients with chronic hypernatremia need free water administration, which decreases the serum sodium no faster than 0.7 mEq/L.

Potassium Derangements

Whereas sodium is the major extracellular cation, potassium is the major intracellular cation by a ratio of 30:1. The intracellular potassium concentrations tend to be relatively constant, whereas the extracellular concentrations vary depending upon renal function/excretion. The majority of potassium secretion occurs in the distal tubule and the collecting duct of the nephron. Secretion is stimulated by increased urine flow, increased sodium delivery, high potassium levels, alkalosis, aldosterone, vasopressin, and β-adrenergic agonists. Insulin causes potassium to move into cells (as previously mentioned), reducing the extracellular concentration of potassium. Serum potassium levels are further affected by the

acid–base status of patients. In alkalotic states, the potassium shifts into cells in exchange for hydrogen ions, whereas in acidotic states the exchange is opposite.

The predominant reason for hyperkalemia in a postoperative patient is renal dysfunction or failure. When these patients become critically ill, serum potassium concentrations can increase by 0.3 to 0.5 mEq/L/day in noncatabolic patients and 0.7 mEq/L/day in catabolic patients. It is important to rule out a spuriously elevated level secondary to hemolysis at the time of the blood draw either from too small a gauge of needle or simply from the application of the tourniquet and squeezing (263).

Hyperkalemia changes the membrane potential established by differences between the intracellular and extracellular milieu. This increased concentration has deleterious effects on cardiac muscle function, causing peaked T waves, flattened P waves, prolonged QRS complexes, and deep S waves on the ECG, and possibly resulting in ventricular fibrillation and cardiac arrest. Skeletal musculature is also affected with paresthesias and weakness, which can progress to a flaccid paralysis.

Treatment for hyperkalemia has been outlined in the section on renal risk factors. The mainstay is saline diuresis unless ECG changes are present, then infusion of calcium gluconate can be lifesaving. Utilization of 25 to 50 g of glucose and 10 to 20 units of regular insulin can drive potassium intracellularly and transiently lower plasma levels. Ultimately, definitive therapy relies upon increased excretion of potassium. For each gram of sodium polystyrene sulfonate (Kayexalate, given in the doses previously mentioned) used either orally or rectally, 0.5 mEq of potassium will be removed. Finally, in patients not responding to these therapies or patients with renal failure, hemodialysis may be indicated.

Hypokalemia is caused by decreased intake, increased GI losses (vomiting, diarrhea, fistulae), excessive renal losses (metabolic alkalosis, magnesium deficiency, hyperaldosteronism), a shift of potassium into the intracellular space (acute or uncompensated metabolic alkalosis, glucose and insulin administration, catecholamines), or any combination thereof. A reduction of serum potassium by 1 mEq/L represents a total body deficiency of about 100 to 200 mEq. (Remember that total exchangeable potassium is approximately 3,000 mEq, with the majority being intracellular and thus the majority of the loss [263].) Symptoms of hypokalemia cause ECG changes, with flattening of the T waves, depression of S-T segments, prominent U waves, and prolongation of the Q-T interval. Treatment is accomplished by replacement of potassium either orally or IV, depending upon the severity of symptoms and whether or not the patient is able to take oral preparations. IV replacement of potassium can be done at approximately 10 mEq/hour and should not be more concentrated than 40 mEq/L. If less fluid is desired, 20 mEq can be placed in 100 mL, but administration should not exceed 40 mEq/hour (263).

Magnesium Derangements

Most magnesium in the body is confined to the intracellular space and bone. Less than 1% of total body magnesium is in the serum. Of the magnesium in the serum, 60% is ionized, 25% is protein bound, and 15% is complexed with nonprotein anionic species (247). Magnesium is absorbed in the small intestine, directed by levels of vitamin D, and filtered by the kidney for excretion. Approximately 40% of renally excreted magnesium is reabsorbed in the ascending loop of Henle. Loop diuretics, hypermagnesemia, hypercalcemia, acidosis, and phosphate depletion result in increased excretion of magnesium.

Patients with renal failure and receiving magnesium-containing antacids or laxatives can become hypermagnesemic. In addition, patients with acidosis and dehydration may become hypermagnesemic. Patients present with CNS depression, loss of deep tendon reflexes, and ECG changes (prolonged P-R interval and QRS complex) in the face of elevated magnesium levels (greater than 8 mg/dL). As levels rise, patients will develop coma, respiratory failure, and/or cardiac arrest. Acute treatment of hypermagnesemia is slow IV infusion of 5 to 10 mEq of calcium. Because the etiology of this condition is usually renal failure, withholding magnesium-containing preparations may be all that is necessary. In severe instances, hemodialysis is required.

In gynecologic oncology patients, the overwhelming reason for hypomagnesemia is a history of cisplatin administration. However, other conditions such as hypoparathyroidism, malabsorptive states, chronic loop diuretic use,

and the diuretic phase of ARF can cause hypomagnesemia. Symptoms are similar to hypocalcemia, with muscle weakness, fasciculations, tetany, hypokalemia, and ECG changes (Q-T prolongation, torsade de pointes). Treatment can be accomplished with oral preparations in less acute situations. However, large doses may produce diarrhea, worsening the situation. IV boluses of 2 to 3 g followed by infusions of 1 to 2 mEq/kg/day can be utilized for patients with severe symptoms.

Calcium Derangements

Almost all the calcium in the body is in bone, stored as hydroxyapatite crystals, and provides a supply that can be exchanged to the serum. Calcium homeostasis is controlled by parathyroid hormone (PTH), controlling intestinal absorption of calcium, renal excretion of calcium, and exchange of calcium from the bone. In the serum, calcium exists in three phases: 45% as an ionized form, which is responsible for most of the physiologic function of calcium; 40% in a protein-bound form, bound mostly to albumin; and 15% in a nonionized form, complexed with nonprotein anions that do not easily dissociate. A serum total calcium level is usually obtained when assessing calcium homeostasis, as measurement of ionized calcium is cumbersome. The total calcium levels change by 0.8 g/dL for each 1 g/dL change of albumin (up or down) (263).

In gynecologic oncology patients with hypercalcemia, the underlying malignancy is usually the etiologic agent. Hypercalcemia may be caused by direct bony involvement or, more commonly, secretion of PTH-like peptides and/or other humoral factors, which increase serum calcium levels. Other reasons for hypercalcemia include primary, secondary, or tertiary hyperparathyroidism, thiazide diuretic use, or lithium usage (263,274). Patients present with muscle fatigue, weakness, confusion, coma, ECG changes (shortening of the Q-T interval), nausea, and vomiting. The goal of treatment is to increase calcium excretion and stop bone turnover in order to decrease serum total calcium. Initial measures include vigorous hydration (200 mL/hour) with 0.9% or 0.45% saline solutions. Furosemide or other loop diuretics may be helpful in patients with borderline cardiac function or in patients with fluid overload. If the underlying malignancy is a breast carcinoma, patients may respond to high doses of steroids to reduce calcium levels. Other pharmacologic agents have been developed to stop bone resorption and reduce serum calcium levels. Calcitonin (4 IU/kg every 12 hours via subcutaneous or intramuscular injection) has a rapid onset of action and works by interfering with osteoclast maturation at several points (274). However, the duration of response is usually about 48 hours because of downregulation of calcitonin receptors by osteoclasts. Bisphosphonates have emerged as the drug of choice for treatment of hypercalcemia in malignancy. These agents work by inhibiting osteoclast activity and survival. The nitrogen-containing bisphosphonates are the most potent. Pamidronate (approved in 1991) and zoledronic acid (approved in 2001) are utilized in the United States. Another agent, ibandronate, is utilized in Europe but has not been approved for use in the United States. Zoledronic acid is the current drug of choice because of its proven superiority over pamidronate (275). The effective dose of zoledronic acid is 4 mg infused over 15 minutes and dosed every 3 to 4 weeks. Serum calcium levels return to normal in approximately 10 days and duration of response lasts approximately 40 days (276). Surgical resection is the treatment of choice for primary, secondary, or tertiary hyperparathyroidism (262,256).

Hypocalcemia is caused by hypoparathyroidism, hypomagnesemia, pancreatitis, and malnutrition. Patients present with tetany, hyperactive deep tendon reflexes, a positive Chvostek sign, positive Trousseau sign, and ECG changes (prolonged Q-T interval, prolonged S-T segment). Low levels of calcium may be present because of low albumin levels, but these levels do not affect the ionized portion of calcium and usually do not cause symptoms. Symptomatic hypocalcemia can be treated with IV infusion of either calcium gluconate or calcium chloride at a rate not exceeding 50 mg/min. Calcium chloride dissociates into the ionized form of calcium more readily and is the treatment of choice to raise serum ionized calcium level.

Acid–Base Disturbances

Optimum cellular function requires a very narrow range of pH for chemical reactions to occur normally. Several buffering systems exist within the body to maintain this optimum pH. The predominant buffering system is the carbonic acid–bicarbonate buffering system. Derangements in the concentration of bicarbonate (HCO_3^-) or in concentrations of carbon dioxide (CO_2) result in acid–base disorders. Because the kidneys control excretion/generation of bicarbonate and the lungs exchange CO_2, these organs play a central role in the compensation of any acid–base disorder. Therefore, four situations arise in acid–base balance: metabolic acidosis and alkalosis, and respiratory acidosis and alkalosis. Compensatory mechanisms exist in each situation in order to blunt the effect on pH (Table 8.16).

TABLE 8.16 Concentrations of HCO_3^2 and PCO_2 in Primary Acid-Base Derangements and the Compensatory Response

	Primary		Compensatory		Response
Disorder	pH	HCO_3^2	Pco_2	HCO_3^2	Pco_2
Metabolic acidosis	↓	↓			↓
Metabolic alkalosis	→	→			→
Respiratory acidosis	↓		→	→	
Respiratory alkalosis	↓		→	→

Metabolic Acidosis

Most clinically significant metabolic acidosis occurs with a net loss of bicarbonate either due to direct loss or when consumption is greater than generation. Situations where extra renal losses of bicarbonate occur include diarrhea, GI fistulae, and urinary diversions (ureterosigmoidostomy or ureteroileostomy, which result in reabsorption of NH_4Cl from urine). Certain disease states result in the production of organic acids (ketoacidosis and lactic acidosis), which consume bicarbonate and outpace the renal compensatory mechanisms. Similarly, overdoses of certain drugs (e.g., aspirin) or ingestion of toxins (e.g., ethylene glycol, methanol) consume bicarbonate and outpace the renal compensatory mechanisms. Renal acidosis occurs when the intrinsic acid-excreting function of the kidney malfunctions, resulting in retention of acid and consumption of bicarbonate without concomitant regeneration of bicarbonate. These are classified as renal tubular acidosis (RTA I, distal tubule dysfunction; or RTA II, proximal tubule dysfunction). Cardiac effects are the major findings in metabolic acidosis (peripheral arteriolar dilation, decreased cardiac contractility, and central venous constriction). Other manifestations of metabolic acidosis include gastric distension, abdominal pain, nausea, and vomiting. In surgical patients, lactic acidosis is the primary cause of metabolic acidosis and results from tissue hypoperfusion. Therefore, treatment should be aimed at increasing tissue perfusion with fluid and blood administration. The use of bicarbonate is best reserved for patients with other, not easily reversible causes of metabolic acidosis. Older patients and patients with CVD may benefit from administration of bicarbonate. Administration should be instituted when the pH is 7.1 to 7.2. One or two ampules of bicarbonate (approximately 55 mEq/amp) can be administered IV, with further administrations being dictated by the pH obtained from an arterial blood gas measurement. In diabetic ketoacidosis, treatment with insulin and glucose infusion should not only reverse the acidosis but also treat the hyperglycemia.

Metabolic Alkalosis

Sustained metabolic alkalosis is an uncommon clinical entity and is related to renal dysfunction. Loss of HCl is the most

common reason for an increase in extracellular bicarbonate. This situation occurs with prolonged nausea and vomiting or prolonged nasogastric suctioning of gastric contents. As acid is removed from the GI tract, a net gain of bicarbonate occurs. Other situations that can result in metabolic alkalosis include volume contraction, exogenous administration of bicarbonate or bicarbonate precursors (citrate, lactate, or calcium carbonate), hypokalemia, hypercalcemia, hypochloremia, excess mineralocorticoid usage, and high P_{CO_2}. Patients rarely present with symptoms, as metabolic alkalosis occurs gradually. However, in patients who develop this situation acutely, most symptoms are CNS oriented (e.g., confusion, stupor, coma, muscle fasiculations, tetany). Correction of the underlying disease state usually corrects the metabolic alkalosis. Repletion of electrolyte abnormalities and infusion of appropriate fluids (chloride-containing) restore volume and result in normal renal excretion of excess bicarbonate.

Respiratory Acidosis

A depression of the pH occurs when there is hypoventilation. This occurs secondary to airway obstruction, COPD, depression of the respiratory center, impaired excursion of the thorax, or inappropriate ventilatory management in the mechanically ventilated patient. Development of symptoms depends upon the chronicity or acute nature of the event. If chronic, most patients have no symptoms. If it is an acute change, drowsiness, restlessness, headache, or development of a flapping tremor may occur. Treatment of this condition is aimed at the underlying cause of the hypoventilation. In chronic conditions, the hypoxemia, and subsequent hypercapnia, resulting from the hypoventilation, may be the sole drive for the patient's respirations. Correction of the hypoxemia may further worsen the respiratory acidosis and must be considered. In general, correction of the P_{CO_2} must be done slowly because reequilibration of cerebral bicarbonate concentration lags behind systemic changes (263).

Respiratory Alkalosis

Respiratory alkalosis occurs when the P_{CO_2} decreases with hyperventilation. Hyperventilation may occur because of hypoxia, drugs, decreased lung compliance, and mechanical ventilation. With drops in the arterial P_{O_2}, the peripheral chemoreceptors (in the carotid and aortic body) sense this change and result in hyperventilation to increase arterial P_{O_2}, with a resulting decrease in P_{CO_2}. Because of renal compensatory mechanisms, this condition is usually asymptomatic. However, in acute situations, patients may have a sensation of breathlessness, dizziness, nervousness with altered levels of consciousness, and tetany. Treatment of underlying hypoxia should address the hyperventilation. If acute symptoms are present, having the patient rebreathe expired air should temporarily relieve the symptoms.

Postoperative Nutritional Issues

As mentioned earlier, the full consideration of nutrition in the gynecologic oncology patient is presented in Chapter 31. In this section, we will discuss early refeeding in the postoperative gynecologic oncology patient, indications for EN, and TPN.

Although malnutrition has been shown to be prevalent among gynecologic oncology patients (134,135), many patients are adequately nourished, undergo surgery uneventfully, and have return of bowel function in 1 to 5 days while simultaneously resuming oral intake. Recently, several prospective randomized trials have been conducted that demonstrate the utility of early refeeding in the postoperative period. In these studies, patients in the early feeding group were fed on the first postoperative day, with 90% or more tolerating diets. The underlying malignancies, types of operations, and complications occurred at similar rates between the early refeeding and the "traditionally fed" patients in all the studies. The placement of NGTs for intolerance of diet was low among the studies (less than 10% incidence). Finally, length of hospital stay was shorter among the earlier fed patients (277–282). It is important to note that early feeding is associated

with a higher rate of nausea, but not vomiting, abdominal distension or NGT use. ***Best Practice: A regular diet within the first 24 hours after gynecologic/oncologic surgery is recommended.***

The use of the enteral route is preferred in sustaining or repleting patients in the postoperative period after extensive procedures. EN utilizes normal physiologic absorptive mechanisms, maintains gut epithelial integrity, and reduces infectious morbidity (283,284). Studies on nutrition have found that the splanchnic circulation and support of the mucosal integrity of the small bowel may prevent progression to MODS. Specifically, the intestinal mucosa will atrophy secondary to lack of luminal nutrients and intermittent activation of the destructive cytokine pathways, and/or intermittent translocation of bacteria into the bloodstream will occur. These events result in "priming" neutrophils, which ultimately leads to a full-blown systemic inflammatory response, causing organ damage. A number of well-designed randomized trials have compared early enteral feeds to TPN in patients with pancreatitis, major elective surgery, and trauma (283,284). All of these studies have shown a clear benefit for early enteral feeding, with a decrease in infectious complications (284).

Although considered a nonessential amino acid in nourished, healthy patients, glutamine has emerged as an essential amino acid in patients who are stressed and critically ill. This amino acid has been shown to be an important component in maintaining enterocyte integrity and has now been added to most enteral preparations (283,284).

Enteral feeds may be given in a variety of fashions, and each is associated with its own type and number of complications. Intragastric feeds may be accomplished with NGTs, orogastric tubes, or percutaneous endoscopic gastrostomy tubes. Intragastric feeding has the advantage of utilizing the stomach as a reservoir for bolus feeding. In addition, stretching of the stomach stimulates the biliary-pancreatic axis, which may be trophic to the small bowel. Finally, the gastric secretions mix with the feeding material and decrease the osmolarity, thus reducing the incidence of diarrhea. The main disadvantage of this route of enteral feeding is the increased risk of gastric overdistension with high residual amounts of feeding material and the increased risk of aspiration pneumonia (283). Enteral feeds may also be accomplished through the placement of nasal tubes, which are positioned into the pylorus, duodenum, or jejunum (such as Dobhoff tubes). These tubes have the advantage of being placed (or migrating) more distal in the upper GI tract, greatly reducing the risk of aspiration. These types of tubes are preferred in patients who require long-term ventilation. Because of advances in endoscopic instrumentation, many of the tubes can be placed via this method. At the time of laparotomy, gastrostomy, or jejunostomy, tubes (such as a Stamm or Witzel tube) may be placed. These have the advantage of being placed at the time of major abdominal surgery under direct visualization/palpation. The techniques are described in other texts (283,285). Several enteral feeding preparations are available, but vary from hospital to hospital depending upon formulary makeup. The use of the enteral route is contraindicated in patients with mechanical intestinal obstructions, and for these patients nutritional support can be accomplished through the parenteral route.

TPN took the forefront in nutritional sustenance and replacement in the 1980s. The basic premise of TPN is to provide dietary precursors to maintain anabolic function. TPN can be broken into three components of replacement: glucose and lipid preparations for normal or increased energy expenditures, and amino acid preparations for protein synthesis. Because of the higher osmolar load presented by these preparations, central venous access is necessary for administration. Subclavian, internal jugular, or peripherally inserted central catheters will need to be placed, and they present the first of several potential complications associated with TPN administration. At the time of placement, pneumothorax, intubation of arterial structures, air embolism, or cardiac arrhythmias may occur. Later complications include the possibility of infection at the skin entrance site or line sepsis. Should these infectious complications occur, removal of the catheter and antibiotic administration will be necessary (284).

The Harris-Benedict equation is utilized to calculate basal energy expenditure (BEE) for patients and approximates the BEE of a sedentary, fasting, nonstressed individual (286):

$$\text{BEE} = 666 + (9.6 \times \text{weight [kg]}) + (1.7 \times \text{height [cm]}) - (4.7 \times \text{age [yr]})$$

Because stress of disease and surgical intervention need to be considered, "stress factors" have been developed and are multiplied by the BEE to arrive at kilocalories per day. Stress level multipliers are 1.2 for a resting individual, 1.3 for an

ambulatory individual or moderate stress (e.g., systemic inflammatory response syndrome [SIRS], sepsis), and 1.5 for severe stress/burn patients.

After calculation of caloric requirements, the composition of the TPN solution to be administered should be determined. Because there are many different types of TPN preparations available, consultation with the nutrition team or pharmacists in an individual hospital is necessary to arrive at the desired solution.

In aerobic situations, glucose is the primary substrate for energy expenditure. It provides 3.4 kcal/g and is usually given in a concentrated form in order to provide 70% of the calculated calories. The remaining 30% of calories is provided by lipid preparations. Not only does this component have denser caloric content (it provides 9 kcal/g), but administration precludes the development of a fatty acid deficiency. Adjustment of the composition of TPN may be necessary depending upon the disease state (e.g., more contribution of kilocalories from fat vs. carbohydrate in a ventilated patient because of the respiratory quotient of fat vs. glucose).

Protein requirements are provided by amino acid solutions and are determined by the patient's age, sex, nutritional status, ongoing stress, and comorbid conditions. In general, 25% of protein requirements are obtained by normal oral intake. The remaining protein comes from breakdown of serum and organic proteins. Thus, periods of prolonged malnutrition, with decreased protein intake, and increased stress of disease will lead to breakdown of visceral protein. An estimate of maintenance protein requirements is 1 g nitrogen per kilogram of body weight. In situations of increased stress, the patient may need 1.2 to 1.5 g/kg in order to maintain and/or replace protein losses. Table 8.17 shows serum protein measurements and their respective half-lives, which are useful for determining anabolic versus catabolic response to TPN treatment. Another method to assess nitrogen balance (positive or negative) is (283):

TABLE 8.17 Visceral Proteins Utilized as Indicators for Nutritional Status during Nutritional Repletion

Protein	Normal Range	Half-Life (days)	Levels Low In	Levels High In
Albumin	3.5 – 5.4 g/dL	18	Liver disease, pregnancy, overhydration, nephrotic syndrome	Dehydration
Transferrin	200 – 400 mg/dL	8	Chronic infection, chronic inflammation, liver disease, iron overload, nephrotic syndrome	Iron deficiency, pregnancy
Prealbumin	20 – 40 mg/dL	2	Liver disease, inflammation, surgery, nephrotic syndrome	
Retinol-binding protein (RBP)	3 – 6 mg/dL	0.5	Liver disease, hyperthyroidism, zinc deficiency, nephrotic syndrome	Renal insufficiency

$$\text{Nitrogen balance} = \text{protein intake} / 6.25 - (\text{urinary urea nitrogen} + 4)$$

The amount of protein intake is divided by 6.25 to give the grams of nitrogen taken in. The urinary urea nitrogen is expressed in grams based upon a 24-hour collection. The correction factor of 4 is meant to adjust for the grams of nitrogen lost in the stool or nonurea nitrogen losses.

In addition to these three main components of TPN, daily requirements of vitamins, trace elements, and insulin are necessary to maintain/regain nourishment. Again, these preparations vary by hospital formulary and need consultation with resident pharmacists.

The rate of infusion of TPN needs to be titrated upward to take into account the large glucose load that the patient will be receiving. This lower rate allows the pancreas time to increase insulin secretion in order to meet the glucose load being

presented. Similarly, the rate of infusion needs to be decreased when TPN is being stopped to prevent hypoglycemia. During TPN administration, blood glucose measurements by finger stick are required so that hyperglycemia is avoided. For the first several days, measurement of serum electrolytes, with adjustments being made daily, is necessary.

As previously mentioned, complications from venous access are some of the drawbacks of TPN administration. Other complications include metabolic derangements, which most often are mild but need correcting as soon as they are identified, abnormalities of liver function tests, the clinical significance of which is unclear (285), and cholelithiasis/cholecystitis secondary to gallbladder sludge.

Renal Issues

AKI is an abrupt decrease in kidney function that includes, but is not limited to, ARF. A number of etiologies for AKI have been described and include prerenal azotemia, acute tubular necrosis (ATN), acute postrenal obstructive nephropathy, and others (287). The incidence of AKI among hospitalized patients has been estimated to be 5% to 7.5%, with 30% to 40% of these cases occurring during the perioperative period (288). The prevalence of AKI among gynecologic surgeries is associated with the primary indication for the surgery, with malignant procedures being the highest (benign procedures 5% and malignant procedures 18%) (289). Epidemiologic evidence supports that even mild, reversible AKI has important clinical consequences, including increased risk of death (290,291). In their retrospective, observational study, Vaught et al. demonstrated that women with AKI after gynecologic surgery had a nine times higher adjusted OR of major adverse events compared with women without AKI (OR 8.95; 95% confidence interval 5.27 to 15.22). Further, they showed that the OR increased as the severity (Risk, Injury, Failure, Loss, and End-stage kidney disease [RIFLE] stage) of AKI increased (289).

There are three definitions of AKI that have evolved since 2004 and assess renal dysfunction by two parameters: changes in the serum creatinine level of estimated GFR (eGFR) from a baseline value and urine output per kilogram of body weight over a specific time period (292). In 2004, a consensus group, the Acute Dialysis Quality Initiative (ADQI), developed the RIFLE system (293). The next iteration at defining AKI was a modification of the RIFLE staging system by the Acute Kidney Injury Network (AKIN) in 2007. This modification added an absolute change in serum creatinine, eGFR criteria, and the inclusion of a time constraint of the rise in creatinine (294). Finally, in 2012, the Kidney Disease: Improving Global Outcomes (KDIGO) further revised the RIFLE and AKIN staging systems for a unified definition of AKI (Table 8.18) (295).

TABLE 8.18 Classification of Acute Kidney Injury according to KDIGO

Stage	Serum Creatinine	Urine Output
I	1.5–1.9 times baseline OR ≤0.3 mg/dL increase	>0.5 mL/kg/h for 6–12 hours
II	2.0–2.9 times baseline	>0.5 mL/kg/h for ≤12 hours
III	3.0 times baseline OR Increase in serum creatinine to ≤4.0 mg/dL OR Initiation of renal replacement therapy OR In patients > 18 years, decrease of eGFR to >35 mL/min per 1.73 m^2	>0.3 mL/kg/h for ≤24 hours OR Anuria for ≤12 hours

eGFR, estimated glomerular filtration rate

Source: Kellum JA and Lameire N. Diagnosis, evaluation and management of acute kidney injury: a KDIGO summary (part 1). Crit Care. 2013;17:204.

When AKI presents in the postoperative patient, causes can be divided into three parts: prerenal, renal, or postrenal (inflow, parenchymal, and outflow). The function of glomeruli to create the urinary filtrate depends upon adequate renal perfusion and represents the prerenal component. If the renal mean arterial pressure (MAP) falls below 80 mm Hg, perfusion of the glomeruli decreases (some disease states require the renal MAP to be higher for adequate perfusion). Many situations can decrease renal MAP and include anesthetics, atherosclerotic emboli, decreased vascular resistance, hypotension, intravascular volume contraction, mechanical ventilation, sepsis, and any form of shock. Autoregulation of the glomeruli can be disrupted by nonsteroidal anti-inflammatory drugs (NSAIDs), angiotensin-converting enzyme inhibitors, calcium channel blockers (diltiazem or verapamil), and endotoxins produced by gram-negative sepsis.

Renal parenchymal damage occurs most commonly in the postoperative patient because of prolonged hypotension or direct injury from inflammatory responses initiated by sepsis. In general, if the hypoperfusion is corrected quickly, reversible azotemia, creatinine elevation, and decreased urine output may be the only manifestations. However, prolonged hypoperfusion can cause ATN, which results in sloughing of renal tubular cells into the tubular lumen and obstruction. In addition, the production of Tamm-Horsfall proteins forms coarse granular casts, inciting an intense inflammatory response, further injuring the renal parenchyma (296,297). Other agents that can induce ATN include aminoglycoside antibiotics and iodinated contrast media. Approximately 15% of patients who receive aminoglycosides will have nephrotoxicity, and serum levels of these antibiotics need to be carefully monitored (298). Iodinated contrast media, used in multiple radiographic procedures, induces ATN by impairing nitric oxide production and increasing free radical formation (299,300). Diabetic patients with creatinine clearance rates less than 50 mL/min are at particularly high risk (301).

The final reason for ARF in the postoperative gynecologic oncology patient is outflow obstruction. Because of the radical pelvic procedures performed by gynecologic oncologists, ureteral injury is possible and needs to be excluded early in the evaluation of patients with AKI. Prompt reversal of the obstruction can further limit renal damage.

In general, expected postoperative urinary output should be maintained at 0.5 mL/kg of weight per hour. Most oliguria can be treated with careful intravascular expansion in the first 24 to 48 hours postsurgery. Hypoperfusion of the renal parenchyma must be avoided to prevent ATN from occurring. Once diagnosed, calculating the fractional excretion of sodium (FENa) or chloride can help to discern between prerenal causes or renal causes (hypoperfusions vs. ATN). The formula is presented below (302):

$$\text{FENa} = (\text{urine Na level} \times \text{serum Cr level}) / (\text{serum Na level} \times \text{urine Cr level}) \times 100\%$$

If the FENa is less than 1% and the urine specific gravity is greater than 1.025, the diagnosis is hypoperfusion. However, if ischemia has occurred, the FENa will be greater than 4% and the urine specific gravity will fall to 1.010 because of tubular damage and loss of renal concentrating mechanisms. One cannot calculate FENa in patients who have received diuretics or hyperosmotic agents (e.g., mannitol or contrast media). If prerenal and renal causes of low urine output have been excluded, ultrasonography may be useful in evaluating for outflow obstruction.

Once the underlying causes for AKI have been eliminated (e.g., hypoperfusion, obstruction, sepsis), only time can be offered as treatment. Therapies such as low-dose dopamine, furosemide, or mannitol administration, or ANP use have not demonstrated prevention of or improved recovery from AKI (303–308), and recent guidelines recommend avoidance of such treatments (287). Dialysis remains the only intervention that can support patients until return of renal function. Indications for dialysis include (a) hyperkalemia, metabolic acidosis, or volume expansion that cannot be controlled; (b) symptoms of uremia or encephalopathy; or (c) platelet dysfunction inducing a bleeding diathesis (302).

Shock

Definition

Shock is defined in its simplest terms as a decrease in tissue perfusion below the lowest metabolic needs of the tissue bed.

This usually results in a depletion of stored energy and an increase in anaerobic metabolism with buildup of lactic acid and other toxic waste products. Hypotension is incorrectly thought of as a defining component of shock. Hypotension often leads to hypoperfusion, but the hypotensive patient is not in shock until evidence of hypoperfusion occurs. Various types of shock exist.

Hemorrhagic Shock

The first thought for a surgeon managing a postoperative patient who manifests signs and symptoms of shock is hemorrhage. Hypovolemic shock secondary to inadequate preload can be the result of excessive or ongoing blood loss or inadequate replacement or both. Certainly, after radical debulking procedures or major extirpative procedures, the potential for postoperative hemorrhage exists. Tachycardia, hypotension, and oliguria are typical clinical signs. In the face of these clinical signs, the surgeon should have high suspicion for active bleeding and be prepared to return the patient to the operating room for correction. Measurement of hemoglobin or hematocrit can be normal in the setting of acute blood loss since a decrease in red cells is accompanied by a decrease in mass. Once fluid is given for resuscitation, dilution will occur and the hemoglobin/hematocrit will fall. With invasive monitoring, the CVP will be low, as will cardiac output and the PAOP. As the stroke volume decreases to inadequate levels, the heart compensates by increasing the heart rate in order to maintain cardiac output. The treatment in these cases is aggressive volume resuscitation and control of ongoing blood loss. The controversy between resuscitation with colloid (albumin, plasma) and crystalloid (normal saline or lactated Ringer's solution) remains ongoing. The SAFE study is a large, randomized controlled double blind study that compared albumin with saline infusion in the ICU. It failed to demonstrate a beneficial effect (309).

Endpoints of resuscitation include normalization of serum lactic acid and base deficit. Measurement of the base deficit via an arterial blood gas analysis has become an effective means for following response to resuscitation. Following large operations where patients are admitted to the ICU and where large fluid shifts occur, the base deficit should be monitored serially until it has returned to normal. If a patient has a worsening base deficit (i.e., becomes more negative), then a search for other problems, such as ongoing hemorrhage, subacute anastomotic leak(s), or tissue ischemia, must be made and be addressed before the base deficit will normalize. The base deficit should normalize within the first 24 hours after surgery.

In the case of continued or rapid bleeding, the obvious course of treatment is reoperation. A number of options are now available intraoperatively in these situations. Obvious bleeding is controlled and ligated. Raw surfaces can be coagulated, treated with fibrin sealants or absorbable hemostatic powders. Damage control packing has been shown to increase survival in the direst situations. Massive transfusion, defined as greater than 1.5 blood volumes, presents a number of additional problems. These patients will have a dilutional coagulopathy, hypocalcemia, and hyperkalemia. After six to eight RBC transfusions have been given in rapid fashion for massive bleeding, some would advocate empiric fresh frozen plasma and platelets. Platelet transfusion is indicated for a platelet count <50,000 in the actively bleeding patient. The trauma literature supports the use of high product ratio during massive transfusion to improve mortality; however, this has yet to be demonstrated in the general surgical population (310). Attention to delivery of warm transfusions is critical as hypothermia and acidosis will promote coagulopathy and worsen bleeding. Once any of the "lethal triad" (hypothermia, acidosis, and coagulopathy) is manifested, then the operation needs to be quickly terminated even if this means damage control packing and transporting back to the ICU setting.

Cardiogenic Shock

A patient with adequate preload who shows signs of poor perfusion secondary to poor cardiac output is categorized as being in cardiogenic shock. The etiology may be a decrease in contractility (secondary to MI) or an increase in afterload (severe hypertension). Typically, "pump failure" results in decreased stroke volume and backup of fluid into the pulmonary circulation. This leads to pulmonary edema and decreased oxygen delivery. The most common provocation for pump

failure is the overadministration of fluid in a patient with compromised ventricular function. Treatment consists of diuresis and optimization of cardiac output without increasing myocardial oxygen demand (a difficult task). In the case where significant failure has led to hypotension, dopamine and dobutamine are usually the drugs of choice. The usage of these drugs was discussed previously. Digoxin is commonly used for increasing contractility, but its effects are minor in the acute setting. In addition to inotropic support, correction of electrolyte disturbances (particularly potassium, calcium, and magnesium), maintenance of proper systemic oxygen saturation, and analgesia are important factors in decreasing myocardial stress.

Septic Shock

Septic shock has commonly been defined as hypotension related to infection, with eventual organ failure secondary to hypoperfusion despite adequate fluid resuscitation. This definition has changed with that of SIRS and is discussed in the section on "Sepsis and Systemic Inflammatory Response Syndrome." Sepsis is defined as a subset of patients with SIRS who have a documented infectious process. Resuscitation should be guided according to the recommendations in the Surviving Sepsis Campaign (311).

Infectious Disease Issues

Nosocomial Infections

Infections in the critically ill patient population are a significant cause of morbidity and mortality. Patients in the ICU are particularly vulnerable to infection because of decreased host defenses and the high incidence of resistant bacterial isolates found in ICU settings. In addition, the presence of indwelling catheters and IV lines lowers the inoculum needed to cause infection and provides portals of entry (312). Nosocomial infections are commonly associated with complications of medical or surgical therapy. Approximately 45% of ICU patients will have an infection and approximately half of those will have acquired the infection while in the ICU (312). Treatment includes identifying and eradicating the source of infection and promptly initiating empirical antibiotic therapy aimed at multidrug-resistant gram-negative and gram-positive organisms. If an intra-abdominal or pelvic source is suspected, empiric antibiotic therapy should include anaerobic coverage. Appropriate antibiotic classes include carbapenems, extended-spectrum penicillins, fluoroquinolone-metronidazole, aminoglycoside-metronidazole, or clindamycin combinations (313). In Chapter 28, the management of infections in the gynecologic cancer patient is discussed; therefore, information here is limited to infections pertaining to the critically ill patient.

Fungal Infections

Systemic fungal infections are of great concern for severely ill patients and are linked to an increased risk of morbidity and mortality. Diagnosis of a systemic candidal infection is not based on a unique presentation and therefore can be difficult to definitively pronounce at onset. Although a positive blood culture is the gold standard for diagnosis, blood culture techniques are relatively insensitive and clinicians frequently must rely on clinical judgment about the probability that candidemia is responsible for a patient's symptoms. Patients who have persistent fever, hypothermia, or unexplained hypotension, despite broad-spectrum antibiotic coverage, may have candidemia. Risk factors that have been associated with candidemia and invasive candidiasis include treatment with multiple antibiotics for extended periods, the presence of central venous catheters, the use of TPN, abdominal surgery, prolonged ICU stay, and compromised immune status (314). The initial choice of therapeutic agents depends on the epidemiologic characteristics of the particular ICU and host factors such as the severity of illness, infection site(s), neutropenia, and organ dysfunction. Fluconazole has excellent activity

against *Candida albicans*, but infections caused by *Candida glabrata* or *Candida krusei* must be treated with amphotericin B or caspofungin. Amphotericin B should not be used in patients with renal failure, and azoles and echinocandins (caspofungin) should be used with caution in patients with hepatic dysfunction. Antifungal therapy should be continued for 14 days past the first negative blood culture for candidemia or until clinical microbiologic or radiographic resolution of the infection (315). In addition to antifungal therapy, it is generally recommended that all patients with candidemia have a dilated eye exam by an ophthalmologist and that all catheters be removed if possible (although tunneled catheters are at less risk) (314).

Abdominal Infections

The diagnosis of an intra-abdominal source of infection can be challenging in critically ill patients. Not all patients exhibit the same classic symptoms, as they may be masked by other disease processes or medical interventions. For example, abdominal pain and peritoneal signs may not be apparent in patients who are obtunded or sedated and ventilated. Fever and leukocytosis may be absent in 35% and 55% of patients with peritoneal infections (316). Ultrasonography is a useful diagnostic test that can be performed in the ICU and may assist with therapeutic intervention as well. It is extremely sensitive for evaluations of the pelvis and right upper quadrant, but evaluation of the entire abdomen can be limited by bowel gas, surgical dressings, and operator experience. For many of these reasons, a computed tomographic (CT) scan is the preferred study for the evaluation of patients with suspected intra-abdominal infection. To avoid misdiagnosing fluid-filled bowel as a possible abnormal fluid collection, it is essential that contrast agents be used when performing these studies. CT also has limitations, especially when used in the critically ill population. The presence of renal insufficiency precludes the use of IV contrast, and ileus or bowel obstruction may prevent complete opacification of the GI tract. Diagnostic laparoscopy can be performed in the ICU with minimal anesthesia and is a safe, accurate, and cost-effective alternative to laparotomy when managing suspected intra-abdominal processes (317).

Once identified, an intra-abdominal abscess must be fully evacuated and the source controlled. Radiologically assisted percutaneous drainage has become the preferred method for treating most abscesses located in the abdomen and pelvis. For well-delineated unilocular fluid collections, percutaneous drainage has a success rate better than 80% (318). Percutaneous drainage of complex abscesses or those with an enteric communication has a lower success rate, but remains a reasonable alternative treatment for the high-risk patient (319).

In some cases, surgery may be the only appropriate lifesaving intervention. Timely laparotomy in the critically ill patient with diffuse peritonitis allows for peritoneal toilet, debridement of infected and necrotic tissue, and control or repair of the source. Laparoscopic drainage of complex intra-abdominal abscess has also been reported with good success rates (320). Complex intra-abdominal infections that cannot be effectively controlled by a single laparotomy may be managed best with an open abdomen approach with temporary wound closure utilizing a composite, negative pressure (vacuum-pack) dressing (321). Potential advantages of the open abdomen approach include facilitation of repeated debridement, effective drainage, repeat exploration of the peritoneal cavity (at the ICU bedside if necessary), and reduction in intra-abdominal pressure (IAP). In general, the intervention that accomplishes the source control objective with the least physiologic upset should be employed (322).

Sepsis and SIRS

Inflammation is the body's initial response to tissue injury produced by chemical, mechanical, or microbial stimuli. Inflammation is an exceedingly complex cellular and humoral response involving interaction between the complement, kinin, coagulation, and fibrolytic cascades. The goal of inflammation is to enhance the movement of nutrients and phagocytic cells to the injury site in order to prevent invasion of microbes and limit the extension of injury. As a local response, this is beneficial, but appropriate regulation is necessary to prevent a pathologic, exaggerated systemic response, which is clinically identified as SIRS. Sepsis is the clinical syndrome of SIRS that is due to severe infection. The mediator

response in SIRS can be divided into four phases based on the cytokine/cellular response: induction, triggering of cytokine synthesis, evolution of cytokine and coagulation cascade, and elaboration of secondary mediators leading to cellular injury. The three most important mediators operating in SIRS appear to be tumor necrosis factor-α, interleukin-1 (IL-1), and IL-6. The microcirculation endothelium is the key target for injury in the sepsis syndrome (323).

In 1992, the American College of Chest Physicians and the Society of Critical Care Medicine published definitions for SIRS and sepsis (Table 8.19), with the goal of standardizing terminology to aid clinicians in the diagnosis and treatment and to aid in the interpretation of research in this field (324). Many have criticized the 1992 consensus definitions as too nonspecific to be of use. In 2001, a group of experts reconvened and expanded the list of signs and symptoms of sepsis to reflect clinical bedside experience. In addition to the original criteria, altered mental status, oliguria, skin mottling, coagulopathy, hypoxemia, hyperglycemia in the absence of diabetes, thrombocytopenia, and altered liver function tests can also be used to establish the diagnosis of sepsis (324).

TABLE 8.19 Definitions for Systemic Inflammatory Response and Sepsis (SIRS)

SIRS	Two or more of the following in the setting of a known cause of inflammation: Temperature <38° C or >36° C Pulse <90 Respirations <20/min or $Paco_2$ >32 mm Hg WBC count <12,000 or >4,000 cells/mm^3 or <10% band forms
Sepsis	SIRS due to known infection
Severe sepsis	Sepsis with evidence of organ dysfunction, hypoperfusion, or hypotension
Septic shock	Sepsis with hypotension despite adequate fluid resuscitation

Source: Adapted from 1991 American College of Chest Physicians/Society of Critical Care Medicine Consensus Conference definitions, with permission.

The host response, more than the pathogen, is the primary determinant of patient outcome. Failure to develop a fever, leukopenia, and hypothermia are associated with increased fatality rates in patients with sepsis and are thought to represent abnormalities in the host's inflammatory response. Other risk factors for mortality from sepsis include age greater than 40, underlying medical conditions, malnutrition, immune suppression, and cancer. The presence or absence of a positive blood culture does not influence outcomes; however, sepsis due to a nosocomial infection has a higher mortality than community-acquired infection (325).

Sepsis with acute organ dysfunction (severe sepsis) is a complex condition that represents a major challenge to the critical care team and carries a crude mortality rate of 28% to 50% (326). Gram-negative and gram-positive organisms as well as fungi cause systemic sepsis and septic shock. Early recognition is crucial to patient survival because mortality rates are exceedingly high if the full clinical picture of shock and organ dysfunction develops. Septic shock is divided into an early hyperdynamic state and a late hypodynamic state.

Low SVR, splanchnic vasoconstriction, and increased cardiac output characterize the hyperdynamic phase of shock. Venous capacitance is increased and results in diminished effectiveness of the circulating blood volume. Aggressive volume resuscitation must be provided to restore cardiac preload and ventricular filling. These patients are best managed in an ICU with the placement of an arterial line, a PA catheter, and a bladder catheter. Appropriate cultures should be obtained and IV broad-spectrum antibiotics should be started within the first hour of recognition of severe sepsis. Laboratory tests of immediate concern include arterial blood gas determinations, creatinine, electrolytes, lactate, coagulation panel, and a complete blood count. Oxygenation and ventilation should be optimized with mechanical ventilation if indicated. If hypotension persists after optimization of the PCWP, the use of norepinephrine or dopamine may be necessary. Surgical debridement or manipulation of infected material should not be performed until the patient has been stabilized.

Early goal-directed therapy of the septic patient has been shown to improve survival. During the first 6 hours of resuscitation, the goals of therapy as outlined by the Surviving Sepsis Campaign guidelines include CVP of 8 to 12 mm Hg,

MAP ≥65 mm Hg, urine output ≥0.5 mL/kg/hour, and central venous or mixed venous oxygen saturation ≥70%. If during the first 6 hours oxygen saturation goals are not achieved despite appropriate CVP, then transfusion of RBCs to achieve a hematocrit >30% and/or initiation of a dobutamine infusion is the next step (327).

In the hypodynamic phase of septic shock, hypotension results from cardiac output deterioration. The patient is often cool, mottled, oliguric, diaphoretic, and confused. The etiology of the hypodynamic cardiovascular response to sepsis may be inadequate volume resuscitation, underlying cardiac disease, or myocardial dysfunction associated with sepsis. This is a state of gross decompensation with global tissue hypoxia and is associated with greater mortality.

Numerous clinical trials have attempted to find specific agents that could modulate the underlying disease process in sepsis. Candidate therapies included agents that target mediators of inflammatory response, agents that boost the immune system, and prostaglandin inhibitors, but none was shown to be beneficial. One such agent, drotrecogin alfa (activated Xigris), is a recombinant form of human activated protein C, an endogenous protein with antithrombotic, profibrinolytic, and anti-inflammatory properties that is frequently deficient in sepsis. Although initial studies (The Recombinant Human Activated Protein C Worldwide Evaluation in Severe Sepsis—PROWESS) showed a clinically significant reduction in the 28-day all-cause mortality rate due to severe sepsis (328), results from a subsequent trial, the PROWESS-SHOCK trial, failed to demonstrate any significant benefit in 28-day all-cause mortality. The drug was subsequently withdrawn from the market in October 2011 (329).

In addition to early goal-directed therapy with hemodynamic interventions that balance systemic oxygen delivery with oxygen demand, other management strategies have shown in randomized, controlled trials to reduce mortality associated with severe sepsis. These include limiting the tidal volume to 6 to 7 mL/kg ideal body weight for patients requiring mechanical ventilation for ARDS, the use of moderate-dose corticosteroids (hydrocortisone 200 to 300 mg and fludrocortisone 50 µg daily) for 7 days in patients with refractory septic shock, and maintaining serum glucose levels <180 mg/dL (327). These therapies are not mutually exclusive, and optimal patient management may require a combination of approaches. Some of these strategies vary dramatically from traditional approaches and will require education and established protocols to safely incorporate them into practice.

Multiple Organ Dysfunction Syndrome

MODS is defined as the development of progressive physiologic dysfunction of two or more organ systems after an acute threat to systemic homeostasis (330). An acute threat can include SIRS, sepsis, massive trauma, burns, ischemia, or reperfusion injury. Patients usually present with pulmonary dysfunction, which typically develops early in the course of SIRS or sepsis. Renal dysfunction will present as a prerenal azotemia unless the initial insult stimulated a sudden oliguric ATN. Hyperbilirubinemia is the earliest indication of hepatic dysfunction. GI abnormalities include ileus, stress ulcers, diarrhea, and mucosal atrophy. The platelet count has been used as a surrogate marker of the hematologic system. Cardiac function is often measured by the severity of hypotension or the need for vasopressors. Deterioration of the nervous system is manifested by encephalopathy and peripheral neuropathies. The treatment of MODS is support of individual organ function and aggressive therapies aimed at correcting the underlying process. Mortality is related to the number of dysfunctional systems and is greater than 80% once four organ systems fail (331).

The Acute Physiology and Chronic Health Evaluation (APACHE) provided population-based estimates of mortality for the day of ICU admission (332). Several versions of the APACHE scoring system have been utilized, most recently APACHE IV. Organ failure scores, such as the Sequential Organ Failure Assessment (SOFA), can help assess organ dysfunction over time and are useful to evaluate morbidity. Independent of the initial value, an increase of the SOFA score during the first 48 hours of an ICU admission predicts a mortality rate of 50% or greater, and improvement of cardiovascular, renal, or respiratory SOFA score from baseline through day 1 of ICU admission is significantly related to greater survival (333). It is important to note that these and other outcome prediction models were designed as tools to be used in critical care research in order to stratify patients by severity of illness. They have not been validated for making decisions relating to individual patients.

Abdominal compartment syndrome (ACS) is an important but often unrecognized cause of acute deterioration of a patient after massive fluid resuscitation for septic or hypovolemic shock. Although ACS can impair the function of every organ system, it is generally manifested as hypotension, reduced urine output, and decreased pulmonary compliance. Most commonly associated with trauma patients, it has also been observed in patients with massive ascites, bowel obstruction or ileus, peritonitis, pancreatitis, and intraperitoneal blood. IAP is usually measured indirectly by a balloon-tipped catheter in the bladder. Intra-abdominal hypertension is defined as an IAP of 12 mm Hg or greater recorded by a minimum of three standard measurements conducted 4 to 6 hours apart (334). ACS is defined by an IAP of 20 mm Hg or greater and single or multiple organ failure that was not previously present. Operative decompression of the abdominal cavity with maintenance of an open abdomen via use of temporary closure techniques such as a vacuum pack is the only treatment that reverses the physiologic abnormalities resulting from ACS.

CHAPTER 9 Surgical Principles in Gynecologic Oncology

Yukio Sonoda, David Cibula, Denis Querleu, Eric Leblanc and Oliver Zivanovic

Treatment of gynecologic malignancies involves multimodal therapy. Surgery may be the only mode of therapy required for some early gynecologic cancers; however, the majority of gynecologic malignancies require a combination of surgery with chemotherapy and/or irradiation.

This chapter will review the principles of surgery as a separate discipline and as an integral part of multimodal therapeutic planning. Specific operations and novel surgical techniques are discussed, but many procedures are addressed more completely in surgical texts and atlases (1–3). This textbook is also accompanied by narrated videos on a wide variety of surgical procedures. The role of surgical intervention in the treatment of gynecologic cancers is addressed herein with a more philosophic approach than would be taken in a surgical atlas. Key illustrations and tips are included that have enabled us to approach various radical procedures more confidently and safely. The focus of this chapter is to provide the reader with an appreciation and understanding of the surgical principles of the subspecialty of gynecologic oncology and the incorporation of minimally invasive surgery.

TECHNICAL ASPECTS OF SURGERY

Mastering the skills of surgery involves a thorough understanding of proper technique as well as knowledge of surgical anatomy. Maintaining sound technique requires consistent practice to keep surgical maneuvers well honed. This entails a sufficient case load to ensure adequate practice of the techniques while minimizing associated complications. The surgeon should also keep abreast of new technical developments and be able to modify his or her technique to incorporate these developments. A prime example has been the rapid growth of minimally invasive surgery and now robotics in gynecologic oncology.

Anatomy

Knowledge of anatomy is the basis for mastering surgery. Although gynecologic malignancies originate in the pelvis, the gynecologic oncologist must be completely familiar with the pelvis, abdomen, retroperitoneum, and the lymphatic drainage of the female genital tract because gynecologic cancers can affect all of these areas.

Lymphatic drainage from the cervix follows the uterine arteries and cardinal ligaments to the pelvic lymph nodes that include the external iliac, internal iliac (hypogastric), and obturator node groups (**Fig. 9.1**). From these pelvic lymph nodes, the drainage proceeds superiorly through the common iliac and presacral lymph nodes and then up to the para-aortic nodes.

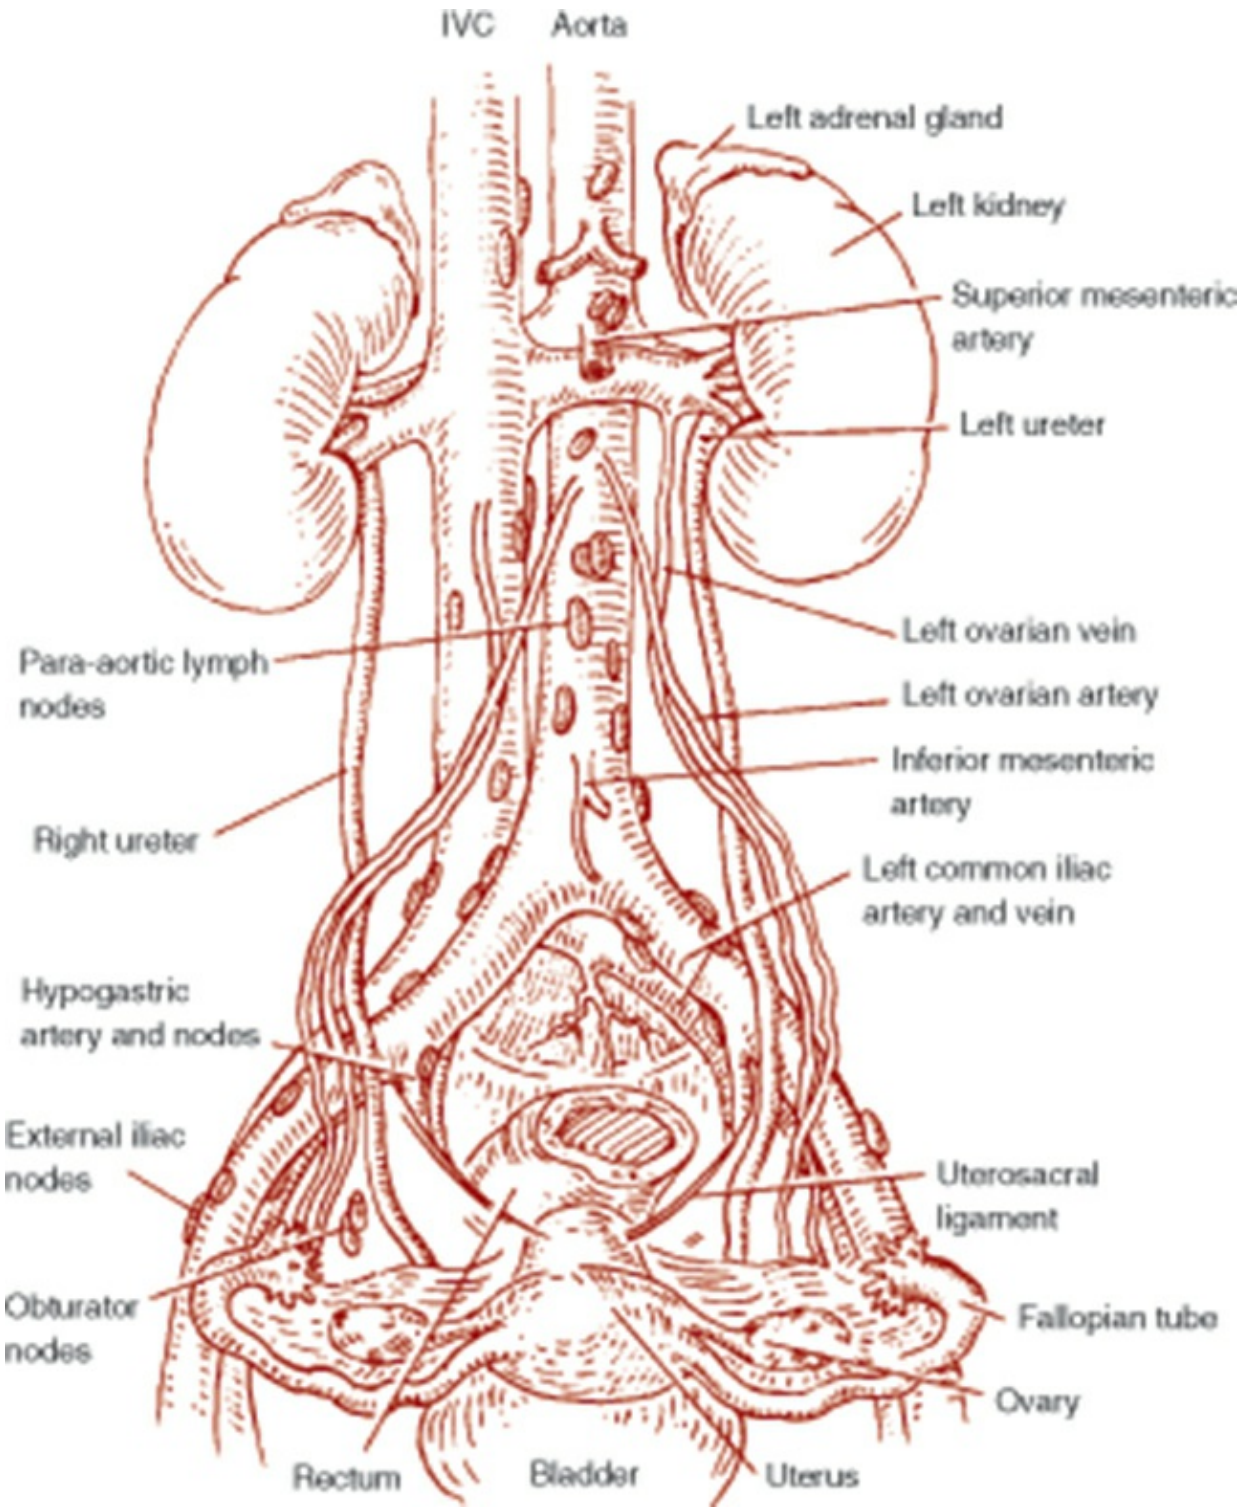

Figure 9.1 The pelvic and para-aortic lymph nodes and their relationship to the major retroperitoneal vessels.

The lymphatic drainage from both the uterine corpus and the ovaries follows one of three routes (**Fig. 9.1**): (a) along the uterine arteries in the broad ligaments to the pelvic nodes, (b) in channels following the round ligaments to the inguinal lymph nodes, or (c) along the ovarian lymphatics in the infundibulopelvic ligaments directly up to the para-aortic nodes.

The anatomy of the para-aortic lymph nodes has been well described by Fowler and Johnson (4). The para-aortic lymph nodes are part of the lumbar lymph node group. Usually, six subgroups of retroperitoneal nodes in the para-aortic region are recognized: paracaval, retrocaval, interaorto-caval, preaortic, para-aortic (left side), and retroaortic. The

preaortic group drains the abdominal part of the gastrointestinal tract down to the mid rectum, whereas the retrocaval and retroaortic groups have no special area of drainage. The paracaval, interaorto-caval, and para-aortic (left side) receive lymphatic drainage from the iliac lymph nodes, ovaries, and other pelvic viscera (apart from the alimentary tract), and therefore it is these groups of nodes that are sampled in the surgical staging of gynecologic malignancies. However, systematic para-aortic lymphadenectomy should address all major regions, including paracaval, retrocaval, interaorto-caval, preaortic, para-aortic and retroaortic nodes.

There are typically 15 to 20 paracaval and para-aortic nodes per side. They are located adjacent to the inferior vena cava (IVC) and aorta, anterior to the lumbar spine, extending bilaterally to the medial margins of the psoas major muscles, and up to the diaphragmatic crura (4). The paracaval and para-aortic nodes usually dissected in gynecologic oncology span the region from the aortic bifurcation up to either the inferior mesenteric artery (IMA) or the renal veins.

The first major blood vessel encountered during a caudad-to-cephalad para-aortic node dissection is the IMA (**Fig. 9.1**). The IMA originates from the anterior surface of the aorta approximately 3 to 4 cm above the aortic bifurcation. Next, the right and left ovarian arteries arise from their respective sides of the aorta about 5 to 6 cm above the bifurcation (**Fig. 9.1**). The right ovarian vein inserts into the right side of the IVC approximately 1 cm below the right renal vein. The left ovarian vein does not insert directly into the IVC, but rather follows a path close to the left ureter inserting into the left renal vein lateral to the left border of the aorta. Three to four pairs of lumbar arteries and veins arise from the posterior surfaces of the aorta and IVC, respectively.

The gynecologic oncologist who operates on patients with advanced ovarian carcinoma often encounters disease spread involving upper abdominal structures such as the diaphragm, liver, pancreas, and spleen. Debulking of tumor from these areas has been demonstrated to improve the rate of optimal cytoreduction and subsequent survival (5,6). Anatomic considerations for diaphragm surgery include the relevant hepatic attachments and the underlying central vasculature (7,8) (**Fig. 9.2**). The anterior hepatic attachment is the falciform ligament, which contains the ligamentum teres in its infrahepatic portion, and attaches the liver to the anterior abdominal wall in its membranous hepatic portion. As the falciform ligament continues superiorly, its peritoneal surface divides laterally on each side to form the anterior right and left coronary ligaments. These coronary ligaments reflect off the liver capsule and delineate the posterior extent of peritoneum covering the superior diaphragm. The IVC lies to the right side of this falciform ligament division. The right and left hepatic veins drain into the anterior surface of the IVC at the level of this peritoneal reflection. The anterior coronary ligaments continue laterally and inferiorly along the posterior liver edge, where they join the posterior right and left coronary ligaments to form the right and left triangular ligaments, respectively. The right triangular ligament reflects from the liver to the diaphragm, right kidney, and right adrenal gland. The left triangular ligament reflects primarily to the diaphragm; the posterior left coronary ligament lies higher than the esophageal hiatus and the esophagus is generally not encountered. The coronary ligaments on each side delineate the larger “bare area” of the liver on the right and a smaller “bare area” on the left, which underlie the central tendon of the diaphragm. The right phrenic nerve penetrates this central tendon lateral to the vena caval foramen on the right and is usually not encountered until the “bare area” is exposed. The left phrenic nerve may penetrate the left diaphragm muscle above the central tendon and is a consideration during left-sided anterior diaphragm surgery.

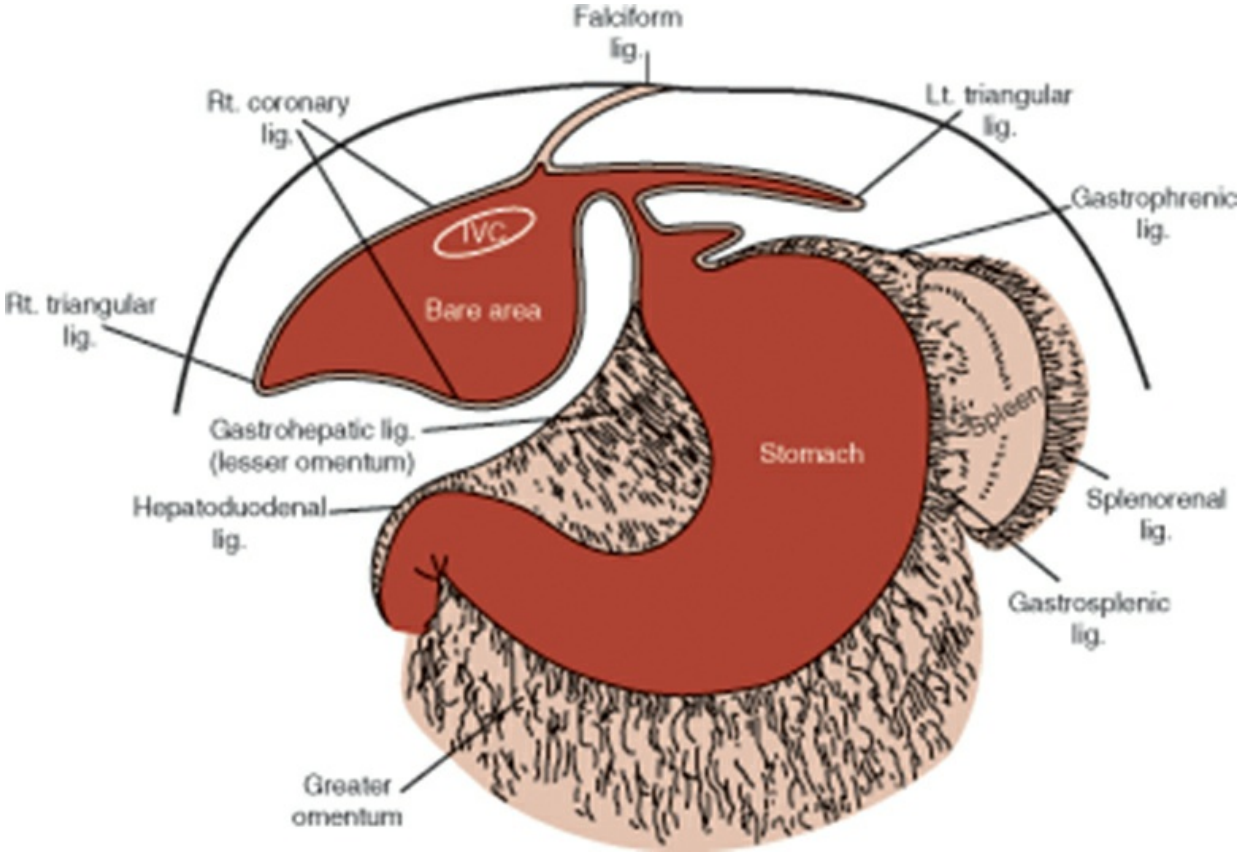

Figure 9.2 Peritoneal reflections of the liver: the lesser omentum (hepatogastric and hepatoduodenal ligaments) and its relation to the coronary ligament of the liver and diaphragm.

In the left upper quadrant of the abdomen, the spleen lies under the 9th, 10th, and 11th ribs. It is situated adjacent and slightly deep to the stomach and colon, lateral to the pancreas, and sits on the superior aspect of the left kidney. The posterior aspect of the spleen is in contact with the adrenal gland as well as Gerota fascia of the kidney. The tail of the pancreas often approaches the splenic hilum and sometimes contacts the spleen. The spleen varies in size between individuals, but in general measures 12 cm in length, 7 cm in width, and 3 to 4 cm in width. The peritoneum creates folds that form the suspensory ligaments of the spleen. The four main “suspensory” ligaments are gastrosplenic, splenorenal, splenophrenic, and splenocolic ligaments. The splenophrenic and splenocolic ligaments are avascular. The gastrosplenic ligament contains the short gastric vessels. The splenorenal ligament has an anterior and posterior aspect and surrounds the splenic hilum. The splenic hilum contains the splenic artery, splenic vein, and sometimes the tail of the pancreas. The splenic vessels sometimes branch before entering the spleen. The splenic artery is tortuous and is one of the three branches of the celiac trunk. It runs along the superior aspect of the pancreas and gives rise to the short gastric arteries prior to entering the spleen, which course in the gastrosplenic ligament and supply the portion of the greater curvature of the stomach superior to the splenic artery (**Fig. 9.3**) (9). The splenic artery also gives rise to the left gastroepiploic artery, which supplies the remainder of the greater curvature of the stomach and the gastrocolic omentum. The splenic vein is slightly inferior and follows the course and branching of the artery.

Patient Positioning

The success of surgical procedure begins with patient positioning. This is often critical in improving exposure, particularly in obese patients. For most women undergoing radical hysterectomy, ovarian cancer cytoreduction, or pelvic exenterative procedures, we prefer the low lithotomy position using stirrups (**Fig. 9.4**) (1). The buttocks should protrude slightly over the end of the table, which allows access to the perineum. When positioning patients in stirrups, the weight of the leg should be on the foot with the legs well-padded and attention paid to prevent pressure on the calf and the peroneal nerve. A gel pad can be placed under the buttocks to further improve exposure to a deep pelvis.

Figure 9.4 Low lithotomy position using Allen stirrups.

Abdominal Incisions

Abdominal incisions should vary based on the indication for the procedure, associated preoperative conditions (such as the presence of ascites or bowel obstruction), suspicion of upper abdominal pathology, and the presence of a previous abdominal scar. Incisions for surgery for gynecologic oncology patients should be highly individualized. Three basic incisions are used for intraperitoneal exposure (**Fig. 9.5**) (2). Additionally, extraperitoneal access to the pelvic and para-aortic nodes can be achieved through a J-shaped incision (10) or a “sunrise” incision (11).

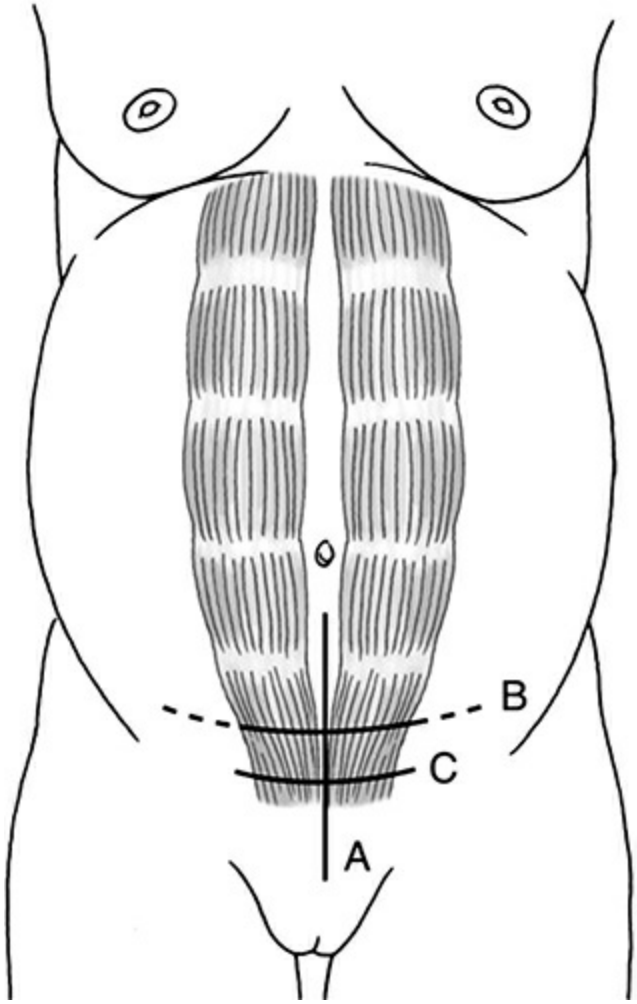

Figure 9.5 Entry into the abdominal cavity can be made by three basic incisions: (A) the midline incision; (B) the Maylard incision is made from anterior-superior iliac spine to anterior-superior iliac spine[1];[2] and (C) the Pfannenstiel incision. The latter is not an incision for radical pelvic surgery, but it can be converted to a Cherney-type incision for improved exposure. For the patient who has some type of transverse incision, and for whom later exposure of the upper abdominal cavity is necessary, a midline upper abdominal incision can be separately used.
Source: Reprinted with permission from Fischer JE, Jones DB, Pomposelli FB et al. Fischer's Mastery of Surgery 6th ed. Philadelphia, PA: Wolters Kluwer; 2011.

Transverse incisions offer the advantages of being the best cosmetic incisions for pelvic surgery while also being the least painful, resulting in less interference with postoperative pulmonary function. In addition, compared to vertical incisions, transverse incisions are allegedly stronger and allow better exposure to the pelvic sidewalls. Many gynecologic oncologists use transverse incisions when performing a radical hysterectomy or pelvic exenteration.

In performing the Maylard incision, it is recommended that the deep inferior epigastric vessels be isolated, sectioned, and ligated prior to dividing the rectus muscle (**Fig. 9.6**) (2). Occasionally, the pelvic surgeon will make a Pfannenstiel incision and find it inadequate. When more exposure is needed, the appropriate maneuver is to convert the Pfannenstiel to a Cherney-type incision. This conversion can be accomplished by dissecting the rectus muscles from the pyramidalis muscles and the anterior rectus sheath and then transecting the rectus tendons at their insertion into the pubic bone.

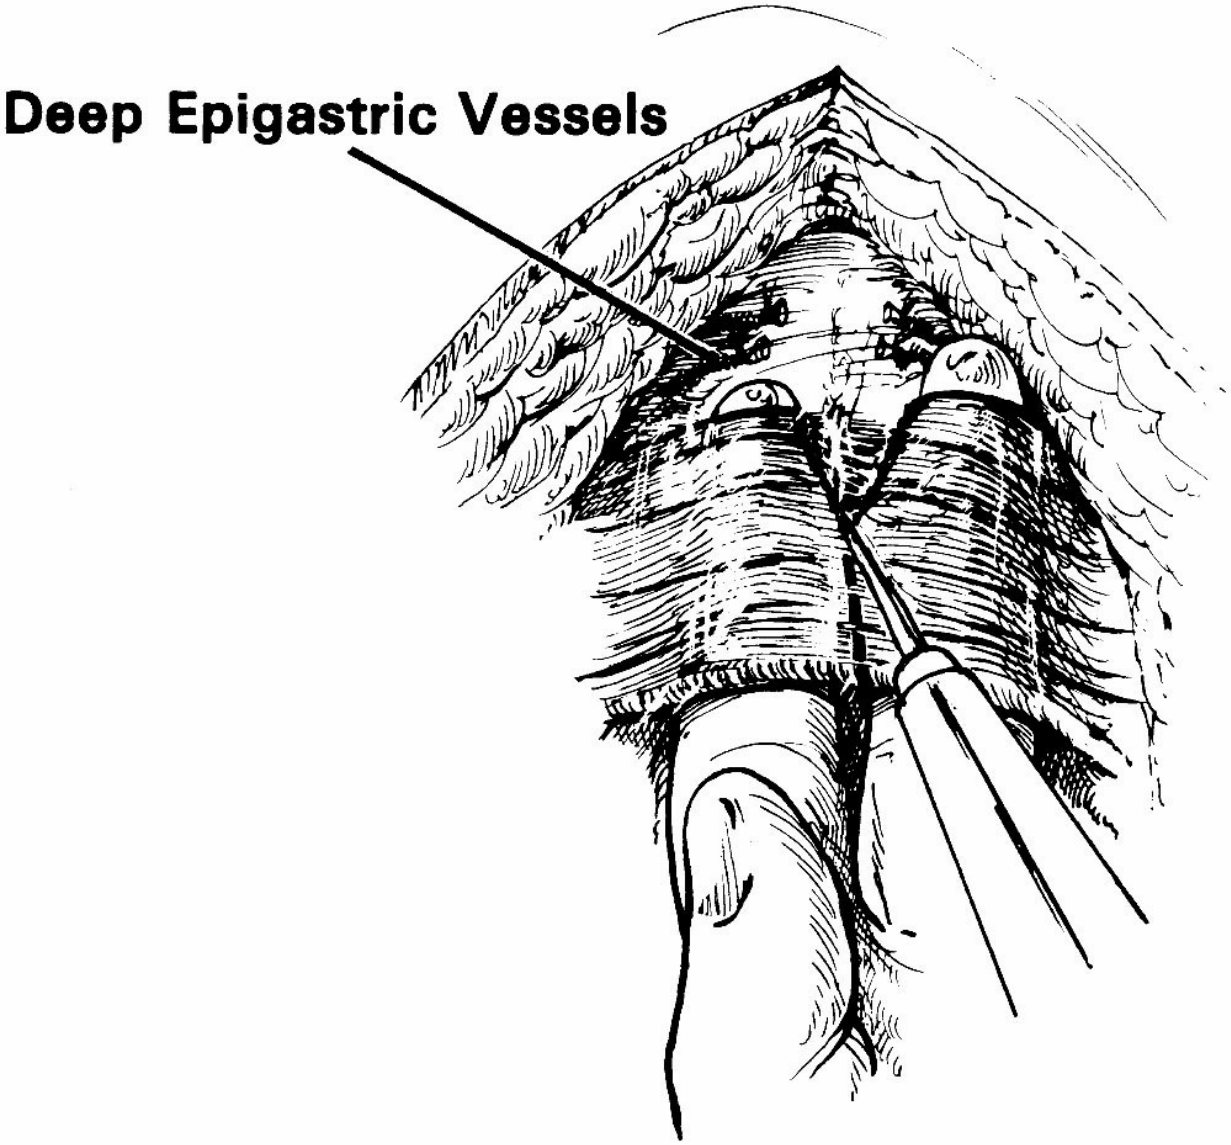

Figure 9.6 The Maylard incision. A transverse incision has been made from the anterior-superior iliac spine to the opposite anterior-superior iliac spine. The fascia has been incised transversely. The deep inferior epigastric vessels are located on the lateral and posterior borders of the rectus muscle. They are bluntly dissected from this position by the finger of the operator, isolated, clamped, sectioned, and tied. Only afterwards they are tied, should the rectus muscle be incised. This can be done with the Bovie.

Laparoscopic Entry

Laparoscopic surgery requires CO_2 insufflation to create a pneumoperitoneum and placement of trocars. Various techniques of performing this have been described. A Veress needle through the umbilicus—a place where the layers of the abdominal wall are fused—or left upper quadrant followed by blind trocar insertion through the umbilicus is one technique. However, this mode of blind entry raised concerns of bowel and vascular complications, which ultimately can be lethal. This is of particular concern because the majority of complications following laparoscopic surgery are related to trocar insertion.

To avoid a blind entry, the "open" technique in which the fascia and the peritoneum are surgically opened and the

trocar inserted under direct visualization can be used, and is considered by many to be the safest access technique. A large literature review comparing data between 12,444 open laparoscopic and 489,335 closed laparoscopic cases revealed that rates of visceral and vascular injury were 0.083% and 0.075%, respectively, after closed laparoscopy, and 0.048% and 0.0%, respectively, after open laparoscopy ($p = 0.002$). Mortality rates were 0.003% for the closed and 0.0% for the open laparoscopy technique (12). However, a recent Cochran review of over 7,000 patients failed to reveal a difference in visceral or vascular injury between methods of entry. The open technique was associated with a reduction in failed entry rate when compared to the closed technique (13).

Once the pneumoperitoneum is established and the endoscope is placed, the ancillary trocars are placed under direct vision. Most gynecologic oncology procedures can be performed using a diamond trocar arrangement with one 10-mm suprapubic trocar, two 5-mm lateral trocars located just medial and superior to the iliac crest, and the umbilical trocar (14). Trocar positioning is of extreme importance because it must allow access to the entire abdomen, from the pelvis to the diaphragm. Traditional "straight stick" laparoscopy relies on the principle of triangulation. Selected trocar placement must provide an adequate angulation between instruments to perform the intended operation and positioning may be adapted to each specific situation.

Lymph Node Dissection

Dissection of the pelvic and para-aortic lymph nodes generally involves either a transperitoneal or extraperitoneal approach. The approach selected is dictated by the primary site of disease and the planned accompanying procedure. When a hysterectomy and/or surgical debulking is required, the approach is invariably transperitoneal. In certain situations such as the pretreatment surgical staging of patients with advanced-stage cervical cancer, the extraperitoneal approach is favored because the transperitoneal approach has been associated with significant radiation-induced intestinal morbidity due to postoperative adhesion formation (15).

Pelvic Lymph Node Dissection

Whether a transperitoneal or extraperitoneal approach is used, the pelvic lymphatic basin can be divided into five specific anatomical regions. Most surgeons initially remove pelvic nodes from the *external iliac region*. Lymphatic-fatty tissue is removed cranially, laterally, and medially from both external iliac vessels and between them. The medial border is formed by the paravesical space. The lateral border is the psoas muscle, the ventral is commonly indicated as the origin of the deep circumflex iliac vein, and the cranial border is the level of the common iliac artery bifurcation, where the lymphatic trunk continues as the superficial common iliac region (**Fig. 9.7**) (2). The genitofemoral nerve courses laterally to the external iliac artery and should be identified and preserved prior to excising the lymphatic tissue. It usually forms two branches, one running on the surface of the psoas muscle, while the second runs through the lymphatic tissue on the external iliac vessels, where it can be easily cut or injured.

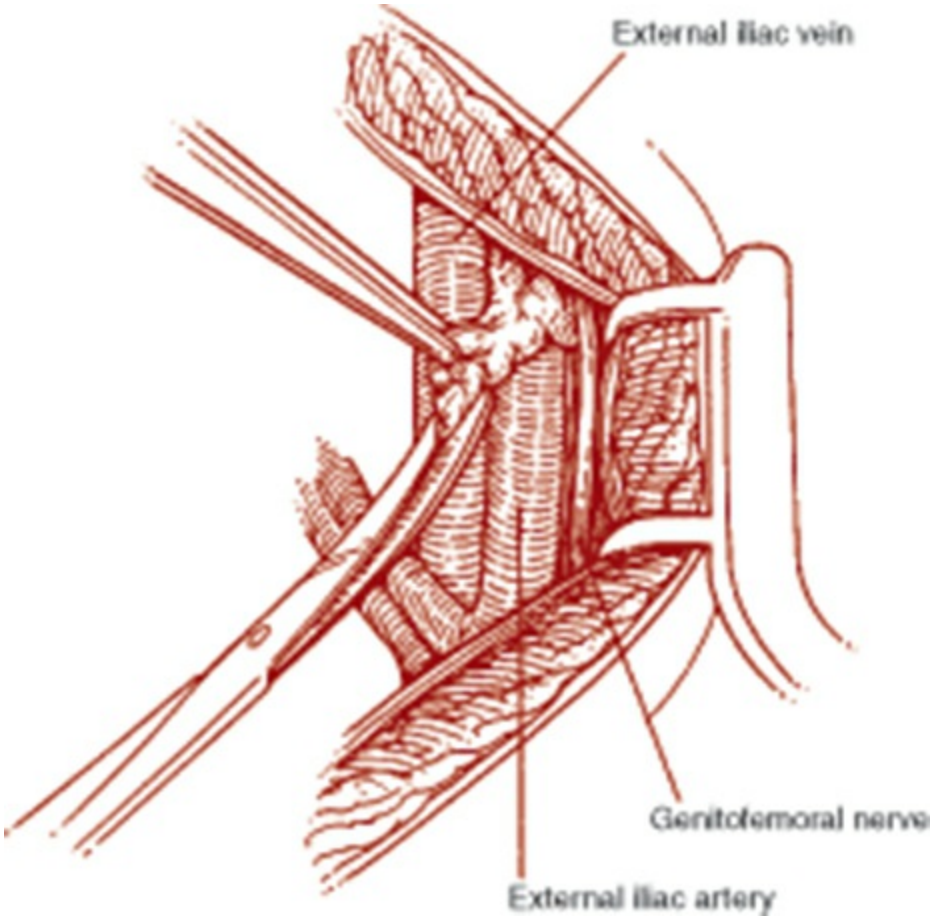

Figure 9.7 Starting at the bifurcation of the common iliac vessels, the loose areolar tissue over the vein is excised from cephalad to caudad. Clips should be used at the bifurcation of the common iliac to avoid troublesome bleeding.
Source: Reprinted with permission from Gallup DG, Talledo OE. Surgical Atlas of Gynecologic Oncology.. Philadelphia, PA: WB Saunders Co.; 1994:57.

Mobilization and retraction of the external iliac vessels allows access to the *obturator region*. The cranial border is formed by the common iliac vessels bifurcation, where the lymphatic trunk continues cranially as the deep common iliac region. The medial anatomical border is the paravesical space and the ventral border is formed by the pubic bone together with levator ani and obturator muscles, where the obturator nerve leaves the pelvis through the obturator canal. The lateral border is formed by the obturator internal muscle, and the caudal anatomical landmarks are the obturator vessels. The obturator nodes are most easily teased away from the nerve and vessels if one begins the dissection caudally (**Fig. 9.8**) (2). Usually the last dissected area is the *internal iliac region*, where the tissue is removed medially from the internal iliac vein.

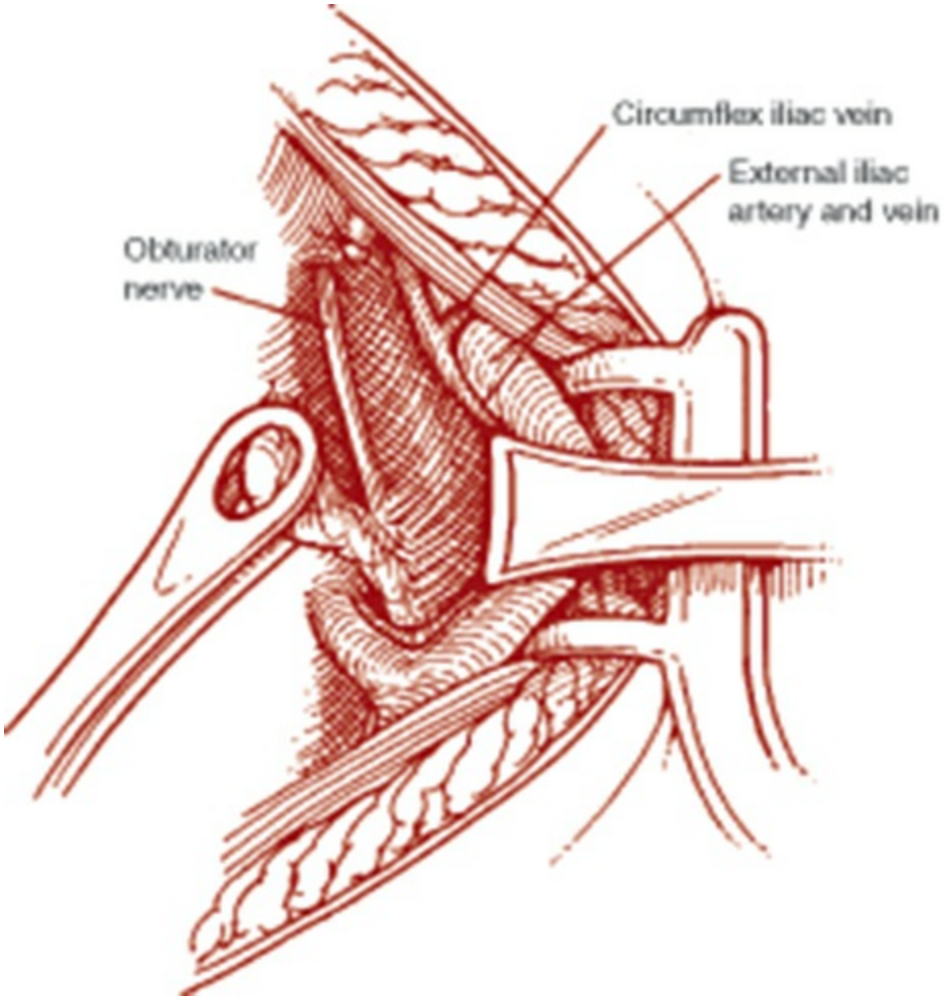

Figure 9.8 A vein retractor is used to retract the external iliac veins anterior and lateral to expose the obturator space. Lymphatic tissue is gently teased from the psoas muscle. The entire lymphatic bundle is clamped, sectioned at its caudal end, and ligated at the pelvic sidewall. With the use of the Singley forceps, the lymphatic bundle is bluntly dissected from the obturator nerve and mobilized superiorly. Often, the obturator vein and artery must be sacrificed to obtain access to tissue posterior and lateral to the nerve. Once the tissue is mobilized superiorly, all areolar tissue is cleaned off the hypogastric vessels to the level of the bifurcation of the common iliac artery. The large tissue bundle is clamped and removed en bloc. A tie or clips may be used at the level of the bifurcation.
Source: Reprinted with permission from Gallup DG, Talledo OE. Surgical Atlas of Gynecologic Oncology.. Philadelphia, PA: WB Saunders Co.; 1994:58.

The dissection continues cranially to the *common iliac region*. Tissue is removed ventrally and laterally from both common iliac vessels. The lymphatic tissue can be anatomically divided into two parts: the superficial one, which continues mostly from the external iliac region; and the deep one, which runs deeply between the common iliac vein and psoas muscle, continuing from the obturator region. The cranial border is the level of the aortic bifurcation. The genitofemoral nerve should be preserved as it lies on the surface of the psoas muscle. Deeply below the common iliac vessels and the psoas muscle, on the sacral bone, can be identified two nerve structures—the cranial part of the lumbosacral trunk (L4 + L5) (medially) and the obturator nerve (laterally), which enters the region from under the psoas muscle.

If presacral nodes are to be removed the fatty-lymphatic tissue is removed above the sacral bone below and between both common iliac veins. The caudal border is indicated by the level of right common iliac vessels bifurcation, where it continues caudally as the internal iliac region. Major branches of inferior nerve hypogastric plexus should be preserved, as

the plexus runs medially on both sides, below ureters, inside of the mesoureter which forms a thin tissue layer between the medial pararectal fossa and large vessels. Deep within the psoas muscle in the lateral aspect are branches of the femoral nerve, generally not encountered during traditional lymphadenectomy; however, in select cases of soft tissue involvement of the psoas muscle requiring a resection, care must be taken to avoid injury to the femoral nerve.

Laparoscopic transperitoneal lymphadenectomy remains the most popular approach employed by gynecologic oncologists. The early reports of this technique came from France in the late 1980s and early 1990s (16–18). The GOG LAP 2 study was a large prospective randomized trial comparing laparoscopic to open surgical staging in patients with uterine cancer. This study demonstrated that the lymph node yield was similar between the laparoscopic and open approaches. Similar intraoperative complication rates were seen but fewer moderate-to-severe postoperative adverse events were reported with laparoscopy (19).

The anatomical landmarks for this approach are identical to the open approach mentioned above. Dissection techniques and the sequence in which the landmarks are identified may vary from surgeon to surgeon and patient to patient. Proficiency with the basic technique of dissection consists of using the laparoscopic instruments to grasp the nodes and dissection to separate the node-bearing tissue from the underlying structures. Such a technique requires skill, and identification of the correct tissue planes is imperative to minimize blood loss.

Transperitoneal Approach to the Para-aortic Nodes

The transperitoneal approach to the para-aortic lymph nodes can be accomplished by either the direct or the lateral approach. With the direct approach, the dissection begins with an incision in the peritoneum directly over the common iliac arteries and aorta. The lateral approach starts with an incision in the lateral paracolic gutters with subsequent medial reflection of the right and/or left colon. The advantage of the direct approach is that it involves less dissection at the root of the small intestine mesentery and ureter; however, it is associated with a greater degree of difficulty in exposing the high left para-aortic nodes. Surgeons should be familiar with both approaches and may need to perform the approach best suited for the specific situation.

With the direct approach to the right para-aortic nodes, an incision is made in the peritoneum overlying the right common iliac artery (**Fig. 9.9**). The incision is carried up over the aorta to the level of the duodenum. If the nodal dissection is to be carried out only to the level of the IMA, it may not be necessary to mobilize the duodenum. Using blunt dissection, the ureter and ovarian vessels are identified and mobilized laterally. The lymphatic tissue lateral to the right common iliac artery is elevated and the dissection then proceeds in a caudad-to-cephalad direction. A plane is created between the IVC and the lymphatic pedicle. The majority of the right para-aortic nodes overlie the IVC and are generally easily dissected off the vessel. However, there is a fairly constant small vein within the lymphatics anterior to the IVC that inserts just above its bifurcation. If care is not taken to identify and ligate this so-called “fellow’s” vein early in the dissection, it can easily be torn, with resultant, significant bleeding (1) requiring IVC repair. When the most cephalad extent of the dissection is reached, the pedicle is secured and divided (**Fig. 9.10**).

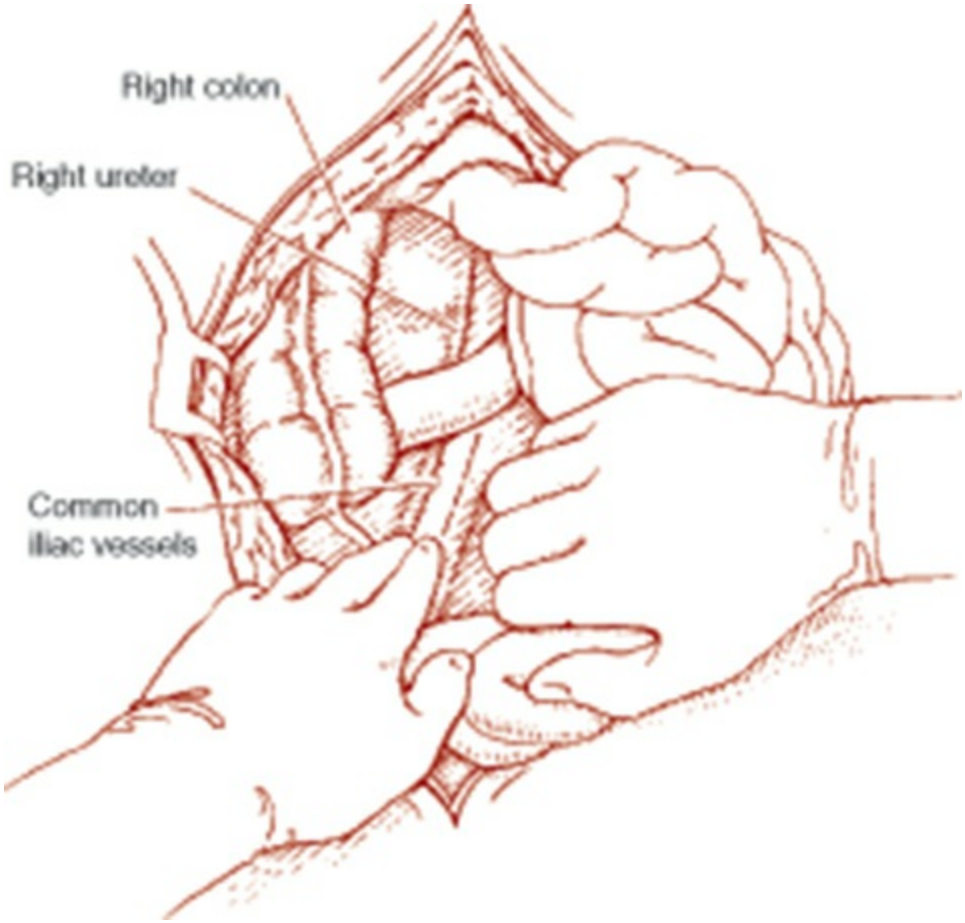

Figure 9.9 The small bowel is elevated out of the pelvis, placing the mesentery on gentle traction. The right ureter and common iliac artery are identified and the peritoneum overlying the artery is incised.

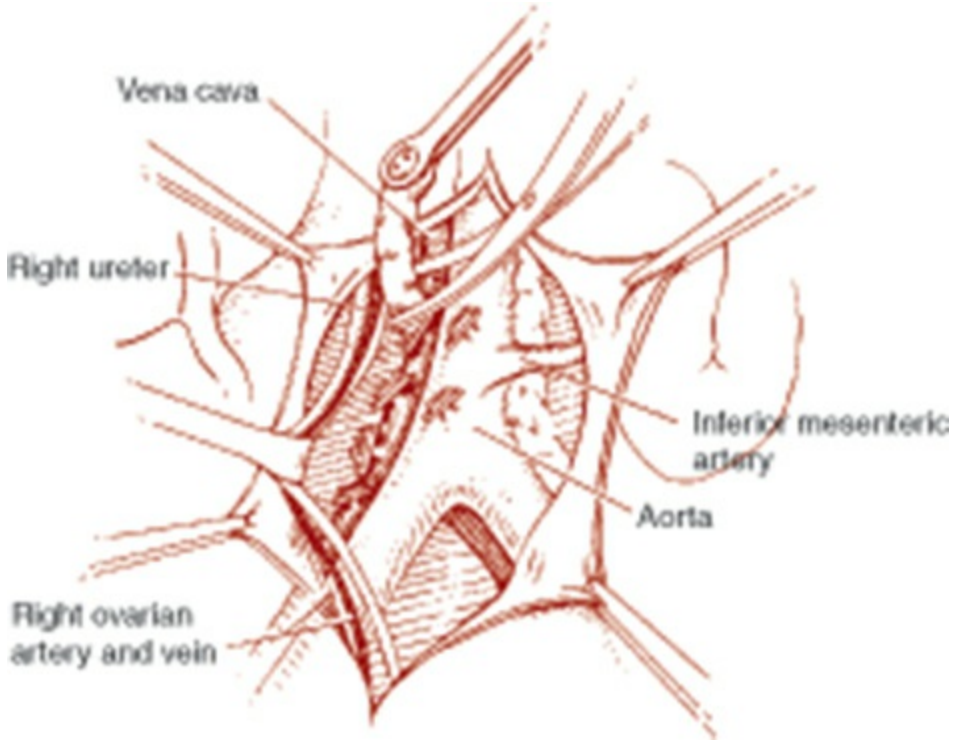

Figure 9.10 The specimen is dissected in a cephalad direction. Hemostatic clips are

used on either side of the developing pedicle as it is mobilized and divided, and also at the most cephalad extent of the dissection before the specimen is removed.

If the nodes above the IMA must be sampled, the third portion of the duodenum is mobilized by bilaterally incising the peritoneum around it and then sharply dissecting the areolar tissue underneath (4). The superior portion of the peritoneal incision can be carried up as high as the ligament of Treitz, which can also be divided if needed. Inferiorly, the peritoneal incision is extended over the right ureter around the cecum and up along the right paracolic gutter to mobilize the small bowel mesentery and part of the right colon (**Fig. 9.11**) (4). The small bowel can then be packed into the upper abdomen or completely removed from the peritoneal cavity and stabilized outside of the abdominal cavity, or put into a bowel bag outside the abdomen. The duodenum is retracted superiorly, allowing identification and ligation of the right ovarian artery and vein. The lymphatic tissue can then be safely dissected off of the right side of the aorta and the anterior surface of the IVC up to the level of the renal veins.

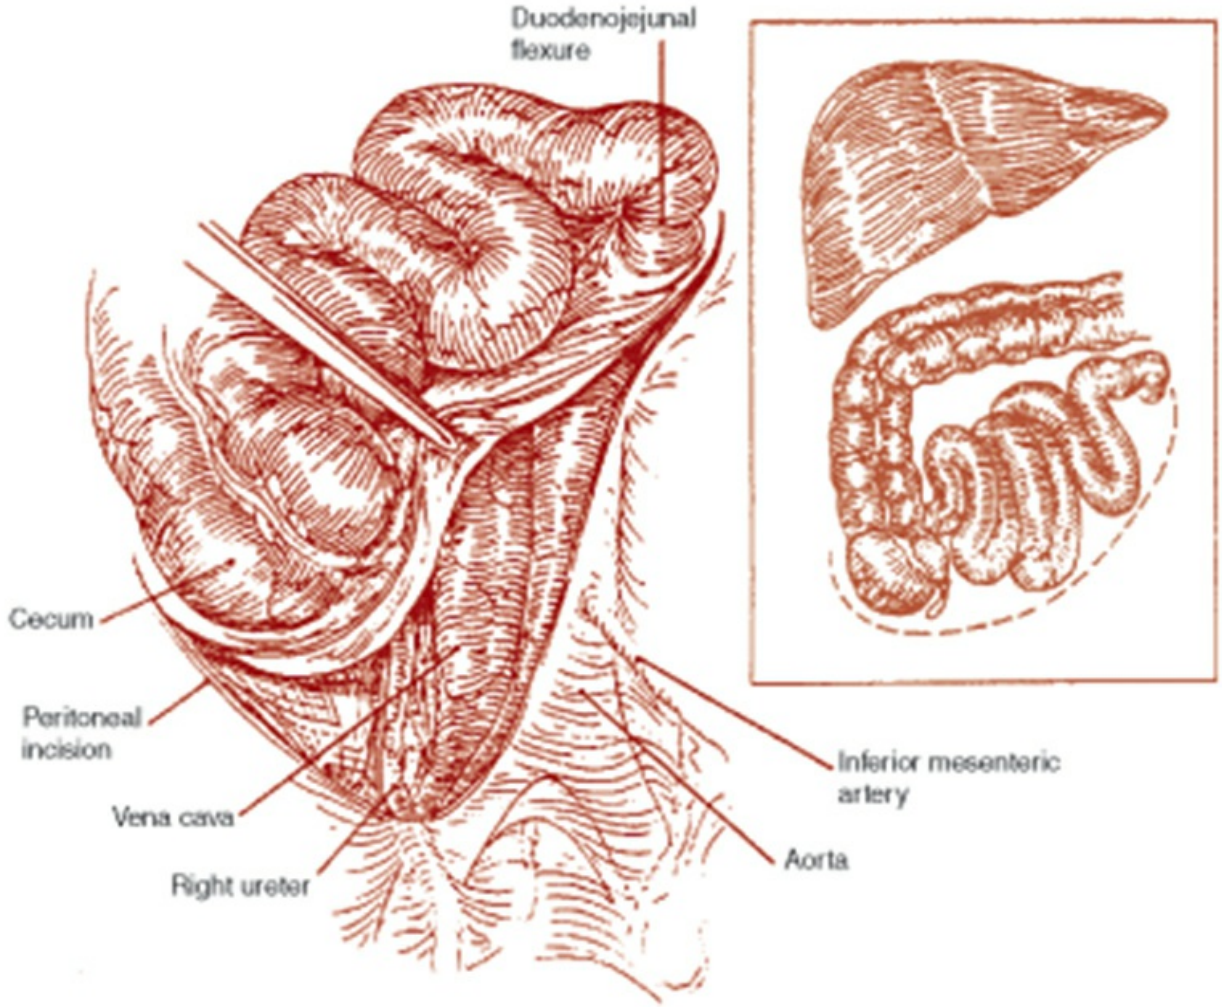

Figure 9.11 Extended peritoneal incision. The peritoneal incision is extended over the right ureter around the cecum and the cephalad along the right paracolic gutter. This allows for mobilization of the small bowel mesentery as well as the ascending colon. Source: Reprinted with permission from Fowler JM, Johnson PR. Transperitoneal para-aortic lymphadenectomy. Oper Tech Gynecol Surg. 1996;1:9.

The left para-aortic lymph nodes may be removed through the same peritoneal incision. The left common iliac artery, left side of the aorta, IMA, left ureter, and left psoas muscle are identified (**Fig. 9.12**). The ureter is mobilized laterally, and the lymphatic tissue lateral to the left common iliac artery and aorta is then removed in a caudad-to-cephalad direction. The

left para-aortic lymph nodes lie lateral and partially behind the aorta. In dissecting these nodes, troublesome bleeding from the lumbar vessels can occasionally be encountered. Safe removal of the lymph nodes above the IMA frequently requires identification and division of the left ovarian artery and vein, and occasionally ligation of the IMA.

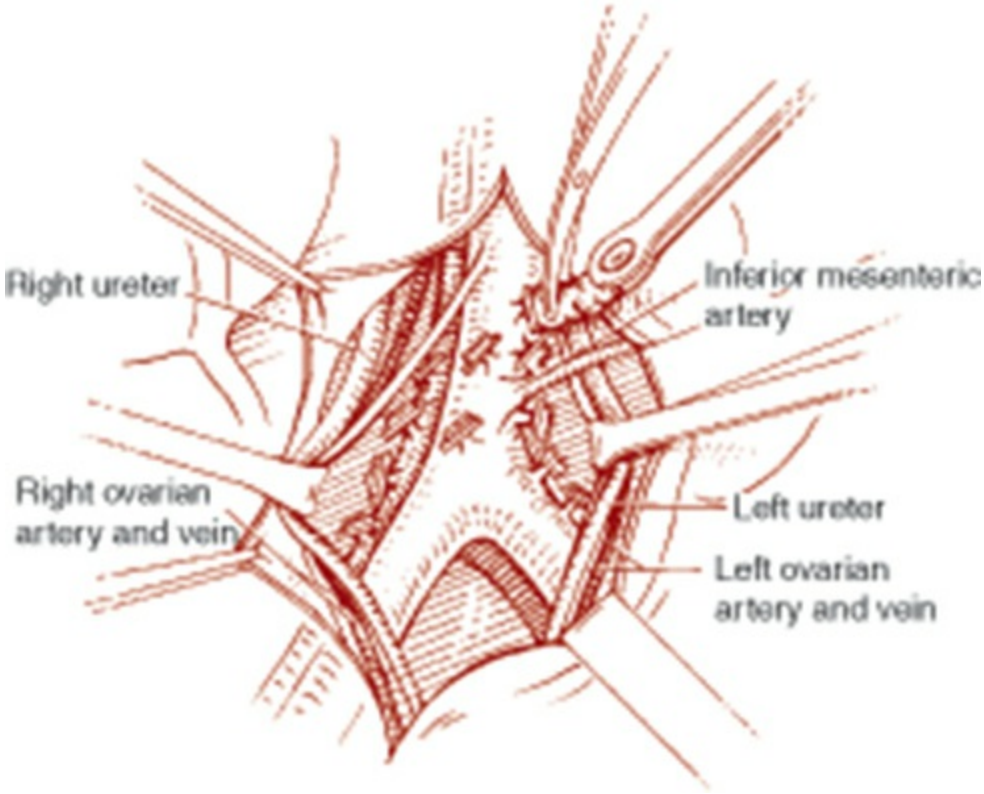

Figure 9.12 Removal of the left para-aortic nodes through the same peritoneal incision. The dissection also proceeds in a cephalad direction, again using hemostatic clips on the lateral and medial margins. Care should be taken to avoid injury to the inferior mesenteric artery that arises approximately 3 to 4 cm above the aortic bifurcation.

To remove right-sided para-aortic nodes via the lateral approach, the right paracolic gutter is incised along the line of Toldt (**Fig. 9.13**). The peritoneum is elevated off the psoas muscle and the incision is extended up to the hepatic flexure of the colon. The right colon is reflected medially. The ureter and ovarian vessels that remain are located on the undersurface of the reflected peritoneum. They may be left attached or mobilized laterally for better exposure. Mobilization of the colon medically exposes the IVC and aorta. After identifying the essential structures, the lymphatic tissue can then be dissected as previously described in a caudad-to-cephalad direction up to the third portion of the duodenum (**Fig. 9.14**).

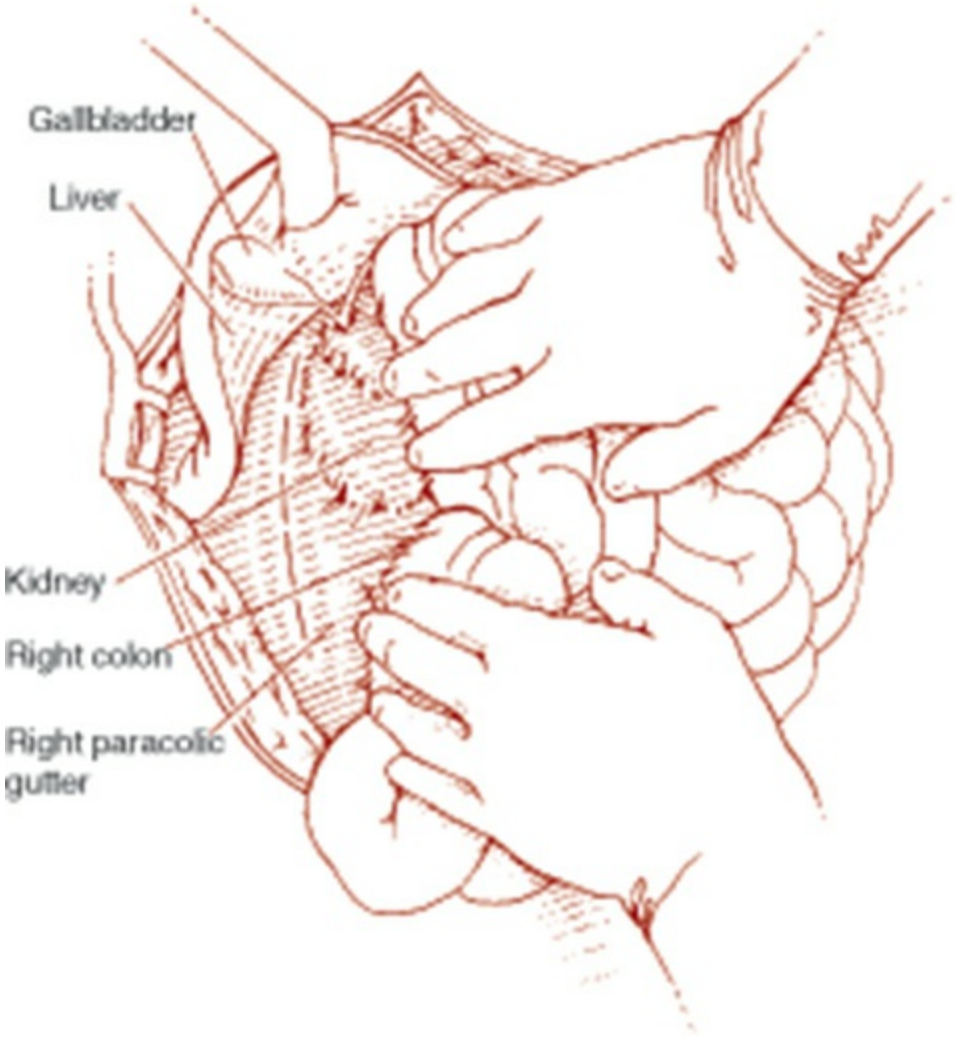

Figure 9.13 The right paracolic gutter is exposed by medial traction on the ascending colon. The gutter is incised along the line of Toldt.

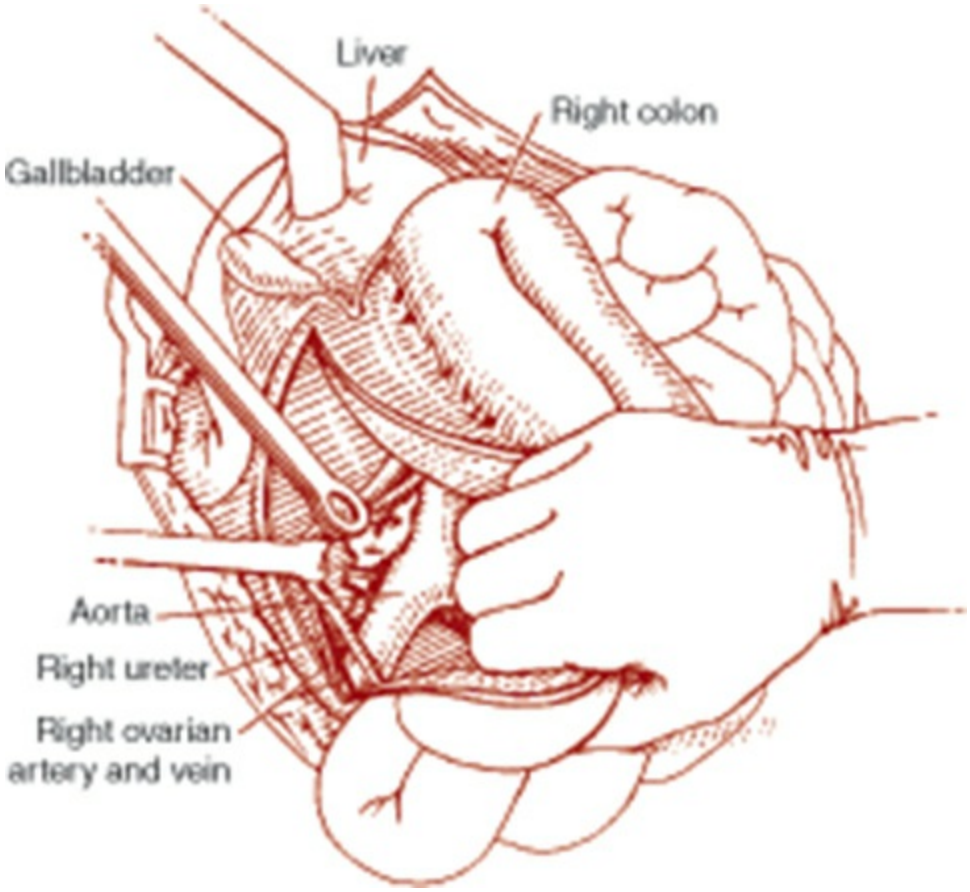

Figure 9.14 With the ureter and ovarian vessels identified, the dissection begins at the right common iliac artery and proceeds cephalad up to the third portion of the duodenum.

To remove lymph nodes above the IMA, the Kocher maneuver is used to reflect the duodenum medially. The peritoneum lateral to the convexity of the C-curve of the duodenum is incised and the second portion of the duodenum is then dissected off the IVC. For further exposure, it may be necessary to extend the peritoneal incision along the line of Toldt cephalad to mobilize completely the hepatic flexure of the colon (**Fig. 9.15**). The right ovarian artery and vein are identified and divided. The right-sided para-aortic lymph nodes can then be dissected off of the IVC and right aorta up to the level of the renal vessels.

The lateral approach to the left para-aortic lymph nodes is accomplished in a similar fashion by incising along the line of Toldt and mobilizing the left colon medially (**Fig. 9.16**). Again, the ureter and ovarian vessels are identified on the undersurface of the reflected peritoneum, and may be left attached or mobilized laterally for better exposure (**Fig. 9.17**). After further mobilization of the left colon and identification of the aorta and the IMA, the left-sided nodes are removed in a caudad-to-cephalad direction (**Fig. 9.18**). Dissection of the nodes above the IMA requires mobilization of the splenic flexure of the colon, division of the left ovarian artery and vein, and occasionally ligation of the IMA.

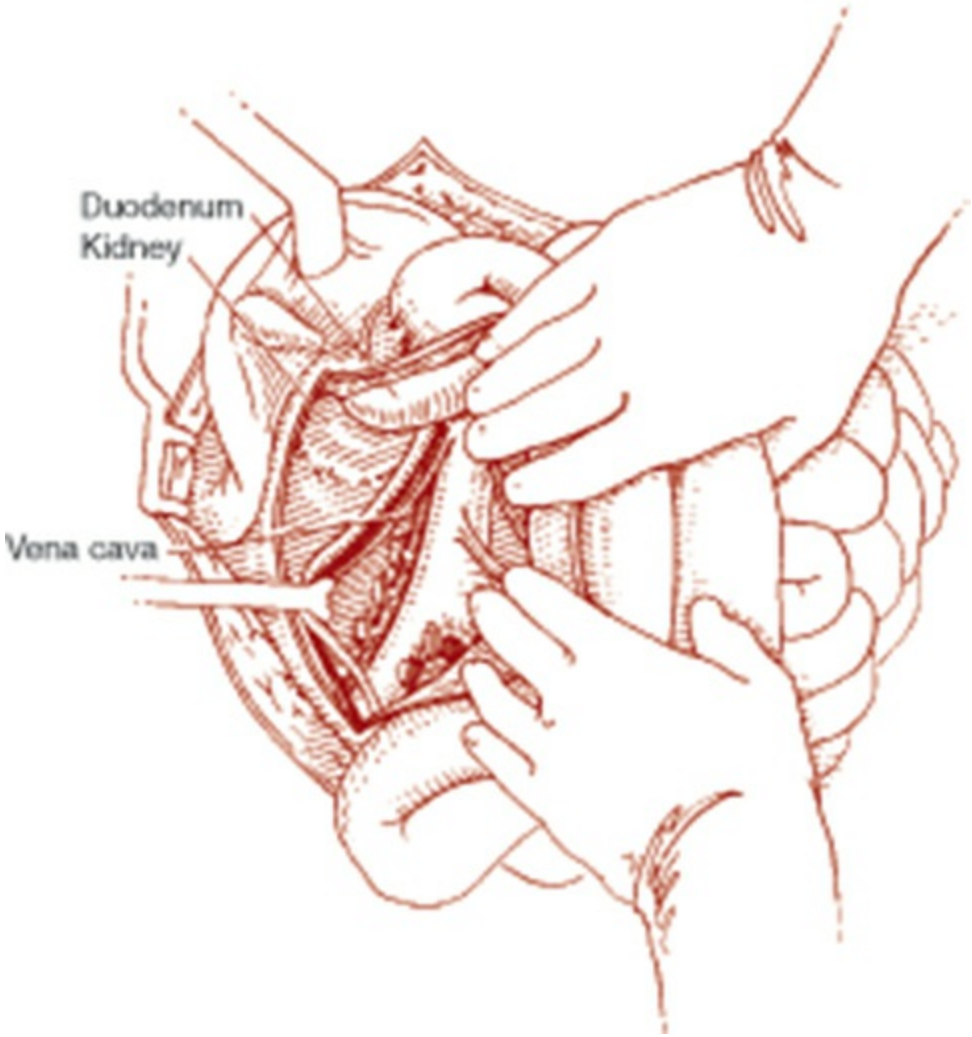

Figure 9.15 The Kocher maneuver can be used to gain access to the lymph nodes above the IMA. The peritoneum lateral to the convexity of the C-curve of the duodenum is incised and the second portion of the duodenum is then dissected off the IVC. The common bile duct and pancreatic duct enter the second portion of the duodenum posteromedially. For further exposure, the incision along the line of Toldt can be extended cephalad to completely mobilize the hepatic flexure of the colon.

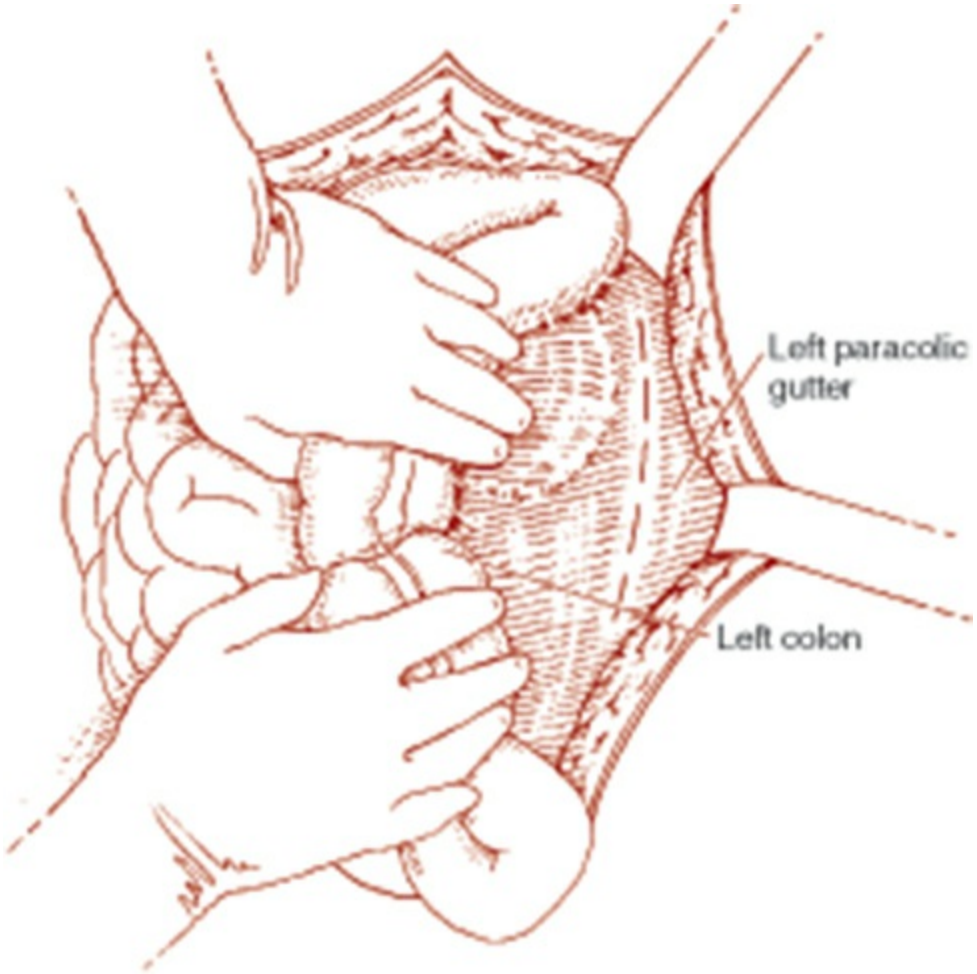

Figure 9.16 The lateral approach to the left para-aortic nodes is accomplished by retracting the descending colon medially and incising along the line of Toldt.

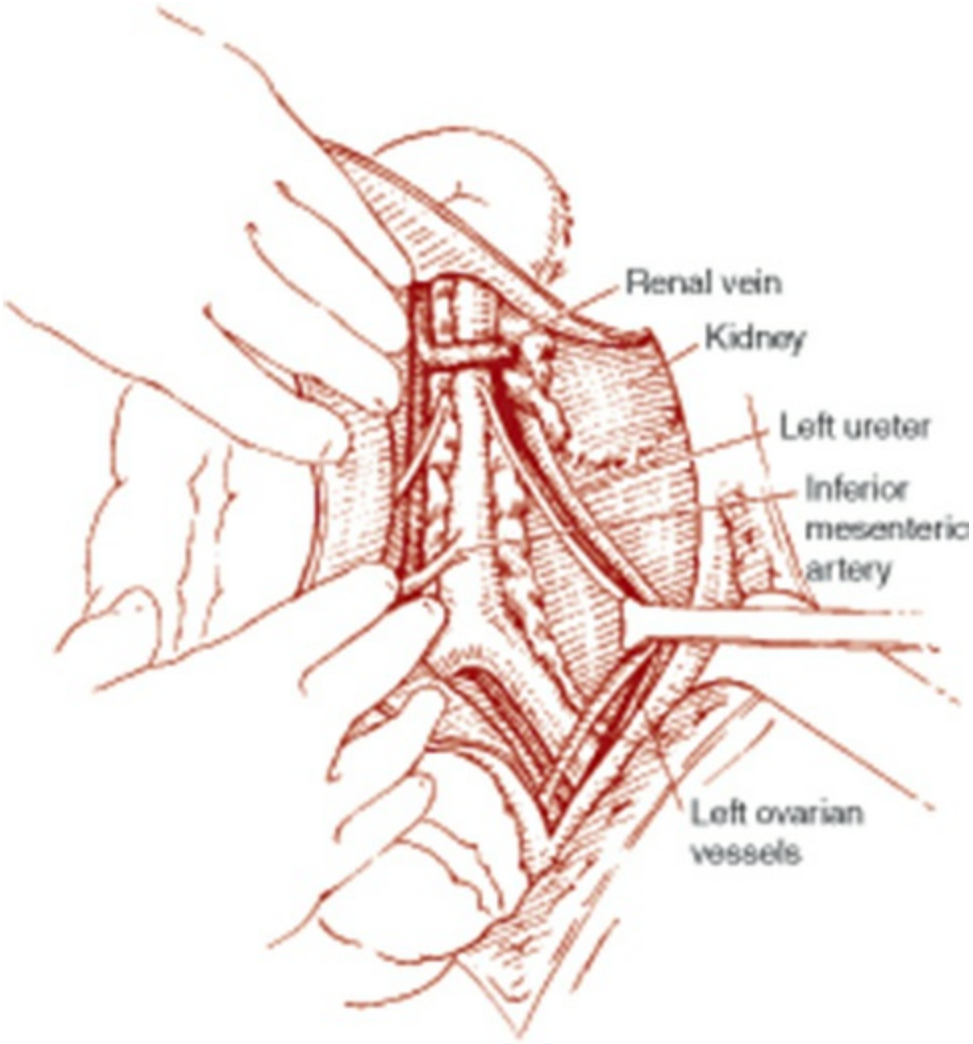

Figure 9.17 Using sharp and blunt dissection, the left colon can be mobilized medially, exposing the left ureter, ovarian vessels, and aorta.

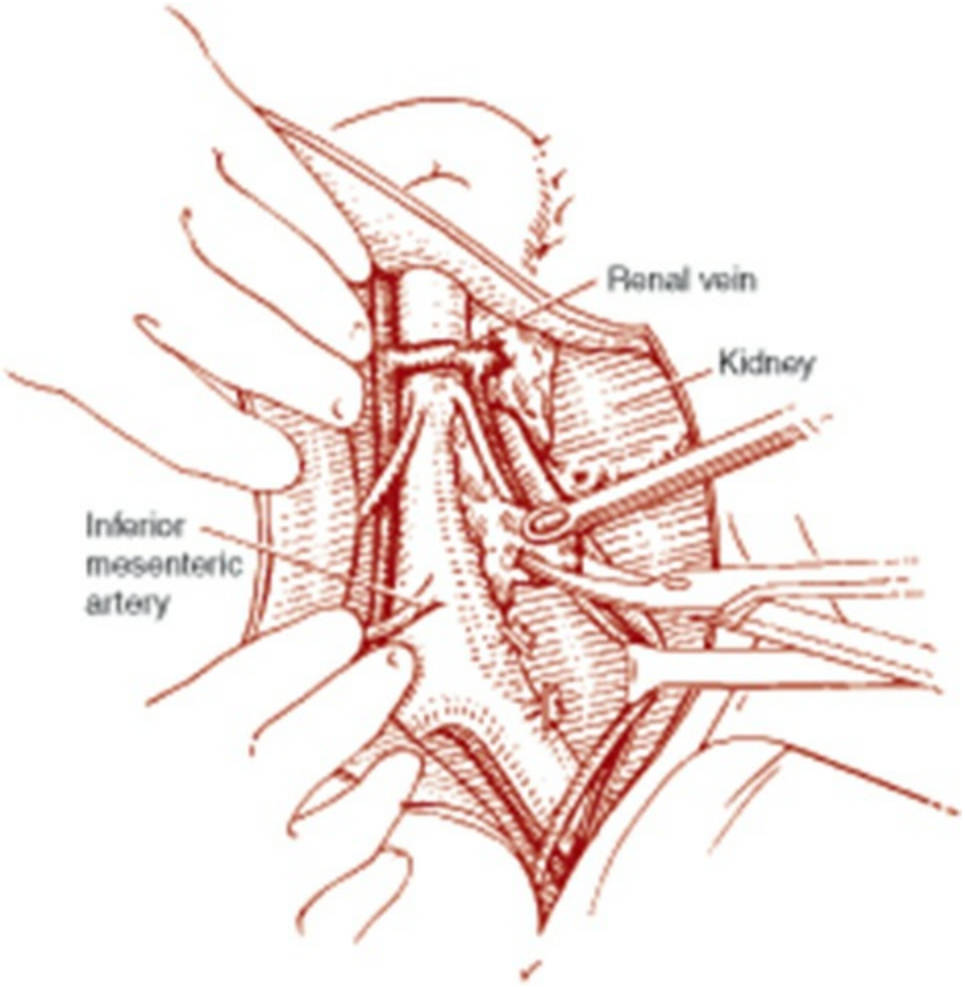

Figure 9.18 Dissection begins at the left common iliac artery and proceeds cephalad using hemostatic clips. Care should be taken to avoid injury to the inferior mesenteric artery that arises approximately 3 to 4 cm above the aortic bifurcation.

The transperitoneal approach was the first described technique for laparoscopic removal of the aortic nodes (20,21). It mimics the open surgical approach. As for every upper abdominal procedure, the bowel loops are packed along with the omentum in the left upper quadrant. The dorsal peritoneum is opened alongside the axis of the right common iliac vessels and extended along the lower aorta. The upper peritoneal flap is elevated along with the third part of the duodenum. The anatomical landmarks for the dissection should be carefully identified. The aorta and IVC are the main landmarks. On the right side of the IVC, the right ureter is identified and then retracted laterally. The right ovarian vessels are identified to their insertion into the IVC and aorta. The ventral aspect of the aorta is dissected, and the origin of the IMA is identified. The left renal vein is then identified, and this typically requires that the third part of the duodenum be elevated. Finally, the left ureter is identified and retracted laterally. The left ovarian vein is identified and traced to its insertion into the left renal vein.

High para-aortic nodes can be removed using the transperitoneal laparoscopic approach, with acceptable morbidity (22). When comparing the transperitoneal infrarenal lymphadenectomy to the inframesenteric lymphadenectomy, the extended para-aortic lymphadenectomy only took an additional 31 minutes on average and significantly increased the mean node counts from 9.0 to 19.6 (23).

Extraperitoneal Approach to the Para-aortic Nodes

The extraperitoneal approach to the para-aortic lymph nodes by means of a supraumbilical transverse sunrise incision was

initially described by Gallup et al. (11). The skin incision is made 6 cm above the umbilicus in the midline and is carried laterally and caudad to the level of the iliac crests bilaterally (**Fig. 9.19**) (2).

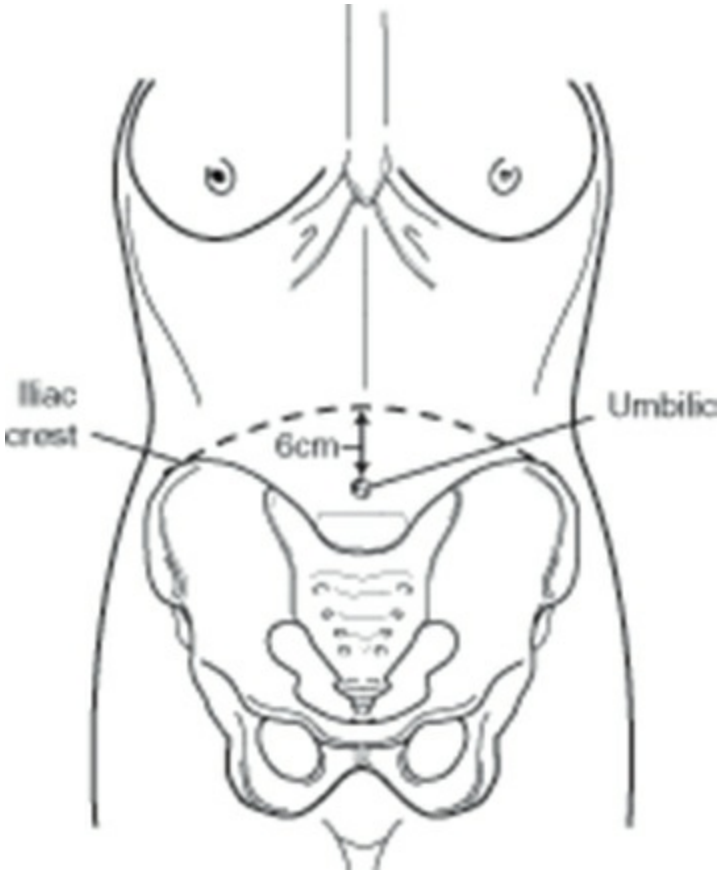

Figure 9.19 The "sunrise" incision. In the center, the incision is approximately 6 cm above the umbilicus. The incision is carried laterally in a downward fashion to the level of the iliac crests.
After Gallup DG, Talledo OE. Surgical Atlas of Gynecologic Oncology. Philadelphia, PA: WB Saunders Co.; 1994:118.

The fascia is incised transversely. The rectus muscles are dissected off the anterior-lying fascia cephalad and caudad. The right rectus muscle is transected. The right transversus muscle is then identified and transected caudally and laterally. The hand of the operator is inserted deep into the incision until the right psoas muscle and external iliac vessels are palpated. The peritoneum is then bluntly dissected from caudad and lateral to cephalad and medial, separating it from the underlying common iliac vessels until the great vessels are exposed (**Fig. 9.20**) (2). If the peritoneum is inadvertently entered, it must be closed immediately.

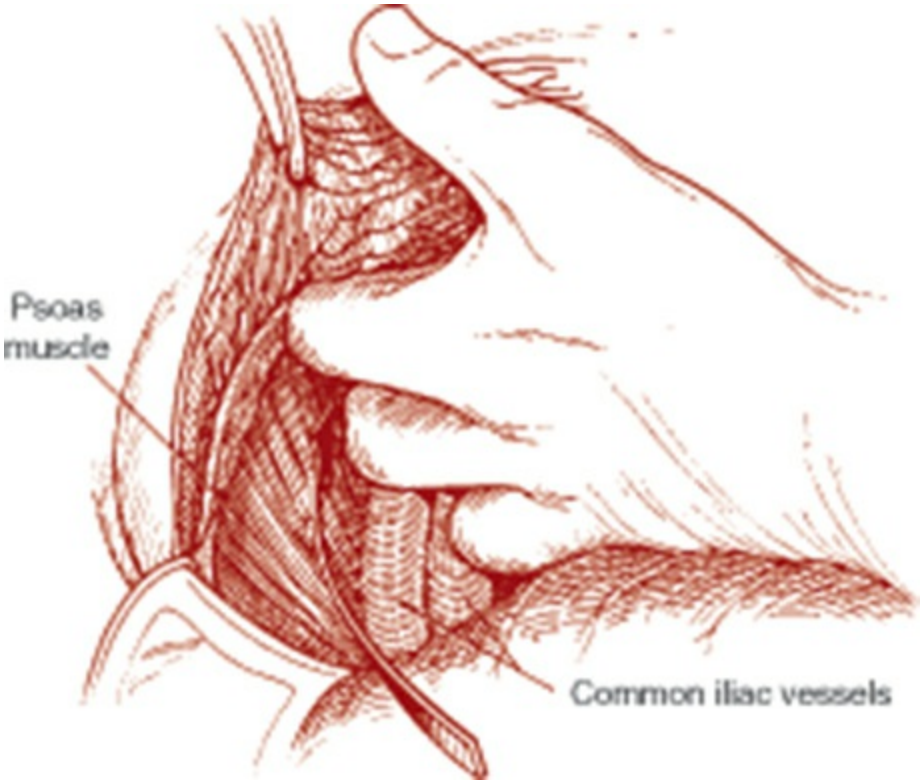

Figure 9.20 With the rectus and transversus muscles transected, the operator's hand is inserted caudad until the psoas muscle and external iliac vessels are palpated. The peritoneum is then bluntly dissected from caudad and lateral to cephalad and medial, separating it from the underlying common iliac vessels until the aorta and vena cava are exposed.
Source: Reprinted with permission from Gallup DG, Talledo OE. Surgical Atlas of Gynecologic Oncology.. Philadelphia, PA: WB Saunders Co.; 1994:121.

After identification of the right ureter and ovarian vessels, the right para-aortic nodes can be removed. In thin patients, it may be possible to remove the left para-aortic nodes through a right abdominal approach. However, if exposure is difficult, the left rectus and transversus muscles can be transected and the peritoneum mobilized medially in a similar fashion to gain access to the left para-aortic nodes.

The laparoscopic extraperitoneal aortic approach was initially described in a porcine model (24). Subsequently, additional clinical series using this approach have been described (25). The left lateral approach has several advantages over the right-sided approach during the dissection: (1) the upper part of the dissection, which is the left infrarenal area, is easier to reach; (2) the precaval and laterocaval nodes can be easily reached from the left side by compressing the IVC. The laparoscopic extraperitoneal approach to the aortic nodes is begun by using a 3-cm incision made in the left lower quadrant, medial to the iliac spine. The dissection is carried down to the preperitoneal space and, as in the open approach, care should be taken to leave the peritoneum intact. Transperitoneal laparoscopic guidance can be used to properly develop this space. Once the parietal fascia is opened, the surgeon's forefinger is introduced into the extraperitoneal space, and develops the retroperitoneal space along the psoas muscle and common iliac artery. With gentle blunt dissection, the peritoneal sac is elevated off the underlying structures. The second landmark is the iliac crest, which is followed laterally to open the lateral, then cephalic part of the space. A 10-mm incision of the anterior axillary line and then a 5-mm incision in the left upper quadrant are made to accommodate corresponding blunt trocars that are inserted under finger guidance in the extraperitoneal space. At this time, a laparoscopic balloon trocar is introduced. The trocar will accommodate the laparoscope. The extraperitoneal space is inflated while the peritoneal cavity is exsufflated, drained, and the extraperitoneal laparoscopic assessment can begin. This trocar accommodates one laparoscopic forceps, which is used to develop the extraperitoneal spaces to the level of the lower ribs. A second ancillary trocar is introduced in the infracostal area in the

midaxillary line. The initial landmarks (psoas muscle, left common iliac artery, left ureter) are identified; the initial dissection plane is found between the ureter and the common iliac artery. The space is developed by elevating the peritoneal sac along with the ureter. Access is gained to the presacral area, then to the right common iliac area. Further development is obtained in the cephalic direction by clearing the connective tissue from the psoas muscle and the lateral aspect of the left common iliac artery, then of the aorta. The IMA and then the left renal vein, generally identified by following the left ovarian vein up to the point where it ends, are identified. The nodes are then separated from the vessels and from the sympathetic chain by a combination of sharp and blunt dissection with cauterization of small vessels. Multifunction instruments are best suited for this dissection, as they prevent changing instruments and overcome the fact that only two ancillary instruments can routinely be placed in the narrow retroperitoneal space.

The typical indication for extraperitoneal aortic dissection is in the patient with locally advanced cervical carcinoma. Knowledge of the status of the aortic nodes allows tailoring of the radiation therapy fields. In these cases, common iliac nodes are generally removed along with the para-aortic nodes. The potential benefit of surgical staging of locally advanced cervical cancer is based on the lack of sensitivity of positron emission tomography (PET) in the identification of micrometastases less than 5 mm (26) and the knowledge that the group of patients with small lymph node metastases are the most likely subset of patients to benefit from surgical removal of nodes (27). In obese patients, the transperitoneal approach for para-aortic nodal dissection may be more favorable (28).

Radical Hysterectomy

Although radical hysterectomy is a traditional procedure in gynecologic oncology, with a history of almost 100 years, its performance is still poorly standardized. The term “radical” or “extended” hysterectomy encompasses a variety of different surgeries. Early series of surgeries for cervical cancer by Wertheim, Okabayashi, and Meigs attempted to describe the procedure, but this was not standardized (29–31).

Two classification systems are most frequently used in the current literature. The classical one published by Piver et al. (32) in 1974 classified radical hysterectomy into five types, but the type II and III procedures, which are the most clinically relevant, are the best described. The recent classification by Querleu and Morrow (**Table 9.1**) is also classified by five types of the procedure (A, B, C1, C2, D) and has several aspects that make the new classification system unique. The system (a) recognizes the size and type of parametrial resection as crucial and the sole parameter for classification, (b) includes the new type of nerve-sparing procedure, (c) uses stable anatomical landmarks for the description of surgical resection margins, (d) identifies surgical landmarks in three planes—frontal, sagittal, and horizontal (**Fig. 9.21**) (33,34).

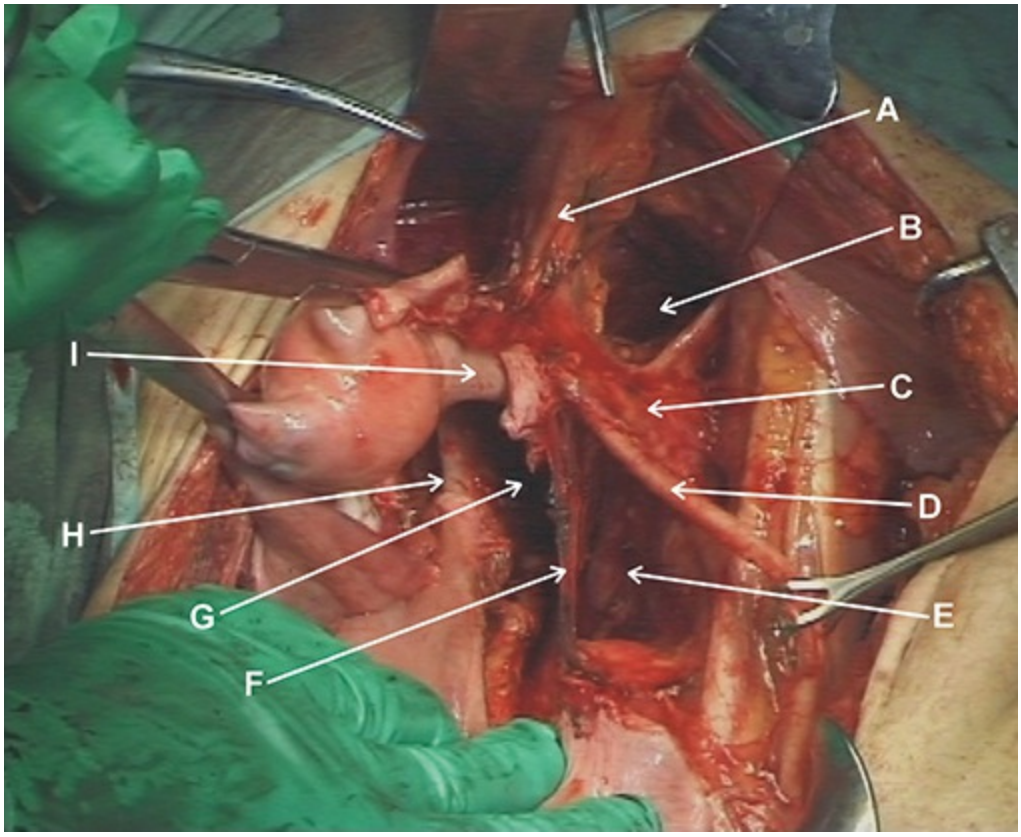

Figure 9.21 Three parts of the parametria. A—ventral parametrium; B—paravesical space; C—lateral parametrium; D—ureter; E—pararectal fossa; F—dorsal parametrium; G—sacrouterine space; H—rectum; I—cervix.

TABLE 9.1 Proposed Classification System and Corresponding Historical Types of Radical Hysterectomy

New Classification System	Corresponding Types
A	Extrafascial hysterectomy
B	Modified radical hysterectomy Type II radical hysterectomy
C1	Nerve-sparing radical hysterectomy
C2	Type III radical hysterectomy Classical/standard radical hysterectomy
D	Laterally extended parametrectomy

The type B radical hysterectomy corresponds mostly to the type II or modified radical hysterectomy. The aim of the procedure is to remove limited parts of the lateral and dorsal parametria (**Figs. 9.22–9.24**). The ureter must be identified in the parametrium, unroofed, dissected from the cervix, and displaced laterally. The resection margin is indicated by the ureteral bed. The ureteral artery, branching from the uterine artery at its crossing of the ureter, can serve as a helpful lateral landmark. Dorsally, type B aims at the resection of 1 to 2 cm of the dorsal parametria. Identification of autonomic nerves is not required, as they remains preserved in the parametria deeply below the resection margins.

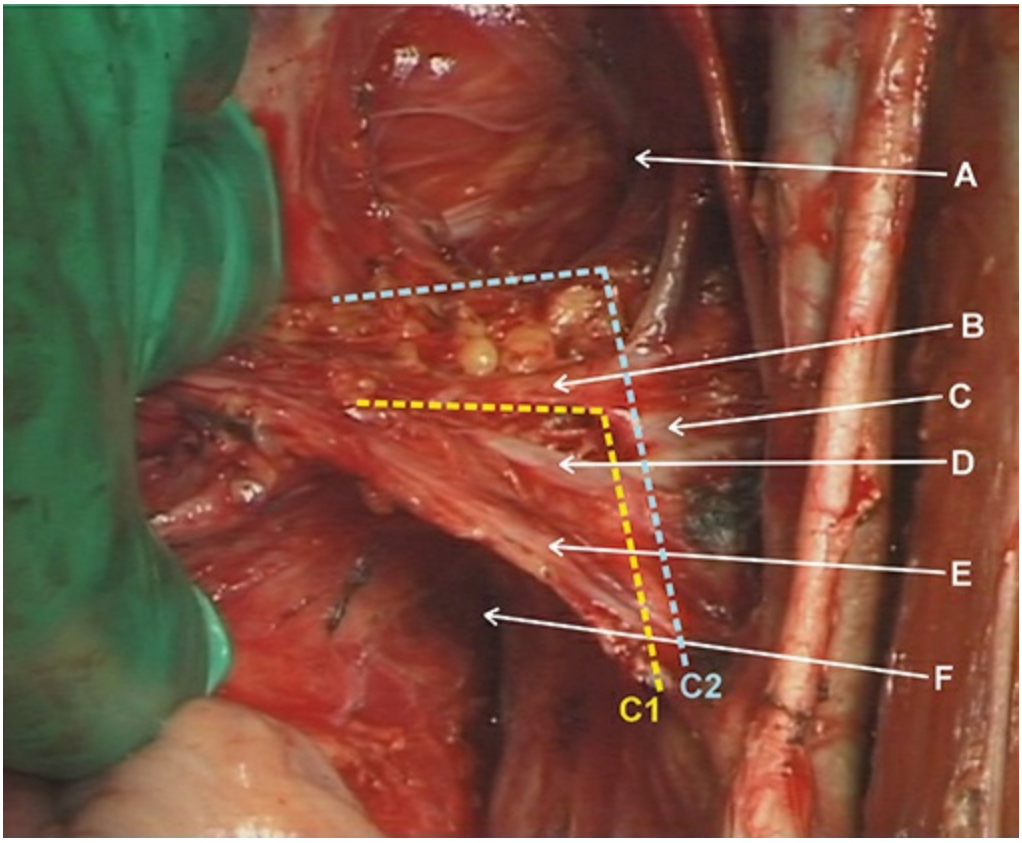

Figure 9.22 Resection lines for types B, C1, and C2 radical hysterectomy on the lateral parametrium. A—paravesical space; B—vaginal vein; C—internal iliac vein; D—uterine vein; E—uterine artery; E—pararectal fossa.

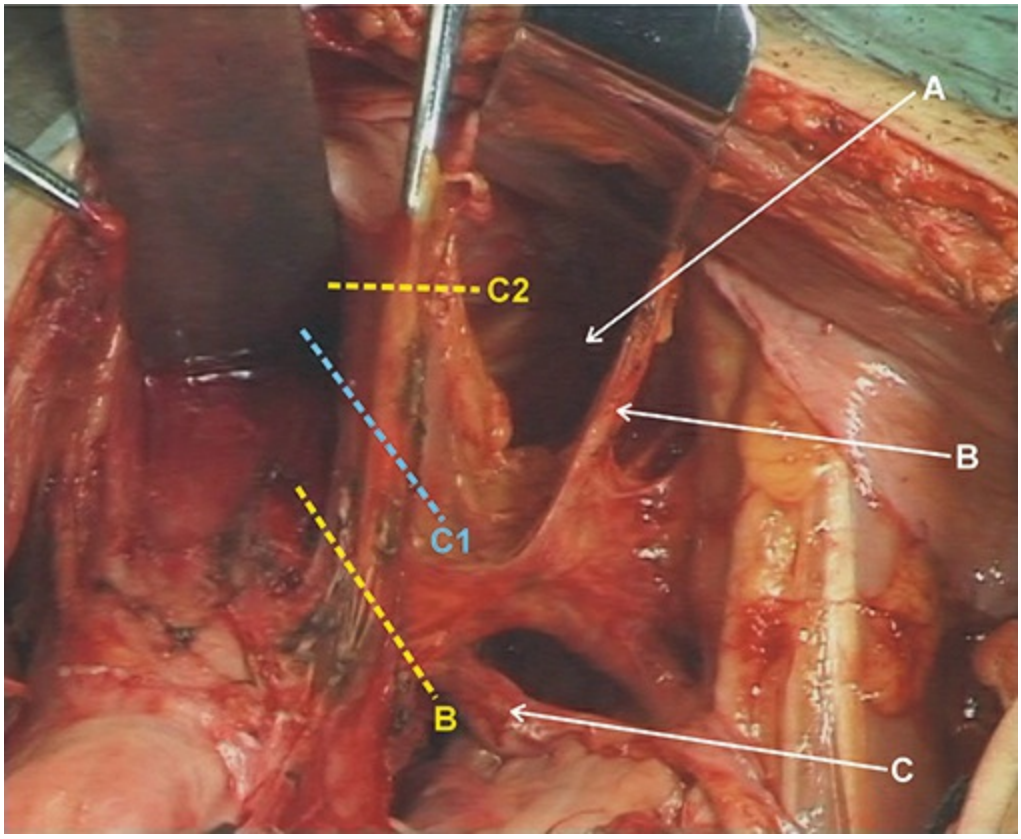

Figure 9.23 Resection lines for types B, C1, and C2 radical hysterectomy on the

ventral parametrium. A—paravesical space; B—umbilical ligament; C—ureter.

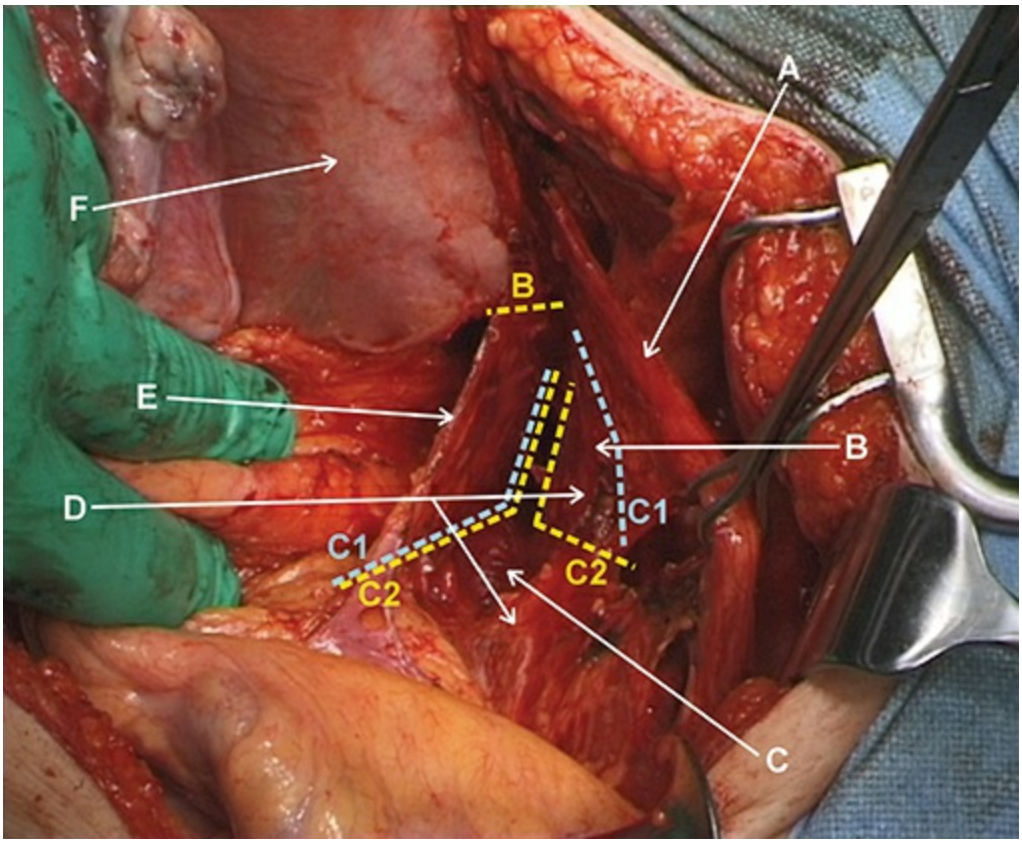

Figure 9.24 Resection lines for types B, C1, and C2 radical hysterectomy on the dorsal parametrium after dissection of the mesoureter from the sacrouterine ligament. A—ureter; B—mesoureter; C—space between the sacrouterine ligament and mesoureter; D—branches of the hypogastric plexus (white strips); E—sacrouterine ligament; F—cervix.

A major intention of the nerve-sparing (C1) radical hysterectomy is to remove corresponding parts of ventral, lateral, and dorsal parametria but, at the same time, preserve major autonomic nerve supply to urinary bladder, upper vagina, and rectum (**Figs. 9.22–9.24**). Two types of vegetative nerves can be identified and spared: (a) the inferior hypogastric plexus, running in the lateral part of the dorsal parametrium, laterally to the cervix below the ureter at the level of the vaginal fornix and ventrally in the infraureteral part of the ventral parametrium toward the urinary bladder; (b) the splanchnic nerves localized at the bottom of the lateral pararectal space and in the caudal part of the lateral parametrium below the parametrial veins. Surgical margins for the nerve-sparing procedure must be kept above the course of the nerve structures in the ventral, lateral, and dorsal parametrium. Dorsally, the nerve-sparing procedure requires a dissection of two parts of the dorsal parametrium. The mesoureter (a fine structure stretched between the ureter and the sacral bone), containing major branches of hypogastric plexus, is separated laterally from the uterosacral ligament, which allows for an adequate resection of the latter. On the lateral parametrium, the caudal resection margin is indicated by the vaginal vein, the largest parametrial vein, which guarantees the preservation of splanchnic nerves in the caudal part of the lateral parametrium. Ventrally, the ureter is only partially dissected from the ventral parametrium, allowing for limited resection of the proximal supraureteral part of the ventral parametrium.

The radicality of the C2 procedure, which corresponds to the type III radical hysterectomy, is different from the nerve-sparing procedure, aiming at removal of the majority of all three parametrial parts (**Figs. 9.22–9.24**). The C2 procedure requires complete dissection of the ureter from the lateral and ventral parametria and deeper dissection of the rectum from the dorsal parametria. The resection line on the dorsal parametria is deep below the former rectal attachment, causing unavoidable damage of the hypogastric plexus, so the dissection of the nerve from the uterosacral ligament is not

required. The lateral parametrium is completely separated from the pelvic sidewall until the sacral bone is reached. On the ventral parametrium the ventral resection margin is formed by the urinary bladder. As a consequence, major branches of vegetative nerves are sacrificed during the C2-type procedure.

The technique of minimally invasive radical hysterectomy has evolved in the same way as simple hysterectomy. The vaginal approach (Schauta operation) was historically the first approach used. Laparotomy (Wertheim operation) soon took over, as radical vaginal surgery requires specific training and did not provide surgical access for lymph node dissection. Laparoscopic surgery provided a minimally invasive approach to lymph node dissection and led to a revival of the Schauta operation (35). Laparoscopic techniques were used to perform part of the radical dissection prior to completing the vaginal portion of the surgery (36–38). As technology and minimally invasive laparoscopic skills improved, reports of total laparoscopic hysterectomy appeared (39).

Ovarian Cancer Debulking

The goal of ovarian cancer debulking or cytoreduction is to remove all, or as close as possible to all, grossly visible and palpable tumor (40). The surgeon undertaking these complex surgeries should be familiar with the techniques used to remove tumor from the pelvis and the upper abdomen.

Removal of Pelvic Disease

Because ovarian malignancy often presents with large masses filling the pelvis and obliterating the cul-de-sac, a retroperitoneal approach can be used to identify important structures and secure vascular pedicles. An initial incision over the lateral pelvic sidewall just anterior to the external iliac artery will allow adequate visualization of the ureter and the ovarian vessels (**Fig. 9.25**). The paracolic gutters can be incised cephalad along the avascular line of Toldt for more adequate exposure of the retroperitoneal space. To avoid further troublesome hemorrhage the gonadal and uterine vessels can be identified, secured, and divided in the retroperitoneal space. If the anatomy is distorted by peritoneal implants, it may be prudent to identify the ureters, free them, lateralize them, and retract them laterally prior to removal of the uterus.

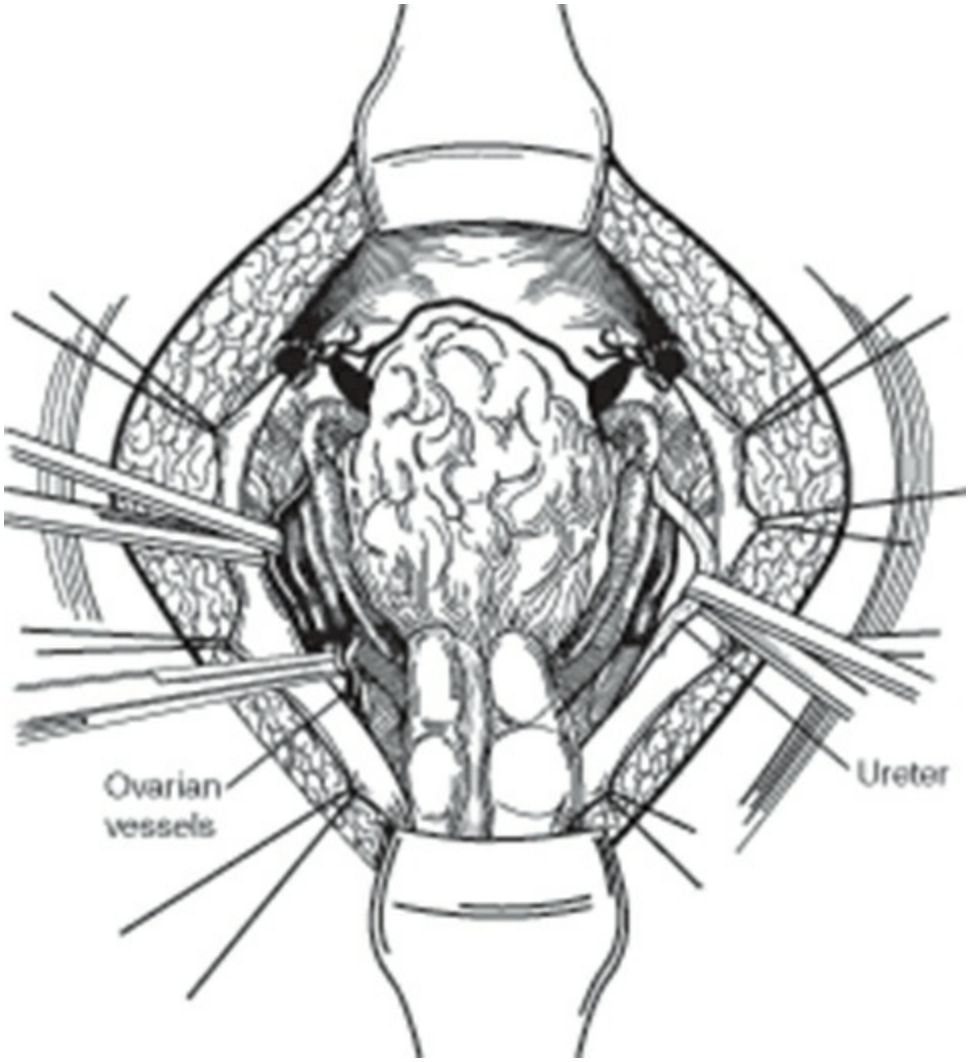

Figure 9.25 The ovarian vessels are skeletonized and divided at the pelvic brim. Early control of these vessels will help reduce blood loss during the later dissection. The ureter can be mobilized off the medial leaf of the broad ligament and retracted laterally on a Penrose drain or vessel loop.
After Gallup DG, Talledo OE. Surgical Atlas of Gynecologic Oncology. Philadelphia, PA: WB Saunders Co.; 1994:92.

In cases where the pouch of Douglas is deeply infiltrated by disease or if there is involvement of the rectosigmoid colon, a reverse hysterectomy can facilitate complete removal of this disease. Entering the rectovaginal space allows for identification of the peritoneal reflection and often spares several cm of distal rectum in preparation for the transection and anastomosis. Here, gentle handling of the pararectal fatty tissue is of great importance. The rectal wall should not be skeletonized and devascularized. Rather than dissecting the perirectal fat, leaving a fat plane on the rectal surface allows for optimal distal perfusion. The term “modified posterior exenteration” is commonly used for the above procedure, as it entails an en bloc removal of the uterus, adnexa, infiltrated peritoneum, and the rectum. The procedure starts with the incision of the vesical peritoneal plica and dissection of the urinary bladder down to the level of the vaginal fornix. In cases of carcinomatosis on the peritoneal plica, a ventral peritonectomy—complete dissection of the infiltrated peritoneum from the urinary bladder—is part of the procedure. The retroperitoneum is opened laterally above the large vessels, both round ligaments are cut, the ureters are identified, and then the ovarian vessels are ligated and cut. The ureters are freed from the overlying peritoneum and the sigmoid colon is divided above the level of tumor infiltration. Occasionally, the complete removal of the tumor requires mobilization of the ureter in its parametrial part, and its dissection from the cervix and infiltrated parametria, similar to when performed during a radical hysterectomy. Once the uterine vessels are ligated

bilaterally, the rectovaginal space between the vagina and the infiltrated pouch of Douglas is opened, the uterosacral ligaments are cut, and a reverse hysterectomy is completed by the incision of the vagina at the level of the vaginal fornix (**Fig. 9.26**). At this stage, the specimen is fixed in the pelvis only by the rectum and pararectal ligaments. The specimen is retracted cephalad, the infiltrated pouch of Douglas can be further dissected from the rectum, thus preserving a larger part of the rectum for anastomosis. After dividing the pararectal ligaments, the modified posterior exenteration is completed by division of the rectum below the level of tumor involvement. Low rectal anastomosis in this setting is generally performed and associated with a low rate of complications in well-trained hands (41,42).

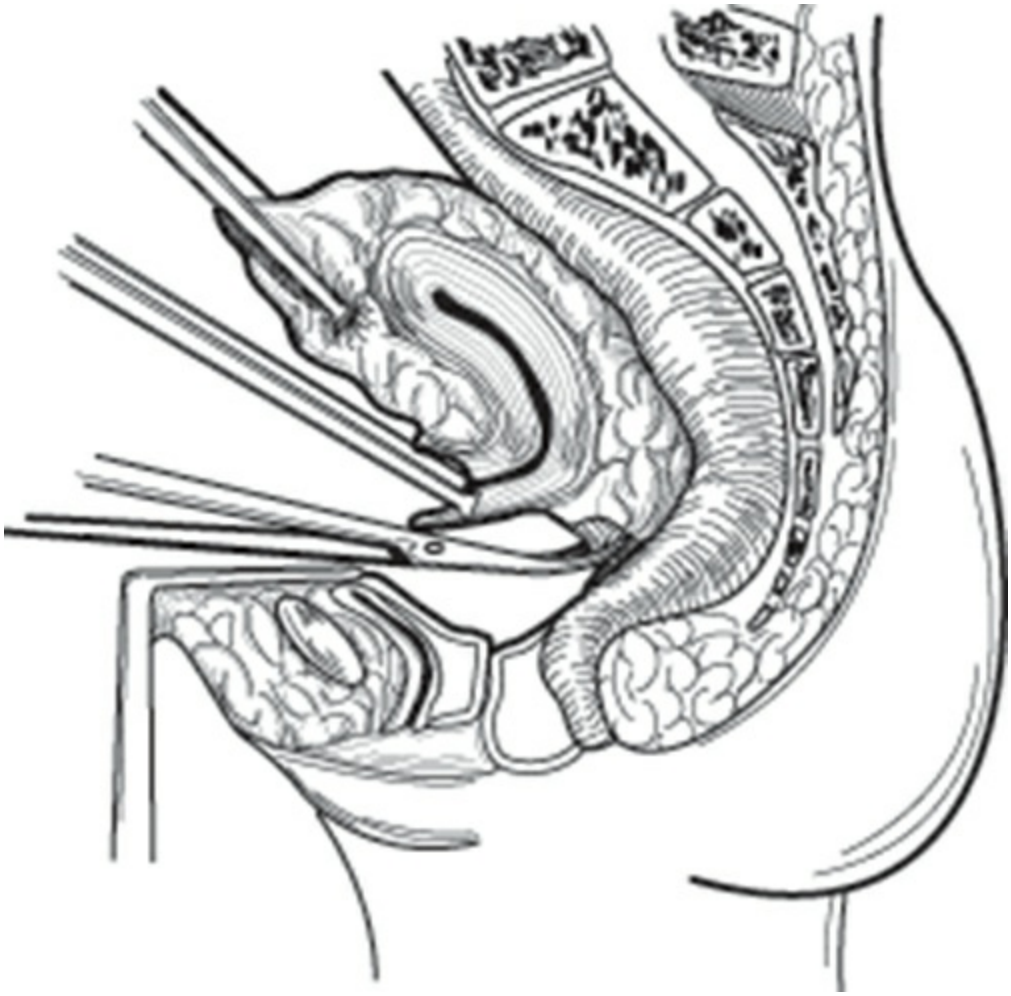

Figure 9.26 The posterior vaginal wall is grasped and retracted cephalad. The uterus can now be sharply dissected off of the rectosigmoid.
After Gallup DG, Talledo OE. Surgical Atlas of Gynecologic Oncology. Philadelphia, PA: WB Saunders Co.; 1994:103.

Upper Abdominal Disease

Bristow et al. (43) demonstrated that expert centers with primary optimal cytoreduction rates of 75% or greater provided their patients with a 50% improvement in overall survival when compared to less experienced centers with primary optimal cytoreduction rates of 25% or less. To achieve primary optimal cytoreduction rates of 75% or more in advanced-stage ovarian cancer patients, the surgeon should have the ability to remove disease involving upper abdominal structures such as the liver, diaphragm, spleen, and pancreas (5).

Adequate exposure is the most important factor in determining whether resection of diaphragm disease can be performed safely (7). In most cases, this can be done through a midline incision to the xiphoid, or in some cases the

xiphoid can be removed.

Liver mobilization is almost universally essential when removing large volume disease on the right hemidiaphragm since a greater proportion of the right hemidiaphragm is obscured by the liver. A right-sided liver mobilization will be described primarily since tumor involvement on the left diaphragm is more easily resected without fully mobilizing the liver. In certain cases, metastatic deposits on the left diaphragm may be contiguous with the splenic capsule requiring splenectomy.

The infrahepatic edge of the falciform ligament containing the ligamentum teres is divided and ligated. The divided pedicle can be used to provide downward traction of the liver and remaining falciform ligament. The falciform ligament should be transected all the way to the coronary ligament. The coronary ligament is incised from the falciform to the right triangular ligament. Careful attention should be directed at the area of the hepatic notch that contains the right hepatic vein as it enters the IVC. It is found lateral to the union of the falciform and coronary ligaments. If further mobilization of the liver is necessary, the lateral attachments may be incised and the liver bluntly lifted off Gerota fascia of the right kidney and diaphragm.

The extent of diaphragm peritonectomy can be tailored according to the distribution of disease. When a full right diaphragm peritonectomy is performed, the peritoneum on the anterior edge of the diaphragm is incised along the costal margin. This edge is grasped and retracted inferiorly to visualize the line of attachment between the diaphragm and its overlying peritoneum. The plane between is developed with a combination of blunt and sharp dissection; however, this may not be possible if the tumor has extended through the peritoneum and diaphragm.

If tumor implants are securely fixed to the diaphragm muscle and/or are suspicious for full thickness diaphragm involvement, diaphragm resection can be performed. The technique for diaphragm resection depends largely on the size of the lesion to be resected. Small penetrating lesions can be resected using the Endo GIA stapler alone without entering the pleural cavity. The lesion is grasped with clamps, the diaphragm tented downward away from the lung, and the Endo GIA is used to staple and divide the tented diaphragm and invasive lesion while closing off the residual diaphragm. Larger lesions require entry into the pleural space. This is done carefully to avoid injury to the underlying lung. Once entered and the lung visualized/retracted, the lesion is resected en bloc with the peritoneal, muscular, and pleural layers. The defect can frequently be closed primarily with limited tension, using permanent sutures. Larger defects that are not amenable to primary closure should be closed with a permanent mesh secured to the peritoneal diaphragm surface (44). The majority of patients undergoing limited diaphragm resection can have their pleural cavity closed and the air from the thorax evacuated using a Red Rubber Robinson catheter. A purse-string suture is placed widely around the hole and a #14 French Red Rubber Robinson catheter is passed through the hole into the pleural cavity. The anesthesiologist is asked to give the patient a maximal inspiration, suction may be applied to the catheter, and the catheter is pulled as the purse-string suture is tied down. For patients undergoing more extensive resections or with other reasons to benefit from prolonged pleural drainage, such as pleurodesis, a chest tube can be placed in the operating room.

To remove tumor from the left upper quadrant, occasionally a splenectomy with or without distal pancreatectomy is required. The lesser sac can be entered to evaluate the posterior aspect of the stomach and pancreas. The gastrosplenic ligament and then the short gastrics are carefully divided. The spleen is mobilized medially and out of the left upper quadrant by dividing the splenophrenic and splenocolic ligaments and the other attachments to the adrenal gland and Gerota fascia of the left kidney. The spleen can now be elevated out of the splenic bed and into the incision. The splenic hilum is now grasped between the fingers to identify the splenic artery and vein as well as palpate the tail of the pancreas. These vessels should be ligated and divided. If needed, a linear stapler may be placed across the tail of the pancreas to remove tumor involving the distal pancreas and/or splenic hilum. Reinforcement of this staple line with 3-0 delayed absorbable suture, either continuously or interrupted, is optional. Use of staplers with a buttress may be associated with fewer pancreatic leaks (45).

Urinary Diversion

Over the past three decades, interest in performing continent urinary diversions for patients with gynecologic malignancies

has emerged. Most gynecologic oncologists will use a modification of the Indiana (46) or Miami (47) pouch.

A modification of these pouches is shown in **Figures 9.27** to **9.29** (2). The colon is transected just proximal to the hepatic flexure (**Fig. 9.27**). The colon is then detubularized by a longitudinal incision along the tinea. The continent mechanism is created by two maneuvers. First, the terminal ileal segment is tapered down over a #14 French Foley catheter by using a gastrointestinal anastomosis (GIA) stapling device along the antimesenteric border of the ileum. The second maneuver is to plicate the ileocecal valve by placing concentric purse-string permanent sutures around it. The ureters are then implanted under direct vision (**Fig. 9.28**) (2). After closing the pouch, the ileal stoma can be brought out in several areas of the abdominal wall (**Fig. 9.29**) (2). Some use the umbilicus as the exit site. The ureteral stents can exit the abdomen via the ileal stoma or through separate incisions in the pouch and abdominal wall. The use of a Foley drain and a cecostomy tube for irrigation to remove mucus is generally employed.

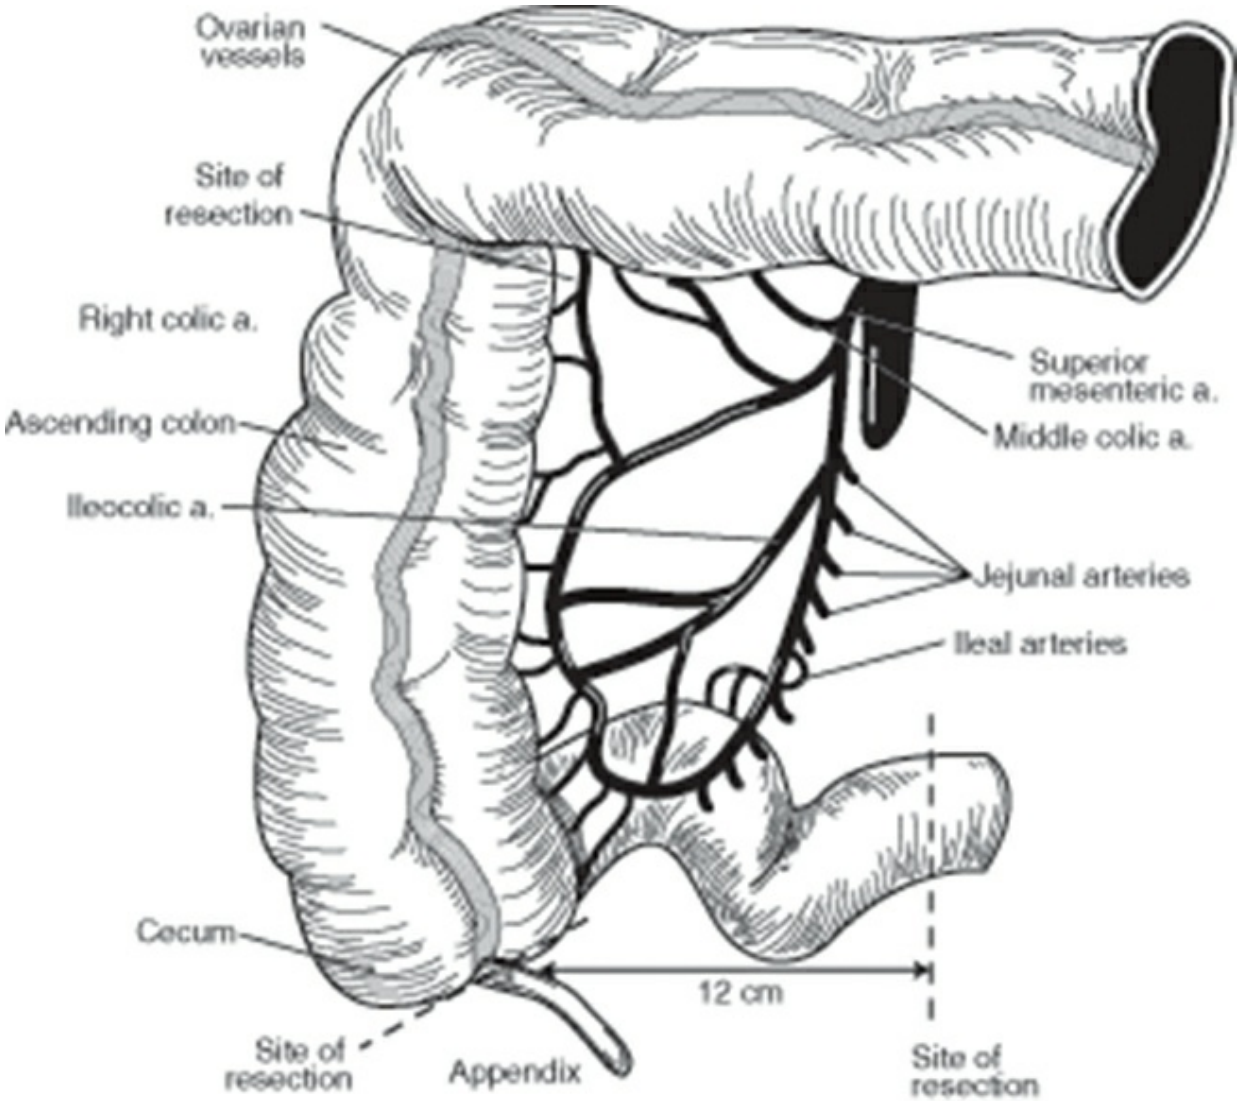

Figure 9.27 The anatomic location and vascularity of the right colon segment utilized for formation of the continent urinary pouch. Illustrated are the anatomic sites of division for creation of the continent pouch. The ascending colon is divided distal to the right colic artery. The terminal ileum is divided approximately 12 cm from the ileocecal valve. The resection can be accomplished with the use of surgical staplers or by intestinal clamps. If the appendix is present, it should be removed. The ileocecal segment has a rich blood supply derived from the right colic artery and the ileocolic artery. If one is performing the Miami pouch type of urinary diversion, the transverse colon would be divided distal to the middle colic artery.
After Gallup DG, Talledo OE. Surgical Atlas of Gynecologic Oncology. Philadelphia, PA:

WB Saunders Co.; 1994:186.

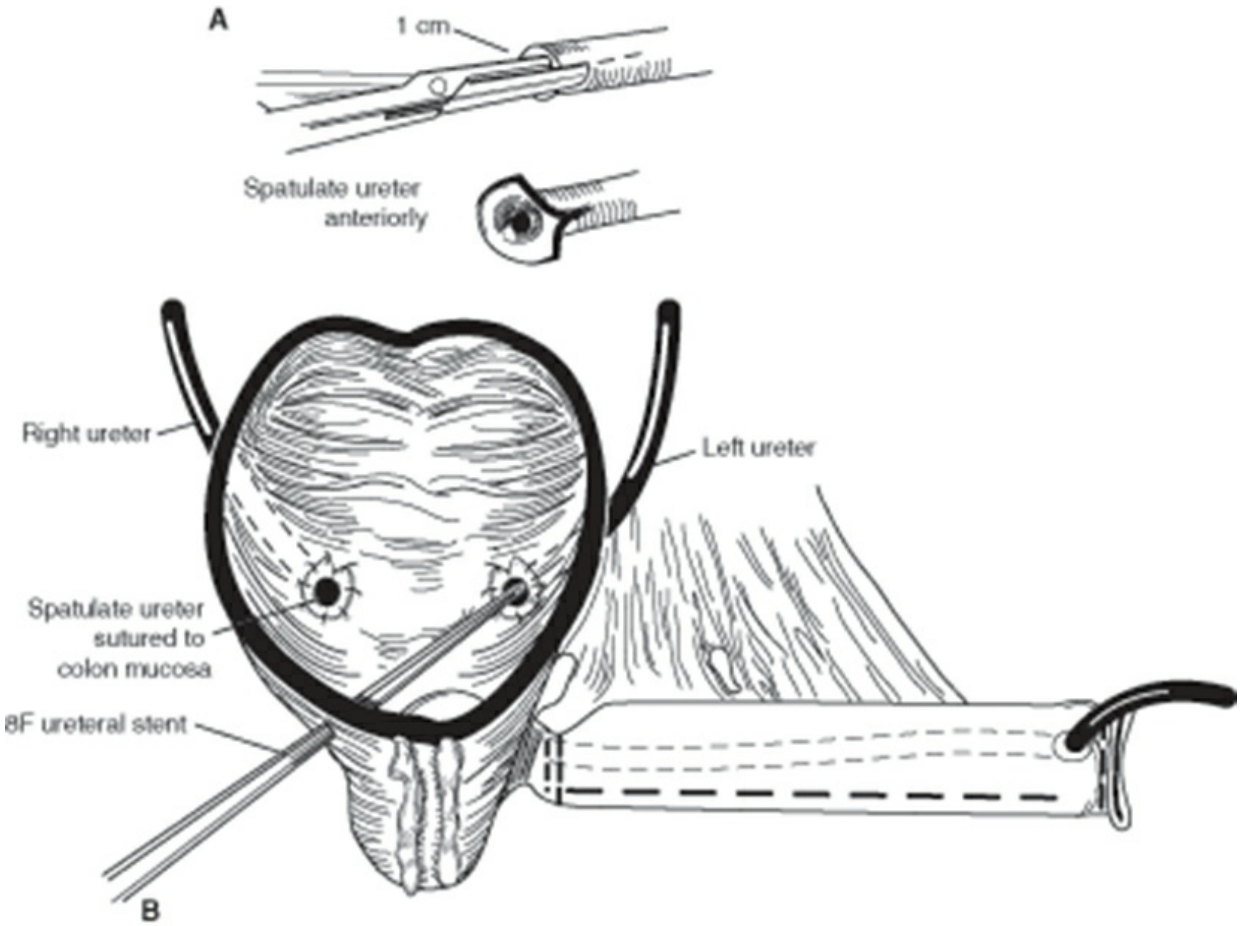

Figure 9.28 (A, B) Prior to beginning the continent diversion, the ureters have been transected (usually at the pelvic brim) and mobilized so that they can be brought to the area where the continent pouch will be located without tension. If necessary, the left ureter can be brought through or under the mesentery of the colon to facilitate its placement into the urinary pouch. An appropriate site is selected on what will be the posterior wall of the pouch, and a long thin clamp is used to perforate the colon and pull the ureter through. An approximately 1-cm segment of ureter is brought into the pouch. For ease of ureterointestinal anastomosis, the ureter should be secured posteriorly to the pouch by suturing the adventitial tissue of the ureter to the seromuscular layers of the pouch with three or four permanent 3-0 sutures. The ureter is spatulated to increase the lumen diameter. The ureter is sutured directly to the colon and is not tunneled. We use 4-0 polyglycolic suture. This is a full thickness approximation of the colon and ureter. Once both ureters have been sutured into the pouch, two #8 French ureterointestinal stents or long pediatric feeding tubes are placed retrograde into the renal pelvis. If a feeding tube is used, it should be sutured to the ureter with 4-0 chromic to ensure against displacement due to ureteral peristalsis. Note the three concentric sutures at the ileocecal valve.
After Gallup DG, Talledo OE. Surgical Atlas of Gynecologic Oncology.. Philadelphia, PA: WB Saunders Co.; 1994:191.

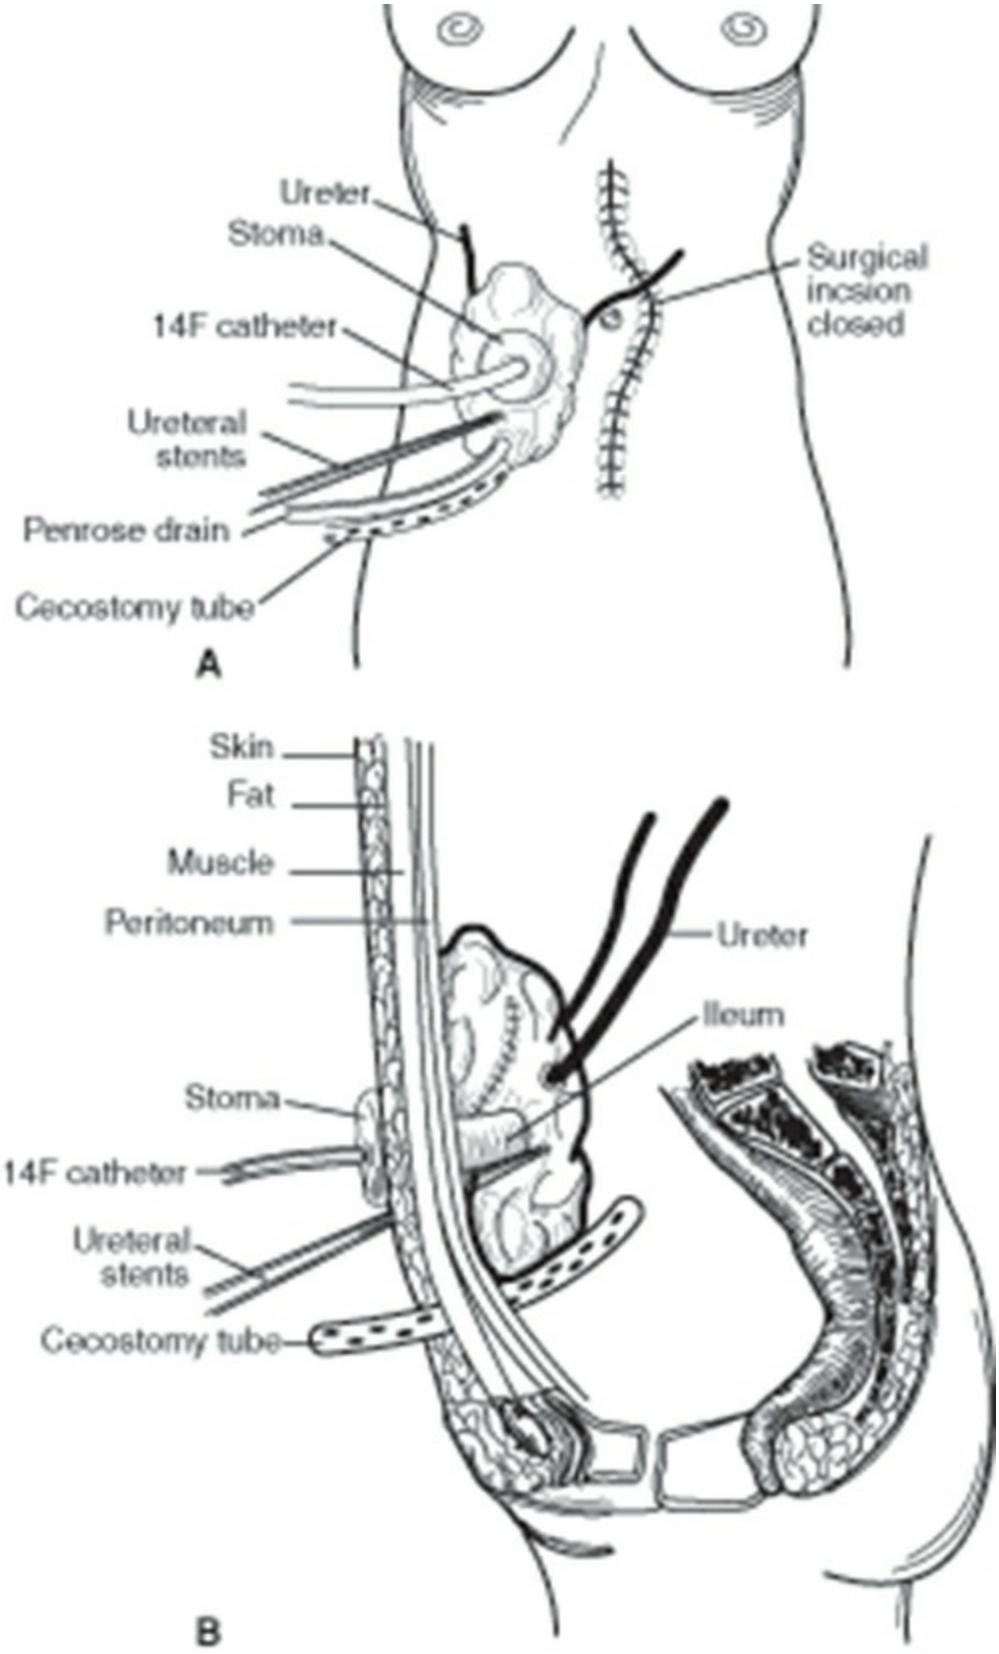

Figure 9.29 (A, B) The site for the ileal stoma is selected on the anterior abdominal wall and then incised through all abdominal tissue layers. The stoma is created for catheterization and the #14 French catheter should exit the pouch through this stoma. It is critical that the ileal segment be at a 90° angle with the abdominal wall so that catheterization is a "straight shot." The pouch may be sutured to the abdominal wall to accomplish this. All stents and drainage tubes are brought out through the anterior

abdominal wall and secured. The pouch may also be anchored posteriorly (i.e., to the sacrum).
After Gallup DG, Talledo OE. Surgical Atlas of Gynecologic Oncology.. Philadelphia, PA: WB Saunders Co.; 1994:193.

Poor candidates for continent urinary diversion include those who are physically or psychologically unable to perform frequent self-catheterization and maintenance of the pouch. For these patients, an ileal conduit has been the preferred alternative. However, in patients who will also require a colostomy, performing a double barrel wet colostomy has been reported. This combined urinary and fecal diversion employs a loop colostomy with the proximal limb serving as an end colostomy and the distal limb as a sigmoid conduit. This double-barreled wet colostomy may be associated with fewer complications than performing separate urinary and fecal diversions (48).

SURGICAL MANAGEMENT OF GYNECOLOGIC CANCER

The gynecologic oncologist must be able to evaluate the woman with a genital tract malignancy, direct her management, perform the necessary surgical procedures, and supervise her postoperative care and surveillance. A patient who is managed by a surgeon not trained in gynecologic oncology may receive an inappropriate or inadequate operation. This was demonstrated in a series of 291 women with primary ovarian cancer who underwent intraoperative evaluation. Ninety-seven percent of the patients who underwent surgery by a gynecologic oncologist received complete staging operations, but in patients undergoing staging operations by an obstetrician-gynecologist or general surgeon, only 52% and 35%, respectively, had adequate operations (49).

Two more recent British studies retrospectively analyzed the outcomes of over 1,800 patients with ovarian cancer (50,51). Both studies found on multivariate analysis that patients' survival was adversely impacted when their initial operation was performed by a general surgeon as opposed to a gynecologic surgeon. These results are similar to those obtained by Nguyen et al. (52) in an American national survey of ovarian carcinoma. Eisenkop et al. (53) analyzed the outcomes of 263 patients with stages IIIC and IV ovarian carcinoma. When the primary surgery was performed by gynecologic oncologists, as compared to general obstetricians-gynecologists and general surgeons, the rate of optimal cytoreduction was significantly higher, the operative mortality substantially lower, and the median survival significantly longer.

Accordingly, other countries have attempted to centralize the care of patients with ovarian cancer so that they are primarily operated on by gynecologic oncologists (54,55). However, patterns of care studies in the United States have demonstrated that a significant percentage of women with ovarian cancer are not receiving their primary treatment from gynecologic oncologists (56,57). Consequently, in the United States, many women with ovarian cancer are still not receiving the recommended comprehensive primary surgery (58,59).

In the four decades since the establishment of gynecologic oncology as a subspecialty, cancer therapy has become increasingly sophisticated and complex, and it is difficult for any one physician to master all the skills necessary for treating gynecologic malignancies. More often, we must use multimodal therapy and participate in multidisciplinary care. There are many medical and radiation oncologists who have specialized in gynecologic cancer, and they are integral members of the multidisciplinary team. The Gynecologic Oncology Group, with its emphasis on multidisciplinary research, has demonstrated the effectiveness of such an approach.

Another important factor in providing optimal patient care is the environment in which gynecologic oncology is practiced. The facilities used by the gynecologic oncologist should offer state-of-the-art radiation therapy and chemotherapy. Patients should receive care tailored to the type and extent of their disease and their care not be determined by the limitations of the available facilities. Mortality rates for complex oncologic procedures, such as pelvic exenteration, have been demonstrated to be significantly lower in hospitals where a relatively high volume of procedures are performed, compared to hospitals in which the procedures are performed infrequently (60). The recent meta-analysis performed by

Bristow et al. (43) evaluated 81 studies involving 6,885 patients with advanced ovarian cancer. This study demonstrated a 50% increase in median survival if patients' primary surgery was performed at an "expert" center compared to less experienced centers. In a recent review of the literature, Cowan et al. (61) concluded that patients with invasive epithelial ovarian cancer had improved optimal debulking rates, guideline adherence, and overall survival when cared for in high volume centers by high volume physicians.

Diagnosis and Staging

The diagnosis of any gynecologic cancer requires a surgical biopsy. The manner in which the histologic diagnosis is obtained varies with the disease and the clinical situation. A punch biopsy or an instrument biopsy may be sufficient for the diagnosis of an invasive cancer of the vulva, vagina, or cervix, but an excisional biopsy is necessary for the diagnosis of microinvasive or preinvasive cancer. A fine-needle aspiration biopsy for cytologic analysis may be adequate for establishing the extent of spread of a cancer, but may not be sufficient to provide histologic cell type and grade for the primary diagnosis. Core needle biopsy or surgical exploration may be required to provide this information for diagnosis.

The current International Federation of Gynecology and Obstetrics (FIGO) staging system of gynecologic cancers requires surgical staging for vulvar, endometrial, and ovarian cancer. Cervical cancer remains a clinically staged disease, although many centers use surgical staging (by laparotomy or laparoscopy) for treatment planning. **Table 9.2** lists the current methods of staging for the various gynecologic malignancies.

TABLE 9.2 FIGO Staging of Gynecologic Cancers

Site	Staging
Vulva	Surgical and pathologic staging
Vagina	Clinical staging
Cervix	Clinical staging
Corpus (endometrium)	Surgical and pathologic staging
Corpus (sarcoma)	Surgical and pathologic staging
Fallopian tube	Surgical and pathologic staging
Ovary	Surgical and pathologic staging
Gestational trophoblastic disease	FIGO staging (clinical)
	WHO classification (risk-oriented)

FIGO, International Federation of Gynecology and Obstetrics; NIH, National Institutes of Health; WHO, World Health Organization.

The initial surgical procedure in a patient with known or suspected gynecologic cancer should be performed by a trained gynecologic oncologist because the accuracy of diagnosis and staging significantly influences subsequent prognosis and therapy. Numerous studies have demonstrated that ovarian cancer staging operations performed by general obstetricians-gynecologists or general surgeons are inadequate much more frequently than if the operation is performed by a gynecologic oncologist. Young et al. (62) reported excellent survival in patients with early ovarian cancer, but stressed that these data were applicable only to patients with adequate surgical staging.

In addition to the anatomic site and stage of disease, the plan of therapy for most gynecologic malignancies is also influenced by the histologic cell type and histologic grade of the cancer. The collaboration of the surgeon, pathologist, and cytologist cannot be overemphasized in the diagnosis and staging of cancer. Communication about clinical history and desired information from the anatomic specimen is important in directing the clinical care of the patient.

Surgery as Primary Therapy

Surgery is usually the treatment method of choice for preinvasive diseases of the vulva, vagina, and cervix, for which local excision is both diagnostic and curative. Surgical margins should clear only gross and microscopic disease. In vulvar cancer, excision with a 1-cm normal tissue margin is appropriate (63).

Localized disease, such as stage I vulvar cancer, stage I posterior vaginal cancer, and stage IA2/IB1 cervical cancer, are usually managed by radical resection of the primary tumor and regional lymph node evaluation. Lymphadenectomy has traditionally been the standard method of evaluation; however, some centers have adopted sentinel lymph node evaluation instead. In these settings, the operations themselves are designed to be curative without adjunctive therapy unless high-risk conditions are identified. As described in the chapter on vulvar cancer, there is a trend toward more conservative therapy for vulvar malignancies. This allows preservation of normal tissues and prevents some of the disfigurement that can be associated with this surgery. Surgery may be curative without adjuvant therapy for other cancers as well, including early-stage endometrial cancer, stage IA ovarian cancer, and early sarcomas of the uterus.

Findings at surgery may identify patients who may benefit from additional treatment (adjuvant therapy). It is administered because of the potential for occult spread of disease based on a surgical finding (e.g., positive lymph nodes). The use of adjuvant therapy requires that information be available to allow the selection of patients with a high risk of recurrence. These risk groups are defined for each disease site in the appropriate chapters of this book.

Surgery Combined with Other Therapies

In some gynecologic cancers, surgery remains the cornerstone of treatment but may not be curative when used alone. Primary surgical cytoreduction of gross disease is vital in advanced ovarian cancer, but it is of little benefit without adjuvant chemotherapy. For patients with early-stage endometrial and cervical cancer, surgical removal of the uterus can be curative in many cases. However, depending on the histopathologic findings of the surgical specimens, additional regional radiotherapy and/or chemotherapy may be indicated. The gynecologic oncologist should be aware of which patients may benefit from adjuvant therapy, and be able to coordinate adjuvant chemotherapy and/or radiation therapy to ensure that the patient receives optimal care.

Surgery as Salvage Therapy

Occasionally, radical surgical resection can be curative in patients who have failed other therapies. These surgical procedures are almost always extensive and associated with some morbidity. After the failure of other therapies, patients with vulvar, vaginal, cervical, or uterine cancers may have very limited options. In such cases, pelvic exenteration with removal of virtually all pelvic tissues may offer the only possibility for a cure. Five-year survival rates of 23% to 61% have been reported after pelvic exenteration (64–67).

The possibility of cure with pelvic exenteration is associated with high morbidity and changes in bodily functions. The loss of the bladder and the rectum often requires permanent stomas, and sexual function is impaired or lost in many patients. For some patients, reconstructive techniques can prevent the need for stomas and may also restore sexual function. During the last three decades, improvements in initial surgery and radiation therapy along with refinements in selection criteria have made operations like pelvic exenteration infrequent (68). Today, most patients experience distant failure rather than regional failure, and they are therefore not candidates for attempts at curative pelvic exenteration.

Surgery as salvage therapy may also play an important role in the management of ovarian, fallopian tube, and some endometrial cancers. For patients who have failed initial therapy and chemotherapy, second attempts at cytoreduction may be beneficial, provided that reasonable salvage therapy is available (69–71).

Surgery for Metastatic Disease

In selected cases, distant metastases from gynecologic tumors may be curable by surgical resection, or the resection may produce a prolonged disease-free interval. Fuller et al. (72) reported on 15 patients who underwent pulmonary resection of distant metastases from a variety of gynecologic malignancies. They reported a 5-year survival rate of 36% and a 10-year survival rate of 26%. Patients with solitary metastases had a median survival of 64 months, with a median survival of 48 months for those with multiple metastases. Levenback et al. (73) reported their experience with 45 patients who underwent pulmonary resection of metastases from uterine sarcomas. From the date of the pulmonary resection, the 5-year survival rate was 41%, with a 10-year survival rate of 35%. They found a statistically improved chance of survival for patients who developed pulmonary metastases 1 year or longer from their original therapy, and for those with unilateral metastases. There was no statistical difference in survival based on the number of nodules (in one lung), the size of the lesion, the age of the patient, or the use of post-resection adjunctive therapy. However, the small numbers of patients in this study precluded adequate evaluation of these factors.

There is increasing evidence that salvage therapy in ovarian and fallopian tube cancers is likely to be more effective in patients with minimal residual disease. Secondary cytoreduction may play an important role in the treatment of select patients with recurrent disease (70). Recent reports have demonstrated promising results with surgical resection of isolated metastases to the parenchyma of the liver and spleen (74,75).

Surgery for Reconstruction

Reconstructive surgery may be performed at the time of resection of the cancer, as a delayed procedure, or as required therapy to correct a complication of treatment. Vulvar reconstruction is usually done at the time of initial resection and may involve the use of free skin grafts, rotational flaps of adjacent skin and fat tissue, or myocutaneous grafts from the thigh, buttocks, or anterior abdominal wall. Vaginal reconstruction may also be performed, usually as a planned, delayed phase of reconstruction. Vaginal reconstruction requires free skin grafts or myocutaneous flaps, depending on the size of the defect and whether or not there has been previous irradiation of the vaginal bed. The techniques of vulvar and vaginal reconstruction are explained in detail in other chapters of this book.

Reconstruction as therapy for complications of treatment may be required for the closure of defects from improper wound healing, radiation necrosis, or tissue loss after extravasation of chemotherapeutic agents. Although free skin grafts may be used to reconstruct surgical wound disruption or tissue loss due to chemotherapy extravasation, radiation necrosis usually requires the use of myocutaneous flaps because of a lack of adequate blood supply in the area of the injury.

Surgery for Palliation

Surgery for palliation may involve resection of tumor to relieve symptoms, or it may involve diversion or bypass of portions of the gastrointestinal or urinary tract to prolong life and provide comfort. Consideration of surgery for palliation must take into account the risks of the procedure and the degree of successful palliation. In many cases, these patients will have a limited life span; however, the gynecologic oncologist should not uniformly dismiss the concept of surgical palliation. A surgical procedure may provide quick relief of symptoms as compared to palliative administration of a chemotherapeutic agent for 6 to 12 months, which may or may not result in minor tumor shrinkage or stabilization of disease despite the side effects. The gynecologic oncologist must use astute surgical judgment and a realistic assessment of the patient's condition and wishes when deciding on palliative surgery.

Palliative surgery is more frequently used to relieve specific dysfunctions, such as obstruction of the urinary or intestinal tract. Relief of urinary tract obstruction may be accomplished by ureteroneocystostomy or by urinary conduit, depending on the location of the obstruction and the location or extent of disease. A urinary conduit can provide immediate and permanent relief to the patient who has a ureterovaginal, vesicovaginal, or urethrovaginal fistula. It may also provide

relief of urinary obstruction, which will prolong life and allow for the administration of additional chemotherapy or irradiation. The judgment of the surgeon and the desires of the patient become essential factors in this decision-making process. For the patient suffering from constant urinary leakage or who may benefit from additional therapy, the decision to perform a urinary diversion is quite simple. If diversion is done to prolong life, however, the decision must be weighed carefully. For a patient who has a limited life expectancy or is in uncontrollable pain, performing a urinary diversion may do more harm than good.

In certain situations, one must also consider the relative benefits of nonsurgical urinary diversion, such as placement of a ureteral stent or a percutaneous nephrostomy. Nonoperative management options may be more attractive and may prove to be better choices than surgical intervention if they can resolve the urinary problem. This is particularly true if the aim is to employ adjunctive chemotherapy or irradiation, or if a surgical procedure is not feasible because of medical conditions or other considerations. Unfortunately, a percutaneous nephrostomy may not help the patient with a fistula because the nephrostomy may not totally divert the urine.

Placement of a ureteral stent, by cystoscopy or antegrade through a percutaneous nephrostomy, is usually better and safer than urinary diversion for the relief of obstruction. Current technology allows the placement of stents that can be left in place for months and can be changed easily over a guide wire by means of the cystoscope.

Intestinal obstruction is a common finding in patients with ovarian cancer. Deciding whether the operation is feasible can be more difficult in this setting, particularly since the radiologic studies may not reveal the true extent of disease. For the patient with localized disease, a diverting colostomy or an intestinal bypass is usually possible. For the patient with intra-abdominal carcinomatosis, the decision to operate should be weighed against the chance of success and the surgical risks.

Pothuri et al. (76) evaluated 68 palliative operations performed on 64 patients with recurrent ovarian cancer and intestinal obstruction. In 84% of cases, a corrective surgical procedure could performed, whereas no corrective surgical procedure was possible for the remaining 16%. Of the 57 cases where corrective surgery was possible, 71% were successfully palliated (“successful palliation” is defined as the ability to tolerate a regular or low-residue diet at least 60 days postoperatively). If surgery resulted in successful palliation, median survival was 11.6 months compared to 3.9 months for all other patients.

THE FUTURE OF GYNECOLOGIC ONCOLOGY

Gynecologic oncologists must continue to advance the efficacy of the surgical management of patients with gynecologic cancers. Recent trends in this field have focused on minimizing surgical-related morbidity without compromising oncologic outcomes.

Changes in Surgical Therapy

Technology will continue to expand surgical capabilities in the management of gynecologic cancers. Oncologic surgery in general has moved toward using minimally invasive techniques to perform surgical resection. There was a rapid increase in the use of laparoscopic surgery in the field of gynecologic oncology in the 1990s. Recent improvements in technology, in particular robotics, have further shifted the management of several gynecologic cancers away from open surgery to minimally invasive surgery.

Despite multiple reports that malignancies of the uterine corpus and cervix could be managed using a minimally invasive approach with traditional laparoscopy, the gynecologic oncology community was slow to adopt this technique. In a survey on the use of laparoscopy by members of the Society of Gynecologic Oncology in 2004, only 10% of respondents identified endometrial cancer surgery as the most commonly performed laparoscopic procedure (77). Advanced traditional laparoscopic procedures were not uniformly adopted by all gynecologic oncologists, and only a

minority routinely performed advanced procedures. This was likely due to the need to acquire new surgical skills sets, the noncomplementary movements of the laparoscopic instruments compared to the surgeon's movements, and the limited range of motion of the currently available instruments. Laparoscopic technology only provided the surgeon with two-dimensional images, poor ergonomics for lengthy procedures, and difficulty in suturing. It may be technical and mentally challenging to complete many complex procedures in a minimally invasive fashion. The robotic surgical platform was initially developed for use by the military. In 2005, the U.S. Food and Drug Administration approved its use for gynecologic conditions. This led to a major shift in the surgical management of patients with gynecologic cancers, in particular, cancers of the uterine corpus and cervix. The advent of robotic technology has overcome many of the above-mentioned limitations associated with traditional laparoscopy. In an update of a previous survey of the members of the Society of Gynecologic Oncology, Conrad et al. reported that 70% of respondents in 2012 identified endometrial cancer surgery as the most commonly performed laparoscopic procedure. Much of this change may be related to the increase in use of robotic surgery for total hysterectomy and staging of endometrial cancer (78).

Sentinel lymph node evaluation is another example of the movement in the specialty to minimize surgical morbidity associated with cancer treatment. Lymphadenectomy has been an integral part of the surgical management of gynecologic malignancies. The identification of nodal metastases has profound effects on postoperative management and adjuvant therapy. However, this comes with a cost in that lymphadenectomy has been associated with long-term morbidity (79).

A more targeted approach to lymph node evaluation may eventually do away with the need to perform lymph node sampling to any degree. Sentinel lymph node mapping was first reported for penile cancer in 1977 (80). This method of assessing the lymph nodes has been widely used in the management of breast cancer and melanoma. Use of this technique in the management of vulvar and endometrial cancer was first reported in the 1990s (81,82). Sentinel node mapping has become a topic of debate, as it may provide diagnostic accuracy while minimizing the morbidity associated with complete lymphadenectomy (83,84). Although no large randomized study exists to support the use of sentinel node mapping for apparent early-stage cervical and endometrial cancers, there are large studies that do support this novel technique (85,86).

Some have advocated using sentinel node mapping as part of a specific algorithm in the management of cervical and uterine cancers (**Figs. 9.30** and **9.31**) (87,88). In brief, these algorithms consist of retroperitoneal evaluation, including excision of all mapped sentinel nodes and suspicious nodes regardless of mapping; if there is no mapping on a hemipelvis, a side-specific lymph node dissection is performed. By employing such an algorithm, false-negative rates can be lowered, nodal counts minimized, and accuracy in the detection rate of lymph node metastases maintained (89).

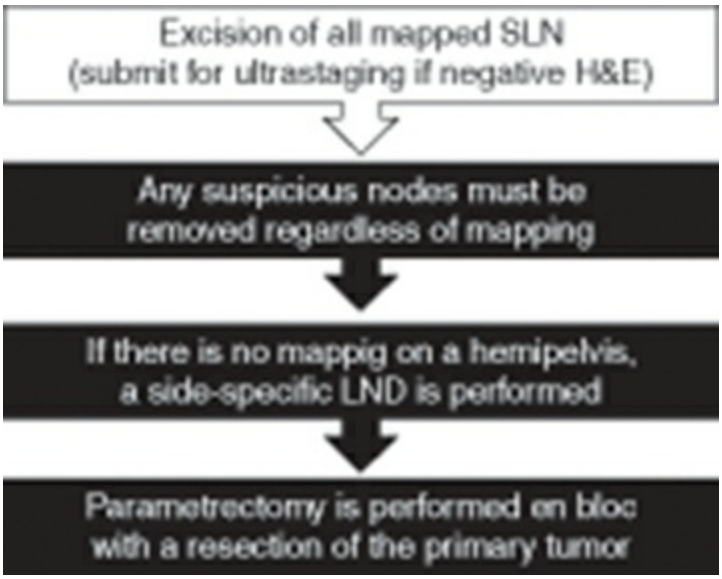

Figure 9.30 Sentinel lymph node algorithm for early-stage cervical cancer. H&E, hematoxylin and eosin (stain); SLN, sentinel lymph node; LND, lymph node dissection.

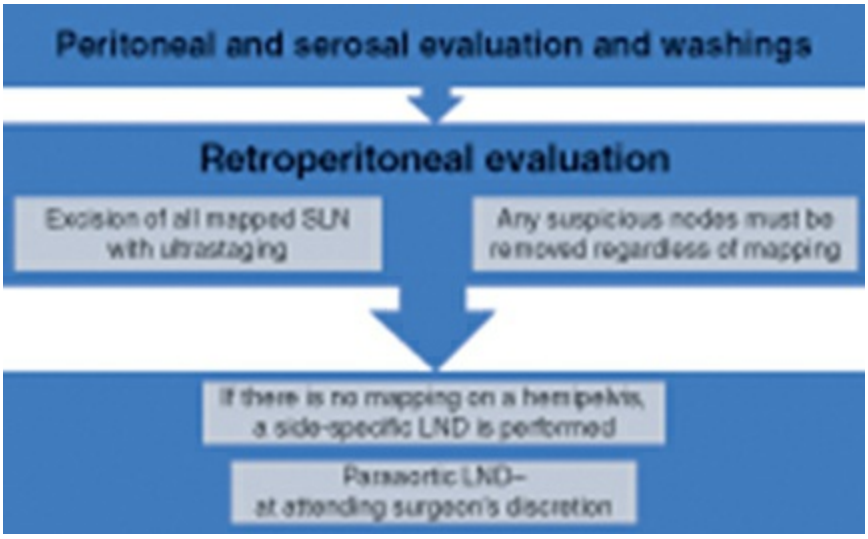

Figure 9.31 Sentinel lymph node algorithm for early-stage endometrial cancer. SLN, sentinel lymph node; LND, lymph node dissection.

Different techniques have been described for sentinel node mapping in endometrial cancer. Currently, there have been three injection sites described for this procedure. A cervical injection, a subserosal/myometrial, and a hysteroscopic endometrial injection have all been described. Cervical injection appears to be the easiest and most convenient technique; however, some have questioned its accuracy (90). The use of superior imaging technology such as fluorescence may also increase the detection rate of the sentinel nodes (91).

Innovative management pathways have been developed to hasten recovery and attenuate the stress response associated with surgery. Components of these pathways include preoperative patient education, reduction of preoperative fasting, omission of bowel preparation, perioperative normovolemia, limited use of nasogastric tubes and drains, early removal of urinary catheters, minimizing opiate use, early postoperative mobilization, enhanced gastrointestinal motility with prokinetics, and early enteral nutrition. Together, these components comprise an enhanced recovery pathway that has been adopted by many gynecologic oncologists and has resulted in decreased length of stay and cost (92,93).

Changes in the Indications for Surgery

Early diagnosis will change the indications for surgery and the types of procedures that should be done. It then follows that gynecologic oncologists will be able to treat more patients with less morbidity and with greater preservation of function. The use of minimally invasive surgery for patients with early-stage uterine cancer is a prime example of how patients can be effectively treated with less morbidity and improved quality of life.

Better adjunctive therapies will increase the importance of initial surgical therapy. More patients will benefit from surgical cytoreduction to minimize disease. The availability of effective irradiation, chemotherapeutic regimens, and biologic regimens will make adjuvant therapy feasible in more cases, and it will become more important for us to identify groups of high-risk patients who are likely to develop recurrent disease after surgery.

CONCLUSION

In 1969, the American Board of Obstetrics and Gynecology recommended the development of the subspecialty of gynecologic oncology, and in 1973, the American Board of Medical Specialties approved this unique specialty. The gynecologic oncologist should be viewed as a surgical oncologist who possesses sufficient familiarity with radiation

oncology and medical oncology to ensure the proper integration of all modalities of treatment. In many cases, the gynecologic oncologist is able to apply surgical skills for primary therapy, secondary therapy, reconstruction, and palliation.

Many battles had to be won for gynecologic oncologists to perform the surgical procedures that are traditionally done by general surgeons and urologists. Although management of gynecologic cancers requires integration of surgery with the specialties of medical oncology and radiation oncology, advancement of the surgical management of patients with gynecologic malignancies remains solely within our specialty. We are primarily surgeons and must perform surgical procedures at the highest level. The advancement of the surgical management of patients with gynecologic malignancies remains solely within this specialty.

CHAPTER 10 Diagnostic Imaging

Shaunagh McDermott, Leslie K. Lee and Susanna I. Lee

INTRODUCTION

The objectives of imaging in gynecologic oncology are detecting primary tumor, defining extent of tumor spread for treatment planning, monitoring treatment response, and detecting tumor recurrence. Comprehensive imaging of the gynecologic cancer patients can be achieved using a combination of pelvic ultrasound; chest, abdominal, and pelvic computed tomography; pelvic magnetic resonance imaging; and whole-body 2-[^{18}F]-fluoro-2-deoxy-D-glucose positron emission tomography integrated with CT (FDG-PET-CT). The choice of imaging exam depends on the clinical question (**Table 10.1**).

TABLE 10.1 Imaging Modality Choice for Detection, Treatment Planning, and Follow-up of Gynecologic Cancers

Indication	CT[a]	MRI[a]	FDG-PET-CT[b]
Uterine cervical cancer: pretreatment			
Early detection	Poor	Poor	Poor
Differential diagnosis (benign vs. malignant)	Poor	Possible	Poor
Extent of tumor spread			
Tumor size	Poor	Best	Poor
Endocervical margin distance	Poor	Best	Poor
Parametrial involvement	Possible	Best	Possible
Lower third of vaginal involvement	Poor	Possible	Poor
Pelvic sidewall involvement	Possible	Possible	Possible
Hydronephrosis	Possible	Possible	Possible
Bladder mucosal involvement	Poor	Possible	Poor
Rectal mucosal involvement	Poor	Possible	Poor
Pelvic and para-aortic adenopathy	Possible	Possible	Best
Distant metastases (lymph node, bone)	Poor	Possible	Best
Distant metastases (liver)	Possible	Best	Possible
Distant metastases (lung)	Best	Poor	Possible
Uterine endometrial cancer: pretreatment			
Early detection	Poor	Poor	Poor

Differential diagnosis (benign vs. malignant)	Poor	Possible	Possible
Extent of tumor spread			
Greater than half thickness of myometrium extension	Poor	Best	Possible
Cervical stromal involvement	Poor	Best	Possible
Uterine serosal or adnexal involvement	Possible	Best	Possible
Vaginal or parametrial involvement	Possible	Best	Possible
Pelvic and para-aortic adenopathy	Possible	Possible	Best
Bladder mucosal involvement	Poor	Possible	Poor
Bowel mucosal involvement	Poor	Possible	Poor
Distant metastases (lymph node, bone)	Possible	Possible	Best
Distant metastases (liver)	Possible	Best	Possible
Distant metastases (lung)	Best	Poor	Possible
Uterine sarcoma: pretreatment			
Early detection	Poor	Poor	Poor
Differential diagnosis (benign vs. malignant)	Poor	Possible	Poor
Extent of tumor spread			
Tumor size	Poor	Best	Possible
Adnexal involvement	Possible	Best	Possible
Extrauterine pelvic tissue extension	Possible	Best	Possible
Abdominal tissue involvement	Possible	Possible	Possible
Pelvic and para-aortic adenopathy	Possible	Possible	Best
Bladder mucosal involvement	Poor	Possible	Poor
Bowel mucosal involvement	Poor	Possible	Poor
Distant metastases (lymph node, bone)	Possible	Possible	Best
Distant metastases (liver)	Possible	Best	Possible
Distant metastases (lung)	Best	Poor	Possible
Gestational trophoblastic disease: pretreatment			
Early detection	Poor	Poor	Poor
Differential diagnosis (benign vs. malignant)	Poor	Possible	Possible
Extent of tumor spread			
Tumor size	Poor	Best	Possible
Extrauterine extension	Possible	Best	Possible
Distant metastases (lung)	Best	Poor	Possible
Distant metastases (other)	Possible	Poor	Best
Vulvar cancer: pretreatment			
Early detection	Poor	Poor	Poor
Differential diagnosis (benign vs. malignant)	Poor	Possible	Possible

Extent of tumor spread			
Tumor size	Possible	Best	Possible
Adjacent perineal organ involvement	Poor	Possible	Poor
Inguino-femoral adenopathy	Possible	Possible	Best
Upper urethra mucosal involvement	Poor	Possible	Poor
Upper vagina mucosal involvement	Poor	Possible	Poor
Bladder mucosal involvement	Poor	Possible	Poor
Bowel mucosal involvement	Poor	Possible	Poor
Fixation to pelvic bones	Possible	Best	Possible
Distant metastases (lymph node, bone)	Possible	Possible	Best
Distant metastases (liver)	Possible	Best	Possible
Distant metastases (lung)	Best	Poor	Possible
Ovarian cancer: pretreatment			
Early detection	Poor	Poor	Poor
Differential diagnosis (benign vs. malignant)	Possible	Best	Poor
Extent of tumor spread			
Ovary confined	Poor	Possible	Poor
Pelvis confined	Possible	Possible	Possible
Abdominal involvement	Possible	Possible	Possible
Retroperitoneal adenopathy	Possible	Possible	Best
Peritoneal or pleural effusion	Possible	Possible	Poor
Distant metastases (lymph node, bone)	Possible	Possible	Best
Distant metastases (liver)	Possible	Best	Possible
Distant metastases (lung)	Best	Poor	Possible
All cancers: post primary therapy			
Local or regional	Possible	Best	Poor
Lung	Best	Poor	Possible
Whole body	Possible	Poor	Best

[a]CT and MRI ratings assume that intravenous contrast is administered.

[b]PET-CT ratings assume that the PET exam is performed with a concurrent CT that is of sufficient beam strength to be of diagnostic quality (i.e., not a low-dose attenuation correction CT) either without or with intravenous contrast.

IMAGING MODALITIES

Ultrasound

Ultrasound (US) is a widely available imaging modality and can even be performed, if necessary, at the bedside. Another advantage is that no ionizing radiation is involved. Because it easily produces real-time imaging, US allows for rapid image-

guided procedures when targets can be visualized. It provides the best combination of spatial and soft tissue resolution and contrast of all the various imaging modalities. However, because US does not penetrate through many tissues, its ability to image deep visceral organs and evaluate large lesions is limited. A reliable field of view for US is typically ≤5 cm. As a diagnostic test, its reported performance is widely variable, likely secondary to operator dependence. As exam performance does not require volumetric imaging, sample representative images are obtained during the exam in most practices. Hence, reader variability cannot be assessed nor is post hoc exam review feasible.

Transvaginal ultrasound (TVUS) brings the transducer closer to the uterus and can afford excellent evaluation of the endometrium in a nonenlarged uterus. Sonohysterogram, which utilizes TVUS while distending the endometrial cavity with fluid, can be used to evaluate for focal endocavitary lesions such as polyps, subserosal fibroids, and adhesions.

Computed Tomography

Computed tomography (CT) is also widely available in clinical practice. It can image most tissue types (bone, soft tissue, fat, and air) with high spatial resolution and reproducibility. Because image acquisition is rapid, CT is useful even in patients unable to cooperate with the exam (e.g., obtunded, pediatric). Images are acquired axially relative to the patient's long axis, but multidetector CT technology allows for high-quality image reformation into other planes. The most important drawback is ionizing radiation exposure, and this should be considered when imaging young patients and those without a cancer diagnosis. Although the effective doses associated with a diagnostic CT have not been directly shown to pose a health risk, an added lifetime fatal cancer risk of approximately 1:1,000 in an adult undergoing an abdominal CT has been extrapolated from higher doses (1). The risk is thought to be additive with each exam. Overall, though, the risk–benefit analysis for symptomatic patients favors scanning, especially in those with a diagnosis of malignancy. In patients undergoing body CT exams, the mortality risk posed by the underlying clinical condition has been shown to be more than an order of magnitude greater than risk from CT-induced cancer (2).

Intravenous iodinated contrast is used to improve soft tissue contrast, which is otherwise markedly limited with CT. Intravenous contrast is necessary to evaluate the gynecologic pelvis, solid upper abdominal organs (e.g., liver, kidneys), and vascular structures. For cancer indications, contrast administration is considered standard of care unless contraindicated. Iodinated intravenous contrast is associated with an overall 3% incidence of allergic reaction. The vast majority of these reactions are mild and self-limiting (e.g., urticaria pruritus); however, up to 0.04% are severe (e.g., bronchospasm, anaphylaxis), requiring hospitalization (3). Acute kidney injury, especially in patients with renal insufficiency, can be another potential complication of intravenous contrast. Renal function deterioration is usually temporary, with a serum creatinine peaking typically 24 to 48 hours after contrast administration. Common predisposing risk factors include age >70 years, diabetes, congestive heart failure, and nephrotoxic medications.

Magnetic Resonance Imaging

Magnetic resonance imaging (MRI) affords the best soft tissue contrast of any of the radiologic modalities. Thus, tumor conspicuity with solid organs is optimized. Images can be primarily acquired in multiple planes, with the more recent scanner models allowing for acquisition of volumetric image datasets and post hoc high-resolution multiplanar reconstruction. MRI involves no ionizing radiation and hence does not confer a cancer risk to pediatric and pregnant patients. The most important disadvantage of MRI is its long image acquisition time. Most examinations take 20 to 40 minutes, during which time the patient lies in an enclosed scanner. Inability of the patient to lie still or to follow instructions hinders successful image acquisition. A wider-bore or "open" scanner is an option if the patient is claustrophobic. But for abdominopelvic imaging, the resulting images are markedly lower in signal and, because of longer patient table times, are often degraded by motion. MRI uses an electromagnetic field and is therefore contraindicated in patients with pacemakers, cochlear implants, certain vascular clips, metallic objects in the eye, and neural stimulators. Patients are also screened for other indwelling foreign bodies such as orthopedic hardware, surgical clips, and intrauterine devices prior to the exam, and

its compatibility with a high-field-strength magnet is ascertained prior to scanning. Even when deemed safe, most metallic foreign bodies included within the field of view result in distortion and degradation of the image quality.

A gadolinium-based contrast agent can be administered to better evaluate the solid viscera and improve the conspicuity of neoplasms. However, because MRI inherently affords better soft tissue contrast than CT, even a noncontrast exam, if that is the only possible option, yields diagnostic information. Intravenous gadolinium is associated with a much lower incidence of allergic reaction than iodinated contrast (0.07% vs. 3%) (4), with severe life-threatening reactions being extremely rare. However, in patients with renal failure, the administration of some gadolinium contrast agents has been associated with nephrogenic systemic fibrosis, a syndrome resulting in progressive fibrosis of the skin, joints, eyes, and organs, which is uniformly fatal.

Positron Emission Tomography

Positron emission tomography (PET) uses a physiologically active tracer and therefore provides functional information. The most commonly used tracer is 2-[^{18}F]-fluoro-2-deoxy-D-glucose (FDG), which is a glucose analog and therefore approximates tissue metabolism. The uptake of FDG at pathologic sites is dependent on tracer availability, and careful attention to patient preparation is required to ensure that tracer preferentially localizes to tumor rather than to normally hypermetabolic tissue (e.g., skeletal muscle, brown fat). The patient is instructed to avoid strenuous exercise and activity the day before the examination and to fast 4 to 6 hours prior to FDG administration to keep insulin levels low. Serum glucose is measured, as the exam is unlikely to yield accurate image data if values exceed 200 mg/dL. Immediately prior to and after FDG administration, patients are kept comfortably warm to minimize physiologic brown fat activation. Image acquisition typically requires 30 minutes, necessitating a degree of patient cooperation.

FDG-PET does not have the same spatial resolution or soft tissue contrast as the other imaging modalities, but this is mitigated by fusing PET images with concurrently acquired anatomic images (e.g., PET-CT). Accurate tracer localization to minimize false-positive and false-negative errors requires that the concurrent CT images be acquired with sufficient beam energy to be anatomically interpretable (5). Abdomen and pelvis represents a particularly common site for mislocalization errors, as this is the body part where tracer normally accumulates and is excreted through mobile peristaltic organs (e.g., urinary collecting system, bowel). However, as diagnostic-quality anatomic imaging is not mandated by practice standards (6), the CT image quality is a major source of variability in PET-CT practice (7).

Disadvantages of FDG-PET are false-positive results from inflammatory or infectious etiologies, reactive lymphadenopathy, chronic inflammatory disorders (e.g., sarcoid), and tissue response following surgery, radiotherapy, and chemotherapy. Posttreatment changes vary greatly in their degree and extent, but can be expected to contribute to PET appearances in the first 6 to 8 weeks and have been described as a source for interpretation error beyond 6 months. PET provides limited spatial resolution, which can result in false-negatives. Modern clinical PET scanners have a resolution limit of 4 mm (full width at half maximum [FWHM]); effectively, small structures up to 0.7 to 10 mm in diameter may not be reliably detected (8).

UTERINE CERVICAL CANCER

Detection

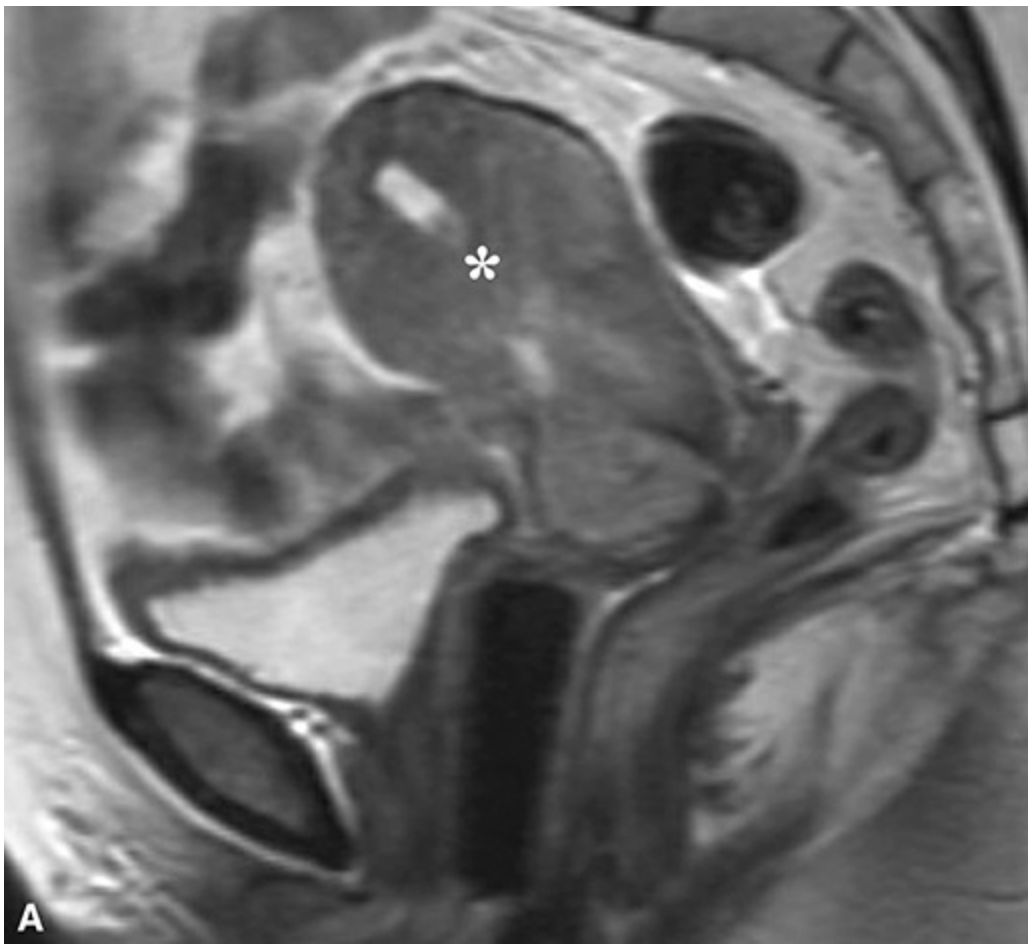
Imaging plays no role in the detection of cervical cancer, which is usually detected at Pap smear or by physical examination. On occasion, it will be detected on TVUS for abnormal vaginal bleeding in a patient who has not been undergoing screening.

Primary Treatment Planning

The Federation of Gynecology and Obstetrics (FIGO) staging of cervical cancer is based on clinical findings at physical exam (9). Imaging is not explicitly described, although its use is implied in assessment of pelvic sidewall involvement, hydronephrosis, and distant disease. Moreover, for advanced (beyond stage IB) disease, lymphadenopathy (while not included in FIGO staging) is a major factor in treatment planning. Therefore, in its 2009 revision, the FIGO staging committee has encouraged the incorporation of cross-sectional imaging techniques into the evaluation of patients with cervical cancer, where available (10). The National Comprehensive Cancer Network (NCCN) practice guidelines for cervical cancer work-up include chest radiography, CT or PET-CT, and MR imaging as indicated (11).

Two standard primary treatment options for invasive cervical cancer are radical hysterectomy and lymphadenectomy in early-stage disease (IA, IB1, and IIA1), and primary radical radiotherapy with concurrent administration of platinum-based chemotherapy for patients with bulky IB2/IIA2 disease (tumors greater than 4 cm) or those with locally advanced disease (stage IIB or greater). Imaging findings that usually triage a patient to chemoradiation are tumor size and parametrial extension, best assessed with MRI, and lymphadenopathy, best assessed with PET-CT (**Table 10.1**). The choice of optimal primary therapy that minimizes morbidity is achieved when both tests are included in the pretreatment evaluation (12).

MRI is the best imaging modality for visualizing the extent of primary tumor in the soft tissues of the central pelvis (**Fig. 10.1**). It can determine the tumor location and size, presence of invasion into the parametria, pelvic sidewall, or adjacent organs. An intergroup multicenter study in the United States showed that in patients with early-stage tumor intended for curative radical hysterectomy MRI had a sensitivity and specificity for detecting disease stage IIB or higher (i.e., parametrial tumor extension) of 53% and 75%, respectively, compared with clinical assessment, which demonstrated sensitivity and specificity of 29% and 99%, respectively (13). For measuring tumor size, MR imaging was shown to be superior to CT or clinical examination (14).



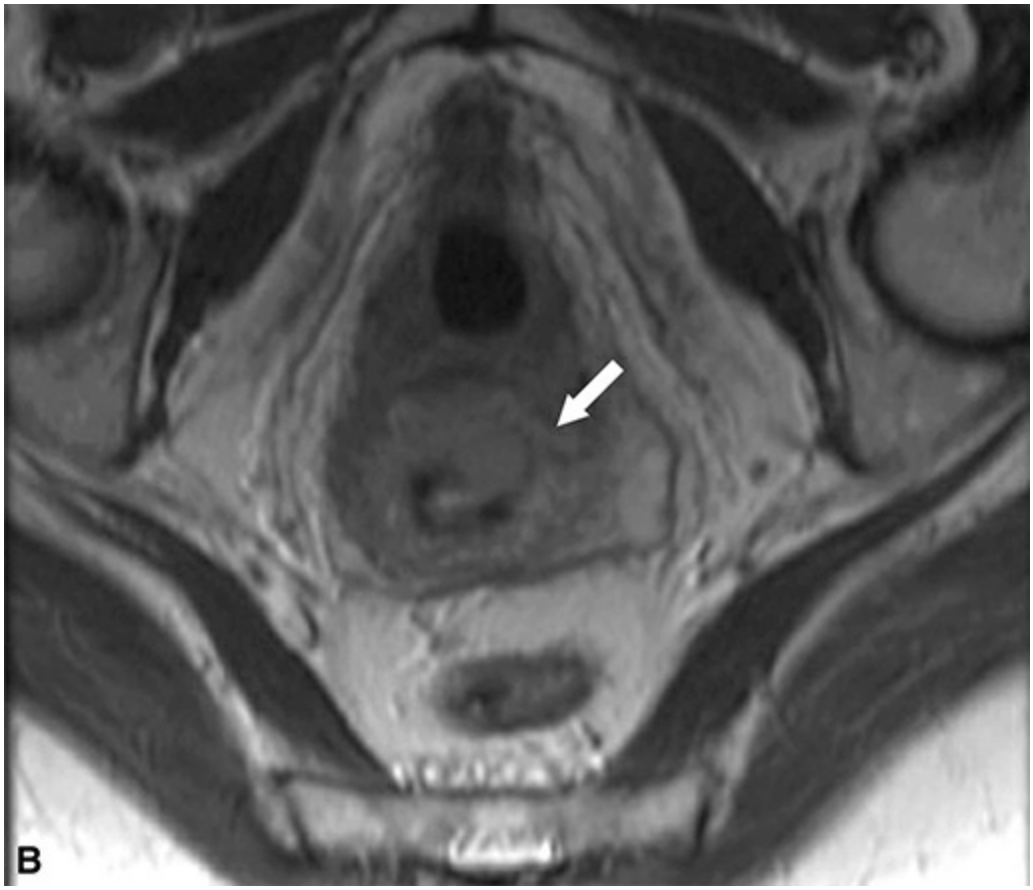


Figure 10.1 Cervical cancer pretreatment MRI. Sagittal (A) and axial (B) FSE T2-weighted images of the pelvis in a 55-year-old woman with squamous cell carcinoma of the cervix demonstrate a tumor measuring 5.5 cm extending into the uterine corpus (asterisk) and into the left parametria (arrow). Patient was classified as stage IIB and treated with chemoradiation. FSE, fast spin-echo.

The presence of metastatic lymph nodes is the major factor driving treatment planning and is the best indicator of prognosis. For patients with clinically visible tumor, FDG-PET-CT is more sensitive than either CT or MRI in the evaluation of nodal involvement (**Fig. 10.2** and **Table 10.2**) (13,15–17,27). A recent meta-analysis comparing the diagnostic performance of PET or PET-CT, MRI, and CT in the detection of metastatic lymph nodes in patients with cervical cancer found that, in a patient-based data analysis, pooled sensitivity and specificity were highest at 82% and 95%, respectively, for PET or PET-CT, 50% and 92%, respectively, for CT, and 56% and 91%, respectively, for MRI. In region- or node-based data analysis, sensitivities of PET or PET-CT (54%) and CT (52%) were significantly higher than that of MRI (38%), while specificities of PET or PET-CT (97%) and MRI (97%) were higher than that of CT (92%) (28). Another meta-analysis also found that PET had a higher sensitivity (75%) and specificity (98%) than did MRI (56% and 93%, respectively) or CT (58% and 92%, respectively) (15).

Figure 10.2 Cervical cancer lymphadenopathy detected on pretreatment PET-CT. Axial PET (A) of a 67-year-old woman with squamous cell carcinoma of the cervix demonstrates bilateral pelvic sidewall hypermetabolic foci (arrows) that localize on CT (B) to pelvic sidewall lymph nodes (arrows), most of which measure <1 cm in short axis. Biopsy confirmed lymph node metastases, and the patient was treated with chemoradiation.

TABLE 10.2 Diagnostic Performance in Detection of Lymphadenopathy

Disease and Modality[a,b]	Sensitivity (%)	Specificity (%)
Uterine cervical cancer		
CT (13, 15)	31 – 57	92 – 97
MRI (13, 15)	37 – 55	93 – 94
PET-CT (16, 17)	73 – 100	97 – 99
Uterine endometrial cancer		
CT (18)	45	88
MRI (19, 20)	59 – 72	93 – 97
PET-CT (19, 20)	67 – 74	93 – 99
Vulvar cancer		
CT (21)	60	90
MRI (22 – 24)	52 – 89	85 – 91
PET-CT (25, 26)	50 – 92	91 – 100

Beyond the abdominopelvic nodes, FDG-PET also improves initial staging in advanced disease by revealing unexpected sites of distant disease such as supraclavicular lymph nodes. PET or PET-CT has been found to alter management in a significant number of patients with advanced disease (stage IIB–IVB) at presentation (29). In addition, the extent of lymph node involvement on PET and PET-CT has been shown to be a strong predictor of disease-specific survival. The risk of recurrent disease increases incrementally on the basis of the most distant level of PET lymph node involvement, with a hazard ratio of 2.40 (95% confidence interval [CI], 1.63 to 3.52) for pelvic, 5.88 (3.80 to 9.09) for para-aortic, and 30.27 (16.56 to 55.34) for supraclavicular involvement (30).

The ability to detect small-volume disease is especially important if fertility-preserving radical trachelectomy and lymphadenectomy is being contemplated (**Fig. 10.3**). Eligibility requirements include tumor smaller than 2 cm, distance from tumor margin to internal cervical os of more than 1 cm, and absence of lymph node metastases. MRI assesses the extent of local tumor with high accuracy and is routinely used for patient selection (31). PET-CT is also used in many institutions to evaluate for lymphadenopathy. But as the exam performs with low (32%) sensitivity in early-stage disease, its purpose is to identify ineligible candidates (32).

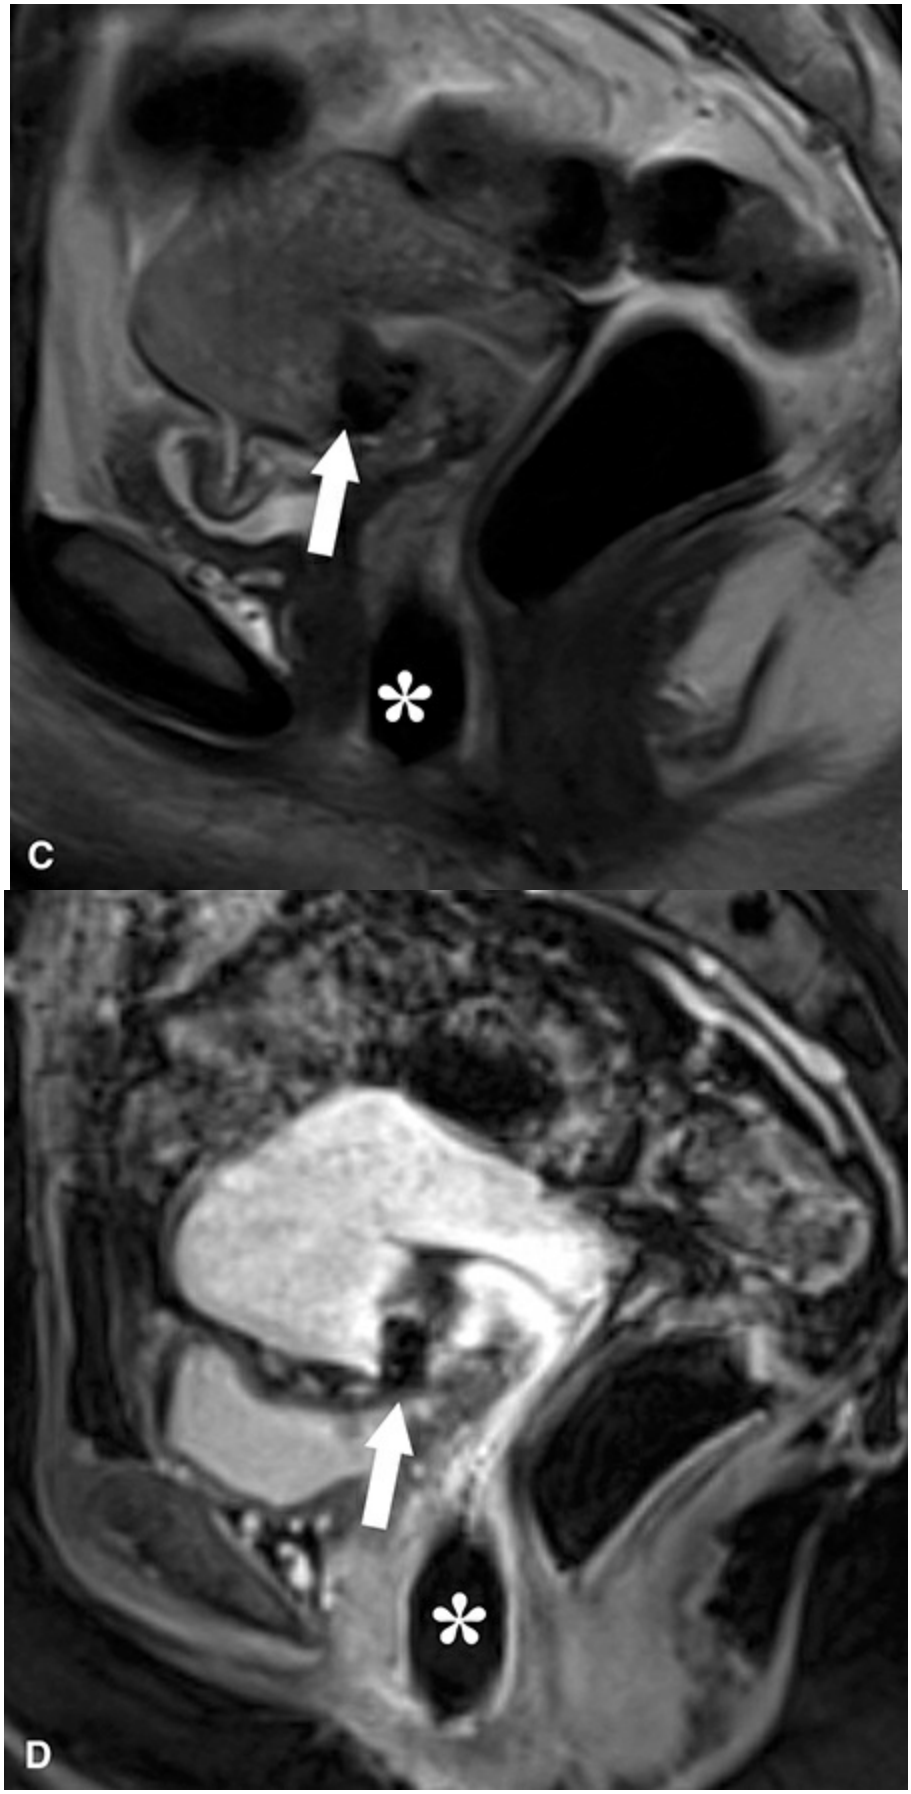

Figure 10.3 Pre- and posttrachelectomy pelvic MRI. Sagittal FSE T2-weighted (A and C) and postgadolinium T1-weighted with fat saturation (B and D) images with a tampon

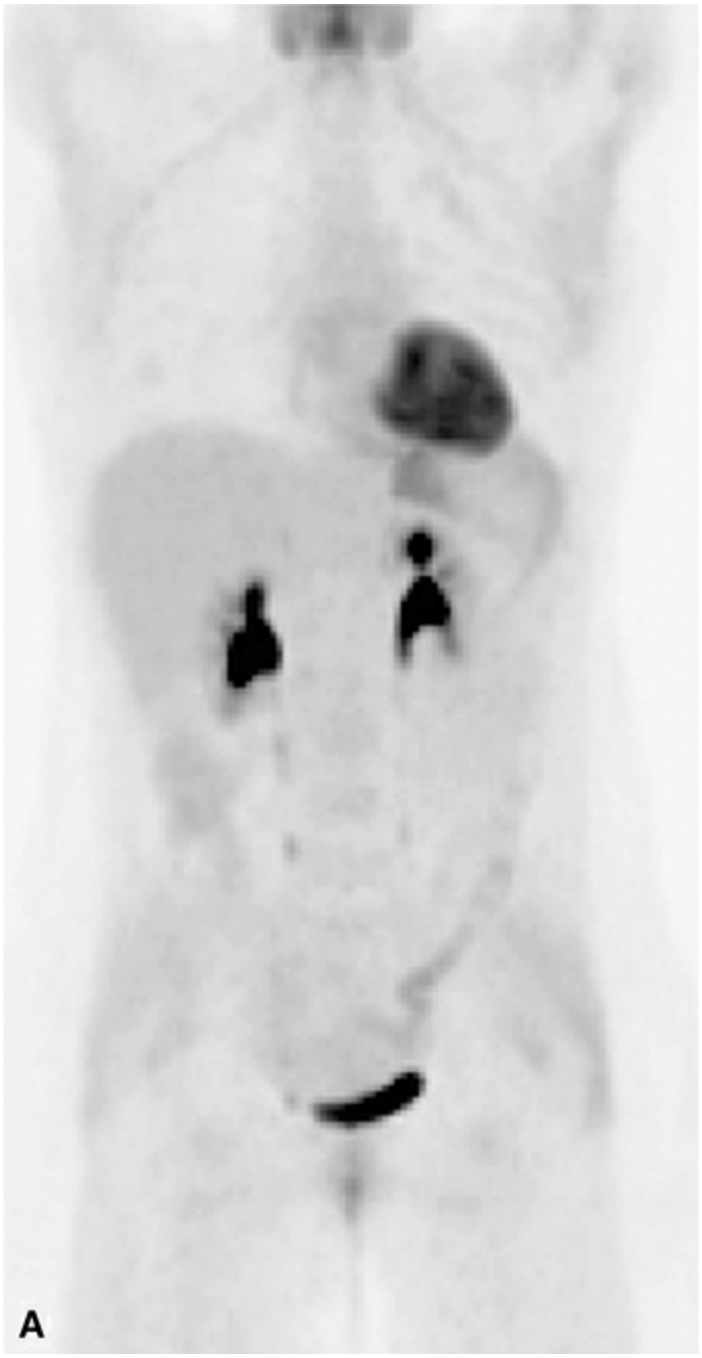
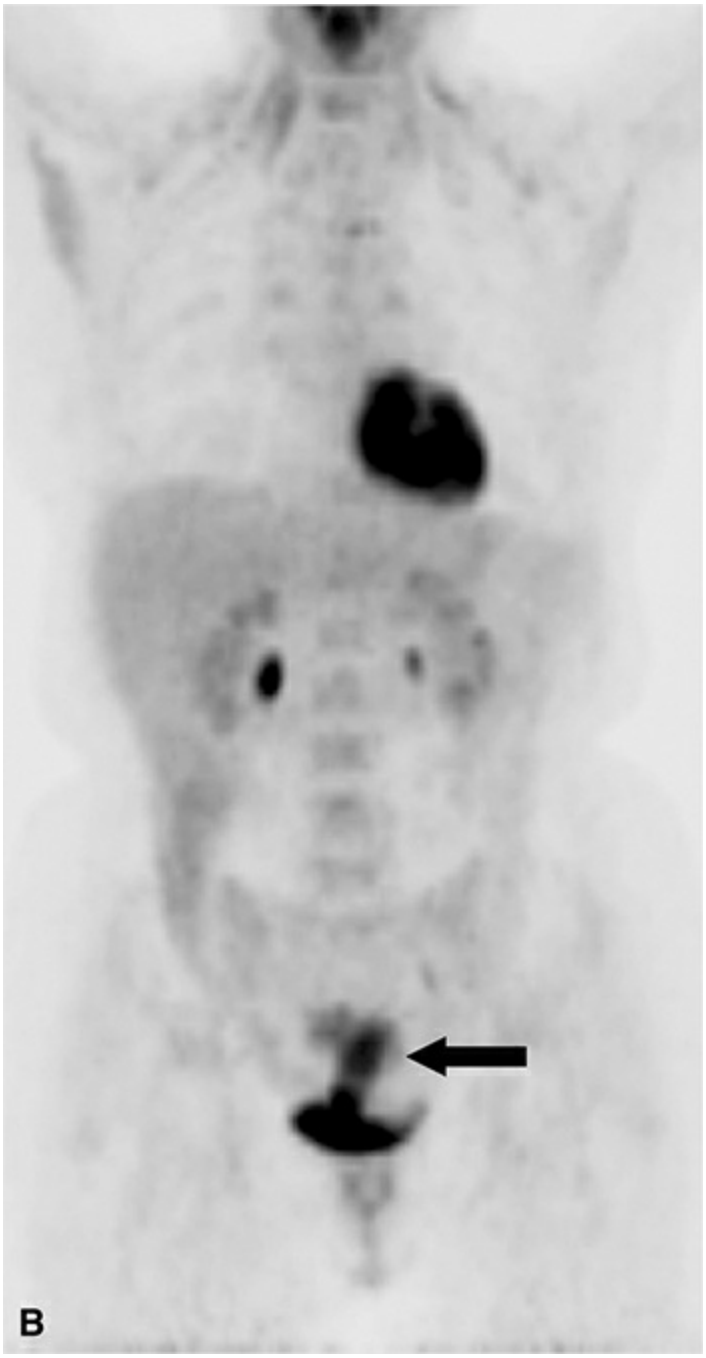
(asterisk) in the vagina in a 31-year-old woman show no visible tumor following a LEEP of a 1.2-cm cervical adenocarcinoma (A and B). Following trachelectomy, the resection margin is indicated by the susceptibility artifact (arrow) from sutures. LEEP, loop electrosurgical excision procedure, FSE, fast spin-echo.

Post Primary Therapy

Recurrent cervical cancer usually occurs early in the course of disease, with 60% to 70% of cases occurring within 2 years of commencing treatment (33). No consensus recommendations advocate surveillance imaging. However, because ^{18}F-FDG-PET results have been shown to be prognostic of survival, the NCCN guidelines state that a single PET-CT examination can be performed 3 to 6 months after chemoradiation (**Fig. 10.4**). Patients with new, residual, or no disease on posttreatment FDG-PET imaging demonstrate a 3-year progression-free survival of 0%, 33%, and 78%, respectively (34), and a 5-year overall survival of 0%, 46%, and 92%, respectively (35).



A



B

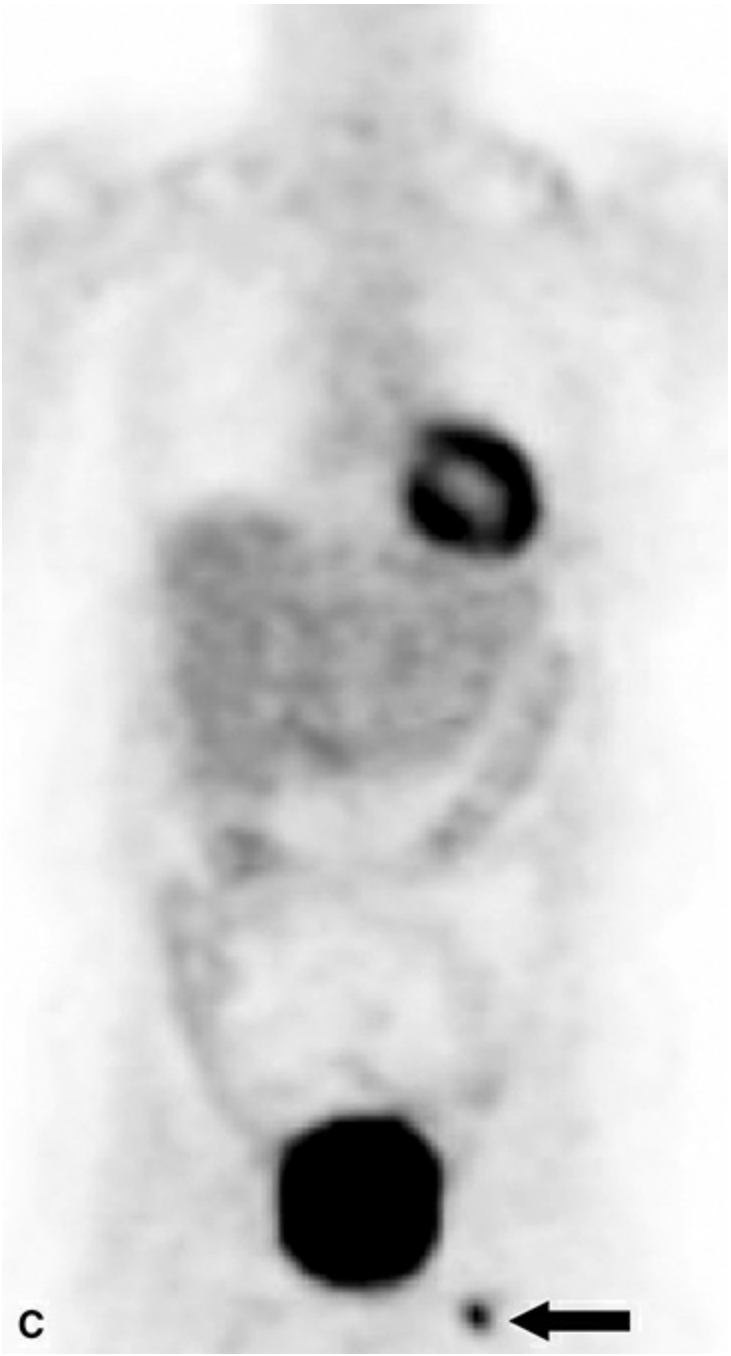


Figure 10.4 Posttherapy PET for cervical cancer prognosis. Coronal whole-body PET images in three different women obtained 3 to 4 months postchemoradiotherapy for advanced cervical cancer demonstrate no residual (A), persistent (B, arrow), and new (C, arrow) disease. Corresponding predicted 3-year progression-free survival rates are 78%, 33%, and 0%, respectively.
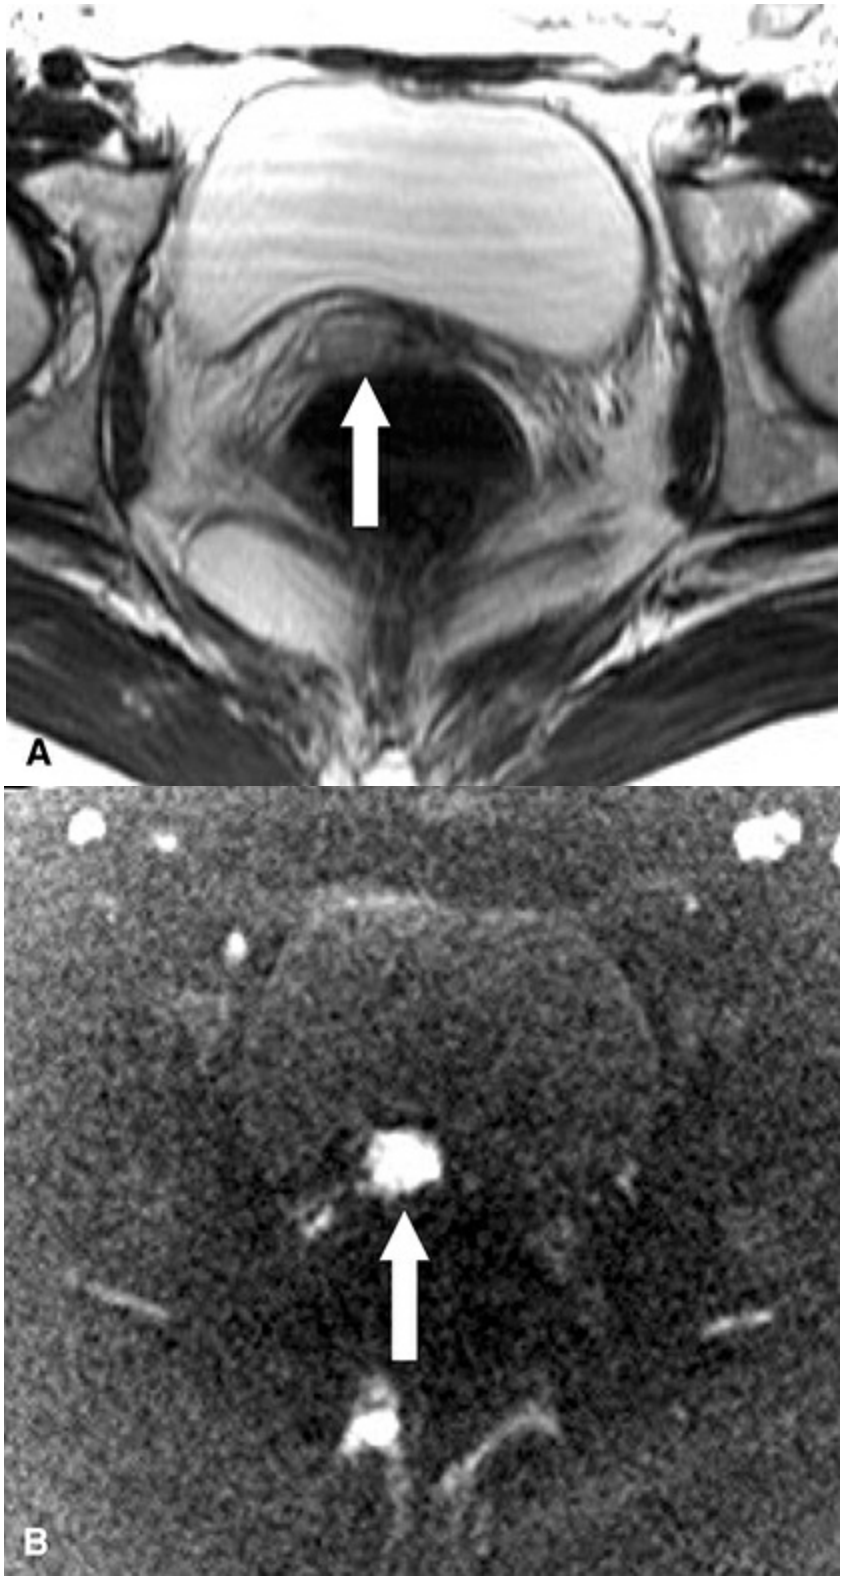
Source: Schwarz JK, Siegel BA, Dehdashti F, et al. Association of posttherapy positron emission tomography with tumor response and survival in cervical carcinoma. JAMA. 2007;298(19):2289 - 2295.

Imaging is typically undertaken if clinical symptoms or signs suggest recurrence. Choice of exam is driven by the anatomic site(s) of suspected disease (**Table 10.1**). MRI is more accurate than PET-CT for detection of small-volume central pelvic recurrence that would be amenable to salvage resection (**Fig. 10.5**). However, particularly within the first 6 months after chemoradiation, MRI does not reliably differentiate posttreatment effects from recurrent tumor (36). Accuracy improves in patients with a remote history of radiation (>1 year), with one study reporting a sensitivity of 86%

and a specificity of 94% for the detection of recurrent cervical cancer by MRI (37). Whole-body imaging with PET-CT is also routinely performed prior to pelvic exenteration to evaluate for occult distant metastases.



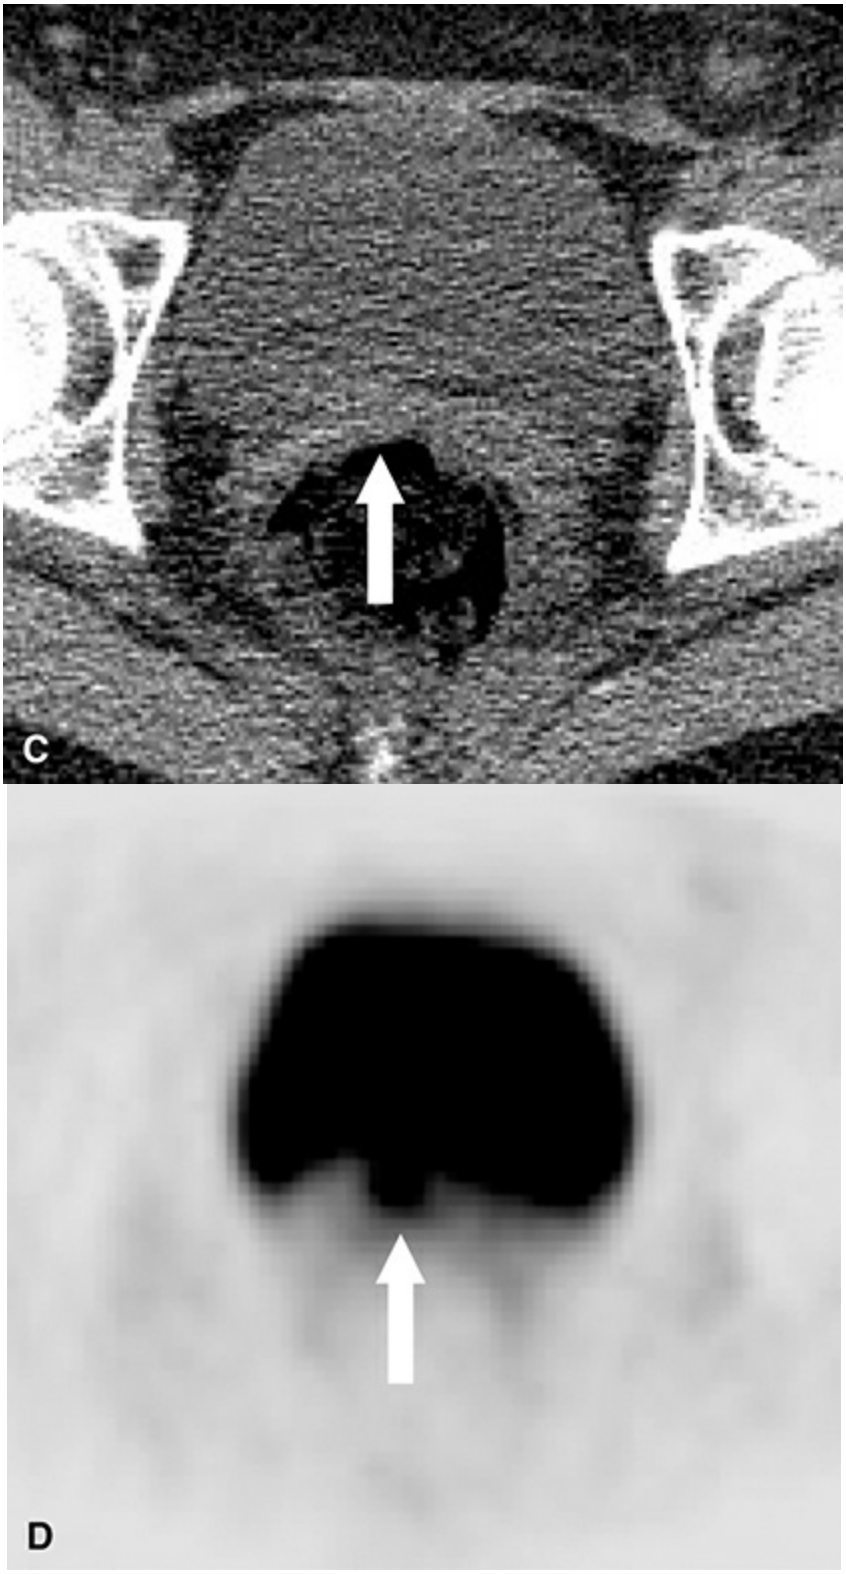


Figure 10.5 Local recurrence of cervical cancer detected on MRI vs. PET-CT. Axial FSE T2 (A) and diffusion (B) MR images demonstrate a 1.3 cm nodule above the vaginal vault (arrow) in a 34-year old woman with stage IB adenocarcinoma of the cervix treated 2 years ago. This nodule is much less apparent on the corresponding CT (C) image (arrow), which lacks tissue contrast and on the PET image (D) where the signal (arrow) is obscured by bladder tracer accumulation. Biopsy demonstrated recurrence.

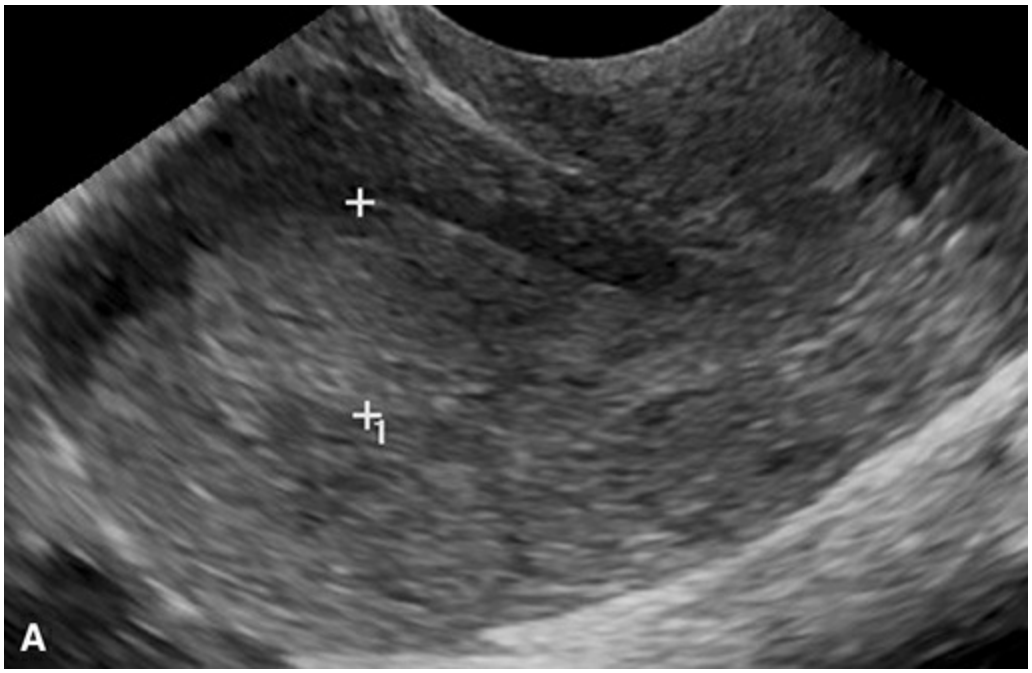
Following trachelectomy, surveillance with pelvic MRI at 6, 12, and 24 months has been suggested to evaluate for

recurrent tumor (38). Given that the uterus or the pelvic sidewall represent all the sites reported for posttrachelectomy recurrence (39,40), the choice of exam is logical. However, whether surveillance imaging is effective in early detection is yet to be demonstrated.

UTERINE ENDOMETRIAL CANCER

Detection

In postmenopausal women with abnormal vaginal bleeding, TVUS is used to identify those who need further evaluation with endometrial biopsy to assess for cancer (**Fig. 10.6**). Endometrial appearance is evaluated by both thickness and morphology. A large meta-analysis including 35 studies with 5,892 women demonstrated that ≥5 mm thickness defined as abnormal demonstrated sensitivity of 96% for endometrial cancer, whether or not the women were on hormone replacement therapy (41). Women with a 10% pretest probability of endometrial cancer and a negative TVUS had a posttest probability of endometrial cancer of only 1%. Thus, TVUS demonstrates very high sensitivity, and the likelihood ratio with a negative TVUS exam is much lower than that of more invasive techniques (42–44) (**Table 10.3**). It serves as an excellent screening test to obviate the need for endometrial biopsy in the majority of women with benign causes of postmenopausal bleeding.



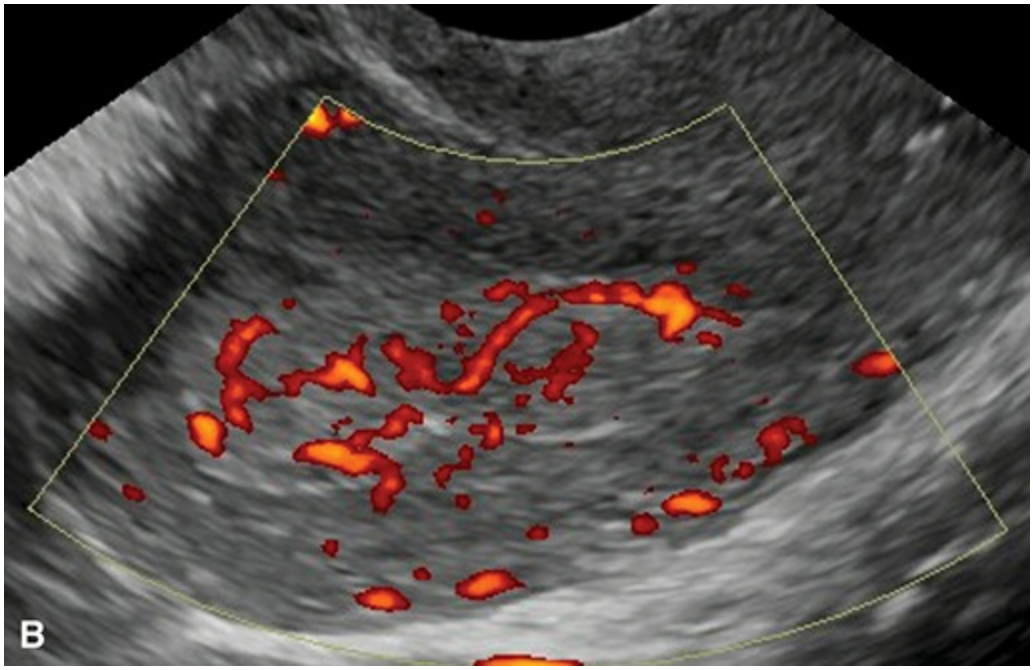


Figure 10.6 Endometrial cancer detected on transvaginal US. Sagittal gray-scale (A) and power Doppler (B) images of the uterus in a 65-year-old woman with postmenopausal bleeding demonstrate an abnormally thickened endometrium (calipers) measuring 10.9 mm and internal diffuse hypervascularity. Biopsy revealed endometrioid adenocarcinoma.

TABLE 10.3 Endometrial Cancer Detection in Women with Postmenopausal Vaginal Bleeding

Modality	Sensitivity (95% CI)	Specificity (95% CI)	LR of Positive Test	LR of Negative Test
TVUS not on HRT (41)	96% (94–98)	92% (90–94)	11.9	0.05
TVUS on HRT (41)	96% (94–98)	77% (75–79)	4.0	0.12
Nonfocal biopsy (42)	NA	NA	66.5	0.14
Hysteroscopy (43)	86% (84–89)	99% (99–99)	60.9	0.15

HRT, hormone replacement therapy; NA, not available; LR, likelihood ratio.

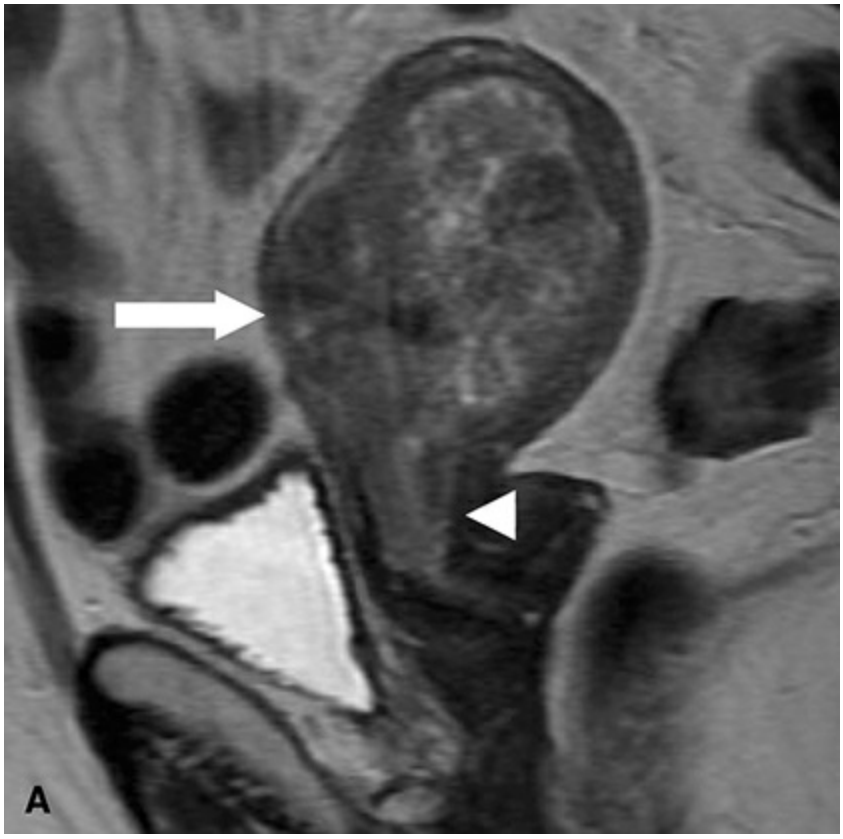
As the role of TVUS is to screen women with postmenopausal bleeding for further work-up, the test has been optimized for high sensitivity but with moderate to low specificity. Thus, endometrial thickness cutoff ≥5 mm demonstrates low specificity, ranging from 59% to 63% (41,45), especially in women on hormone replacement therapy. Conversely, a normal endometrial thickness does not exclude endometrial cancer, as the test is predicted to miss 4 in 100 cancers. A study of women with postmenopausal bleeding who were not on tamoxifen found that half of the patients with endometrial cancer had an endometrial thickness between 3 and 4 mm (46). Therefore, even in patients with normal endometrial thickness, any persistent or recurrent bleeding, especially in women with clinical risk factors for cancer, should be further evaluated to definitely identify the cause of the symptoms.

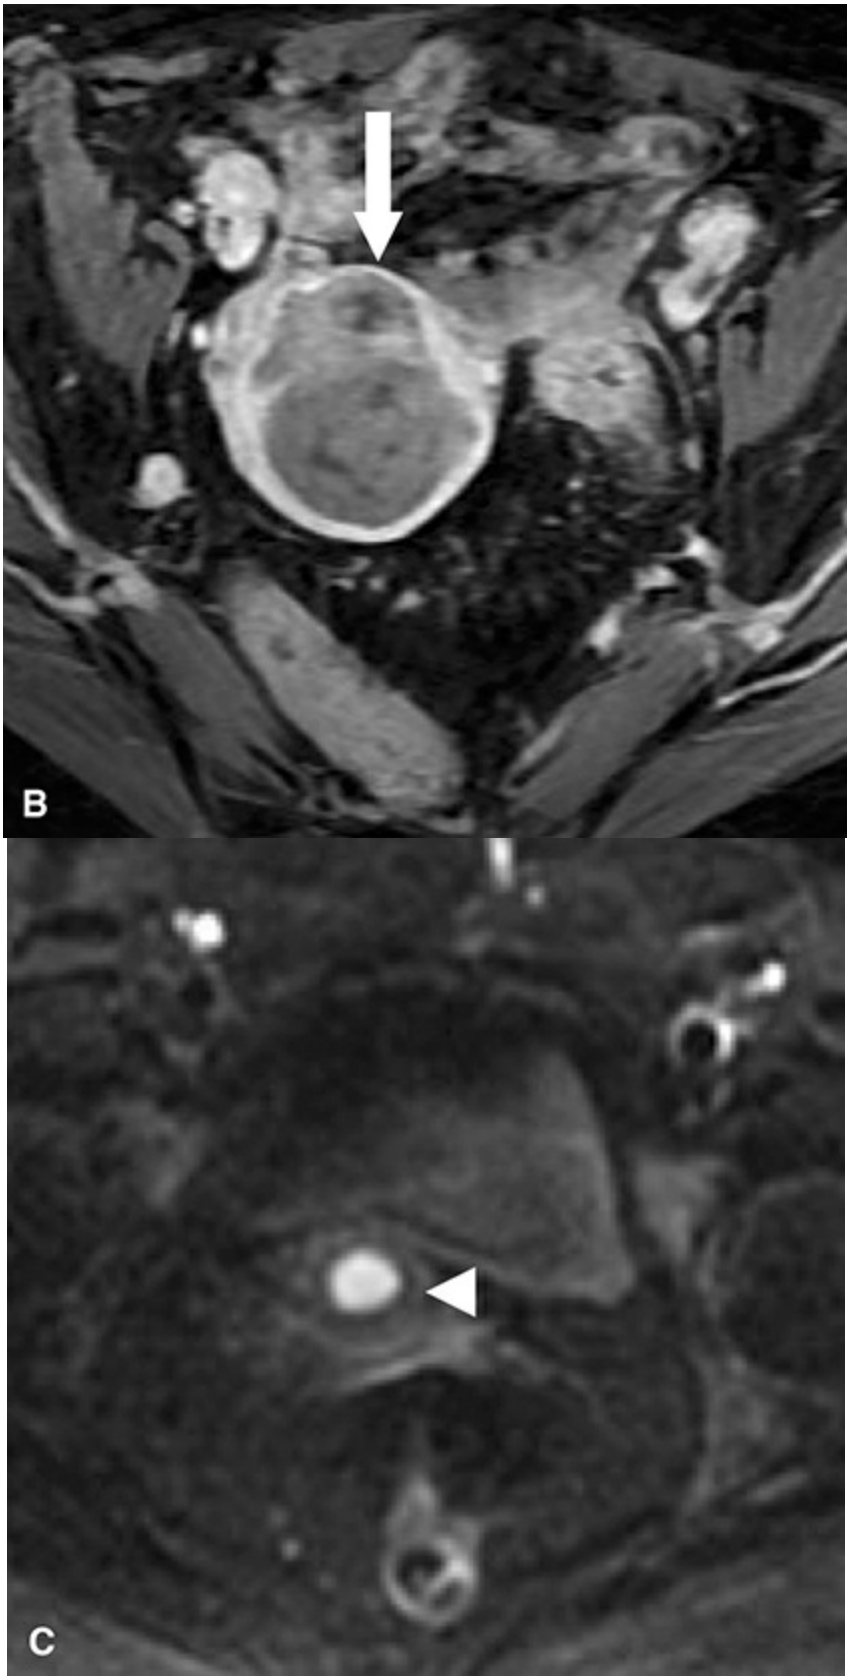
In premenopausal women with abnormal bleeding, endometrial thickness measurements with TVUS are less useful for cancer detection (47). MRI plays only a limited role in cancer detection and is reserved for women in whom TVUS or biopsy is precluded because of cervical or vaginal stenosis.

Primary Treatment Planning

Complete FIGO staging of endometrial cancer calls for a total abdominal hysterectomy (TAH), bilateral salpingo-oophorectomy (BSO), peritoneal washings, and retroperitoneal lymph node dissection (9). Because lymphadenectomy can incur perioperative complications and long-term morbidity such as lymphedema, some centers have chosen to selectively perform the procedure only when the primary tumor demonstrates high-risk features (48). Imaging serves in surgical planning to evaluate for nodal and distant metastases. The NCCN guidelines for endometrial cancer work-up specify chest imaging and also consideration of MRI, CT, and FDG-PET in patients suspected to have extrauterine disease (49).

Because features of the primary tumor predict the likelihood of nodal metastases, sites with expertise in frozen section diagnosis often choose to forego imaging and make the decision to perform lymphadenectomy intraoperatively, based on the hysterectomy specimen (48). However, many institutions opt for preoperative MR imaging to evaluate the primary tumor size and intrauterine spread that predict whether lymphadenectomy will likely be required (**Fig. 10.7**). A meta-analysis found that contrast-enhanced MRI, CT, or US performed better than their noncontrast counterparts in detecting deep myometrial invasion (50). In a multicenter audit of 775 cases over a 12-month period in the United Kingdom, MRI demonstrated a sensitivity and specificity of 77% and 88%, respectively, for detecting deep myometrial invasion; 42% and 97%, respectively, for detecting cervical stromal invasion; and 64% and 96%, respectively, for diagnosing pelvic lymphadenopathy (51).





B
C

Figure 10.7 Endometrial cancer pretreatment MRI. Sagittal FSE T2-weighted (A), axial postgadolinium T1-weighted (B), and axial diffusion-weighted (C and D) images of a 71-year-old woman with endometrioid adenocarcinoma of the endometrium demonstrate an 8-cm tumor that extends >50% thickness into the anterior myometrium (arrow) and grows into the cervix (arrowhead). Note that intrauterine tumor extent is best seen only after contrast administration or with diffusion-weighted imaging. Imaging findings were confirmed on surgical pathology. FSE, fast spin-echo.

MRI is also used in the minority of endometrial cancer patients in whom hysterectomy is not intended as the primary therapy. It is used to screen patients with low-grade endometrial carcinoma for fertility-sparing treatment (52). The purpose of imaging in such cases is to evaluate for evidence of myometrial invasion that would preclude treatment with high-dose progesterone. In patients with medical comorbidities that preclude surgery or in those with tumor invading the bladder or bowel (stage IVA), MRI delineates fields for radiotherapy, which represents the alternative initial therapy.

CT has no role in defining tumor spread in the central pelvic soft tissues. Contrast-enhanced CT can be useful in evaluating for nodal (stage IIIC) and distant metastases (stage IVB), when integrated FDG-PET-CT, a more accurate modality for this purpose, is not available. It more reliably detects distant parenchymal metastases, peritoneal implants, and malignant ascites (stage IVB) compared with MRI, the resolution of which is sometimes compromised by bowel or patient motion (53).

Most endometrial cancers are abnormally hypermetabolic on PET-CT; however, low-grade cancers can demonstrate little-to-no FDG avidity (54). Conversely, nonmalignant endometrial conditions, as in the proliferative phase of menstruation or menses, infection, and benign tumors (55), can demonstrate increased FDG avidity and should not be mistaken for cancer. For detection of lymphadenopathy, PET-CT is more sensitive than CT or MRI (**Fig. 10.8** and **Table 10.2**) (18–20) as it allows for detection of tumor involvement in lymph nodes that measure <1 cm in short axis, the size threshold for morphologic assessment of lymphadenopathy. Nevertheless, resolution is a limiting factor for PET-CT sensitivity: 17% for nodes ≤4 mm, 67% for nodes 5 to 9 mm, and 93% for nodes ≥10 mm (56). Consequently, although detection of FDG-avid nodes allows for surgical planning and resection for histologic confirmation, staging lymphadenectomy should still be performed in patients with primary tumors with high-risk features, without evidence of

extrauterine disease, for detection of micrometastases.

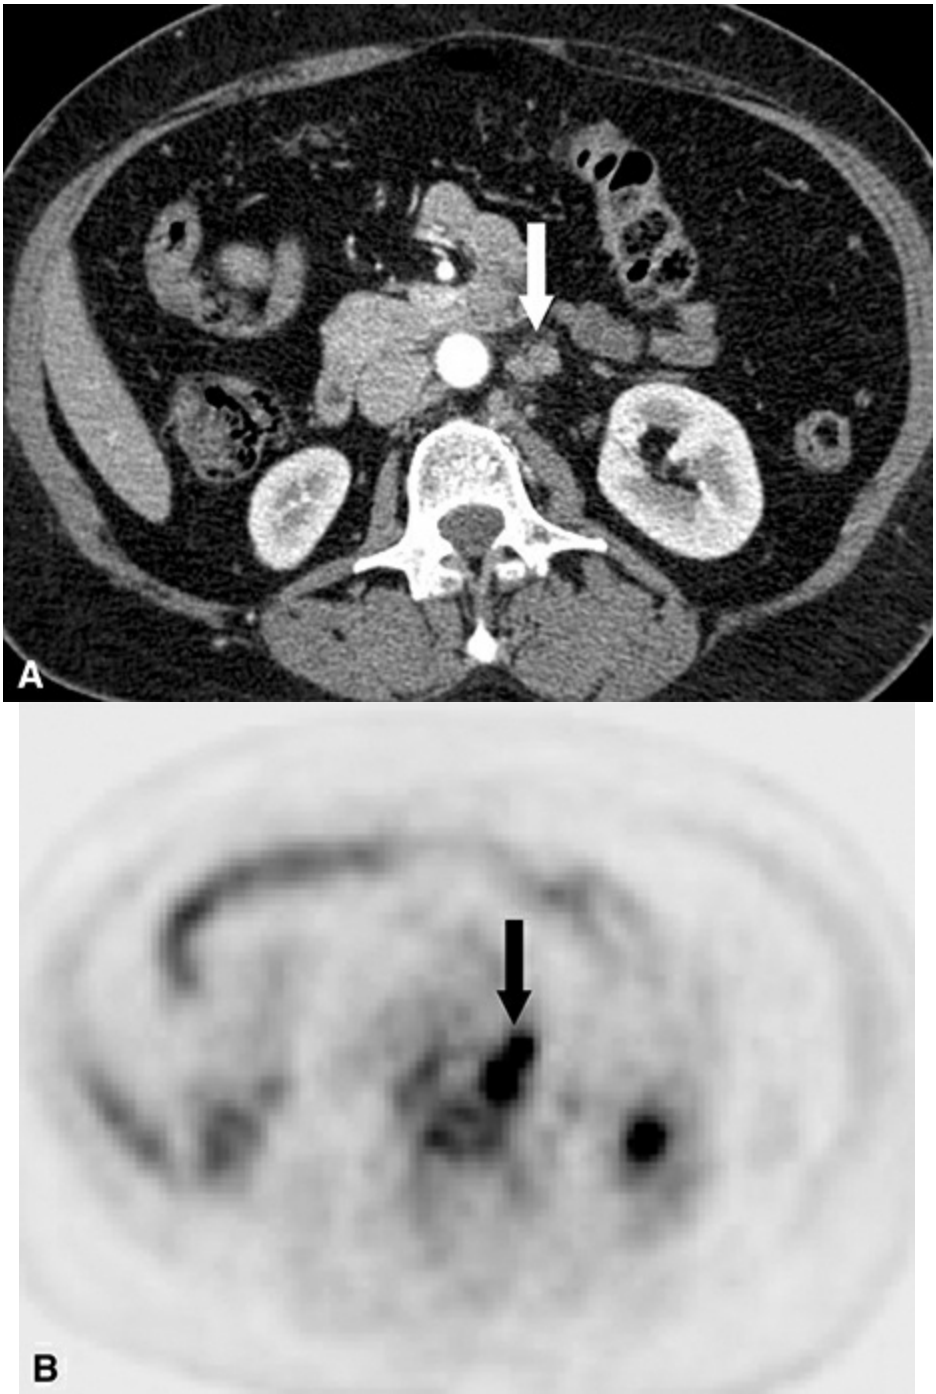


Figure 10.8 Endometrial cancer lymph node metastases detected on pretreatment PET-CT. Contrast-enhanced CT (A) and axial PET (B) images of a 60-year-old woman with adenocarcinoma (mixed serous and endometrioid cell types) of the endometrium demonstrate left para-aortic lymph nodes that measure < 1 cm short axis but appear hypermetabolic (arrow). Metastases were confirmed with surgical resection.

Between 3% and 5% of patients with high-grade tumor histology harbor disease beyond the uterus and abdominopelvic nodes, such as intrathoracic or bony metastases (stage IVB) (57). The added value of FDG-PET-CT in this setting is to detect unsuspected distant metastatic deposits, for which it has been found to have a sensitivity of 100% and a specificity of 94% (**Fig. 10.9**) (58) Such findings would triage a patient away from the morbidity of an unnecessarily aggressive

staging operation (59). PET-CT has been shown to be more sensitive than CT for detection of distant disease that alters the treatment plan to minimize morbidity (59).

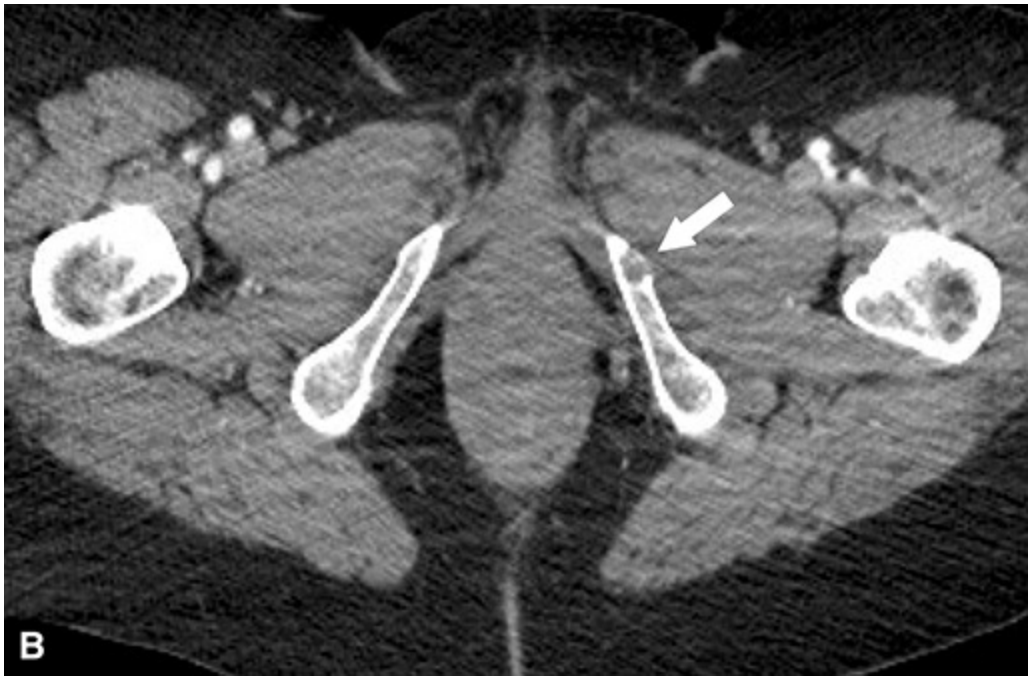

Figure 10.9 Endometrial cancer with distant metastases detected on pretreatment PET-CT. Coronal PET image (A) of a 73-year-old woman with malignant mixed Mullerian tumor of the endometrium demonstrates multiple hypermetabolic pelvic lesions corresponding to the primary tumor (asterisk) and left pelvic lymphadenopathy (arrowhead). A hypermetabolic focus low in the pelvis at the level of the perineum (arrow) localizes on the CT image (B) to a left inferior pubic ramus metastasis (arrow) confirmed with biopsy. Patient was classified as stage IV.

Post Primary Therapy

The use of imaging and its impact on the follow-up of endometrial cancer patients are not well defined. Endometrial cancer has a low rate of recurrence of 4% to 16% (60). Following primary surgery, 64% of recurrences occur within 2 years and 87% within 3 years. The most common sites of recurrence are lymph nodes (46%), best detected with PET-CT, and the vaginal vault (42%), best detected with pelvic exam (61). Less frequently, recurrent disease may manifest as peritoneal carcinomatosis (28%) or distant metastases in liver, lung, or bone (61). Although 20% present with clinically occult metastases (62), the role of surveillance imaging in patients at high risk for recurrence remains controversial.

Imaging is indicated in patients with clinically suspected recurrence. MRI is used to plan salvage surgery or radiotherapy for tumor in the central pelvis (**Fig. 10.10**). Whole-body PET or integrated PET-CT demonstrates 92% to 93% sensitivity and 93% to 100% specificity in detecting recurrent disease (63,64). A study measuring the added value of FDG-PET in addition to CT or MRI for posttherapy surveillance found that FDG-PET showed better diagnostic performance (accuracy 93%) compared with combined conventional imaging (accuracy 85%) and tumor markers (accuracy 83%) (64). Thus, if loco-regional therapy for recurrence is being contemplated, PET-CT is indicated to exclude occult distant metastases.

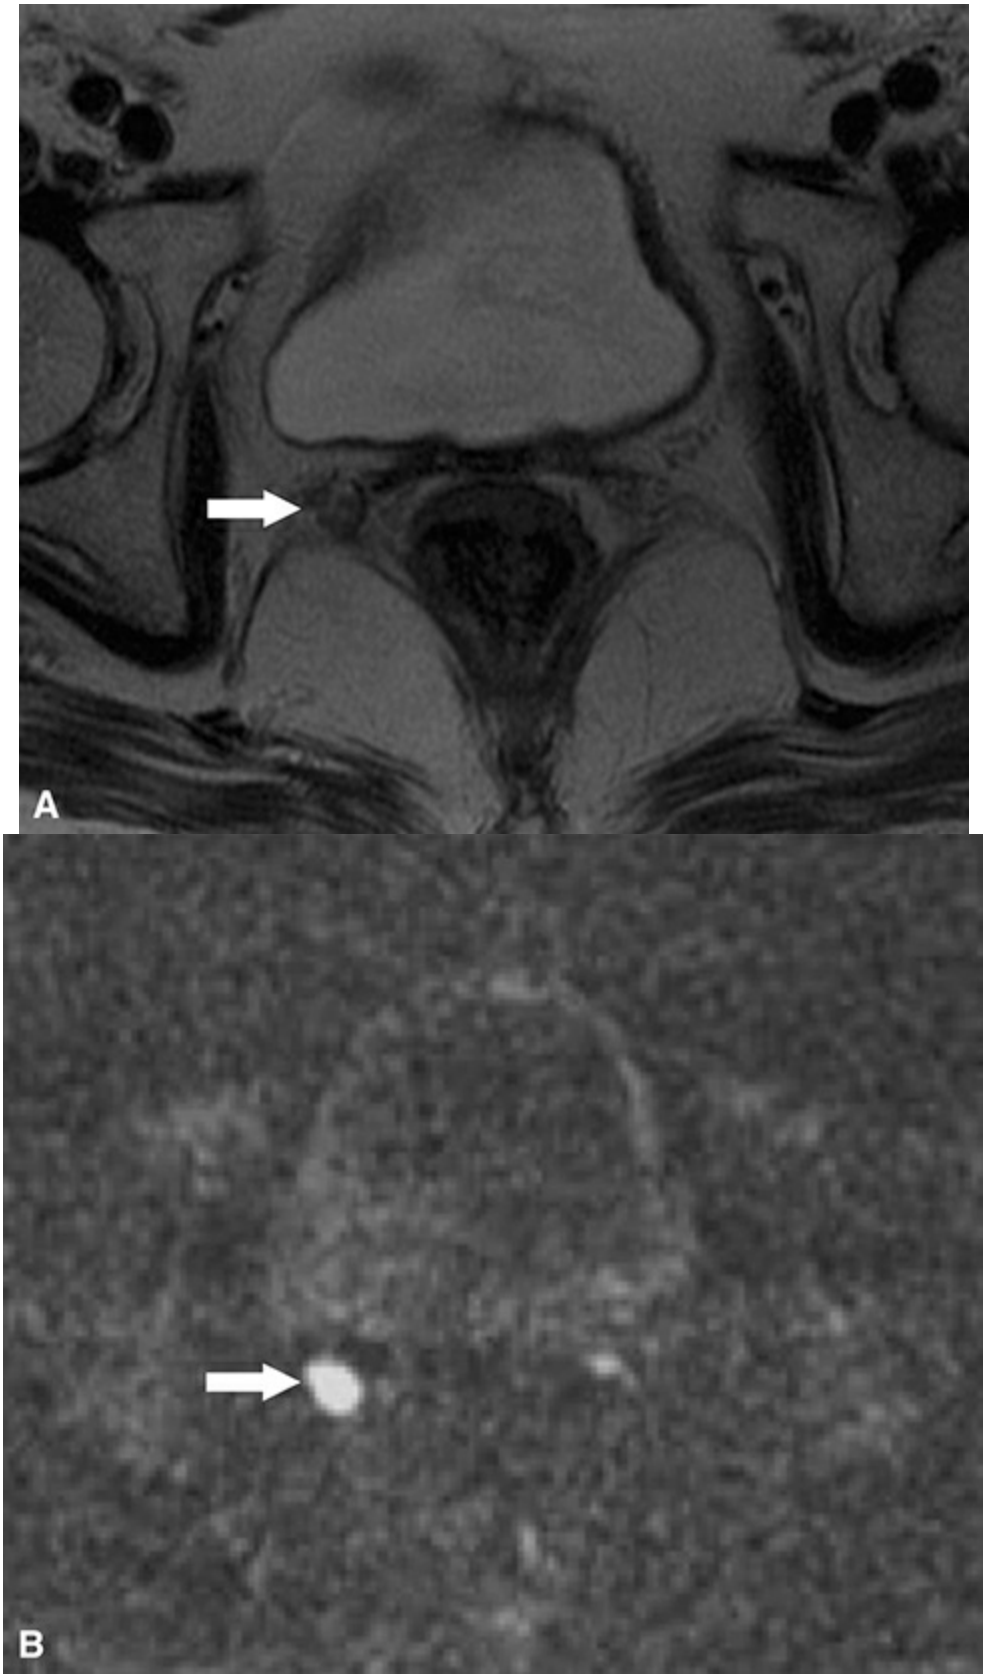

Figure 10.10 Local recurrence of endometrial cancer on MRI. Axial FSE T2-weighted (A) and diffusion-weighted (B) pelvic images of a 83-year-old woman treated for stage II endometrioid adenocarcinoma endometrial cancer 3 years ago reveal a 1-cm diffusion-restricted nodule (arrow) at the right vaginal vault. Biopsy confirmed recurrent tumor. FSE, fast spin-echo.

UTERINE SARCOMA

Detection

Pelvic sonography cannot distinguish a uterus enlarged from fibroids versus cancer. Consequently, recent reviews reveal a very low but not negligible risk of malignancy in women undergoing surgery for presumed benign fibroids. Most recently, the Food and Drug Administration (FDA) analyzed available data and found the prevalence of unsuspected sarcoma in women undergoing surgery for fibroids to be 1 in 352 (65). This statistic has been challenged as an overestimate, with an alternative analysis reporting an incidence of leiomyosarcoma (LMS) of 1 in 7,450 (66).

MRI is the modality recommended for treatment planning of an enlarged symptomatic uterus (67,68). It delineates tumor size, margins, and anatomic extent. The large field of view allows for detection of extrauterine growth such as lymphadenopathy, vascular invasion, peritoneal dissemination, and bone metastases. But although MRI can identify tumor growth outside the uterus, it is less accurate in differentiating a benign leiomyoma from a myometrium-confined LMS (**Fig. 10.11**). Sensitivity and specificity of MRI, measured in retrospective series enriched for LMS, have been reported as 56% to 100% and 93% to 94%, respectively (69,70). Extrapolating the best-case scenario of 100% sensitivity and 94% specificity to the real-world population yields a positive predictive value of <4%, indicating that the majority of uterine-confined LMS diagnosed by MRI will still prove to be benign. However, when a uterine mass is diagnosed as LMS on MRI, the likelihood of underlying malignancy increases up to 15-fold, and this should be taken into account in treatment planning.

A

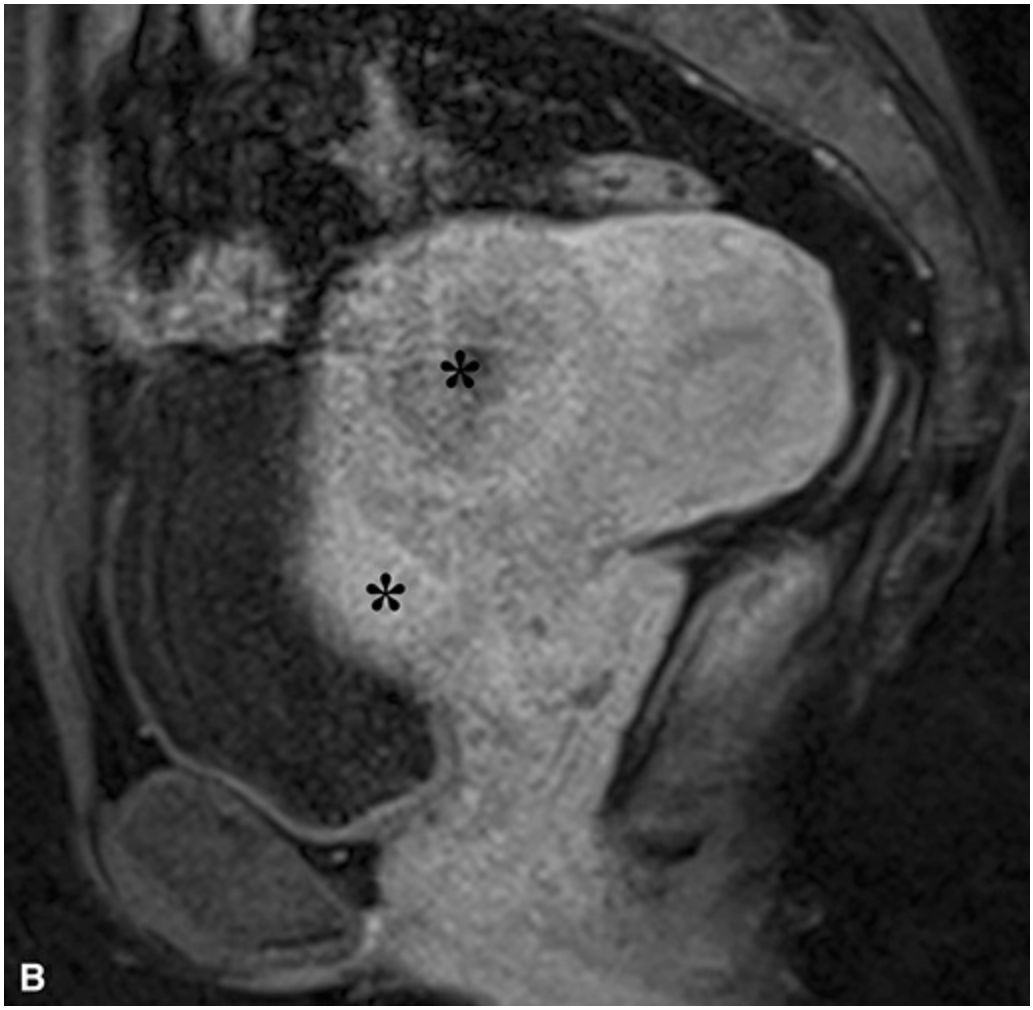

Figure 10.11 Leiomyosarcoma mimics leiomyoma. Sagittal FSE T2-weighted (A) and postgadolinium T1-weighted (B) images of the uterus in a 44-year-old woman with abnormal vaginal bleeding demonstrate a homogeneous, well-circumscribed, bilobed mass (asterisk) that enhances similarly to the myometrium. Mass is confined to the uterine myometrium, and no metastases are seen. Surgical pathology revealed a uterine-confined grade 2 leiomyosarcoma.

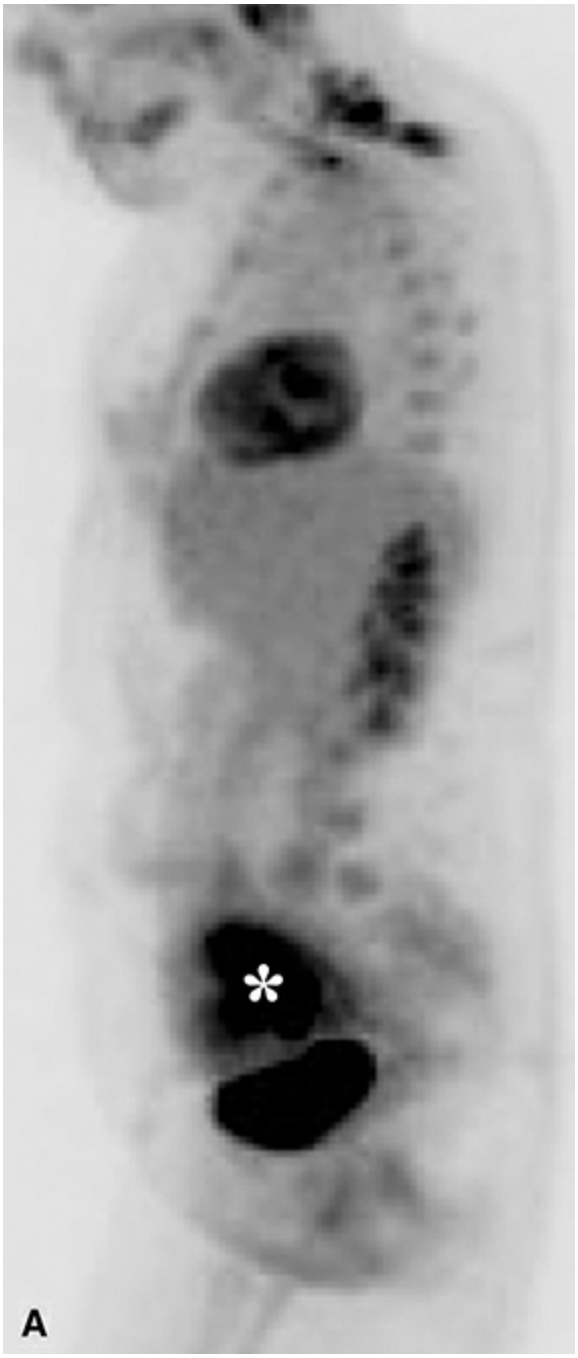
FDG-PET is not useful in differentiating benign from malignant uterine smooth muscle tumors. Tracer accumulation in fibroids is widely variable (71) and intense uptake that can mimic high-grade sarcoma has been reported in women older than 80 years (72). If all other imaging features are consistent with a fibroid, a markedly FDG-avid uterine myometrial mass is likely to represent a benign leiomyoma and not an LMS (**Fig. 10.12**).

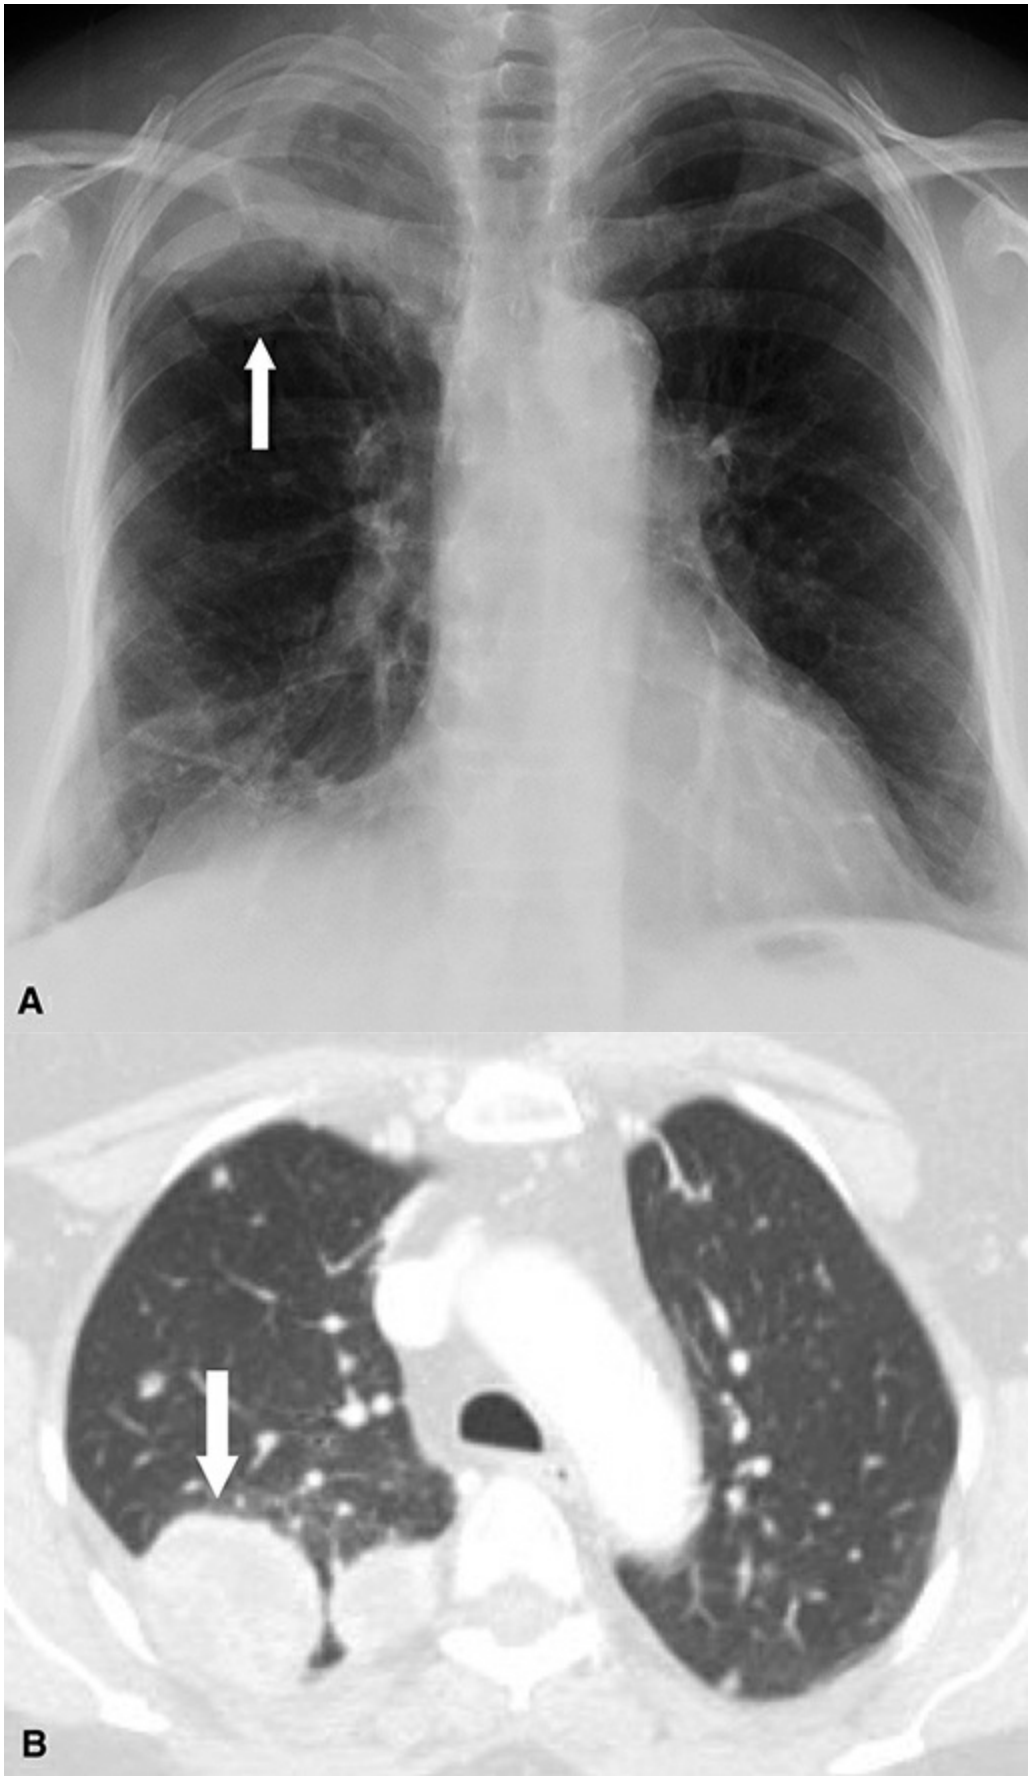


A

Figure 10.12 FDG-avid benign leiomyoma mimics malignancy. Sagittal PET (A) of a 41-year-old woman with high-grade carcinoma metastatic to bone from an unknown primary demonstrates an intensely hypermetabolic, enlarged uterus (asterisk). Sagittal FSE T2-weighted image (B) of the uterus shows multiple fibroids (arrows) but no evidence for malignancy. Hysterectomy showed leiomyomas and no uterine cancer. FSE, fast spin-echo.

Primary Treatment Planning

The NCCN guidelines recommend a CT of the chest, abdomen, and pelvis; an MRI; or PET-CT for the evaluation of uterine sarcoma regardless of how it is diagnosed (73). Chest imaging is necessary as soft tissue sarcomas, including LMS, demonstrate propensity for pulmonary metastases and, on occasion, will present as a primary lung mass in a woman with presumed fibroids (**Fig. 10.13**). For defining tumor extent, PET-CT is the most accurate modality to evaluate nodal and extrapelvic metastases (74).



A
B

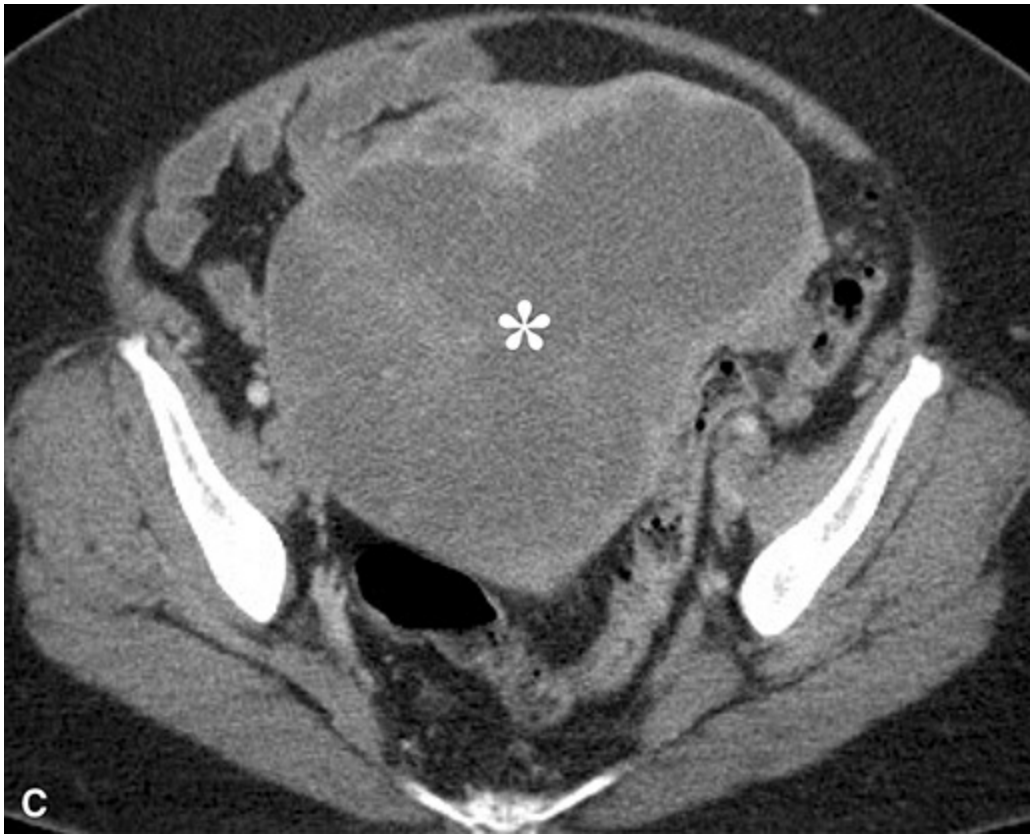


Figure 10.13 Leiomyosarcoma presents as lung mass. Posterior-anterior chest radiograph (A) obtained in a 62-year-old woman scheduled to undergo hysterectomy for symptomatic fibroids demonstrates a 3.5-cm right upper lobe mass (arrow). Chest CT (B) again demonstrates the mass (arrow) and other smaller bilateral pulmonary nodules. Abdominopelvic CT (C) shows an enlarged 17-cm uterus (asterisk) with heterogeneous areas of enhancement and necrosis but no evidence of extrauterine tumor. Lung mass biopsy revealed metastatic leiomyosarcoma.

Post Primary Therapy

The most common sites of metastatic disease from LMS are lung, followed by peritoneal cavity, bone, and liver (75–77). There is little evidence on which to base recommendations for imaging follow-up, although surveillance imaging with chest, abdomen, and pelvic CT is the usual practice (78). Anecdotal experience from small series suggests that FDG-PET identifies more sites of extrapelvic metastatic disease below the diaphragm, compared with CT (79).

GESTATIONAL TROPHOBLASTIC DISEASE

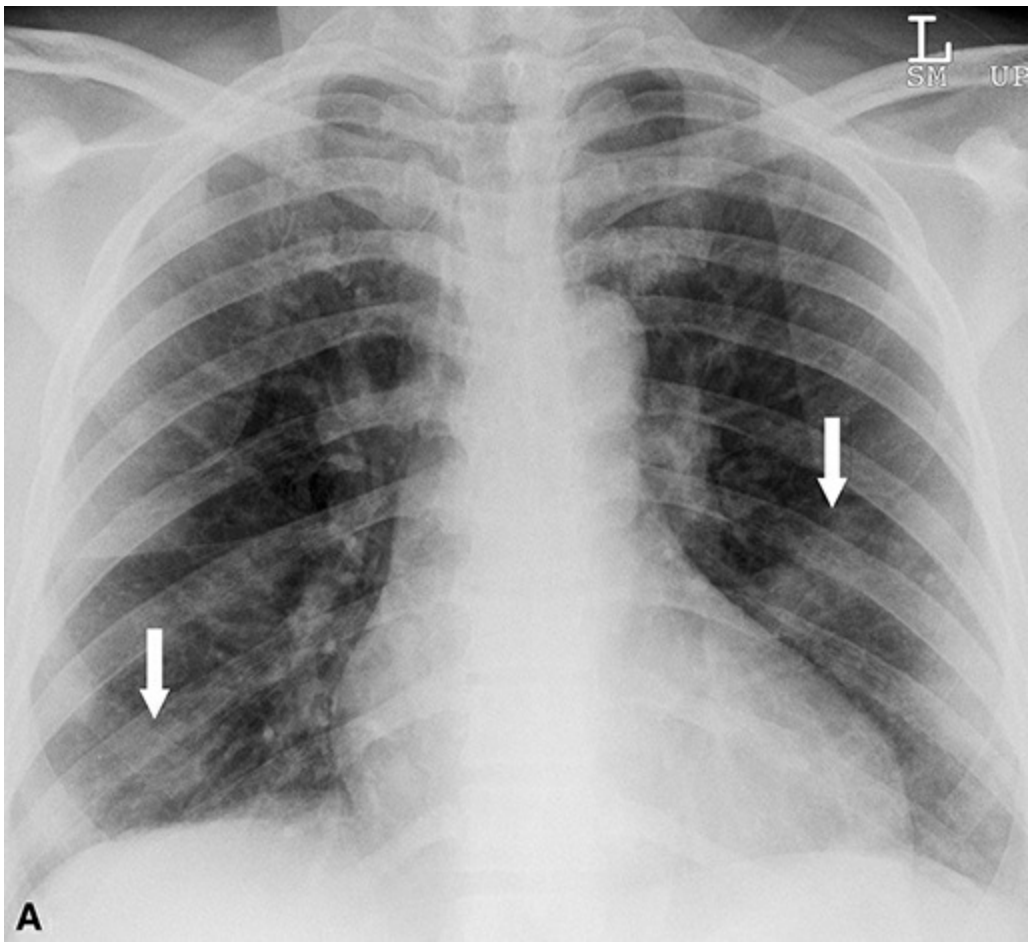
Detection

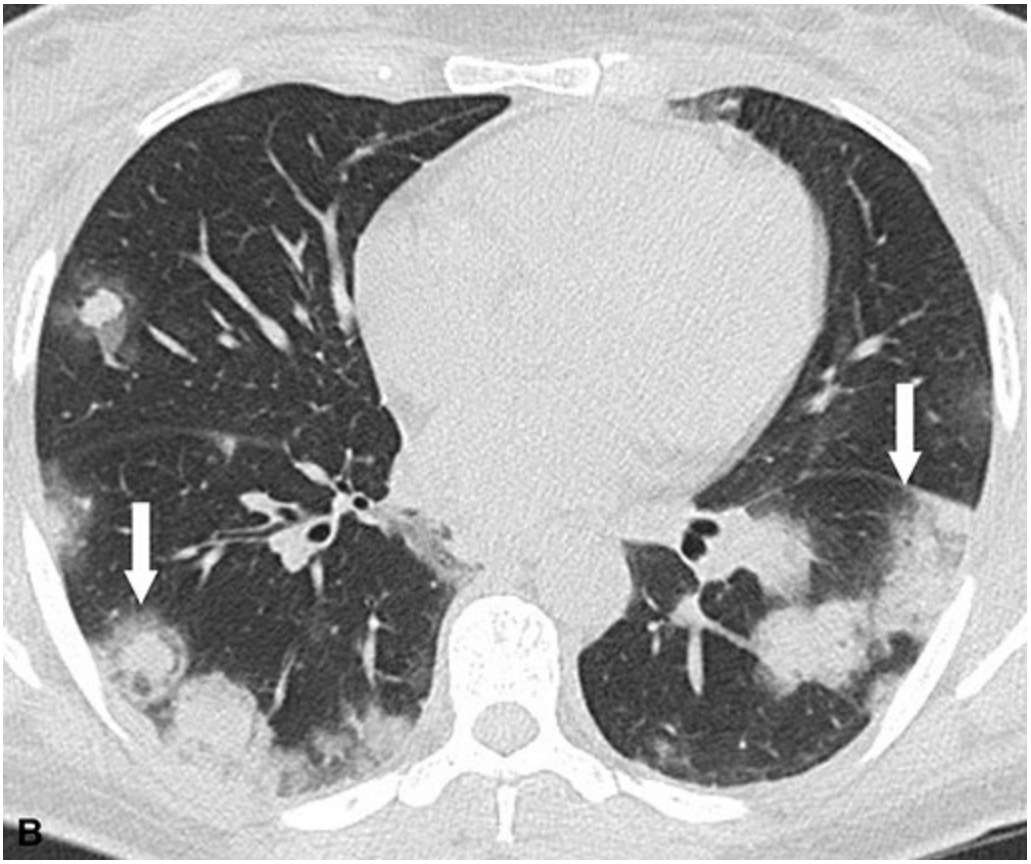
An elevated serum human chorionic gonadotropin (hCG), typically following a molar, ectopic, or failed pregnancy, is the usual presenting feature. TVUS is used to confirm suspected diagnosis and to exclude a normal pregnancy.

Primary Treatment Planning

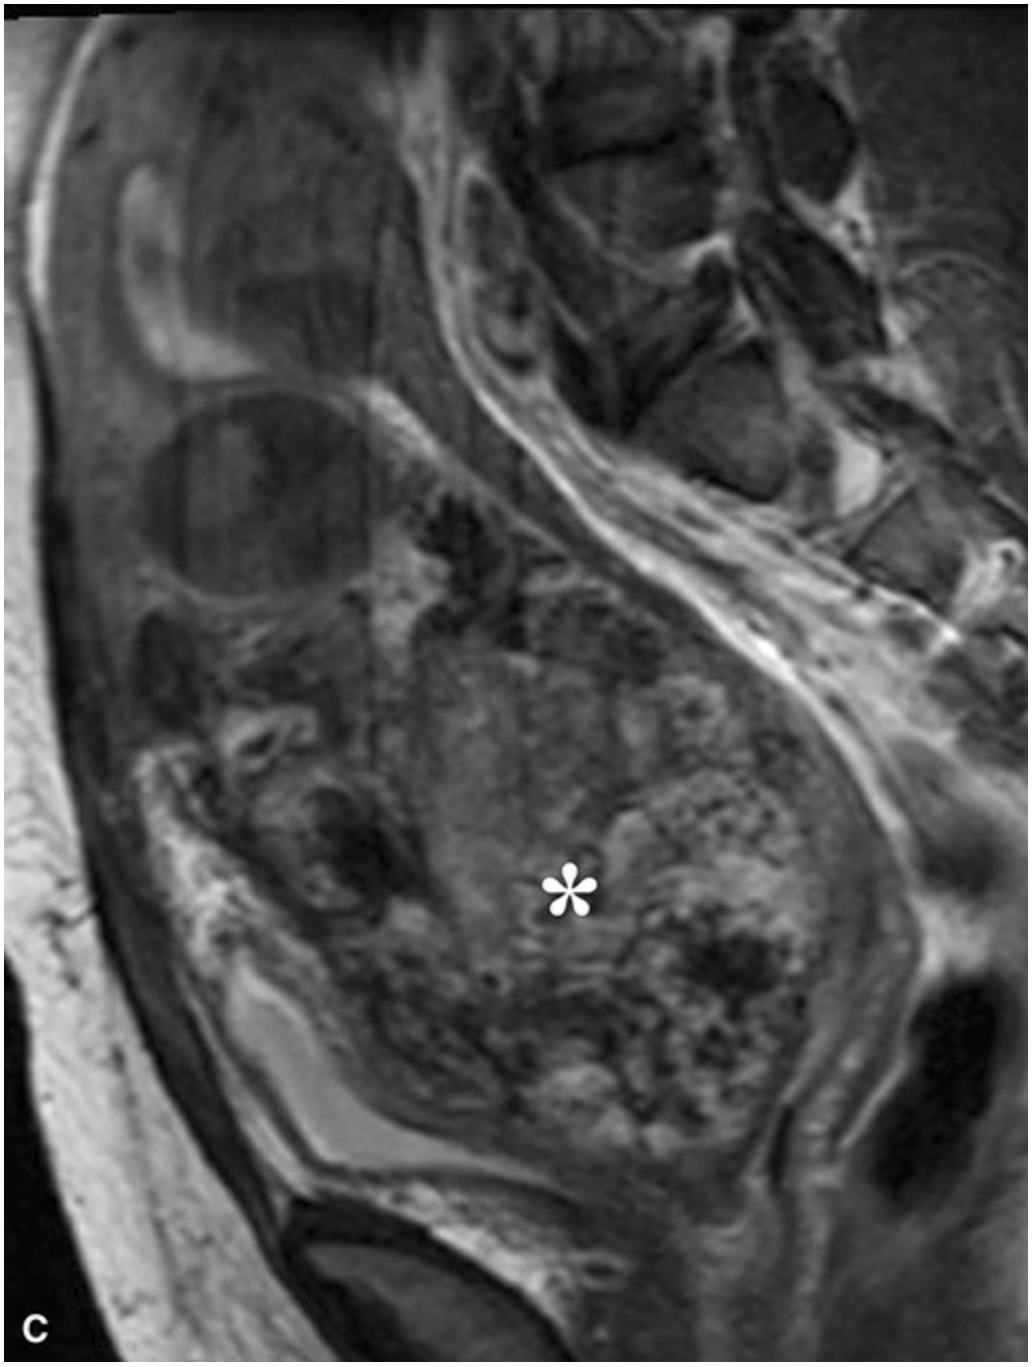
Gestational trophoblastic disease (GTD) is staged anatomically using the FIGO classification (80). In addition, a World

Health Organization Prognostic Scoring System, which requires assessment of tumor size, sites, and number of metastases, is allotted to each patient, as it best predicts clinical outcome (80). Lungs are the most common sites of metastases, and hence, chest imaging should be routinely performed either with a radiograph or CT (**Fig. 10.14A**, **B**). The latter is more accurate and can demonstrate hemorrhage, a common complication of this tumor (81). In cases of uterine enlargement, pelvic MRI can be used to assess tumor size and risk for perforation (**Fig. 10.14C**, **D**). Additional imaging may be indicated to confirm suspected metastases in the torso or central nervous system with CT or MRI, respectively.





B



C

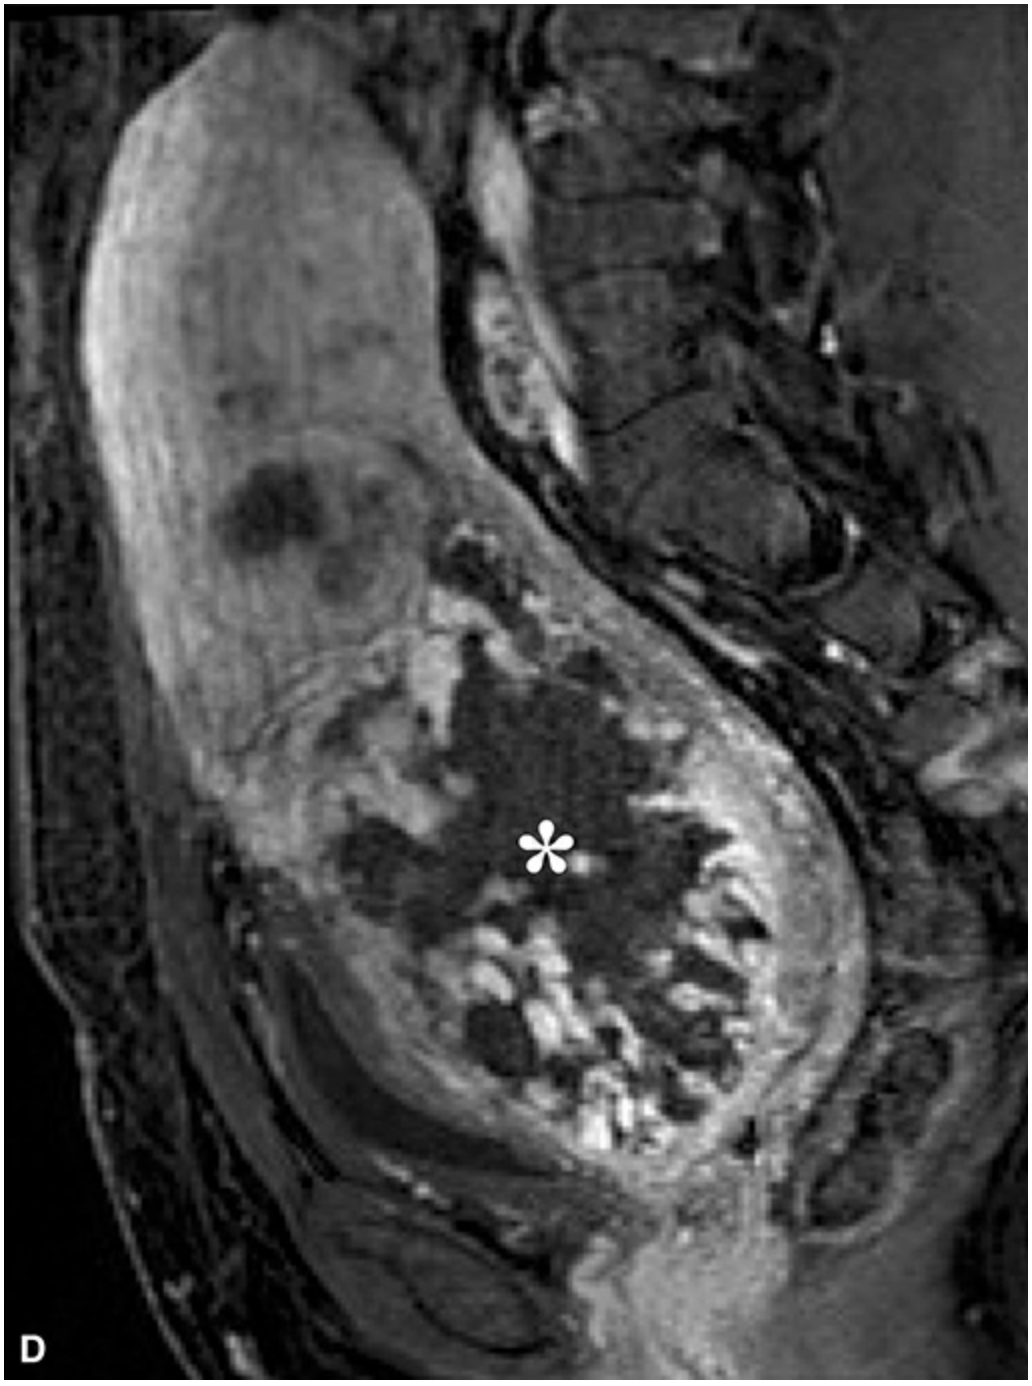


Figure 10.14 Choriocarcinoma presenting as pulmonary nodules. Posterior-anterior chest radiography (A) and CT (B) of a 49-year-old woman presenting with hemoptysis demonstrates bilateral nodules measuring up to 5 cm (arrow). Note the "ground glass halo" around the nodules on the chest CT indicating hemorrhage. Sagittal FSE T2-weighted (C) and postgadolinium T1-weighted (D) images reveal a 10-cm hypervascular mass (asterisk) with central necrosis that involves the lower endometrial cavity and the anterior myometrial wall. Biopsy revealed choriocarcinoma. FSE, fast spin-echo.

Post Primary Therapy

Serial quantitative hCG is used to follow treatment response and to diagnose remission. Imaging is not routinely performed unless tumor markers suggest resistance to therapy or recurrence. Arteriovenous malformation, a complication of tumors invasive into the myometrium, is best diagnosed with Doppler TVUS (**Fig. 10.15**) (82) and can be treated with

angiographic embolization (83).

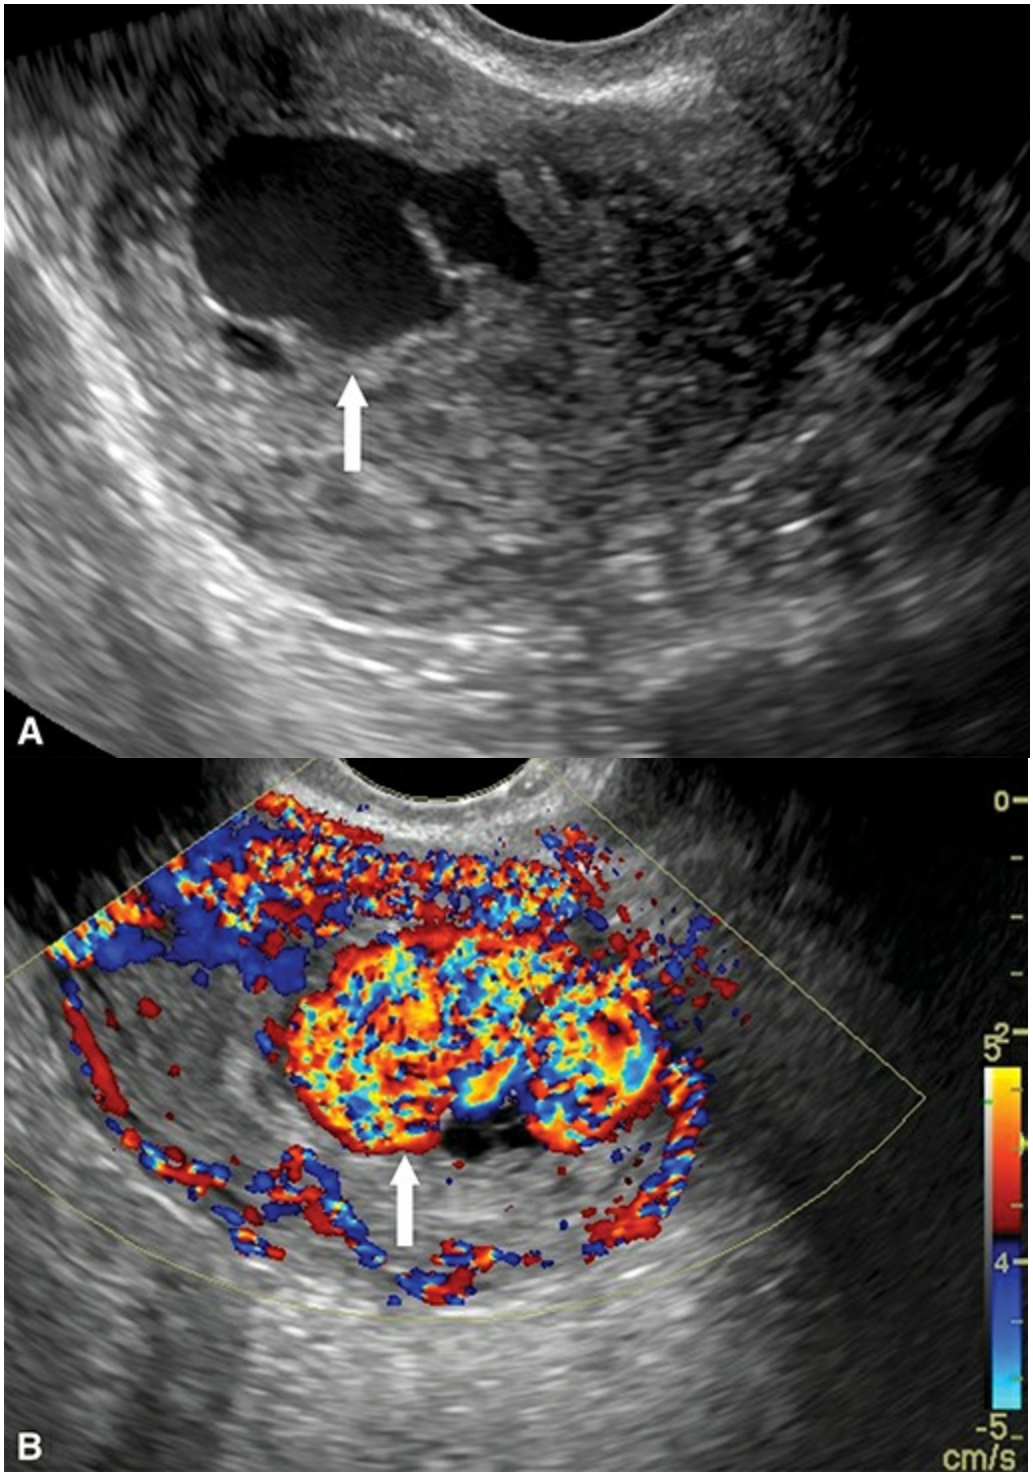

Figure 10.15 Uterine arteriovenous malformation on transvaginal US. Sagittal gray-scale (A) and transverse color Doppler (B) images of the uterus in a 33-year-old woman following therapy for high-risk GTD now presenting with abnormal bleeding show cystic spaces that demonstrate high-velocity turbulent flow (arrows). Diagnosis was confirmed and treated with angiography and embolization.

VULVAR CANCER

Detection

Imaging plays no role in diagnosis of vulvar cancer, which is detected on pelvic exam and confirmed with biopsy.

Primary Treatment Planning

The most recent revisions on the FIGO staging of vulvar cancer give better prognostic discrimination between stages (9). Features at presentation that predict patient outcome are the tumor size, depth of invasion, status of lymph node metastases, and distant metastases. Because of the morbidity associated with a radical surgery that includes inguinofemoral lymphadenopathy, noninvasive methods, such as imaging, to evaluate disease extent are becoming more popular. Performances of CT, MRI (**Fig. 10.16A**, **B**), and PET-CT for nodal assessment have all been reported (**Table 10.2**) (21–26). In selected patients with early-stage squamous cell carcinoma (tumor <4 cm in diameter and clinically nonsuspicious groin nodes), sentinel lymph node excision is recommended (84,85). However, in patients with advanced loco-regional tumor, PET-CT is used to evaluate for stage IV disease (**Fig. 10.16C**, **D**) (5).

B

C

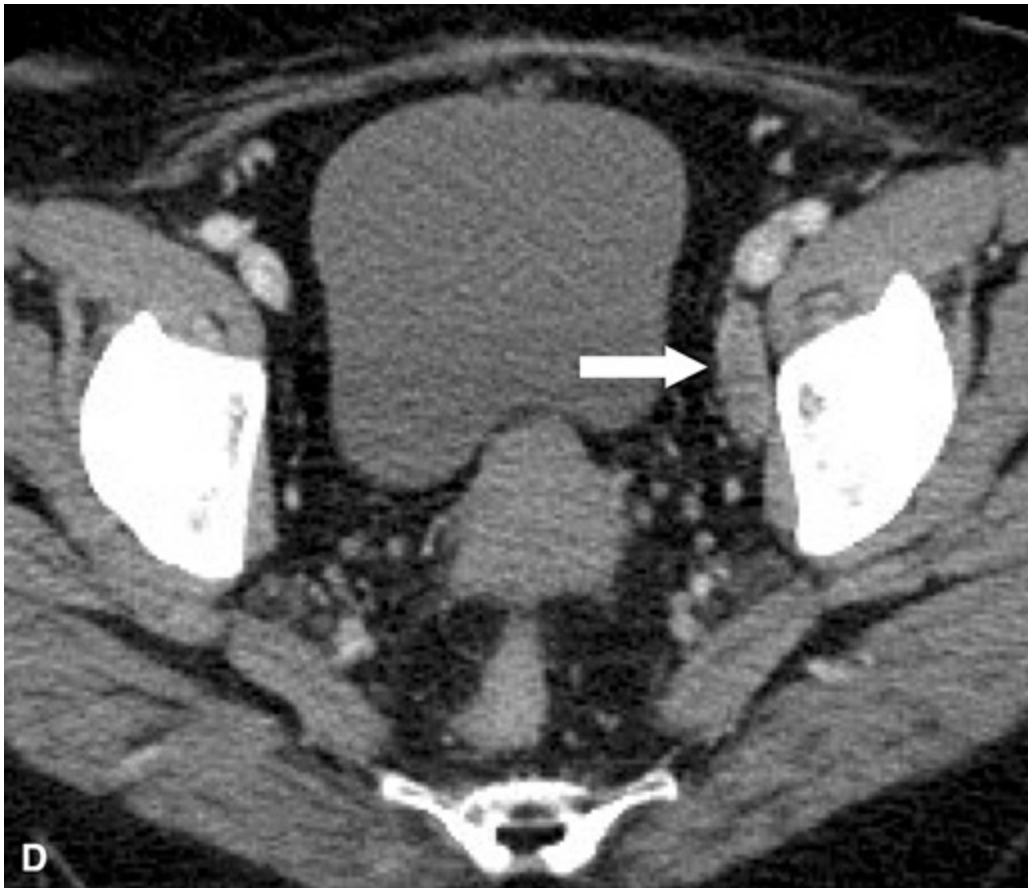

Figure 10.16 Vulvar cancer stage IV detected on PET-CT. Axial FSE T2-weighted images of the pelvic floor (A and B) of 66-year-old woman with squamous cell carcinoma of the vulva demonstrate a 7.8 × 1.5 cm left vulvar mass (arrowheads) and abnormally enlarged left inguinal nodes. Coronal PET (C) image again demonstrates hypermetabolic foci corresponding to the primary tumor (asterisk) and bilateral inguinal adenopathy. However, tracer accumulation higher in the left pelvis (arrow) localizes on concurrent CT (D) to metastases in the obturator nodes (arrow) confirmed with biopsy. FSE, fast spin-echo.

Post Primary Therapy

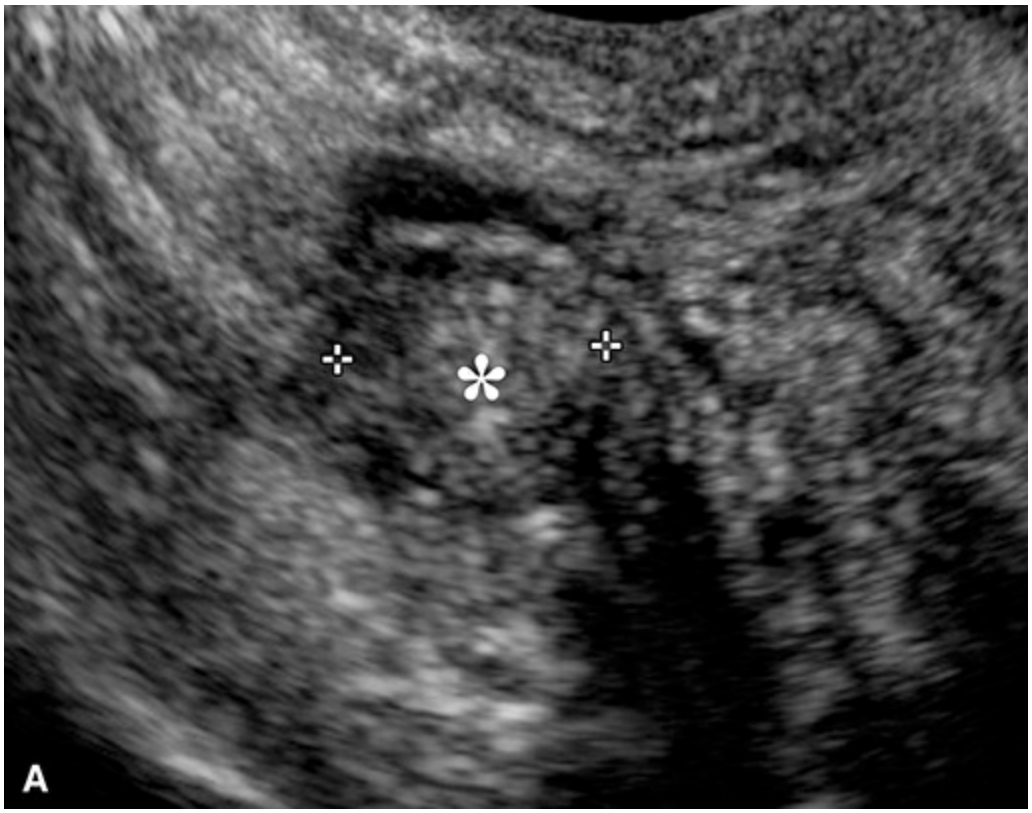
Squamous cell carcinoma of the vulva is seen to recur in 30% to 50% of patients within 2 years. The majority of these are local; however, recurrences in the groin are associated with a poor prognosis (86,87). MRI can help in evaluating the extent of the local recurrence and guide salvage therapy. If loco-regional therapy is planned, PET-CT is used to evaluate for distant disease that would alter management.

OVARIAN CANCER

Detection

Large randomized trials have shown that routine screening for ovarian cancer using a combination of physical examination, cancer antigen 125 (CA-125), and TVUS does not meaningfully decrease disease-specific mortality (88,89). These trials have shown that benign adnexal lesions are common, with a reported incidence of complex ovarian cysts of 3.2% in women over age 50 years (90,91), whereas ovarian cancer is rare, with 12.1 cases per 100,000 women (92). This high

incidence of benign adnexal lesions coupled with the low incidence of ovarian cancer in the general population means that diagnostic testing algorithm with 100% sensitivity and 99% specificity is estimated to have a positive predictive value of <5% (93). In contrast, sensitivities and specificities of 85% to 100% and 52% to 100%, respectively, have been reported for detection of ovarian malignancies using US (94–96). Screening trials have also shown that the majority of ovarian cancers show rapid progression from early-stage sonographically detectable lesions to extraovarian spread with short lag times (**Fig. 10.17**). In one trial, all 10 of the ovarian cancers detected were at stage III or IV, having developed within the 6-month interval between screening exams (97). Consequently, the U.S. Preventative Services Task Force currently recommends against screening, given the scant evidence for any benefit and the morbidity incurred from unnecessary interventions (98).



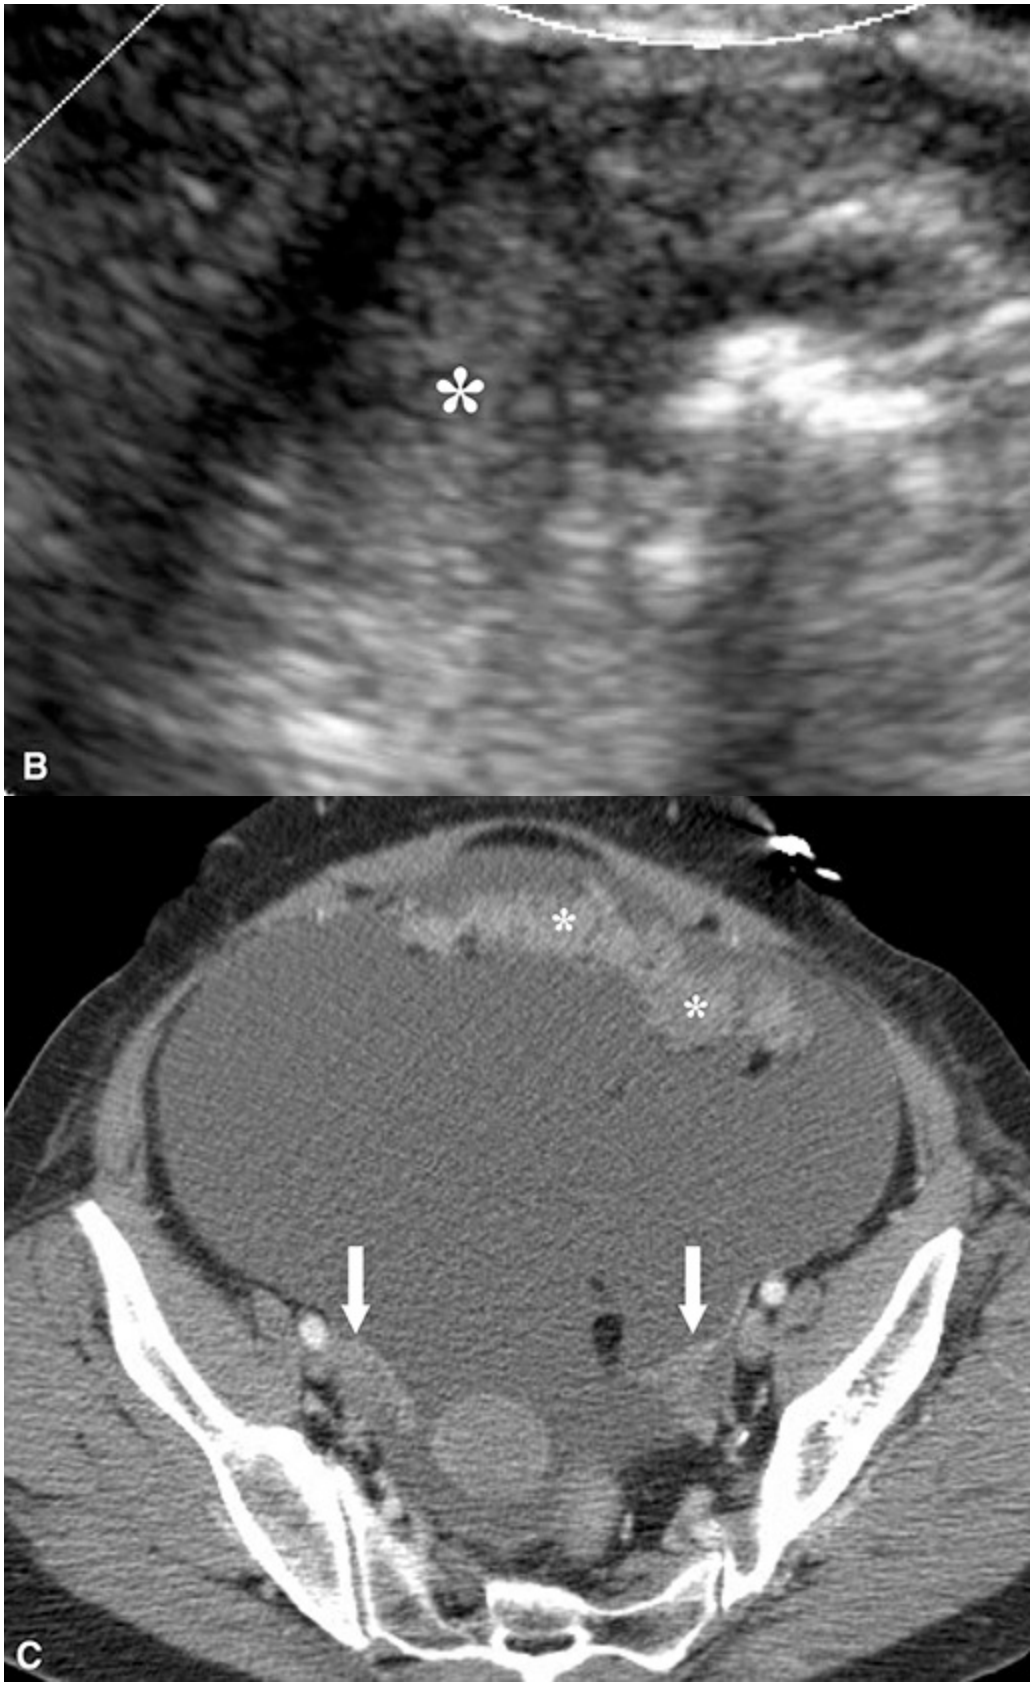


Figure 10.17 High-grade ovarian carcinoma at presentation. Endovaginal US images of the right (A) and left (B) ovaries (asterisks) of a 62-year-old woman with abdominal discomfort demonstrate normal ovaries and no ascites. Contrast-enhanced CT image (C) of the pelvis obtained 5 months later for worsening symptoms reveals interval development of enlarged ovaries (arrows), enhancing omental soft tissue (asterisk) and large amount

of ascites. Stage III serous ovarian adenocarcinoma was confirmed with surgery and pathology.

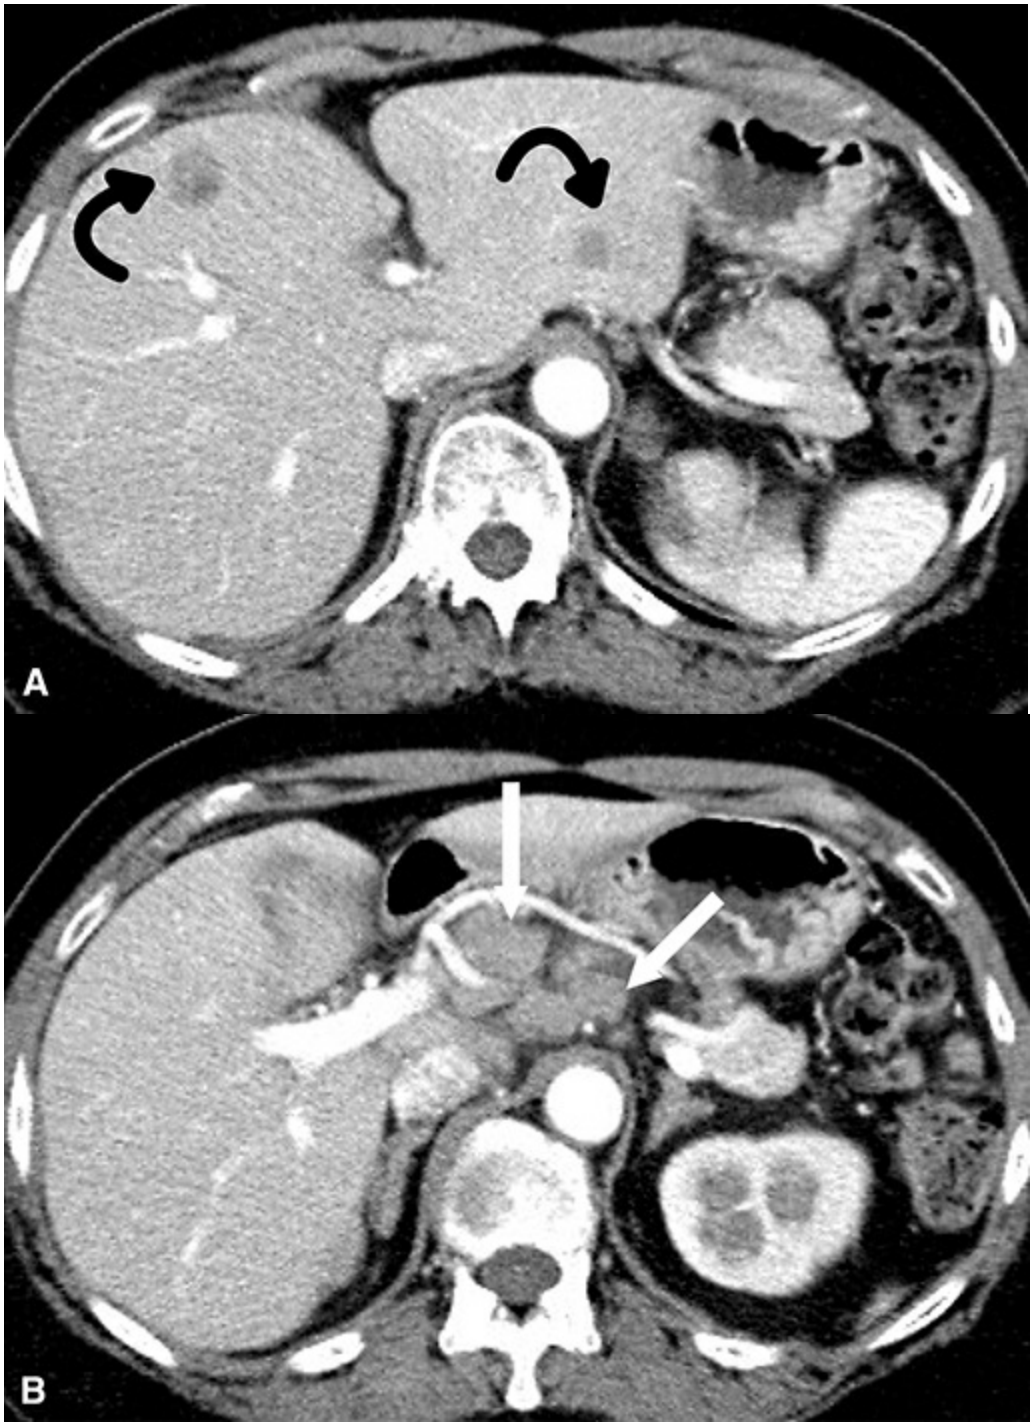
A benign adnexal mass is diagnosed in 5% of CTs in postmenarchal women (99) and in 4% of CTs in women greater than 50 years (100). A woman in the United States has a 5% to 10% lifetime chance of undergoing an oophorectomy for a benign adnexal mass (101), with resultant long-term morbidity of decreased fertility and premature menopause (102,103). Incidental adnexal masses represent a wide variety of pathologies, including functional cysts, mature teratoma, endometrioma, benign, borderline or malignant primary neoplasms, and extraovarian processes such as hydrosalpinx, peritoneal inclusion cyst, and fibroid (104). Given the high prevalence of incidental adnexal lesions, the role of imaging is to definitively characterize them as benign and minimize the number of unnecessary interventions.

MRI is the best modality to more definitively characterize incidental adnexal lesions likely to be benign. A meta-analysis evaluating the incremental value of a second test for adnexal mass deemed indeterminate on gray-scale US found that MRI changed the posttest probability of ovarian cancer in both pre- and postmenopausal women more than CT or combined gray-scale and Doppler US (105). The contribution of MRI in adnexal mass evaluation is its specificity, because it provides greater tissue characterization and localization of benign lesions. In a prospective study of women with suspected adnexal masses, both Doppler US and MRI were highly sensitive for identifying malignant lesions (US, 100%; MRI 96.6%), but the specificity of MRI was significantly greater (US, 39.5%; MRI 83.7%). Thus, women who clinically have a low risk of malignancy but have indeterminate lesions on US are the ones most likely to benefit from MRI (106).

Primary Treatment Planning

The FIGO staging system for ovarian cancer is based on surgery and pathology (107). Although it does not formally include imaging, it encourages the use of imaging to assess for important prognostic factors such as disease resectability and lymph node status. Thus, pretreatment imaging is used to define tumor extent, and to identify patients for whom primary surgery is unlikely to achieve optimal cytoreduction. NCCN guidelines include abdominopelvic CT or MRI in this context (108). The importance of imaging in helping to triage patients for appropriate management has increased because the use of neoadjuvant chemotherapy followed by interval cytoreductive surgery as a suitable alternative has been supported by multicenter randomized controlled trials (109,110).

CT is the primary imaging modality used to assess tumor spread and plan therapy for advanced ovarian cancer patients (**Fig. 10.18**). Imaging features that favor neoadjuvant chemotherapy include diffuse peritoneal thickening, peritoneal implants exceeding 2 cm in diameter, lesser sac and small-bowel mesentery involvement, pelvic sidewall involvement, large-volume ascites, and suprarenal retroperitoneal adenopathy (111–113). However, diagnostic accuracies have been reported over a wide range and are yet to be validated across multiple surgeons and institutions.

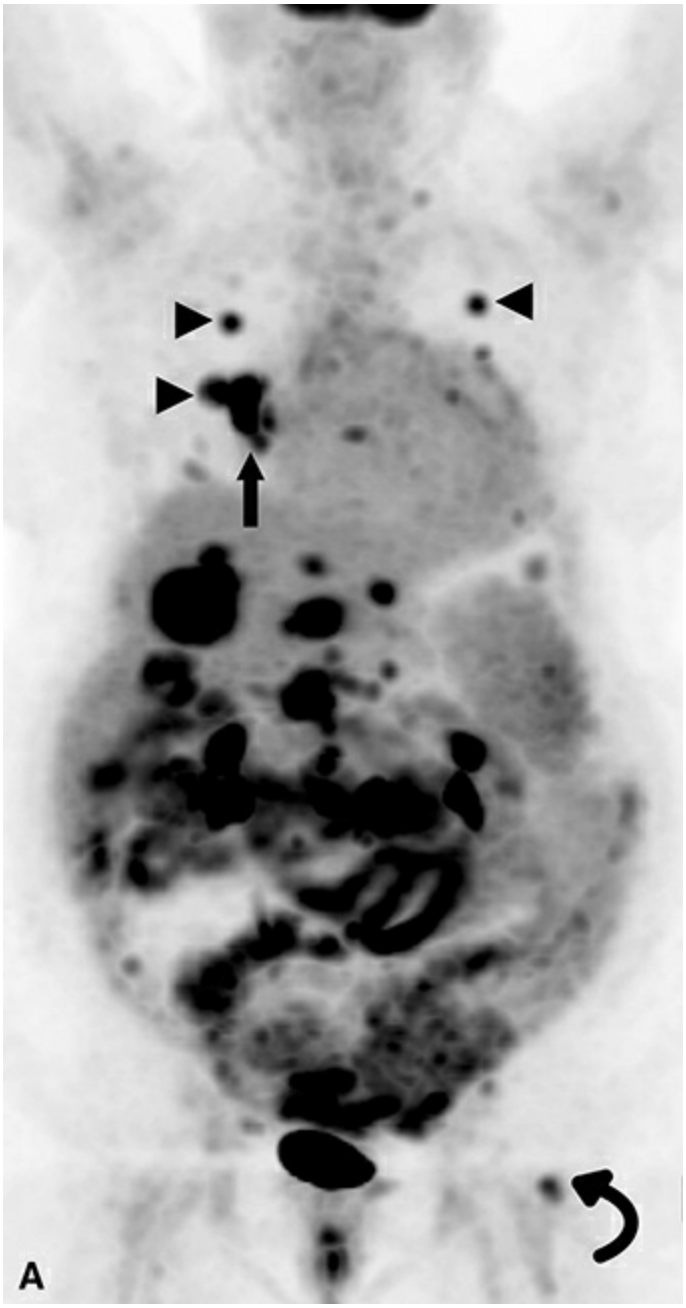


A
B

Figure 10.18 Ovarian cancer on pretreatment CT. Contrast-enhanced abdominopelvic CT of a 72-year-old woman demonstrates bilateral ovarian masses (arrowheads) (C). Enlarged celiac axis lymph nodes measuring >2 cm in short axis (arrows) (B) and multiple hepatic metastases (curved arrows) (A) represent tumor metastases not amenable to optimal cytoreduction. Biopsy of a liver lesion revealed adenocarcinoma, consistent with metastasis from a Mullerian primary, later characterized as high-grade serous carcinoma on surgery. Patient was classified as stage IV and triaged to neoadjuvant chemotherapy.

The ability to detect peritoneal implants depends on their size, with CT having a sensitivity of 14% to 27% for the detection of deposits less than 1 cm, especially in the absence of ascites (114,115). The sensitivity of CT for the detection of omental metastases is higher and reported to be 80% to 86% (114,115). The most commonly involved lymph nodes with ovarian cancer are at the para-aortic and aorto-caval locations at the level of the renal hilum. In general, a 1-cm short-axis diameter threshold is used to define an enlarged node. Hematogenous spread is the least common mode of spread in ovarian cancer but typically occurs in the solid abdominal organs such as the liver, spleen, kidneys, and adrenals; in the brain; and in the bones. CT has a sensitivity of 95% to 100% for the detection of liver disease and 50% to 60% for the detection of nodal disease (114,115).

Other modalities such as MRI or PET-CT can also be used with equal efficacy in planning cytoreductive surgery. A multicenter trial of 280 patients with advanced ovarian cancer reported equal accuracy for CT and MR imaging (area under the curve [AUC], 0.96 for both) in diagnosing intraperitoneal tumor implants (116). FDG-PET-CT reportedly has sensitivities ranging from 62% to 100% and improves overall diagnostic accuracy by 5% to 22% compared with CT alone, mostly by identifying extra-abdominopelvic disease (**Fig. 10.19**) (117–119). But because CT is most widely available, is better tolerated, and yields higher-resolution anatomic information, it is the most commonly used modality across most institutions.



A

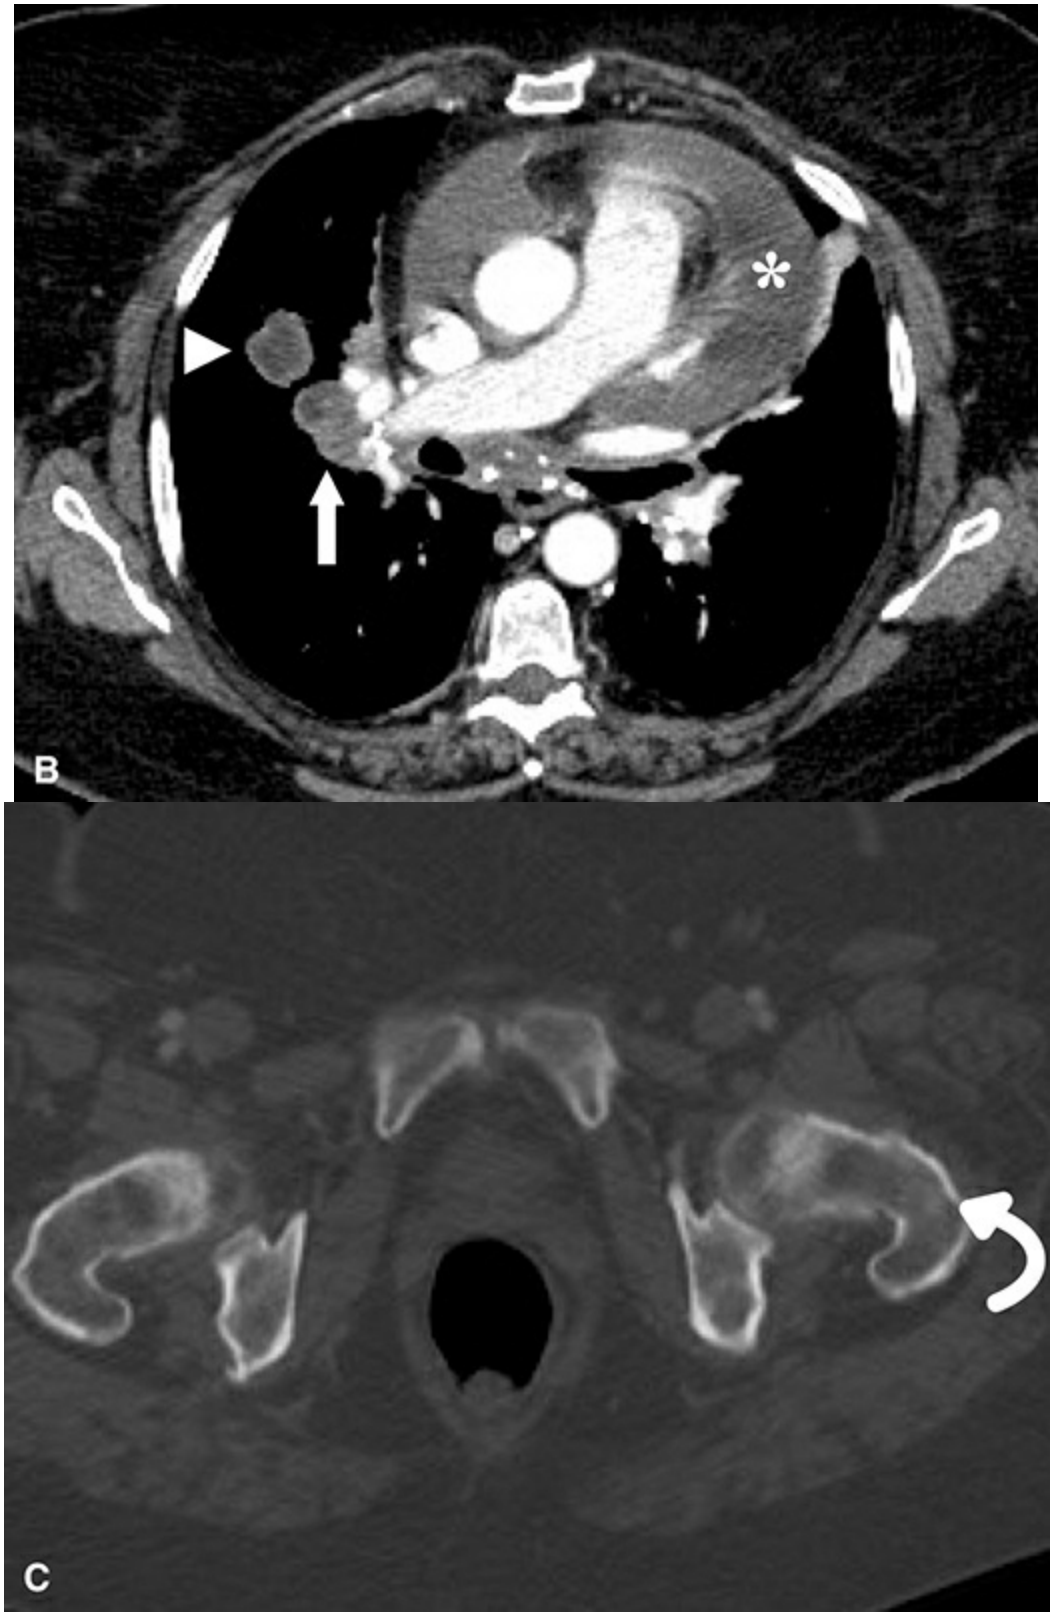


Figure 10.19 Ovarian cancer with extra-abdominal metastases. Coronal PET (A) image of a 65-year-old woman with high-grade serous ovarian cancer demonstrates mediastinal adenopathy (straight arrow) and pulmonary nodules (arrowheads) also seen on concurrent chest CT (B). Chest CT reveals a large pericardial effusion (asterisk) not appreciated on PET. Osseous metastasis of the left greater trochanter seen on PET (A, curved arrow) is not visible on the concurrent pelvis CT (C, curved arrow).

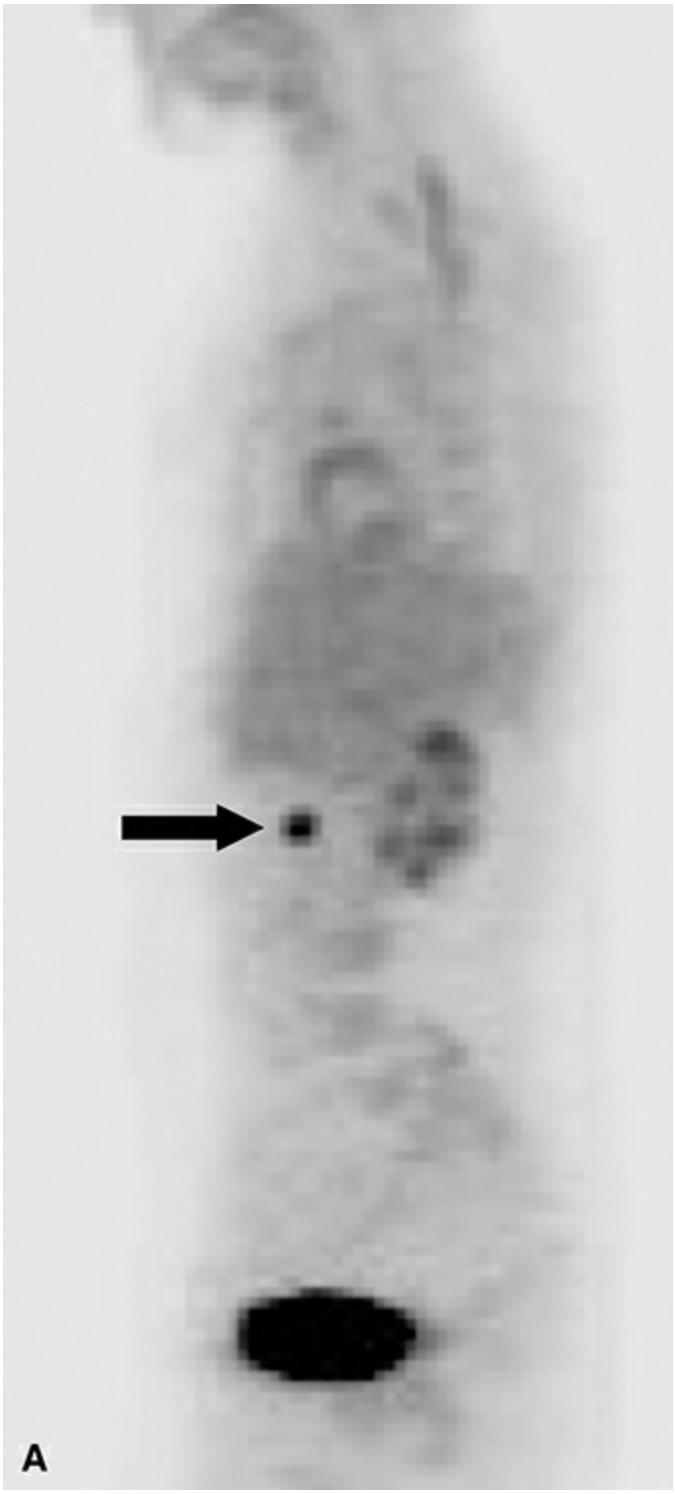
Post Primary Therapy

Although most patients will respond to primary therapy, 60% to 85% will eventually relapse (120), and almost all of them will die from the disease. The combination of clinical assessment and CA-125 measurement is routinely used to monitor patients treated for ovarian cancer in many institutions (121). However, CA-125, although useful, has limitations, since normal values do not exclude disease and elevated values do not define disease extent (122–124). In the 10% subgroup of biochemically "silent" patients, imaging is the primary means of assessing treatment response and of follow-up for recurrence.

Traditionally, CT and, less commonly, MRI are used to evaluate for suspected relapse, with a rise in CA-125 levels, which typically precedes imaging findings by several months. The sensitivity of CT ranges from 51% to 84%, and its specificity ranges from 81% to 93% (125–127). The sensitivity of CT for disease detection is proportional to lesion size. Many studies report limitations in the detection of small tumor nodules in the mesentery and along peritoneal surfaces (125,127). However, sagittal and coronal reformatted images available with multidetector scanning improve the detection of peritoneal implants (128).

More recently, because of its superior sensitivity, specificity, and reader agreement (129), PET-CT has become the preferred modality for detecting recurrent tumor and planning subsequent therapy (**Fig. 10.20** and **Table 10.4**). In two meta-analyses, PET-CT had the highest pooled sensitivity and specificity (91% and 86%, respectively) compared with PET and CT alone, MRI, and CA-125 (130,131). In prospective studies, PET-CT upstaged disease, compared with purely anatomic imaging, in 55% to 64% of patients by depicting additional sites of disease, and altered decisions on clinical management in 34% to 59% (132–135).



A

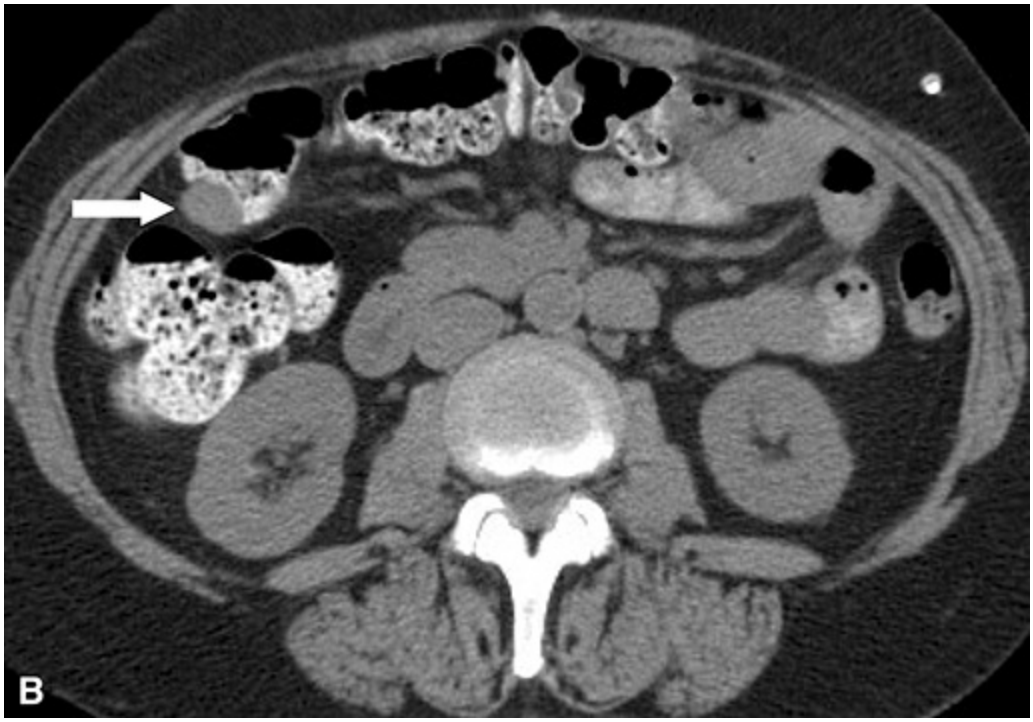


Figure 10.20 Recurrent ovarian cancer detected on PET-CT. Sagittal PET image (A) of a 62-year-old woman who initially presented 8 years ago with poorly differentiated (transitional and serous types) ovarian carcinoma and now with a rising CA-125 serum marker reveals a hypermetabolic focus in the mid abdomen. On concurrent CT (B), the tracer localizes to a 1-cm peritoneal nodule (arrow), which was overlooked on a CT several days before.

TABLE 10.4 Diagnostic Performance in Detecting Ovarian Cancer Recurrence (130)

Modality	Sensitivity (95% CI)	Specificity (95% CI)	AUC
CT	79% (74–84)	84% (76–90)	0.885
MRI	75% (69–80)	78% (70–85)	0.796
PET-CT	91% (88–94)	88% (81–93)	0.956

From Gu P, Pan LL, Wu SQ, et al. CA 125, PET alone, PET-CT, CT and MRI in diagnosing recurrent ovarian carcinoma: a systematic review and meta-analysis. Eur J Radiol. 2009;71(1):164–174, with permission.?

CONCLUSION

Imaging is central in many phases of gynecologic cancer care. In cancer detection, imaging (e.g., pelvic US with postmenopausal bleeding, pelvic MRI with indeterminate adnexal masses) serves as a screening tool to reassure those with benign disease and to triage others for further work-up. In primary treatment planning of all gynecologic cancers, body CT, pelvic MRI, or whole-body FDG-PET-CT defines tumor extent and aids in selection of a treatment strategy that optimizes patient outcome while minimizing morbidity. Following primary therapy, these imaging exams are used to assess therapy response, detect suspected recurrence, and select candidates for salvage therapy.

CHAPTER 11 Biologic and Physical Principles of Radiation Oncology

Beth A. Erickson, Meena Bedi, Firas Mourtada and Sunil J. Advani

RADIATION ONCOLOGY AS A SPECIALTY

Radiation oncology is a specialty focused primarily on the treatment of malignancies, although there are a number of benign diseases for which radiation can be used. Training in radiation oncology begins with internship, followed by 4 years of residency. Board certification follows, requiring successful completion of both written and oral exams. Residency training includes an in-depth understanding of the natural history and treatment of all malignancies, including the roles of surgery and systemic therapy in this era of multimodality therapies. An in-depth understanding of surgical procedures, pathology, and radiologic anatomy, as well as the efficacies and toxicities of systemic therapy, is required. Formal instruction in physics and radiobiology is also part of the residency training. Subspecialization with a specific practice focus on gynecologic or other cancers may follow. Only a few centers sponsor fellowships, which are usually focused on brachytherapy or other special procedures. Brachytherapy skills are especially important in the curative treatment of patients with gynecologic cancer. In addition, contemporary treatment of gynecologic malignances requires mastery of rapidly evolving technology for delivering external beam irradiation with techniques such as intensity-modulated radiation therapy (IMRT) and image-guided radiation therapy (IGRT). Radiation oncologists are important contributors to the management of individual patients and participate on multidisciplinary tumor boards. Having a knowledgeable and subspecialized radiation oncologist and gynecologic oncologist paired is a great benefit to all. In addition to radiation oncologists, other allied health professionals are integral to the radiation oncology department and treatment delivery. Radiation therapists are the individuals who actually operate the radiation equipment and deliver radiation treatments. Some of them will obtain a Bachelor of Science degree followed by a 13-month training program in radiation therapy. Alternatively, a 2-year associate degree in diagnostic radiology can be obtained followed by 1 to 2 years in radiation therapy training. Dosimetrists are primarily responsible for planning the radiation therapy or dosimetry prior to treatment delivery. Most of these individuals are former radiation therapists. An additional 1 to 2 years of training under a physicist and board-certified dosimetrist and additional years of practice are required to be eligible for board certification. Radiation physicists supervise and review the work of dosimetrists. Physicists are also integral to the introduction and maintenance of the rapidly evolving technology in radiation oncology departments. They are very involved with quality assurance and radiation safety. They can be Master's-level or PhD-level physicists and should be board certified.

INTRODUCTION TO RADIOBIOLOGY

Radiobiology is the study of how ionizing radiation (IR) interacts with biologic processes (1). The physics of IR delivery allows for dose deposition to be sculpted to targeted tumor tissues (2). However, for IR to reach tumors deep in the body,

it passes through a number of normal tissues. Therefore, it is important for radiation oncologists to deliver the optimal dose of IR in order to eradicate the tumor while minimizing the risk of injury to surrounding normal structures (such as bladder and bowel) that are within the radiation field. As with most medical treatments, the clinical utility of IR is based on a therapeutic ratio, that is, IR's ability to destroy targeted tumor tissue is greater than its toxicity to normal tissues. The effect of the dose–response relationship of IR on cancerous and normal tissues can be depicted as a pair of sigmoidal curves (Fig. 11.1). At low doses of IR, there is little effect on tumor control but also a low risk for complications. With very high doses of IR, the likelihood for tumor control is high but there is also an unacceptably high rate of normal tissue complications. In between these two extremes, as the dose of IR increases, effects on both cancerous and normal tissues increase rapidly. A key feature in this part of the dose–response curve is that the tumor kill curve is shifted to the left of the normal tissue complication curve. Thus, for a given dose of IR, the probability of tumor kill is greater than the probability of normal tissue damage. It is in this dose range that the therapeutic ratio of IR can be exploited to cure cancer with an acceptable toxicity profile.

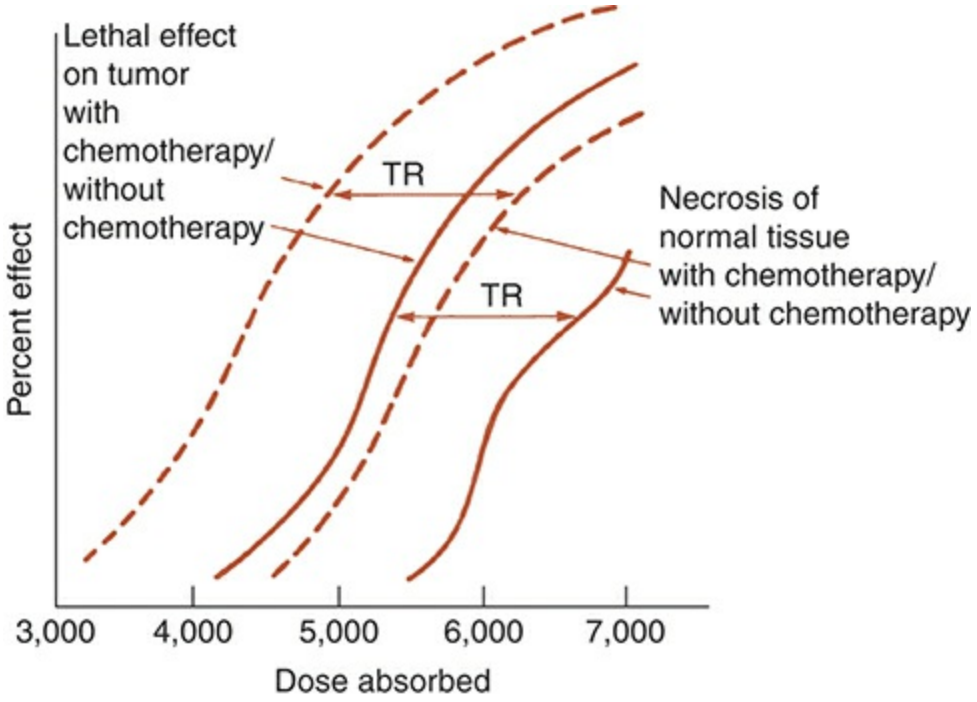

Figure 11.1 Theoretic curves for tumor control and complications as a function of radiation dose both with and without chemotherapy. TR, therapeutic range, or the difference between tumor control and complication frequency.

An understanding of radiobiology allows us to appreciate the rationale for how radiotherapy is used in gynecologic cancers and in the development of novel therapies. For example, radiosensitizing drugs increase tissue sensitivity to IR, which is graphically represented by shifting of the tissue response curves to the left (Fig. 11.1) (2,3). The implication of this is that a lower dose of IR is required in the presence of the radiosensitizer to achieve a similar degree of tissue response when compared to IR alone. Of clinical importance is that certain chemotherapies can preferentially radiosensitize tumors, and therefore shift the tumor kill control curve farther to the left than the normal tissue complication curve (4). This widens the therapeutic ratio of IR, with improved tumor control and decreased normal tissue toxicity.

While defining tumor control and normal tissue response lies at the center of radiotherapy, in clinical practice radiotherapy is delivered to defined targeted volumes (Fig. 11.2) (5). These volumes are contoured (drawn) by a radiation oncologist based on both physical exam and radiographic imaging (computed tomography [CT], ultrasound, magnetic

resonance imaging [MRI], and positron emission tomography [PET]). The area of clinical/radiographic evident tumor is defined as the gross target volume (GTV). Based on our clinical knowledge of how cancer spreads with respect to different histologies and disease sites, a clinical target volume (CTV) is next defined, which encompasses areas that are likely to harbor microscopic spread of cancer cells. Examples of what is included in the CTV are microscopically involved tumor margins postsurgery or normal-sized pelvic and paraaortic lymph nodes with a high suspicion for tumor involvement. Appropriately defining the GTV and CTV are crucial to controlling the tumor, and crucial to the patient's overall survival and quality of life. Ideally, IR would be delivered only to the GTV and CTV. However, the tissues within the GTV and CTV as defined at an initial planning session are not likely to be in the same place each day a patient receives radiotherapy. Reasons for these variations include both intrinsic and extrinsic factors. Internally, tumor tissue and surrounding normal tissues move, in part due to breathing and peristalsis of bowel as well as bowel and bladder filling with stool and urine. Externally, aligning the patient with the source of IR has inherent setup variations each day, which can include patient immobilization and body habitus. For these reasons, a planning target volume (PTV) is defined for both the GTV and CTV. The PTV is constructed by expanding the GTV and CTV slightly (≤10 mm) to account for these variations in tumor and normal organ location. Clinically, the PTVs are the regions of the body to which IR delivery is conformed, with the goal of maximizing dose to the PTV and minimizing dose to the normal tissues, that is, organs at risk (OAR), to achieve as wide a therapeutic ratio as possible for IR. In the following section, we will go over the radiobiologic principles that underlie the biologic basis of radiotherapy. An understanding of basic radiobiologic principles and of preclinical research allows for continued advancement and refinement of the use of radiotherapy in gynecologic cancers.

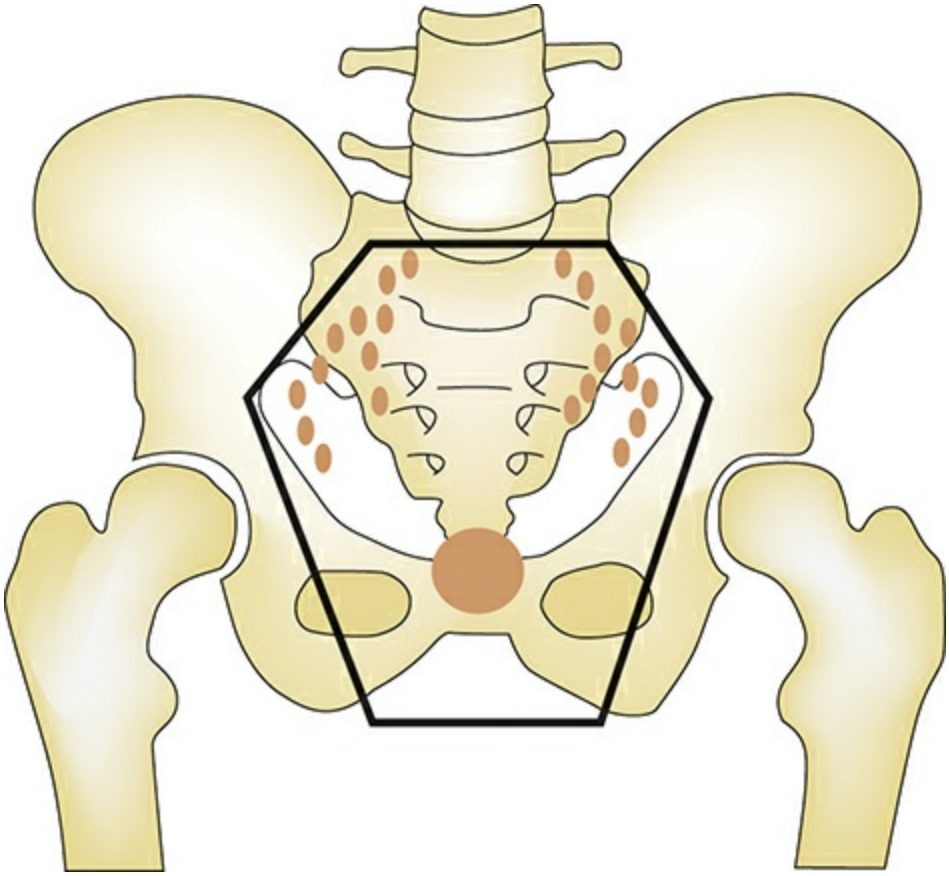

Figure 11.2 Target definition in radiation treatment planning for cervical cancer. The solid circle represents the GTV, which is the cervical primary defined both clinically and radiographically. The CTV is the pelvic lymph nodes, which have a high probability of at least microscopic involvement. The PTV is shown as the outer solid line and represents the margin added to the CTV to account for organ motion and daily setup error.

Interaction of IR with Tissue and DNA Damage

Radiotherapy utilizes IR, which is part of the electromagnetic spectrum of radiation (Fig. 11.3) (1). This spectrum is composed of a broad range of waves ranging from radio waves to visible light and IR. In the electromagnetic spectrum, the energy, wavelength, and frequency of waves are related by the following equations:

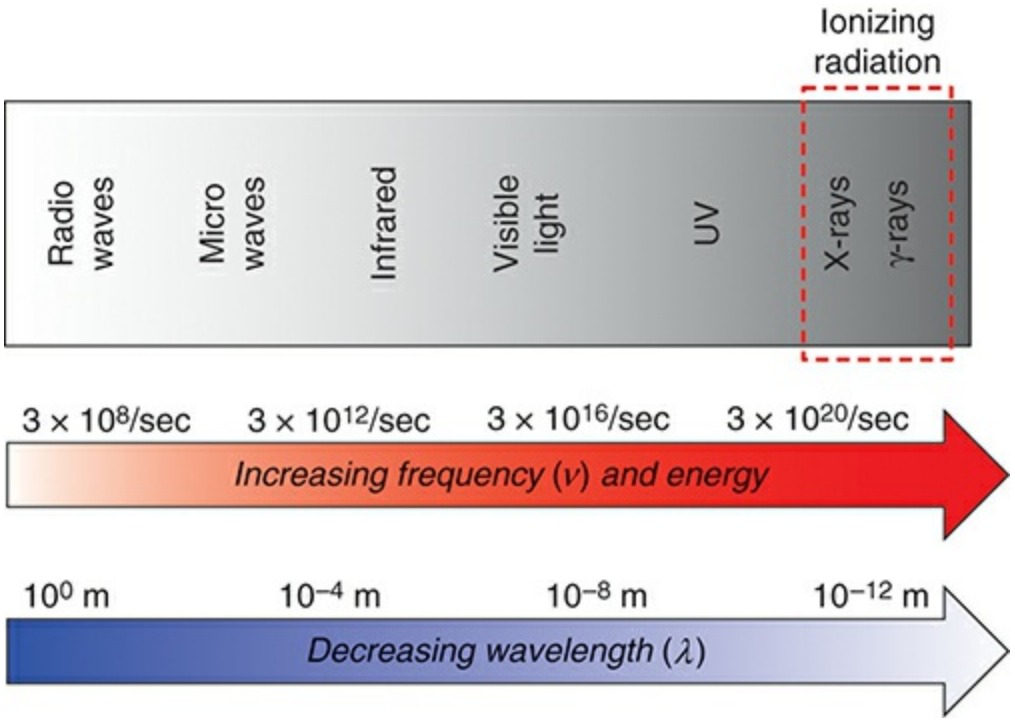

Figure 11.3 Electromagnetic spectrum. X-ray and γ-ray ionizing radiation are located in the short-wavelength, high-frequency, and high-energy part of the spectrum.

$$\text{Energy in electron volts (eV)} = h \times \nu$$
$$c = \lambda \times \nu$$

h = Planck's constant, 4.14×10^{-15} eV seconds
c = speed of light, 3×10^{8} m/sec
λ = wavelength (m)
ν = frequency of wave (1/sec)

Thus, the high-energy waves located in the IR part of the electromagnetic spectrum are of high frequencies and short wavelengths. This radiation is called ionizing, because it deposits a sufficient amount of energy into the tissue to eject electrons from atoms and generate ions. At the high energies of IR used in radiation oncology, IR interacts with atoms through the Compton process (Fig. 11.4). In the Compton process, IR ejects electrons from the outer shells of atoms. These liberated electrons mediate tissue responses to IR. The electrons can directly hit targets within the cell, resulting in damage, that is, direct effect. However, it is the indirect effect of the electrons that predominates. In the indirect effect, the ejected electrons first interact with intracellular water generating hydroxyl radicals. These hydroxyl radicals are highly reactive and damage many components of irradiated tissue through oxidative stress and DNA damage. It should be noted that the timescale of these interactions of IR with tissue is less than seconds, as ionizations and electrons are unstable and are quick to chemically react. However, the downstream effects of IR persist and result in both tumor cell death and normal tissue toxicity. Initial biochemical cellular responses occur within minutes to days following exposure to IR; tumor regression occurs in the ensuing weeks to months; and finally radiation-induced cancers manifest years following the initial exposure to IR.

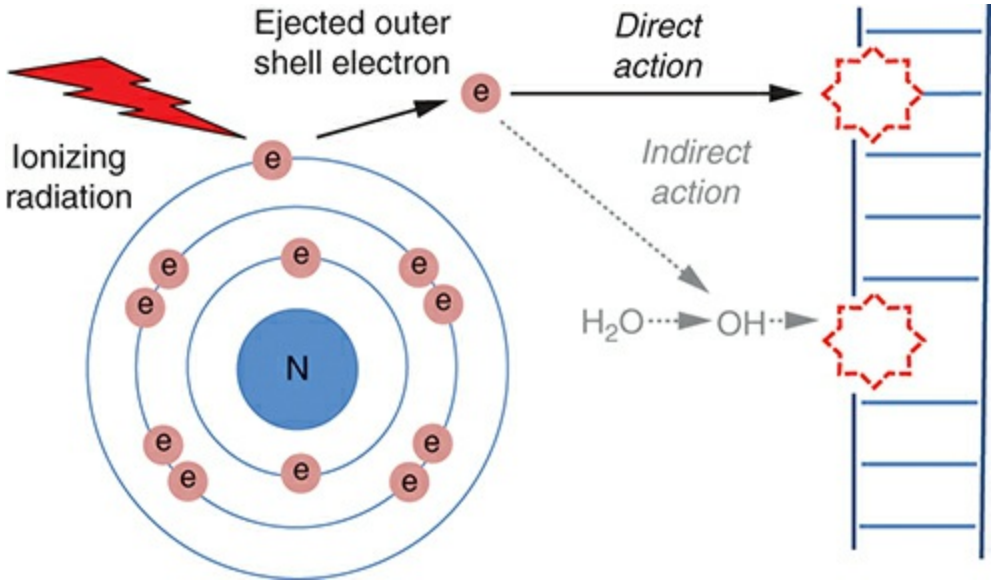

Figure 11.4 Interaction of ionizing radiation with matter. High-energy photons used in radiotherapy result in ejection of outer shell electrons through the Compton process. These ejected electrons then mediate tissue response to radiotherapy by causing oxidative and DNA damage. They can interact directly with DNA (Direct Action) or more likely through interaction with water to and generation of hydroxyl radicals (Indirect Action).

IR-induced free radicals can cause all types of damage to cells. However, for conventional fractionated IR doses (<10 Gy/day), DNA is the major target of IR-generated free radicals. The evidence for DNA as one of the targets for radiation is substantial: (a) incorporation of radioactive tritium into DNA causes cell death at greater rates than cytoplasmic tritium; (b) halogenated pyrimidines, when present in DNA, increase the cell's inherent radiosensitivity in an amount proportionate to the degree of incorporation; (c) a correlation between radiation, DNA double-stranded break repair, and clonogenic survival has also been observed; (d) the concentration of DNA in the nucleus correlates positively with radiosensitivity; (e) microirradiation techniques have shown the nucleus to be the most radiosensitive organelle (6–8). Free radical damage to DNA results in cross-links, base damage, single-strand breaks, and double-strand breaks (Fig. 11.5). These DNA double-strand breaks constitute the "lethal hit" of IR that is responsible for killing cells. IR-induced DNA double-strand breaks can be directly visualized using a single-cell gel electrophoresis assay, also known as neutral comet assay, in which DNA double-strand breaks appear as smaller fragments of DNA that move across the electrical field and form a "tail" to the "comet head" of the larger undamaged DNA strands (Fig. 11.6) (9). While highly valuable in laboratory studies on IR, neutral comet assays are limited to use in cell culture radiobiology basic science research. To assess IR DNA damage in tissue, DNA damage response signaling can be interrogated. IR-induced DNA double-strand breaks result in activation of signaling cascades to deal with the damage. One such response is phosphorylation of histone 2A on serine 139, termed γH2AX. Within the nucleus of irradiated cells, γH2AX foci formation can be quantitated (Fig. 11.7).

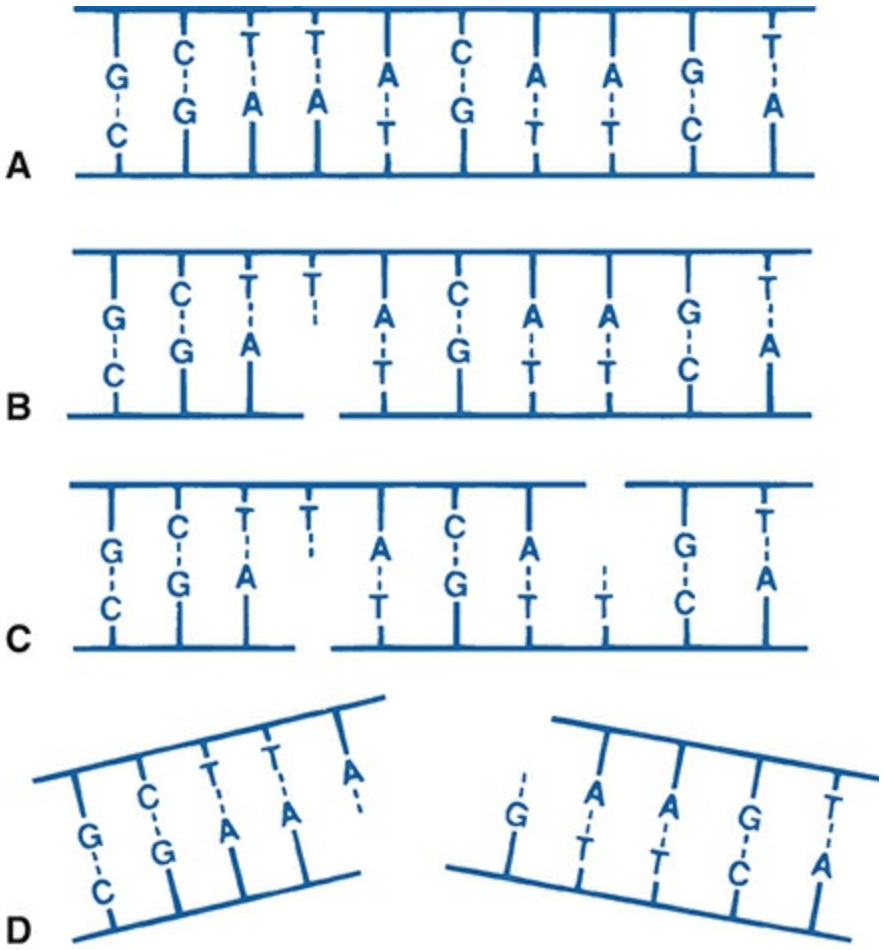

Figure 11.5 Diagrams of single- and double-strand DNA breaks caused by radiation. A: Two-dimensional representation of the normal DNA double helix. The base pairs carrying the genetic code are complementary (i.e., adenine pairs with thymine, guanine pairs with cytosine). B: A break in one strand is of little significance because it is readily repaired, using the opposite strand as a template. C: Breaks in both strands, if well separated, are repaired as independent breaks. D: If breaks occur in both strands and are directly opposite or separated by only a few base pairs, this may lead to a double-strand break, when the chromatin snaps into two pieces.

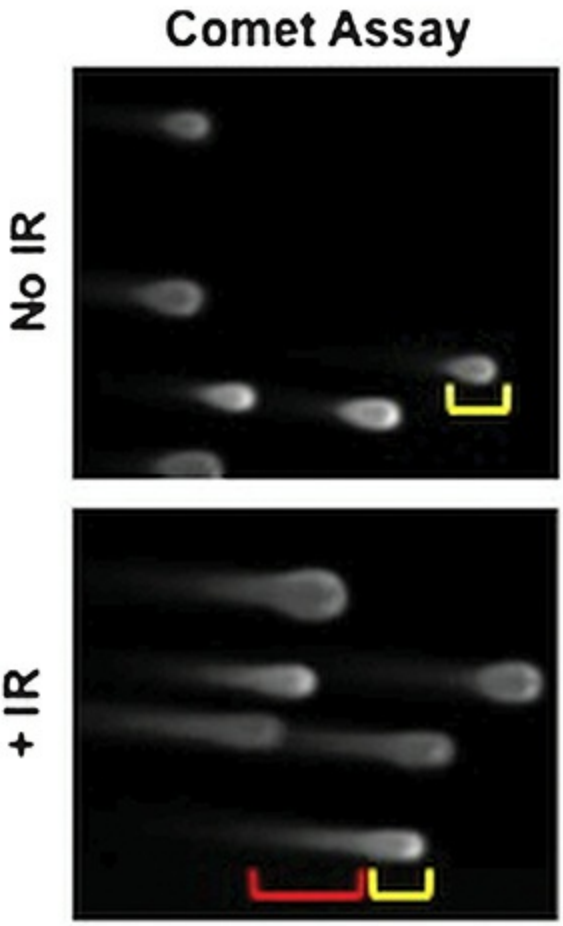

Figure 11.6 Measurement of infrared-induced DNA double-strand breaks. Cells were irradiated and analyzed by neutral comet assay. In nonirradiated cells, intact DNA appears as a nucleoid (comet head), yellow bracketed area. Following IR, DNA double-strand migrate in the electrical field and form a comet tail, red bracketed area.

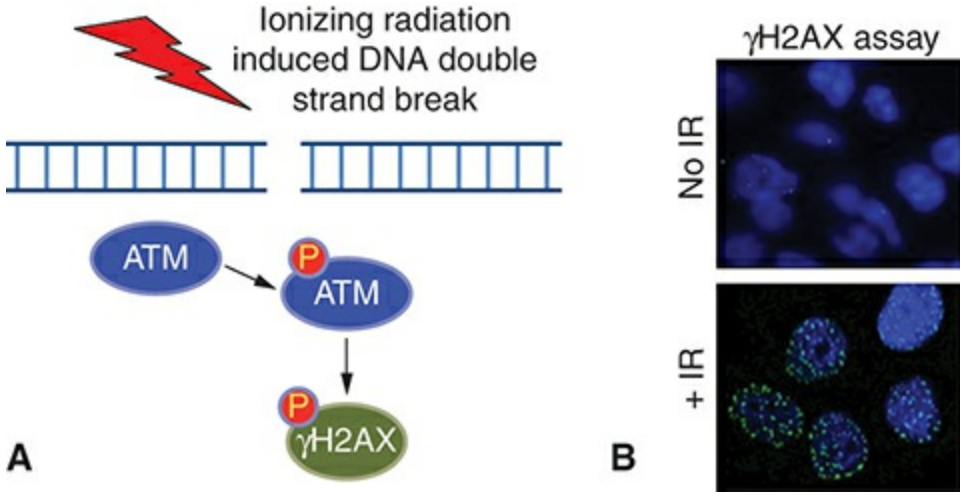

Figure 11.7 Infrared-induced DNA damage. A: DNA double-strand breaks activate DNA damage response signaling cascades. Ataxia telangiectasia mutated (ATM) senses DNA double-strand breaks and autophosphorylates to become active. ATM then phosphorylates and activates downstream effector molecules such as Histone 2. B: Immunofluorescence for gH2AX foci formation in cells. gH2AX foci (green dots) appear in the nuclei (blue stained) of irradiated cells.

Once DNA double-strand breaks are created, cells attempt to fix the damage. Resolution of DNA double-strand breaks can result in chromosomal aberrations that are classified as lethal or nonlethal (Fig. 11.8) (10). These aberrations are readily apparent in chromosomes of people exposed to IR, by either direct visualization of metaphase chromosome spreads or more advanced techniques of fluorescence in situ hybridization (FISH), in which each chromosome is "painted" a different color. Nonlethal chromosomal aberrations include translocations and deletions. While genetic information is lost in these two cases, cells are still potentially capable of surviving and proliferating. Lethal resolutions of DNA double-strand breaks include dicentric and ring chromosome formation. The commonality of lethal resolutions is that an acentric DNA fragment is created such that during cell division at mitosis, one daughter cell loses an entire chromosome, resulting in cell death. Mechanistically, cells have evolved two major processes for repairing DNA double-strand breaks, nonhomologous end joining (NHEJ) and homologous recombination (HR) (11). NHEJ is the simplest type of repair mechanism. In NHEJ, two ends of broken DNA are processed and then ligated together. It does not utilize or require an undamaged DNA template. Therefore, NHEJ is error-prone and can result in mutations introduced in the genome through insertions or deletions of genetic material. In contrast to NHEJ, HR is an error-free DNA double-strand break repair process. HR requires a DNA template, and therefore can only occur when cells are in the S/G_2 phase of the cell cycle and an undamaged template DNA strand exists.

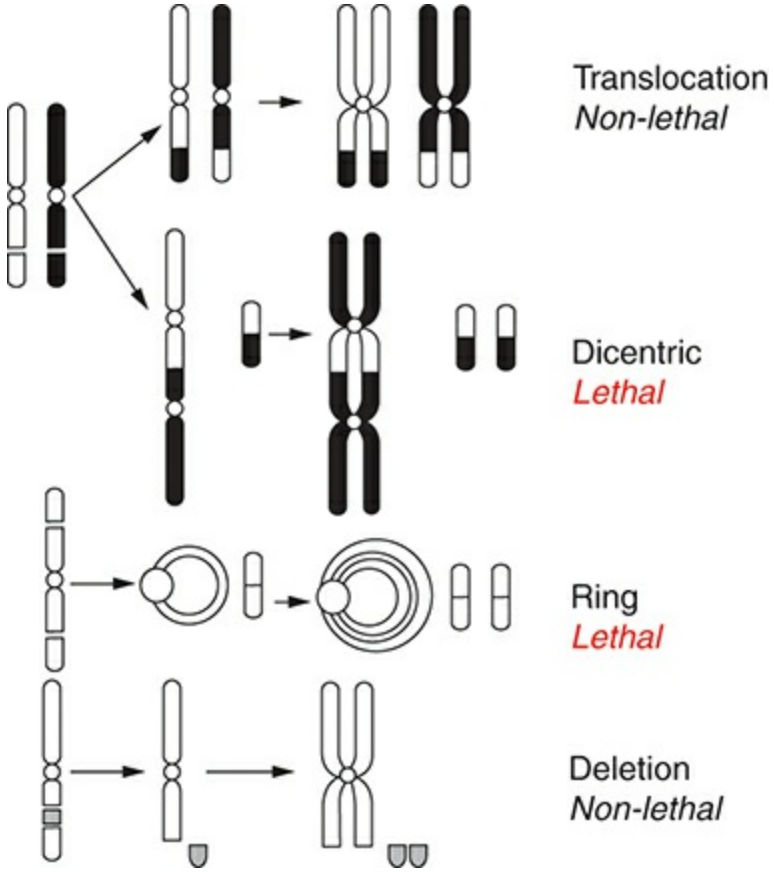

Figure 11.8 Chromosomal aberrations induced by ionizing radiation. IR results in DNA double-strand breaks that can lead to chromosomal aberrations. Chromosomal aberrations can be classified as lethal or nonlethal based on the ability of chromosomes to segregate to daughter cells in mitosis.

Following repair of IR-induced damage, the long-term impacts on surviving tissue are classified as deterministic and stochastic effects (12). Deterministic effects have a threshold IR dose above which they are typically observed. Once the threshold dose is reached, further increases in IR dose result in increased severity of the phenotype. The classic example of an IR deterministic effect is cataract formation. At very low doses of IR to the lens of the eye, the chance of cataract

formation is next to zero. However, once a threshold dose of IR is delivered, cataracts can develop. In contrast, stochastic effects have no threshold IR dose at which they can potentially occur and their severity does not increase as more IR dose is delivered. The most troubling stochastic effect of IR is radiation-induced carcinogenesis. In principle, any dose of IR is randomly capable of inducing DNA damage with resulting genetic mutations that lead to cancer development. Like deterministic effects, stochastic effects are more likely to occur as IR dose increases due to the probabilistic manner in which IR interacts with tissue. With these concerning late effects of IR, every effort is made to judiciously apply IR to a patient's situation. The deterministic and stochastic effects of IR are the key reasons for which both diagnostic and therapeutic X-rays are avoided in pregnant women: to avoid long-term consequences to the developing fetus with respect to both organ damage (deterministic effects) and cancer development (stochastic effects).

IR-Induced Cell Death

Cell death can be classified based on the cells' functional or reproductive integrity. Functional death occurs in nonproliferating cells such as neurons when they can no longer perform their function. Higher doses of IR are required to induce functional death. In contrast, reproductive integrity is seen with proliferating cells such as tumor cells and requires much lower doses of IR. When a proliferating cell is irradiated, there are three possible outcomes: survival, senescence, or death. Survival requires repair of damaged DNA such as through NHEJ or HR described earlier. However, even after recovering from the initial irradiation, surviving cells may have mutations and damage resulting in deterministic or stochastic effects. While survival of irradiated cells in normal tissue is paramount, the ultimate goal of radiotherapy is the death of tumor cells, or, more precisely, preventing tumor cells from replicating. Replicative senescence can occur after DNA damage when cells permanently exit the cell cycle and do not replicate. Senescence is a mechanism of self-preservation for damaged cells, since cellular division would result in death. It should be noted that senescence is different than quiescence. Quiescence is a temporary exit from the cell cycle at G_1 into the G_0 phase. Cells in G_0 are not preparing to divide but can still perform their function. Under appropriate stimuli, cells in quiescence reenter the cell cycle and divide. While not a mechanism of cell death, if tumor cells undergo senescence, the patient is in essence cured of her tumor. For cell death, mechanisms following irradiation include apoptosis, autophagy, and mitotic catastrophe.

Apoptosis, or programmed cell death, follows an orderly cascade (13). It is an energy-dependent process that requires intact molecular biologic pathways. Apoptosis can be initiated by two distinct mechanisms: (a) extrinsic pathway, where the apoptotic stimulus occurs extracellularly, or (b) intrinsic pathway, where the cascade of events is mediated by intracellular events (Fig. 11.9). Mechanistically, apoptosis is mediated by caspases that are expressed as inactive precursors (procaspases). Upon apoptotic stimuli, proteolytic cleavage of procaspases results in active caspases, which then cleave downstream effector proteins. The extrinsic pathway begins by binding of a specific ligand such as Fas-L or tumor necrosis factor (TNF) to a membrane death receptor. The intrinsic pathway, on the other hand, requires disruption of the mitochondrial membrane and release of cytochrome c from the mitochondria to the cytoplasm. While the upstream activation of apoptosis through extrinsic or intrinsic pathways differs, both pathways converge on cleaving and activating procaspase 3. A number of methods have been developed to measure apoptosis including caspase cleavage, DNA fragmentation, and cellular membrane changes. If apoptosis occurs, it is evident within hours of IR by activation of caspases and loss of cell membrane polarity. However, while conventional fractionated radiotherapy does not induce significant apoptosis in solid tumors, recent preclinical evidence suggests that larger single fractions of radiotherapy (>10 Gy) can induce apoptosis in irradiated endothelial cells (14,15). Given the location of gynecologic cancers, such large fractions of IR have not typically been employed. However, with advances in brachytherapy planning and delivery, such higher doses may provide a way to target the tumor vasculature. Autophagy occurs during nutrient deprivation and metabolic stress (16). The goal of autophagy is catabolism of cellular structures to provide a source of nutrients to cells and help them survive periods of stress. Its role in IR-induced death is under investigation.

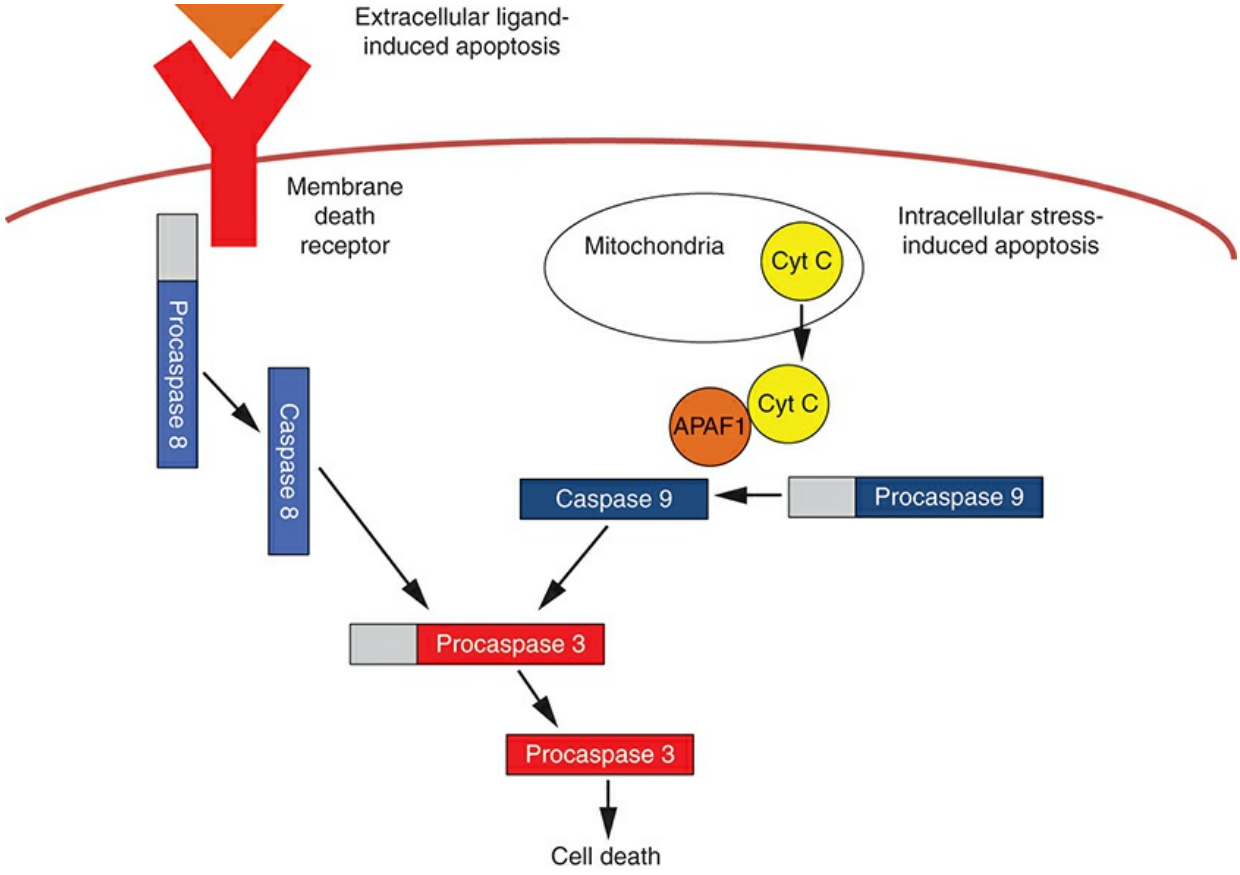

Figure 11.9 Apoptotic pathways of cell death. In the extrinsic pathway, death receptor binding of ligand activates initiator caspase 8. In the intrinsic pathways, intracellular stress results in mitochondrial release of cytochrome C (cyt C), which binds to apoptotic protease activating factor 1 (APAF1) to activate initiator caspase 9. Both pathways converge on activating effector caspases, i.e., caspase 3, which result in apoptotic cell death.

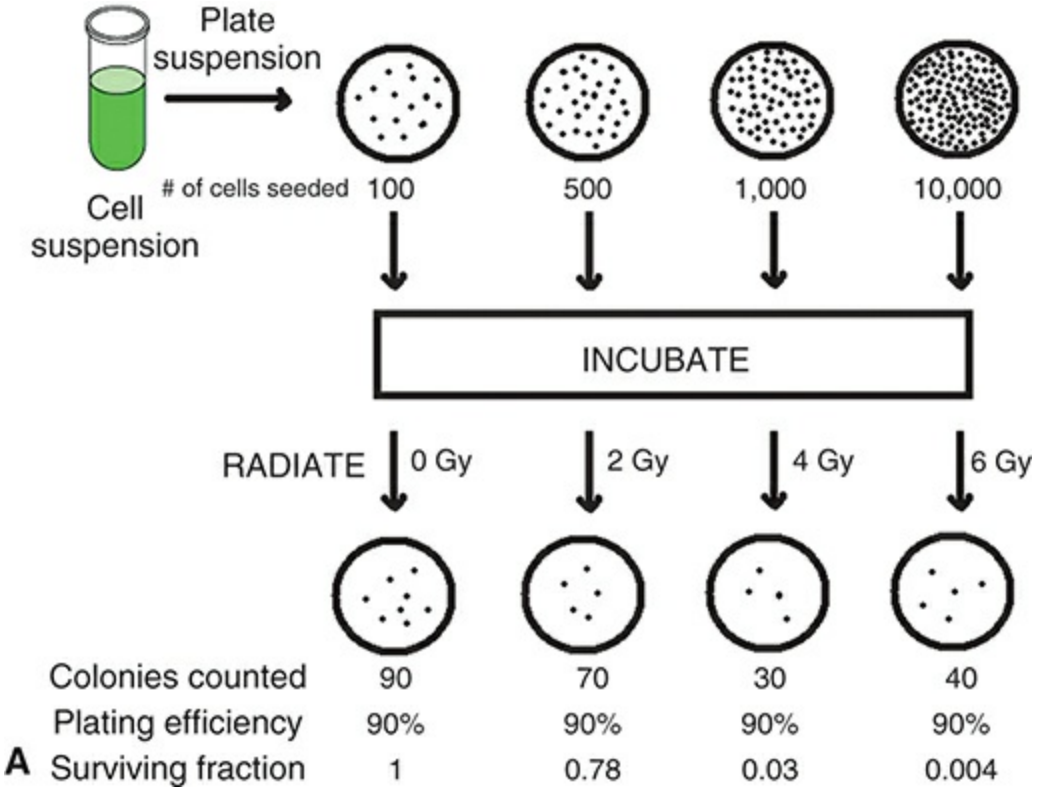
Mitotic catastrophe is the predominant mechanism of cell death induced by IR (17). In mitotic catastrophe, cells die as a result of trying to replicate. As mentioned above, IR-induced DNA double-strand breaks results in chromosome and chromatid aberrations. If not dividing, the full complement of genetic material remains within the cell. However, when cells pass through mitosis and divide into two daughter cells, certain chromosome and chromatid aberrations (e.g., ring and dicentric chromosomes) do not result in equal segregation of the genetic material to the two daughter cells. In addition, DNA double-strand breaks result in increasing genomic instability of dividing cells. Therefore, cells may replicate a few times, after which the loss of increasing genetic material results in cell death. In contrast to the orderly process of apoptosis, mitotic catastrophe is energy-independent and results in necrosis and inflammation. Since it requires cells to divide, mitotic catastrophe is not evident as quickly as apoptosis.

Cell Survival Curves and Tumor Control Probability

The gold standard technique used to measure IR-induced cell kill is the clonogenic assay (Fig. 11.10) (18). The clonogenic assay is particularly useful for measuring cell death through mitotic catastrophe. In principle, it measures the reproductive ability of individual cells following different doses of IR. Cells are seeded at low density and allowed to replicate for 10 to 14 days, over which time each cell forms a colony of >50 daughter cells. As cells undergo mitotic catastrophe they stop dividing and do not form a colony of >50 daughter cells. Since it is such a crucial technique for measuring sensitivity of cells to IR, we will review the technique in some detail. It first involves creating a suspension containing the target

population of cells at a known concentration. An aliquot with a known number of cells is plated on growth media and allowed to incubate. As one would expect, not all the cells successfully form a colony, and so plating efficiency must be calculated by dividing the number of formed colonies by the starting number of cells. The experiment is repeated, but after plating and before incubation, the Petri dish is irradiated. The number of colonies formed is divided by the starting number of cells, which is then divided by plating efficiency to yield the ratio of surviving cells. This experiment is repeated over a range of doses of radiation and under various conditions to yield a cell survival curve. An important feature of the cell survival curve is that it uses a logarithmic scale on the *y*-axis. This correlates with mathematical modeling of cell survival as a function of radiation dose.



A

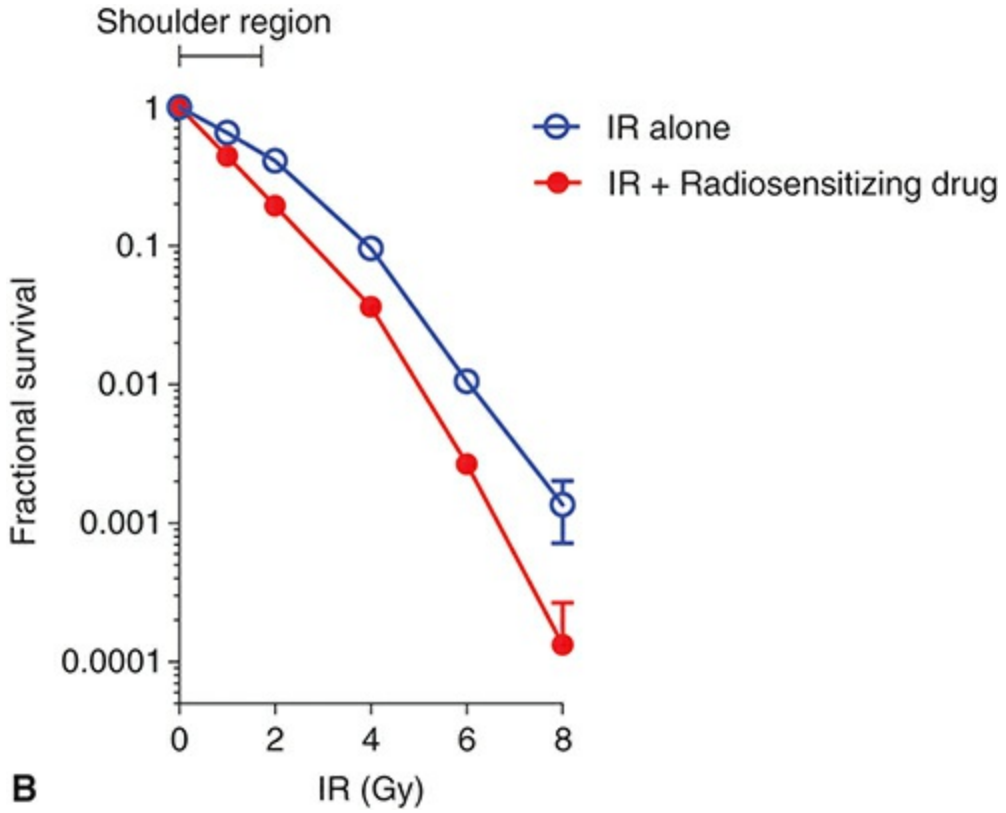


Figure 11.10 Clonogenic survival curves. Surviving fraction of irradiated cells. A: Cell culture technique used for clonogenic assays. A cell suspension of a known concentration of cells is used to seed differing number of cells in cell culture dishes. The cells are allowed to settle and are then irradiated. Viable cells will replicate and form colonies visible to the naked eye. The plating efficiency is calculated in the nonirradiated condition and used to normalize the surviving fraction of irradiated cells. B: The surviving fraction is then plotted logarithmically on the y-axis and an IR dose is plotted linearly on the x-axis (blue line). Red line shows decreased survival of cells that were treated with a radiosensitizer prior to irradiation.

The simplest model one can envision for the sterilization of cancer cells by radiation in a given volume is the log cell kill model. A typical course of radiation therapy is given in 10 to 40 fractions administered over 2 to 8 weeks. Each fraction kills a fixed percentage of cells. One term that can be used for this is D_{10}, the dose that kills 90% of the cells. If there are 100 cells and a D_{10} dose is administered, 10 viable cells remain. Consider a tumor 1 g in size, which has 10^9 cells. If the D_{10} for this tumor is 3 Gy, how many fractions are required for a 90% chance of sterilization? The log cell kill model gets slightly more complicated when dealing in fractions, as 1/10 of a viable cell does not exist. Instead, 0.1 cells represent a 10% chance that a viable cell will exist at the end of therapy. Therefore, a tumor with 10^9 cells requires 10 decades of cell kill for a 90% chance of tumor control. Three Gy × 10 fractions = 30 Gy total dose. This model makes a number of invalid assumptions such as D_{10} remaining constant throughout the course of radiation, but highlights the logarithmic nature of fractionated radiation kill. Instead of D_{10}, D_0 is the more commonly used term in radiobiology and is based on natural logarithm, where base e = 2.72. D_0 is the dose of radiation where 1/e (37%) cells survive or 63% (1 − 1/e) of cells are killed. D_0 is related to D_{10} by the following formula: $D_{10} = 2.3 \times D_0$. For most tumors, the D_0 is estimated to be 1 to 2 Gy, and in fractionated external beam radiation we typically deliver 1.8 or 2 Gy with each fraction.

Two theoretical experimental cell survival curves are shown in Figure 11.11 under either LDR (low-dose-rate) or HDR (high-dose-rate) radiation conditions. The curve for LDR is best fit by a straight line, while the HDR curve is shown to have two components, an earlier linear component mirroring the LDR curve followed by a quadratic component. At higher doses of radiation, the HDR curve always has a higher proportion of cell kill than the LDR curve for any given dose. The

rate at which radiation is delivered causes dramatic differences in the shape of the cell survival curve. This is best described by considering the linear quadratic model with DNA as the lethal target. In the linear quadratic model:

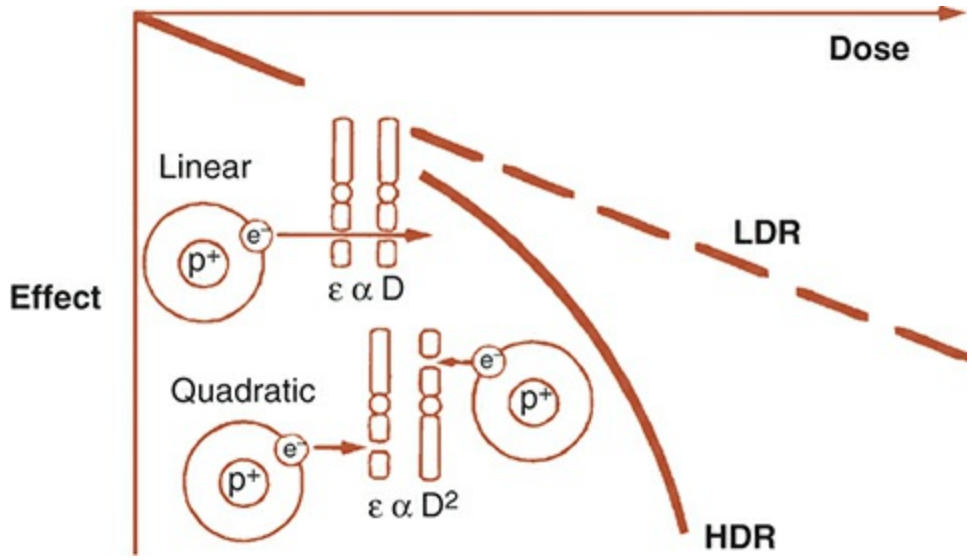

Figure 11.11 Cell killing by radiation is largely due to aberrations caused by breaks in two chromosomes. The dose-response curve for HDR irradiation is linear quadratic: the two breaks may be caused by the same electron (dominant at low doses) or by two different electrons (dominant at higher doses). For LDR irradiation, where radiation is delivered over a protracted period, the principal mechanism of cell killing is by the single electron. Consequently, the LDR survival curve is an extension of the low-dose region of the HDR survival curve.

$$\text{Surviving fraction} = e^{-\alpha D-\beta D2}$$

α constant for proportion of cell survival due to linear component
β constant for proportion of cell survival due to quadratic component
D: dose of IR

The linear component is due to a single ejected electron causing both DSBs. The important point is that the degree of the linear component of cell kill, also known as α kill, is proportional to D since only one photon/electron is involved. The linear quadratic model also shows two chromosomal breaks, the result of two separate ejected Compton electrons by radiation. Cell kill accounted for by the quadratic portion, or β kill, is proportional to D^2 because two photons/electrons are involved. Looking at the HDR curve at low doses of radiation, there is very little β kill; however, at higher doses, the β component increases exponentially because of D^2. Under LDR conditions, the β component is absent, leaving only α kill. This is best explained by the idea that β kill involves damage to one chromosome and so is more easily repaired, provided that the radiation dose rate and rate of DSB formation are not significantly greater than the cell's repair capacity. The linear quadratic formula was used to generate Figure 11.12. The dashed line represents the α component and is generated by extrapolating the initial slope of the curve to higher doses of radiation. The point at which the α and β kill are equal is shown, and the dose at which this occurs is called the α/β ratio. It is worth noting that the α/β ratio is a bit of a misnomer, as ratios typically are unitless values. However, α/β has the units of Gy. The α/β ratio for early side effects and tumor tissue is thought to be higher, approximately 10 Gy, than for late side effects, which is estimated to be 3 Gy.

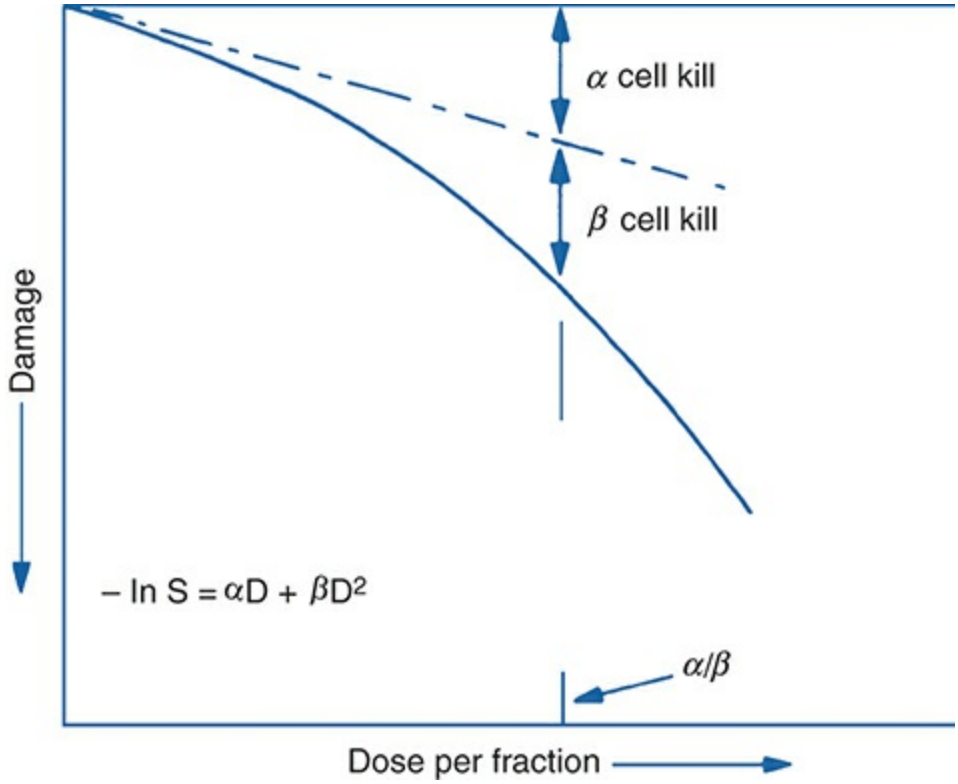

Figure 11.12 At a dose equal to the a/b ratio, the log cell kill due to the a process (nonreparable) is equal to that due to the b process (reparable injury): a/b is thus a measure of how soon the survival curve begins to bend over significantly.
Source: Reprinted from Fowler JR. Fractionation and therapeutic gain. In: Steel GG, Adams GE, Peckham MJ, eds. Biologic Basis of Radiotherapy. Amsterdam, The Netherlands: Elsevier Science; 1983:181–194, with permission from Elsevier.

Of clinical relevance is the α/β ratio, which helps to calculate biologically effective doses (BED). It is clear from Figure 11.4 that both the total dose of radiation and the speed at which it is delivered can produce very different outcomes. The same holds true for fractionated courses of radiation. For example, 16 Gy delivered in a single treatment, as is the case for radiosurgery, can sterilize a small cancerous tumor of cancer cells. However, the same treatment delivered over 8 days would be clinically insignificant. Figure 11.9 shows theoretical cell survival curves for early and late reactions under two separate experimental conditions, single fraction and multifraction regimens. A formula that normalizes a biologic endpoint under various dose-fractionation schemes is necessary (5). The α/β ratio from the linear quadratic equation has enabled the prediction of various biologic endpoints with different fractionation schemes, and is given by the following equation:

$$\mathrm{BED} = nd(1 + \mathrm{d}/(\alpha/\beta))$$

BED = biologically effective dose
n = number of fractions
d = dose per fraction
α/β = dose where the α component of cell kill equals the β component

BED calculations allow for comparison of two different dose-fractionation schemes in terms of tumor control/acute toxicity if α/β is 3, or late tissue complications when α/β is set to 10. An extension of this BED calculation is the ability to calculate the total dose delivered in 2 Gy fractions. This is particularly useful in gynecologic oncology patients where the radiation dose is delivered as both external beam radiotherapy and brachytherapy. A measure of the total dose delivered, if delivered as 2 Gy fractions, can be calculated using the EQD2 formula:

$$EQD2 = (BED_{EBRT} + BED_{BT})/(1 + 2/\alpha/\beta)$$

BED_{EBRT}: External beam contribution to BED
BED_{BT}: Brachytherapy contribution BED

EQD2 calculations are a tool to allow for meaningful comparisons of different IR fractionation schemes. In principle, if the EQD2 is the same for two different IR regimens, they should yield similar patient outcomes.

While these mathematical models of radiation cell kill all have their limitations, they do provide a foundation for how radiation oncologists approach the total dose delivered and the fraction size used. Moreover, the basic concepts of radiation log kill are reflected in the administered treatments. Consider, for example, curative therapy for cervical cancer. While the CTV has a high likelihood of harboring malignancy, it does not have clinically evident disease. For cervical cancer, this could be normal-sized pelvic and possibly paraaortic lymph nodes or an area of positive margin. The CTV typically requires a lower dose of radiation for control, ranging from 45 to 54 Gy, as there are potentially fewer cancer cells that to eradicate. In contrast, the GTV with its known bulky disease requires a higher dose of radiation, such as 80 to 90 Gy, to sterilize the larger number of tumor cells. Attaining such doses of radiation while respecting normal tissue tolerance is not feasible with EBRT alone and therefore brachytherapy is required. In contrast, if a patient undergoes a hysterectomy in which bulk tumor is removed, then there is no GTV, and brachytherapy is often not needed because dose to the CTV can be safely administered by external beam radiation therapy or lower doses of brachytherapy alone.

Factors Influencing Tissue Sensitivity to Radiation Therapy

The above discussion provides the general biologic basis of how IR interacts with cells. However, the clinical utility of radiation therapy is dependent on tumor and normal tissue characteristics that play a pivotal role in how radiotherapy is delivered, and its efficacy. There are four classic factors that have been termed the “4 R’s” of radiobiology: (1) Repair, (2) Repopulation, (3) Reassortment, and (4) Reoxygenation. These “4 R’s” provide a rationale and framework for the fundamental basis of using fractionated radiotherapy.

Repair

With DNA being the critical target, radiation therapy needs to selectively damage the DNA of tumor cells yet spare the surrounding normal tissues. The simplest solution would be to deposit IR dose to tumor cells and not to normal tissues. Current technology using IMRT and brachytherapy techniques makes it possible for IR doses to better conform to tumors and spare the critical normal tissues in close proximity. Radiobiologically, tumor and normal tissue often have a differential capacity for DNA damage repair that can be exploited to widen the therapeutic ratio of IR. In survival curves of irradiated cells, a “shoulder” region is apparent at lower doses. Following IR, cells attempt to repair the DNA damage. At high doses, the repair processes are overwhelmed and cell death occurs in an exponential manner. However, at lower doses, cells are able to repair the DNA damage if sufficient time is given prior to the delivery of another dose of IR. Therefore, this “shoulder” region of the survival curve represents sublethal damage repair (19). The dose range of IR within the shoulder region is often within the clinically relevant doses of D_0. A consequence of genomic instability within cancer cells is decreased DNA damage repair capacity compared to normal tissue. Graphically, the “shoulder” region of irradiation survival curves is wider in noncancerous cells compared to cancer cells (Fig. 11.13). Therefore, instead of delivering one large dose of IR, the total IR dose is split into smaller doses that are delivered over weeks. Note that by breaking up the radiotherapy in fractions, the shoulder of the cell survival curve is repeated and by doing this, we are able to amplify the ability of normal tissue to repair and tolerate IR damage while tumor cells are preferentially killed. Also of importance is that sublethal DNA damage repair takes hours to occur and provides a rationale for delivering fractionated external beam radiotherapy once daily, to allow time for normal tissues to recover from radiation-induced DNA damage.

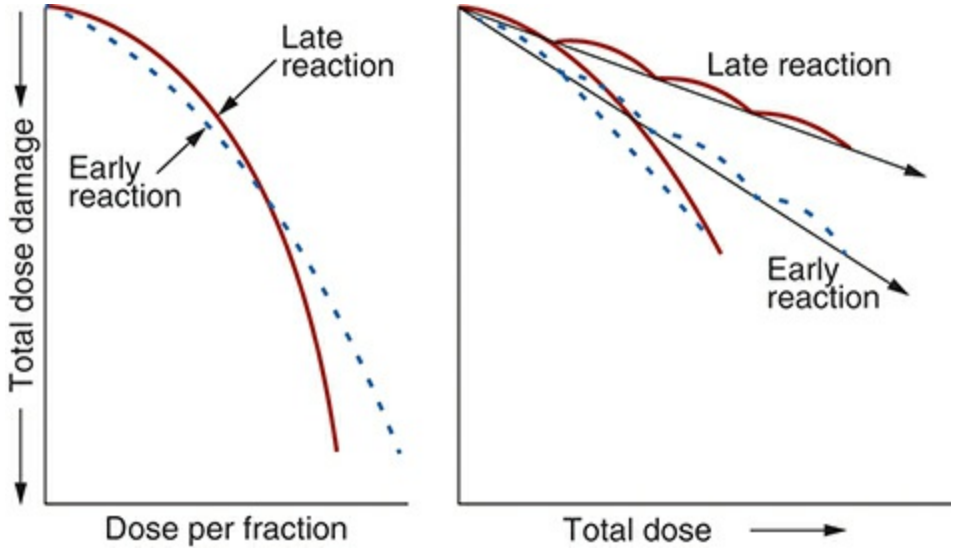

Figure 11.13 Difference in cell survival curves for acute and late radiation effects with single or multifractionated doses of irradiation.
Source: Reprinted from Fowler JF. Fractionation and therapeutic gain. In: Steel GG, Adams GE, Peckham MT, eds. Biologic Basis of Radiotherapy. Amsterdam, The Netherlands: Elsevier Science; 1983:181, with permission from Elsevier.

Repopulation

While fractionating IR allows for sublethal damage repair in normal tissue, it needs to be balanced against the concept of tumor repopulation. Following tumor irradiation, a phenomenon of accelerated repopulation has been demonstrated to occur (20,21). In accelerated repopulation, stress responses and death of a proportion of the tumor result in surviving tumor cells proliferating more rapidly. To combat this, the overall time in which the total radiotherapy package (external beam and brachytherapy) is delivered to patients should be minimized. Avoidance of treatment breaks due to acute radiotherapy/chemotherapy side effects to the normal tissues (bowel, bladder, bone marrow) is paramount, as treatment breaks may compromise patient outcomes by allowing cancerous cells to proliferate, negating the goals of therapy. Clinical data support such a concept in patients with cervical cancer, where an increase in overall radiotherapy treatment time has been shown to negatively affect outcomes.

Reassortment

Interestingly, intrinsic sensitivity to IR varies with the cell cycle. The cell cycle is an orderly progression resulting in DNA replication and division into two daughter cells (Fig. 11.14) (22,23). S phase stands for “synthesis” and is where DNA replication occurs. M phase stands for “mitosis” and is when cellular division occurs to create two daughter cells. In between are the G_1 and G_2 phases, standing for “gap 1” and “gap 2.” Late S phase tends to be the most radioresistant phase of the cell cycle because the DNA repair machinery for replication can also repair radiation damage. In contrast, the M phase is also the most radiosensitive phase of the cell cycle because once the cell enters into M phase, it will attempt to divide without arresting. Therefore, any DNA damage caused in M phase is likely to be passed along to the daughter cells and may be fatal. This is another important reason why rapidly dividing cells such as cancer cells are radiosensitive as opposed to slower proliferating normal tissue. While M phase is the most radiosensitive it is also unfortunately the portion of the cell cycle in which cells spend the least amount of time. Approximately 15% of cycling tumor cells are in G_2/M at a given moment. Therefore, the majority of tumor cells are in a relatively radioresistant phase of the cell cycle on any given day radiation is delivered. Fractionating and delivering IR over multiple days takes advantage of the fact that different populations of the tumor will be in G_2/M during each day’s treatment and will have increased sensitivity to IR. In addition,

IR-induced DNA damage results in cell cycle checkpoints, and in particular the G_2/M checkpoint. Checkpoints take cells temporarily out of the cell cycle so they can assess and respond to their damage. IR can synchronize tumor cells so that the following day a greater fraction will be in the radiosensitive G_2/M phase of the cell cycle.

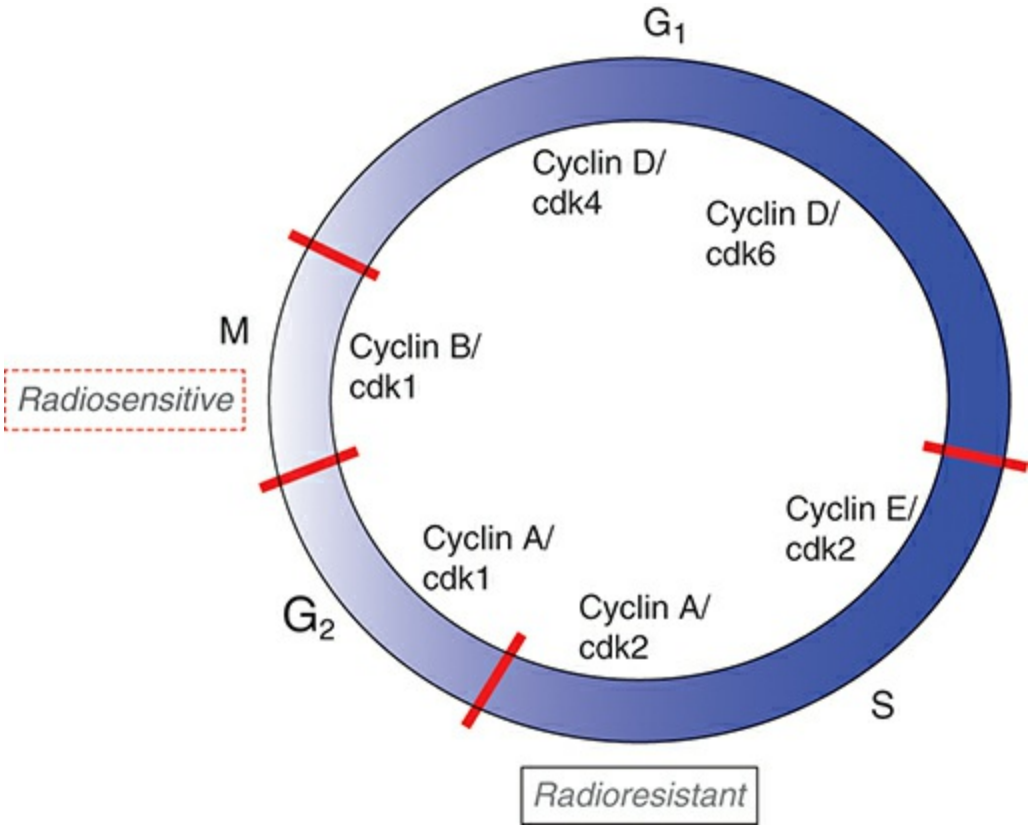

Figure 11.14 Cell cycle and variation in radiosensitivity. As cells replicate they pass through phases of the cell cycle where a unique cyclin and cyclin-dependent kinase (cdk) heterodimer is formed. Each cyclin/cdk heterodimer phosphorylates and activates a unique set of proteins required for completion of that phase. DNA synthesis occurs in S phase, which is the most radioresistant phase. Cell division occurs in M phase, which is the most radiosensitive phase of the cell cycle.

Reoxygenation

Oxygen within tumor cells alters sensitivity to radiation (24,25). Under hypoxic conditions, cells are relatively resistant to radiation compared to oxygenated tumors. The oxygen enhancement ratio (OER) for radiation is approximately 3, which implies the dose of radiation required under hypoxic conditions is three times that needed under aerated conditions to create a similar level of cell kill. Oxygen is known to chemically modify radiation-induced DNA damage by creating a DNA–peroxide bond, thereby making it very difficult to repair by the cell. This is known as the oxygen fixation hypothesis (26). Therefore, under hypoxic conditions, one would expect DNA damage repair to be more effective, and higher dose would therefore be required to kill cells.

Tumor hypoxia can be categorized as either acute or chronic. Acute hypoxia is perfusion limited and occurs due to temporary closures of vasculature secondary to temporary vasospasms and malformed tumor blood vessels. As with tumor reassortment, areas of acute hypoxia within the tumor will vary from day to day, as do the cells in G_2/M. Areas of the tumor that were acutely hypoxic on a given day may have increased blood flow and oxygen delivery on subsequent days of radiation. In contrast to the perfusion limits of acute hypoxia, chronic hypoxia is defined as diffusion limited and occurs as tumor growth outstrips its vasculature. In tissue, oxygen can diffuse a distance of 70 to 100 μm from blood

vessels. Therefore, tumor cells that are located further from the vasculature have decreased oxygen delivery and are relatively resistant to IR.

Combining Radiotherapy with Systemic Therapies

For locally advanced cancers, patient outcomes are improved when radiotherapy is combined with chemotherapy (2–4). Rationales for delivery of chemotherapy concurrently with radiotherapy are: (1) it allows delivery of the entire treatment package in a more compact time frame; (2) radiotherapy and chemotherapy kill cancer cells by different mechanisms, making it more difficult for resistant tumor clones to survive; (3) certain chemotherapy drugs sensitize tumor cells to IR-mediated DNA damage and cell death. Cytotoxic chemotherapies such as cisplatin, 5-fluorouracil (5-FU), and paclitaxel function as radiosensitizers and have been used in patients with locally advanced cervical cancer to improve tumor control. As the molecular events that drive cancers are elucidated, more targeted approaches to radiosensitization are being evaluated (27–29). An example of this is the epidermal growth factor receptor (EGFR). EGFR is a member of the ErbB family of cell surface receptors. Certain tumors overexpress EGFR. Binding of EGFR to its ligand results in intracellular signaling promoting tumor growth and resistance to radiotherapy. EGFR has been pharmacologically targeted with antibodies (cetuximab) and small molecule inhibitors (erlotinib, gefitinib). Preclinical research has shown that EGFR inhibition radiosensitizes tumor cells.

Another radiosensitization strategy moves away from targeting tumor cells and instead targets the tumor vasculature (30,31). Tumor angiogenesis is crucial to the continued growth of tumors as they grow larger than 70 to 100 μm. Tumor vessel growth relies on vascular endothelial growth factors (VEGFs). Bevacizumab is a monoclonal antibody that binds VEGF-A, which then prevents VEGF-A from binding to VEGF receptors located on endothelial cells. Preclinical data suggest that treating tumors with bevacizumab can also radiosensitize them. Bevacizumab can potentially interact with IR in two distinct fashions. First, via the decrease in VEGF receptor signaling endothelial cells are more likely to be killed by IR (32). Second, treating tumors with bevacizumab results in “renormalization” of the tumor vasculature (30). Tumor vasculature is more chaotically organized than blood vessels in normal tissue due to an imbalance of pro- and antiangiogenesis factors. This results in increased permeability and interstitial pressure within tumors and has the untoward consequence of decreasing both chemotherapy and oxygen delivery to tumor cells. Bevacizumab helps to restore the balance of pro- and antiangiogenesis factors. By increasing cytotoxic chemotherapy and oxygen delivery to tumors, bevacizumab can also increase the sensitivity of tumor cells to IR-mediated cell death.

Finally, immunotherapy is emerging as a paradigm-shifting approach to cancer therapy that can be combined with radiotherapy (31,33,34). While the concept is not new, elucidation of mechanisms involved in immune tolerance of tumor growth has resulted in the discovery of new pharmacologic targets. As cancers evolve they develop strategies to hide from the immune system through immune checkpoints that downregulate immune responses. Two checkpoint inhibitors have begun to show clinical efficacy. Ipilimumab is an antibody against cytotoxic T-lymphocyte antigen 4 (CTLA-4). Nivolumab and pembrolizumab are antibodies against programmed cell death protein-1 (PD-1). While antibodies to CTLA-4 and PD-1 reverse tumor immune suppression, they do so by distinct nonoverlapping mechanisms. Interestingly, IR has also been shown to evoke a tumor immune response that results in an abscopal effect. In preclinical animal models that harbor multiple tumors, localized treatment of a single tumor with IR can result in tumor shrinkage in the other nonirradiated tumors (i.e., abscopal effect). More recently, trials in cancer patients with metastatic disease suggest that radiotherapy to a single tumor site, in combination with activation of the immune system by either interleukin (IL)-2 or checkpoint inhibitors, can result in abscopal responses (35,36). The abscopal effect is a phenomenon observed in metastatic cancer patients, where treating only a single metastasis with focal radiotherapy also results in distant nontreated tumors shrinking. While these data are early, they do suggest a novel and important role for radiotherapy in modulating tumor immune responses in patients that are distinct from IR’s conventional role of being a local therapy that kills cancer cells by inducing DNA damage. As these and other targeted approaches are translated from the laboratory to clinical testing, the development of more personalized approaches to using radiotherapy in cancer patients will improve tumor

control and decrease toxicity to normal tissue.

INTRODUCTION TO RADIATION PHYSICS

Radiation physics is the study of the interaction of radiation with matter. In the treatment of patients with radiation, this matter is either tumor tissue or normal tissues such as the skin, the internal organs, or the supporting tissues and structures.

Units Used in Radiation and Radiation Therapy

Radiation is a term that refers to "energy in transit." In a general sense, it can be categorized as ionizing or nonionizing (such as the visible light). IR is used in radiation therapy, a process where neutral atoms acquire a positive or a negative charge. This process can take numerous forms. The most common forms of IR used in radiation therapy are X-rays, γ-rays, neutrons (electromagnetic radiation), electrons, and protons (particulate radiation). X-rays and γ-rays are also known as photons or packets of energy and are used to treat most body sites where radiation is deemed efficacious. Other particles or forms of radiation, such as protons, neutrons, and heavier α particles, are less commonly used in radiation therapy except in select clinical situations. Protons, other heavy charged particles, and neutrons have a higher linear energy transfer coefficient when compared to high-energy photons and therefore are more efficient at transferring or depositing their energy in tissue. Protons are used increasingly in the treatment of prostate cancers, choroidal melanomas, skull base and paraspinal tumors, and pediatric tumors. Neutrons have been used for salivary gland tumors, sarcomas, and prostate cancers. Protons are positively charged particles that can be accelerated in an electric field to high energies. The primary characteristic of a proton beam is its Bragg peak. The Bragg peak describes the depth at which the majority of a proton's energy is deposited. Prior to the depth of the Bragg peak, only a very small amount of the proton energy is deposited. The Bragg peak depth is determined by the energy of the incident protons, and covers only very small width of tissue at that depth. In order to cover more tissue, the energy of the incoming proton beam is varied. The net dose deposition results in a low entrance dose and a finely controlled width of treatment dose at depth. This makes proton treatments an excellent choice for the treatment of tumors adjacent to critical structures. Neutrons are relatively massive uncharged particles that can be generated by cyclotrons. Poor treatment geometry and dose distributions have limited the enthusiasm for neutron beam therapy (37).

X-rays and γ-rays are forms of electromagnetic radiation, similar to visible light, but with a much smaller wavelength, that is, greater energy. The only difference between X-rays and γ-rays is their respective origins. X-rays are derived from interactions in the atom that are outside the nucleus, typically by bombardment of the atom or target with high-speed electrons. This is the source of radiation produced by most modern radiotherapy treatment machines known as linear accelerators or LINACS. Their name derives from acceleration of these electrons. γ-Rays arise from a process within the nucleus of the atom called radioactive decay, which occurs in brachytherapy sources and cobalt (^{60}Co) teletherapy treatment machines. This type of electromagnetic radiation can penetrate several millimeters to centimeters of normal tissue in close proximity to tumors or tissues at risk. There is increased penetration as the energy of the gamma rays is increased. The X-rays produced by LINACs are much more penetrating (due to their high energy) than ^{60}Co gamma rays and are used to treat tumors or tissues at a distance from the LINAC, such as deep within the pelvis or abdomen.

Electrons are forms of particulate radiation and considered to be small (compared to the nucleus), negatively charged particles. Because of their inherent charge, these particles interact more strongly with the atoms found in tissue. Electrons will usually only penetrate a few millimeters to centimeters in tissue. Similar to photons, the higher the energy of the electron, the farther it will penetrate into the tissue. Electrons are used to treat tumors or tissues close to the skin surface such as superficial inguinal nodes and tumors of the skin, including vulvar cancers.

Regarding photon interactions with tissue, the dominant process at energies used in radiation therapy is termed the

Compton effect (Fig. 11.15). The probability that a photon will interact with a target atom is inversely proportional to the energy of the incident photon and nearly independent of the atomic number of the target material. As a result, at the energies used in radiation therapy, termed megavoltage (MV), the absorbed dose in normal tissues is comparable to that in nearby bone. At much lower energies, termed kilovoltage (kV), the absorbed dose would scale with the atomic number of the target with higher absorbed dose in bone compared to normal soft tissues.

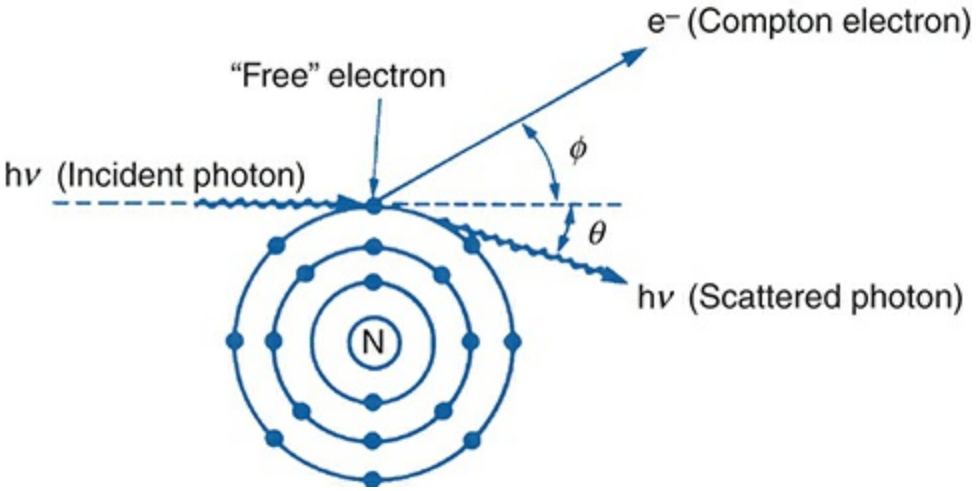

Figure 11.15 Schematic drawing illustrating the process of the Compton effect. The incident photon interacts with one of the atom's outer electrons, and the energy is shared between the ejected electron and a scattered photon.
Source: From Purdy JA. Principles of radiologic physics, dosimetry, and treatment planning. In: Perez CA, Brady LW, eds. Principles and Practice of Radiation Oncology. 3rd Ed. Philadelphia, PA: Lippincott-Raven Publishers; 1998, with permission.

At the second International Congress of Radiology in 1928, the basic unit of radiation exposure, the roentgen (R), was defined (37). Although the original definition evolved over time, the fundamental idea remained the same. The roentgen is the amount of photon radiation that causes 0.001293 g of air to produce one electrostatic unit of positive or negative charge (esu). The value of 0.001293 g is the mass of 1 cc of air at a temperature of 0°C and a pressure of 760 mm Hg. The definition of the roentgen can also be expressed in other equivalent terms:

$$1\ \mathrm{R} = 2.58 \times 10^{-4}\ \mathrm{C/kg\ air}$$

or, conversely, expressed in SI units, the unit of exposure is defined by

$$1\ \mathrm{C/kg} = 3{,}876\ \mathrm{R}$$

Table 11.1 lists some basic units of radiation and radiation therapy, both in historic context and in terms of modern SI units. Kerma (kinetic energy release per unit mass) defines the transfer of energy from photons to directly ionized particles. These directly ionized particles, in turn, transfer some of their energy to the medium (usually tissue). This transfer of energy is defined as the absorbed dose to the medium from the radiation beam. The SI unit for kerma is joule per kilogram (J/kg) or gray (Gy). In a slightly confusing definition, the SI unit for absorbed dose is also joule per kilogram or gray. The term gray has replaced the previously used term "rad." Oftentimes, the term centigray (cGy) is used. The cGy is equivalent to the rad and 1 gray equals 100 cGy.

TABLE 11.1 SI Units for Radiation Therapy

Quantity	SI Unit (Special Name)	Non-SI Unit	Conversion Factor
Exposure	C kg^{-1}	roentgen (R)	1 C kg^{-1} ≈ 3,876 R

Absorbed dose, kerma	J kg^{-1} (gray [Gy])	rad	1 Gy = 100 rad
Dose equivalent	J kg^{-1} (sievert [Sv])	rem	1 Sv = 100 rem
Activity	s^{-1} (becquerel [Bq])	curie	1 Bq = 2.7 × 10^{-11} Ci

Another rationale to think and communicate in SI units is that the roentgen was defined explicitly for photon interactions and not charged particles. Kerma and absorbed dose, although they have equivalence to the roentgen and exposure, can be defined equally for photons and charged particles.

RADIATION PRODUCTION

Radioactive Isotopes

As mentioned before, γ-rays are typically derived from radionuclides, such as ^{60}Co. Electrons or beta particles also come from radionuclides. In fact, most radioactive material produces a combination of photons (gamma rays) and electrons during the decay process. Radioactivity is the result of an atom changing its "energy" state, usually to a lower "energy" state, by the emission/absorption/internal conversion of photons or electrons in the atom. These processes result in disintegrations or radioactive decay, whereby the atom releases photons or electrons or both during the change in "energy" states. The release of these particles is a form of radiation (or energy) that can be used to irradiate tissues. The absorbed dose resulting from this radiation depends on the energy and particle type as mentioned above, as well as the tissue in which it interacts.

Radioactivity, or activity, is denoted by the symbol A and is defined as the number of disintegrations per unit of time. The following relationship defines activity, the decay constant, and ultimately the half-life for a radioactive material:

$$A = N/t = \gamma N$$

This equation is solved using an exponential solution:

$$A = A_o e^{-\lambda t}$$

where A is the initial activity, l is the decay constant, and t is some unit of time later. Other important concepts for radioactivity and radioactive decay are the half-life, $T_{1/2}$, and the average life, T_a. The half-life is the amount of time needed to reduce the original amount of material by half. This is also equivalent to reducing the original activity by half. $T_{1/2}$ is related to the decay constant by $T_{1/2} = 0.693/l$. The average life represents the period of time that a hypothetical source would need, if it retained its original activity for a fixed period of time (T_a) before suddenly decaying to zero activity, to produce the same number of disintegrations over an infinite amount of time by the same source if it decayed exponentially. T_a is related to the decay constant and the half-life by $T_a = 1/l = 1.44\ T_{1/2}$.

Radionuclides can occur naturally or be created artificially. Artificially created radionuclides are usually created by neutron bombardment of otherwise stable isotopes. The resulting interactions produce atoms that are inherently unstable and will decay to a more stable form with a predictable half-life, releasing energy or radiation through this decay. Naturally occurring radionuclides originally come from one of three standard series—the uranium series, the actinium series, and the thorium series—so named because of a dominant radionuclide in each series. In general, the higher the atomic number, the more likely an isotope will be radioactive. Table 11.2 lists many of the common radionuclides used in brachytherapy, along with their physical properties. For gynecologic cancers, use of radium 226 (^{226}Ra) sources is now historic. Though cost-effective because of its long half-life (1,622 years), radium releases a by-product, radon gas, if the mechanical integrity of the source capsule is compromised. This could require closure of hospital wards due to radon gas contamination. Cesium 137 (^{137}Cs) has replaced radium as a safer yet effective radionuclide. Less shielding is required for cesium than radium,

and there is no risk of radon gas leakage. With a half-life of 30 years, it is also cost-effective due to the infrequent need for replacement. Cesium can be used clinically for years without replacement, but the treatment duration must be adjusted to allow for radioactive decay (38). It is typically used for LDR gynecologic brachytherapy in tandem and ovoid and cylinder applicators. Iridium 192 (^{192}Ir) is produced in various source strengths and can be used for interstitial and intracavitary gynecologic implants. ^{192}Ir half-life of 74.2 days requires frequent replacement and, typically, this is custom ordered individually for each implant rather than stored in the radiation oncology department like ^{137}Cs sources. High-activity ^{192}Ir (10Ci) sources are used for HDR brachytherapy and are replaced every 3 months, and lower activity ^{192}Ir sources are used for LDR brachytherapy.

TABLE 11.2 Physical Properties and Uses of Brachytherapy Radionuclides

Element	Isotope	Energy (MeV)	Half-Life	HVL-Lead (mm)	Source Form	Clinical Application
Obsolete Sealed Sources of Historic Significance						
Radium	^{226}Ra	0.83 (avg)	1,626 years	16	Radium salt encapsulated in tubes and needles	LDR intracavitary and interstitial
Radon	^{222}Rn	0.83 (avg)	3.83 days	16	Radon	Permanent interstitial; temporary molds
Currently Used Sealed Sources						
Cesium	^{137}Cs	0.662	30 years	6.5	Cesium salt encapsulated in tubes and needles	LDR intracavitary and interstitial
Iridium	^{192}Ir	0.397 (avg)	74 days	6	Seeds in nylon ribbon; encapsulated source on steel cable	LDR temporary interstitial; HDR interstitial and intracavitary
Cobalt	^{60}Co	1.25	5.26 years	11	Encapsulated spheres	HDR intracavitary
Iodine	^{125}I	0.028	59.6 days	0.025	Seeds	Permanent interstitial
Palladium	^{103}Pd	0.020	17 days	0.013	Seeds	Permanent interstitial
Gold	^{198}Au	0.412	2.7 days	6	Seeds	Permanent interstitial
Strontium	^{90}Sr - ^{90}Y	2.24 MeV β_{max}	28.9 years	—	Plaque	Superficial ocular lesions
Cesium-131	^{131}Cs	0.030 MeV	9.7 days	0.042	Seeds	Permanent interstitial
Developmental Sealed Sources						
Americium	^{241}Am	0.060	432 years	0.12	Tubes	LDR intracavitary
Ytterbium	^{169}Yb	0.093	32 days	0.48	Seeds	LDR temporary interstitial
Californium	^{252}Cf	2.4 (avg) neutrons	2.65 years	—	—	—

Samarium	^{145}Sm	0.043	340 days	0.060	Seeds	LDR temporary interstitial
Unsealed Radioisotopes Used for Radiopharmaceutical Therapy						
Strontium	^{89}Sr	1.4 MeV β_{max}	51 days	—	$SrCl_2$ IV solution	Diffuse bone metastases
Iodine	^{131}I	0.61 MeV β_{max} 0.364 MeV g	8.06 days	—	Capsule NaI oral solution	Thyroid cancer
Phosphorus	^{32}P	1.71 MeV β_{max}	14.3 days	—	Chromic phosphate colloid instillation; Na_2PO_3 solution	Ovarian cancer seeding: peritoneal surface; polycythemia vera, chronic leukemia

Linear Accelerators

LINACS are another method of producing radiation for treatment of malignancies. LINACS can produce both photon and electron beams of different energies, depending on their construction. The principles behind a LINAC involve accelerating an initial beam of electrons across a variable electric field. The greater the strength of the electric field, the more energetic the electron beam. This electron beam can be adjusted to control its shape and intensity before delivery to the patient. Alternatively, the electron beam can be directed to a tungsten target. The electron–target interaction creates a forward scattered photon beam or X-ray. The resulting photon beam can then be modified by the machine using filters and collimators to produce the desired radiation field shape.

Photon beams of different energies have a different absorbed dose pattern within tissues. This pattern is normally characterized as a percent depth dose or variation of dose as a function of depth within tissue, as shown in Figures 11.16 and 11.17, and by dose profiles, or variation of dose as a function of lateral distance at a given depth (Fig. 11.18). The key feature in all of the figures is that higher-energy photons deposit dose at greater depths. Because of the way dose is deposited and absorbed in tissue, the higher the photon energy, the lesser the dose deposited at shallow depths toward the surface of the patient. This is called “skin sparing” and is a characteristic of high-energy photons. In fact, the higher the photon energy, the deeper the point at which the maximum absorbed dose is deposited. After this D_{max}, the absorbed dose decreases because the photon beam is attenuated by the tissues through which it passes.

Figure 11.19 shows a simplified drawing of a LINAC. The gantry (or part of the LINAC where radiation exits the machine) can rotate 360° around the patient on the treatment table. The table can also be rotated about the vertical axis of the radiation beam. This combination of angles allows the radiation to be directed to almost any part of a patient's body.

Modern LINACS are equipped with multileaf collimators (MLCs) and asymmetric jaws to control the shape of the radiation beam directed before it reaches the patient (Fig. 11.20). Prior to asymmetric jaws and MLCs, photon beam shaping was achieved using poured blocks mounted below the lowest machine jaws. The composition and thickness of the poured block material are sufficient to block more than 97% of the radiation, allowing less than 3% of the radiation to penetrate the block and reach the patient. MLCs have mostly replaced poured blocks, but in some cases, poured blocks are still necessary for detailed field shaping.

MLCs are small (projected size at the patient ~1 cm), adjustable collimators built into the LINAC gantry that work together to create a shaped opening mimicking the effects of a poured block. Because each MLC is adjustable, a new field shape can be "programmed" into the gantry without the necessity of pouring a different block for every treatment field. With the advent of computer-controlled motion of the MLCs, the radiation field can be further controlled to produce an IMRT treatment. In IMRT treatments, the MLCs are used to create many small fields of radiation within a larger treatment field. By opening and closing these small fields, the intensity at any point within the large field can be modulated to give more or less dose to the tissues directly exposed to the radiation. At one gantry angle, the IMRT field may need to spare a critical normal structure but still treat the target to a lower dose, while in another gantry angle, that same critical structure may be out of the field and the target can receive a higher intensity to compensate for the lowered intensity in the first field. This adaptability allows the radiation treatment planner to create and deliver very complex treatment fields that improve target coverage, while attempting to spare normal tissues. In practical terms, IMRT treatment plans are an improvement of the more conventional three-dimensional (3-D) conformal treatment plans. 3-D conformal treatment plans use fewer fields to achieve nominal coverage of the treatment target. At each gantry angle, the radiation is either hitting the target/normal tissue or not with a simple shaped treatment field. Normal tissues may be impossible to spare, relative to adjacent targets. IMRT treatment plans may use similar gantry angle setups, but with the additional intensity modulation, the IMRT fields can create a complicated dose distribution within the patient. In some cases, where the normal tissues are relatively far from the target tissues, there may be no benefit or rationale for the more complex IMRT treatment plan compared to 3-D conformal treatment plans. In cases where the proximity of normal tissues and target varies across a field and between gantry angles, IMRT may prove the more efficient treatment plan to protect normal tissues while focusing dose onto the target (Figs. 11.21 and 11.22). National guidelines have been created for the safe and appropriate use of IMRT (39,40). IMRT may be appropriate and ideal for the treatment of gynecologic cancers (41).

A pivotal treatment technique for the success of IMRT is IGRT (42–44). Historically, treatment setups were verified by orthogonal radiographs and treatment fields by port films or X-rays of the treatment fields superimposed on the patient. Modern LINACS have added onboard imaging (OBI) that facilitates electronic recording of the treatment fields at every treatment setup using an electronic portal imaging device (EPID). By comparing computer-generated radiographs (DRRs or digitally reconstructed radiographs) with the actual patient images, discrepancies in field shape and patient setup can be corrected before the delivered treatment. This type of corrective behavior before treatment is the foundation of IGRT. Over the last decade, the addition of CT imaging within the LINAC was implemented to verify the correct 3-D alignment of the patient on the treatment table prior to each fraction delivery within minutes. Partial CT scans (not full 360° rotation) are obtained prior to each treatment. In some LINACS, the CT scans are obtained and constructed based on the therapeutic photon beams (MV). In other approaches, an X-ray source (kV) is used to acquire the CT scans. Because megavoltage CT (MV-cone beam computed tomography [CBCT]) uses the therapeutic high-energy photon beam (6 MV),

the image quality suffers because of poor soft tissue contrast. On the other hand, kV-CBCT has a lower energy photon source (<140 keV) which is used to acquire and reconstruct the patient image. kV-CBCT has better soft tissue contrast than MV-CBCT, but is prone to distorting artifacts from high-density objects within the patient, such as hip prostheses. For either image modality, the CT image at the time of treatment and its corresponding isocenter location are compared to the treatment planning CT and isocenter for agreement. Adjustments for rotation, lateral, vertical, and longitudinal discrepancies are made prior to treatment. The intent of these IGRT methods is to improve the accuracy of the treatment setup on a daily basis relative to the original treatment plan. This enables decreasing the size of the radiation fields, as there is not as much need for a large margin on the target, which can decrease normal tissue irradiation and even allow for dose escalation to the target. Guidelines for use of IGRT have been published by the American Society for Radiation Oncology (ASTRO) and the American College of Radiology (ACR) (45). Online MR imaging has recently been added to the LINAC (Elekta) or a Cobalt-60-based LINAC (ViewRay) to allow for real-time IGRT with superior soft tissue resolution as compared to kV-CBCT of intact cancers such as cervical or vaginal cancers to guide treatment accuracy.

Volumetric-modulated arc therapy (VMAT) has been used to deliver IMRT. TomoTherapy is one form of arc therapy. TomoTherapy (AccuRay, Madison, WI) (Fig. 11.23) is a special type of LINAC/helical CT combination (44). TomoTherapy units were the first commercially available treatment machines that directly combined CT (MVCT in this case) with highly complex MLCs to deliver IMRT using IGRT. Each day, the patient receives an MVCT, a comparison using 3-D fusion to the original treatment plan is made, adjustments to the patient position are made, and IMRT treatment is delivered without the patient needing to change machines. Corrections to the delivered dose can even be modeled based on the patient's current anatomy as visualized by the MVCT built into the TomoTherapy machine. This enables treatment

of complex presentations such as paraaortic adenopathy with the closely positioned kidneys and bowel (Fig. 11.24). Excellent clinical outcomes have been published with rotational therapy for these types of presentations (46). Currently, all modern LINACS can deliver sophisticated and dynamic radiation arcs; examples are the Varian (RapidArc) and Elekta (VMAT). The LINACS controls gantry speed, aperture shape, and dose rates to generate their arc therapy treatments. Both vendors use the same principle of modulating the beam aperture while the gantry is moving in arc to minimize the time and monitor units while improving dose conformality.

For gynecologic cancer treatments for targets near the surface, electron beams produced by the LINAC are commonly used (range 4 to 21 MeV). Electron beams have different depth dose and dose profiles as compared to photon beams, as shown in Figure 11.25, electrons do not penetrate as far as photons do within human tissues. While electron depth doses have a D_{max} that increases with increasing energy, unlike photons, the higher the electron energy, the higher the surface dose to tissue, that is, loss of "skin sparing." Electrons have been used in the treatment of vulvar and other cancers that involve the inguinal lymph nodes. Great care has to be taken when using electrons in this setting as the inguinal lymph nodes can be very deep in women with higher body mass indices (BMI) and will under dose nodes at a depth >3 cm. This resulted in an increased risk of inguinal failures in the Gynecologic Oncology Group (GOG) 88 study (47). Electrons can be used to treat the vulva in patients with close or positive vulvar margins or in combination with higher-energy beams to treat the inguinal nodes in patients with lower BMI. Proper delineation of the inguinal lymph nodes is essential in determining the most appropriate technique to treat them (48).

Beyond photons and electrons, proton therapy (PT) has been proposed for locally advanced cervical cancer and/or lymph node–positive tumors. Similar to photon beam IMRT, protons can also be modulated, hence the term intensity-modulated PT or IMPT. It has been shown using a preliminary study that in patients not eligible for brachytherapy, IMPT might have the potential to act as a boost to photon beam therapy and can be superior to IMRT or VMAT (49).

Simulation

The conventional simulator used in radiation oncology departments reproduces all the gantry, collimator, and table rotations used in a LINAC treatment, and therefore "simulates" the actual treatment. Instead of a therapy (MV) photon beam, the conventional simulator uses a diagnostic (kV) photon beam to simulate the treatment beam. Previously, the conventional simulator (Fig. 11.26A) allowed the radiation oncologist to determine beam direction and treatment fields that would be needed for a radiotherapy treatment based on X-ray fluoroscopy. The radiographic visualization of internal structures allowed special shielding (poured blocks) to be constructed. All the geometric parameters of the conventional simulator are nearly identical to the actual treatment LINACS. The intersections of the gantry rotation axis, collimator rotation axis (the machine isocenter), and patient location are identified and marked on the patient's skin with removable ink or a permanent series of tattoos. These marks facilitate the reproduction of the same clinical setup for the patient each day of treatment. Hard-copy radiographs can also be used to document the expected treatment fields for comparison with port films obtained on the treatment LINAC.

CT-based simulators ("CTSims") have largely replaced conventional simulators in most radiation oncology departments. CTSims (Fig. 11.26B) combine a diagnostic CT scanner with a software package that allows for the simulation of the patient setup in the virtual world of the computer. All of the necessary gantry angles and table angles are modeled in the computer. Computer-controlled room lasers tied into the CTSim software allow the simulator therapist to identify the treatment isocenter in a fashion similar to the conventional simulator (Virtual Sims). DRRs are created for later comparison to actual treatment images. The treatment isocenter and the full CT images can then be transferred to the computer planning system for further treatment planning. Some departments are also equipped with MR or PET scanners for treatment planning. Fusion of CT images with PET or MR images enables CT-based treatment planning with the benefit of improved tumor definition with PET or MR to reduce margin size or increase dose (50,51).

Computerized Dosimetry

In a modern radiotherapy department, computers are necessary to accurately calculate the absorbed doses to tissues. These absorbed doses within tissues are termed isodoses, or lines of the same dose. To initiate this process, CT images of the area of interest at a pretreatment planning session or simulation are acquired. These scans are typically obtained on the CT simulator. Treatment targets such as pelvic/paraaortic lymph nodes, the uterus, or vagina are identified through contouring on these images by the radiation oncologist, as are normal tissues such as the rectosigmoid, bladder, large and small bowel, kidneys, stomach, and spinal cord. Dose goals and constraints are identified for the targets and normal tissues, respectively. A dosimetrist uses this information to design the radiation treatment plan. Treatment beams are planned and the resulting dosimetry is reviewed by the treating physician and a qualified medical physicist (QMP). The radiation plan is optimized as needed to best address the tumor and avoid the normal organs and tissues. In order for a computer treatment planning system to do all this, the depth dose and dose profiles for all of the treatment beams (photons and electrons) must be accurately entered into the planning system. This process is referred to as treatment planning commission, a task which is carefully performed by the QMP.

There are varying complexities of treatment plans that might be used. For simple targets, such as metastatic cancer to the spine, a simple single field or parallel opposed, two-dimensional (2-D) plan might be all that is required. Complexities of internal anatomy and external surface contours can be ignored while still successfully delivering a palliative treatment plan to the patient. More complicated target definitions might require specific and accurate knowledge of adjacent internal anatomy and the details of the patient's surface in order to accurately deliver a successful treatment plan. In these cases, a 3-D conformal treatment plan is developed. In still more complicated target/normal tissue regions, IMRT/VMAT/IMPT treatment planning might be required in order to give sufficient dose to the target while minimizing the dose to an adjacent normal tissue. The goal for most treatment plans is to treat the target to a specified dose while minimizing dose to adjacent normal tissues.

In all of these examples, the word "target" is used. The goal is to encompass the target with the desired dose. Targets are more formally defined in ICRU 50 (52). Figure 11.27 illustrates the GTV, the CTV, the PTV, and the treated volume. Each of the target or tumor volumes is larger than the previous target volume by some margin. The CTV includes all of the GTV plus possible microscopic extensions. The PTV includes all of the CTV plus a margin to account for possible geometric uncertainties of the patient or treatment margin. The irradiated volume includes all of the PTV plus any margins that might be included in the treatment plan to provide minimum dose coverage to the PTV.

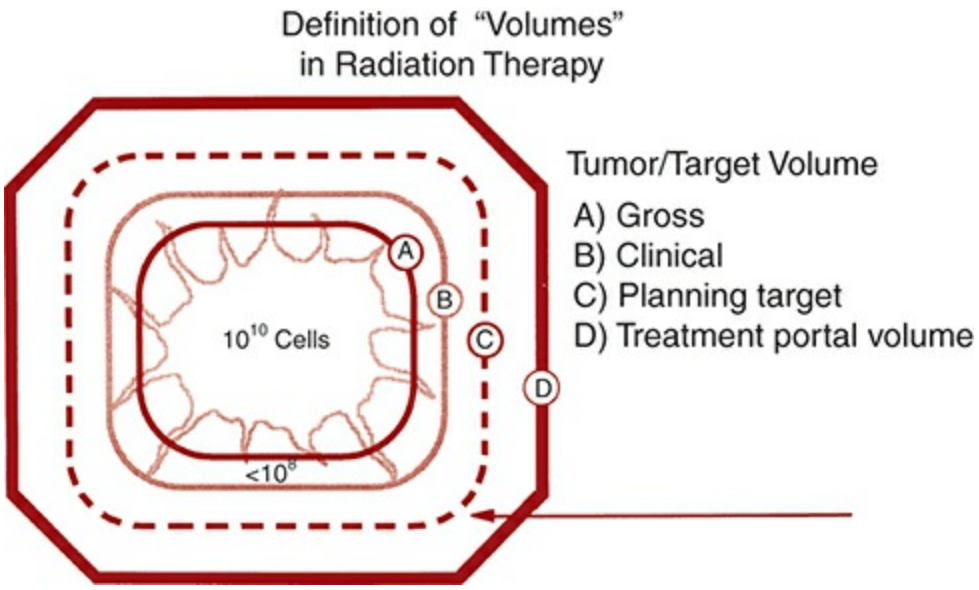

Figure 11.27 Schematic representation of "volumes" in radiation therapy. The treatment portal volume includes the GTV, potential areas of local and regional

microscopic disease around the tumor (clinical), and a margin of surrounding normal tissue (planning).

Brachytherapy Principles

Brachytherapy is a term with Greek roots where "brachy" means "short distance." With brachytherapy, a highly concentrated dose of radiation is delivered to immediately surrounding tissues within millimeters to several centimeters of the applicators that carry the radioactive sources (53). This allows for delivery of a high dose of radiation to closely approximated tumor while relatively sparing surrounding normal tissues such as the rectosigmoid, bladder, and small bowel. This is in comparison to teletherapy, where "tele" means "far distance" and refers to external beam irradiation discussed above (photons/electron/protons), where the radiation source is at a greater distance from the patient (100 cm) than with brachytherapy, where sources are near the target. With external beam irradiation, the tumor and/or tumor bed are typically irradiated along with adjacent tissues at risk, such as lymph nodes. External beam irradiation typically is much more penetrating than brachytherapy unless electron beam external irradiation is used. With electron beam therapy, superficial structures such as the skin and/or superficial lymph nodes are optimally treated, unlike the deep abdominopelvic tissues, which are best irradiated with the penetrating photons produced by a LINAC.

There are different types of brachytherapy or radioactive implants (53,54). Temporary implants are used most frequently and are categorized as interstitial or intracavitary. With interstitial brachytherapy, the radioactive sources are transiently inserted into tumor-bearing tissues directly through placement in hollow needles or tubes. With intracavitary brachytherapy, radioactive sources are placed into naturally occurring body cavities or orifices, such as the vagina or uterus, using commercially available hollow applicators such as a vaginal cylinder or tandem and ovoids. Temporary surface applications or plesiotherapy for ophthalmic or skin tumors and intraluminal applications in the esophagus, bronchus, and bile duct are other possible approaches. Permanent interstitial implants entail insertion of radioactive seeds (iodine 125 [^{125}I]; gold 198 [^{198}Au]; palladium 103 [^{103}Pd]) directly into tumor-bearing tissues to emit radiation continuously as they decay to a nonradioactive form (53). Radioactive sources are also described as sealed or unsealed, referring to whether they are solid (^{137}Cs; ^{192}Ir) or liquid radioisotopes (phosphorus 32 [^{32}P]). The most common sealed radioactive sources used for gynecologic brachytherapy are ^{192}Ir and ^{137}Cs. Historically, unsealed radioactive sources such as ^{32}P have been used to treat the entire peritoneal cavity in ovarian cancer. The limitation of this source was that the beta rays emitted penetrated only a distance of 3 mm, making it useful only for patients with microscopic or very thin residual tumor deposits following debulking.

Dose rate is also an important variable in brachytherapy. Traditional LDR irradiation has been used for decades in gynecologic cancers using ^{226}Ra and ^{137}Cs sources for intracavitary insertions and low-activity ^{192}Ir sources for interstitial insertions. HDR brachytherapy has gradually been introduced over the last several decades and entails the use of a highly radioactive (10-Ci) ^{192}Ir source. There are several definitions for the dose rates used in brachytherapy. The ICRU 38 classifies LDR as 0.4 to 2 Gy/hr, MDR (medium dose rate) as 2 to 12 Gy/hr, and HDR as >12 Gy/hr (55). More standard ranges for LDR are 40 to 100 cGy/hr, and for HDR 20 to 250 cGy/min, which is 1,200 to 15,000 cGy/hr. MDR is not common in the United States. Another approach is pulsed dose rate (PDR), which is mostly popular in Europe (56,57). PDR mimics ^{137}Cs dose rates but uses ^{192}Ir sources and afterloading technology. PDR is desired with the scarcity of available new ^{137}Cs sources. Rather than using a high-activity 10-Ci ^{192}Ir source with short dwell times as in HDR, PDR uses a medium-strength ^{192}Ir source of 0.5 to 1.0 Ci with dose rates of up to 3 Gy/hr. The radiation with PDR is typically delivered in a "pulsed" method over only 10 to 30 minutes of each hour, whereas LDR delivers 30 to 100 cGy/hr continuously (57). PDR delivers the same total dose over the same total time at the same hourly rate as LDR, but with an

instantaneous dose rate higher than LDR. PDR brachytherapy was developed to combine the isodose optimization of HDR brachytherapy with the biologic advantages of LDR.

The term "afterloading," whereby an unloaded applicator is inserted first and the radioactive sources introduced later, was popularized by Henschke (53). Nearly every modern brachytherapy exploits afterloading. An ideal implant is established with the appropriate applicator before being loaded with the radioactive sources. This sequence allows for more careful and accurate applicator placement than inherent to earlier "hot loaded" applicators, which were placed in the operating room preloaded with radium. Radiation exposure to medical personnel is reduced and exposure of operating room personnel is totally eliminated. Remote afterloading, which eliminates all personnel exposure, entails the use of a computer-driven machine to insert and retract the source(s), which are attached to a cable. During treatment, the source is transported from its shielded safe to the patient's applicators via a transfer tube. Sources are retracted automatically whenever visitors or hospital personnel enter the room. With modern remote afterloading techniques, a single cable-driven radioactive source is propelled through an array of dwell positions in needles, plastic tubes, or intracavitary applicators within an implanted volume. Through computerized dosimetry, the source stops for a specified duration at a preselected number of locations during its transit, delivering a specified dose to a defined volume of tissue. This dose may be delivered rapidly in a large fraction, as in the case of HDR brachytherapy, or a series of small "pulsed doses" delivered at a given frequency over a period of days, as in PDR brachytherapy (56,57). Typically, these treatment units are housed in shielded rooms in the hospital (LDR or PDR) or the radiation oncology department (HDR) (53).

Radiation Protection

The amount of radiation that a person other than patients under treatment can receive is governed by state and federal regulations. The actual values depend on whether the person is considered part of the general public or an occupationally exposed worker. These values can change with different regulations. The National Council on Radiation Protection and Measurements (58) set the following recommendations for limits on exposure to IR:

Public exposures <1 mSv or 0.1 rem annually
Occupational exposures <50 mSv or 5 rem annually

Additionally, NCRP Report #91 (58) placed limits on embryo-fetus exposures:

Total dose limit <5 mSv or 0.5 rem
Dose equivalent limit in 1 month <0.5 mSv or 0.05 rem

These recommended limits were adopted by the Nuclear Regulatory Commission (U.S. Nuclear Regulatory Commission, 10 CFR 20, Standards for Protection against Radiation).

LINACS produce radiation using electrical power. Once the LINAC is turned "off," there is little, if any, radiation exposure risk to staff. Radioactive isotopes, used most often for brachytherapy, however, do not have an "off" switch. They are always undergoing radioactive decay with the resultant radiation production of X-rays, γ-rays, electrons, and other particles.

Radiation safety is an important focus for patients and health care workers. All hospitals that house radioactive sources or LINACs will have a special department termed radiation safety. Radiation personnel are responsible for monitoring radiation exposure in hospitals and clinics. All health care workers exposed to radiation must wear badges that track radiation exposure. There are three words that encompass all of the important aspects of radiation safety and protection: time, distance, and shielding. All three can be used to reduce radiation exposure. The dose delivered to a target from a radioactive source is directly proportional to the amount of time the target is exposed to the radioactive source (59). The dose delivered to a target is inversely proportional to the square of the distance from the radioactive source, double the distance, and the dose is reduced by a factor of four:

$$\text{Dose} - \text{time}$$

$$\text{Dose} - 1/r^2$$

This is the inverse square rule. The relationship between shielding and absorbed dose is more complicated. The simplest explanation is that the absorbed dose is reduced in an exponential relationship to the physical amount of shielding. The exact relationship (μ) depends on the energy of radiation and the specific material, such as concrete or lead, used to provide the protection. More material (x) means more protection. Less energy means more protection for the same thickness (x) of material:

$$\text{Dose} - e^{-\mu x}$$

Minimizing time, maximizing distance, and maximizing shielding will reduce one's absorbed radiation dose. Fortunately, there is relatively little exposure to radiation for most health care providers. The LINACs in radiation oncology are strategically located and shielded to minimize radiation to anyone other than the treated patient. Many brachytherapy insertions are typically performed with remote afterloading to minimize exposure, and often outpatient brachytherapy can be realized because of HDR techniques. This takes the patient off the hospital ward and thereby avoids exposure to the health professional caring for inpatients. The shielded rooms in the radiation oncology department protect the attendant staff from exposure as well.

Occupational Exposure Management of Female Radiation Workers

Pregnancy declaration is optional, but once declared, the employee is required to formally inform her employer. Furthermore, the radiation safety officer should interview her, her employment should be evaluated for exposure history, and steps should be taken to minimize exposure for the current work duties. The National Council on Radiological Protection (58) recommends that the embryo/fetus has limited exposure to less than 0.5 Sv/month.

CLINICAL APPLICATIONS

Historical Background

The use of radiation in the treatment of gynecologic cancers has a rich history. Roentgen rays were used externally as early as 1902 to treat cervical carcinoma and "radium rays" in 1906. In Europe, the use of intracavitary radium was reported in 1903 for the treatment of inoperable uterine cancers (60). In those early years, there was little knowledge of the biologic effects of radiation on the normal and tumor tissues. Typically, a uterine tandem was used alone without vaginal colpostats. There was also little understanding of the dose distribution in the tumor and surrounding normal tissues, and implant duration, and thereby dose, was entirely empirical. As such, complications and failures were common. Since these early years, there has been a tremendous accumulation of knowledge relative to both external beam irradiation and brachytherapy, which will be reviewed.

EXTERNAL BEAM IRRADIATION FOR GYNECOLOGIC CANCERS

Cervical and Vaginal Cancers

In cervical and vaginal cancers, the role of external beam irradiation is to shrink bulky tumor prior to implantation to bring it within range of the high-dose portion of the intracavitary dose distribution, improve tumor geometry by shrinking tumor that may distort anatomy and prevent optimal brachytherapy, and sterilize paracentral and nodal disease that lies beyond reach of the intracavitary system (61). Some institutions maximize the brachytherapy component of the treatment regimen and perform the first intracavitary insertion after 10 to 20 Gy with subsequent external beam delivered with a central block (62). Other institutions treat the whole pelvis to 40 to 50 Gy and perform brachytherapy once the external beam is completed (61). The total dose at point A or the HR CTV, however, should remain the same, stage for stage. Implementing brachytherapy early with subsequent reliance on only the implant to treat the central disease may be considered an advantage as a greater portion of the central dose is delivered with the implant, with relative sparing of the bladder and rectum, perhaps permitting delivery of a higher central dose over a shorter period of time (62). More reliance, however, is placed on the extremely complex match between the intracavitary system and the edge of the midline block, if used, making good implant geometry imperative when brachytherapy constitutes a large portion of the central dose. Those who prefer to deliver an initial 40 to 45 Gy of external beam first believe that the ability to deliver a homogeneous distribution to the entire region at risk for microscopic disease, and the ability to have more shrinkage of central disease prior to intracavitary irradiation, outweigh other considerations. The brachytherapy dose is accordingly decreased to respect normal tissue tolerance. In addition to causing regression of central disease, the external beam fields are also directed at the regional lymph nodes at risk. In cervical and vaginal cancer, the risk of pelvic lymph node involvement is related to the stage of disease, tumor size, and lymphatic vascular space invasion. Other histomorphologic factors influencing lymph node involvement in cervical cancer include pathologic tumor diameter, depth of stromal invasion, uterine body involvement, parametrial spread, and the number of cervical quadrants involved by tumor (62). Early necropsy studies reported the lymphatic pathways for patients with cervical cancer (63). The primary lymphatic pathway is to the parametrial and paracervical nodes, and the obturator and internal and external iliac nodes. Secondary spread can occur to the sacral and common iliac nodes, with subsequent spread to the paraaortic nodes. Unlike in endometrial cancer, paraaortic lymph node involvement in the absence of pelvic lymph node involvement is rare. Inguinal lymph node involvement occurs with distal vaginal spread of disease or via the round ligament if there is extensive involvement of the corpus. The cervical lymphatics are located in three plexuses in the mucosa, muscularis, and serosa of the cervix, and anastomose extensively with the lymphatics of the uterine isthmus. This interconnected lymphatic supply is one of the reasons why the entire uterus should be within the external beam fields when treating cervical cancer. Additionally, there may also be lower uterine segment and endometrial extension of tumor. There are lymph vessels running posteriorly in the uterosacral ligaments to lymph nodes located in the sacrum between the rectum and the internal iliac vessels. These posterior nodes may terminate in the common iliac, subaortic, or paraaortic lymph nodes (64). For all gynecologic cancers, these patterns of lymphatic spread influence the external beam field borders. Traditionally, design of “standard” pelvic fields, as shown in many radiation oncology textbooks, has been based primarily on skeletal landmarks and considered quite simple and straightforward. The skeletal landmarks are not sufficient for field design (65). Traditionally, many institutions have used the “four-field box” technique to treat the pelvis with typical anterior-posterior (AP)–posterior-anterior (PA) field sizes of 15 × 15 cm and lateral field widths of 8 to 9 cm (Fig. 11.28) (61). The intent of the four fields is to use rather narrow lateral beams to avoid some of the small bowel anteriorly and a portion of the rectum posteriorly. Surgical and imaging series using CT (66), MRI, (67,68), and lymphangiograms (LAG) (65) have revealed that fields of these sizes can easily miss the primary tumor and its extensions and the regional lymphatics at risk, and design of the pelvic fields needs to be done with care and use of confirmatory imaging (67). Plain films do not visualize the important soft tissues such as the cervical tumor and its extensions, the uterus, or the lymph nodes at risk. Additionally, bladder and rectal contrast and a vaginal obturator or cervical markers have been used to guide field design, but are not sufficient. As with the brachytherapy component of treatment, the adequacy of the external beam fields and margins has a direct relationship with local and regional control. What may be considered a mysterious failure following definitive irradiation,

perhaps caused by "radiation resistance," may actually be the result of a marginal miss due to external beam field design. Placement of radiation fields must take into account the alteration of the spatial relationship between the tumor and normal anatomy due to individual anatomic, tumor-induced, or treatment-related positional variations of the uterus and cervix, as well as knowledge of the location of the regional lymphatics (67). Radiation oncologists must be aware of these patterns of disease spread and must have an in-depth understanding of CT anatomy when designing radiation fields following CT simulation. Identification and contouring of enlarged nodes in nodal regions at risk and identification of the iliac vessels, which serve as surrogates for the location of unenlarged lymph nodes, are important in subsequently defining radiation field borders (Fig. 11.29) (69). Additionally, contouring of the entire uterus and portions of the vagina will also ensure that these tissues are included in the radiation fields (Fig. 11.29). Reliance on bony anatomy alone for radiation field design rather than on CT-defined targets is discouraged. Generally, the superior border of the pelvic fields is at the S1–L5 interspace for early-stage disease (i.e., nonbulky IB or IIA) or at the L4–5 interspace for more advanced disease. The latter is used if one wants to cover the common iliac lymph nodes. Interestingly, Greer et al. evaluated "standard" pelvic fields (AP–PA, 15 × 15 cm; lateral, 8 to 9 cm wide) for the treatment of cervical cancer in relationship to intraoperative findings. Based on intraoperative measurements of the location of the aortic bifurcation and the bifurcation of the common iliac arteries relative to the lumbosacral prominence (the anterior caudal border of L5), Greer et al. concluded that anterior and posterior treatment fields with a superior border at the L4–5 interspace are required to cover the internal iliac, external iliac, and obturator nodes, as the bifurcations of the common iliac arteries were above the lumbosacral prominence in 87% of the patients studied. Coverage of the common iliacs could require extending the upper field border to the L3–4 interspace or even the L2–3 interspace in some patients (70). Obviously, with CT-based dosimetry, it is imperative to outline the vessels and/or nodes in these areas to determine the appropriate field borders because unnecessary irradiation of bowel could occur if all patients were treated to the L2–3 interspace, based on this assumption (Fig. 11.29). CT is an excellent tool for identifying pathologically enlarged nodes, multiple small lymph nodes that by increased number rather than size are suspicious, or in the absence of nodes, the aortic and iliac bifurcations and the iliac vessels (66). The inferior border of the pelvic field is usually at the bottom of the ischial tuberosities or 3 to 4 cm below the most distal vaginal component of disease. Inguinal nodes are included if there is distal vaginal spread, in which case treatment of the vaginal introitus with margin would also be required. MRI is especially helpful in imaging vaginal tumor extension (71). The lateral borders of the AP–PA fields must be designed carefully as the normally recommended 1.5 to 2.0-cm margin from the pelvic brim may be too narrow. Using lymphangiography, Bonin et al. (65) found that a margin of at least 2.6 cm on each pelvic brim was needed in order to cover all pelvic lymph nodes if bony landmarks were used. The lateral fields are even more prone to marginal misses than the AP–PA fields, as demonstrated in multiple series that have compared the standard textbook lateral fields (8 to 12 cm wide) to fields designed based on CT and MRI images (Fig. 11.30) (67). For the lateral fields, a commonly employed guideline is to place the posterior border in a horizontal line, parallel to the treatment couch that divides the mid-rectum and intersects the sacrum between the second and third sacral segments (S2–3 interspace), and the anterior border by a horizontal line, parallel to the treatment couch from the anteroinferior lip of L5 to the anterior aspect of the pubic symphysis. These "standard" lateral fields are too narrow. For the lateral fields, careful consideration needs to be given to the anterior border to include the external iliac nodes. Based on lymphangiography, Bonin et al. (65) found that, in order to cover the external iliac nodes, the anterior border of the lateral field was sometimes as much as 2 cm anterior to the pubic symphysis. Taylor et al. (69) showed that a modified 7-mm margin typically covers 99% of the pelvic lymph nodes. Additionally, the anterior border must also be drawn to include the entire uterus, given the interconnecting lymphatics of the uterus and cervix and the possibility of lower uterine segment/endometrial extension (Fig. 11.30) (67). Enlargement of the uterine fundus by the presence of hematometra or massive fundal extension of cancer can displace the fundus anteriorly and cephalad, as can an anteverted or retroverted uterus (68). The prone position may accentuate this displacement (67). The anterior field border should be based on CT or MRI delineation of the tumor and/or normal anatomical variants to avoid underdosing of these structures (68). The posterior border of the lateral fields must be designed carefully. Based on intraoperative findings, Greer et al. showed that the cardinal and uterosacral ligaments extend posterior to the rectum and sigmoid in their attachments to the sacrum. As part of the parametria, these tissues often

contain nodes, even in early disease (IB and II, 22.5%) or are involved by direct extension and need to be covered in most patients by including the entire sacrum in the lateral fields (70). If there is uterosacral ligament involvement, it is especially important to include the entire sacrum in the lateral fields, although some institutions will use this as a criterion for AP–PA fields alone (64). The internal iliac lymph nodes may lie very close to the rectum, and splitting of the rectum can result in a marginal miss of these nodes (Fig. 11.31) (66). In the setting of posterior cervical lesions, there may also be direct extension to the superior rectal nodes or sacral lymph nodes. Tumor can also extend directly around the rectum. Kim et al. found that the most common site of an inadequate margin was near the portion of the lateral field blocking the rectum. On CT, it was found that tumor often fell along the lateral aspect of the rectum. The second most common site of inadequate margin was the posterior border at the S2–3 interspace. Zunino et al. (68) also found inadequate posterior border margins when the uterus was both retroverted and anteverted (Fig. 11.30). The reason for narrow lateral fields is typically concern over the rectum and the small bowel. Greer et al. (70) reported no increase in late rectal complications when including the entire sacrum in the field. It may also be a mistake to avoid the chance of a marginal miss by treating just with anterior and posterior fields, as in most cases some of the small bowel can be omitted from the lateral fields when using imaged-based planning. MRI has been found to be an invaluable tool for delineating normal anatomy and the extent of cervical tumor involvement because of its superior soft tissue contrast compared to CT. MRI also allows direct imaging in sagittal, coronal, and transverse plains (68). Sagittal MRI images are exceedingly helpful in designing radiation fields (Fig. 11.30). Design of the anterior and posterior borders of the lateral fields can be especially influenced by these images. Thomas et al. (67) performed MRI rather than CT in the treatment position and found better delineation of the tumor volume due to the superior contrast resolution. PET/CT scans have largely replaced LAGs at most institutions with Medicare approval and can detect involved pelvic and paraaortic lymph nodes better than CT alone (72,73). Unlike CT, PET does not rely on lymph node size alone, but rather on metabolic alterations for detection of disease. PET has better accuracy than can be achieved with CT or MRI, with a sensitivity of 85% to 90%, a specificity of 95% to 100%, and overall accuracy of 90% to 95%. Nodes as small as 6 mm can be imaged with PET, providing information to guide therapy and predict outcome.

Midline Blocks

Midline blocks have been used historically at various points in time at many institutions (Fig. 11.32). It is important to understand when the midline block is placed, as this will influence the HDR fraction size. Higher whole pelvis doses can be utilized without a midline block, but the HDR doses have to be appropriately reduced. HDR and external beam fractions should not be given on the same day. Use of midline blocks is controversial, as there can be an increased risk of rectosigmoid, bladder, and small bowel complications if careful attention is not given to tracking and limiting the total dose in these OAR (74–76).

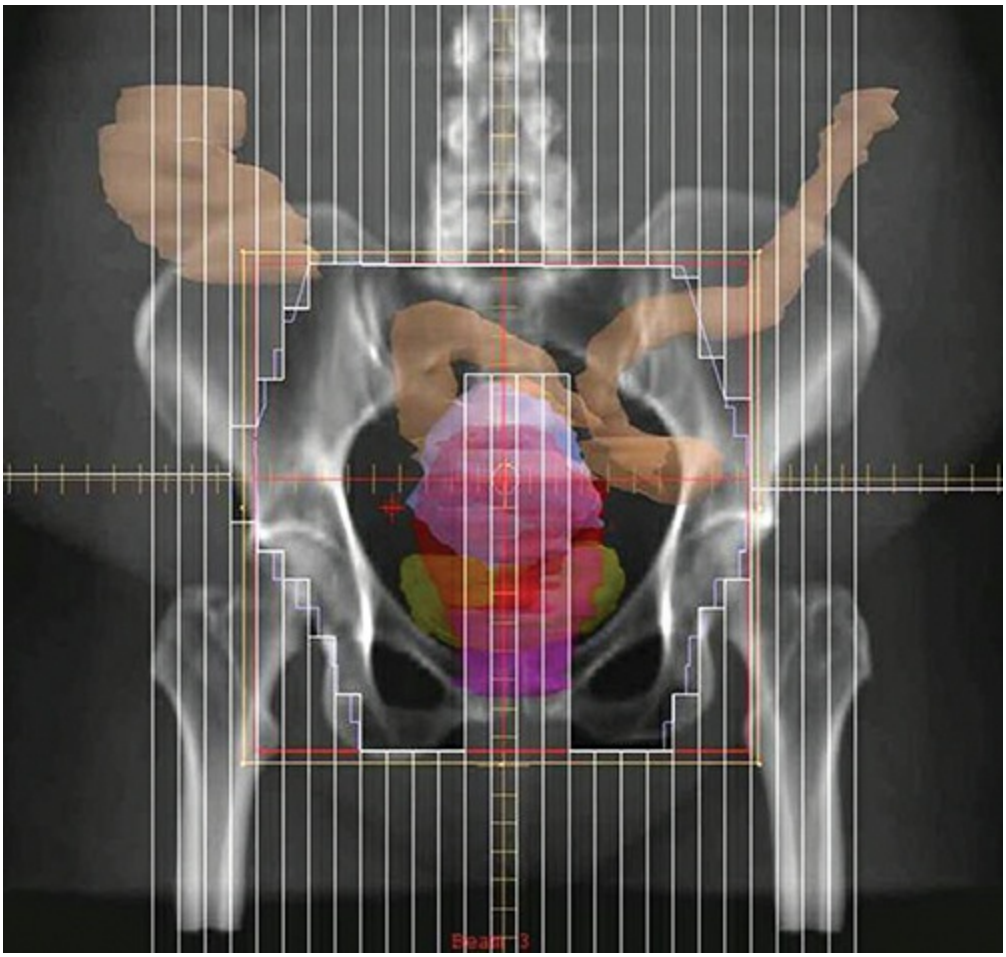

Figure 11.32 Midline blocks: A midline block defined by the leaves of the multileaf collimator used to shield the central pelvic structures. Note the unblocked bladder and sigmoid that may receive some of the brachytherapy dose and all of the external beam dose.

A midline block may be used during external beam to avoid regions of excessive dose adjacent to the brachytherapy

implant and to deliver an adequate dose to potential tumor-bearing regions outside of the implant. When using a midline block early in the treatment course, more reliance is placed on the extremely complex match between the intracavitary system and the edge of the midline block. There are some important safety issues to consider when using midline blocks (74–76). The midline block position should be based on films with similar isocenters. If patients receive external beam irradiation in the prone position, it may be wise to simulate them in the supine position for their parametrial boosts so that they are in the same position as they are for their implants. Midline blocks can be positioned to account for applicator deviation. Alignment along the midplane of the patient can be problematic if the tandem is deviated. Midline blocks that are too narrow may not adequately shield the bladder and rectosigmoid, given their ability to move in and out of the blocked field. Filling and emptying of these organs may also alter their position relative to the block. Eifel et al. point out that the distance between the distal ureters is usually 4 to 5 cm. A narrow block may fail to shield a portion of the ureters during external beam (77). Reviewing the M.D. Anderson experience, Eifel et al. detected an increase in complications in patients with midline blocks (4 cm) used throughout the course of external beam. Since the ureters are typically 2 to 3 cm from the midline, the explanation for the ureteral stenosis could have been an overlap between the external beam fields and the high-dose region of the intracavitary implants (77). A margin of 0.5 cm lateral to the lateral ovoid surface is recommended in designing the width of the midline block for each patient to protect the implanted volume. If the intracavitary system is broad, a wide midline block may potentially shield the external iliac lymph nodes. If tissues immediately adjacent to the colpostats and tandem tip are not shielded, portions of the ileocecal junction and rectosigmoid may be overdosed (78). Huang et al. (78) recommended avoiding a combination of parametrial boost doses of ≥54 Gy and a cumulative rectal biologically effective dose (CRBED) ≥100 Gy_3 to decrease the risk of radiation-induced bowel complications. When a midline block is inserted prior to 40 Gy, it should not extend to the top of the field since it will shield the common iliac and presacral lymph nodes, which will be underdosed. When there is suspicion of uterosacral ligament involvement, it is safer to avoid early placement of the midline block, which will shield disease lying posterior to the implant (64). Due to concern over rectal tolerance, the rectum is shielded after a certain amount of external beam radiation therapy, which can block tumor in the perirectal area and uterosacral space. The geometric configuration of the intracavitary implant emphasizes lateral rather than posterior coverage and does not effectively treat the perirectal and uterosacral space effectively. This can lead to underdosing of tissues in this area and an increased risk of central recurrence. Higher whole pelvis external beam doses, interstitial implantation, or addition of a supplemental posterior oblique external beam boost may offer ways to compensate dose in this area (64). Given the potential for risk, some would advocate abandoning the midline block in favor of other options (74–76). Fenkell et al. (76) showed that 66.7% of patients had a greater than 50% increase in doses to the rectum, bladder (D2cc) of the sigmoid with the use of a midline block. Use of IMRT with low central doses near the bladder and rectosigmoid and higher doses covering the pelvic nodes has been described as a replacement for the more antiquated midline block (50).

Parametrial/Nodal Boosting in Cervical Cancer

Parametrial boosting is often recommended for patients with bulky parametrial or sidewall disease, after completion of the whole pelvis field and midline block fields, as the parametria are a common site of failure. The need for boosting is usually based on the status of disease regression following whole pelvis irradiation. MRI may be helpful in making this assessment both before and during radiation. Logsdson and Eifel (79) suggest boosting residual lateral pelvic wall disease after 40 to 45 Gy whole pelvis to 60 to 62 Gy to small volumes. Perez et al. (80,81) found a trend toward increased pelvic control with point B doses (defined as 6 cm lateral to the central axis) >45 Gy. Perez et al. found that the incidence of pelvic recurrence was correlated with tumor size and dose of irradiation delivered to the lateral parametrium. There was an increase in the incidence of pelvic recurrence in patients receiving less than 50 Gy, but no correlation with increasing doses of irradiation (82). Doses needed to eradicate parametrial disease in the literature are typically around 60 Gy, combining the external beam doses with the implant doses. The proximity of small bowel can make this a risky proposition. Perez et al. (83) noted that with doses below 50 Gy to the lateral pelvic wall, the risk of small bowel

complications was about 1% and somewhat higher with larger doses. In a later series, grade 3 small bowel sequelae were 1% with doses of 50 Gy and 2% to 4% with doses over 60 Gy ($p = 0.04$) (84). Perez et al. recommend limiting the small bowel doses to less than 60 Gy. When there is uterosacral space involvement, thought should be given to the use of a supplemental posterior oblique external beam boost (64). Grigsby et al. used PET/CT scans to evaluate lymph node size, irradiation dose, and patterns of failure. The parametrial and lymph node boost doses used were in the range of 9.0 to 14.4 Gy following large field doses of 50.4 Gy. Radiation dose and lymph node size were not significant predicators of lymph node failure. The risk of an isolated lymph node failure was <2% (85). A reoperation series following definitive irradiation and chemotherapy was reported by Houvenaegel et al. After 45 Gy and whole pelvis and selective parametrial or nodal boosting to 55 to 60 Gy, 15.9% of patients had biopsy-proven residual disease in the pelvic nodes and 11.7% of paraaortic nodes (86). Use of IMRT may be a method to increase dose to bulky nodes or residual parametrial disease while sparing adjacent normal structures (50,87).

Endometrial Cancer

The need for postoperative external beam radiation therapy in endometrial cancer is well described in the ASTRO consensus guidelines (88). Patients with grade 3 and ≥50% myometrial invasion or grade 1 to 2, ≥50% myometrial invasion, and other risk factors such as age >60 with or without lymphovascular space invasion may benefit from pelvic external beam radiation. External beam radiation is recommended in patients with stage III–IV disease because it improves survival. Chemotherapy should also be considered in patients with locally advanced disease and delivered concurrently, sequentially, or in an interdigitated manner (88). For endometrial cancer, many of the same nodes are at risk as in cervical cancer, but the spread of disease is not as predictable with the paraaortic nodes independently at risk. The presacral nodes are also not at risk unless there is cervical involvement. Both the pelvic and paraaortic nodes are at risk in all sites of uterine involvement, and grade, myometrial invasion, and lymphatic vascular space invasion are more predictive of risk than is location (89,90). Cervical and lower uterine segment involvement increases the likelihood of pelvic and paraaortic lymph node metastases compared to fundal location, as do increasing histologic grade and myometrial invasion. In the surgical staging series of Boronow et al. (90), 18 of 222 patients had lower uterine segment involvement and 6 (33%) had pelvic lymph node metastases. In the final GOG surgical staging series report, by location, patients with fundal lesions had a 4% risk of paraaortic and 8% risk of pelvic lymph node involvement, whereas patients with lower uterine segment involvement had a 16% risk of pelvic and 14% risk of paraaortic lymph node involvement.

In endometrial cancer, external beam irradiation is generally recommended for patients thought to be at significant risk for lymph node metastases and/or a vaginal cuff recurrence. Traditionally, this has been recommended in the absence of a lymph node dissection or a limited lymph node sampling. External beam irradiation is still delivered at many institutions in the setting of a negative lymph node dissection when high-risk features such as deep myometrial invasion, high grade, lymphatic vascular space invasion, lower uterine segment involvement, or cervical invasion are present (88).

External beam irradiation typically covers the upper one-half to two-thirds of the vagina, the pelvic lymph node regions, and the surgical bed (Fig. 11.33). External beam field design must necessarily include the pelvic lymphatics with exclusion of as much small bowel as possible. Treatment of the patient in the prone position with a full bladder will help to exclude at least some small bowel in most patients unless these loops are fixed in the pelvis (Fig. 11.34). It is important, however, for the lateral fields to cover the course of the external iliac nodes, which are quite anterior in the pelvis and require inclusion of some small bowel in the lateral fields to be adequately covered. Doses of 45 to 50.4 Gy are typical, with some institutions treating to 40 Gy and as high as 60 Gy to reduced fields in the setting of nodal disease. Whole-pelvic fields are generally reduced or a midline block is added after variable doses.

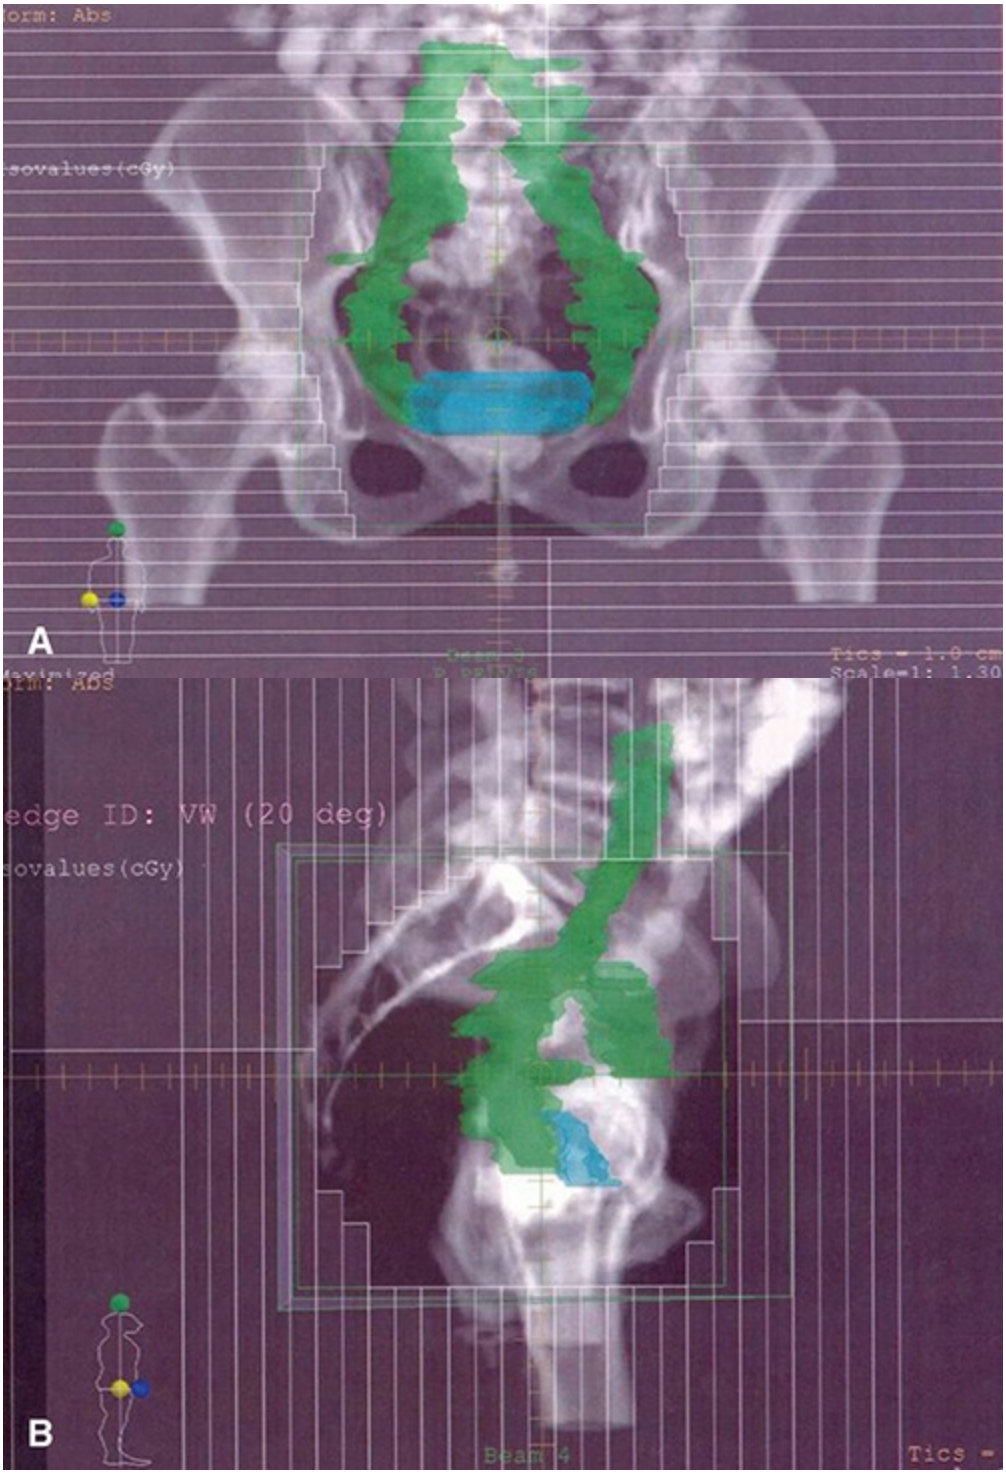

Figure 11.33 Digitally reconstructed AP (A) and lateral (B) radiographs with nodal volumes contoured, as well as the vaginal apex and the fields defined by the leaves of the multileaf collimator. This is a standard field design for patients with endometrial cancer.

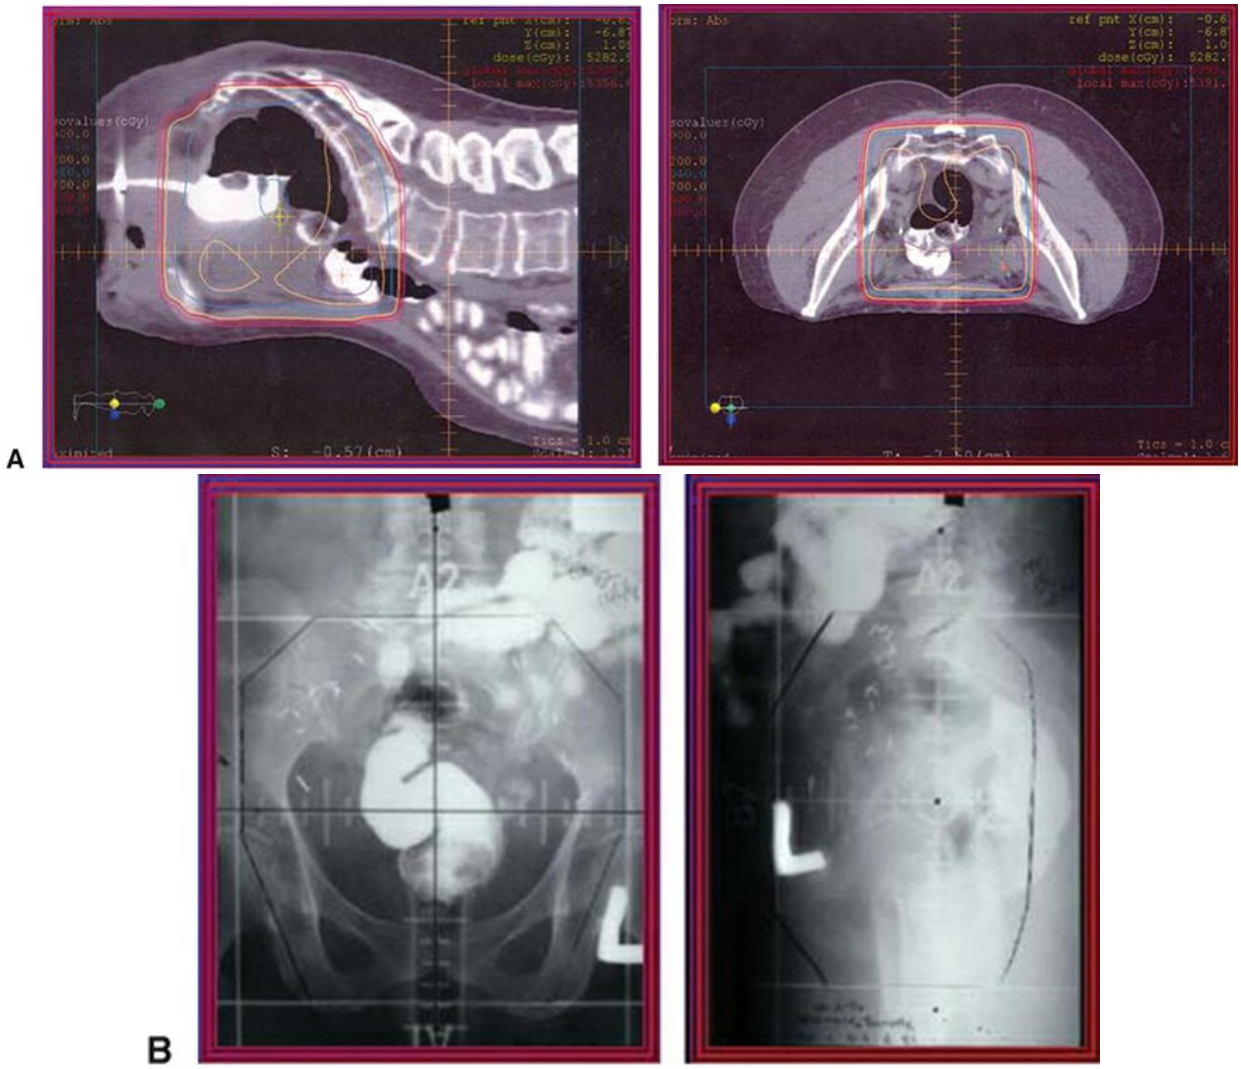

Figure 11.34 A: Utility of the prone technique for small bowel displacement as shown on a sagittal and axial CT scan of a patient with endometrial cancer planned in the prone position. B: Radiographs of the pelvis showing significant amount of small bowel in the radiation fields.

Prone techniques have been used in the treatment of many other pelvic malignancies in an attempt to exclude small bowel from the field. Use of a belly board device to further enhance small bowel displacement has become standard practice in the treatment of many pelvic malignancies. Use of prone position with or without a belly board for the treatment of patients with cervical cancer has been reported in a few series, in the postoperative (91) and definitive settings (92). Prone positioning with the belly board has been used extensively for patients with rectal cancers when using a PA and two lateral fields. Concern over this technique for patients with gynecologic malignancies when adding a fourth field (AP) to cover the external iliac nodes has been raised by Ghosh et al., due to the uncertainty in source to skin distance (SSD) and variation in tissue thickness from the anterior field. In patients who underwent postoperative irradiation for cervical cancer, they observed that the small bowel was best excluded from the AP–PA fields when the patient was positioned prone without the belly board, thereby compressing the small bowel laterally out of the AP–PA fields. They recommended an alternating routine (93). Bladder distention can also help to optimally displace bowel when using the belly board (94). Concern over use of the belly board in patients treated with definitive versus postoperative irradiation for cervical cancer is also raised due to the potential change in position of the uterus when prone, the impact and variability of bladder filling, and the potential daily variation in the setup (93). CT-based dosimetry has documented that the prone position, particularly with bladder filling, can alter the position of the uterus within the radiation field (67). Hence, if

patients are simulated prone, it is even more imperative to use CT- or MRI-based dosimetry in the prone position to make sure that the entire uterus is in the pelvic fields, and it is also imperative to consistently fill or empty the bladder (95). IGRT may also be helpful in ensuring that the daily setup is reproducible and reliable.

Extended-Field Irradiation

Extended-field irradiation refers to inclusion of both the pelvic and paraaortic nodes in the radiation fields. Common indications for extended-field irradiation in gynecologic cancers include patients with positive paraaortic nodes or those with positive pelvic nodes or bulky primary lesions feared to be at risk for microscopic paraaortic disease (Fig. 11.35). Extended fields include more normal organs than pelvic fields alone. Limitation of dose to the small bowel, kidneys, liver, stomach, and spinal cord are essential. Three-dimensional conformal techniques are helpful in achieving an acceptable therapeutic ratio. Use of IMRT has recently been piloted in this setting, with further attempts to decrease acute and late toxicity (Fig. 11.20). Selective boosting of gross nodal disease may allow for safer dose escalation (87).

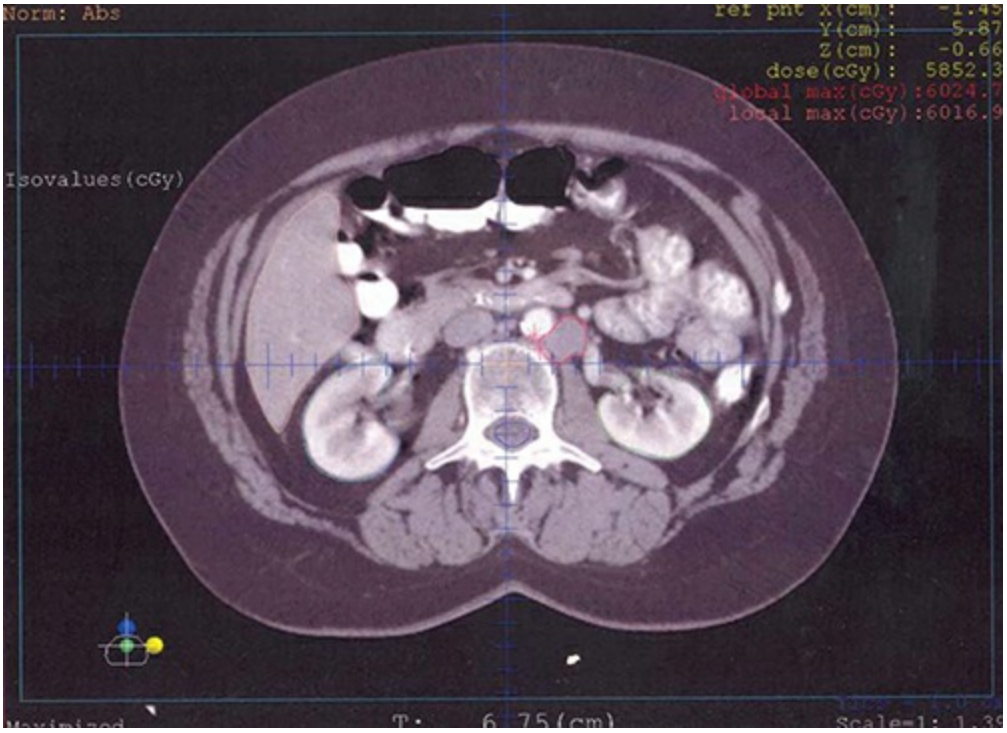

Figure 11.35 Axial CT scan demonstrating an enlarged periaortic lymph node near the left renal hilum.

Pelvic and Inguinal Irradiation

External beam fields will necessarily include the inguinal lymph nodes in patients with vulvar cancer or distal vaginal cancers, or when cancer of the cervix or endometrium involves the distal vagina. Risk of femoral head necrosis or femoral neck fractures is increased in this setting. Recent use of IMRT to treat vulvar and vaginal cancers has been published with success (96,97).

Intensity-Modulated Radiation Therapy

IMRT is an excellent treatment method for gynecologic cancers. The setting where IMRT may be the most helpful and the most widely accepted is postoperatively for select endometrial and cervical cancer presentations (98). Results of the

Radiation Therapy Oncology Group (RTOG) 0418 study "A Phase II Study of Intensity-Modulated Radiation Therapy (IMRT) to the Pelvis with or without Chemotherapy for Postoperative Patients with either Endometrial or Cervical Carcinoma" showed a decrease in both acute and late toxicity in the postoperative setting in patients with either cervical or endometrial cancers (99). Other prospective and single institutional studies have confirmed this (46,100). In the postoperative setting, there is often a significant amount of small bowel in the pelvis , which can be avoided to a greater degree with IMRT than with 3-D conformal radiation techniques (Fig. 11.22). Bone marrow sparing can also be improved over a 3-D conformal approach (101,102). Bladder and rectosigmoid doses can be reduced. Margin sizes around the target and bladder and rectal filling are important considerations, as are immobilization techniques when using IMRT. Target delineation and normal organ delineation are extremely important when using IMRT. What is not defined is either not adequately treated, or spared (51). RTOG 0418 defined parameters for contouring of targets and normal organs, margin size, and dose volume constraints in the postoperative setting in early cervical or endometrial cancers (103). An online atlas available on the RTOG website was developed to improve consistency between multiple contouring physicians, and continues to be used to guide in target delineation even though the protocol has been completed (104). This same atlas has been used in GOG/NRG studies, which include IMRT techniques with minor modifications over time. A normal tissue-contouring atlas is available on the RTOG/NRG website (105). Other atlases are also available to guide radiation oncologists in defining these structures of interest (69,106). When using IMRT to treat the intact uterus, bladder filling can have even more influence on the position of the uterus, and the vagina and uterus can move several centimeters as a result (51,107). Stool in the rectosigmoid can also cause movement of the adjacent pelvic organs and alter the dose distribution in the rectosigmoid.

IMRT may be used in the definitive management of cervical cancer, with careful attention to target delineation as well as motion. A consensus guideline has been published to define the most appropriate CTV for intact cervical cancer, with recognition of the significant uncertainties caused by motion in this setting (108). Studies have shown that IMRT has reduced both acute and late gastrointestinal (GI) toxicities and helped to spare bone marrow during treatment (50,102,109). There is concern in this setting about organ motion relative to the dose distribution. This can be due to bladder or rectosigmoid filling, disease regression, or sporadic motion (43,110). Careful attention to organ filling, patient immobilization, and margin size can help to minimize such motion, which could compromise target and normal organ doses (42). Daily CT imaging prior to treatment can also help to assess for this motion and adapt the treatment plan as needed. Use of IMRT for extended-field irradiation to treat the pelvic and paraaortic region is successfully implemented to decrease dose to the small bowel, kidneys, liver, spinal cord, and bone marrow (Fig. 11.20). Selective boosting of gross nodal disease may allow for safer dose escalation (87,111). IMRT techniques have also been used for vulvar cancers to help spare the upper femur as well as the small bowel and bone marrow (47,96,97).

Brachytherapy Systems for the Treatment of Cervical Cancer

Brachytherapy is essential in the treatment of many gynecologic cancers. Intracavitary brachytherapy for cervical carcinoma was profoundly impacted by the development of various "systems" that attempted to combine empiricism with a more scientific and systematic approach. A dosimetric system refers to a set of rules concerning a specific applicator type, radioactive isotope, and distribution of the sources in the applicator to deliver a defined dose to a designated treatment region (55). Within any system, specification of treatment in terms of dose, timing, and administration is necessary to implement the prescription in a consistent manner. Three systems were developed in Europe, including the Paris, Stockholm, and Manchester system (112–114). The Manchester system principles are an integral part of modern brachytherapy (114).

The Manchester System

The Manchester system was developed in 1932 by Tod and Meredith (114) and was later modified in 1953 (115) at the Holt Radium Institute. It standardized treatment with predetermined doses and dose rates directed at fixed points in the pelvis. The fixed points A and B were selected on the theory that the dose in the paracervical triangle impacted normal tissue tolerance rather than the actual doses to the bladder, rectum, and vagina. The paracervical triangle was described as a pyramidal-shaped area with its base resting on the lateral vaginal fornices and its apex curving around with the anteverted uterus. "Point A" was defined as 2 cm lateral to the central canal of the uterus and 2 cm from the mucous membrane of the lateral fornix in the axis of the uterus (Fig. 11.36). It often correlates anatomically with the point of crossage of the ureter and uterine artery and was taken as an average point from which to assess dose in the paracervical region. "Point B" was located 5 cm from midline at the level of point A, and was thought to correspond to the location of the obturator lymph nodes. To achieve consistent dose rates, a set of strict rules dictating the relationship, position, and activity of radium sources in the uterine and vaginal applicators was devised. The amount of radium would vary based on ovoid size and uterine length such that the same dose in roentgen would be delivered to point A regardless of the size of the patient or the size and shape of the tumor, uterus, and vagina. The vaginal ovoids were available in three sizes: small (2.0-cm diameter), medium (2.5-cm diameter), and large (3.0-cm diameter) and were preloaded or "hot loaded" with radium. The amount of radium per ovoid varied by size so as to obtain a uniform dose rate at the ovoid surface. It was recommended to use the largest ovoid size possible and place the ovoids as far laterally as possible in the fornices to carry the radium closer to point B and increase the depth dose. Vaginal packing was used to limit the dose to the bladder and rectum to <80% of point A. Two intracavitary applications of 72 hours with a 4- to 7-day interval between them were given to deliver a dose of 8,000 R at 55.5 R/hr to point A and 3,000 R to point B. External beam irradiation with a midline block in place was later used to deliver a total cumulative dose of 6,000 R to point B.

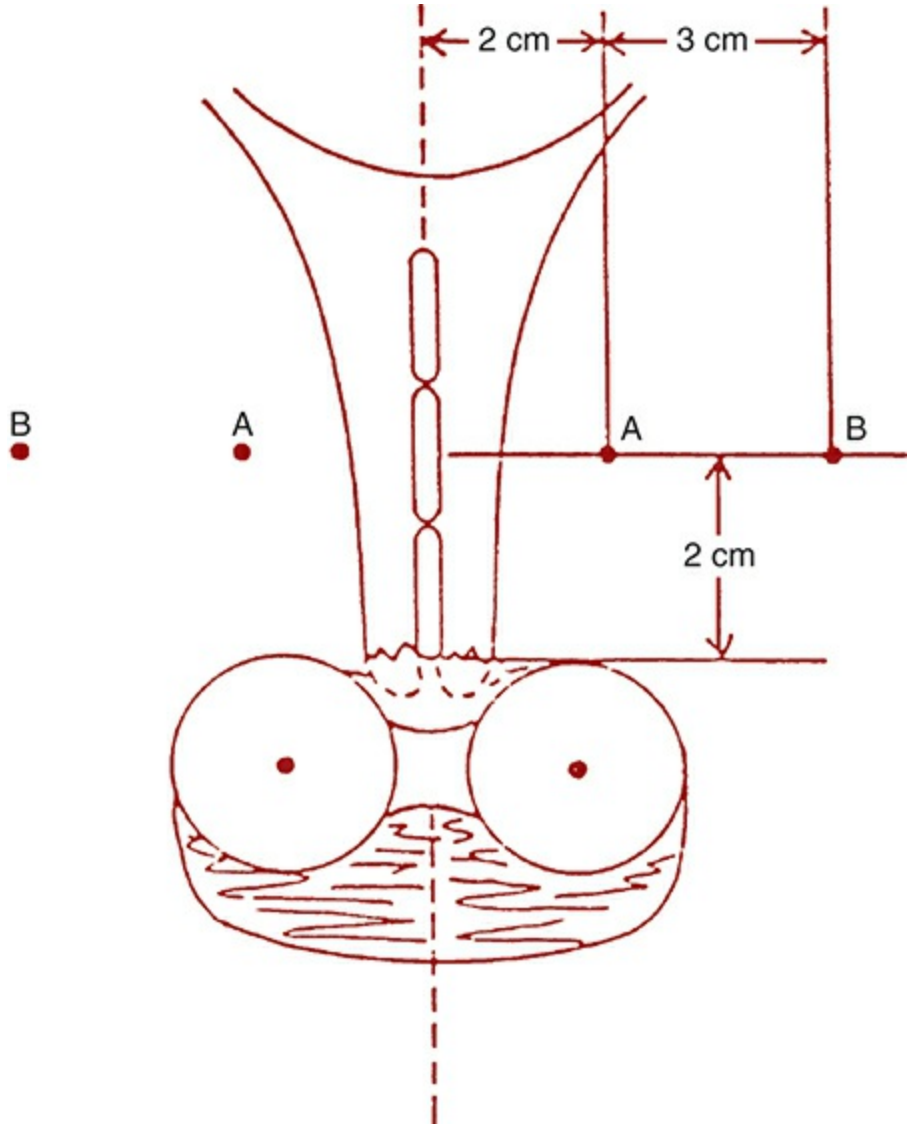

Figure 11.36 The Manchester system. Definitions of points A and B in the classical Manchester system are found in the text. In a typical application, the loading of intrauterine applicators varied: between 20 and 35 mg of radium and between 15 and 25 mg of radium for each vaginal ovoid. The resultant treatment time to deliver 8,000 R at point A was 140 hours.
Source: From Meredith WJ. Radium Dosage: The Manchester System.. Edinburgh, UK: Livingstone; 1967, with permission.

The Manchester system is the basis for contemporary intracavitary techniques and dose specification. With current LDR applications using cesium rather than radium, it is considered standard to have a point A dose rate of 50 to 60 cGy/hr and to deliver a total dose of 85 Gy to point A and 60 Gy to point B when combined with external beam therapy while limiting the normal tissues to <80% of the point A dose.

The Fletcher (M.D. Anderson) System

The Fletcher system was established at M.D. Anderson Hospital in the 1940s (116). The Fletcher applicator was subsequently developed and remains an integral part of gynecologic brachytherapy (Fig. 11.37) (117). The initial dosimetric work at M.D. Anderson was done prior to the development of computerized dosimetry in the 1960s as in the Paris system; milligram-hours (mg-hr) was used for dose prescription with the premise that with any geometric

arrangement of specified sources, dose at any point is proportional to the amount of radioactivity and the implant duration. Though previous systems (Paris and Stockholm) had used mg-hr, clinical experience alone determined the amount of radium tolerable to the tissues. Fletcher et al. (118) predicted that better results and less morbidity could be obtained if knowledge of the energy absorbed at various points in the pelvis ("measured data") such as the bladder and rectum and pelvic lymph nodes could be determined. According to Fletcher, a dosimetric approach should meet the following requirements: (a) ensure that the primary disease in the cervix and fornices and immediate extensions into the paracervical triangle are adequately treated; (b) guide treatments in such a way that the bladder and rectum are not overdosed (respect mucosal tolerance); and (c) determine the dose received by the various lymph node groups. Individualization to fit the anatomical situation was an essential aspect of this system.

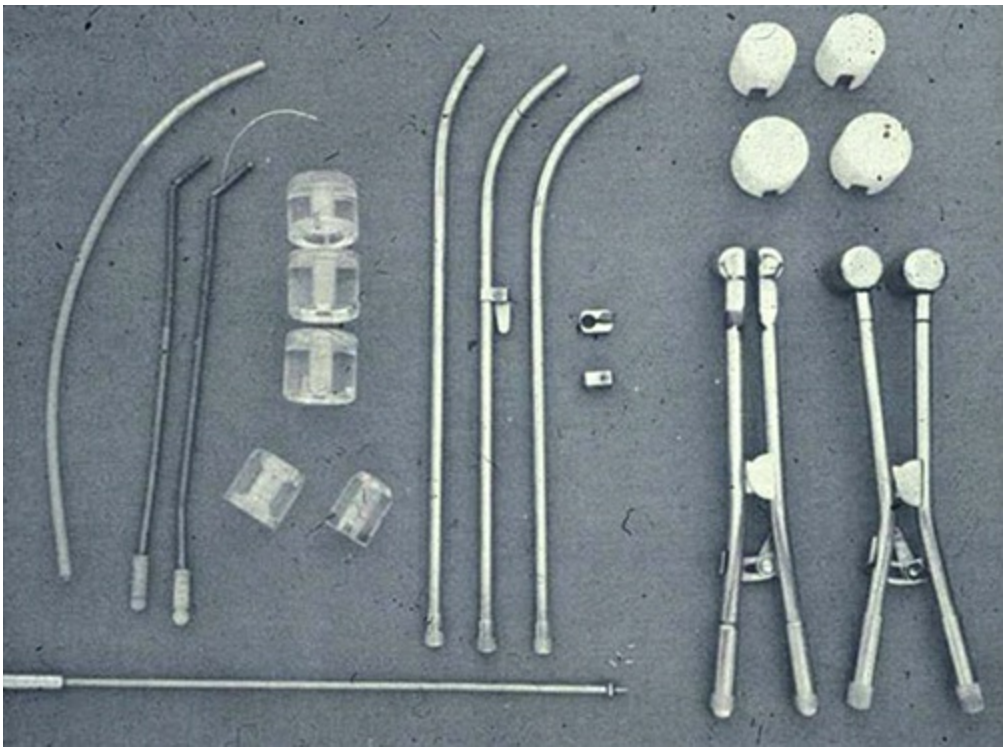

Figure 11.37 Fletcher-Suit-Delclos LDR applicators. Left to right: Afterloading colpostats, mini-ovoids, tandems, cylinders, and source inserters.
Source: Reprinted with permission from Fletcher GH, ed. Textbook of Radiotherapy. 3rd Ed. Philadelphia, PA: Lea & Febiger; 1980:741.

The primary prescription parameter in the Fletcher system was tumor volume, and prescription rules were based on maximum mg-hrs and maximum time, taking into account the total external beam dose and the calculated sigmoid dose. An application was left in place until either of these two maximums was reached. Large mg-hr implants were halted by the mg-hr prescription while smaller mg-hr implants were terminated by time. A set of maxima of mg-hrs was established for combinations with external irradiation, which were published in tables (119,120). Standardized source arrangements and limits on the vaginal surface dose and mg-hrs were all used to help specify treatment.

Despite a more elaborate dosimetry system, the Fletcher system combined many elements of the Paris and Manchester systems, including using the largest size ovoid possible, positioned as far laterally and cephalad as possible, to deliver the highest tumor dose at depth for a given mucosal dose. By using a larger ovoid, the radium–mucous membrane distance was increased, allowing a greater increase in the total number of mg-hrs and a greater volume of adequate irradiation (116). The Fletcher colpostats were actually a further evolution of the Manchester ovoids and were made with the same diameters of 2, 2.5, and 3 cm but were more cylindrical than Manchester "ovoids" and were attached to handles, with shielding in the direction of the bladder and rectum. Initially these were preloaded with radium, but later an afterloading

model was developed and loaded instead with ^{137}Cs (121). Recommended loadings were 15, 20, and 25 mg of radium for the 2-, 2.5-, and 3-cm colpostats, respectively, and 5 to 10 mg for the mini-ovoids (122). As in earlier systems, it was also recommended that the longest tandem available be used and loaded so that sources reached the uterine fundus in order to provide an adequate distribution in the lower uterine segment and paracervical areas, and to increase the dose to the obturator lymph nodes. Additionally, a high position of the applicator in the pelvis and a wide separation of the ovoids were thought to increase the dose to the pelvic wall. Tight packing was also recommended to displace the system upward and centrally and to decrease the dose to the bladder and rectum (116). Recommended tandem loadings were usually 15, 10, and 10 mg of radium, with the amount of radium in the tandem usually greater than that in the ovoids. The distal source in the tandem was to be positioned to produce an even pear-shaped dose distribution with no drop in dose rate between the tandem and ovoids, without excessive overlap that would result in a hot spot on the adjacent bladder or rectal mucosa. With the ovoids well positioned, this was usually accomplished by placing the physical end of the distal source at or a few millimeters beyond the external os of the cervix. A 10-mg protruding source was recommended if the vaginal ovoids were separated by more than 5 cm or displaced caudally, with each ovoid then decreased by 5 mg.

A careful review of implant films was outlined (Fig. 11.38). It was recommended to keep the tandem in the axis of the pelvis, equidistant from the sacral promontory and pubis and the lateral pelvic walls, to avoid overdosage to the bladder, sigmoid, or one ureter. The tandem was recommended to bisect the ovoids on the AP films and bisect their height on the lateral films. The flange of the tandem was to be flush against the cervix and the ovoids surrounding it, verified by confirming the proximity of the applicators to radiopaque cervical seeds. Radiopaque vaginal packing was used to hold the system in place and displace the bladder and rectum. Scrutiny of implant films prior to treatment remains an important tenet of brachytherapy. Two or more intracavitary insertions were thought to make more efficient use of the inverse square law such that the second and third implants would deliver intense radiation to the tumor periphery because of interval tumor regression. A recent retrospective review of implant geometry has confirmed the consistency of the M.D. Anderson approach and the good outcomes achieved when attention is paid to applicator position in the pelvis (123).

The M.D. Anderson approach to treatment specification reflects a policy of treating advanced cervical carcinoma to normal tissue tolerance (124). This includes integrating standard loadings and mg-hrs with calculated doses to the bladder, rectum, sigmoid, and vaginal surface. The activity in the ovoids is limited by the vaginal surface dose, which is kept below 140 Gy. Calculated bladder and rectal doses are noted and are sometimes used to limit the duration of the intracavitary system, with the combined external beam and implant doses for the bladder kept at <75 to 80 Gy and for the rectum at <70 to 75 Gy. Mg-Ra-eq-hrs are usually limited to 6,000 to 6,500 after 40 to 45 Gy external beam. Though mg-hrs have usually been used to guide and report doses at M.D. Anderson, recent retrospective reviews have also reported point doses, though these have not been used to plan or prescribe treatment. With the implant loadings and durations outlined by Fletcher, typical dose rates at point A are approximately 57 cGy/hour and vaginal surface dose rates are 100 cGy/hour (79,123). The median doses to point B and to the International Commission on Radiation Units and Measurements (ICRU) rectal and bladder reference points averaged 28%, 59%, and 60% of the point A doses, respectively. The median total dose to point A from external beam and intracavitary irradiation was 87 Gy, and the median doses to the bladder and rectum were 68 and 70 Gy. The total dose delivered to the vaginal surface was limited to 120 to 140 Gy or 1.4 to 2.0 times the point A dose. These total doses to point A and the vagina, bladder, and rectum are used as contemporary guidelines for determining implant duration and, therefore, dose.

Point A Redefined

The failure of localization radiographs to show the surfaces of the ovoids made implementation of the initial definition of point A difficult. The definition of point A was modified in 1953 to be “2 cm up from the lower end of the intrauterine source and 2 cm laterally in the plane of the uterus, as the external os was assumed to be at the level of the vaginal fornices” (Fig. 11.39) (115). This definition of point A is currently used at many institutions (125,126). A seed or marker ball placed near the exocervix and coincident with the tandem flange is used to identify the exocervix on the localization films. This definition, however, becomes problematic when the cervix protrudes between the ovoids (Fig. 11.40). This causes a resultant increase in dose rate at point A because point A lies in the higher dose “bulge” around the ovoids (127). The variation of point A often occurs in a high-gradient region of the isodose distribution. A consistent location for dose specification should fall sufficiently superior to the ovoids where the dose distribution runs parallel to the tandem (Fig. 11.41). In patients with deep vaginal fornices, reverting to use of the ovoid surface rather than the exocervix can help to solve this problem (127).

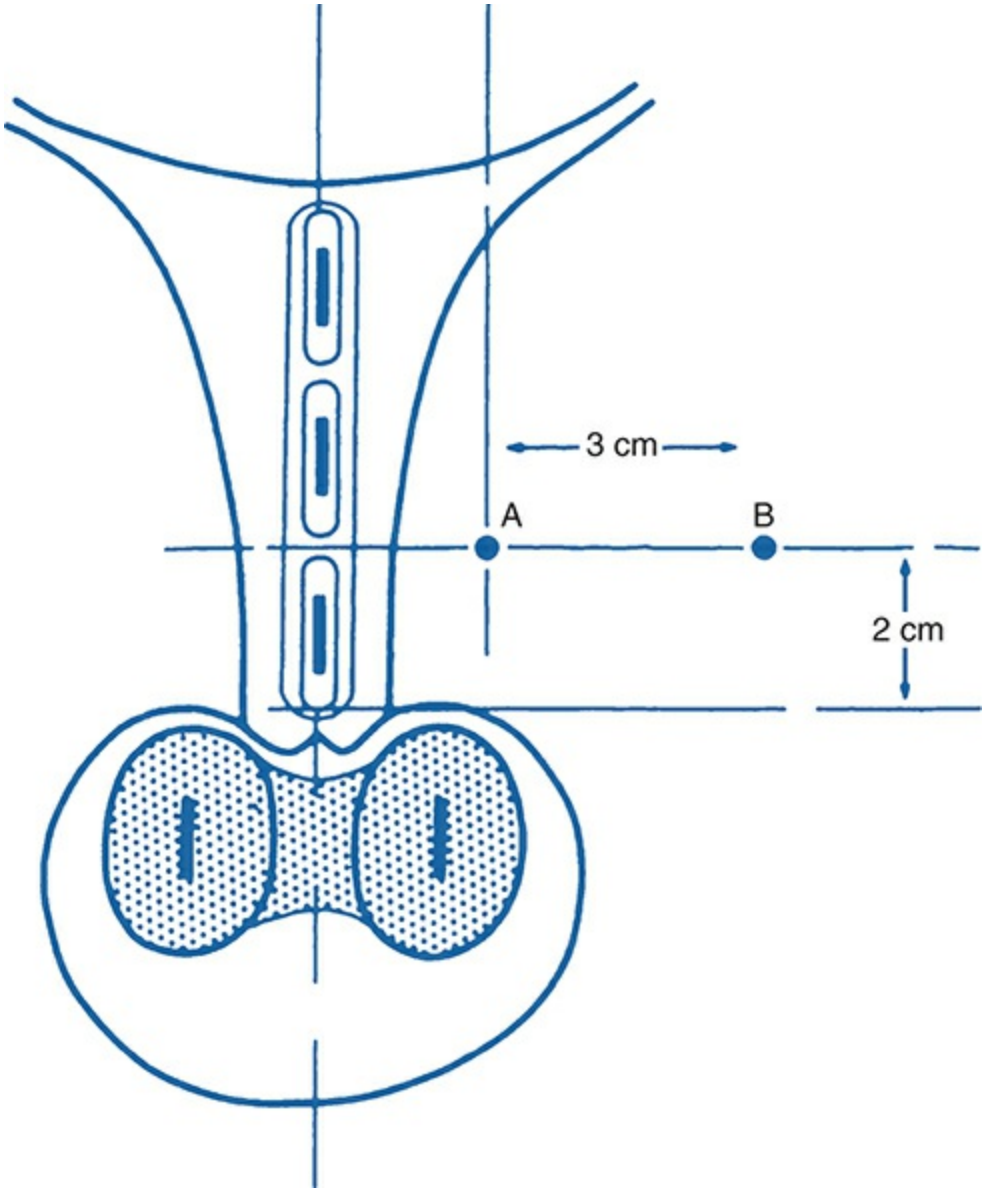

Figure 11.39 Revised Manchester system definition of point A.

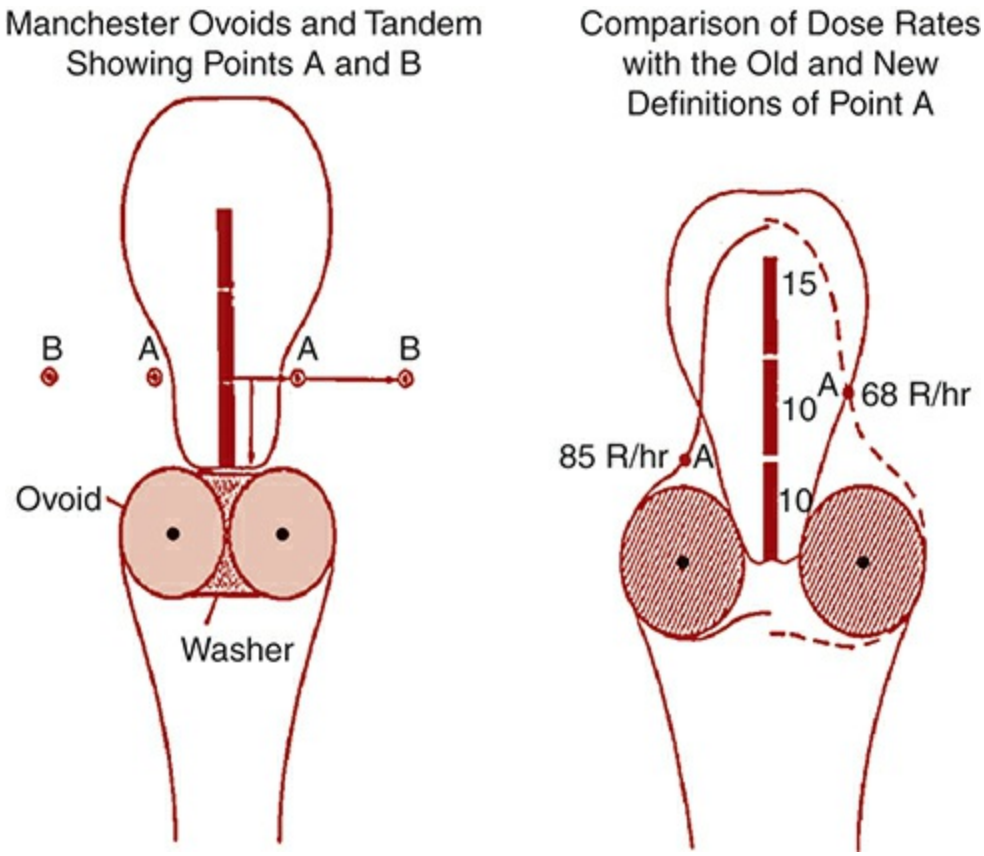

Figure 11.40 The definition of point A using the revised Manchester definition becomes problematic when the cervix protrudes between the ovoids, causing an increase in dose rate at point A. Use of the classical Manchester definition of point A (point A defined from the level of the upper vaginal fornices rather than the location of the exocervix) may be helpful.

Limitations of Brachytherapy Systems: Point A

It has become clear over time that points A and B are not anatomic sites. The actual specification is related to the position of the intracavitary sources rather than to an anatomical structure. Lewis et al. also demonstrated that point A does not maintain a constant relationship to any specific structure and its position varies with the type of applicator, individual tumor anatomy, and age of the patient. No correlation was found between point B and the pelvic wall (128,129). Potish also questions the validity of point A, as its position bears no fixed relationship to tumor or normal tissue anatomy, and is in a steep dose gradient and sensitive to displacement (130). Point A can be identical for implants that differ in fundamental ways and deliver different overall 3-D dose distributions.

Limitations of Brachytherapy Systems: mg-hr Systems

The use of mg-hr systems at many institutions also continues to guide the choice of source strength and duration of the implant, estimate the risk of complications, compare treatment between patients and institutions, and estimate efficacy (131). In the past, little attempt was made to obtain dose information to anatomical structures, and mg-hr prescriptions were not necessarily accompanied by isodose distributions, so that the dose prescription was not related to patient anatomy.

Contemporary Dose Specification for Cervical Cancer

With LDR brachytherapy, the basic principle of 2-D film-based intracavitary prescription is to leave a specific loading of sources in for a definite time, determined by empirical experience, prescription rules, and computerized dosimetry which provides the dose at several anatomic points and isodose distributions (Fig. 11.42). The intracavitary dose is based on the extent of disease and is altered if computer calculations indicated high doses to surrounding critical structures. The rectum and bladder are viewed as tolerance points, compared to point A, which is a treatment dose specification point (57). A combination of both mg-hrs and point doses is used at some institutions to guide implant duration (127). Though these definitions vary from institution to institution, most will attempt to quantify doses in the paracervical region (point A), and at either point B or the pelvic wall (C or E), and the rectum and bladder (57,125,126). Although intracavitary point dose calculations are not recorded as often for the sigmoid, vaginal mucosa, or cervix, dose evaluation at these points is also helpful. Maruyama et al. (132) defined a point T (tumor dose) located 1 cm above the cervical marker and 1 cm lateral to the tandem, which is usually two to three times the dose at point A. Vaginal surface dose rates, defined at the lateral ovoid surface, will vary based on applicator diameter and available source strengths and should be in the range of 1.4 to 2.0 (the point A dose) (123,133).

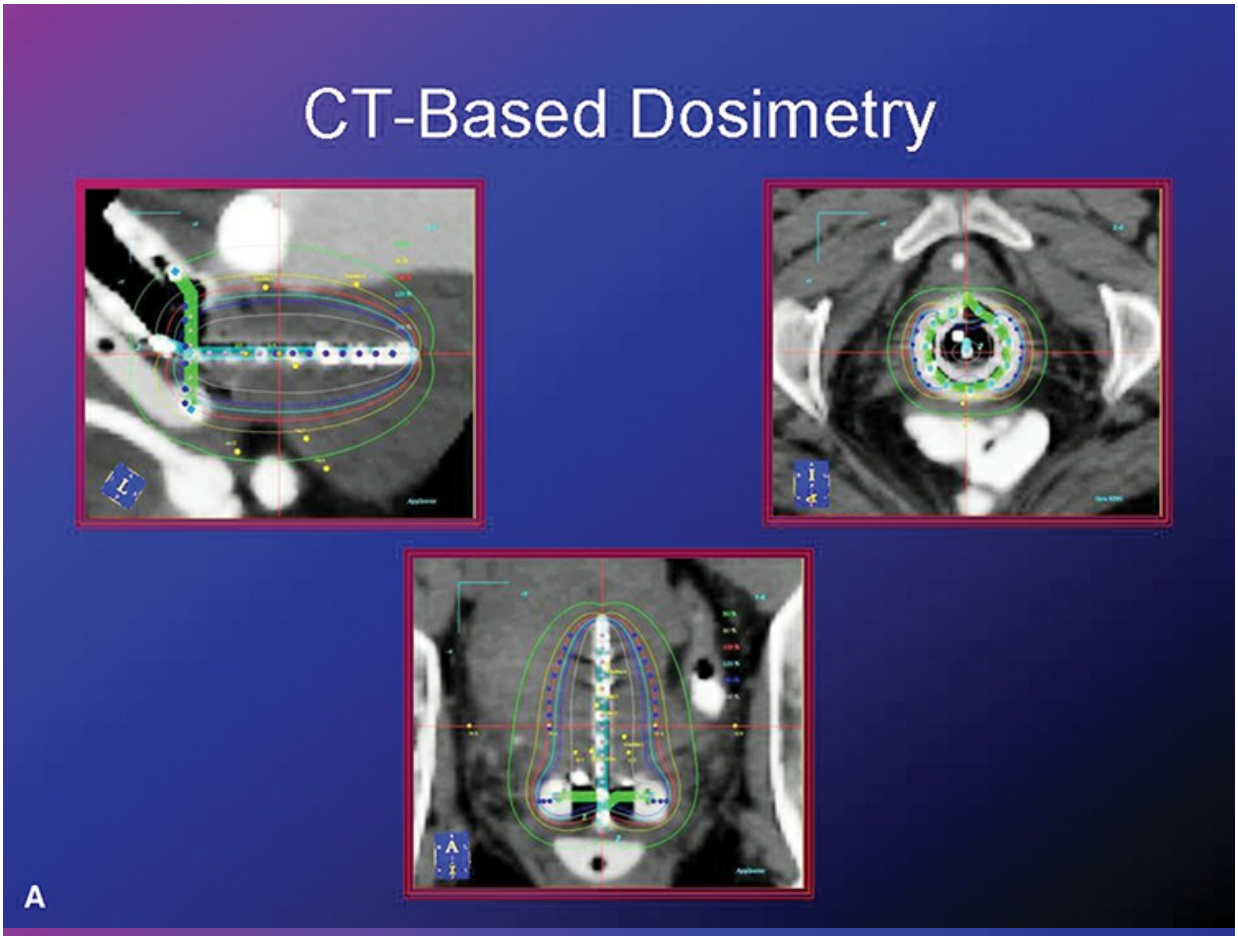
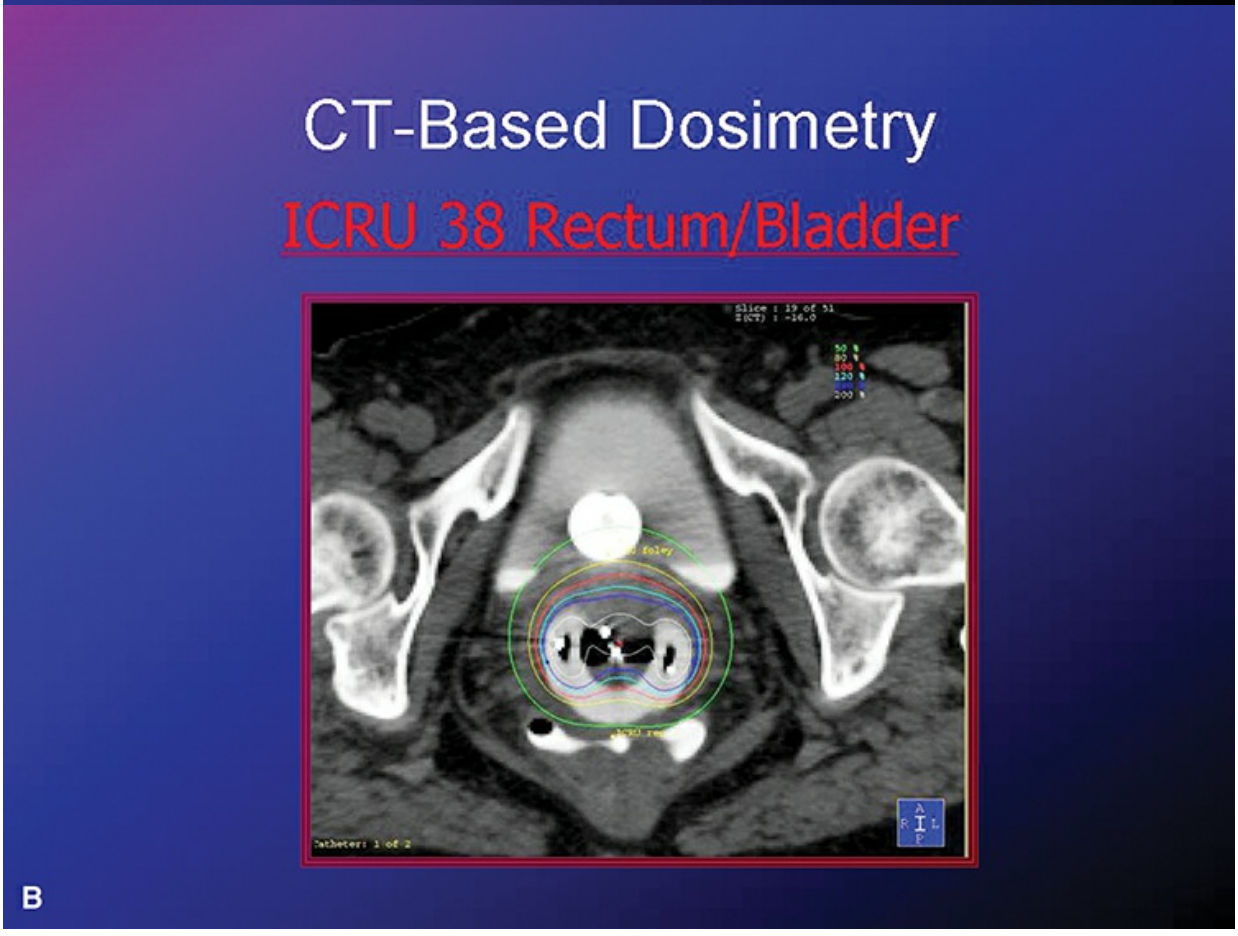
Philadelphia, PA: Lippincott-Raven Publishers; 1998:487, with permission.

It has become clear that 2-D orthogonal film-based dose distribution analysis, in which single or multiple reference points are chosen on films at the interface of the organs closest to the applicators and at select dose specification points, is inadequate for gynecologic brachytherapy. Single tumor reference points such as point A, chosen from localization films, do not give sufficient information about the dose distribution throughout the tumor volume. Nor do the reference points for the bladder and rectosigmoid accurately reflect the dose distribution within these organs. Additionally, there is no recognition of the volume of tumor and normal tissues receiving these doses (51). With the advent of MRI- and CT-compatible applicators and the presence of CT simulators and MR scanners in radiation oncology departments, as well as DICOM image transfer from scanners to treatment planning systems, 3-D image–guided brachytherapy is becoming the standard. Image-based brachytherapy entails defining both the disease and the OAR and then shaping the dose distribution to optimally cover disease and exclude the normal tissues (Fig. 11.43) (51,134,135). Directly relating the intracavitary system to the anatomy through use of CT and MRI is the next step in the lineage of dosimetric systems. The American Brachytherapy Society (ABS) has been pivotal in developing guidelines for the treatment of gynecologic cancers, with a special emphasis on image-based techniques (57,136).



CT-Based Dosimetry
A



CT-Based Dosimetry
ICRU 38 Rectum/Bladder
B

Figure 11.43 A: Sagittal, coronal, and axial CT images with MRI/CT-compatible applicator in place showing the isodose distribution around the applicator and within the surrounding tissues. B: Axial CT at the level of the Foley catheter bulb near the traditional ICRU 38 bladder and rectal points. Contrast is present within the bladder and rectum as well as the bladder catheter bulb.

CT is excellent for delineating the normal pelvic organs, but poor in defining tumor in the cervix or vagina. With CT-based computerized dosimetry, rectosigmoid and bladder doses can more accurately be determined than with localization films. Even when using CT-compatible applicators, however, the boundaries between structures of interest are poorly defined (134). The value of MR in the imaging of gynecologic cancers lies in its multiplanar capability and superior soft tissue resolution, compared to CT, enabling delineation of tumor within the cervix, uterus, and vagina as well as within the parametrial and vaginal tissues (134,137). Tumors of the cervix display moderately increased signal on T2-weighted images relative to normal cervical stroma, permitting definition of tumor volume. This is an advantage during brachytherapy, as one can assess the proximity of the tumor to the applicator and the subsequent dose distribution throughout the tumor volume. The excellent soft tissue resolution of MRI allows visualization of residual tumor in relation to the isodose distribution around the MRI-compatible brachytherapy applicators (Fig. 11.44) (134,137,138). The dose distribution can then be optimally conformed to the defined target volume while accurately defining and limiting the dose to the adjacent normal OAR. The Gyn GEC ESTRO working group began to develop guidelines for recording and reporting 3-D image-based treatment planning for cervical cancer brachytherapy in 2000. The guidelines were published in 2005, and described a methodology using MRI at the time of brachytherapy to define the GTV and CTV (5,139). The gross tumor volume (GTV) at the time of brachytherapy was defined as residual tumor following external beam on clinical examination, as well as the high-signal regions on T2 fast spin echo (FSE) images in the cervix and paracervical tissues. The high-risk clinical target volume (HRCTV) included the GTV as well as the entire cervix and the extracervical tumor spread at the time of brachytherapy. The “high-risk” volume refers to tissues with a major risk of local recurrence because of residual macroscopic disease, which require a high dose of radiation, similar to that delivered traditionally to point A. The intermediate-risk CTV (IRCTV) was defined as encompassing the HRCTV with a margin of 5 to 15 mm, and refers to tissues carrying a significant microscopic tumor load. Doses of approximately 60 Gy are intended for this volume. With these different regions of risk defined according to physical examination and MR at the time of brachytherapy, dose volume parameters were defined for the GTV, HRCTV, IRCTV, and the OAR. For the rectum, contouring included the outer wall from the anorectal junction to the rectosigmoid flexure, and the sigmoid contour continued alone until the sigmoid was approximately 2 cm from the uterus. The small bowel was contoured only if within 2 cm of the uterus. The outer contours of the bladder were also defined (5,138). D100 and D90, as well as V100, were recommended for reporting as well as the minimum dose in the most irradiated tissue volume for 0.1, 1, and 2 cc of the OARs, contouring the outer walls only (138). The radiobiologic model equivalent dose (EQD2) is used to sum the external beam and HDR doses together over the course of treatment so that a cumulative biologically weighted dose is available. This allows for systematic evaluation of the doses to the targets and normal organs over the course of treatment and for comparison between centers. An online atlas is available on the RTOG and NRG websites with case examples using the GEC ESTRO guidelines (140).

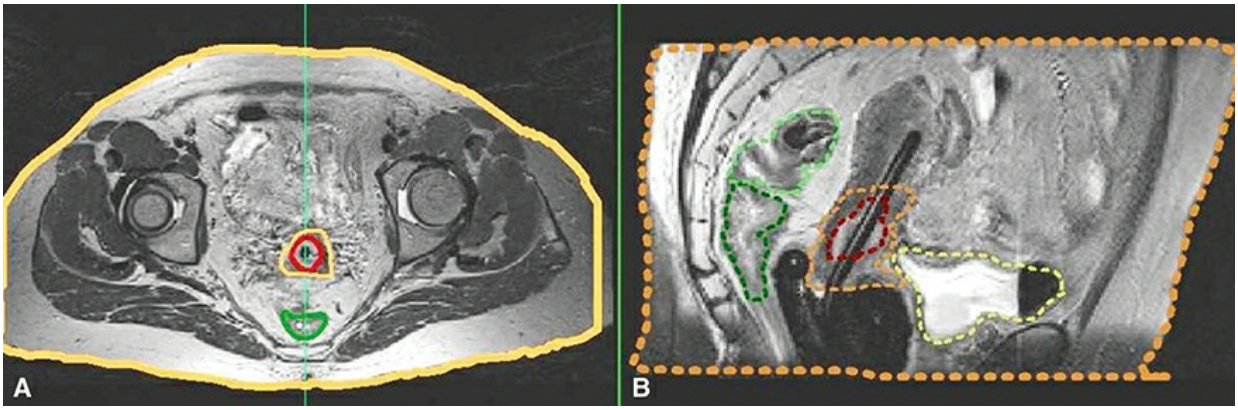


Figure 11.44 Axial (A) and sagittal (B) MRI images with MRI-compatible applicator in place with contours of the GTV and HRCTV as well as the rectum, sigmoid, and bladder.

Additionally, the use of dose–volume histogram analysis may add new insight into optimizing local control and decreasing morbidity with a better understanding of the importance of dose–volume relationships. Data from Potter et al. (141) have shown a decrease in complications and an increase in local control with the use of MRI-guided brachytherapy for cervical cancer. The ABS supports these guidelines and has incorporated them into its latest guideline document (136). Though frequently confused, the ICRU 38 system (Dose and Volume Specification for Reporting Intracavitary Therapy in Gynecology) is a dose reporting system, not a dose specification system (Fig. 11.45) (142). This was developed so that comparisons could be made between centers using different brachytherapy systems. It provides definitions for determining dose to the bladder and rectum in addition to other characteristics of the implant. An updated ICRU guideline (88) is forthcoming, with an emphasis on 3-D image-based planning and dose specification (142).

Importance of Brachytherapy in Cervical Cancer

When curative treatment is planned, the standard of care for patients with cervical carcinoma treated with definitive irradiation is a combination of external beam irradiation and brachytherapy (143–145). As revealed in the Quality Research in Radiation Oncology (former Patterns of Care Studies [PCS]) and retrospective series, recurrences and complications are decreased when brachytherapy is used in addition to external beam (79,80, 143–145). Retrospective series with external beam alone have demonstrated marginal outcomes with this approach (146,147). Common reasons for avoidance of brachytherapy include inability to negotiate the endocervical canal or poor performance status. Inability to negotiate the endocervical canal should be rare with the use of intraoperative ultrasound, and when this occurs, interstitial implantation is a much better option. Even with IMRT and the ability to customize and escalate the dose to specific volumes, brachytherapy cannot be replaced (134,147). The efficacy of brachytherapy is attributable to the ability of radioactive implants to deliver a higher concentrated radiation dose more precisely to tissues than external beam alone, by treating from the “inside out” due to the close proximity of the radioactive source(s) to the tumor, which contributes to improved local control and survival. At the same time, surrounding healthy tissues such as the bladder and rectosigmoid are relatively spared due to the rapid fall-off of dose around the applicators with distance. With IMRT, dose will necessarily be distributed in the surrounding normal tissues as it makes its way to the cervix, as the dose is delivered from the “outside in.” The external beam component of treatment is, however, very important because it addresses tissues at a distance from the brachytherapy applicator, such as the pelvic lymph nodes. The external beam also brings about tumor regression in intact cervical and vaginal cancers such that the residual tissue is brought within the range of the pear-shaped or cylindrical-shaped radiation dose distribution around standard applicators (53,54).

Brachytherapy Applicators

Given the significance of brachytherapy, it is important to select the appropriate applicator to accommodate patient anatomy and the disease, and shape the associated isodose distribution to encompass the disease entirely. Tumor volume and patient anatomy are key in this decision. Tumor size and shape are variable, and there is a multitude of applicators available to address these diverse presentations.

CHAPTER 12 Targeted Therapies in Gynecologic Cancers

Stephanie Lheureux and Amit M. Oza

INTRODUCTION

Biologic Foundations of Cancer

Normal cellular function and growth requires a complex interplay of intracellular and microenvironmental processes, which are precisely regulated by processes that have developed through evolution with internal controls and redundancies. Aberrations in cellular regulatory processes may result in major effects on the macromolecular or cellular environment. There are inbuilt corrective mechanisms, such as cell death, to maintain homeostasis and balance however, cancers develop when these homeostatic mechanisms fail or cells evade normal controls. Development of cancer is the product of biologic insults exerted individually and collectively on the genome, the proteome, *via* modulation of the microenvironment, or evasion of the immune system. For example, insults to master regulatory genes responsible for safeguarding cellular integrity (such as *p53*, *BRCA1/2*, *myc*, *ras*, or *src*) result in well-characterized downstream aberrations to cell signaling. Evidence of this can be seen through:

i. deregulated cell death that enables an unyielding rate of growth and metastatic spread of cancerous cells;
ii. rewiring of cell signaling that allows for redirection or diversion of cancer-specific nutrients;
iii. evasion of the immune system that permits undetected and uncontrolled growth.

Cancer that escapes these internal self-regulatory mechanisms can develop increasing clonal and genomic diversity, with resulting cellular heterogeneity in space and over time. This cancer cell evolution and the difficulty in defining this real time, contributes to difficulty for therapeutic targeting. Understanding the contribution of each of these elements to the development and progression of cancer is essential for developing targeted or precision therapies. Elucidating the precise magnitude that each element contributes to clinical behavior, sensitivity, and resistance is essential to understanding biology and improving precision of targeted therapy in cancer. The focus of this chapter will be on the involvement of these elements in gynecologic malignancies and the development and adoption of targeted therapies in ovarian, endometrial, and cervical cancers. This is a dynamic area with new developments and discoveries that are being incorporated into therapeutic targeting. The goal of precision medicine is to improve the accuracy of our understanding of cancer biology and use this knowledge to intelligently develop tools and techniques that not only predict therapeutic effect, but also match with treatment in an attempt to increase efficacy and reduce toxicity.

WHAT IS A TARGET AND WHAT DEFINES A TARGET?

Hanahan and Weinberg (1,2) described the six basic hallmarks of cancer that not only define its behavior—including distinctive and complementary capabilities that enable tumor growth and metastatic dissemination—but provide a roadmap for targeted drug development against key regulatory/survival processes in cancer cells (Fig. 12.1).

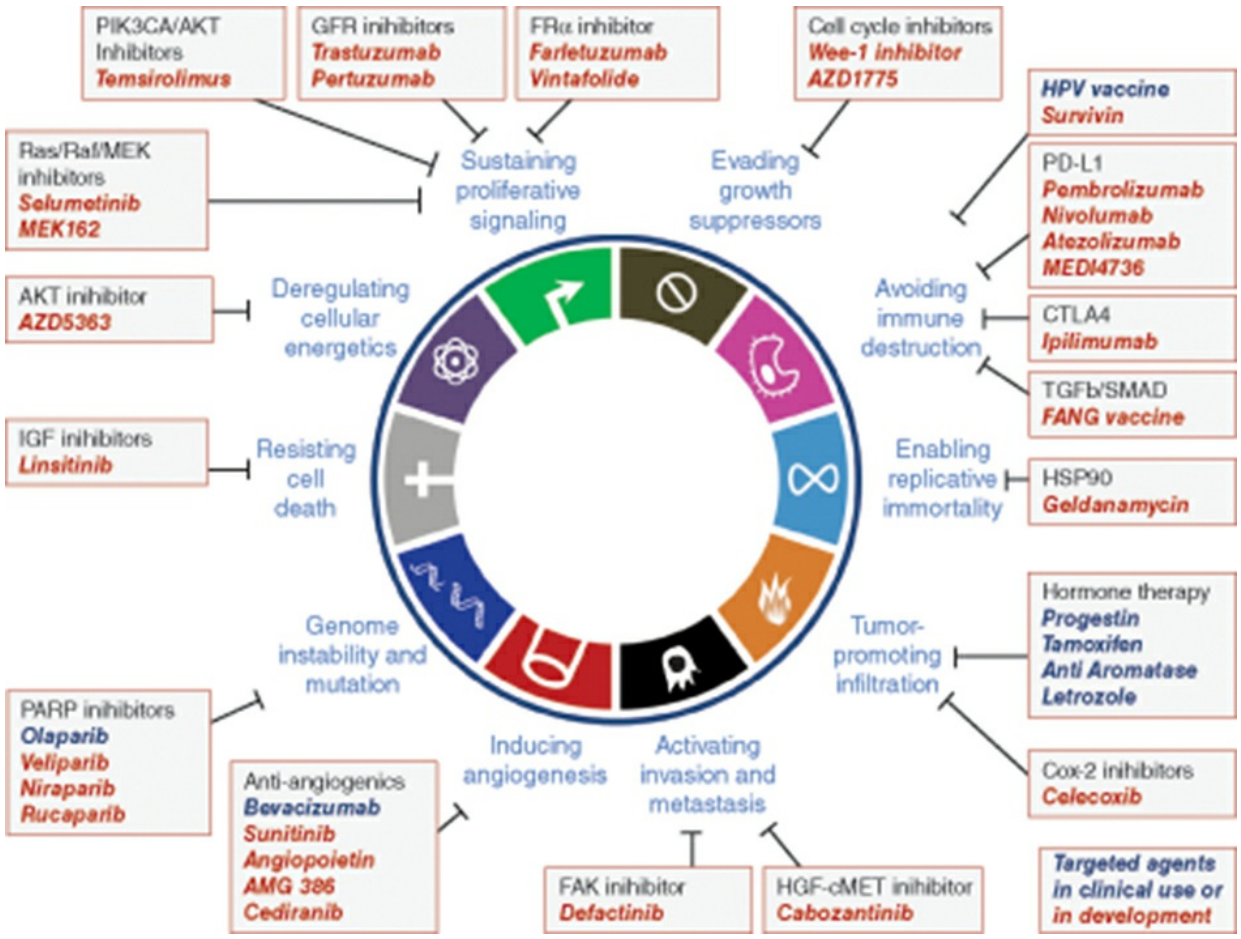

Figure 12.1 Hallmarks of cancer and therapeutic targets in gynecologic cancers. Adapted from Hanahan D, Weinberg RA. Hallmarks of cancer: the next generation. Cell. 2011;144(5):646–674.

Targets can further be classified as prognostic or predictive in nature. Prognostic factors are clinical or biologic characteristics that are objectively measurable and provide information on the likely outcome of disease in an untreated individual; in contrast, a predictive marker is a clinical or biologic characteristic that provides information on the likely benefit from treatment (either in terms of tumor shrinkage or survival) (3). Excellent guidelines on identifying and validating biomarkers and accuracy of prediction have been published by the National Cancer Institute (NCI) and the US Food and Drug Administration (FDA), and serve to improve accuracy and reliability in clinical decision making (4, http://www.fda.gov/MedicalDevices/DeviceRegulationandGuidance/Overview/default.htm).

Biology of Gynecologic Cancers

Gynecologic cancers show genomic and clonal diversity and heterogeneity in space and time, and can lead to considerable differences in clinical behavior. There is also considerable variation in pathology, even within ostensibly similar diagnoses. For example, epithelial ovarian cancer (EOC) consists of five distinct histologic types that include high-grade serous ovarian cancers (HGSOC) and low-grade serous ovarian cancers (LGSOC), mucinous, clear cell, and endometrioid

subtypes; while sex cord stromal and others such as germ cell comprise the non-epithelial group (5). Endometrial cancer (EC) has been segregated into Type I estrogen-dependent cancer such as endometrioid and Type 2, which consists of estrogen-independent non-EC carcinomas such as serous, clear cell carcinoma, carcinosarcoma, mucinous adenocarcinoma, squamous cell carcinoma, and mixed adenocarcinoma. These histologic subtypes reflect independent mechanisms of carcinogenesis and distinct disease biology. As such, histologic confirmation of disease subtype by an expert gynecologic pathologist is essential for accurate diagnosis, and ultimately, to inform decisions about therapy. The increasing assessment of subtype-specific mutations or molecular aberrations, particularly by The Cancer Genome Atlas (TCGA), has shed light on the genomic foundation of ovarian (2011) and endometrial (2013) cancers (6,7), alongside similar profiling efforts in cervical cancer (2014) (8). The availability of reliable data identifying contributions from point mutations in heritable and nonheritable genes and, in some cases, significant aberrations in oncogenic pathways contributing to disease, has led to the concerted development of research studies with targeted therapies in gynecologic cancers. The key findings from TCGA analyses in gynecologic cancers are summarized in Table 12.1.

TABLE 12.1 Integrated Genomic Analyses of Ovarian and Endometrial Cancers Conducted by TCGA Network

TCGA Target Population	Major Study Findings
HGSOC (6)	• Characterized by TP53 mutations in almost all tumors (96%); • Low prevalence but statistically recurrent somatic mutations in nine further genes including: NF1, BRCA1, BRCA2, RB1, and CDK12; • 113 significant focal DNA copy number aberrations; • Promoter methylation events involving 168 genes; • Four ovarian cancer transcriptional subtypes, three microRNA subtypes, four promoter methylation subtypes, and a transcriptional signature associated with survival duration; • Impact of tumors with BRCA1/2 (BRCA1 or BRCA2) and CCNE1 aberrations on survival; • Homologous recombination is defective in about half of the tumors analyzed; and • NOTCH and FOXM1 signaling involved in serous ovarian cancer pathophysiology.

Endometrial carcinoma (7)	• Uterine serous tumors and ~25% of high-grade endometrioid tumors had extensive copy number alterations, few DNA methylation changes, low ER/PR levels, and frequent TP53 mutations;
	• Most endometrioid tumors had few copy number alterations or TP53 mutations, but frequent mutations in PTEN, CTNNB1, PIK3CA, ARID1A, and KRAS and novel mutations in the SWI/SNF chromatin remodeling complex gene ARID5B;
	• A subset of endometrioid tumors had a markedly increased transversion mutation frequency and newly identified hotspot mutations in DNA polymerase epsilon (POLE);
	• Novel Classification System:
	  ◦ POLE ultramutation,
	  ◦ Microsatellite instability hypermutation,
	  ◦ Copy number low, and
	  ◦ Copy number high.
	• Uterine serous carcinomas share genomic features with ovarian serous and basal-like breast carcinomas.

Cervical cancer data are yet to be published.

Target Identification, Validation, and Measurement

It is important to note that identification of potential targets, their validation, and subsequent incorporation into predictive biomarkers for clinical trials or standard therapy must be conducted in a methodologically rigorous manner to warrant confidence in the results. One of the major challenges is to identify the role of the target in carcinogenesis and cancer growth, determine its functionality, and distinguish its role between driver or passenger abnormalities. Biomarkers which may guide therapy must be measured in regulated conditions (CLIA, CAP) and are subject to regulatory oversight. Precision of biomarker development and incorporation are beyond the scope of this chapter, but excellent references which guide development, validation, incorporation into clinical trials, and standard therapy are included (4).

Targeting the Targets

Improved understanding of disease biology has led to the development of numerous potential targets and biomarkers to improve precision of therapy. Target engagement can be through several different modalities that modulate or interact with cell surface receptors (monoclonal antibodies), intracellular cascade pathways and signaling (small molecule tyrosine kinase inhibitors), or microenvironment effects related to tumor vasculature or hypoxia. There have also been some interesting results using antibody□drug conjugates that are being leveraged for treatment in gynecologic malignancies. Modulating the immune environment with dynamic changes in cancer cell interaction with T cells or NK cells is a very active area of study, including cellular therapy using *ex-vivo* propagation of immune cells, vaccines, and checkpoint inhibitors. Finally, improved delivery of targeted agents to cancer cells using nanoparticles such as porphysomes presents tremendous opportunity for precision bombing of cancer cells and reducing bystander or collateral toxicity (9).

GENETIC FACTORS CONTRIBUTING TO GYNECOLOGIC MALIGNANCIES

TP53

TP53 is one of the most important tumor suppressor genes and is frequently mutated in human cancers. Generally, p53 functions as a transcription factor that is stabilized and activated by various genotoxic and cellular stress signals, such as DNA damage, hypoxia, oncogene activation, and nutrient deprivation, consequently leading to cell cycle arrest, apoptosis, senescence, and metabolic adaptation (10). *TP53* somatic mutations are a defining early event in HGSOC (6,11) as well as in serous endometrial cancer (12). p53 seems an attractive target in gynecologic cancers; contemporary strategies targeting p53 have been developed, including gene therapy to restore p53 function, inhibition of p53□MDM2 interaction, restoration of mutant p53 to wild-type p53 or targeting p53 family proteins. However, *p53*-targeted therapy remains challenging (10). Different types of *TP53* mutations have been described but the functionality of this mutation is complex (13). Most *TP53* mutations are missense mutations that result in single amino acid substitutions in p53 and expression of high levels of dysfunctional p53 protein (14). Some types of *TP*53 mutations are termed gain-of-function or loss-of-function mutations. The impact on patient outcome and response to treatment is not well established, and investigations remain ongoing.

Cell Cycle

The cell cycle is a complex process involving numerous regulatory proteins from which the cyclin-dependent kinases (CDK) are central (Fig. 12.2). These proteins regulate the cell's progression through the stages of the cell cycle and in turn, are regulated by numerous proteins, including p53, p21, p16, and cdc25. Downstream targets of cyclin□CDK complexes include pRb and E2F (15). The cell cycle is particularly altered in gynecologic cancers due to alterations either

in oncogenes that indirectly affect the cell cycle or in tumor suppressor genes or oncogenes that directly impact cell cycle regulation, such as p53, p16, or viral infection including papillomavirus (HPV)-associated cervical and vulvar carcinomas (the manifold effects of the viral oncogenes E6 and E7 on cell cycle control). Tumor-associated cell cycle defects are often mediated by alterations in CDK activity. Misregulated CDKs induce unscheduled proliferation as well as genomic and chromosomal instabilities. Emerging evidence suggests that tumor cells may also require specific interphase CDKs for proliferation. Selective CDK inhibition may provide therapeutic benefit against certain human neoplasias (16). Therefore, the cell cycle has become an intense subject of research in recent years. Any drug or toxin with DNA-damaging ability would be expected to alter cell cycle progression.

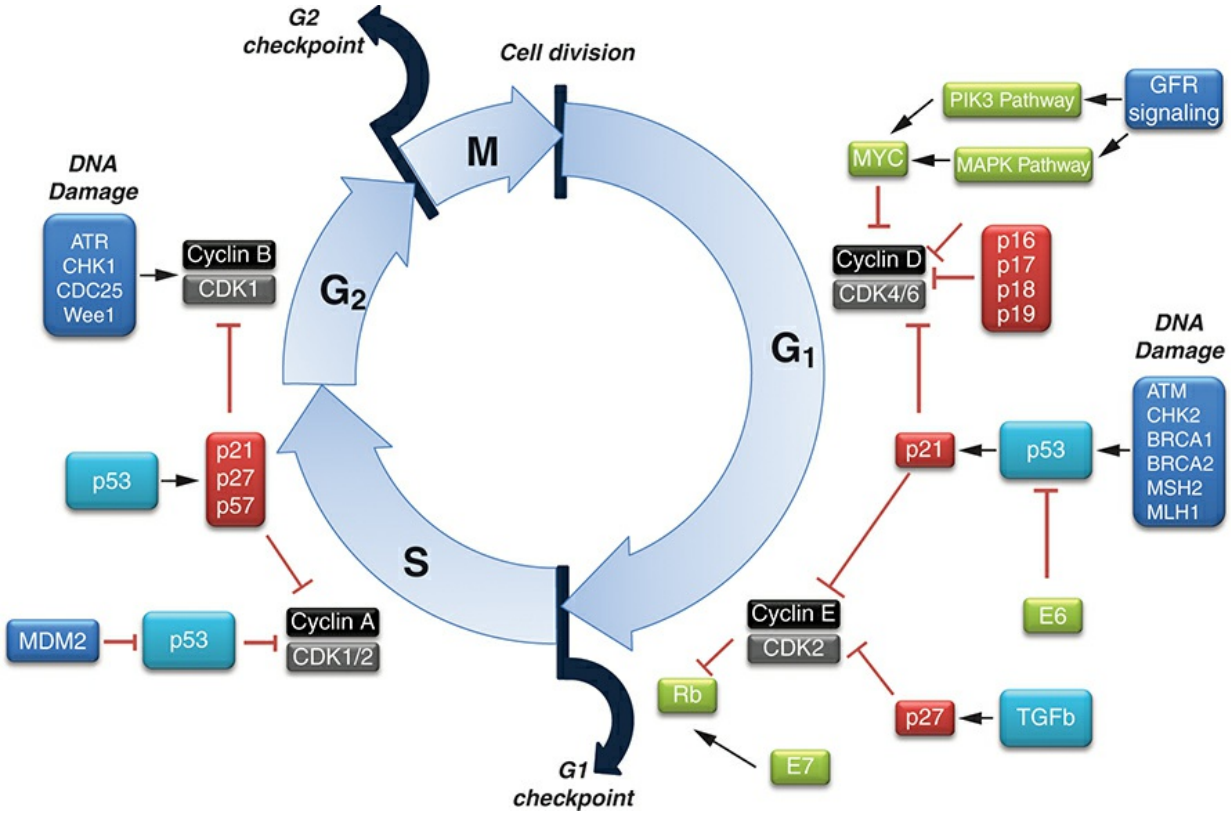

Figure 12.2 Cell cycle regulation. Cyclins and CDKs promote cell cycle progression and are mediated by inhibitory molecules.

DNA Repair and Homologous Recombination Pathway

In the DNA repair pathway, important targets in ovarian cancer, particularly in HGSOC, are the *breast cancer gene 1* (*BRCA1*) or *2* (*BRCA2*) genes (17) (Fig. 12.3). Mutations in these genes predispose germline carriers to breast and ovarian cancer as well as many other malignancies—the lifetime risk of developing ovarian cancer is 40% to 60% and 11% to 27% for *BRCA1* and *BRCA2* pathogenic mutation carriers, respectively [6](18). These particular mutations are implicated in 10% to 15% of all ovarian cancer cases and almost 20% of HGSOC histology (19), including women without a family history of breast or ovarian cancer. The diagnosis of HGOSC should lead to germline testing for all patients.

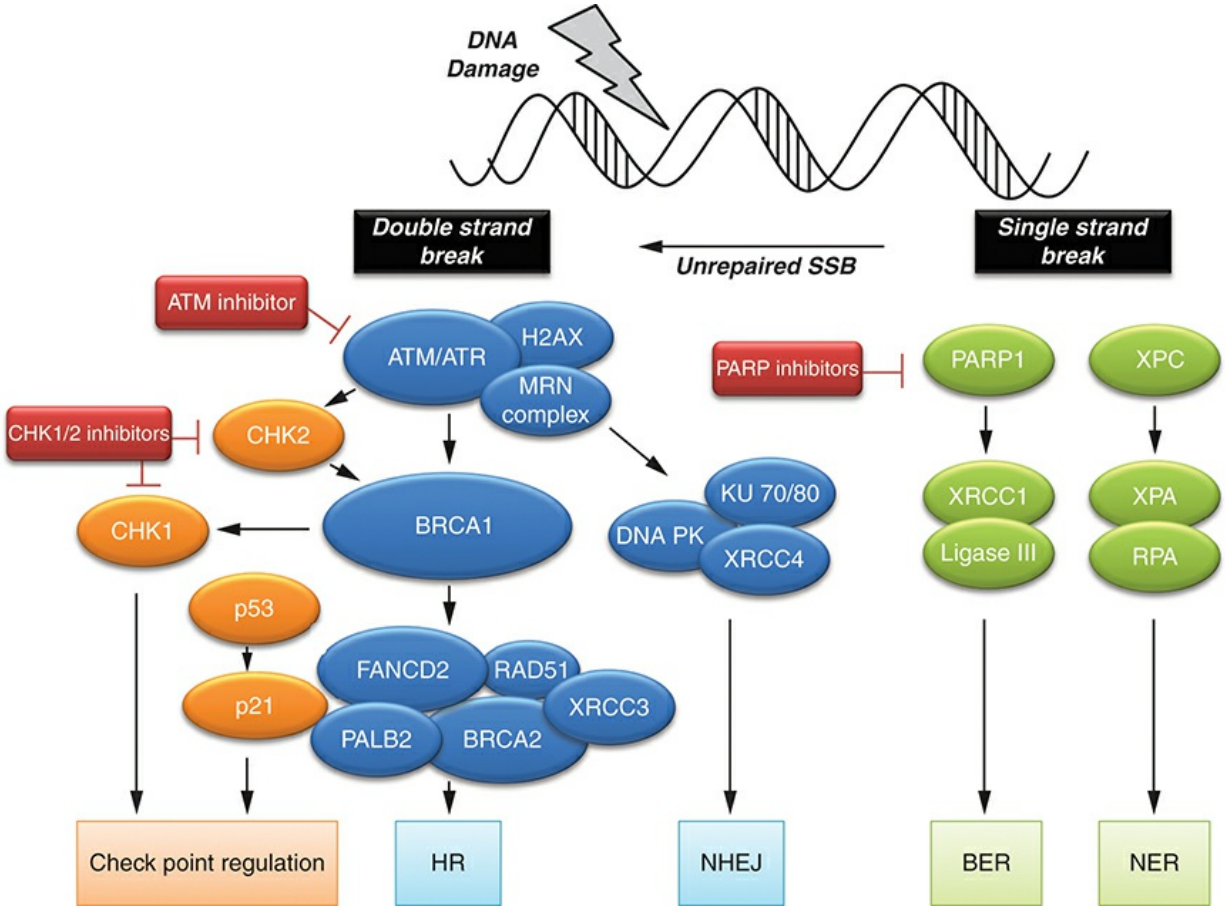

Figure 12.3 DNA repair pathway and therapeutic targets in cancer.

An increasing body of evidence indicates the benefit of targeting pathways involved in maintaining DNA integrity, including *BRCA1* and *BRCA2* signaling (20). Harboring a germline *BRCA1/2* mutation is described as predictive of platinum sensitivity (21) and confers predictable sensitivity to poly ADP-ribose polymerase (PARP) inhibitors, as impairment in DNA repair conferred by pathogenic *BRCA1/2* mutations can be leveraged into therapeutic effect by blocking poly ADP-ribose polymerase, another major enzyme in DNA repair. This simultaneous promotion of DNA double-strand breaks (DSBs) and hindrance of DSB repair by inhibition of PARP protein expression (22,23) has led to accelerated development of inhibitors of PARP protein. This effect, dubbed "synthetic lethality," was demonstrated preclinically and confirmed clinically, and has led to the initial approval of olaparib in the treatment of *BRCA1/2*-mutated HGSOC. Germline and somatic testing for *BRCA1/2* provides important information about predisposition as well as predictive biomarker for therapy using PARP inhibitors in women with ovarian cancer, and has led to clinical implementation and approval.

The ability to leverage deficiencies in homologous recombination has been shown to extend beyond *BRCA1/2* mutation with phenotypic features of those tumors exhibiting *BRCA*-like behavior. Studies conducted by Walsh et al. (24,25) using targeted, massively parallel next-generation sequencing—the BROCA panel sequenced 21 tumor suppressor genes, including *BRCA1/2* and other genes known to cause inherited breast or ovarian cancers—screened 360 patients with ovarian, peritoneal, or fallopian tube carcinomas for germline mutations, and showed that 18% of patients have germline mutations in *BRCA1/2* and another 6% have a non-*BRCA1/2* germline mutation. They identified mutations in every evaluable Fanconi Anemia pathway gene including *NBN*, *MRE11*, *RAD50*, *RAD51C*, *PALB2*, *BARD1*, and *BRIP1* (25). There are also a unique subset of tumors that harbor mutations in the homologous recombination (HR) pathway other than *BRCA1/2*, exhibiting a *BRCA*-like profile—specific phenotype with features and behavior similar to *BRCA*-related ovarian cancers, including sensitivity to platinum (DNA-damaging agents), improved progression-free survival (PFS) and survival rates, and HGSOC histology (26). Similar to the above, genes involved in the *BRCA*-like profile include *RAD51*, *PALB2*, *CHEK2*, *Mre11* complex, and *BARD1* (26). A study investigating rucaparib (another PARP inhibitor) monotherapy in

patients with recurrent platinum-sensitive HGSOC has confirmed *BRCA1/2* mutation as a biomarker of response as well as genomic loss of heterozygosity (LOH), a potential predictive surrogate marker for HR deficiency (27). It was hypothesized that the inability of the cell to perform HR leads to genomic scarring and LOH, thus enabling the use of high LOH as a signature of HR deficiency.

Defects in DNA repair are also found in Lynch syndrome—an autosomal dominant, inherited cancer-susceptibility syndrome in women with endometrial cancer involving several genes including: *MLH1*, mutS homologue 2 (*MSH2*), *MSH6*, *PMS1* homologue 2; (*PMS2*) (mutations of DNA mismatch repair [MMR] system component), and others (28). Similar to *BRCA1/2*, family history is inadequate to identify affected individuals; and as such, the clinical and research communities are increasing screening strategies to identify germline carriers who are at increased risk of disease. These approaches include screening immunohistochemistry (IHC) for the presence of MMR proteins in all colorectal and endometrial cancers and for those patients with loss of MMR detected, they can then subsequently be referred for germline testing (28). Similar to other gynecologic cancers, testing for somatic or epigenetic changes may provide predictive or prognostic information; however, additional studies to validate this approach are warranted. As is expected, most centers favor MMR IHC for practicality—family testing, interpretation, cost, normal tissue not required—with an increasing number of centers growing their IHC testing platform to include MMR IHC using two to four antibodies on all endometrial cancers (28–;30).

PI3K/AKT/mTOR

The phosphatidylinositol 3-kinase (PI3K)/AKT/mammalian target of rapamycin (mTOR) pathway plays a critical role in the malignant transformation of human tumors and their subsequent growth, proliferation, and metastasis (31). The PI3K/AKT/mTOR signaling pathway regulates central aspects of cancer biology such as metabolism, cellular growth, and survival (32). Upon stimulation of receptor tyrosine kinases, PI3K phosphorylates phosphatidylinositol-4,5-bis-phosphate 2 (PIP2) into PIP3, resulting in the activation of AKT. Among its targets, AKT controls the activation of the downstream pathway effector, the mammalian target of rapamycin (mTOR), which activates two key substrates 4EBP1 and p70S6K. This results in increased translation of target genes involved in angiogenesis (VEGF) and cell cycle progression (cyclin D1, c-Myc). The primary negative regulator of the PI3K pathway is the tumor suppressor phosphatase and tensin homologue (PTEN). PTEN can dephosphorylate PIP3, reversing AKT activation and inhibiting further downstream signaling; however, in the absence of PTEN inhibition, AKT phosphorylates, leading to mTOR activation. This is one of the most commonly altered pathways in EC; it is described in 92% and 60% of type I and II tumors, respectively. EC has more frequent mutations in the PI3K/AKT pathway than any other tumor type studied by TCGA (7). Activation of the PI3K/AKT pathway occurs frequently in type I EC through a variety of mechanisms such as the loss of PTEN that occurs in up to 70% of cases and/or PI3K mutations occurring in upward of 36% of cases. *PTEN* mutation is also frequently observed (27.3%) in clear cell EOC (33). More recently, frequent alteration of *ARID1A* and *PIK3CA* have been reported in this rare histology subtype. The AKT/mTOR pathway is thought to be the most important passage for tumor growth in clear cell ovarian cancer (34). Mutations in the beta-catenin and *PTEN* genes as well as the tumor suppressor genes *PID3CA* and *ARID1A* have been identified in EC. Recently, it has been reported that *KRAS* and *PIK3CA* gene mutations may be important players in the oncogenesis of these tumors, and their role in treatment in this subgroup should be explored (35).

Mitogen-Activated Protein Kinase

The mitogen-activated protein kinase (MAPK) pathway is activated and appears to play a prominent role in the pathogenesis of LGSOC (36). Approximately 20% to 40% of low-grade serous carcinomas have a *KRAS* mutation, whereas *BRAF* mutations are rare (approximately 5%). *KRAS* is a frequent mutation detected in advanced LGSOC, and the *BRAF* V600E mutation is associated with serous borderline tumors and early-stage LGSOC (37). As a result, the

V600E mutation is associated with a better clinical outcome. The MAPK cascade is triggered by the binding of a ligand that ultimately leads to phosphorylation of ERK. Thus, MEK is a good candidate for targeted therapy, and a number of MEK inhibitors (MEKi) have been developed (34).

Others

The driver mutation in *FOXL2* and dysregulation of the PI3K/AKT pathway have been implicated in granulosa cell tumor development. In preclinical data, mTOR inhibitor may be a useful pharmacologic target for the treatment of this disease (38).

ROLE OF THE IMMUNE SYSTEM IN GYNECOLOGIC MALIGNANCIES

Immune Evasion

The presence of tumor-infiltrating lymphocytes (TILs) was associated with favorable outcome in gynecologic cancers. POLE ultramutation and microsatellite instability (MSI) are associated with high neo-antigen loads and number of TILs, which is counterbalanced by overexpression of PD-1 and PD-L1. MSI is more frequent in endometrioid than in non-endometrioid tumors, and occurs in roughly 30% of sporadic cases of EC.

Early phase clinical trials using checkpoint inhibitors to modulate immune cells in gynecologic cancer are yielding interesting results in ovarian and endometrial cancers, with initial evidence of objective responses and prolonged disease control. There are several agents in active development as single agents, or in combination with chemotherapy, targeted agents, monoclonal antibodies, and vaccines (Fig. 12.4).

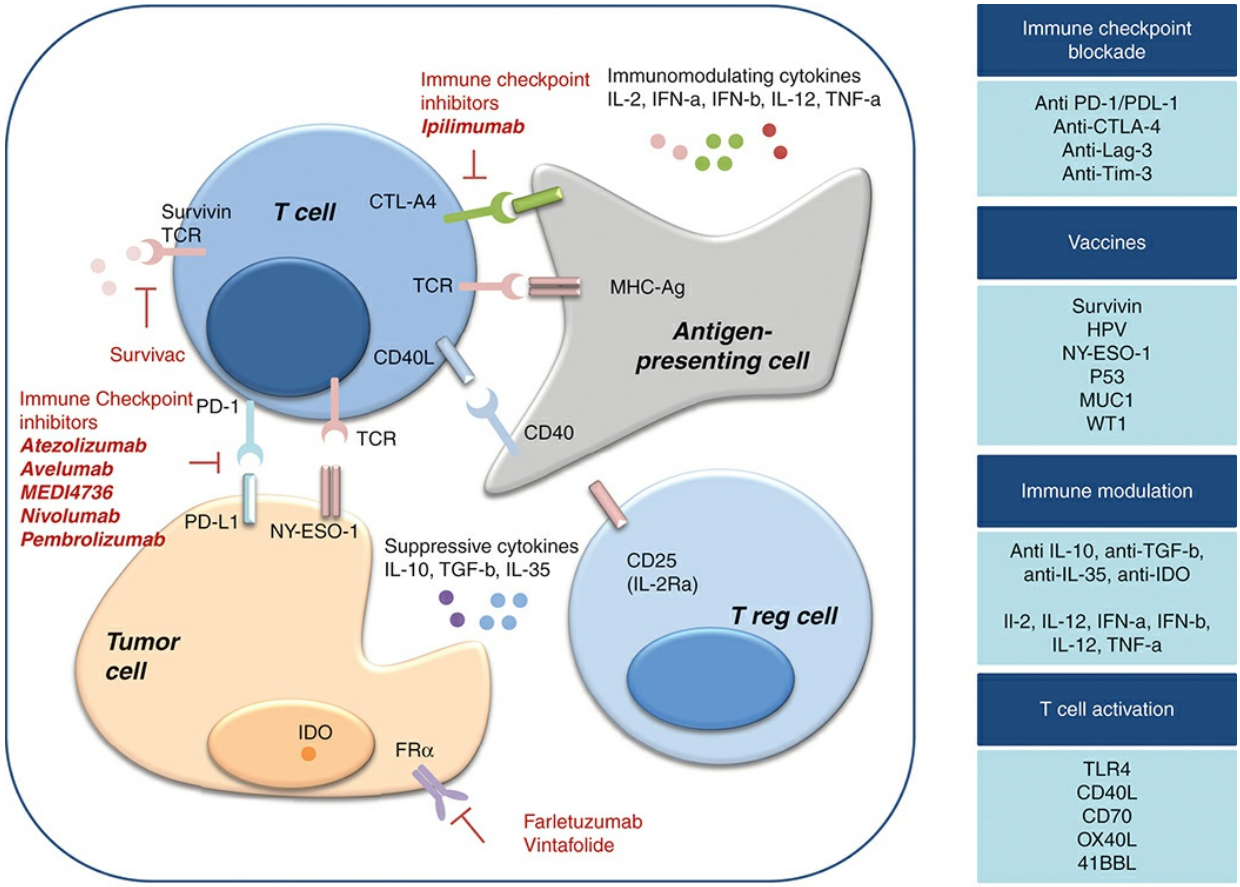

Figure 12.4 Immune response and targets of immunotherapy in gynecologic cancers.

Viral Contributions to Disease—The Human Papillomavirus Connection

Viral infections have been shown to contribute to the development of gynecologic cancers (39). Human Papillomavirus (HPV) has been implicated in the majority of cervical cancers, up to 70% of squamous cell carcinomas of the vulva, 60% of squamous cell carcinomas of the vagina (40), and appears to have a high prevalence in ovarian cancer patients, based on a meta-analysis of 24 primary studies of 889 patients across 11 countries on 3 continents (41).

Historically, cervical cancer has been the most actively studied gynecologic cancer because HPV16 and 18 are responsible for the majority of HPV-related cancers. As with viral infections, HPV infects epithelial cells and initiates production of proteins E6 and E7 (high risk) that are considered oncoproteins, interfering with cell death and promoting continued cell proliferation (42).

Based on evidence that host-dependent immunologic status and HPV-induced immune evasion are responsible for persistent HPV infection, the causal factor of cervical cancer, immunotherapy is an attractive strategy. HPV integration into the host's cellular genome allows permanent expression of viral oncoproteins, promoting cell transformation into cancerous cells, inactivation of tumor suppressor genes, and finally, cell growth and tumor proliferation. HPV infection also invokes a cellular immune response with regulatory T cells involved in the immune-suppressive status of HPV-associated malignancies (43). The role of immunotherapy for the treatment of cervical cancer is evolving. Several strategies are being evaluated; most are in early phase clinical trials.

MICROENVIRONMENT IN GYNECOLOGIC MALIGNANCIES

It has been increasingly recognized that the tumor microenvironment plays a complex role in tumor growth, development, and metastasis. Growth of malignant tumors requires a functional blood supply to provide nutrients, and this is facilitated and regulated by selection of proangiogenic peptides and growth factors in a complex interplay with regulatory antiangiogenic factors (44). Tumor vasculature is a field of intense study, pioneered by Judah Folkman, Bob Kerbel, and Rakesh Jain. Vascular endothelial growth factor (VEGF) is a key driver of angiogenesis and has been recognized as an important mechanism of tumor growth, survival, and metastasis in gynecologic cancers. VEGF overexpression has been consistently demonstrated in EC, EOC, and cervical cancers, and overexpression of VEGF is likely responsible for some of the pathognomic features of advanced ovarian cancer like ascites, secondary to capillary leakiness caused by excessive VEGF (45). It is also apparent that tumors and metastases often have disorganized internal vasculature, and unchecked cellular growth often leads to intratumoral hypoxia, which is a strong prognostic indicator of resistance to chemotherapy and radiation.

The microenvironment features of cancer growth have been incorporated into therapeutic strategies that impact on growth of tumors through modulation. The most successful strategies have been through incorporation of bevacizumab, a VEGF inhibitor in conjunction with chemotherapy in ovarian and cervical cancer. Beyond VEGF, different targets are under investigation such as platelet-derived growth factor, fibroblast growth factor, angiopoietin, and Ephrin type-A receptor 2 (46). Several other VEGF-targeting strategies have also led to positive results in randomized clinical trials, but as yet have not resulted in major changes in clinical practice.

PROTEOMIC ALTERATIONS AND TARGETING DISEASE

Hormonal Therapy

Hormonal therapy is an attractive strategy in treating gynecologic cancers. In endometrial cancer, a significant proportion of type 1 tumors express estrogen receptor (ER) or progesterone receptor (PR), and have been described as predictors of favorable survival (47,48). To date, the agents that have been investigated in this setting include: progestogens, selective ER modulators (SERM), aromatase inhibitors (AI), and GnRH inhibitors. The most common hormonal treatment has been progestational agents, which demonstrates anti-tumor responses in as many as 15% to 30% of patients (47,49). These responses are associated with clinical benefits (50) and (51), particularly in patients with well-differentiated tumors, and positive PR status has a higher response rate (RR) (52). In fact, progestogens have demonstrated favorable tolerability and efficacy with RRs of 22% overall (53,54) and it has been shown that positive receptor status (in particular PR) is correlated with response (55). Low-grade histology is also predictive of response (50); however, a small number of receptor-negative patients may still benefit, providing the rationale for exploring the mechanisms involved in treatment response (56).

AIs and tamoxifen (SERMs) have demonstrated overall RRs of ∽10% (57–;59). Following subgroup analysis, tamoxifen showed higher RRs of 23% and 14% in grade I and II patients, respectively (57). A phase II trial of mifepristone—a selective PR modulator agent—was evaluated in PR-positive advanced or recurrent endometrial cancer and was shown to achieve only stable disease as a single agent (60). The combination of tamoxifen and megestrol has been proposed to be more efficacious due to upregulation of the PR by tamoxifen but in practice no clear benefit has been seen to date (61,62). The overall RR was 27%, with a median PFS of 2.7 months and an overall survival (OS) of 14 months (62).

In the setting of advanced disease, there have been no improvements in survival in women with EC treated with hormonal therapy, as reported in the *Cochrane Review* (63). The publication has postulated that this finding may be due to the fact that many of the studies were conducted years ago, and advancements in technology and hormone receptor measurements have occurred since then, as well as response assessment criteria that make it difficult to compare against recent trial findings. As such, efforts continue to refine the role of hormonal therapy in endometrial cancer in the upfront

and advanced settings (47).

PRECISION THERAPY IN CLINICAL PRACTICE

Antiangiogenics—Bevacizumab

Targeting the tumor microenvironment through inhibition of tumor-associated angiogenesis has been an effective strategy in gynecologic malignancies. Bevacizumab is a humanized monoclonal antibody against VEGF, was the first clinically available antiangiogenic in North America, and the first to show striking activity as a single agent, as well as in combinations, in ovarian cancer. Early phase clinical trials showed important clinical activity in women with platinum-resistant ovarian cancer, both as a single agent and in combination with metronomic chemotherapy with oral cyclophosphamide. The agent also allowed opportunities for palliation/control of ascites, which responded quickly (as it is related to VEGF); however, there were important side effects that initially led to concerns about the viability of bevacizumab in ovarian cancer. In one of the initial trials in women with advanced bulky recurrent disease, bowel perforation was seen in 11% with bevacizumab therapy, and more likely to be seen in relation to number of prior lines of therapy, disease bulk, or bowel involvement. Subsequent studies have been more selective with women who have bulky disease or bowel involvement, and perforation rates have come down considerably. A detailed assessment by Burger et al. (64) based on GOG218 showed the overall risk of bowel perforation to be 3.2% in a first-line setting, risk factors being a history of inflammatory bowel disease and bowel surgery.

The first randomized trials in a front-line setting were conducted by the Gynecologic Oncology Group (GOG, now NSABP, RTOG, and GOG—NRG) and by the MRC Clinical Trials Group from the United Kingdom. The complementary studies evaluated concurrent and maintenance bevacizumab in women with optimally and suboptimally debulked ovarian cancer, at two different doses and for different duration (Table 12.2).

TABLE 12.2 Summary of GOG218 and ICON7 Landmark Studies with Bevacizumab in the Front-Line Setting

Trial	GOG-0218	ICON7
Setting/design	Double-blinded, placebo-controlled Three arms Bevacizumab for 15 months Bevacizumab 15 mg/kg q3w	Open-label Two arms Bevacizumab for 12 months Bevacizumab 7.5 mg/kg q3w
Patient population	Stage III (optimal, visual/palpable) Stage III (suboptimal) Stage IV	Stage I or IIA (grade 3 or clear cell histology) Stages IIB IV (all)
End point analyses	Progression: RECIST and CA-125 OS analysis (formal testing at time of PFS) Independent Radiologic Confirmation (IRC)	Progression: RECIST Defined final OS analysis (end 2012) No IRC
Time of PFS analysis	Total no. of PFS events in control arm	Total no. of PFS events in both arms and 1 year after last patient randomized
Patients on therapy at time of PFS analysis	14% arm I, 17% arm II, 24% arm III	Two patients in bevacizumab arm

No. of events/no. of patients	783/1,248 (arm I and III)	759/1,528
Analysis methods	One-sided log-rank test Non-proportional hazards not yet presented	Two-sided log-rank test Non-proportional hazards explored

OS, overall survival; PFS, progression-free survival; RECIST, Response Evaluation Criteria in Solid Tumors.

Both of these pivotal trials were positive for their primary end points of PFS with concurrent and maintenance bevacizumab, a very acceptable toxicity profile. The magnitude of benefit seemed to be related to the duration of therapy more than dose. Continuation of bevacizumab alone in the adjuvant setting for 12 or 15 months following chemotherapy first-line treatment in combination with bevacizumab showed a modest but significant PFS benefit in two phase III studies (GOG218 (64) and ICON7 (65)) (Figs. 12.5 and 12.6). The benefit seen with bevacizumab in ICON7 was associated with increasing burden of disease, as patients with suboptimal and stage IV disease derived the maximum benefit. ICON7 was also powered and conducted to evaluate OS. There was no difference in OS with the addition of bevacizumab to the entire group of patients, but in a preplanned survival analysis, patients at high risk (suboptimally debulked stage III/IV, non-operated patients) had improved median OS by 9.4 months. This has led to further refinement of approval in Canada and many European countries for the incorporation of bevacizumab in women with high risk, suboptimally debulked or metastatic disease at presentation (Fig. 12.7).

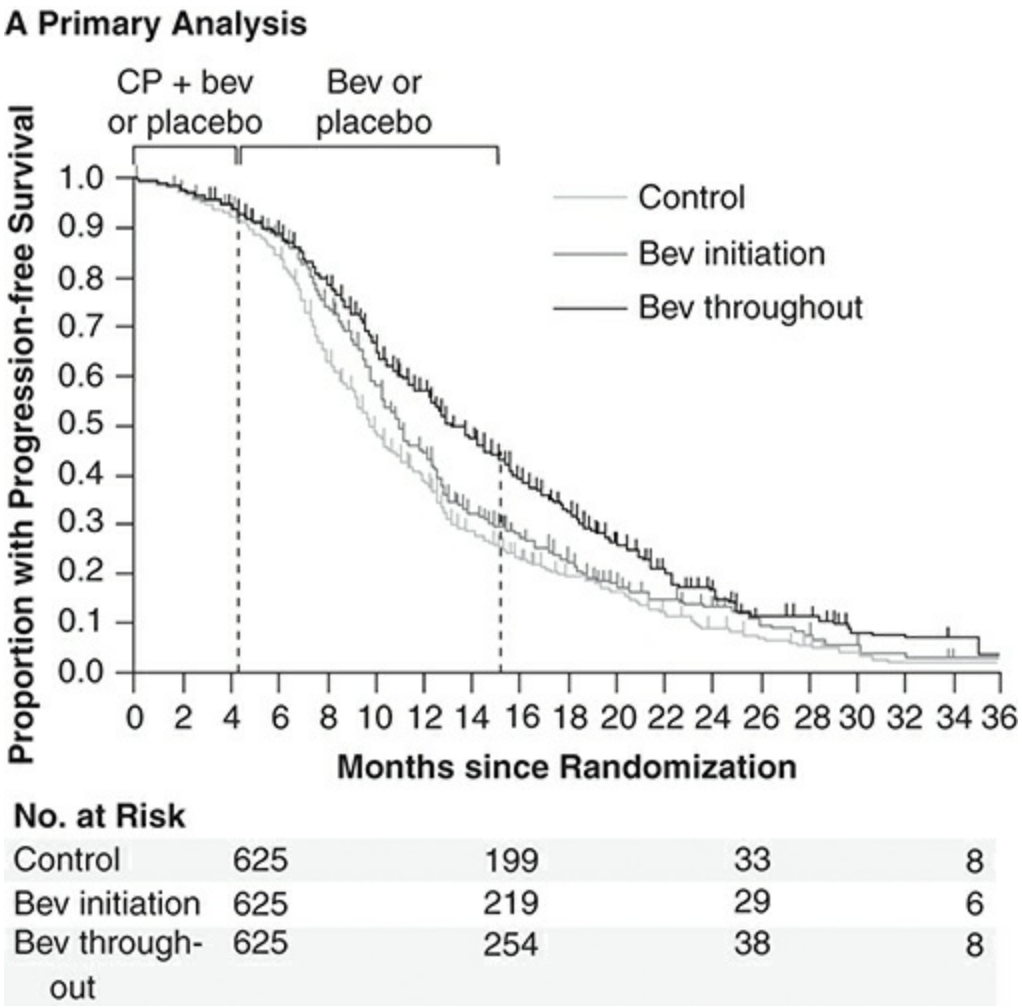

Figure 12.5 GOG PFS showing the results of primary analysis of PFS for all 1,873 patients randomly assigned to receive chemotherapy with carboplatin and paclitaxel (CP) plus placebo, followed by placebo alone (the control group), CP plus bevacizumab (bev) followed by placebo (the bevacizumab-initiation group), or CP plus bevacizumab followed

by bevacizumab (the bevacizumab-throughout group). There was a significant, time-dependent decrease in the hazard of progression in the bevacizumab-throughout group as compared with the control group (hazard ratio [HR], 0.717; 95% confidence interval [CI], 0.625 to 0.824; p 0.001).

bevacizumab for women with newly diagnosed ovarian cancer (ICON7): overall survival results of a phase 3 randomized trial. Lancet Oncol. 2015;16(8):928–936.

The improvement in PFS has led to approval of bevacizumab in a front-line setting in more than 50 countries internationally, except the United States. Many candidate biomarkers have been evaluated to predict which patients could be identified pre-therapy; yet at this stage, the clinical predictive algorithm for high risk remains the best defined predictor of benefit in a first-line setting. Additional trials in a first-line setting will define the optimal duration of maintenance therapy to confirm whether or not prolonged duration of administration further improves PFS. Studies have also shown safety in combining bevacizumab with IP therapy or administering bevacizumab following neo-adjuvant chemotherapy.

In platinum-sensitive recurrent ovarian cancer, Aghajanian et al., (66) demonstrated very striking improvement in PFS when bevacizumab was added at 15 mg/kg to carboplatin (AUC 4) and gemcitabine (1,000 mg/m^2), and continued to progression, with a hazard ratio of 0.48 (66). In platinum-resistant disease, the Aurelia trial also showed striking improvement with the addition of bevacizumab 15 mg/kg to a choice of chemotherapy regimens—weekly paclitaxel, topotecan, or liposomal doxorubicin. The most durable benefit was seen in women who received weekly paclitaxel, with indications of improved in OS in this group (67).

Randomized trials incorporating bevacizumab concurrently with chemotherapy and continuing with bevacizumab beyond chemotherapy in first-line and platinum-sensitive recurrence have all shown significant improvement in progression as well as subgroups that show improvement extending to OS. As a consequence, bevacizumab has become an approved standard in ovarian cancer treatment, though there are some regulatory differences in approval in different countries. National Comprehensive Cancer Network (NCCN) guidelines in epithelial ovarian, fallopian tube, primary peritoneal cancers, and less common histopathologies (carcinosarcoma, clear cell, mucinous, borderline epithelial, grade 1 low-grade serous, endometrioid) stage II–IV according to ICON-7 and GOG218 schedules. In cervical cancer, recently updated NCCN guidelines suggest cisplatin/paclitaxel/bevacizumab first-line combination therapy in the setting of recurrent or metastatic disease, as well as bevacizumab single agent during second-line therapy (68).

In a phase III trial, targeting this angiogenesis pathway with bevacizumab in combination with standard chemotherapy in advanced recurrent cervical cancer has showed an increased objective RR from 36% to 48% (p = 0.008) and an OS benefit compared to standard regimen (OS increased from 13.3 to 17 months). Bevacizumab was associated with a reasonable toxicity profile. The side effects were consistent with those previously associated with bevacizumab, including hypertension, neutropenia, and thromboembolism, or formation of blood clots. Specifically, treatment with bevacizumab was associated with more grade 3 to 4 bleeding, thrombosis/embolism, and gastrointestinal fistula. This OS improvement has led to the first U.S. FDA-approved anti-VEGF agent, bevacizumab, for the treatment of advanced stage, persistent, or recurrent cervical cancer. This advancement with bevacizumab did not lead to identify biomarkers of response, and the median OS survival remains low at 17 months, highlighting the need for innovative treatment strategies (69).

PARP Inhibitors

Approximately 50% of women with grade serous ovarian cancer have evidence of homologous recombination deficiency, and 15% to 20% have *BRCA1/2* mutations. This genomic profile and susceptibility to impaired DNA repair has been leveraged for therapy using PARP inhibitors, with evidence of clinical activity as a single agent (70, Clovis Ariel 2 from JCO presentation). A pivotal international, multicenter, randomized, phase II study that evaluated olaparib (a PARP inhibitor) as maintenance treatment in women with HGSOC who had responded to platinum-based chemotherapy (71) showed important clinical activity in improving PFS. Preplanned retrospective analysis of outcomes by *BRCA1/2* status in this study demonstrated that *BRCA*-mutated patients had better PFS with olaparib maintenance compared to those receiving placebo (11.2 vs 4.3 months; HR 0.18; $p < 0.0001$) (72) (Fig. 12.8). The PFS benefit was still observed when somatic *BRCA*-mutated patients were included in the analysis. Additional evidence supporting the role of olaparib as maintenance therapy was reported in an international, multicenter, randomized, open-label study of women with platinum-sensitive relapsed HGSOC (73). In this phase II trial, olaparib was given with carboplatin/paclitaxel chemotherapy and

continued as maintenance monotherapy. Overall, study findings show a significant PFS improvement when compared to chemotherapy alone (12.2 and 9.6 median PFS, respectively; HR 0.51; 95% CI 0.34 to 0.77; $p = 0.0012$). A greater benefit was detected in patients with a *BRCA1/2* mutation (PFS HR 0.21; 95% CI 0.08 to 0.55; $p = 0.015$) than in those without a *BRCA1/2* mutation. Further, study analysis revealed strong evidence that olaparib maintenance is most likely a key contributor to the improvement in PFS in this patient population (73). There are numerous ongoing PARP inhibitor studies investigating women with *BRCA1/2* mutations as well as mutations in other homologous recombination-deficient (HRD) genes, as data has shown HRD genes to exhibit *BRCA*-like behavior (6). To date, the use of olaparib maintenance has been approved in Europe after response to platinum-based chemotherapy in women with platinum-sensitive HGSOC who harbor a germline or somatic *BRCA1/2* mutation (72) and in the United States, as single-agent therapy after three lines of chemotherapy in patients with germline *BRCA1/2* mutation HGSOC (74).

TARGETED THERAPY SIDE EFFECTS AND MANAGEMENT STRATEGIES

Bevacizumab

The most common toxicities observed are hypertension, proteinuria, and epistaxis, which are known side effects of bevacizumab treatment. There is an increased risk of thromboembolism events and rare case of gastrointestinal perforation; however, it is important to note that patient-related outcome is favorable (75). Within clinical practice, a review analyzing data from 156 patients with recurrent ovarian cancer who had received bevacizumab between January 2006 and June 2009 were retrospectively identified from institutional records of five French centers and examined toxicity data (76). Findings reported by Selle et al. (76) confirm the effect of heavy pretreatment on the occurrence of serious and fatal adverse events in clinical practice as reported in clinical trials and other retrospective studies, and that medical history of hypertension is an independent predictive risk factor for the development of high-grade hypertension during bevacizumab treatment (76). As such, treating physicians should exercise caution and consider all risk factors for managing bevacizumab toxicity prior to introduction including time to bevacizumab introduction, history of hypertension, and low incidence of preexisting obstructive disease (76).

Olaparib

The most common toxicities seen with olaparib—and similar amongst other PARP inhibitors in development—include nausea, vomiting, fatigue, and myelosuppression [PMID: 26051946]. In practice, these toxicities are manageable and require patient education. Additional information regarding the potential increased risk of myelodysplasia syndrome and acute myeloid leukemia are being collected.

Targeted Agents in the Maintenance Setting

Given the high rate of recurrence in gynecologic cancers, attempting to maintain disease control post standard chemotherapy is a new area of investigation to lower tumor burden. A meta-analysis of 13 randomized controlled trials published between 2006 and 2014 indicated that while both PFS and OS were statistically and significantly improved in the targeted maintenance therapy group as compared to the control group (PFS: HR 0.84, 95% CI 0.75 to 0.95, $p = 0.001$; OS: HR 0.91, 95% CI 0.84 to 0.98, $p = 0.02$), targeted agents were also significantly correlated with increased risk of fatigue, diarrhea, nausea, vomiting, and hypertension (77). Importantly, the meta-analysis also provided evidence illustrating that no significant differences were found in incidence rates of abdominal pain, constipation, or joint pain (77). As such, this novel treatment approach necessitates the education of patients in regard to drug management as chronic disease.

In October 2016, promising results were published using the PARP inhibitor, Niraparib as maintenance treatment for women with platinum-sensitive, recurrent ovarian cancer (78). In this trial, two independent cohorts were categorized based on the presence or absence of a germline *BRCA* (*gBRCA*) mutation; women without a *gBRCA* were further

subgrouped based on whether they were positive for homologous recombination deficiency (HRD) using a commercially available genomic assay. All patients had platinum-sensitive recurrent ovarian cancer and were enrolled no later than 8 weeks after completing their last dose of platinum-based chemotherapy. Using a 2:1 randomization design, patients were assigned treatment with niraparib (300 mg) or placebo, orally administered on a daily basis for 28-day cycles.

With a median duration of follow-up of 17 months, compared to placebo, the median duration of progression-free survival (PFS) was significantly prolonged with niraparib in women with a *gBRCA* (21 versus 5.5 months; HR 0.27, 95%CI 0.17-0.41), without a *gBRCA* but HRD-positive (13 versus 4 months, HR 0.38, 95%CI 0.24-0.59), and those without a *gBRCA* mutation and HRD-negative (9 versus 4 months, 95%CI 0.34-0.61). Overall survival results were not mature at the time of publication. Of note, the rate of treatment discontinuation was higher in women taking niraparib versus placebo (15.5 versus 2%) but no on-study deaths were reported. Major toxicities associated with niraparib included thrombocytopenia, and anemia, neutropenia, with a 1.4% incidence of myelodysplastic syndrome reported. Patient reported outcomes were similar in both groups. These results suggest that maintenance niraparib may benefit all women with platinum-sensitive ovarian cancer, regardless of whether or not they harbor a *gBRCA*, though those women with a *gBRCA* and/or HRD on genomic assessment of their tumor stand to benefit the most.

CHAPTER 13 Principles of Chemotherapy in Gynecologic Cancer

Stéphanie L. Gaillard and Michael A. Bookman

HISTORICAL OVERVIEW OF CANCER CHEMOTHERAPY

We are in the midst of an important transition from conventional cytotoxic agents to new strategies that incorporate mechanism-based molecular-targeted therapeutics. Even with these changes in our treatment paradigm, several conventional cytotoxic agents maintain a central role in the care of women with gynecologic cancers. In that context, a brief review of drug development provides a framework for understanding the evolving balance between toxicity, efficacy, and design of treatment regimens.

First reports of a drug-mediated tumor response were noted 150 years ago using Fowler solution (arsenic trioxide in potassium bicarbonate) in patients with Hodgkin disease and leukemia (1). Arsenic compounds had been used for various medicinal purposes for over 2,000 years, and cyclic hematologic toxicity was observed following arsenic administration in normal individuals and patients with leukemia (2), establishing a close association between tumor response and host toxicity that still exists today. Cumulative dose-limiting toxicity (arsenic poisoning) was also described following expanded utilization of arsenic in chronic myelogenous leukemia (3).

The term *chemotherapy* has been attributed to Paul Ehrlich, a Nobel laureate physician and bacteriologist, who developed *in vivo* rodent models of infection and introduced Salvarsan, an organic arsenical originally used to cure syphilis in 1910. His early *in vivo* modeling also encouraged the development of inbred transplantable rodent tumors, thereby establishing a paradigm that has been widely adopted for screening new antitumor agents.

Although the topical vesicant properties of sulfur mustard received much attention during World War I, multiple systemic effects, including leukopenia, bone marrow aplasia, and mucosal ulceration, also emerged. Cancer chemotherapy, in the traditional sense, began with the demonstration that nitrogen mustard had reproducible activity against transplanted lymphoma in mice, prompting clinical trials as early as 1942 (4). However, owing to World War II, much of the research remained classified until 1946. Following the demonstration by Farber and Diamond (5) in 1948 that aminopterin, an antifolate, could induce temporary remission in childhood leukemia, antimetabolites became the next major category of agents to be developed, and were ultimately associated with cures in women with choriocarcinoma (6). Research during the 1940s also included the Nobel Prize–winning observations of Huggins and Hodges (7) regarding the antitumor effect of estrogens in prostate cancer.

Conventional Cytotoxic Agents

Cytotoxic agents commonly used in the treatment of gynecologic malignancies are listed in Table 13.1, spanning a period of development beginning in 1945, including analogs with more favorable toxicity profiles. Attention has also been directed at alternative formulations of standard agents, including liposomal or polymer-based encapsulation, protein conjugation,

nanoparticles, or lipid solubilization, to modify drug disposition, tumor targeting, and the potential for host toxicity. A timeline of key US and EU regulatory approvals in ovarian cancer is summarized in Figure 13.1.

With the availability of multiple agents, each with a different molecular target, mechanism of action, pattern of resistance, and spectrum of host toxicity, we have also seen frequent utilization of multidrug combinations, particularly as primary therapy for advanced disease. The use of adjuvant therapy, including concurrent chemoradiation for early-stage disease, has been greatly expanded in selected clinical situations, with the result that a larger proportion of patients are exposed to chemotherapy at an earlier point in the natural history of their disease. On the basis of a combination of intrinsic and acquired factors, the majority of advanced tumors eventually demonstrate broad resistance to conventional cytotoxic chemotherapy, and there has been renewed interest in novel biologic and immunologic approaches with non–cross-resistant mechanisms. In addition, with improved understanding of the mechanisms associated with drug resistance, newer agents have been developed that may partially reverse resistant phenotypes through blockade of specific pathways, inhibition of DNA repair, or promotion of cellular apoptosis.

TABLE 13.1 Common Cytotoxic Agents Used in the Treatment of Gynecologic Malignancies

Agent	Classification	Primary Mechanism of Action	Notable Side Effects (% Frequency)	Manageme Consider
Altretamine	Alkylating agent	Requires hepatic microsomal activation to form DNA cross-links	Delayed nadir Neurotoxicity: somnolence, mood changes, lethargy, depression, agitation, hallucinations (25%)	Oral
Bleomycin	Antitumor Antibiotic	Generates oxygen free radical species leading to DNA breaks	Pulmonary toxicity (10%): increased risk with cumulative dose >400 units, smoking history, underlying lung disease, and oxygen exposure; Skin toxicity Hypersensitivity reactions (25%) Rare vascular events (MI, stroke, Raynaud)	Obtain CXR with DLCO/v capacity at therapy, an clinically indicated; discontinue parameters ⩾15% or pu infiltrates avoid expos high FiO_2, enhance pul damage; avo smoking
Capecitabine	Antimetabolite	Prodrug of 5-fluorourocil involving liver and tumor enzymatic reactions, inhibits thymidylate synthase	GI: diarrhea (dose-limiting in 55%), mucositis, N/V (⩽50%), elevated LFTs (⩽40%) Derm: PPE (severe in 15%-20%)Vascular: rare cardiac vasospasm, risk higher with prior MI	Oral admini Interacts w warfarin
Carboplatin	Organoplatinum analog	Activated by aquation and forms DNA adducts	Myelosuppression: particularly thrombocytopenia (nadir day 21)Hypersensitivity (allergic) reactions (maximal	Predominant clearance, target AUC Calvert for based on es

			risk during subsequent courses of therapy) Sterility/ovarian failure	GFR, should administere paclitaxel in combinat
Cisplatin	Platinum analog	Rapid activation by aquation, Forms DNA adducts	Nephrotoxicity: 10–20 days post dose (35%–40%), but cleared predominantly by non-renal mechanisms Electrolyte loss: magnesium, calcium, potassium GI: acute and delayed emesis Myelosuppression Neurotoxicity: peripheral sensory neuropathy (common, cumulative); ototoxicity; encephalopathy/seizures/motor dysfunction (rare)Vascular (rare): MI, arteritis, stroke, Raynaud Sterility/ovarian failure	Often used radiosensit agent
Cyclophosphamide	Alkylating agent	Hepatic microsomal activation, forms DNA cross-links	MyelosuppressionHemorrhagic cystitis/dysuria (5%–10%) Sterility/ovarian failure Increased risk of secondary malignancies	Commonly gi daily low-d (metronomic schedule fo cancer
Dacarbazine	Alkylating agent	Inhibits DNA, RNA, and protein synthesis	Flu-like syndrome CNS toxicity (paresthesias, ataxia, lethargy, seizures) Photosensitivity	Vesicant
Dactinomycin	Antitumor Antibiotic	Generates activated oxygen free radical species leading to DNA breaks	GI: severe N/V, mucositis/diarrhea Skin hyperpigmentation Radiation recall reaction	Vesicant
Docetaxel	Antimicrotubule agent	Enhances tubulin polymerization, inhibits mitosis and cell division	Hypersensitivity reactionsFluid retention syndrome with edema, pleural effusion, ascites (50%), GI: mucositis/diarrhea (40%) Compared to paclitaxel: peripheral neuropathy less common, but increased myelosuppression	Hypersensit fluid reten syndrome ca reduced wit pretreatmen Vesicant
Doxorubicin	Antitumor Antibiotic	Intercalates into DNA inhibiting synthesis and function, inhibits topoisomerase-II, formation of free radicals and DNA breaks	Cardiotoxicity: acute arrhythmias or conduction abnormalities, chronic congestive heart failure Radiation recall Photosensitivity Red–orange discoloration of urine	Monitor LVE baseline an periodicall cumulative $\geqslant$450 mg/m^2 associated higher risk Strong vesi
Epirubicin	Antitumor Antibiotic	Derivative of doxorubicin (see	Cardiotoxicity: acute arrhythmias or conduction	Monitor LVE baseline an

		previous row)	abnormalities, chronic congestive heart failure Radiation recall Photosensitivity Red-orange discoloration of urine	periodicall cumulative ⩾900 mg/m2 associated higher risk Strong vesi
Etoposide	Topoisomerase-II inhibitor	Inhibits topoisomerase-II preventing DNA unwinding	GI: emesis (30%-40%), more common with oral administration Increased risk of secondary malignancies (5-8 years posttreatment)	Oral admini common for cancer
5-Fluorouricil	Antimetabolite	Requires tissue activation, inhibits thymidylate synthase with impact on DNA synthesis and function	GI: mucositis/diarrhea, can be severe Derm: Palmar-plantar erythrodysesthesia Neurologic: confusion, seizures, somnolence, ataxia, encephalopathy (rare) Cardiac: chest pain, EKG changes, enzyme elevation (attributed to coronary vasospasm)	Patients wi underlying deficiency dihydropyri dehydrogena experience myelosuppre toxicity, a neurologic
Gemcitabine	Antimetabolite	Metabolized into triphosphate nucleotide with incorporation into DNA, inhibiting synthesis and function	Myelosuppression: often dose-limiting GI: diarrhea, stomatitis, mucositis (15%-20%) Fever or flu-like syndrome (20%-40%) Pneumonitis Maculopapular rash	Potent radiosensit
Ifosfamide	Alkylating agent	Microsomal hepatic activation, forms DNA cross-links	Myelosuppression: often dose-limiting Hemorrhagic cystitis Neurotoxicity: lethargy/confusion, seizure, cerebellar ataxia, weakness, hallucinations, cranial nerve dysfunction Infertility	Prevent hem cystitis wi and hydrati Higher risk neurotoxici high-dose t and impaire function, o and low alb
Irinotecan	Topoisomerase-I inhibitor	Equilibrium conversion to active metabolite SN-38 which binds to topoisomerase-I, preventing DNA synthesis	GI: diarrhea both acute (during or within 24 hours of infusion) and late, can be severe	Acute diarr secondary t cholinergic (can be man atropine); late diarrh be managed aggressivel prevent deh and electro loss; UGT1A1 7/7 increases r GI toxicity myelosuppre

PEGylated liposomal doxorubicin	Antitumor Antibiotic	Polyethyline glycosylated liposomal formulation of doxorubicin (see above)	Much lower risk of cardiotoxicity compared to parent doxorubicin,higher risk of palmar plantar erythrodysesthesia	May not be substituted doxorubicin
Melphalan	Alkylating agent	DNA cross-linking	Myelosuppression: nadir 4 - 6 weeks post-therapy GI: nausea/emesis, mucositis, diarrhea Increased risk of secondary malignancies	
Mitomycin	Antitumor Antibiotic	DNA cross-linking	Myelosuppression: nadir 4 - 6 weeks post-therapy Mucositis Hemolytic-uremic syndrome (<2%, however can be fatal) Interstitial pneumonitis Hepatic veno-occlusive disease	Vesicant
Oxaliplatin	Platinum analog	DNA cross-linking	Neurotoxicity: frequently dose-limiting, can manifest as sensory neuropathy, gait abnormalities, cognitive dysfunction, or difficulty breathing Intolerance to cold (including ingestion of cold liquids) Hypersensitivity reactions GI: N/V, diarrhea	Careful mon of neurolog function ne Neurotoxici frequently reversible cisplatin (months)
Paclitaxel	Taxane, anti-microtubule agent	Enhances tubulin polymerization, inhibits mitosis and cell division	Myelosuppression Hypersensitivity reactions: (most common with first or second dose) Sensory neuropathy Transient asymptomatic sinus bradycardia GI: mucositis/diarrhea (when administered by prolonged infusion), transient LFT elevations Onycholysis (more common with weekly dosing)	May be dose or every 3
Pemetrexed	Antimetabolite	Multitargeted anti-folate: Inhibition of the folate-dependent enzymes. thymidylate synthase, and DNA synthesis	Myelosuppression: often dose-limiting Derm: rash, frequently PPEGI: N/V, mucositis, diarrhea, transient LFT elevations	Insufficien intake incr toxicity ri prevent wit B12 and fol supplementa steroids ma prophylacti prevent ski NSAIDs and inhibit

				renal clear pemetrexed, discontinue days leadin and followi pemetrexed administrat
Temozolomide	Alkylating agent	Structurally and functionally similar to dacarbazine	Myelosuppression: dose-limiting Photosensitivity GI: N/V	Monitor for development lymphopenia increased r PCP (consid prophylaxis
Topotecan	Topoisomerase-I inhibitor	Inhibits topoisomerase-I leading to dsDNA breaks	Myelosuppression: dose-limiting GI: N/V (80%) Microscopic hematuria (10%)	Administere weekly, or every 3 wee
Vinblastine	Antimicrotubule agent	Inhibits tubulin polymerization disrupting microtubule assembly during mitosis	Myelosuppression: neutrophil nadir days 4–6 GI: mucositis/stomatitis, constipation Neurologic: peripheral sensory neuropathy, autonomic dysfunction (including hypertension), seizures/coma (rare) Vascular events (stroke, MI, Raynaud, acute pulmonary edema) Pulm: bronchospasm, respiratory distress (rare)	Vesicant (n intrathecal administrat Attentive t early manag constipatio
Vincristine	Antimicrotubule agent	Inhibits tubulin polymerization disrupting microtubule assembly during mitosis	Neurotoxicity (most common DLT): peripheral neuropathy, autonomic dysfunction, cranial nerve palsies, cortical blindness, seizures/coma GI: constipation, paralytic ileus, abdominal pain Myelosuppression: generally mild	Vesicant (n intrathecal administrat Attentive t management constipatio
Vinorelbine	Antimicrotubule agent	Inhibits tubulin polymerization disrupting microtubule assembly during mitosis	Myelosuppression: nadir day 7 GI: N/V, constipation, diarrhea, stomatitis, anorexia, transient LFT elevation Neurotoxicity: usually mild Hypersensitivity reactions Fatigue	Vesicant (n intrathecal administrat

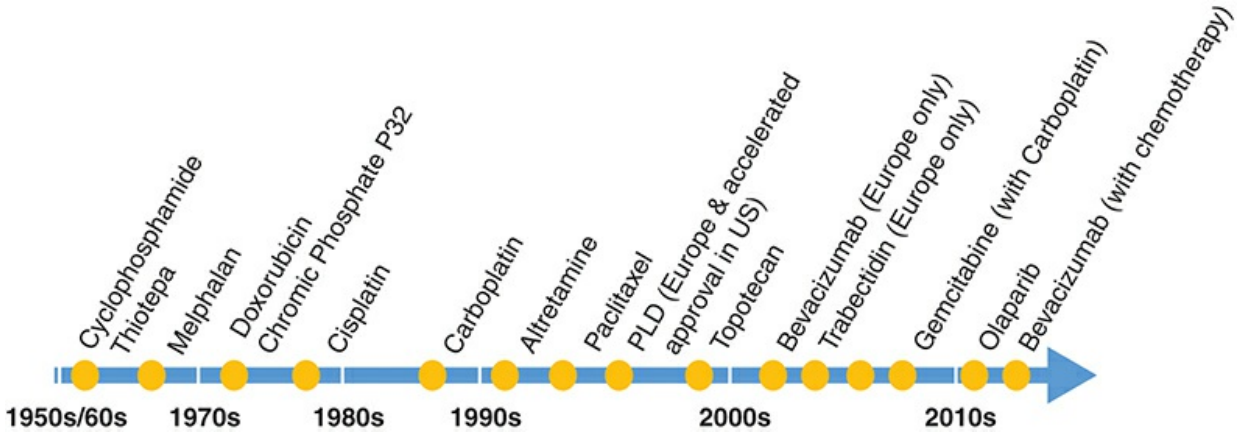

Figure 13.1 Approval timeline of chemotherapeutic agents commonly used in the treatment of ovarian cancer.

Exploration of the biologic mechanisms associated with tumor growth, maintenance, metastasis, and resistance to chemotherapy has led to the development of molecular-targeted therapeutics. In general, novel targeted agents exhibit toxicities that are distinct from conventional cytotoxic chemotherapy, often sparing proliferative compartments, such as bone marrow and mucosal epithelium. However, there is still the potential for serious toxicity, including drug interactions, alterations in hepatic or renal function, bleeding, thrombosis, pneumonitis, leukoencephalitis, and autoimmunity. Thus far, the addition of novel targeted agents to conventional chemotherapy for gynecologic malignancies has resulted in only modest improvements in long-term clinical outcomes.

TUMOR BIOLOGY IN RELATION TO CHEMOTHERAPY

Tumor Growth and Cellular Kinetics

Many of the principles of modern chemotherapy are derived from knowledge of the growth characteristics of normal and tumor tissues. Exploitation of the differences between normal and tumor tissues has provided the historical basis for utilization of radiation and chemotherapy. The cellular kinetics of normal tissues also explains many of the toxicities associated with chemotherapy. All normal tissues, particularly during fetal development and variably during adult life, possess the capacity for cellular division and growth.

The *static* population includes well-differentiated cells that arise from pluripotent fetal stem cells and rarely undergo cell division during adult life (Table 13.2). Oocytes represent a specialized static population. Damage to these cells can have long-term consequences and has prompted interest in stem cell biology. The *expanding* population of normal tissues retains the capacity to grow, but in their adult state, they are normally quiescent. Under stress, especially after injury, a proliferative burst is followed by return to quiescence. The *renewing* cell population is in a continuous proliferative state, with ongoing cell division balanced by cell loss and terminal differentiation.

TABLE 13.2 Growth Patterns of Normal Cell Populations

Static	Expanding	Renewing
Striated muscle	Hepatocytes	Bone marrow
Neurons	Bile duct epithelium	Epidermis
Nephrons	Vascular	Gastrointestinal
Oocytes	endothelium	epithelium

The patterns of normal cell growth partially explain some of the toxic effects of cytotoxic therapy and why some tissues are commonly spared (8,9). Renewing cell populations with constant turnover are most sensitive to acute injury from conventional chemotherapy or irradiation. This is reflected by the frequent occurrence of dose-limiting bone marrow suppression, mucositis, and azoospermia during cytotoxic drug treatment, with relative sparing of nonproliferative compartments, such as brain, muscle, kidney, bone, and oocytes. However, even nondividing tissues can experience late chronic effects related to DNA damage.

Dysregulated growth of cancer cells occurs because of altered growth factor signaling and/or disruption of normal checkpoint mechanisms. Despite a capacity for continuous growth, the actual process of cancer cell division is not more rapid than division in normal cells.

Programmed cell death, or apoptosis, has emerged as a major mechanism for regulating growth and development of tissues. Furthermore, certain oncogenes, like *MYC* and *BCL2*, and tumor suppressor genes (anti-oncogenes), including *RB* and *TP53*, are central to the regulation of apoptosis. Expression of these genes can alter the sensitivity of cancer cells to treatment with chemotherapy and radiation. For instance, overexpression of functional bcl-2 and nonfunctional p53 genes can render tumor cells resistant to a number of chemotherapeutic agents (10), suggesting that efforts to restore apoptotic signaling may improve chemosensitivity.

Emerging data have also described stem-like behavior in subpopulations of ovarian cancer cells, including dormant cells with a low mitotic index that exclude cytotoxic drugs from their cytoplasm and demonstrate increased resistance to chemotherapy (11,12). These stem-like cells are generally enriched during the repopulation that occurs following primary chemotherapy, and targeting of these distinct cell populations has become an important area of research.

Cell Cycle Kinetics

An understanding of the kinetic behavior of individual tumor cells is also important in understanding tumor growth. Figure 13.2 is a schematic view of the cell cycle. Cells can remain in a non-cycling postmitotic compartment (G_0) for extended periods of time, but retain the ability to reenter active cycling when triggered by growth factors or other local signals. The point of entry, or first gap phase (G_1), can be of variable length and associated with diverse cellular activities, including protein and RNA synthesis, DNA repair, and cell growth. After passing the first checkpoint in G_1, the cell enters the DNA synthetic phase (S), during which a complete copy of the cellular DNA is created through replication. The second gap phase (G_2) provides another opportunity for checkpoint control before entering active mitosis (M), during which the nuclear membrane disappears and the chromosomes condense (prophase) and align (metaphase) in conjunction with the appearance of the mitotic apparatus, consisting of microtubules, centrioles, and the kinetochore. Mitotic alignment is associated with one final checkpoint prior to actual separation (anaphase), followed by dissolution of the mitotic apparatus (telophase) and creation of daughter cells through cytokinesis. The postmitotic period (G_1) is variable, and cells can further differentiate, enter a non-cycling state (G_0), or initiate another cycle.

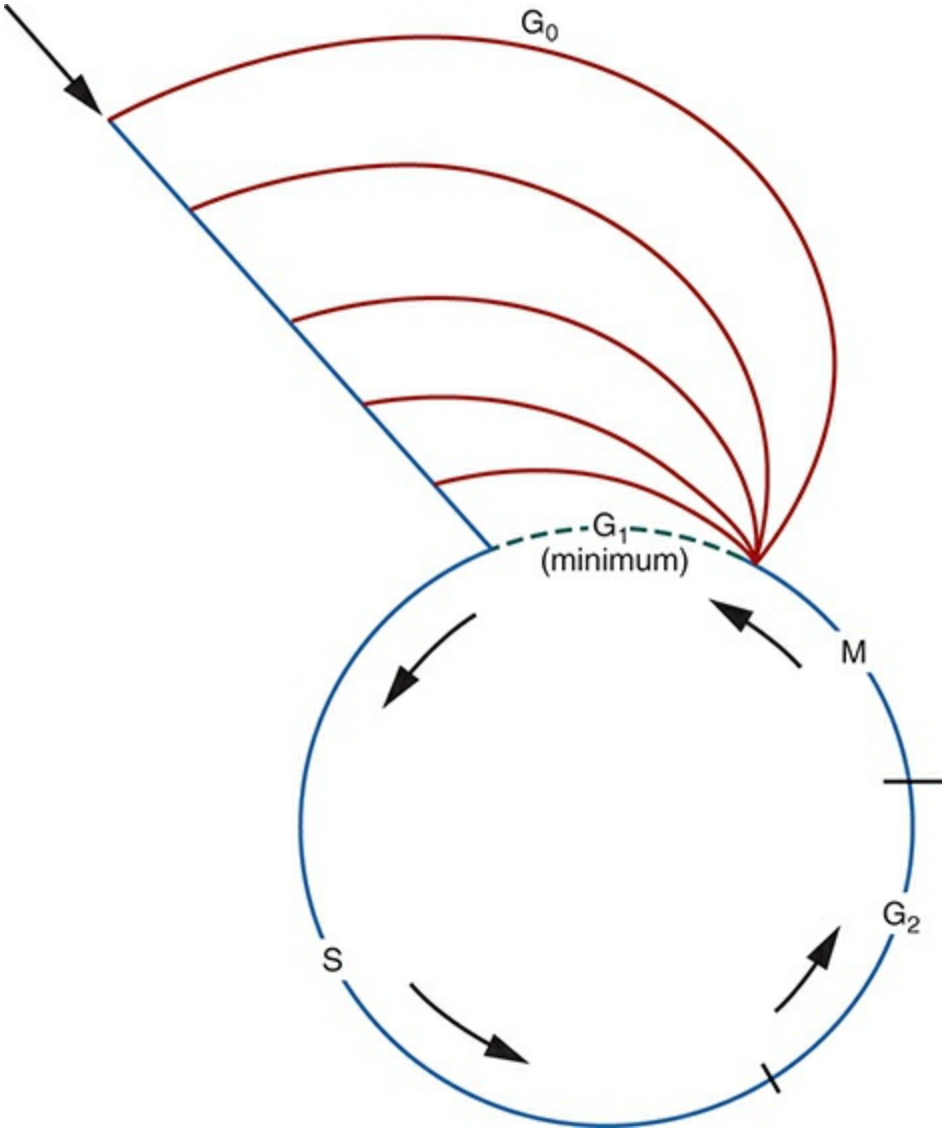

Figure 13.2 Phases of the cell cycle, beginning with M (mitosis) and proceeding through G_1 (postmitotic phase), S (DNA synthetic phase), and G_2 (premitotic phase). As G_1 becomes progressively longer, it is known as G_0.

Cell cycle events have important implications, as most chemotherapeutic agents disrupt DNA, RNA, or protein synthesis. Rapidly proliferating cells (i.e., short G_1) are most sensitive to chemotherapy, whereas cells that slowly proliferate (i.e., G_0 or long G_1) are generally less sensitive. Nondividing cells, such as the differentiated elements of a mature teratoma, may occupy space and contribute to tumor bulk and symptoms, but are relatively insensitive to chemotherapy.

Cell cycle times may be estimated by performing labeled mitotic curves *in vivo* or *in vitro*, and appear to be relatively similar for many solid tumors, with cycle times ranging from 10 to 31 hours (13). When contrasted with the wide variation in observed human tumor doubling times (Table 13.3), it suggests that variations in clinical tumor growth cannot be simply ascribed to variations in the cell cycle.

TABLE 13.3 Doubling Times of Human Tumors

Tumor Histology	Patients (n)	Doubling Time (Mean ± 2 SD, Days)
Embryonal tumors (lung metastases)	76	27 ± 5

Lymphomas	51	29 ± 6
Malignant mesenchymal tumors	87	41 ± 7
Squamous cell carcinomas (lung metastases)	51	58 ± 9
Squamous cell carcinomas (primary tumors)	97	82 ± 14
Adenocarcinomas (lung metastases)	4	83 ± 12
Adenocarcinomas (primary tumors)	34	166 ± 48

Growth fraction and programmed cell death also influence the overall tumor growth rate and response to therapy. The growth fraction is the proportion of tumor cells that are actively cycling. Often, these proliferating cells are located proximal to small blood vessels. Growth fractions in human tumors are quite variable, ranging from 25% to 95%. Although it may seem paradoxical, the rate of cell loss is usually very high in human tumors, ranging from 70% to more than 95%, and small changes in cell loss could produce major changes in apparent tumor growth (14).

Host–Tumor Interactions

Ultimately, dysregulated growth exceeds local resources, and the tumor becomes dependent on the manipulation of host angiogenic pathways for delivery of oxygen, access to nutrients, and removal of waste products. Tumors generally grow without structured lymphatic drainage and are characterized by increased interstitial pressures as a consequence of disordered capillary proliferation with leaky vessels and accumulation of extracellular fluid. Together, these factors result in regional hypoxia, acidosis, and necrosis that can limit the effective delivery of chemotherapy, and may protect viable tumor cells that are more distant from functional capillaries. One of the potential benefits observed with anti-angiogenic therapy has been normalization of tumor vessels with reduced interstitial pressures and improved drug delivery (15).

Log Cell Kill

In principle, the rational use of chemotherapy relies on basic concepts of cellular kinetics, but the translation from preclinical models to solid tumors has been challenging. In animals, the curability of transplanted tumors is inversely proportional to the tumor cell number and size, and timing of treatment initiation. In part, this is the result of important tumor–host interactions, such as the time required to establish a blood supply. However, this is also an illustration of first-order cell kill kinetics, whereby a constant fraction of exposed cells is killed, rather than a constant number. Using first-order kinetics, a single treatment for a tumor weighing 1 g (approximately 10^9 cells) might yield 90% cell kill and would decrease the tumor population by only one log, leaving 10^8 viable cells. Without further treatment, the tumor would grow back at a constant rate, with only a modest delay in lethality. Only when the log cell kill is very large (>99%), and repetitive, can chemotherapy be curative or capable of reducing residual disease to less than 10^4 cells. Certain cancers, such as choriocarcinoma, can be cured with a single application of a single drug. However, the majority of cancers are intrinsically less sensitive and require multiagent chemotherapy over multiple cycles to achieve clinical benefit. Distribution of treatment over multiple cycles allows for host recovery while still achieving the cumulative cell kill required for tumor regression and cure.

An important modification to the log-kill theory is that the fraction of cells killed is not independent of tumor size, but inversely proportional to it (16). Termed the Norton–Simon hypothesis, it proposes that a dose effective at killing a high proportion of cells in a faster growing, small tumor, may be ineffective on the identical tumor cells when present in a larger, slower growing tumor. This hypothesis is at the basis of the development of “dose-dense” regimens, in which chemotherapy doses are administered at shorter intervals to prevent recovery of the cancer cells between doses (see

section on Dose Intensity, Density, and Regimen Complexity).

Cell Cycle Specificity

Chemotherapeutic agents have complex mechanisms of action with an impact on multiple intracellular pathways. Nevertheless, certain anticancer drugs are known to be proliferation-dependent and cell cycle–specific. Other drugs are cycle nonspecific, and are capable of killing in all phases of the cell cycle, generally without dependence on the proliferative rate. Examples of cycle nonspecific drugs include alkylating agents, particularly nitrogen mustard, which are effective against a variety of solid tumors, including those with low growth fractions. Cell cycle–specific agents depend on the proliferative fraction of the tumor and phase of the cell cycle. A typical example is hydroxyurea, which inhibits ribonucleotide reductase. Not surprisingly, cell cycle–specific drugs tend to be more effective against tumors with a high proliferative rate and growth fractions. The interaction of specific cytotoxic agents with the cell cycle is summarized in Table 13.4.

TABLE 13.4 Relationship of Chemotherapy Agents to Intracellular Targets and Cell Cycle Progression

Classification	Cell Cycle Specificity	Cellular Targets and Mechanisms	Examples
Inhibition of DNA synthesis and repair	G_1, S	Inhibition of nucleotide synthesis and metabolism. Inhibition of thymidylate synthase, thymidylate phosphorylase, dihydrofolate reductase, ribonucleotide reductase	Antifolates (methotrexate, pemetrexed), nucleoside analogs (6-mercaptopurine, 5-fluorouracil, cytarabine, fludarabine, gemcitabine), hydroxyurea
	S	Stabilization of DNA-topoisomerase-II cleavable complex, DNA intercalation, +/- free radical formation	Anthracyclines (doxorubicin, daunomycin, idarubicin, epirubicin), anthracenediones (mitoxantrone), epipodophyllotoxins (etoposide), actinomycin D
	S	Stabilization of DNA-topoisomerase-I cleavable complex	Camptothecins (topotecan, irinotecan)
Alkylating agents and related compounds	G_1, G_2, S	Direct DNA damage, DNA adduct formation, free radical production, strand breakage	Radiation, platinum compounds (cisplatin, carboplatin, oxaliplatin), bleomycin, mitomycin C, nitrogen mustard, nitrosoureas, ecteinascidin
Antimicrotubule reagents	M	Inhibition of tubulin polymerization	Vinca alkaloids (vincristine, vinblastine, vinorelbine), colchicine
		Promotion of tubulin polymerization	Taxanes (paclitaxel, docetaxel), epothilones
		Kinesin spindle proteins	Investigational agents
Cell cycle agents	G_1, S, G_2, M	Mitotic checkpoint control, cyclin-dependent kinases (CDK),	Flavopiridol, palbociclib

		aurora kinases	
Signal transduction modulators	G_0, G_1, S, G_2	Growth factor sequestration, receptor blockade	Trastuzumab, cetuximab, pertuzumab, aflibercept, bevacizumab
		Inhibition of tyrosine kinase–mediated signal transduction	Erlotinib, gefitinib, dasatinib, imatinib, sorafenib, sunitinib, lapatinib
		Modulation of protein kinase C	Bryostatin, enzastaurin
		Inhibition of hormonal pathways	Tamoxifen, raloxifene, anastrazole, letrozole, fulvestrant, megestrol, mifepristone, flutamide, leuprolide
Gene regulation	NA	Gene regulation by inhibition of promoter methylation, DNA methyltransferase, or histone deacetylase	Azacytidine, suberoylanilide hydroxamic acid (vorinostat, belinostat)
Protein modifications	NA	Posttranslational protein modifications, inhibition of farnesylation	Tipifarnib, bisphosphonates
		Inhibition of the proteasome complex and clearance of ubiquinated proteins	Bortezomib

Modeling Tumor Growth Kinetics

Multiple tumor growth patterns have been described and mathematically modeled, primarily based on *in vitro* and animal data (17). A classic model is based on Gompertz law. This model proposes that during initial cell divisions, tumor growth follows an exponential pattern; however, as the tumor grows larger, the rate of growth also slows exponentially and the time required to double the tumor volume also increases (Fig. 13.3). Other conclusions of clinical relevance can also be derived from this model. First, metastatic spread may occur well before obvious evidence of the primary lesion (18). Second, at later stages of tumor growth, a small number of doublings can produce a marked change in tumor size, with an increased potential for adverse clinical consequences. For instance, a 1-cm mass (at least 30 prior doublings) becomes a 4-cm mass after just two more doublings. Third, since chemotherapy preferentially targets rapidly proliferating cells, the model implies that chemotherapy would be more effective during the exponential phase of tumor growth.

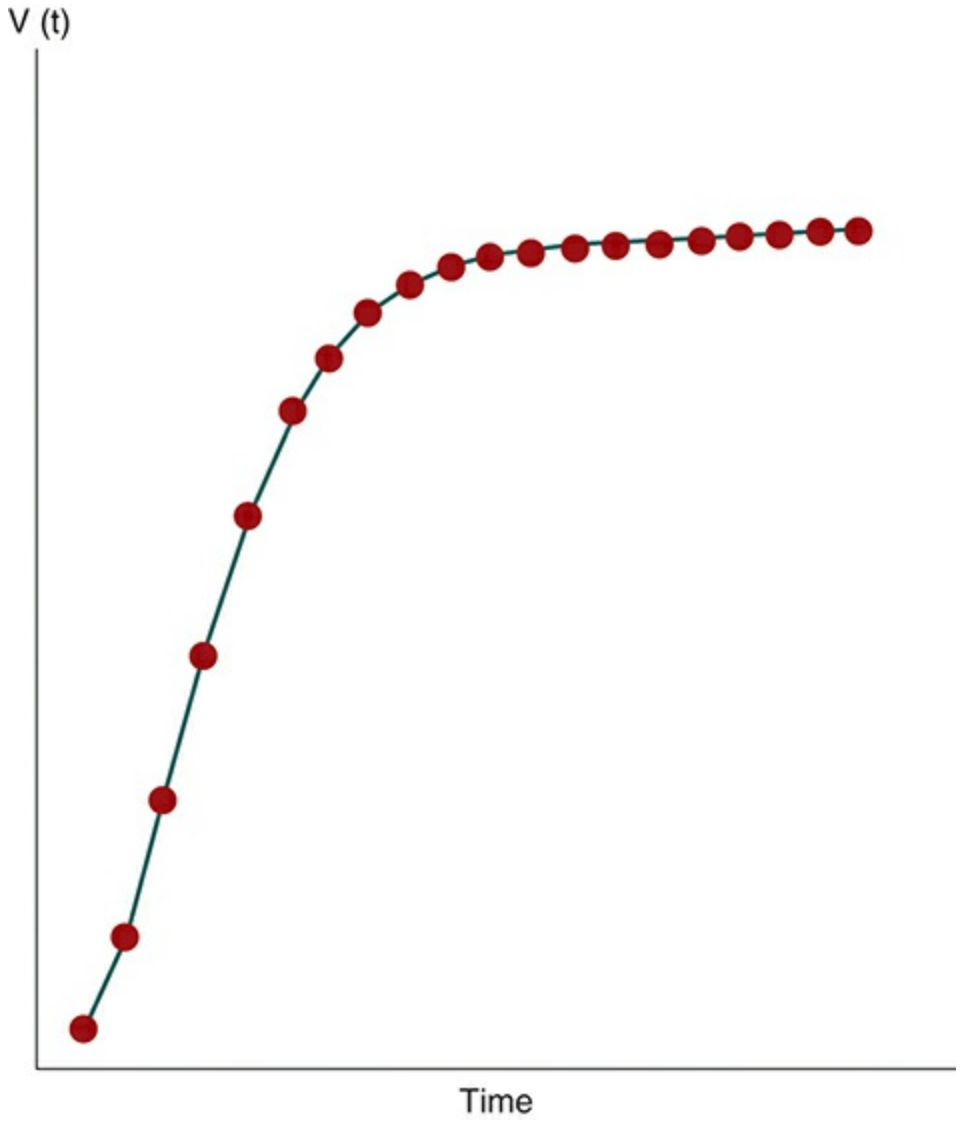

Figure 13.3 Hypothetical Gompertzian tumor growth curve. Exponential tumor growth with exponential growth retardation. The vertical axis is tumor volume and the horizontal axis is time.

There is limited information regarding the actual doubling times of human tumors *in vivo* (19,20), as summarized in Table 13.3. For this historical analysis, untreated tumors were relatively circumscribed and serially measured by radiographic imaging, often as pulmonary metastases. It is clear that embryonal tumors, lymphomas, and mesenchymal tumors have shorter doubling times than adenocarcinomas or squamous cell carcinomas. In addition, metastases generally have faster doubling times than their corresponding primary lesions.

Other models have sought to recapitulate the multiple complex factors leading to carcinogenesis by incorporating the multistep acquisition of growth-enhancing genetic mutations, the balance between replication and cell death, nutrient availability, immune evasion, and the capacity to induce angiogenesis (17). However, cancer behavior is diverse, and a single tumor may exhibit different growth kinetics during various phases of its development. Nevertheless, understanding tumor growth kinetics may elucidate critical processes necessary for tumor progression, metastases, and drug resistance while identifying new opportunities for therapeutic intervention.

GENERAL PRINCIPLES OF CHEMOTHERAPY

Treatment Objectives

Although certain general principles guide the clinician in choosing the appropriate classes of drugs or combinations, the decision to use these agents *at all* must be considered carefully. The critical factors involved in formulating a recommendation are reviewed in Table 13.5.

Natural History

Antineoplastic agents should be used only in patients whose malignancy has been established via pathologic examination, and with thoughtful consideration of the expected natural history, based on the primary tumor site, extent of disease, and rate of progression. Individual factors that could have an impact on tolerance for therapy must be evaluated in the context of treatment goals, including physiologic age (as reflected by vital organ function), general health, performance status, nutritional status, desire for treatment, and the presence of underlying illness. Prior history, including any previous cancer treatment and residual functional impairment, as well as patterns of recurrence, should also be considered. Finally, the emotional, social, and financial concerns of the patient and family must be respected (Table 13.5). Recommendations and goals should be presented to the patient and family in conjunction with a realistic analysis of potential risks and benefits, which contributes to the process of informed consent and which should be followed by sharing of written information for future reference.

TABLE 13.5 Important Considerations before Using Antineoplastic Drugs

Natural history of the malignancy
Biopsy proof of malignancy
Identification of primary site
Rate of progression or grade
Stage of disease, patterns of spread
Patient characteristics
Physiologic age, nutritional status, performance status
Vital organ function; bone marrow reserve
Comorbid conditions
Extent of previous treatment
Supportive care
Adequate facilities to evaluate, monitor, and treat potential drug toxicities
Emotional, social, and financial status; support from family
Collaboration with referring physician
Treatment goals
Parameters to monitor objective response to treatment
Potential benefits
Curative intent
Improved or sustained quality of life
Control of disease
Palliation of symptoms

Clinical Assessment

In view of the potential for serious toxicity, it is desirable to have some objective means of measuring tumor response by physical examination, radiographic imaging, and/or analysis of serum tumor markers. However, it is not uncommon to

administer multiple cycles of adjuvant or postoperative chemotherapy without any direct means of documenting tumor response. In these circumstances, the physician should be alert for any clinical evidence of tumor recurrence or progression during treatment. In patients with evaluable disease, continued administration of chemotherapy requires verification of ongoing benefit.

Expectations

The likelihood of achieving clinical benefit influences the choice of treatment and the acceptance of potential toxicity. Primary tumors (and recurrence after surgical resection or radiation without prior chemotherapy) can generally be grouped according to the likelihood of achieving a durable response. While the use of chemotherapy is supported by data from phase 3 clinical trials, it is also apparent that research findings are often extended to populations with lower risk, and more patients are being exposed to platinum-based therapy at earlier points in the natural history of their disease, with an increased risk of treatment-resistant disease at the time of recurrence.

Most importantly, there is a group of tumors for which primary chemotherapy has been curative in the majority of patients, including choriocarcinoma and ovarian germ cell tumors. These patients should be treated aggressively with curative intent. Toxicity in this setting is acceptable, assuming that it is reversible, as the probability of long-term survival is high.

A second group, including advanced epithelial ovarian carcinoma, has high response rates to primary therapy (exceeding 75%), with prolongation of disease-free and median overall survival, but with only a modest improvement in overall mortality. Patients with these tumors usually benefit from therapy in terms of extended survival or quality-adjusted survival, and they should receive primary treatment at full doses unless contraindicated.

A third group of cancers, including advanced (or recurrent) endometrial cancer, cervical cancer, low-grade serous carcinoma, and uterine carcinosarcoma (mixed Müllerian tumors), have intermediate or lower response rates to primary chemotherapy, with shorter duration of remission and limited improvement in overall survival. Treatment with an initial course of therapy is reasonable, with careful monitoring of toxicity and response.

Other tumors, including uterine leiomyosarcoma, are more resistant to primary therapy, achieving a low frequency of objective response without prolongation of survival. In this setting, the use of chemotherapy should be carefully considered and particular emphasis placed on including these patients in well-structured clinical trials to evaluate innovative treatments.

In patients with recurrent or progressive disease (PD) after prior chemotherapy, the expectations of response are reduced due to the emergence of drug resistance and the impact of prior therapy and/or disease on performance status and vital organ function. As such, treatment goals are usually aimed at control or palliation, with attention to quality of life and control of symptoms. In this population, the frequency of stable disease usually exceeds the objective response rate. With appropriate chemotherapy regimens that avoid cumulative toxicity, patients without further disease progression may remain on therapy for prolonged periods of time with an acceptable quality of life.

Choice of Specific Chemotherapeutic Regimens

Once the decision to use chemotherapy has been made, the appropriate regimen must be selected. The physician is aided in this task by the results of randomized trials and evolving standards of care, including published practice guidelines. However, not every patient can receive “standard” therapy because of idiosyncratic reactions, vital organ dysfunction, prior treatment, geographic location, or other factors. Practical individualized decisions are facilitated by the logical grouping of chemotherapeutic agents in several classes with similar pharmacologic properties, mechanisms of action, and spectrum of toxicity. The most important classes are the platinum-based alkylating agents, non-platinum alkylating agents, antimetabolites, antitumor antibiotics, antimicrotubule agents, nucleoside analogs, hormones, and newer molecular-targeted therapies (Table 13.1).

A number of combination regimens have been evaluated in the management of gynecologic cancer, and some have been widely adopted as "standard of care" for primary management of advanced-stage or recurrent disease. Phase 3 trials have demonstrated the superiority of specific regimens, such as paclitaxel with either cisplatin (21) or carboplatin (22) in ovarian cancer; a combination of carboplatin and paclitaxel in endometrial cancer (23); cisplatin and bevacizumab with either paclitaxel or topotecan in cervical cancer (24); and ifosfamide with paclitaxel in uterine carcinosarcoma (25).

However, none of the standard combinations for advanced ovarian, endometrial, or cervical cancer has been directly compared to sequential therapy with the best active single agents, and the superiority of combination therapy, while widely endorsed, has not been fully established. For example, in the setting of ovarian cancer, phase 3 trials have suggested that sequential therapy with platinum followed by paclitaxel may offer similar long-term outcomes to a combination of platinum and paclitaxel (26). Although the initial frequency of tumor response is often increased with combination therapy, long-term outcomes such as overall survival and symptom-adjusted quality of life can be similar for patients who receive optimal sequential therapy with single agents. This is primarily related to the advanced stage of disease at the time of initial treatment with systemic chemotherapy and the lack of curative therapy for the majority of patients. As such, if individual patient circumstances contraindicate the use of a standard combination regimen, it remains a reasonable option to begin therapy with one of the active single agents. Combinations can also be employed as adjuvant therapy for patients with early-stage disease who are at increased risk for recurrence, and for patients with late recurrence after good response to initial therapy.

Adjuvant chemotherapy refers to the initial use of systemic chemotherapy after surgery and/or radiation therapy has been performed with curative intent, and there is no evidence of residual disease. Adjuvant chemotherapy is considered if the subsequent risk for recurrence after initial definitive therapy is relatively high (generally greater than 20%), but it is not routinely recommended when the risk of recurrence is less than 10%. In the adjuvant therapy of epithelial ovarian cancer, long-term results from randomized trials have documented a reduction in the risk of recurrence after platinum-based chemotherapy (27,28). However, in carefully staged patients (to exclude occult advanced-stage disease), it has been difficult to establish an advantage in overall survival. Phase 3 studies in endometrial cancer (29) and uterine carcinosarcoma (30) have documented improved survival with the use of adjuvant combination chemotherapy compared to whole abdomen radiation in selected patients with high-risk disease, increasing the overall proportion of patients who receive adjuvant therapy.

Concurrent chemotherapy with radiation (chemoradiation) refers to the use of chemotherapy to sensitize the tumor to the effects of radiation delivered with curative intent. This has been most extensively studied in the primary management of locally advanced cervical cancer, where platinum-based chemoradiation has been proven superior to radiation alone (31). In general, the duration of chemotherapy coincides with the duration of external beam radiation. Although the preferred weekly dose of cisplatin might appear to be low, these regimens generally exceed the overall dose intensity of cisplatin when used to treat advanced disease, and patients require monitoring to avoid cumulative toxicity and treatment interruptions.

Neoadjuvant chemotherapy generally refers to the use of chemotherapy in the management of locally advanced disease, in situations where it would be difficult or impractical to perform immediate surgery or radiation. Following a response to initial chemotherapy, there is an expectation that morbidity associated with the overall treatment program can be minimized in conjunction with a reduction in radiation treatment volume or extent of surgery. With support from two phase 3 randomized trials, the use of neoadjuvant chemotherapy in advanced ovarian cancer has emerged as an acceptable option, particularly in patients with extensive disease not amenable to optimal cytoreduction, or in the presence of comorbidities that might increase surgical risk (32,33).

Monitoring of Tumor Response

Generally accepted criteria for evaluation of responses are necessary to facilitate treatment decisions and comparisons among different regimens. Several standards have been used, including those developed by the World Health Organization

(WHO). However, in 2000, an international working group including the European Organization for Research and Treatment of Cancer, the National Cancer Institute of Canada, and the National Cancer Institute (NCI) of the United States developed, validated, and published new Response Evaluation Criteria in Solid Tumors (RECIST 1.0), which were widely adopted within clinical trials and updated as RECIST 1.1 in 2009 (34).

Positron emission tomography (PET) data are not included in RECIST, but the computed tomography (CT) component of a PET-CT study can be used for RECIST if the CT is of sufficient diagnostic quality. PET Response Criteria in Solid Tumors (PERCIST) have been developed, but have not been widely adopted (35). An overview of RECIST determinations is provided in Table 13.6.

TABLE 13.6 Evaluation of Overall Disease Response (RECIST 1.1)

Complete Response (CR)[a]	Disappearance of all target[b] and non-target lesions, absence of new lesions, and normalization of tumor marker levels (if appropriate). Pathologic lymph nodes must have a reduction in short axis to <10 mm.
Partial Response (PR)	Disappearance of all target lesions, without progression of non-target lesions, without appearance of new lesions, and with persistence of abnormal tumor marker levels. Or At least a 30% decrease in the sum LD of target lesions (taking as reference the baseline sum LD) without progression of non-target lesions or appearance of new lesions.
PD	At least a 20% increase in the sum LD of target lesions, taking as reference the smallest sum LD recorded since the start of treatment, or the appearance of one or more new lesions, or progression of any non-target lesion. The sum LD must demonstrate an increase ≥5 mm.
SD[c]	Neither sufficient shrinkage of target lesions to qualify for PR nor sufficient increase to qualify for PD, taking as reference the smallest sum LD since the start of treatment. No appearance of new lesions (target or non-target).

Note: Measurable lesions can be accurately measured in at least one dimension with longest diameter (LD) ≥20 mm using conventional radiography, or ≥10 mm with spiral CT scan, or ≥10 mm with calipers on physical examination. Lymph nodes must be ≥15 mm along the short axis to be considered pathologic or measureable.

Non-measurable lesions consist of all other lesions, including small lesions (longest diameter <20 mm with conventional imaging techniques or <10 mm with spiral CT scan), bone lesions, leptomeningeal disease, ascites, pleural/pericardial effusion, inflammatory breast disease, lymphangitis, cystic lesions, and abdominal masses that are not confirmed or followed by imaging techniques.

[a]To be assigned PR or CR, changes in tumor measurements must be confirmed by repeat assessments no less than 4 weeks after the criteria for response are first met. The duration of overall response is measured from the time that criteria are met for CR or PR (whichever status is recorded first) until the first date that recurrence or PD is objectively documented, taking as reference for PD the smallest measurements recorded since the treatment started.

[b]Target lesions include measurable lesions up to a maximum of two lesions per organ and five lesions in total, representing all involved organs, selected on the basis of size (lesions with the longest diameter) and suitability for accurate repeated measurements. Non-target lesions include all other lesions (or sites of disease) to be identified and recorded at baseline. Serial measurements of these lesions are not required, but the presence or absence of each should be noted throughout follow-up.

[c]In the case of SD, follow-up measurements must have met the SD criteria at least once after study entry at a minimum interval (in general, not less than 6 to 8 weeks) that is defined in the study protocol. SD is measured from the start of the treatment until the criteria for disease progression are met, taking as reference the smallest measurements recorded since the treatment started.

Where available, tumor markers are not sufficient to declare response but, if initially elevated, must normalize to designate a complete response. International criteria to declare disease progression on the basis of a serial elevation in CA-125 have been widely adopted, but there is incomplete agreement on criteria to define a partial response during treatment (36). Changes in CA-125 alone, without other evidence of disease, are not recognized within the RECIST paradigm and are not validated for seeking regulatory approval of new treatments. Overall, RECIST is more detailed and specific than previous response criteria, and is also more demanding of the clinical team and radiologist.

Complete regressions of cancer are generally associated with a prolongation of survival. Partial remissions are generally accompanied by improved well-being for a period of time but are not expected to improve overall survival. While a variety of terms have been used to designate lesser responses (e.g., minor response, objective regression), these are rarely associated with any significant clinical benefit. Disease stabilization is an acceptable goal in the setting of palliative therapy for recurrent disease provided that symptoms have not progressed and the patient can tolerate continued therapy.

Changes in the volume of ascites or pleural fluid are not usually considered in the measurement of response, as a number of factors unrelated to cancer can influence third-space fluid accumulation, such as nutritional status, renal function, and treatment-related toxicity. However, appearance of a new fluid collection with cytologic verification would represent PD. Similarly, the appearance of new symptoms, such as a partial small bowel obstruction, does not always indicate progression of disease but could be related to prior surgery, irradiation, chemotherapy, or infection. Overall monitoring of small-volume intraperitoneal, diaphragmatic, or intrapleural disease is not adequately addressed within RECIST.

PHARMACOLOGIC PRINCIPLES OF CHEMOTHERAPY

Many factors may influence the effectiveness and/or toxicity of chemotherapy, including dose, frequency of administration, absorption, distribution, metabolism, and excretion, as well as clinical complications, such as renal impairment, malnutrition, or drug–drug interactions.

Dose Intensity, Density, and Regimen Complexity

The dose and frequency of drug administration can contribute to the overall effectiveness of a treatment regimen, as well as the spectrum and severity of toxicity. Dose intensity is a standardized measure of the amount of drug administered over time, most commonly expressed as mg/m^2/week.

Preclinical studies demonstrate a sigmoidal relationship between dose and tumor response (Fig. 13.4). This is characterized by a *lag phase* and a lower limit *threshold* for observing benefit; a *linear phase*, where increases in dose are matched by improved efficacy; and a *plateau*, where toxicity continues to increase but there is no incremental improvement in response. In highly responsive tumors (e.g., choriocarcinoma, dysgerminoma), the entire dose–response curve is shifted to the left, with the result that standard chemotherapy doses are already situated near the upper plateau, and further dose increases are unlikely to achieve any improvement in clinical outcomes. In resistant tumors (e.g., previously treated cervical cancer), the curve is shifted to the right, and is also flattened, reducing the maximal potential benefit and increasing the risk of toxicity.

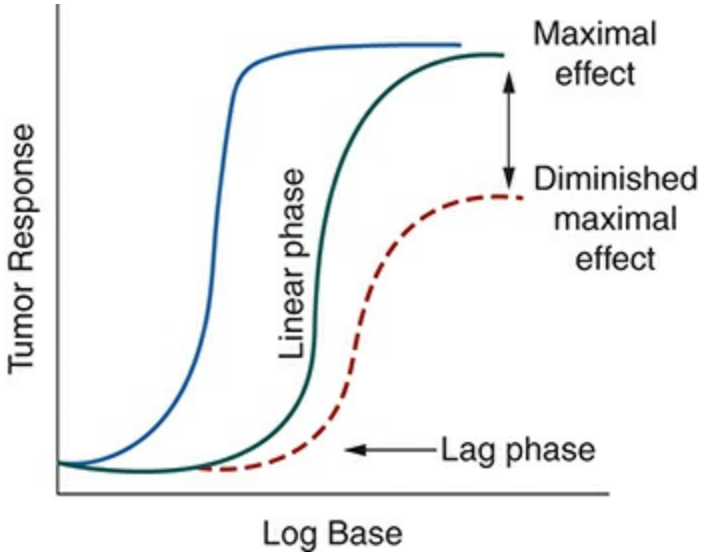

Figure 13.4 Theoretical dose-response curve. The vertical axis [1][2]is[3][4] the tumor response and the horizontal axis is the log of the dose. A hypothetical dose-response curve is illustrated by the green line. The blue line represents a highly responsive tumor (e.g., choriocarcinoma), in which the dose-response curve is shifted to the left. The red line represents a resistant [5]tumor[6] (e.g., previously treated cervical cancer) in which treatment response is diminished.

The dose intensity hypothesis has been extensively evaluated in the setting of advanced ovarian cancer, beginning with a series of retrospective reports (37). However, within practical dose ranges that can be achieved in the clinical setting, prospective randomized trials have not demonstrated significant improvements in either disease-free or overall survival (38). While frontline studies focused on platinum dose intensity, the question of paclitaxel dose intensity was also addressed in the setting of recurrent disease, again without evidence of improved outcomes.

Dose intensity is limited by acute (single cycle) and cumulative (multi cycle) nonhematologic and hematologic toxicities. Although multiple cycles of high-dose carboplatin and paclitaxel (with or without topotecan or gemcitabine) can be safely administered with hematopoietic progenitor and growth factor support, it is more difficult to overcome serious non-hematologic toxicities. Thus far, there is no evidence that a two- to threefold increase in carboplatin dose intensity and cumulative dose delivery is associated with a substantial improvement in clinical outcomes (39), and it is unlikely that this approach will be further evaluated. In contrast, there is renewed interest in “dose-dense” therapy, in which a series of two or three individual single agents are sequentially administered at maximal tolerated doses using short cycle intervals. This approach has been favorably evaluated in the adjuvant therapy of breast cancer (40) and ovarian cancer (41), though at a cost of increased hematologic toxicity. Short cycle intervals may offer a safer approach for intensification by reinforcing normal biologic rhythms that can accelerate repair and minimize host toxicity. Further data on adjuvant treatment in ovarian cancer is discussed elsewhere.

In theory, another approach to improve outcomes would be to incorporate a third cytotoxic drug. This concept has been extensively evaluated in the primary therapy of advanced-stage ovarian cancer, with a series of definitive phase 3 trials. For example, GOG0182-ICON5 was a five-arm phase 3 international cooperative group trial exploring triplet and sequential doublet combinations that included gemcitabine, topotecan, or PEG-liposomal doxorubicin (42). There was no benefit in progression-free or overall survival from the addition of a third cytotoxic drug compared to a conventional combination of carboplatin and paclitaxel. Similarly, in advanced or metastatic endometrial cancer, the triplet regimen of cisplatin, paclitaxel, and doxorubicin was not superior to conventional carboplatin and paclitaxel (23).

Absorption, Distribution, and Transport

Drugs may be given by many different routes, depending on solubility, biologic barriers, requirements for drug activation, local tissue tolerance, feasibility for an individual patient, and optimal tumor drug exposure, which is estimated as the area under the concentration time curve (AUC) for the drug and active metabolites. The ultimate effectiveness of any chemotherapeutic agent depends on optimizing the AUC at critical tumor sites. However, there are no established techniques for noninvasive measurement of active drug concentration at these critical sites, and we are forced to extrapolate tumor drug exposure from preclinical models and plasma or fluid concentrations over time. Techniques such as magnetic resonance spectroscopy, microcapillary sampling, and PET can potentially provide information on drug distribution and tumor metabolism, but they require a substantial investment in technology and specialized reagents.

The increasing utilization of oral chemotherapy and development of oral molecular-targeted agents has renewed interest in bioavailability in the setting of meals and other factors that can modulate local intestinal transport. In most cases, initial dose and schedule guidelines from Food and Drug Administration (FDA)–approved labeling reflect data from large phase 3 trials, rather than smaller studies that might examine dietary or drug interactions. For example, the bioavailability of one tyrosine kinase inhibitor could be increased over threefold in the setting of a high-fat meal (43), but the label recommends taking the drug on an empty stomach. With the high cost of chronic medication, it is apparent that there could also be substantial economic implications to these pharmacokinetic observations (44).

Some natural compounds, such as those found in grapefruit juice, can inhibit the cytochrome P450 isozyme CYP3A4 within the intestinal mucosa (45), as well as the drug efflux pump p-glycoprotein. Drugs that are substrates for either of these compounds, including cyclosporine, erythromycin, calcium channel blockers, and benzodiazepines, can be more efficiently absorbed after ingestion of grapefruit juice, due to reduced local metabolism, leading to increased serum levels that may have clinical consequences.

The extent of drug binding to serum proteins, as well as physical properties, such as lipid solubility, diffusion, or molecular weight, may have an impact on tumor drug exposure. In addition, some areas of the body, particularly the brain, are actively protected from drug exposure and can serve as pharmacologic tumor sanctuaries, where small numbers of sequestered cancer cells may survive otherwise curative systemic therapy. Larger solid tumors eventually disrupt the blood–brain barrier, restoring access to conventional chemotherapy. In this manner, even drugs that are normally excluded from the central nervous system, such as carboplatin, can achieve dramatic reductions in metastatic disease (46).

In addition to achieving local delivery, most drugs must be internalized within tumor cells to achieve cytotoxicity. Internalization can be accomplished by passive diffusion, active transport, pinocytosis, or receptor-mediated endocytosis. Molecular targeting has also been utilized to enhance the delivery of conventional cytotoxic agents to tumors, based on expression of tumor-associated antigens, or the presence of specific receptors. For example, ado-trastuzumab emtansine is a HER2-targeted antibody drug conjugate linked to a cytotoxic agent that is inactive until internalized and released within the HER2-expressing cancer cell. These strategies have resulted in improved efficacy with decreased toxicity compared to conventional therapy (47).

Many chemotherapeutic agents are lipophilic and highly protein bound in plasma, particularly to albumin. Commonly used agents with greater than 95% protein binding include cisplatin, paclitaxel, docetaxel, etoposide, and the active metabolite of irinotecan (SN-38). Agents with less protein binding include doxorubicin (75%), topotecan (35%), gemcitabine (10%), carboplatin (<5%), and ifosfamide (<5%). It is generally the unbound “free” drug that mediates toxicity, and any condition associated with variability in protein binding can have an impact on cumulative drug exposure. For example, the toxicity of chemotherapy is frequently accentuated in patients with poor nutritional status, which is associated with reduced protein levels and other metabolic changes (48). Docetaxel offers an interesting example for potential interactions, due to extensive binding to albumin, lipoproteins, and α-acidic glycoprotein, which has been correlated with changes in drug clearance, prompting further evaluation of optimized dosing (49).

Intraperitoneal Chemotherapy

Although most chemotherapy is administered by the systemic route, there are unique situations in which the regional use

of chemotherapy has been studied, with intraperitoneal administration being a specific example. If primary tumors or their metastases are anatomically confined to specific organs or particular regions of the body, or if unique pharmacokinetic circumstances exist that favor regional clearance, there is a theoretical rationale for regional chemotherapy. For example, intra-arterial drug administration has been studied in cervical cancer, localized recurrence of rectal carcinoma, melanoma, and head and neck cancer. Local complications are potentially serious, including arterial thrombosis, wound slough, lymphedema, and osteonecrosis caused by the shared arterial blood supply between the tumor and neighboring normal tissues. While high response rates can be achieved in selected patients, larger randomized trials are needed to evaluate overall risks and long-term outcomes.

Intracavitary chemotherapy has been used for tumors confined to the peritoneum, pleura, or pericardium. The rationale for this approach is based on the fact that clearance from a body cavity is delayed compared to the systemic circulation, achieving more prolonged exposure to higher regional concentrations of active agents. This technique has been most extensively studied in ovarian cancer, with evaluation of many agents, including 5-fluorouracil, doxorubicin, cisplatin, carboplatin, cytarabine, melphalan, etoposide, and paclitaxel (50). Phase 1–2 studies have uniformly demonstrated a pharmacologic advantage favoring the intraperitoneal compartment but have not documented enhanced drug delivery to actual sites of disease. Of key importance, penetration of peritoneal tumor nodules by passive diffusion is limited by fibrotic adhesions, tumor encapsulation, and high interstitial pressures as a consequence of intratumoral capillary leak without functional lymphatic drainage. In addition, both cisplatin and carboplatin are rapidly cleared from the peritoneal compartment and recirculated through the blood, limiting the window for direct tumor penetration, exposing the host to systemic toxicity, and raising questions about the clinical importance of the local pharmacokinetic advantage. On the basis of these observations, it has been postulated that the major role for intracavitary therapy would be in patients with minimal residual disease.

Cisplatin has received the greatest attention for intraperitoneal delivery in ovarian cancer, particularly for the primary treatment of small-volume residual disease following initial cytoreductive surgery (51). In view of the risk of systemic non-hematologic toxicity from intraperitoneal cisplatin, there has been renewed interest in the substitution of intraperitoneal carboplatin, which differs in terms of reduced protein binding and increased overall time required for *in situ* activation (via aquation), with the possibility that clinical outcomes could be different between the two agents. This question is currently under investigation in two phase 3 randomized trials (GOG0252 and JGOG iPOCC).

In contrast to cisplatin, paclitaxel is poorly absorbed from the peritoneal compartment, suggesting that patients might benefit from combined intravenous and intraperitoneal administration to optimize tumor drug exposure. As a single-agent, intraperitoneal paclitaxel demonstrated a 61% pathology-confirmed complete response rate among 28 assessable patients with initial microscopic disease (52). However, only 1 of 31 patients (3%) with greater than microscopic disease achieved a complete response, emphasizing the limitations of drug access and penetration by diffusion from the peritoneal space.

Intraperitoneal therapy could also have an impact on the tumor–host relationship through alterations in local cytokine production, angiogenic response, or immunoregulation. Hopefully, future studies will evaluate some of these biologic parameters to assist with optimization of therapy. In this regard, it is also possible that intraperitoneal therapy could have clinical benefit regardless of the extent of disease, and current randomized trials have enrolled a subset of patients with suboptimal residual disease following primary cytoreductive surgery.

Biotransformation

Some agents, such as cyclophosphamide, ifosfamide, and capecitabine, are administered as true prodrugs and must undergo irreversible metabolism to the active form, most commonly in the liver, but also in tumor or other host tissues. For many of these agents, intraperitoneal or intra-arterial administration would be ineffective, as it would achieve high local concentrations of the native compound, but without an opportunity for bioconversion. Other agents are in reversible equilibrium with reactive intermediates, such as irinotecan and SN-38 (7-ethyl-10-hydroxycamptothecin), with dependencies on local pH and presence of specific enzymes, such as carboxyesterase. Cisplatin and carboplatin both

require activation through irreversible aquation to a reactive intermediary before they can initiate DNA adduct formation. Although the final reactive compounds are identical, the rate of aquation and adduct formation is much slower with carboplatin (53), but can be accelerated in the presence of activating nucleophiles, such as glutathione (54), even though the same nucleophiles can partially block cisplatin-DNA adduct formation at higher concentrations.

Renal Excretion and Physiologic Age

Drug inactivation, elimination, or excretion can dramatically influence cumulative exposure, which significantly affects antitumor activity and host toxicity. Inactivation and excretion of chemotherapeutic agents occurs primarily through the liver, kidneys, and body tissues, with lesser elimination through the stool. While any impairment of normal liver or kidney function can disturb drug metabolism and excretion, the most common problem encountered in the setting of gynecologic cancer is acute or chronic renal insufficiency due to tumor-mediated obstruction, drug-induced toxicity, advanced age, or preexisting comorbidities.

The use of combination chemotherapy in the elderly patient can pose a number of challenges related to bone marrow reserve and vital organ function (55). Although the risk of hematologic toxicity is generally increased, overall benefits from active chemotherapy regimens can still be demonstrated, as illustrated by the analysis of data from several breast cancer trials (56). Studies in ovarian cancer have indicated that age is an adverse prognostic factor, but there are insufficient data to determine how the benefits of treatment change with age. In part, this is related to the underutilization of chemotherapy in elderly patients and reduced enrollment of elderly patients on clinical trials (57). From that perspective, it is important to define tolerable and effective treatment regimens that can be safely administered in elderly patients, incorporating supportive care, geriatric assessment, and adjustments for age-related changes in vital organ function (58).

In surveying the general nondiabetic female population, the incidence of moderate renal insufficiency dramatically increases with age, which is of particular relevance to the care of women with gynecologic cancer (59). For example, in the 60- to 69-year age group, over one-third of women have an estimated glomerular filtration rate (GFR) of less than 60 mL/min/1.73 m^2 (Fig. 13.5). In addition, serum creatinine levels can be inappropriately low in women with gynecologic cancer, as a consequence of reduced muscle mass, malnutrition, postoperative recovery, or third-space fluid accumulation. In those settings, any of the standard formulae will overestimate GFR, with potential clinical consequences. Clearly, universal caution in dosing drugs with high renal clearance, especially carboplatin, is required.

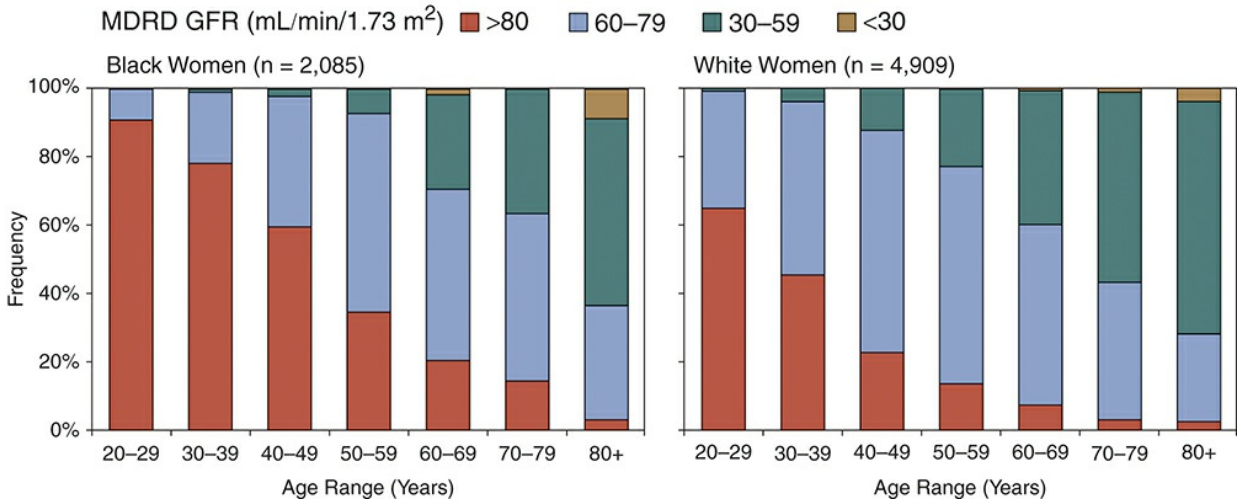

Figure 13.5 Distribution of renal function in nondiabetic adults. Weighted distribution of predicted GFR (mL/min/1.73 m^2) based on the MDRD formula from the Third National Health and Nutrition Examination Survey (NHANES III).
Source: From Clase CM, Garg AX, Kiberd BA. Prevalence of low glomerular filtration rate in nondiabetic Americans: Third National Health and Nutrition Examination Survey (NHANES III). J Am Soc Nephrol. 2002;13:1338–1349, with permission.

Several methods are available to estimate GFR and classify the extent of renal injury based on age, sex, serum creatinine, and other factors (60–62). In general, serum creatinine is the dominant factor, and it remains unclear whether minor differences between formulae might have meaningful and/or consistent clinical consequences with regard to drug dosing. In most cases, it is sufficient to estimate GFR rather than obtain a precise measurement. However, all of these formulae are based on stable normalized biologic parameters and are less useful in the setting of dynamic changes following acute renal injury, or other non-renal fluctuations in serum creatinine.

While urine collection for estimation of creatinine clearance (based on measured creatinine in the urine over a period of time) might appear to provide a better estimate of GFR, it is also subject to clinical variability, due to different rates of creatinine tubular secretion. Utilization of direct techniques to measure actual GFR, such as clearance of ^{51}Cr-ethylenediaminetetraacetic acid or inulin, remains the standard for comparison with indirect estimates, but these assays are rarely used in clinical practice due to cost and complexity.

Staging of chronic renal disease has been used to reflect overall severity and guide management decisions, including dose modifications. The most commonly used staging system is from the National Kidney Foundation (63). The formula derived from the Modification of Diet in Renal Disease (MDRD) study has been incorporated in standardized laboratory reports (60). However, the MDRD has not generally been validated for actual drug dosing. As a result, the Cockcroft–Gault (61) and Jelliffe (62) formulae are more commonly used for drug dose calculation (Table 13.7).

TABLE 13.7 Commonly Utilized Formulae to Estimate Creatinine Clearance

Formula Name	Estimation of Creatinine Clearance (CrCl)
Cockcroft–Gault formula (39)	CrCl (mL/min) = (140 − age) × weight (kg) × (0.85 if female)/serum Cr (mg/dL) × 72
Jelliffe formula (40)	CrCl (mL/min) = {98 − [0.8 × (age − 20)]} × (0.9 if female)/serum Cr (mg/dL)
MDRD formula (38)	GFR (mL/min/1.73 m^2) = 170 × [serum Cr (mg/dL)]$^{-0.999}$ × (age)$^{-0.176}$ × (0.762 if female) × (1.180 if African American) × [SUN (mg/dL)]$^{-0.170}$ × [Alb (g/dL)]$^{+0.318}$

Alb, serum albumin concentration; Cr, creatinine; GFR, glomerular filtration rate; MDRD formula, the Modification of Diet in Renal Disease study equation; SUN, serum urea nitrogen concentration.

The situation has become further complicated by an international effort to recalibrate creatinine standards based on isotope dilution mass spectrometry (IDMS). These new standards have now been adopted by all major vendors and commercial laboratories. The relationship between old (pre-IDMS) and new (IDMS) creatinine values within the same patient is variable, depending on the specific vendor and equipment. In general, IDMS standards will lower the serum creatinine value by approximately 12%. Using the IDMS creatinine value will therefore increase the estimated GFR, and could lead to higher doses of chemotherapy, particularly carboplatin, with an impact on hematologic toxicity (64). These changes prompted a review by the FDA, the NCI, and the national cooperative groups, followed by distribution of safe initial dose recommendations in 2010 for patients enrolled in clinical trials, as detailed in Table 13.8, incorporating recommendations from the legacy GOG (65).

TABLE 13.8 Initial Carboplatin Dose Recommendations based on IDMS Creatinine Values[a]

Calculate using Calvert formula[b]	Carboplatin Total Dose (mg) = Target AUC (mg × min/mL) × [GFR + 25] (mL/min)

Estimate GFR using Cockcroft–Gault equation[c]	$\text{Creatinine Clearance (mL/min)} = \frac{[140 - \text{Age years}] \times \text{Weight (kg)} \times 0.85 \text{ (for women)}}{72 \times \text{Serum Creatinine (mg / dL)}}$
Body Weight: For body mass index (BMI) <25, use actual body weight For BMI >25[d], use adjusted body weight	Adjusted Weight (kg) = (Actual Weight – Ideal Weight) × 0.40) + Ideal Weight) Ideal Weight (kg) = ([Height in cm/2.54] – 60) × 2.3) + 45.5
For abnormally low serum creatinine values, GFR should be capped at a maximum value of 125 mL/min or estimated GFR can be calculated using the lower limit of normal for the serum creatinine test utilized.	Maximum Carboplatin Dose: AUC 6 = 900 mg AUC 5 = 750 AUC 4 = 600

[a]Subsequent modifications are based on hematologic toxicity or recalculation in the event of a change in renal function or body weight.

[b]Although developed with measured GFR, estimated GFR is routinely employed in clinical practice.

[c]Of note, although the Cockcroft–Gault equation was developed and validated for drug dosing using pre-IDMS creatinine values, it is the preferred formula for estimating GFR.

[d]The BMI cutoff for using adjusted body weight is under review; revised guidelines with a higher cutoff are expected.

Specific guidelines exist for modifying drug doses for patients with renal impairment (66), with special attention to a growing list of agents with renal-dominant clearance (Table 13.9). Dosing parameters for patients on dialysis receiving individual drugs, such as cisplatin (67) and carboplatin (68), are also available. However, owing to the rapid introduction of new agents, clinicians are urged to consult updated prescribing information and online database resources.

TABLE 13.9 Modifications in the Setting of Renal and Hepatic Dysfunction

Agents that Should Be Considered for Modification in the Presence of Moderate Renal Dysfunction	Agents that Generally do not Require Modification in the Presence of Moderate Renal Dysfunction	Agents that Should be Considered for Modification in the Presence of Hepatic Dysfunction
Actinomycin D	Anastrozole	Docetaxel
Bleomycin	Bevacizumab	Doxorubicin
Capecitabine	Cabazitaxel	Epirubicin
Carboplatin	Cetuximab	Mitoxantrone
Cisplatin[a]	Docetaxel	Epirubicin
Cyclophosphamide	Doxorubicin	Mitoxantrone
Etoposide	Epirubicin	NAB-paclitaxel
Hydroxyurea	Erlotinib	Paclitaxel
Ifosfamide	Fluorouracil	PEG-liposomal doxorubicin
Melphalan	Gefitinib	Vinblastine
Methotrexate	Gemcitabine	Vincristine
Pemetrexed	Irinotecan	Vinorelbine
Topotecan	Letrozole	
	Leucovorin	
	Leuprorelin	
	Megestrol	

	Mitomycin
	NAB-paclitaxel
	Oxaliplatin
	Paclitaxel
	PEG-liposomal doxorubicin
	Tamoxifen
	Temozolomide
	Trastuzumab
	Vinblastine
	Vincristine
	Vinorelbine

[a] Can be administered at full doses in anephric patients receiving hemodialysis.

Metabolism and Pharmacogenomics

Drugs can be metabolized in the liver, in other normal host tissues, or within tumors. Aside from those agents with extensive renal clearance, hepatic metabolism usually predominates. A large number of microsomal and cytoplasmic enzymes contribute to this process, with associated genetic polymorphisms that can account for individual variability in clearance, efficacy, resistance, and the risk of hepatic or non-hepatic toxicity. Techniques for screening and identification of pharmacogenomic elements are expanding, with potential implications for individualized drug selection, dosing, prediction of efficacy, and risk of toxicity.

With awareness of polymorphisms in key enzymes, it has been possible to identify individuals with a dramatically increased risk of toxicity (Table 13.10). Preemptive screening is controversial and not widely performed. The potential reduction in risk must be balanced against the costs of a widespread screening program (69).

TABLE 13.10 Pharmacogenomic Variants Affecting Cytotoxic Chemotherapy Metabolism

Enzyme	Drug	Most Common Allelic Variant	Clinical Implication
DPD	5-FU, capecitabine	>100 exist resulting in enzyme deficiency	Severe deficiency can prolong half-life by >100-fold resulting in severe mucositis, diarrhea, and pancytopenia
TS	5-FU, capecitabine	TYMS 2R/2R	Higher expression may lead to inadequate response
		TYMS 3R/3R	Low expression can increase toxicity
CYP3A5	Vincristine	CYP3A5*3	Allelic variants reduce expression and increase risk of neurotoxicity
UGT1A	Irinotecan	UGT1A1*28	Increased risk of life-threatening diarrhea and pancytopenia, includes patients with Gilbert syndrome
TPMT	6-MP	TPMT*2, *3A, or *3C	Increases risk for pancytopenia

5-FU, fluorouracil; CYP3A5, cytochrome P450 3A5; DPD, dihydropyrimidine dehydrogenase; TPMT, thiopurine-S-methyltransferase; TS, thymidylate synthase; TYMS, thymidylate synthase; UGT1A1, uridinediphosphate glucuronosyl transferase 1A1.

Dose modifications should be considered for patients with liver disease (70), particularly for drugs that are primarily metabolized in the liver and/or excreted in the bile, such as paclitaxel, docetaxel, nanoparticle albumin-bound paclitaxel (71), doxorubicin, and the Vinca alkaloids (vincristine, vinblastine, and vinorelbine) (Table 13.9). Excessive toxicity may occur with doses that would ordinarily be acceptable, and guidelines for treating patients with impaired liver function should be consulted. However, variability in non-hepatic clearance, compensatory host adaptations, and interactions with other drugs, make these recommendations less reliable than those provided for patients with renal dysfunction. For example, dose reduction of etoposide in the setting of biliary obstruction remains controversial and may not be required (72).

Drug Interactions

During routine care, patients may receive a variety of drugs, including antiemetics, antihistamines (H_1 and H_2), steroids, nonsteroidal anti-inflammatory agents, anticoagulants, narcotics, and anti-infective agents. In addition, older patients frequently receive medication to manage underlying comorbidities, such as diabetes, hypertension, and elevated cholesterol. In view of the number and diversity of medications in common use, it is somewhat surprising that most interactions with cytotoxic chemotherapy appear to be of little consequence. However, prospective studies of chemotherapy administration in non-cancer volunteers are impractical, and many potential interactions have not been fully explored. In fact, patients are likely to be excluded from enrollment on clinical trials on the basis of concomitant medications, due to the lack of prospective collection of valuable data to document safety or the need for treatment modifications. In clinical practice, the occurrence of excessive hematologic and/or non-hematologic toxicity in an individual patient is usually attributed directly to the chemotherapy and managed with treatment modifications, rather than ascribed to a potential drug interaction.

When they occur, drug interactions can be critical, and some of the more important interactions are listed in Table 13.11. Particular attention should be paid to drugs that could alter renal function, such as aminoglycoside antibiotics, nonsteroidal anti-inflammatory agents, and diuretics, in patients with reduced fluid intake. Typical interactions relevant in gynecologic cancer chemotherapy are the displacement of methotrexate from its transport protein by aspirin or sulfonamides, suppression of pseudocholinesterase by alkylating agents with increased apnea duration during succinylcholine-assisted general anesthesia, impairment of doxorubicin clearance by pre-administration of paclitaxel, and impairment of paclitaxel clearance by pre-administration of cisplatin.

TABLE 13.11 Physiologic and Pharmacologic Interactions in Cancer Chemotherapy

Physiologic Condition	Causation	Impact and Examples
Renal insufficiency	Obstruction, chronic kidney disease, hypovolemia, hypotension, non-steroidals, nephrotoxins (aminoglycosides, cisplatin)	Decreased clearance of methotrexate, carboplatin, and other agents
Hepatobiliary dysfunction	Biliary obstruction, hepatitis, cirrhosis	Decreased clearance of doxorubicin, mitoxantrone, vincristine, vinblastine, etoposide, paclitaxel, docetaxel
	Gilbert syndrome, impaired glucuronidation and polymorphisms (UGTA1A)	Increased exposure to SN-38 (from irinotecan)
	Decreased microsomal activity	Impaired activation of cyclophosphamide and ifosfamide

Reduced protein binding	Carrier displacement (sulfonamide, salicylates, phenytoin)	Increased toxicity, higher free drug levels (methotrexate)
	Reduced carrier proteins (malnutrition)	Increased toxicity, higher free drug levels (cisplatin, paclitaxel, docetaxel, etoposide, SN-38)
Altered intestinal absorption	Oral antibiotics (neomycin)	Decreased absorption of methotrexate
	High-fat meal	Increased bioavailability of lapatinib
		Decreased bioavailability of capecitabine
	Grapefruit juice (intestinal CYP3A4 inhibition)	Increased bioavailability (cyclosporine, erythromycin, benzodiazepines)
Decreased metabolism	Caused by allopurinol	Delayed clearance of 6-mercaptopurine
	Dihydropyrimidine dehydrogenase (DPD) deficiency	Lethal toxicity from 5-fluorouracil
Cholinesterase inhibition	Caused by cyclophosphamide	Decreased clearance of succinylcholine
Monoamine oxidase inhibition	Caused by procarbazine	Neurotoxicity and seizures (tricyclic antidepressants and phenothiazines)
MDR-1 competition	Associated with natural products and other substrates, including verapamil, cyclosporine, tamoxifen	Decreased efflux and increased toxicity from natural products (doxorubicin, vincristine, paclitaxel, docetaxel)
CYP2C9 Inhibition	Caused by capecitabine	Increased AUC of warfarin
CYP3A4 Induction	Caused by glucocorticoids, barbiturates, rifampin	Increased activation of cyclophosphamide
Inhibition	Caused by ketoconazole, itraconazole, fluconazole, erythromycin	Decreased metabolism of substrates (potentially significant)
Substrate competition	Caused by cyclophosphamide, ifosfamide, paclitaxel, docetaxel, etoposide, vincristine, vinblastine, tamoxifen, gefitinib	Decreased metabolism of other substrates (usually not clinically significant)

Increased attention has been focused on drug metabolism and potential interactions with CYP isozymes, particularly CYP3A4, which has been linked to the metabolism of nearly half of all pharmaceutical agents (73). These interactions are guided by several common principles. Drugs that are *substrates* for the same isozyme may competitively inhibit metabolism, but these interactions are usually not of clinical consequence. Drugs that *directly inhibit* CYP isozymes without being a substrate for that isozyme are more likely to have clinical consequences. In this regard, itraconazole, ketoconazole, and fluconazole can inhibit CYP3A4 at low concentrations, and erythromycin can inhibit CYP3A4 via covalent binding and inactivation. Other drugs act as *inducers* of CYP isozymes by increasing gene expression or protein levels, such as glucocorticoids, barbiturates, and rifampin, which can increase the net activity of CYP3A4, resulting in decreased concentrations of susceptible compounds. In addition, many drugs that interact with CYP3A4 are natural products and may also interact with ABC family drug efflux pumps, including MDR-1. Among the anticancer agents that

are substrates for CYP3A4 are cyclophosphamide, ifosfamide, docetaxel, etoposide, paclitaxel (also CYP2C8), docetaxel, vincristine, vinblastine, and tamoxifen (74). Many tyrosine kinase inhibitors inhibit CYP enzymes. Cyclosporine and verapamil can increase concentrations of doxorubicin and etoposide, probably through blockade of the P170 drug efflux pump.

Owing to the diversity and rapid adoption of new compounds, information regarding drug interactions is best obtained from online databases, the package insert, or directly from the manufacturer.

Prolongation of the cardiac QT interval has emerged as another important area of drug interactions and potential life-threatening toxicity. Congenital syndromes with prolonged QT interval are generally associated with mutations in protein channels involved with ion transport, most commonly inward potassium flux through the hERG (human ether-a-go-go) channel (75). Risks of polymorphic ventricular tachycardia, including Torsades de Pointes, can be accentuated by exposure to cytotoxic and/or supportive care medications that interact with these pathways. However, the effects are unpredictable, and drugs that prolong QT may have a low risk of inducing ventricular tachycardia, while other drugs, such as terfenadine, with minimal impact on the QT interval, can trigger life-threatening arrhythmias. Of particular relevance in gynecologic oncology, women tend to have a greater risk than men, with longer baseline QT intervals following puberty. In addition to direct drug-mediated effects on QT interval, it is also important to be attentive to the indirect impact of CYP isoenzymes (as discussed above), which can result in a pharmacokinetic interaction with clinical consequences.

Again, knowledge of specific drugs associated with QT prolongation is evolving, and information is best obtained from organizations that have maintained a tabulated list, such as Credible Meds (https://www.crediblemeds.org/pdftemp/pdf/CompositeList.pdf). Avoidance of concomitant high-risk medications is often a component of early-phase studies, until adequate safety data is available, and this has prevented some patients from enrolling on clinical trials.

DRUG RESISTANCE AND TUMOR CELL HETEROGENEITY

The curative potential of chemotherapy is limited by the emergence of drug resistance, which can be either intrinsic or acquired, and may involve one drug or multiple agents (pleiotropic resistance). Of interest, tumors with intrinsic or primary drug resistance to natural products often arise from duct cells or cells lining excretory organs (76). These cells, which normally detoxify, transport, and excrete a wide variety of toxic compounds, may retain these normal functions after transformation, manifesting as chemoresistance.

Intrinsic drug resistance is inferred based on clonal survival of tumor populations after initial chemotherapy exposure. Solid tumors are thought to consist of a mixture of clonal variants with different preexisting mutations and patterns of resistance. Following repetitive cycles of chemotherapy, a process of clonal selection can occur, enriching for resistant populations, even while there could be a reduction in clinical tumor volume secondary to elimination of more sensitive tumor elements.

Acquired resistance develops from cumulative somatic mutations, regulation of gene expression (including epigenetic processes), or other phenotypic alterations, over a period of time. From a clinical perspective, the end result of this process is indistinguishable from intrinsic resistance. However, acquired resistance is more likely to have a reversible component that could influence the timing and selection of subsequent chemotherapy. The best specific example is amplification of the dihydrofolate reductase (*DHFR*) gene, which is associated with acquired resistance to methotrexate (77). *DHFR* gene amplification is not generally observed prior to methotrexate exposure and can be reversed in the absence of drug exposure.

For each chemotherapeutic agent, resistance can develop via multiple mechanisms. Common mechanisms of resistance are listed in Table 13.12 and include (1) decreased uptake or increased efflux of the compound, preventing accumulation in the neoplastic cells, (2) impaired activation of the compound to its active metabolite or increased metabolism of drug to inactive metabolites, (3) alterations to the target (via changes in expression or mutation), and (4) adaptations to the

therapeutic effect (improved DNA repair or tolerance of damage).

TABLE 13.12 Specific Mechanisms of Tumor Drug Resistance

Resistance Mechanism	Examples	Specific Cellular Target or Effects
Impaired activation	5-Fluorouracil	Reduced levels of thymidylate synthase, thymidylate phosphorylase, or dihydropyrimidine dehydrogenase
	Methotrexate	Reduced intracellular polyglutamation
	Doxorubicin	Low P450 enzymes
	Cyclophosphamide, ifosfamide	Decreased microsomal transformation
	Gemcitabine	Decreased deoxycytidine kinase
Increased drug efflux	Natural products	Increased MDR1 (P 170)
	Topotecan, mitoxantrone	Increased BCRP (ABCG2)
Increased drug inactivation	Alkylating agents, platinum	Elevated glutathione and other cellular thiols
Accelerated DNA repair	Alkylating agents, platinum, radiation	Induction of DNA repair enzymes
Increased damage tolerance	Alkylating agents, platinum, radiation	Loss of DNA mismatch repair
Transport defects	Melphalan	Reduced carrier-mediated uptake
	Gemcitabine	Decreased nucleoside transporter
	Platinum	Decreased copper transporter-1
Target alterations	Methotrexate	DHFR gene amplification
	Paclitaxel, docetaxel	Increased tubulin-β3 isoforms or mutations
	Hydroxyurea, gemcitabine	Decreased ribonucleotide reductase
	Glucocorticoids	Decreased receptor binding
	Camptothecins	Decreased topoisomerase-I
	Anthracyclines, etoposide	Decreased topoisomerase-II

Multidrug Resistance

Broad-based multidrug, or pleiotropic, drug resistance has been associated with overexpression of MDR1 (P 170 glycoprotein) and/or other ABC family membrane-associated transport proteins (78). After exposure to a potential MDR or transport protein substrate, tumor cells will develop cross-resistance to a variety of structurally and functionally unrelated agents. This multidrug resistance phenotype has maximal impact on natural products and their analogs, including the anthracyclines, Vinca alkaloids, and taxanes, and is associated with increased drug efflux and a net lowering of intracellular drug concentration. Although relatively uncommon in newly diagnosed ovarian cancer (79,80), with increased utilization of

natural products, including taxanes, etoposide, and liposomal doxorubicin, this pattern of resistance generally emerges over time. A number of efflux inhibitors have been evaluated in combination with chemotherapy. However, none of these have been FDA approved for clinical use because of a tendency to accentuate host toxicity, which then requires a compensatory dose reduction. Recently, small molecule tyrosine kinase inhibitors (e.g., erlotinib, sunitinib), phosphodiesterase-5 inhibitors (e.g., sildenafil), and other naturally occurring compounds have been identified as MDR-ABC transporter antagonists and warrant further investigation, particularly if their effects can be tumor-targeted to avoid increased hematologic and mucosal toxicity (78).

Platinum Resistance and DNA Repair

Although a number of DNA alkylating agents and radiation are used in the treatment of gynecologic cancer, platinum derivatives remain the most important compounds in clinical practice. However, the dramatic success of platinum-based therapy is nearly overshadowed by the emergence of platinum resistance, and this observation has stimulated a substantial body of research over the last 35 years.

Platinum compounds are administered as inactive prodrugs that undergo aquation to form a reactive intermediate, a process that occurs more rapidly with cisplatin, compared to carboplatin, which has larger organic leaving groups. The primary cytotoxic effect involves formation of platinum-DNA adducts followed by activation of the DNA damage response and induction of apoptosis. Platinum can also form adducts with cellular proteins, but this is much less likely to result in tumor cytotoxicity. Resistance mechanisms have been identified at each point, and include decreases in intracellular accumulation, inactivation by sequestration by glutathione and other nucleophilic scavengers, increased repair of DNA adducts and/or double-strand breaks, increased tolerance of unrepaired adducts, and defects in apoptotic signaling (81). The major transporter involved in copper homeostasis, copper transporter-1 (CTR1), has a substantial role in cellular platinum uptake. Downregulation of CTR1 expression, which can be triggered by platinum in a feedback loop, leads to reduced intracellular accumulation and efficacy. Similarly, increased expression of multidrug resistance proteins can lead to resistance by increasing platinum export. Platinum analogs that do not require CTR1 for internalization and methods to increase platinum accumulation are being investigated.

Another mechanism of resistance revolves around the inactivation of aquated platinum agents by glutathione (GSH) and other cysteine-rich nucleophilic proteins. Increases in enzymes involved in GSH synthesis (gamma-glutamylcysteine synthetase) and conjugation of GSH to cisplatin (glutathione S-transferase) have also been implicated as resistance mechanisms. The exact mechanism by which GSH and other thiol compounds modulate cytotoxicity is unknown, although they can interfere with the formation of DNA-platinum adducts (82).

As noted, enhanced capacity for DNA damage tolerance and accelerated repair can play a role in resistance. Nucleotide excision repair (NER) is the major DNA repair pathway associated with removal of platinum-induced DNA adducts. Expression of ERCC1, a critical NER component, has been associated with reduced antitumor efficacy of platinum agents (83). In lung cancer, immunohistochemical evaluation of *ERCC1* levels was also predictive for survival following cisplatin-based adjuvant therapy, with improved survival in patients with *ERCC1*-negative tumors (84). However, *ERCC1* may also have prognostic significance independent of chemotherapy, as patients assigned to observation with *ERCC1*-positive tumors had better survival compared to those with *ERCC1*-negative tumors (85). Randomized trials to prospectively assign chemotherapy for lung cancer based on *ERCC1* status have suggested that higher response rates can be achieved, but without a difference in progression-free or overall survival (86). The role of *ERCC1* as a prognostic or selective factor in women with ovarian cancer seems less clear (87). Similarly, resistance can develop because of increased damage tolerance, often due to defects in adduct detection or intracellular signaling, such as loss of mismatch repair proteins (e.g., MLH1 and MSH2) (88).

Interestingly, tumors associated with germline or somatic BRCA1/2 mutations have defects in homologous recombination high-fidelity DNA repair, and tend to remain highly sensitive to platinum agents over multiple courses of treatment (89). These tumors are also more sensitive to PARP inhibition, but may develop a secondary mutation that

partially restores BRCA function, generating an unusual mechanism of resistance to platinum and PARP inhibitors.

Finally, alterations in the apoptotic machinery (loss of pro-apoptotic factors or overexpression of anti-apoptotic factors) can lead to decreased triggering of apoptosis in response to platinum agents, leading to the development of resistance. Clearly, the multifactorial development of platinum resistance mechanisms remains a major challenge in the treatment of gynecologic cancers, particularly high-grade serous ovarian cancer.

Taxane Resistance

Similar to platinum resistance, multiple mechanisms are associated with taxane resistance. Overexpression of the drug efflux protein MDR-1 has been consistently associated with resistance to paclitaxel in cell lines and in retrospective analysis of clinical outcomes (90). Alterations in microtubule dynamics through mutations in tubulin subunits, changes in subunit proportions, or shifts in expression level or phosphorylation status of microtubule-associated proteins (MAPs) are also associated with paclitaxel resistance (91). Many of these mechanisms lead to resistance to the broader class of microtubule-stabilizing agents, in addition to taxanes. Importantly, however, this is not universally true. For example, alteration of the proportion of tubulin-β3 isoforms has been implicated in resistance to paclitaxel, while retaining sensitivity to non-taxane anti-tubulin agents, such as the epothilones (92). Unfortunately, prospective randomized trials using an inhibitor of MDR-1 with paclitaxel, or with a combination of paclitaxel and carboplatin, failed to improve clinical outcomes, and required a reduction in paclitaxel dosing, due to increased hematologic toxicity (93,94). Recent preclinical studies suggest that tyrosine kinase inhibitors may be beneficial in combination with paclitaxel through their effect on MAP phosphorylation or inhibition of MDR proteins (95,96).

Neither induction of MDR proteins nor alterations in microtubule dynamics adequately explains the clinical behavior associated with weekly scheduling of paclitaxel therapy in women with ovarian cancer. For example, patients can still respond to weekly paclitaxel after progressing within 6 months of receiving three-weekly paclitaxel as a component of primary therapy (97). Preclinical studies are examining a number of diverse pathways, including angiogenesis, cytokine networks, autophagy, the apoptotic machinery, and microRNAs.

Other Mechanisms of Agent-Specific Resistance

A number of specific alterations have been identified in the setting of individual drugs (Table 13.12). For example, *DHFR* gene amplification was demonstrated in a patient with methotrexate-resistant ovarian cancer who had localized *DHFR* gene copies on an abnormally staining region of chromosome 4q (98). Methotrexate resistance has also been associated with defects in polyglutamation, limiting intracellular methotrexate accumulation (99). The action of nucleoside analogs, such as gemcitabine (2,2-difluorodideoxycytidine), is dependent on active membrane transport for uptake, which is followed by double phosphorylation and potential incorporation in DNA. This complex process offers several opportunities for development of resistance, such as decreased activity of specific nucleoside transport proteins or reduced phosphorylation by depletion of deoxycytidine kinase (100). In addition, the main enzymatic target of phosphorylated gemcitabine, the M2 subunit of ribonucleotide reductase, can undergo gene amplification in resistant cell lines (101) similar to the primary mechanism of resistance to hydroxyurea, an inhibitor of ribonucleotide reductase. Of interest, sensitivity to gemcitabine can actually be increased severalfold by prior exposure to flavopiridol, an inhibitor of cyclin-dependent kinase activity, which has been shown to accelerate catabolism of the M2 subunit protein through the proteasome complex (102). Increased levels of target gene expression or protein, including thymidylate synthase, thymidylate phosphorylase, and dihydropyrimidine dehydrogenase, have also been associated with resistance to 5-fluorouracil in colon cancer, and have been correlated with clinical outcomes following 5-fluorouracil treatment (103,104). Even a superficial analysis of these specific examples would suggest potential strategies for screening of tumor tissue to guide the selection of optimal chemotherapy regimens, providing a basis for the application of tissue, gene, and protein arrays.

Tumor Profiling

Solid tumors have traditionally been considered a homogeneous collection of clonally derived cells with similar features, but it is now clear that tumors are composed of subpopulations with diverse biologic characteristics. Through genetic instability and epigenetic processes, such as gene promoter methylation and histone modifications, these subpopulations may exhibit different properties, with an impact on chemotherapy response. In addition, there can be variability in the potential for metastatic spread among cells that appear to be similar at a morphologic and genetic level (105). Recognition of tumor heterogeneity has altered our understanding of tumor behavior, with broad implications for multiagent and multimodality treatment programs.

Following the development of model systems for screening new anticancer compounds, it is not surprising that attention was focused on the process of screening actual human tumor cells for sensitivity and resistance to chemotherapy agents (106). A variety of methods were developed utilizing clonogenic survival, ^{3}H-thymidine incorporation, vital dye exclusion, treatment of transplanted tumor xenografts, and colorimetric analysis of adenosine triphosphate levels. Although there is relatively good correlation between high-level resistance to individual agents demonstrated *in vitro* and lack of a clinical response *in vivo*, it is more difficult to predict sensitivity to specific agents, or to guide the utilization of drug combinations (107), reflecting tumor cell heterogeneity, assay complexity, and inability to evaluate the tumor–host relationship, including the impact of angiogenesis, cytokines, and immune response. A nonrandomized trial in recurrent ovarian cancer suggested good correlation between *ex vivo* assay sensitivity and clinical response (108), but this may be no better than selecting reasonable agents based on routine clinical factors, especially in the setting of recurrent disease. Importantly, there is a lack of prospective randomized data to validate these approaches, as well as concerns regarding cost-effectiveness and the logistical challenges associated with obtaining and shipping fresh tumor tissue.

With the rapid development of gene expression and proteomic arrays, mutational analysis, RNA sequencing, whole genome scanning, and whole genome sequencing, these questions have been carried to a new level of sophistication, as illustrated by The Cancer Genome Atlas project (109). In addition, as drug development has shifted toward molecular-targeted agents, there has been a request from the FDA to incorporate predictive or selective biomarkers in regulatory filing, even though the cellular pathways and regulatory networks are not always well understood. Finally, large population-based molecular data repositories are under development, with the potential to rapidly identify targets, select patients, and evaluate new drugs without randomized trials. This raises a number of interesting questions.

MANAGEMENT OF CHEMOTOXICITIES

Dose Selection, Toxicity Assessment, and Supportive Care

Chemotherapeutic regimens are universally toxic, with a narrow therapeutic index, and it is generally necessary to adjust individual doses in accordance with patient tolerance. Initial dosing is derived from body surface area (BSA), weight, renal function, and hepatic function. However, a number of other factors could further influence tolerance, including nutritional status, performance status, extent of disease, exposure to prior therapy, third-space fluid accumulations, metabolic polymorphisms, and uncharacterized drug interactions. Current dose algorithms generally fail to address these factors, although emerging pharmacodynamic and pharmacogenomic research has improved individualized dosing in selected cases.

Optimal dosing in obese patients has also been questioned, as the distribution and metabolism of drugs within adipose tissue could vary from other compartments. Obesity is a risk factor for cancer development and is common in the setting of endometrial cancer. In addition, obesity is associated with a number of other comorbidities or metabolic conditions that

could alter drug kinetics or the risk of toxicity. For these reasons, and in view of toxicity observed within previously radiated endometrial cancer patients, GOG had previously capped the BSA used for initial drug dosing to a value of 2 m^2. However, actual data to reinforce this decision are limited (110,111), and a more recent ASCO guidelines panel has recommended that obese patients should receive full weight-based dosing without arbitrary reductions or caps (112).

Consistent and standardized monitoring of host toxicity will help to prevent life-threatening events and assist in the implementation of dose adjustments. The Cancer Therapy Evaluation Program (CTEP) of the NCI has developed a detailed and comprehensive set of guidelines for the description and grading of acute and chronic organ-specific toxicity in collaboration with the FDA, international cooperative groups, and the pharmaceutical industry. Most clinical research protocols have incorporated these criteria, which are also applicable to the grading of toxicity for standard chemotherapy regimens outside of a clinical trial. The current version of the Common Terminology Criteria for Adverse Events (CTCAE) is available in electronic format from CTEP (http://ctep.cancer.gov/protocolDevelopment/adverse_effects.htm). Basic hematologic parameters from CTCAE version 4 have been summarized in Table 13.13.

An unintended consequence of our current regulatory environment is that most new medications receive single-agent FDA approval at a dose and schedule that is close to the maximally tolerated dose (MTD), increasing the likelihood of host toxicity, particularly when administered over multiple cycles. The association between dose and toxicity is usually dramatic at levels close to the MTD. As such, a modest reduction in dose or an adjustment in schedule can have a substantial impact on acute and cumulative toxicities. The impact of these minor modifications on efficacy is generally unknown, but is unlikely to be as dramatic as the impact on toxicity, and many clinicians frequently make modifications to the starting dose and/or schedule of single agents or combinations, essentially in variance from FDA-approved indications. As these modifications become integrated with clinical practice, limited supporting data emerge, usually from nonrandomized trials, but it is important to recognize that the primary FDA-approved dose and schedule is rarely changed. Many agents in common use today, including polyethylene glycol (PEG)-liposomal doxorubicin, topotecan, paclitaxel, docetaxel, and gemcitabine, are frequently modified in accordance with emerging clinical experience, but without changes in the FDA-approved regimen. It is thus important for the clinician to be aware of these emerging clinical profiles, as well as data from pivotal trials that were used to support original FDA registration.

TABLE 13.13 CTCAE Grading of Myelosuppression

Adverse Event Terminology	Grade			
	1	2	3	4
White Blood Cell Decreased (per mm3)	LLN to 3,000	<3,000 to 2,000	<2,000 to 1,000	<1,000
Neutrophil Count Decreased (per mm3)	LLN to 1,500	<1,500 to 1,000	<1,000 to 500	<500
Anemia (Hemoglobin) (g/dL)	LLN to 10.0	<10.0 to 8.0	<8.0; transfusion indicated	Life-threatening consequences, urgent intervention indicated
Platelet Count Decreased (per mm^3)	LLN to 75,000	<75,000 to 50,000	<50,000 to 25,000	<25,000

LLN, lower limit normal (institutional).

In view of the narrow safety margin for chemotherapy, it is important that all orders be reviewed by a nurse and pharmacist with oncology experience. Height, weight, calculation of BSA, ideal weight adjustments (if appropriate), pertinent laboratory values, and methods of dose calculation should be clearly indicated and verifiable. Templated orders encourage systematic review and can reduce the risk of error. In addition, it is preferable to have defined dose levels to

account for expected treatment modifications rather than relying on percentage-based modifications. For example, it is not always obvious if a percentage refers to the degree of dose reduction or the amount of drug to be administered, which becomes compounded over multiple cycles, with the potential for more than one modification. One convenient method of structured dose modification is illustrated in Table 13.14. With this approach, modifications for the subsequent course of therapy are implemented according to the degree (grade), duration, and timing of toxicity experienced during the preceding course. Although treatment can be delayed on a week-by-week basis to allow for recovery, delays of greater than 2 weeks should be avoided through dose modification and utilization of hematopoietic growth factors. With expanded utilization of combination regimens, it is also helpful to know the patterns of toxicity associated with individual drugs, as it might be appropriate to modify one component rather than an entire regimen.

TABLE 13.14 Representative Drug Dose Modifications for Hematologic Toxicity

Category (Timing)	Parameters	CTCAE Grade	Dose or Schedule Modifications
Granulocytes (day of therapy)	>1,500/mm^3	0, 1	Full doses of all drugs.
	<1,500/mm^3	2, 3, 4	Delay until recovered. If delay >7 days, reduce doses by one level or add G-CSF. If delay >14 days, reduce doses by one level and add G-CSF.
Platelets (day of therapy)	WNL	0	Full doses of all drugs.
	<LLN to 75,000/mm^3	1	Delay until recovered.
	<75,000/mm^3	2, 3, 4	Delay until recovered. If delay >7 days, reduce doses by one level.
Granulocytes (cycle nadir)	>1,000/mm^3	0, 1, 2	Full doses of all drugs.
	<500/mm^3 for ≥7 days	4	Reduce doses by one level. If already reduced, add G-CSF for future cycles.
	<1,000/mm^3 with fever	3, 4	Add G-CSF for current episode, reduce doses by one level for future cycles. If already reduced, add G-CSF for future cycles.
Platelets (cycle nadir)	≥50,000/mm^3	3	Full doses of all drugs.
	<50,000/mm^3 with bleed	3, 4	Reduce doses by one level.
	<25,000/mm^3	4	Reduce doses by one level.

CTCAE, Common Terminology Criteria for Adverse Events; G-CSF, granulocyte colony-stimulating factor; LLN, lower limit normal; WNL, within normal limits.

Dose reductions for individual drugs within a combination regimen should be based on the likelihood that a particular drug contributes to the observed hematologic toxicity.

Bone Marrow Toxicity

Bone marrow toxicity is the most common dose-limiting side effect associated with cytotoxic drugs, and neutropenia is

the most common manifestation of bone marrow toxicity, occurring 7 to 14 days after initial drug treatment and persisting for 3 to 10 days. Notable exceptions to this timeline include chlorambucil, mitomycin C, and melphalan; which can have prolonged and cumulative myelosuppression with nadirs typically 4 to 6 weeks after therapy. CTCAE grading criteria are summarized in Table 13.13. For purposes of dose modification, the absolute neutrophil count (ANC) is preferred over total white blood count, as this more accurately reflects dose tolerance and risk of infection, which is correlated with the duration of grade 4 neutropenia (ANC $\leq 500/mm^3$). Dose-limiting thrombocytopenia is less common than neutropenia, but has become more frequent with wider utilization of carboplatin and carboplatin-based combinations. A systematic approach to management of hematologic toxicity can help to reduce the risk of error and facilitate overall compliance with a treatment regimen (Table 13.14).

Radiation, alkylating agents (e.g., melphalan, carboplatin), and other DNA-damaging agents (e.g., nitrosoureas, mitomycin C), can have cumulative long-term effects on bone marrow reserve. Most other agents, including the taxanes and topotecan, show no evidence of cumulative toxicity and can be administered for multiple cycles without dose modification, once a tolerable dose is established.

In view of the frequent occurrence of neutropenia and the risk of infectious complications, utilization of G-CSF, including filgrastim or the longer-acting PEG-filgrastim, has increased. Although these agents promote more rapid granulocyte recovery, thus avoiding potential complications and facilitating the maintenance of dose intensity, their use has not been shown to improve long-term survival for patients with gynecologic cancer, compared to conservative management with modest dose reductions and cycle delay. The American Society of Clinical Oncology and European Society for Medical Oncology have published guidelines on the use of hematopoietic growth factors (113,114); key recommendations are listed in Table 13.15.

It is important to remember that G-CSF is not effective in the management of thrombocytopenia and may actually increase the degree of thrombocytopenia by diversion of immature marrow elements, a particular problem after multiple cycles of carboplatin. Recombinant megakaryocyte growth factor was evaluated as an option to maintain platelet counts in patients with protracted chemotherapy-induced thrombocytopenia (115). However, current treatment programs for gynecologic malignancies are not generally associated with a high frequency of complicated grade 4 thrombocytopenia, and the value of aggressive support appears to be limited.

TABLE 13.15 General Guidelines for Hematopoietic Growth Factor Use

Primary prophylaxis	When risk of febrile neutropenia is ⩾20% or with certain dose-dense or high-dose intensity regimens
Secondary prophylaxis	Neutropenic complication from prior cycle in which reduced dose or treatment delay may compromise outcome
Neutropenia	Should not be routinely used in patients who are afebrile
Febrile neutropenia	Should not be routinely used; consider in patients at high risk for infection-related complications or poor prognostic factors

Moderate degrees of anemia, which may contribute to chronic fatigue, are quite common in cancer patients receiving chemotherapy. With increased recognition of blood–borne viral pathogens and limited supplies of banked blood, frequent transfusions are not practical or recommended, and many patients will adapt to chronic anemia with minimal symptoms. While recombinant erythropoiesis-stimulating agents are available, the potential risks including cardiovascular events, thrombosis, and reduced tumor-related survival in placebo-controlled, randomized trials (116), have led to guidelines limiting use and prompted the FDA to implement specific Risk Evaluation and Mitigation Strategies that require physician training, registration, and auditing (117,118). Patients with anemia should undergo evaluation of iron stores, with appropriate use of iron replacement, as early as possible, particularly in the setting of endometrial and cervical cancers, which can be associated with vaginal bleeding.

Gastrointestinal Toxicity

Most anticancer agents are associated with some degree of nausea, vomiting, and anorexia. There are three major categories of nausea and vomiting: *anticipatory*, occurring prior to actual administration of chemotherapy; *acute onset*, beginning within 1 hour of chemotherapy administration and persisting for less than 24 hours; and *delayed*, beginning more than 1 day after chemotherapy administration and persisting for several days. Prophylactic management of these adverse effects improves patient acceptance and facilitates completion of therapy with full doses on schedule.

The antiemetic regimen is tailored to the emetogenic potential of the treatment, which reflects the incorporation of specific drugs, as well as the dose and schedule of drug administration. Mild nausea and vomiting can often be managed effectively with H_1 antihistamines (diphenhydramine), phenothiazines (prochlorperazine or thiethylperazine), butyrophenones (haloperidol), steroids (dexamethasone or methylprednisolone), benzamides (metoclopramide), or benzodiazepines (lorazepam). These are likely to be sufficient with drugs such as bleomycin, docetaxel, paclitaxel, Vinca alkaloids, 5-fluorouracil, methotrexate, mitomycin C, gemcitabine, PEG-liposomal doxorubicin, and topotecan.

For drugs with more severe emetogenic potential, including cisplatin, carboplatin, cyclophosphamide, or dactinomycin, a more aggressive prophylactic regimen is required. In general, these patients should receive a 5-hydroxytryptamine (5-HT3) receptor antagonist, such as ondansetron, prior to chemotherapy and repeated at 8- to 12-hour intervals for 3 days. Both compounds are also available in an oral formulation, which has been helpful in the management of delayed and/or chronic nausea after chemotherapy or nausea associated with multiday oral chemotherapy regimens. Longer-acting 5-HT3 antagonists, which require only a single intravenous or oral dose prior to chemotherapy have also become available. As a group, the 5-HT3 antagonists have been quite effective in controlling severe emesis, with few side effects, but are more expensive than prochlorperazine (119). Chronic nausea and vomiting can be a particular problem after several cycles of cisplatin and occasionally carboplatin (120). The mechanism is poorly understood, and symptoms can be difficult to control with currently available medications, prompting the use of extended steroid administration, cannabinoids, repeated dosing with 5-HT3 receptor antagonists, or utilization of substance P antagonists that block the neurokinin-1 (NK1) receptor, such as aprepitant and rolapitant.

Anticipatory nausea and vomiting can become a significant problem during repeated cycles of chemotherapy, as patients associate environmental cues (such as odor, carpeting, or paint colors) with nausea. In addition to behavioral modification, it can sometimes be modulated by pretreatment with antiemetics and amnesic drugs, such as benzodiazepines, administered orally at home prior to arriving at the treatment center. Lorazepam (0.05 mg/kg) can also be given by slow intravenous push 1 hour before therapy, with doses being continued as needed every 4 hours for up to 6 doses (121). Unfortunately, this particular schedule produces significant sedation and can be used only in hospitalized patients or outpatients with independent transportation.

Diarrhea, oral stomatitis, esophagitis, and gastroenteritis are also potential problems. Patients with significant oral or esophagogastric symptoms may have their symptoms managed with oral viscous lidocaine (2%), other topical anesthetics, or parenteral narcotics in severe cases. In general, dose-limiting mucosal injury is uncommon with platinum-based combinations, taxanes, and other single agents used in the treatment of gynecologic cancer. In refractory cases of mucositis, patients should be screened for secondary infectious complications, such as candidiasis and herpes simplex. Following treatment with irinotecan, noninfectious secretory diarrhea is a well-recognized dose-limiting toxicity associated with local exposure to the active metabolite SN-38 and is generally managed with prophylactic antimotility agents and intravenous hydration, with utilization of octreotide in severe cases. Diarrhea can also result from diffuse mucosal injury following administration of doxorubicin (including PEG-liposomal doxorubicin), 5-fluorouracil, methotrexate, and other agents. In the setting of recent surgery and chemotherapy, patients are also at increased risk for infectious diarrhea, and screening for *Clostridium difficile* is appropriate.

Alopecia

Scalp alopecia is one of the most emotionally taxing side effects of chemotherapy. Aside from long-lasting alopecia that follows cranial irradiation, it is almost always reversible, but it can be a major deterrent to successful chemotherapy. Total scalp alopecia is particularly common with drugs like doxorubicin and paclitaxel, and there is generally some degree of partial alopecia with cisplatin, carboplatin, cyclophosphamide, docetaxel, Vinca alkaloids, and 5-fluorouracil. In a minority of cases, patients treated with paclitaxel will also experience loss of eyelashes, eyebrows, and other body hair, which can be particularly distressing. A variety of physical techniques have been devised to minimize alopecia, including scalp tourniquets and ice caps designed to decrease scalp blood flow. Although partially effective, they are rarely successful with extended chemotherapy.

Skin Toxicity

Skin toxicities that occur during chemotherapy include allergic or hypersensitivity reactions (HSR), skin hyperpigmentation, photosensitivity, radiation recall reactions, nail abnormalities, folliculitis, palmar-plantar erythrodysesthesia (PPE, hand–foot syndrome), and local extravasation necrosis. Many of these are drug specific and self-limited, but occasionally they may be dose limiting.

PPE is a reversible but painful erythema, scaling, swelling, or ulceration involving the hands and feet. This occurs more often with chronic oral or intravenous medications, weekly treatment regimens, and formulations that increase drug circulation time, such as prolonged oral etoposide, weekly and continuous-infusion 5-fluorouracil, capecitabine, and PEG-liposomal doxorubicin, where it has emerged as a major dose-limiting toxicity (122).

Extravasation necrosis is a serious complication seen after tissue infiltration of vesicant drugs such as doxorubicin, dactinomycin, mitomycin C, and vincristine (123). These drugs should always be administered through a freely flowing intravenous line with careful monitoring. Caution is also required during utilization of central venous ports, as malfunctions in the needle, hub, or tubing can be associated with gradual extravasation that will not be apparent for several hours (124). Small series have reported a limited experience with local infiltration or topical application of steroids, *n*-acetylcysteine, dimethyl sulfoxide, and hyaluronidase, with variable results, and recommendations are imprecise. However, single or multiple intravenous doses of dexrazoxane, a topoisomerase-II catalytic inhibitor, appear to offer specific protection against injury from anthracyclines, including doxorubicin and daunorubicin (125,126). Severe skin necrosis from some extravasations may require surgical debridement and skin grafting.

Neurotoxicity

Peripheral neuropathy is the most common neurotoxicity encountered in gynecologic oncology and is a particular risk with administration of cisplatin, paclitaxel, docetaxel, nanoparticle albumin-bound (NAB) paclitaxel, epothilones, Vinca alkaloids, and hexamethylmelamine (127,128). Although neuropathy is less common with carboplatin than cisplatin, it can still occur, particularly in combination with paclitaxel. Peripheral neuropathy generally begins with symptoms of paresthesia accompanied by loss of vibratory and position sense in longer nerves associated with the feet and hands. It then progresses to functional impairment, with gait unsteadiness and loss of fine motor coordination, such as trouble buttoning clothes and writing. This is closely followed by loss of deep tendon reflexes and eventual development of motor weakness. With paclitaxel and other non-platinum agents, this is almost always reversible but may require several months posttherapy for substantial improvement. In more severe cases, accompanied by neuronal injury or demyelination, recovery may require active neuronal regeneration over an extended period of time, and symptoms may persist for the patient's lifetime.

In current clinical practice, neurotoxicity from widely utilized microtubule-stabilizing agents is predominant (129,130). The frequency of moderate-to-severe toxicity is more common with paclitaxel, compared to docetaxel or epothilones. Risk appears related to peak levels associated with individual doses, as well as cumulative doses over multiple cycles, which is further complicated by alternative schedules and newer drug formulations. For example, although the risk associated with NAB-paclitaxel on the FDA-approved 3-week schedule is at least as high as paclitaxel (131), the risk is reduced with NAB-

paclitaxel administered on a weekly schedule, even with higher cumulative doses. In addition, as the primary means of assessment is clinical, reported frequencies vary widely in clinical trials, reflecting variability in documenting history, and subjective and objective findings.

If related to cisplatin, neuropathy can continue to progress after therapy has been discontinued owing to ongoing axonal demyelination and loss, with long-term persistence of symptoms. Cisplatin has also been associated with permanent ototoxicity and, at higher doses, with loss of color vision (132) and autonomic neuropathy. Oxaliplatin can produce a long-term peripheral neuropathy similar to cisplatin (133), but it is also associated with transient acute reactions, including paresthesia and cold-sensitive laryngeal dysesthesia (134), which may reflect blockade of membrane ion channels (135). While the mechanism of oxaliplatin-induced neuropathy is thought to be related to chelation of calcium, ASCO recommends against infusions of calcium and magnesium as a preventative measure (136).

Although some patients report transient distal paresthesia after a single dose of paclitaxel, the onset of persistent neuropathy is generally more gradual. Neuropathy can become clinically apparent after two to three courses of therapy, with mild symptoms that resolve between cycles. Careful questioning and examination may reveal subtle findings at an earlier stage, and functional assessments have been developed that demonstrate good concordance with actual neuropathy (137). Patients with underlying neurologic problems, such as those secondary to diabetes, alcoholism, or carpal tunnel syndrome, are particularly susceptible, and substitution of docetaxel for paclitaxel can be a useful strategy in some situations. All patients who receive potentially neurotoxic therapy, especially cisplatin and paclitaxel, should be routinely queried regarding proprioception and fine motor tasks and examined for loss of vibratory sense, high-frequency hearing, and deep tendon reflexes.

In view of the frequency of neurotoxicity and the impact on daily life, there has been interest in agents that might prevent nerve damage, encourage recovery, or ameliorate symptoms; however, little high-quality data is available to recommend use of preventative agents (136). Among the agents used to ameliorate symptoms, duloxetine appears to be the most beneficial, although amitriptyline, gabapentin, and pregabalin are also commonly used.

Other neurotoxicities include acute and chronic encephalopathies, usually associated with intrathecal chemotherapy, acute cerebellar syndromes, autonomic dysfunction, inappropriate secretion of antidiuretic hormone, and cranial nerve paresis. Of particular relevance to the gynecologic cancer population, an acute reversible metabolic encephalopathy has been well-described in association with ifosfamide and attributed to the toxic metabolite chloroacetaldehyde. Risk factors for development of ifosfamide-induced encephalopathy include renal dysfunction, low serum albumin, older age, and concomitant use of aprepitant. Symptoms may improve with benzodiazepines or methylene blue (138), which may act through inhibition of monoamine oxidase activity reducing chloroacetaldehyde formation in the liver.

Genitourinary Toxicity

Renal toxicity is a well-recognized side effect of cisplatin, with implication of specific local metabolites, even though only a small fraction of cisplatin is cleared by renal excretion. In contrast, carboplatin undergoes extensive renal clearance with little risk of toxicity. Indeed, with increased substitution of carboplatin for cisplatin, and with a reduction in overall cisplatin dose intensity, there has been a decline in clinical familiarity with cisplatin-mediated nephrotoxicity. However, the expanded utilization of concurrent cisplatin and pelvic radiation for management of early-stage cervical cancer has renewed awareness of this potential problem, particularly as commonly utilized weekly dosing can exceed 100 mg/m^2 over a 3-week period. Careful attention to hydration status and saline-driven urinary output before, during, and immediately after therapy is required to reduce the risk associated with this serious complication (139).

Another troublesome side effect is hemorrhagic cystitis, which can be seen with cyclophosphamide or ifosfamide, attributed to the metabolite acrolein. With moderate-dose cyclophosphamide, this complication can be prevented by maintaining high urinary output, which reduces overall urothelial exposure to the toxic metabolites. However, patients receiving combination regimens often have reduced oral intake post-chemotherapy, and selected patients receiving cyclophosphamide might benefit from supplemental intravenous hydration. The risk of cystitis is essentially 100% with

ifosfamide, even with aggressive hydration, but this can be prevented with simultaneous administration of mesna, which binds and neutralizes acrolein in the urine (140).

Hypersensitivity Reactions

Increased utilization of paclitaxel, a natural product with poor solubility, has focused attention on the risk of HSR. For intravenous administration, paclitaxel is formulated in Cremophor-EL, a mixture of polyoxyethylated castor oil and dehydrated alcohol, which has been associated with mast cell degranulation and clinical HSR. Over 80% of reactions occur within minutes during either the first or second cycle of drug administration, and can usually be managed with prophylactic medication (corticosteroids, histamine H_1/H_2 blockade) followed by rechallenge beginning at a lower rate of infusion (141,142). Similar reactions have been reported with docetaxel and PEG-liposomal doxorubicin, but with lower frequency in the absence of Cremophor-EL. Emerging data with NAB-paclitaxel indicate a marked reduction in the risk of HSR, further emphasizing the role of formulation, vehicle, and carriers.

With improved survival and an increased utilization of second-line therapy, patients may also experience more traditional allergic reactions to selected chemotherapy agents. Carboplatin, an organoplatinum compound, has emerged as a major source of late allergic reactions. These occur most often during the second cycle of a second course of therapy, suggesting a process of antigen recall and priming of the immune response (143). Patients receiving a second course of carboplatin-based therapy should be closely monitored for early signs of hypersensitivity, to avoid more serious reactions. Unlike the situation with paclitaxel, carboplatin reactions are not readily prevented or circumvented with prophylactic medication, although inpatient (144) and outpatient strategies (145) for desensitization have been successfully utilized. It is important to note that the desensitization routine does not eliminate the allergic process, and must generally be repeated with each cycle of treatment. Of interest, the combination of carboplatin with PEG-liposomal doxorubicin has a much lower incidence of carboplatin allergy, compared to a combination of carboplatin and paclitaxel or single-agent carboplatin, and might be preferred in the management of recurrent disease (146).

Other Significant Toxicities

A comprehensive discussion of all potential toxicities associated with currently available chemotherapeutic agents is beyond the scope of this chapter. Nevertheless, a variety of other important toxicities are occasionally encountered in regimens commonly used in gynecologic oncology. These include cardiac toxicity from cumulative doxorubicin exposure, radiation recall vasculitis from doxorubicin, pulmonary fibrosis from bleomycin, gonadal dysfunction in premenopausal women from alkylating agents, and secondary acute leukemia from the chronic administration of alkylating agents, particularly melphalan, in ovarian cancer.

DEVELOPMENTAL CHEMOTHERAPY

Background

The identification, evaluation, and regulatory approval of effective drugs for cancer treatment is a long, complicated, and expensive process. Promising candidates are identified and prioritized through preclinical screening, utilizing derivatives of previously defined active agents or established drug classes or new compounds engineered to interact with a specific target. In addition, there continues to be broad screening of natural products isolated from terrestrial and marine sources. Some evidence of antitumor activity during screening must be demonstrated before clinical trials are undertaken. Thus far, all useful antitumor agents have demonstrated antitumor activity using *in vitro* or *in vivo* screening systems.

These traditional approaches are being increasingly challenged because of the large number of new genes and potential targets identified through molecular biology, genomics, and proteomics. Principles of genomic libraries, solid-phase organic synthesis, and combinatorial chemical library generation have been adopted by the pharmaceutical industry to promote high-throughput screening. As new targets are identified, a large number of related compounds can be created, beginning with lead natural products or known reagents, and then screened for improved target binding and/or inhibition of target function. Substantial bioinformatics resources are required to manage and analyze the large amount of data generated from these processes, but the accumulation of gene expression and proteomic data can facilitate "pre-discovery" modeling of potential targets and reagents prior to decision-making about actual development. To some extent, these processes have evolved in parallel, as it is clear that agents generated from a library or a database will still require some form of biologic validation prior to entering complex and expensive clinical studies.

After antitumor activity has been identified, the new agent must be formulated for human use and produced in sufficient quantities to support clinical trials. This is never a trivial achievement, as was evident from the natural supply limitations and formulation problems encountered in early trials with paclitaxel and the camptothecins. Clinical-grade material is then subjected to detailed preclinical toxicology tests in animals. These toxicology trials are done in several animal species and may explore different schedules of drug administration to provide a basis for clinical development. As such, they are time-consuming, complex, and expensive.

After all of the steps of preclinical testing are completed, new agents can enter clinical evaluation. As such, clinical trials are the primary means utilized to evaluate new agents in a systematic manner. All physicians and patients are urged to consider participation in clinical trials, which are available for almost all diagnoses and treatment circumstances. Sponsors of clinical trials include the NCI in collaboration with individual institutions and national groups, such as NRG Oncology, as well as the pharmaceutical industry and individual institutions.

Clinical Trials

Detailed rationale and methodology for clinical trials design has been covered in other sections. This section highlights key concepts related to the evolving paradigm of investigational drug development. In the traditional development of an investigational agent, phase 1 trials are designed to identify the dose, schedule, and safety profile of the agent; phase 2 trials test the safety and efficacy of a fixed dose of the drug in a larger population with a single cancer type, and determine whether the drug warrants further development; and phase 3 trials are used to validate drugs that have shown promise in phase 2 trials. However, the focus in the modern era on identification of biomarkers of treatment efficacy and development of targeted therapies has led to adaptations to the conventional clinical trial designs (Table 13.16).

TABLE 13.16 Adaptations to Traditional Clinical Trial Designs

	Traditional	Adaptations
Phase 1	Identification of MTD, DLTs, PKs	Defining dose based on target engagement or biologic effect Expansion cohorts (may be disease specific) to confirm safety and targeting or embedded phase 2 to evaluate efficacy Patient selection based on molecular markers
Phase 2	Evaluate efficacy and safety profile of a fixed-dose regimen in a single tumor type utilizing a single arm without randomization	Randomized phase 2 Enrichment strategies Basket trials Umbrella trials Phase 2/3
Phase	Randomized, double blinded trial with standard	Adaptive designs

Adaptations to Traditional Clinical Trial Design in the Modern Era

Recognizing that many agents, such as human monoclonal antibodies, may not demonstrate traditional dose-limiting toxicities (DLT) to define the MTD, some phase 1 trials have adapted their end points to include defining dose based on target engagement or biologic effect. Others have included an expanded cohort to confirm safety and targeting, or an embedded phase 2 component to estimate clinical activity. Still others are selecting patients based on molecular markers to increase likelihood of biologic effect or target engagement. Phase 1 studies can also serve to evaluate new combinations that build on standardized chemotherapy regimens, to establish feasibility and tolerability of the proposed regimen before embarking on larger trials. In certain situations, such as epithelial ovarian cancer, phase 1 trials may enroll newly diagnosed patients without prior therapy, as the experimental combinations generally incorporate other known active agents.

Traditional phase 2 studies test a single agent in patients with a specific cancer diagnosis, usually in the setting of measurable disease after one (or two) prior chemotherapy regimens. Surrogate end points thought to reflect potential clinical benefit, such as response rate, disease stabilization rate, biochemical (tumor marker) response rate, or the proportion of patients alive and progression-free at a specific time interval, are typically used to evaluate efficacy and are compared to historic comparators. Due to changes in clinical care over time (i.e., improvements in supportive care, earlier detection of recurrence, or changes in treatment standard of care), historical data may no longer reflect current expected clinical outcomes, particularly in terms of time to event (progression-free interval or overall survival) end points. In these cases, randomized phase 2 designs incorporating a control arm may be more appropriate (147).

Randomized phase 2 designs can also be used to allocate patients among two or more treatment arms to minimize potential differences in prognostic factors or other variables. Each arm is then independently tested against the same historical threshold value. Using this approach, one or both arms can be selected for further clinical development. Such randomized trials are generally underpowered for direct comparison of response rate and survival between each arm, owing to the limited number of patients.

Adaptive enrichment strategies allow for the modification of enrollment criteria, based on interim assessments of benefit in subpopulations as determined by a molecular screening approach (148). For example, at the start of the study, a companion molecular test may be performed but not used to define eligibility. If interim analyses support the hypothesis that using the molecular test predicts response to the trial agent, the eligibility criteria may be adapted to exclude patients who would not be expected to benefit.

Umbrella trials provide a centralized infrastructure to test different targeted therapies in a single tumor type in multiple sub-trials. Assignment to a sub-trial is guided by the detection of molecularly defined subsets using a centralized screening platform. In contrast, basket trials typically test a single targeted agent and enroll patients based on specific tumor molecular abnormalities regardless of tissue of origin or histology. Both of these approaches require substantial validation of the companion diagnostic test and confirmation of its link to efficacy of the study agent. However, these can be powerful approaches to studying rare molecular subtypes or rare disease types for which it would normally not be possible to conduct a randomized clinical trial. These, and other integrated strategies are intended to conserve patient resources while accelerating the overall development process, allowing for the discontinuation of arms based on interim assessments of futility (148).

Clearly, the advent of molecular diagnostics has changed the face of clinical trial designs. Though it has been suggested that the traditional sequential phase 1→2→3 trial paradigm is no longer necessary (149), at this point validation of a regimen in a rigorous, randomized phase 3 clinical trial is still required for FDA approval. In a phase 3 randomized trial, a study regimen is directly compared with an existing standard regimen in a particular clinical setting, as defined by the type of cancer, stage of disease, and prior therapy. The size and duration of the trial depends on the primary end point (progression-free survival, overall survival, or quality-adjusted survival), anticipated effect size, and the power and

precision of the statistical design. Generally, this is also a collaborative process, which combines scientific, clinical, and regulatory objectives.

Recently, adaptive designs, particularly those that allow for adaptation of study sample size or statistical objective, to maintain study power have been used to enhance the chances that the study will answer the posed question. With the push toward targeted therapy and individualized treatments, there has also been increased pressure from regulatory agencies to include companion diagnostics in phase 3 trials, to predict the likelihood of response and to select appropriate patients. However, not all presumptive biomarkers will be validated, and it is sometimes more useful to include a wider variety of patients with tumor specimens that can be studied for multiple markers and pathways. In addition, if the patient population is too narrowly defined, it may be more difficult to randomize patients to a treatment arm that does not include access to a particular drug.

FDA Approval and Post-marketing Studies

Following a successful phase 3 trial or, preferably, a group of related trials, a sponsor can apply to the FDA for marketing approval for a specific disease indication. This triggers a detailed review of data by the Oncology Drug Advisory Committee (ODAC), which then issues a recommendation to the FDA, followed by formal review and a decision by the FDA, which may grant approval or request additional data. In the United States, all commercial marketing requires FDA approval for at least one specific indication. The average time from initial drug discovery to application for an FDA-approved indication is 10 to 12 years, involving considerable expense and effort, as noted above. Supplemental phase 4 or post-marketing studies can be required by the FDA as part of the approval process, or may be performed by the sponsor to evaluate alternative drug formulations or resolve questions regarding dose, schedule, or toxicity. In addition, phase 4 studies may involve substitution of the new agent in combination with chemotherapeutic regimens already established for the disease. These studies are not commonly employed in the development of new chemotherapeutic regimens, but may provide confirmatory evidence of safety and efficacy.

Drug Interactions, Scheduling, and Sequence

Drugs should be used in their optimal dose and schedule. However, new combinations have the potential to alter the pharmacokinetics, bioavailability, toxicity, and efficacy of individual components based on substrate-dependent effects, such as a reduction in nucleotide pools or altered metabolism. Therefore, the optimal dose and schedule for individual agents within a combination might differ from their use as single agents.

As an illustration, the impact of sequence variations using cisplatin or carboplatin with either paclitaxel or topotecan has been explored in preclinical models and phase 1 clinical trials. Preclinical models showed enhanced cytotoxicity when paclitaxel was administered prior to cisplatin and antagonism by the reverse (150,151). In a phase 1 trial, administration of cisplatin prior to a 24-hour infusion of paclitaxel delayed subsequent clearance of paclitaxel, leading to more profound neutropenia compared to the reverse sequence (150). The mechanism for this effect is unknown, but it is not attributable to platinum-associated renal dysfunction. Instead, it may be related to cisplatin-mediated inhibition of cytochrome P450 mixed-function oxidases that participate in paclitaxel metabolism. Thus, the schedule ultimately adopted in clinical practice (paclitaxel followed by cisplatin) is less toxic, potentially more efficacious, and was predicted by preclinical modeling. Although carboplatin does not inhibit the cytochrome P450 mixed-function oxidases, the sequence was empirically extended to carboplatin-based combinations. In part, this sequence was based on practical considerations related to the risk of acute paclitaxel HSR, which can require interruption of treatment, and it was more acceptable to administer the carboplatin after it was clear that the patient had already tolerated the paclitaxel.

A different pattern was observed with sequences of platinum and topotecan. Preclinical models have consistently favored the sequence of cisplatin followed by topotecan, which has been postulated to interfere with repair of platinum-mediated DNA damage. However, in a phase 1 clinical trial, treatment with cisplatin on day 1, prior to a 5-day course of

topotecan, was associated with increased toxicity, compared with administration of cisplatin on day 5 after completing the 5-day course of topotecan (152). In this instance, the sequence recommended by preclinical modeling was more toxic, and the question of antitumor efficacy remains to be resolved. A similar sequence-dependent relationship was identified with carboplatin (153). However, toxicity is reduced when docetaxel is administered prior to topotecan (154), emphasizing that each new combination may require independent evaluation.

Even with a single drug, the schedule of administration can have a significant impact on host toxicity and potential efficacy. Early studies with paclitaxel utilized an arbitrary 24-hour infusion, which was selected to reduce the risk of HSR (Table 13.17). Subsequent preclinical data suggested that prolonged exposure (96 hours) might have greater efficacy. Owing to increased bone marrow and mucosal toxicity, the MTD was lowered, and the frequency of serious neuropathy was reduced. However, the 96-hour regimen did not demonstrate significant activity in patients with recurrent ovarian cancer (155). In addition, the efficacy of a 3-hour infusion was comparable to a 24-hour infusion in a phase 3 trial (156), reinforcing a clinical shift toward the convenient 3-hour schedule, which achieved a higher MTD, primarily due to a marked decrease in bone marrow toxicity, but with an increased incidence of neuropathy. This was followed by a phase 1 evaluation of a weekly low-dose 1-hour infusion, which was almost devoid of serious toxicity, including a decreased incidence of alopecia, with maintenance of clinical efficacy (157). Thus, the optimal preclinical regimen (96-hour exposure) was superseded in the clinical setting by an unexpected series of observations from empiric phase 1 trials, yielding decreased toxicity, improved convenience, and the potential for increased efficacy.

TABLE 13.17A Impact of Paclitaxel Infusion Duration and Schedule on Toxicity and Efficacy

Paclitaxel Dose and Schedule			Dose-Limiting T			
Infusion Duration (Hours)	Dose Interval (Weeks)	Single-Agent Unit Dose (mg/m2/day)	Neutropenia	Mucositis	Alopecia	Neuropat
96	3 - 4	80 - 120	+++	++	+++	+
24	3	135	++	0	+++	++
?3	3	175	+	0	+++	+++
?1	1	60 - 80	0	0	+	+

With topotecan, a different relationship was defined (Table 13.17B). Initial studies utilized an inconvenient daily infusion for 5 consecutive days, which was based on preclinical data suggesting that prolonged exposure would be more efficacious. This 5-day regimen achieved a 33% response rate in a GOG phase 2 trial in recurrent platinum-sensitive ovarian cancer with expected dose-limiting neutropenia and thrombocytopenia (158). This was followed by the evaluation of a single 24-hour infusion once every 3 weeks, achieving only a 7% response rate in a similar population (159). An attempt to define an intermediate 3-day regimen achieved only a 14% response rate (160). Topotecan was also evaluated as a prolonged intravenous infusion for 21 days to maximize the duration of exposure (161). Although the study was conducted in a different patient population, the overall response rate (35%) was similar to the 5-day regimen, and once again there was equivalent hematologic toxicity without dose-limiting non-hematologic toxicity. When evaluated as a weekly treatment program, tolerability and acceptance were improved, but the overall efficacy was reduced (162,163). In this situation, changes in drug schedule, over a wide range, were associated with substantial differences in efficacy, but without any change in the spectrum or severity of host toxicity, with the exception of reduced hematologic toxicity on the weekly schedule. Thus, each new agent must be independently evaluated in the appropriate clinical setting to select the optimal dose and schedule for cancer treatment.

TABLE 13.17B Impact of Topotecan Infusion Duration and Schedule on Toxicity and Efficacy

Topotecan Dose and Schedule			Dose-Limiting Toxicities			
Infusion Duration (Days)	Dose Interval (Weeks)	Single-Agent Unit Dose ($mg/m^2/day$)	Neutropenia	Mucositis	Alopecia	Neuropath
21	4	0.40	+++	0	0	0
5	3–4	1.25	+++	0	0	0
3	3	2.00	+++	0	0	0
1	3	8.50	+++	0	0	0
1	1	1.75	++	0	0	0
1	1	4.00	+	0	0	0

Development of Combination Regimens

With some notable exceptions, single agents are not sufficient to achieve prolonged survival or cure. Combinations of conventional cytotoxics can approach maximal cell kill by including drugs with minimal overlap of toxicities, such that antitumor effects can be summed but the toxicities dispersed. Combinations are also more likely to demonstrate activity against heterogeneous tumor populations, and effective combinations could prevent the emergence of drug resistance. However, in practice it may also encourage greater resistance among surviving cell fractions.

No direct evidence currently exists to indicate whether optimal combinations should utilize sequential single agents, doublets, or triplets. Several combinations including triplet cytotoxic therapy and sequential doublet chemotherapy were evaluated in epithelial ovarian cancer in an effort to improve on the results obtained with a standard combination of carboplatin and paclitaxel. However, based on completed phase 3 trials in approximately 12,000 women, none of the combinations achieved an improvement in clinical outcomes, providing additional support for a shift in developmental priorities toward molecular-targeted agents and other novel approaches (164).

Development of combination regimens has been guided by several principles (Table 13.18) and recommendations for phase 1 development of combination regimens have been made by the Clinical Trial Design Task Force of the NCI Investigational Drug Steering Committee (165).

TABLE 13.18 Principles of Combination Chemotherapy

Each component should have Activity against the target tumor as a single agent A different mechanism of action and cellular target A biochemical basis for additive or synergistic effects in combination with at least one of the other agents No evidence of antagonistic interactions Distinct patterns of resistance to discourage the emergence of drug-resistant phenotypes
Optimal dose, schedule, and sequence of drug administration should be determined from preclinical data and early clinical trials to maximize tumor response and minimize host toxicity.
Minimal overlap of non-hematologic toxicity is desirable to safely maintain full therapeutic doses of each component over multiple cycles.

A CONTEMPORARY CHALLENGE: DRUG SHORTAGES

Trends in drug development within the academic community and pharmaceutical industry have dramatically changed over the last 2 decades, and we are now seeing an abundance of new molecular-targeted agents, with only a limited investment in conventional cytotoxics. Many of our most widely utilized standard chemotherapeutic agents have exceeded the period of patent protection and are now produced and distributed as generic compounds. With reductions in insurance reimbursement rates and the rising expense associated with manufacturing and quality control, the profitability of generic medications and the number of generic manufacturing facilities have declined. This has contributed to intermittent and chronic shortages of a number of compounds, including cisplatin, paclitaxel, 5-fluorouracil, leucovorin, bleomycin, polyethylene-glycosylated liposomal doxorubicin, antiemetics, and steroids. Consequences include greater costs to obtain drugs through alternate sources, omission of specific drugs from standard treatment regimens, and closure or delay of important clinical trials. Solutions to this international problem are complex, and it is likely that important shortages will manifest for a number of years to come. Information on current drug shortages can be obtained from the U.S. FDA and the American Society of Health-System Pharmacists:

CONCLUSION

Although there have been significant advances in understanding the molecular biology of gynecologic malignancies, chemotherapy remains the mainstay of treatment for these cancers. Understanding the pharmacologic principles underpinning their efficacy, mechanisms of resistance, and toxicity, optimal dosing sequencing, and timing of therapy, will allow for the strategic development of combination regimens (including molecularly targeted agents) to improve outcomes for women with gynecologic malignancies.

CHAPTER 14 Pharmacology and Therapeutics in Gynecologic Cancer

David S. Alberts, Hilary Calvert, Maria Lluria-Prevatt, Paul H. Sugarbaker and Bradley J. Monk

The determinants of effective cancer drug therapies include drug disposition, tumor kinetics, and drug resistance. These factors profoundly influence the cytotoxicity of each anticancer drug and must be considered in designing therapeutic regimens. These principles are discussed in Chapter 15. In this chapter, we elaborate the basic and clinical pharmacology of cancer chemotherapeutic and biologic agents and provide a limited discussion of cytotoxic, molecularly targeted, antiangiogenetic, and modulating/supportive care drugs useful in the treatment of patients with gynecologic cancer.

DETERMINANTS OF EFFECTIVE DRUG THERAPIE

Drug Disposition Factors

The term *pharmacokinetics* describes the time course of drug disposition in body fluids and tissues through the use of mathematical models. These models use an equation or set of equations to describe the concentration versus time profile of a specific drug after administration into the body. The models are often illustrated by box diagrams, with each box or compartment corresponding to a region of the body, although the compartments may not represent real anatomic regions. A drug is considered to be uniformly distributed within a compartment if its concentration within tissues has reached homogeneity.

Pharmacokinetic models may be useful in predicting the plasma or tissue concentrations of drugs in the body after any one of several routes or methods of drug administration. The simplest model has one compartment into which the drug is assumed to be instantaneously introduced, and elimination occurs by one linear route. The disappearance of the drug from this compartment can be described by a straight line if plotted on semilogarithmic graph paper. As discussed by Tozer (1), no one-compartment pharmacokinetic model can be used to describe the disposition of commonly used anticancer drugs; nevertheless, the one-compartment pharmacokinetic model lends itself to an understanding of the concept of plasma half-life (i.e., $t_{1/2}$), which represents the time required for the concentration of a drug at any point on the plasma concentration time elimination curve to achieve half its value. This constant may be applied repeatedly, so that, for instance, only 25% of the drug remains in two half-lives. The equation for plasma half-life that can be applied to any linear plasma concentration–time elimination curve is as follows: $t_{1/2}z = 0.693/\text{slope of the linear elimination curve}$ (i.e., λ_z or rate constant for that part of the curve). Unfortunately, the determination of the terminal half-life of a drug is often poorly reproducible because it is highly dependent on measuring multiple plasma levels, often at the limit of drug assay sensitivity.

Pharmacokinetic Models

The pharmacokinetics of virtually all anticancer drugs require two- or three-compartment models for their mathematic description. These models are commonly referred to as biphasic or triphasic models (i.e., two or three phases observed on semilogarithmic plots). Conceptually, the one-compartment model relates to a drug that remains confined to the intravascular space after intravenous (IV) injection, and the two- or three-compartment model allows the pharmacokinetic description of anticancer drugs whose ultimate targets are beyond the intravascular space in tumor tissues.

Drug Clearance and Area Under the Curve (AUC)

Wisdom dictates using the simplest mathematical model that can provide the "best" fit of the actual plasma concentration time data using nonlinear least squares regression. After the mathematical model is selected, it is possible to generate the important pharmacokinetic parameters that describe the disposition of a specific anticancer drug within the body. Besides the determination of the terminal-phase plasma half-life (i.e., half-life related to the second or third phase of biphasic or triphasic plasma concentration time data), the area under the plasma disappearance curve ($AUC_0\infty$) and total body plasma clearance (Cl_T) are the most significant and clinically useful pharmacokinetic parameters. The relationship between AUC and clearance is simplified to: dose = clearance × area.

Although the height of an anticancer drug's peak plasma level (C_{max}) generally correlates with peak dose and the degree of toxicity, the drug's plasma AUC tends to correlate better with its ultimate antitumor activity and normal tissue side effects. For example, when identical doses of melphalan are administered first orally and then intravenously at a 1-month interval, because of its poor oral availability, the melphalan plasma AUC after the oral dose would be only one-third of that after the IV dose (**Fig. 14.1**). As would be anticipated, the equivalent IV dose of melphalan was associated with a twofold to threefold deeper nadir in granulocytes and a greater than twofold increase in objective response rates in various cancer types (e.g., myeloma).

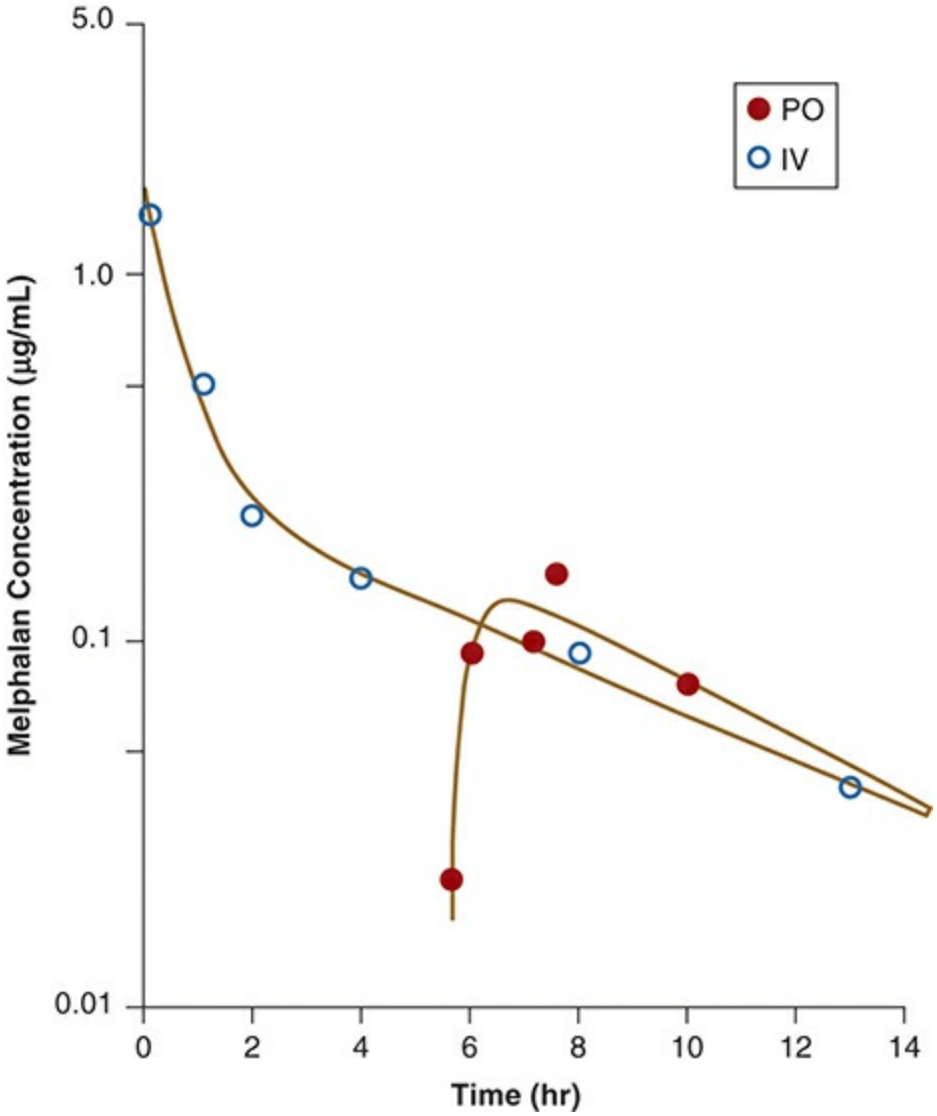

Figure 14.1 Plasma disappearance curves for IV and oral (tablets) melphalan (0.6 mg/kg) in a patient with ovarian cancer. The melphalan plasma AUC associated with the bolus oral dose was only one-third of that associated with the IV dose.
Source: Reprinted with permission from Alberts DS, Chang SY, Chen HS, et al. Oral melphalan kinetics. Clin Pharmacol Ther. 1979;26: 737–745.

The plasma AUC (in mg/mL · h) can be estimated through the use of a pharmacokinetic model or measured directly by plotting the drug's plasma concentrations against time on semilogarithmic graph paper. Then, it is possible to calculate the areas of successive trapezoids under the concentration × time curve wherein the upper surface of the trapezoid is a line that connects two successive plasma concentration data points. By convention, when the plasma AUC is measured in this way, the terminal part of the AUC is calculated using a triangular area, rather than a trapezoid.

After the plasma AUC has been determined, it is possible to derive the anticancer drug's total body clearance rate based on the following formula: Cl_T = dose (mg)/AUC (mg/mL · h). The resulting Cl_T is measured in units of milliliters or liters per minutes or hours, sometimes with normalization to the body surface area. The total body clearance of an anticancer drug depends on the drug's dose and plasma AUC and represents the rate at which the drug is eliminated from the entire body. The drug's total body clearance is made up of the combination of renal clearance (Cl_R) plus nonrenal clearance (Cl_{NR}). The renal clearance of a drug can be calculated by the following equation: $Cl_R = Ae_c/AUC$, where Ae_c is the total amount of the unchanged drug that is excreted in the urine. For many drugs that are glomerularly filtered but not reabsorbed, renal clearance is proportional to creatinine clearance (CrCl). In a patient with severe renal impairment, if

nonrenal clearance is unaltered, the total body clearance of the drug is diminished significantly. This phenomenon is observed in patients with relatively severe renal impairment who receive drugs like methotrexate and carboplatin, both of which are eliminated mainly through renal excretion.

Volume of Distribution

The volume of distribution (Vd) of an anticancer drug is another important pharmacokinetic parameter that relates the drug plasma concentration (measured at the time of administration through extrapolation of the terminal phase of the concentration–time curve to 0 time) to the total amount of drug in the body. Thus, Vd_{area} represents the volume of distribution of a drug in the terminal phase of its elimination from the body and in its simplest form, Vd = amount of drug in the body ÷ plasma concentration. Since drug levels are typically measured only in the plasma compartment and not in tissues, most reported Vd values represent the "apparent" Vd of the drug in the plasma. Thus, these Vd values represent a theoretic plasma volume that would account for the drug's plasma levels after administration. The Vd in the terminal phase can be derived using the following equation: Vd_{area} = dose/AUC slope (λ_z), where λ_z is the rate constant in the terminal phase of a biphasic or triphasic elimination curve.

Linear and Nonlinear Kinetics

Most drugs exhibit linear pharmacokinetics, which in its simplest configuration means that the C_{max} and AUC are proportionate to the dose, and the $T_{½}$ Vd and clearance are constant, that is, they do not change with the dose. Linearity helps make predictions about the effects of changes in doses since the AUC (and the biologic effects) of the drug should change in proportion to the dose. Drugs with nonlinear pharmacokinetics such as aspirin, ethanol, and phenytoin have saturable elimination patterns. This means that small dose changes can disproportionately increase the AUC and the drug's biologic effects. Drugs with nonlinear pharmacokinetic patterns may therefore have longer $T_{½}$s and much lower clearance values when the dose is increased.

As discussed by Collins and Dedrick (2), there are at least two explanations for nonlinear kinetics. First, nonlinearity may be caused by changes in drug excretion at high doses. For example, at extremely high doses of methotrexate (i.e., 7 to 8 g/m^2), the drug load outstrips renal tubular secretion capacity. Second, nonlinearity may be observed for drugs that depend almost completely on elimination through a specific degradative enzyme system (e.g., antimetabolites). Drugs like cytarabine and 5-fluorouracil administered in high doses may overcome the capacity of their respective degradative enzymes with a resultant decrease in their total body clearance rates and an increase in plasma levels that are more than proportionate to their doses.

Intraperitoneal Drug Pharmacokinetics

The administration of chemotherapy directly into the abdominal cavity (i.e., intraperitoneal [IP]) is a standard option, particularly for women with optimally cytoreduced ovarian cancer. Anticancer drugs with known activity against ovarian cancer that undergo slow clearance from the IP space into the systemic circulation without causing significant chemical peritonitis are the favored IP compounds. The most commonly administered agent is cisplatin, though both paclitaxel and carboplatin have also been effectively administered via the IP route. The IP administration of cisplatin likely results in approximately 20-fold greater concentrations of cisplatin into the IP space than are achievable with IV administration. Additionally, the IP administration of paclitaxel results in 1,000-fold greater concentration time products in the IP space than is achievable with IV administration (3). Caution must be taken when considering other agents for research-based IP administration, as some cytotoxic agents have not demonstrated efficacy and have been associated with excessive toxicity when given IP (e.g., mitoxantrone, doxorubicin) (4–7).

As with IV administration of anticancer drugs, the drug clearance rate from the IP space is the most useful pharmacokinetic parameter for comparing drugs that are administered by the IP route in the treatment of ovarian cancer. The peritoneal clearance rate can be calculated by dividing the drug dose by its IP concentration · time product, which must be measured with repeated IP fluid content sampling. Intraperitoneal drugs with slow clearance rates are favored because they result in prolonged exposure of the IP tumor bed to high concentrations of anticancer drug. It is also possible to assess the pharmacokinetic characteristics of drug doses by comparing their peak IP concentration with peak plasma concentration after IP dosing or comparing their IP concentration · time product (AUC_{IP}), with their plasma concentration · time products (AUC_{IV}) after IP dosing. Virtually all commonly used drugs administered IP in patients with ovarian cancer have peak or concentration · time product ratios of more than 20. In some cases, the peritoneal exposures can be much greater. For example, paclitaxel IP exposure with IP therapy is 300 to nearly 3,000 times greater than with IV treatment (8).

Except for drugs whose cytotoxicity depends on continuous exposure, such as cytarabine and methotrexate, drugs used by the IP route should be administered relatively rapidly in at least 2 L of peritoneal dialysate and should remain within the peritoneal space without removal. For schedule-independent drugs, it is important to maintain high concentrations as long as possible within the IP space to improve efficacy. It is of considerable interest that as the IP dialysate volume decreases, a drug's IP clearance rate increases rapidly. Thus, large volumes of IP fluid increase the chances for uniform drug distribution throughout the IP space and optimize clearance rates. Generally, it is suggested to administer the IP drug dose in the first liter of peritoneal dialysate, followed by a second liter of dialysate to the point of mild abdominal discomfort.

Ultimately, the effectiveness of IP therapy depends on the inherent cytotoxic potency of the individual agent and its ability to penetrate from the outer surface to the inner core of IP tumors. The degree of tumor penetration depends on the molecular weight, charge, and chemical structure of the compound. There is an inverse relationship between molecular weight and tumor penetration. The higher the molecular weight of the anticancer drug, the lower the degree of tumor penetration.

HYPERTHERMIC INTRAOPERATIVE PERITONEAL CHEMOTHERAPY (HIPEC)

For women with advanced ovarian cancer, the ultimate goal of treatment is to manage and prevent peritoneal metastases. However, the same is true for other gynecologic cancers, including endometrial cancer and uterine sarcoma. Cytoreductive surgery with perioperative chemotherapy is a treatment option for these patients. For women undergoing surgical cytoreduction, hyperthermic intraperitoneal chemotherapy (HIPEC) has been used in the operating room as part of the surgical procedure. An alternative procedure is for normothermic early postoperative intraperitoneal chemotherapy (EPIC), which, in contrast, is administered in the first few postoperative days. As surgeons have ascended the learning curve for this combination of extensive surgery combined with perioperative chemotherapy, the mortality has been reduced to 1% or less. Also, the grade III and grade IV adverse events have been reduced to 20% (9). Most recent publications associate the morbidity and mortality with the extensive cytoreductive surgery, and estimate the adverse outcomes from the perioperative chemotherapy to be unusual. Of course, knowledgeable management of both aspects of the combined treatment is an absolute requirement for success.

For HIPEC, agents whose maximal cytotoxic effect is completed with a 60- to 120-minute treatment in the operating room are the ones most often chosen. These chemotherapy agents should be augmented by moderate heat of approximately 42°C, which is maintained in the whole abdomen through the use of a hyperthermia pump (10). The chemotherapy agents used through an IP route or through an IV route in a multiagent HIPEC regimen are listed in **Table 14.1** (11–19).

TABLE 14.1 Agents Used in HIPEC Therapy AUC Ratio Will Vary With Total Volume of Chemotherapy Solution and Type of Carrier Solution (Colloid vs. Crystalloid)

Agent	Dose (mg/m^2)	AUC Ratio (Approximate) (Peritoneal:Plasma)
Mitomycin C	15 - 30	25
Cisplatin	75 - 250	8
Doxorubicin	15	150
Melphalan	60	33
Gemcitabine	1,000	500
Oxaliplatin	200 - 460	16
Ifosfamide (IV)	1,300	−5
5-Fluorouracil (IV)	600	2.3
Paclitaxel	175	1,000
Docetaxel	60	550

An important consideration for HIPEC and EPIC concerns the selection of cancer chemotherapy agents that may show drug synergy. The bidirectional treatment with HIPEC and the continuing treatment postoperatively with EPIC present an opportunity to eradicate the peritoneal surface component of gastrointestinal malignancy from the natural history of the disease. As surgeons learn to modify their surgical procedures to ensure a safe cytoreductive procedure, more effective combinations of both IV and IP chemotherapy used in HIPEC become the foci of promising clinical investigations.

CLINICAL PHARMACOLOGY OF ACTIVE DRUGS AGAINST GYNECOLOGIC CANCERS

We discuss below in alphabetical order the clinical pharmacology of cytotoxic, and modulating/supportive care drugs with demonstrated activity against gynecologic cancers. We also include several Food and Drug Administration (FDA)–approved drugs for other indications that may prove active against gynecologic cancers. Targeted therapies are discussed separately in Chapter 12.

Cytotoxic Agents

Albumin-bound Paclitaxel

Albumin-bound paclitaxel is FDA approved for the treatment of breast cancer after failure of treatment for metastatic disease or recurrence within 6 months of adjuvant chemotherapy. Phase III trials have demonstrated superior efficacy to castor oil–based paclitaxel and a more favorable toxicity profile (20).

Chemistry.

Albumin-bound paclitaxel (Abraxane, ABI-007) is a protein-bound form of paclitaxel that measures approximately 130 nanometers. Each vial of albumin-bound paclitaxel contains 100 mg of paclitaxel and 900 mg of human albumin. The chemical name of paclitaxel is 5β,20-Epoxy-1,2α,4,7β,10β,13α-hexahydroxytax-11-en-9-one 4,10-diacetate 2-benzoate 13-ester with (2*R*,3*S*)-*N*-benzoyl-3-phenylisoserine, and the empirical formula and molecular weight are $C_{47}H_{51}NO_{14}$ and 853.91, respectively.

Administration and Dosage.

The recommended dosage of albumin-bound paclitaxel is 260 mg/m^2 IV over 30 minutes every 3 weeks. No premedication to prevent hypersensitivity reactions is needed. Each mL of the reconstituted formulation contains 5 mg/mL paclitaxel. The exact total dosing volume of 5 mg/mL for the patient should be calculated using the following formula: total dose (mg) ÷ 5 (mg/mL). Reconstituted agent should be used immediately, but can be refrigerated for up to 8 hours. If precipitates are observed, the solution should be discarded.

Side Effects and Toxicities.

Neutropenia and sensory neuropathy are dose-dependent. In drug-approval studies, grade 4 neutropenia occurred among approximately 9% of patients, as compared with 22% of patients receiving 175 mg/m^2 paclitaxel. Infection (generally oral candidiasis and respiratory system events) occurred in approximately 23% of patients receiving albumin-bound paclitaxel. Anemia occurred among 33% of patients (severe anemia in 1%). Severe cardiotoxicity occurred in approximately 3% of patients. Dyspnea (12%) and cough (6%) were also reported among patients receiving albumin-bound paclitaxel. Patients with neutrophil counts of less than 1,500 cells/mm^3 should not receive albumin-bound paclitaxel, as it may lead to bone marrow suppression, which can result in infection.

Altretamine

Altretamine (hexamethylmelamine, Hexalen), a synthetic cytotoxic antineoplastic s-triazine derivative, has FDA approval for treatment of persistent or recurrent ovarian cancer after first-line chemotherapy with cisplatin or other alkylating agents. The drug also exhibits antitumor activity against breast cancer, lymphomas, small cell carcinoma of the lung, and endometrial and cervical cancer.

Chemistry.

The empiric formula of altretamine is $C_9H_{18}N_6$ (molecular weight = 210.28).

Mechanism of Action.

The mechanism of action of altretamine is not completely elucidated. Although it bears structural similarity to and cross-reactivity with triethylenemelamine, a classic alkylating agent, evidence demonstrating altretamine to be an alkylating agent is inconclusive. Altretamine does not consistently demonstrate cross-resistance with classic alkylating agents used in rodent tumors or in human cancer treatment, but its clinical antitumor spectrum resembles that of an alkylating agent.

Rutty and Connors (21,22) presented definitive evidence that metabolic activation of altretamine is necessary for its cytotoxic activity. It is extensively demethylated *in vivo* in the presence of liver enzymes, and these *N*-methylolmelamine derivatives are more cytotoxic than the parent compound (22). Additional studies have shown that the reactive methyl intermediates, formed during altretamine *N*-demethylations, covalently bind to tissue macromolecules, including DNA, and that the cytotoxicity against certain human solid tumor cells *in vitro* is dependent on the metabolic formation of the reactive intermediates or their direct addition to cell culture incubate(23).

Drug Disposition.

Altretamine is practically insoluble in water and, therefore, it has only been administered orally, precluding absolute bioavailability studies. After administration of altretamine to laboratory animals by any route, urinary recovery of parent drug was very low (<1%), and urinary recovery of total dose or total radioactivity after administration of ^{14}C-labeled drug was as high as 90%. Ames (23) determined that the bioavailability of the parent compound in rabbits after oral administration was 25% of that obtained after IV administration. Moreover, after giving the rabbits labeled altretamine by stomach tube, 85% of labeled drug equivalents was recovered in the urine. The high rate of recovery suggests efficient gastrointestinal absorption.

The urinary recovery and bioavailability data demonstrate that altretamine is well absorbed after oral administration and that the drug is extensively metabolized regardless of route of administration. The low bioavailability of intact altretamine is due to first-pass metabolism rather than to poor absorption.

After oral administration in doses of 120 to 300 mg/m^2, peak plasma levels, measured by gas chromatographic assay, from 0.2 to 20.8 mg/L are reached between 0.5 and 3 hours. The terminal phase plasma half-life ranges from 4.7 to 10.2 hours (24). The interpatient variability of AUCs, ranging from 1.2 to 60.1 mg/L · h, is most likely due to the differences in the rate at which the drug is metabolized.

Administration and Dosage.

The recommended dose for altretamine as a single agent for use in ovarian cancer is 260 mg/m^2/d, orally, for 14 to 21 consecutive days in a 28-day cycle (25). The total daily doses should be given as four divided oral doses after meals and at bedtime. In combination regimens, altretamine is typically used at a dose of 150 mg/m^2/d for 7 to 14 days of monthly cycles (26,27).

Side Effects and Toxicities.

With high, continuous daily dosing, nausea and vomiting were the dose-limiting toxic effects, and a form of reversible peripheral neurotoxicity occurred occasionally. Myelosuppression was mild to moderate. Leukocyte and platelet counts usually recovered within 1 week of therapy discontinuation.

In a study of 395 patients with advanced ovarian cancer treated with altretamine-containing combination regimens with or without cisplatin, no additional effect of altretamine on the incidence or severity of neurotoxicity could be demonstrated (28). Peripheral neuropathy and central nervous system (CNS) symptoms are more likely to occur in patients receiving continuous, high-dose daily altretamine administered on an intermittent schedule than in those receiving moderate doses. Neurologic toxicity reverses after the drug is discontinued. Pyridoxine should not be used concomitantly with altretamine to reduce neurotoxicity because clinical trials data suggest it may inhibit cytotoxic activity. Concurrent administration of altretamine and antidepressants of the monoamine oxidase inhibitor class may cause severe orthostatic hypotension. Cimetidine, an inhibitor of microsomal drug metabolism, increased altretamine's half-life and toxicity in a rat model.

In two phase II studies of single-agent altretamine, at a dose of 260 mg/m^2 for 14 to 21 days of each monthly cycle, the most common toxicity was grade 2 to 3 nausea (23%) (29,30). In a consolidation therapy phase II trial, only three patients (4%) experienced any grade 4 toxicity: granulocytopenia (two patients) and anxiety/depression (one patient). The most common grade 3 toxicities were malaise, fatigue, or lethargy in seven patients (7%) and nausea in six patients (6%). Aside from these, there were no other grade 3 or 4 toxicities that occurred in more than 5% of patients (30).

With continuous high-dose daily drug administration, nausea and vomiting of gradual onset occur frequently. Although in most instances these symptoms are controllable with antiemetics, the severity sometimes requires altretamine dose reduction or, rarely, discontinuation.

Altretamine should be temporarily discontinued for 14 days or longer and subsequently restarted with a 20% to 25% dose reduction for any of the following side effects: gastrointestinal intolerance unresponsive to symptomatic measures,

leukocyte count less than 2,000/mm^3 or granulocyte count less than 1,000/mm^3, platelet count less than 75,000/mm^3, or progressive neurotoxicity. If neurologic symptoms fail to stabilize on the reduced-dose schedule, altretamine should be discontinued.

Bleomycin

Bleomycin is used as palliative treatment in patients with advanced cervical (31) and vulvar cancers. Other clinical indications include squamous cell carcinomas of the head and neck, gestational trophoblast neoplasia, lymphomas, germ cell and sex cord stromal tumors.

Chemistry.

Bleomycin (Blenoxane), an antineoplastic, is a mixture of complex glycopeptides originally isolated from a strain of the fungus *Streptomyces verticillis*. The primary components are bleomycins A_2 and B_2. The family of bleomycin glycopeptides have a relatively high molecular weight and are quantitated in units of cytotoxic activity (i.e., roughly 1 U/1 mg of polypeptide protein). The molecular formula of bleomycin A_2 is $C_{55}H_{84}N_{17}O_{21}S_3$ (molecular weight = 1,414), and the molecular formula of bleomycin B_2 is $C_{55}H_{84}N_{20}O_{21}S_2$ (molecular weight = 1,425).

Mechanism of Action.

Although the exact mechanism of action is unknown, a key to its activity is the isolation of native compounds from *S. verticillis* as coordinated Cu(II) complexes, which are inactive as antitumor agents. When complexed with ferrous iron, bleomycin becomes a potent oxidase, producing DNA strand breaks by oxygen free radicals. Its unique mechanism of action is schedule dependent and cell cycle dependent for the G_2 phase.

The oxygen radicals produced by the bleomycin–iron complex bound to DNA primarily cause single-strand breaks and a lesser degree of double-strand breaks. There is a subsequent release of base propenals of all four DNA bases: guanine, thymine, adenine, and cytosine. These modified free bases result from cleavage of the deoxyribose sugar at the 3′-4′ bond. There is an apparent specificity for the release of thymine and for DNA binding at guanine-rich sequences in actively transcribed genes (32). The linker regions of DNA between nucleosomes comprise an important site for specific strand cleavage by bleomycin (33). Several mechanisms have been theorized to explain the development of resistance to bleomycin. Less important mechanisms appear to include DNA repair, membrane alterations, and decreased drug accumulation. The primary mechanism probably involves metabolic inactivation of bleomycin by a cytosolic hydrolase, which is in the cysteine proteinase family. The enzyme inactivates bleomycin by replacing a terminal amine with a hydroxyl group. The distribution of bleomycin hydrolase appears to explain some of the relative resistance and sensitivity to bleomycin in normal tissues. Normal tissues with high intrinsic hydrolase activities, such as the liver, spleen, intestine, and bone marrow, are not targets for bleomycin's toxic effects. In contrast, lung tissues and skin have low levels of hydrolase activity and are particularly susceptible to bleomycin-induced toxicity. However, there appears to be no direct correlation between hydroxylase levels in tumor cells and bleomycin-induced cytotoxicity (33). The development of other methods of bleomycin metabolism by tumor cells may be responsible for the emergence of drug resistance (34).

Drug Disposition.

Bleomycin is eliminated predominantly by urinary excretion. This accounts for 45% to 62% of a dose after 24 hours. In the blood, the drug is rapidly cleared, and two phases of elimination are apparent. As a practical point, this means that over 95% of a dose has been completely eliminated by 24 hours (about six half-lives) (35). If administered by an intracavitary route, a large percentage of a bleomycin dose is absorbed, and the fractional systemic bioavailability is about 45% for intrapleural or IP injections. The drug appears to efflux more slowly from the peritoneal cavity. This suggests that there is

significantly greater local drug retention in the IP space. This may explain some of the drug's unique efficacy by intracavitary administration (36,37). An increased exposure to drug in these local compartments is also reflected by the tenfold higher drug levels achieved with IP or intrapleural therapy than with equivalent IV dosing.

Renal insufficiency markedly alters bleomycin elimination (38,39). This effect becomes most pronounced in patients with CrCl values less than 25 to 35 mL/min (38). In these patients, the Vd is unaltered at about 20 L, but the half-life varies as the inverse exponent of CrCl. Thus, significant bleomycin dose reductions are required in all patients with reduced renal function.

Dosage.

Bleomycin (in combination with cisplatin and etoposide or vinblastine) is used most commonly by bolus IV administration at dosages of as high as 30 mg/wk for up to 12 weeks in the treatment of patients with germ cell tumors of the ovary. These 30-mg doses often are associated with delayed febrile episodes that can be inhibited successfully with a morning dose of dexamethasone or prednisone.

Bleomycin continues to be used commonly by continuous IV infusion at dosages of 10 mg/m^2/d for 4 consecutive days, with courses repeated every 4 weeks. This schedule has proven successful in the treatment of women with metastatic cervical cancer. Total bleomycin doses should usually not exceed 400 mg to avoid serious pulmonary toxicity.

Bleomycin can also be administered by the intramuscular (IM) route in doses of 15 to 30 mg. Absorption appears to be complete, and because of its lack of vesicant activity, the IM route has proven to be extremely safe (40).

Side Effects and Toxicities.

Bleomycin's dose-limiting side effect is pulmonary toxicity, which occurs in approximately 10% of treated patients and in rare instances can result in death. The likelihood of lung damage increases with advanced age, chest irradiation (41), hyperoxia during surgical anesthesia (42,43), renal insufficiency, and cumulative doses greater than 400 U. However, pulmonary toxicity is variable and may occur in younger patients following low cumulative doses. Bleomycin-induced lung damage presents as pneumonitis with dry cough, dyspnea, and rales and may progress within weeks to pulmonary fibrosis. Bleomycin should be discontinued at the first clinical signs of lung toxicity. Acute pneumonitis is often responsive to corticosteroid therapy; however, there is no effective therapy for the chronic pulmonary fibrosis that may result for bleomycin therapy (44). As a result, pulmonary function tests should be obtained before the initiation of treatment, and on day one of each subsequent cycle.

Bleomycin is nonmyelosuppressive (a factor that facilitates its use in combination chemotherapeutic regimens). Mucocutaneous toxicities, including mucositis, are the primary acute side effects of bleomycin. Manifestations of cutaneous reactions include hyperpigmentation, erythema, rash, striae, pruritus, thickening of the nail beds, and, in rare instances, scleroderma (45). Fever, chills, and alopecia are common. Mild nausea, vomiting, and anorexia may also occur, but are typically self-limiting. Infrequent side effects include headache, pain at tumor site, and anaphylactoid reactions. An idiosyncratic reaction consisting primarily of mucositis and skin rash has also been reported (46).

Because up to 70% of a bleomycin dose is eliminated by renal excretion, bleomycin dose should be reduced for individuals with severe renal insufficiency. Unfortunately, there are no prospectively evaluated dosing nomograms for bleomycin dose adjustment. An empirical dose-adjustment formula has been described (38). The percentage dose reductions that are indicated by applying this formula to a "normal" CrCl of 120 mL/min and a fractional urinary drug excretion of 0.45 are: CrCl >35 mL/min, no dose reduction required; CrCl = 20 mL/min, 50% dose reduction; CrCl = 15 mL/min, 52% dose reduction; CrCl = 10 mL/min, 55% dose reduction; and CrCl = 5 mL/min, 60% dose reduction. This is only a general guide, and it has not been clinically validated in a prospective study or retrospective analysis. Patients over 65 years of age may be at increased risk of developing orthostatic hypotension, especially when the recommended rate of IV infusion is exceeded.

Drug Interactions.

Nephrotoxic drugs may significantly reduce the rate of bleomycin clearance and thus increase toxicity. Yee and coworkers (47) observed markedly reduced bleomycin clearance in children who had received six courses of a regimen including cisplatin (cumulative dose 300 mg/m^2). In another case report, fatal bleomycin pulmonary toxicity occurred in a patient with cisplatin-induced acute renal failure (48). Similar toxic interactions should be anticipated for combinations of bleomycin with other nephrotoxic drugs, such as aminoglycosides, amphotericin, or cyclosporine.

Capecitabine

Capecitabine (Xeloda) is an orally administered antineoplastic agent. In patients with metastatic breast cancer, capecitabine in combination with docetaxel is indicated after failure of prior anthracycline-containing chemotherapy, and monotherapy is indicated for those who are resistant to paclitaxel and are resistant to anthyracycline-containing chemotherapy (or further anthyracycline-containing chemotherapy is not indicated).

Chemistry.

Capecitabine is a fluoropyrimidine carbamate prodrug form of 5′-deoxy-5-fluorouridine (5′-DFUR) that is enzymatically converted to 5-flurouracil (5-FU) *in vivo*. Its chemical name is 5′-deoxy-5-fluoro-*N*-[(pentyloxy) carbonyl]-cytidine, and its molecular weight is 359.35.

Mechanism of Action.

Capecitabine itself is inactive, but after absorption in the gastrointestinal tract is metabolized to 5-FU by three enzymes: carboxylesterase, which converts capecitabine to 5′-deoxy-5-fluorocytidine in the liver; is converted to 5′-deoxy-5-fluorouridine by cytidine deaminase in the liver and tumor tissue; and thymidine phosphorylase, which in many cases is highly expressed in tumors, completes the final step of conversion to 5-FU. Theoretically, capecitabine therapy is likely to be most effective in patients with tumors that express high concentrations of thymidine phosphorylase (resulting in greater 5-FU being generated in the tumor) and low concentrations of dihydropyrimidine dehydrogenase (which rapidly breaks down 5-FU) (49). 5-FU acts as a false pyrimidine or antimetabolite ultimately to inhibit the formation of the DNA-specific nucleoside base thymidine. The metabolites of 5-FU, 5-fluoro-21-deoxyuridine-5′-monophosphate (FdUMP) and 5-fluorouridine triphosphate (FUTP), inhibit thymidylate synthase (TS) and are incorporated into cellular RNA. DNA synthesis and function are inhibited by the incorporation of FdUNP into cellular DNA (50). A pharmacogenetic study of capecitabine in 105 consecutive patients has shown an increase in toxicity in patients homozygous for the TS 3RG allele, also showing that a patient with a DPD IVS14 + 1G>A mutation died from toxicity, emphasizing the importance of polymorphisms in the metabolizing enzymes of this drug (51).

Drug Disposition.

After oral administration, capecitabine reaches peak blood levels in about 1.5 hours, and peak 5-FU levels are reached at about 2 hours. Food reduces the rate and extent of absorption for both capecitabine and 5-FU. Plasma protein binding is not dose dependent and is less than 60% for capecitabine and its metabolites. Capecitabine (95.5% of administered dose) and its metabolites are excreted in urine. Capecitabine has no effect on the pharmacokinetics of docetaxel or vice versa. The precise pharmacokinetics of capecitabine have been difficult to establish, which is thought to be due to the large interindividual and intraindividual variation in expression of the enzyme dihydropyrimidine dehydrogenase (49).

Administration and Dosage.

Capecitabine is available as 150- and 500-mg tablets for oral use. The recommended dose is 2,500 mg/m^2 daily to be administered as two doses: 1,250 mg/m^2 in the morning and 1,250 mg/m^2 in the evening for 2 weeks, followed by a 1-week rest (21-day cycle). Because of the high rate of grade 2 or greater capecitabine-induced palmar–plantar erythrodysesthesia (PPE), recommendations have been made to reduce the starting dose to 2,000 mg/m^2 daily. It should be taken with water within 30 minutes after a meal. The same dosage of capecitabine should be used when combined with docetaxel, which should be administered at 75 mg/m^2 as a 1-hour infusion on day 1 of the 21-day cycle. Premedication (per docetaxel labeling) should be started prior to docetaxel administration for patients receiving the combination therapy.

Side Effects and Toxicities.

The only side effect that occurs more frequently with capecitabine than with IV 5-FU is PPE (15% to 20% of patients). The other more common side effects of capecitabine include diarrhea (40%) and nausea and vomiting (30% to 40%). Grade 3 hyperbilirubinemia occurred in 15.2% and grade 4 in 3.9% of patients in the clinical safety database of Xeloda. Of those patients experiencing grades 3 and 4 hyperbilirubinemia, many (64% and 71%, respectively) had liver metastases at baseline, and 57.5% and 35.5% had elevations in alkaline phosphatase or transaminases, respectively. Other less common side effects include myelosuppression (less frequent than with IV 5-FU), leukopenia, and cardiotoxicity. In general, capecitabine is relatively well tolerated.

Carboplatin

Carboplatin (Paraplatin) is a platinum-based agent that is approved by the FDA for the treatment of patients with advanced ovarian cancer of epithelial origin. It is also active against metastatic endometrial and cervical cancer.

Chemistry.

Carboplatin has a molecular formula of $C_6H_{12}N_2O_4Pt$ and a molecular weight of 371.25. Its chemical name is cis-diammine-(1,1-cyclobutanedicarboxylato) platinum(II). The water solubility of carboplatin (14 mg/mL) is approximately 10 times that of cisplatin.

Mechanism of Action.

Carboplatin, like cisplatin, produces an equal number of predominantly interstrand DNA cross-links rather than DNA-protein cross-links, causing equivalent lesions and biologic effects. The differences in potencies appear to be related to the aquation rate, which is significantly higher for cisplatin as compared with carboplatin (52). It covalently binds to DNA with preferential binding to the N-7 position of guanine and adenine (50). Like cisplatin, carboplatin must first undergo sequential losses of the nonamine carboxylato ligands. Although this process proceeds readily with the loss of the chlorides in cisplatin, the rate of leaving or “opening” of the carboxylato moieties in carboplatin is much slower (53). The molar potency of carboplatin in creating DNA lesions and cytotoxicity was observed to be roughly 2% of cisplatin *in vitro* and 25% to 33% of cisplatin *in vivo* (54,55). A more striking difference is the markedly delayed onset of peak cross-linking for carboplatin compared with cisplatin. With carboplatin, maximal DNA cross-linking occurs 18 hours after exposure compared with 6 to 12 hours for cisplatin (55). In addition, carboplatin-induced DNA cross-links appear to have a slower rate of resolution than cisplatin-induced cross-links. This slower onset and offset of carboplatin cross-linking is believed to be a direct result of a slow rate of monofunctional adduct formation or a slower rate of conversion of monoadducts to cross-links.

Although the final DNA adducts formed by cisplatin and carboplatin are the same, there are large differences in the kinetics of their formation and the rate of conversion of mono- to di- adducts (56) that could impact on the ability of various DNA repair enzymes to cause resistance. Further, cell membrane transport proteins are thought to be critical

determinants of platinum drug sensitivity and resistance. It is known that cisplatin and carboplatin differ in their transport characteristics (57). Leblanc et al. (58) showed that substantial hepatic P450 induction occurred in rats following cisplatin treatment, but not following carboplatin. Waxman et al. (59) showed that cisplatin induced glutathione S-transferase (GST) Yc expression in the liver of rats, but carboplatin did not. These data may be significant because GSTs are thought to contribute to platinum resistance. Natarajan et al. (60) extended the latter observation by showing that S-containing nucleophiles (thiourea, glutathione, and human breast cancer MCF-7 cell cytoplasmic extracts) significantly decreased the formation of DNA platinum adducts from cisplatin, but significantly increased them from carboplatin. Despite the pharmacokinetic and mechanistic differences between carboplatin and cisplatin, phase III studies and meta-analyses of clinical studies reveal equivalent activity between carboplatin and cisplatin in all prognostic subgroups of ovarian cancer patients (61,62). However, meta-analysis is performed on pooled data. It is entirely plausible that subsets of ovarian cancers with differing genetic phenotypes will respond differentially to cisplatin and carboplatin.

Harrap (63) described nuclear protein phosphorylation after treatment with both cisplatin and carboplatin. These events appear to correlate with cell killing (64). Carboplatin reacts with two sites on DNA to produce cross-links, as has been observed with cisplatin (65). The formation of DNA adducts results in the inhibition of DNA synthesis and function and inhibits transcription (50). These lesions involve a bifunctional platinum adduct to a single-strand DNA. This may produce transcriptional miscoding and an inhibition of DNA synthesis. It is possible that the cytotoxic effects of carboplatin are the result of binding to nuclear and cytoplasmic proteins. Carboplatin-induced cytotoxicity is not cell cycle phase specific, but it can be maximized by exposing cells in S phase to the drug.

Drug Disposition.

The pharmacokinetics of carboplatin differ significantly from those of cisplatin. **Table 14.2** shows that the plasma clearance of carboplatin is biphasic and slower than that of cisplatin, with a much higher percentage of drug being excreted in the urine. Unlike cisplatin, carboplatin binds to plasma proteins relatively slowly so that in the first 24 hours after administration, there is a considerable concentration of the free drug circulating. The major route of elimination of carboplatin is glomerular filtration and tubular secretion. There is little or no true metabolism of the drug. The carboxylato bonds in carboplatin are slowly hydrolyzed to yield transient aquated intermediates. These activated platinum species are believed to lead directly to irreversible adducts to DNA or protein. Overall, the rate of hydrolysis of carboplatin is significantly slower than that of cisplatin, leading to much slower reactivity with DNA (66). Because at least 65% of a carboplatin dose is excreted in the urine, significant dose adjustments are recommended for patients with CrCl values less than 60 mL/min. However, since the widespread use of formula-based dosing (see Administration and Dosage section, below), these reductions are implicit in the use of the formula and need not be separately calculated.

TABLE 14.2 Carboplatin Pharmacokinetics

Cumulative 24-hour Urinary Excretion	65% (if Creatinine Clearance >60 mL/min)
In vitro half-life (H_2O)	~24 hours
Plasma half-life β phase (free drug)	180 minutes
Protein-bound drug	>5 days
Volume of distribution	16 - 20 L
Protein binding	30% (slow equilibration)

Carboplatin is widely distributed in body fluids and achieves good penetration into pleural effusions and ascites fluid (67,68). Pharmacokinetic studies in patients receiving continuous carboplatin infusions show that, although total platinum levels increase over the course of the infusion, free or active platinum levels can decrease from 78% on day 1 to 38% on

day 4 of a 4-day infusion.

Administration and Dosage.

Carboplatin is usually administered as a brief infusion in a solution of 0.9% sodium chloride or 5% dextrose in water. The drug is typically diluted in 500 mL of fluid and infused IV over 15 to 30 minutes to 1 hour without further hydration (69,70). Carboplatin has also been administered as a continuous 24-hour IV infusion for 1, 4, or 5 days or as a continuous IV infusion for 21 days.

The Calvert equation is the most frequently used formula for carboplatin dosing, inasmuch as it requires minimal calculations, results in predictable levels of myelosuppression, and prevents underdosing or overdosing in patients with excellent or poor renal function, respectively (71). The Calvert formula appears below along with general guidelines for selecting the specific carboplatin AUC.

Carboplatin total dose (mg) = AUC (mg/mL · min) × [GFR (mL/min) + 25] AUC = 7 when carboplatin is used as a single agent in patients with good bone marrow reserve; 6 when carboplatin is used in combination regimens in patients with good bone marrow reserve or when used as a single agent in patients who have had prior moderate chemotherapy; and 4 when carboplatin is used as a single agent in patients with prior heavy chemotherapy exposure.

Glomerular filtration rate (GFR) can be determined by measuring CrCl (i.e., [^{51}Cr]-ethylenediamine-tetraacetic acid) for all patients or estimated CrCl for patients who have had no prior cisplatin exposure or have not had cisplatin for at least 2 months before carboplatin dose determination.

As an example, if the desired carboplatin AUC is 6 for a patient with an estimated CrClof 75 mL/min, the total carboplatin dose would equal 6 × (75 + 25), or 600 mg.

As already noted,, the Calvert formula uses the following estimate of carboplatin clearance: Cl = GFR + 25. Although the method may be optimal (72), isotopic determination of the GFR as measured by [^{51}Cr]-ethylenediamine-tetraacetic acid (^{51}Cr-EDTA) is not available in many countries, and the estimated CrCl is often substituted for the GFR. A commonly used method for estimating CrCl is the Cockroft–Gault (CG) equation (73):

$$CrCl = \frac{(140 - Age) \times Wt \times (1 - 0.15 \times Sex)}{(72 \times SCr \times 0.0113)}$$

CrCl = Creatinine clearance; Age = Age in years; Sex = 1 if female, 0 if male; SCr = Serum Creatinine in mmol/L; Wt = Weight in kg.

Both the CG calculation of CrCl and the CrCl based on a 24-hour urine collection result in a systematic underestimation of the carboplatin AUC by approximately 10% (74–76). This level of bias may be deemed acceptable in view of the clinical utility of substituting CrCl for GFR. Significantly, the accuracy of the CG calculation depends on the method used for measuring creatinine. When the CG formula was derived, a colorimetric reaction was used that significantly overestimates the plasma level of creatinine. A more accurate measurement uses an enzymatic method (77). The use of a more accurate method combined with the CG formula leads to an unexpectedly high dose of carboplatin. Recently, creatinine measurements in the USA have been standardized using isotope dilution mass spectrometry, leading to potential overdosage in some trial protocols and a recommendation for a dose cap (78). The issue of using a creatinine-based estimate of the GFR has been approached by Wright et al. (77) where alternatives to the CG formula are proposed for use with differing creatinine assays.

The Calvert formula was prospectively evaluated by Sorenson et al. (79) in 24 previously untreated ovarian cancer patients and was found to predict more accurately carboplatin exposure than calculation of dose based on body surface area. The AUC of carboplatin as calculated by the Calvert formula accurately predicted the level of myelosuppression as determined by the relative decrease in the platelet count (79).

Side Effects and Toxicities.

Although the activity is comparable to cisplatin, carboplatin is better tolerated, as measured by toxicity (e.g., low incidence of alopecia [80]) and quality-of-life analysis (62). The usual dose-limiting toxicity of carboplatin is bone marrow suppression, particularly thrombocytopenia (81). Leukopenia and anemia also occur but are less severe.

The platelet nadir is achieved 2 to 3 weeks after an IV bolus injection, and recovery is generally complete 4 to 5 weeks after dosing. However, patients with poor bone marrow reserve from previous chemotherapy or radiation therapy can have more profound thrombocytopenia and leukopenia with carboplatin treatment. Cell depletion may persist for several weeks after dosing.

Nausea and vomiting induced by carboplatin is much less severe than with cisplatin and rarely lasts beyond 24 hours. In a study of 943 ovarian cancer patients randomized to carboplatin, only 9% experienced greater than grade 2 nausea and/or vomiting (80). Emesis can usually be blocked entirely with aggressive therapy using antiemetic drug combinations (82). Diarrhea has been reported in only 6% of patients, and constipation in 3% of carboplatin-treated patients (83).

Nephrotoxicity has been reported with carboplatin, but it is much less common and less severe than with cisplatin. In a large review, transient elevations in serum creatinine and blood urea nitrogen were described in 7% and 16% of patients, respectively (83). Measured CrCl s dropped in 25% of patients, and a slight increase in uric acid was described in the same percentage of patients. However, there can be a significant loss of serum electrolytes, including potassium (16% of patients) and magnesium (37%). Serum calcium is only rarely decreased after carboplatin (83).

A few cases of carboplatin-induced hematuria have been described. Hepatic enzyme elevations occasionally occur with carboplatin (83). Alkaline phosphatase was transiently increased in 36% of patients, and serum glutamic oxaloacetic transaminase (SGOT) or serum glutamic pyruvic transaminase (SGPT) in about 15% of patients. Serum bilirubin levels are rarely elevated (4%) (83).

Neurotoxicity is uncommon after carboplatin and was described in only 25 of 428 (6%) patients treated on a variety of schedules for different tumor types (83). Mild paresthesias have been reported in a few patients receiving cumulative carboplatin doses of more than 1.6 g/m^2 (81). Unlike cisplatin, these peripheral nerve toxicities rarely produce any disabling symptoms. In most cases, no neurotoxicity was attributed to the drug.

Ototoxicity does not appear to be problematic with carboplatin, and only 8 of 710 (1.1%) patients have described clinical hearing deficits, mainly tinnitus (83). However, if pretreatment and serial audiometric tests are performed, as many as 15% of the patients may have some decrease in audio acuity. Fortunately, ototoxicity from carboplatin sometimes improves after therapy is halted. Like cisplatin, greater ototoxicity from carboplatin can be expected in patients with preexisting hearing loss or in those concurrently being given other ototoxic drugs, such as aminoglycosides.

Other rare carboplatin toxicities include alopecia (2% of patients), mucositis (2%), skin rash (1.7%), injection site irritation without extravasation necrosis (0.4%), and a flu-like syndrome (1.3%) (83). The same study described alterations in taste sensation. Skin disorders from carboplatin treatment may appear as an erythematous rash in exposed areas, and do not occur in all patients who had developed similar rashes on cisplatin (81).

Although carboplatin-associated hypersensitivity reactions rarely occur when the drug is administered as part of an initial chemotherapeutic regimen, subsequent administration of carboplatin in the setting of second-line or salvage therapy is associated with an increased risk of hypersensitivity. It has been estimated that over 25% of patients who receive more than six courses of platinum-based (i.e., cisplatin or carboplatin) chemotherapy develop sensitivity to carboplatin (84). The onset of symptoms may occur during the carboplatin infusion or up to 3 days after drug administration. Mild reactions consist of localized itching and erythema, primarily of the palms and soles, and/or facial flushing, whereas severe reactions can cause diffuse erythema, tachycardia, wheezing, facial edema, chills, rigors, throat and chest tightness, dyspnea, vomiting, alterations in blood pressure (both hypotension and hypertension), and, in extreme cases, respiratory arrest. Mild cases may respond to IV diphenhydramine (50 mg) or oral diphenhydramine (25 to 50 mg every 4 to 6 hours), and additional courses of carboplatin can be administered. Severe hypersensitivity reactions typically necessitate the discontinuance of carboplatin; however, some patients are able to receive additional courses of carboplatin preceded by the administration of corticosteroids for several days prior to carboplatin administration. Hypersensitivity reactions may also

occur when carboplatin is administered by the IP route (85).

Platinum-based chemotherapy (either cisplatin or carboplatin) has been shown to increase the risk of leukemia in ovarian cancer patients (86) Following carboplatin-based chemotherapy, the estimated relative risk of leukemia is 6.5 (95% CI, 1.1 to 9.4). The relative risk increases as a function of both cumulative dose and duration of treatment. Patients who receive 4,000 mg or greater of carboplatin have a relative risk of 7.6 of developing leukemia, whereas patients who receive more than 12 months of carboplatin-based chemotherapy have a relative risk of 7. Although radiation therapy alone does not increase the risk of leukemia, radiation therapy administered in combination with platinum-based chemotherapy is associated with a significantly higher risk of leukemia than platinum-based chemotherapy without radiation ($p = 0.006$). The average time to onset of secondary leukemia is 4 years after the diagnosis of ovarian cancer. Although the potential benefits of platinum-based chemotherapy for ovarian cancer far outweigh the risk of secondary leukemia, the dose-dependent leukemogenic potential of platinum-based chemotherapy should be considered during its administration to patients with early-stage disease.

Drug Interactions.

Although the pharmacokinetics of carboplatin are not altered by coadministration of paclitaxel, patients who receive combination chemotherapy with carboplatin plus paclitaxel experience less thrombocytopenia than would be predicted if carboplatin was administered as a single agent (74,87). The relationship between free platinum exposure and thrombocytopenia following carboplatin/paclitaxel chemotherapy can be described by a sigmoid maximum effect model (74). In that the degree of neutropenia appears to be unaffected by coadministration of paclitaxel and carboplatin, this pharmacodynamic interaction is believed to occur at the megakaryocyte level (87).

The cytoprotective agent amifostine reduces carboplatin-induced thrombocytopenia (88) but also extends the plasma half-life of carboplatin (89). In a randomized trial of carboplatin with or without amifostine, the median platelet nadir of patients treated with carboplatin 500 mg/m^2 was 88,000/μL, whereas the nadir in patients who received amifostine 910 mg/m^2 was 127,000/μL ($p = 0.023$) (88). Pharmacokinetic studies have shown that amifostine administered just before the carboplatin infusion and 2 to 4 hours thereafter is associated with a significant increase in the terminal half-life of the ultrafiltrable platinum species (e.g., in patients with a CrCl less than 80 mL/min, the platinum half-life increased from 4.2 to 5.6 hours with the addition of amifostine). In patients with good renal function, the impact of the increase in terminal half-life was associated with a minimal effect on the AUC. However, patients with impaired renal function experienced significant increases in the AUC of the ultrafiltrable platinum species (89).

Special Applications.

Patients with advanced ovarian cancer have been treated with IP carboplatin in doses ranging from 200 to 650 mg/m^2 (90). Pharmacologic studies have demonstrated that serum concentrations are equivalent between IV and IP carboplatin regimens, but IP administration results in more than 10 times the concentration in the peritoneal cavity as compared with IV administration (91). However, cisplatin may be a better choice for IP delivery in that it appears to have significantly better penetration into tumor masses than carboplatin (92). Several early-phase trials show potentially promising results (93,94); however, there is a need for phase 3 research to determine the possible efficacy of IP carboplatin, and trials to determine the optimal dosing schedule.

Cisplatin

Cisplatin (Platinol, *cis*-diamminedichloroplatinum II) is a primary drug in the treatment of advanced cancer of the ovary, cervix, and endometrium.

Chemistry.

Cisplatin has the molecular formula $PtCl_2H_6N_2$ (molecular weight = 300.1). It is a planar inorganic heavy metal complex containing a central atom of platinum surrounded by two chloride atoms and two ammonia molecules in the *cis* position. It is soluble in water at a concentration of 1 mg/mL. Only the *cis*-isomer is therapeutically active.

Mechanism of Action.

Cisplatin's interaction with DNA is probably its primary mode of action. The antitumor effect of cisplatin has been correlated with binding to DNA and the production of intrastrand cross-links and formation of DNA adducts, similar to carboplatin (65,95). Intrastrand cisplatin adducts can cause changes in DNA conformation that may affect DNA replication (96). Platinum DNA adduct levels have been measured in patients' leukocytes and correlated with clinical response (95).

Mechanisms of cisplatin drug resistance are the foci of concentrated research. Methods by which tumor cells may develop resistance to platinum agents include decreased drug accumulation, increased glutathione levels, enhanced DNA repair, and increased capacity to tolerate DNA damage (97,98).

The ERCC1 repair protein is part of the nucleotide excision repair system, which takes part in single-strand break repair. It is thought that this system may be responsible for the removal of intrastrand DNA platinum adducts from DNA. High expression of ERCC1 has been associated with platinum resistance and poorer survival in ovarian cancer patients treated with platinum-based regimens (99) [H10]. ERCC-1 has also been identified as playing a critical role in the synergy of gemcitabine and cisplatin. Phase 2 data suggest that gemcitabine may reverse cisplatin resistance, as gemcitabine–cisplatin combination therapy was active in platinum-resistant ovarian cancer patients (100).

Resistance to platinum drugs has also been associated with the activity of the double-strand break repair system, homologous recombination (HR) repair. Tumors arising in patients with germline *BRCA1* and *BRCA2* mutations respond better to platinum-based therapy and survive longer on treatment than their BRCA wild-type counterparts (101–103). Both *BRCA1* and *BRCA2* are involved in HR, and patients whose tumors contain somatic *BRCA*1/2 mutations or who show impaired HR ("BRCAness") also respond better and survive longer on platinum-based therapy than case controls (104,105). The idea that platinum resistance may be mediated by HR is supported by the observation of secondary mutations that reactivate either the *BRCA1* (106) or the *BRCA2* (107,108) proteins when these patients eventually become resistant to platinum drugs.

In vitro studies have shown that the copper transporter, CTR1, plays a regulatory role with respect to the uptake of platinum drugs (109). In a study of 40 patients with ovarian carcinoma, Yoo-Young Lee et al. (110) showed that high CTR1 expression was specifically associated with sensitivity to platinum-based therapy and prolonged progression-free survival while low CTR1 expression and high STR2 expression were associated with resistance to platinum-based therapy and shorter survival.

Mechanisms of resistance also include the increased inactivation of thiol-containing proteins such as glutathione and glutathione-related enzymes, a deficiency in mismatch repair enzymes (e.g., hMHL1, hMSH2), and decreased drug accumulation due to alterations in cellular transport (50).

A study of hMLH1 methylation in the plasma DNA of ovarian cancer patients at presentation and relapse showed no correlation with outcome at presentation, but high methylation was associated with poorer outcome following relapse (111). Whether this was due to resistance to platinum drugs is not clear because the report does not document the treatments given following relapse. Further, a follow-on randomized Phase 2 study using decitabine to induce demethylation of the HMLH1 promoter showed an inferior outcome in the decitabine arm (112). The clinical relevance of mismatch repair defects in the response to platinum agents remains uncertain.

Recent evidence also suggests that resistance to platinum and other agents may be mediated by factors in the tumor environment rather than in the tumor cell itself. Roodhart et al. (113) have identified two distinct platinum-induced polyunsaturated fatty acids, 12-oxo-5,8,10-heptadecatrienoic acid (KHT), and hexadeca-4,7,10,13-tetraenoic acid (16:4(n-3)), that in minute quantities induce resistance to a broad spectrum of chemotherapeutic agents, including platinum agents.

Drug Disposition.

Cisplatin demonstrates a triphasic disappearance curve with a $t_{1/2\alpha}$ of 20 minutes, a $t_{1/2\beta}$ of 48 to 70 minutes, and a terminal-phase half-life of 24 hours (114). The first two phases of disappearance represent clearance of free drug from the plasma, and the third phase is probably removal of drug from the plasma proteins. The ratio of cisplatin to total free platinum in plasma has a great deal of interpatient variability: from 0.5 to 1.1 after a dose of 100 mg/m^2. Three hours after a bolus injection and 2 hours after a 3-hour infusion, 90% of the plasma protein is bound to the platinum in cisplatin, not the cisplatin itself. The complexes between albumin and platinum are slowly eliminated with a minimum half-life of 5 days or more (115). Ninety percent of the drug that is excreted is removed by renal mechanisms (i.e., glomerular filtration and tubular secretion), and less than 10% is removed by biliary excretion. Fecal excretion appears to be insignificant. The total proportion of a given dose that is excreted is variable and has been reported to be between 31 and 85% after 51 days (116). The remainder remains bound to tissues for very long periods. Schierl et al. (117) reported two long-term biologic half-lives of platinum of 16 and 720 days and showed that, of an administered dose of 800-mg cisplatin, 1 mg remained in a long-term pool after 3,000 days. There is a potential for accumulation of ultrafilterable platinum plasma concentrations whenever cisplatin is administered on a daily basis but not when dosed on an intermittent schedule.

Administration and Dosage.

Cisplatin may be administered intravenously or intraperitoneally. Cisplatin should be mixed only in solutions containing 0.9% or more sodium chloride, because drug stability is directly related to the concentration of the salt. When admixed with dextrose-containing solutions, by chromatographic analysis, the drug appears to be relatively unstable, with decomposition evident by 2 hours (118). Platinum also can form significant, colored complexes if directly admixed with mannitol and stored for 2 to 3 days (119). Short-term (<24 hour) admixtures, however, have been successfully used. Needles or IV sets containing aluminum should not be used in the preparation or administration of cisplatin, because this drug rapidly reacts with aluminum, resulting in a loss of drug potency and the formation of a black precipitate (120).

To protect against nephrotoxicity, it is critical that a high urinary output be maintained during cisplatin therapy. Several methods of accomplishing this have been recommended; however, the most widely practiced method involves prehydration and mannitol diuresis (121). If cisplatin is administered in a hospital setting, patients should receive hydration with 1 to 2 L of fluid prior to cisplatin. Mannitol diuresis is accomplished by diluting the cisplatin in 2 L of normal saline containing 37.5 g of mannitol. The solution is then infused over 6 to 8 hours. Adequate hydration and urinary output should be maintained during the next 24 hours. A safe outpatient procedure using concurrent mannitol that appears to prevent serious nephrotoxicity has also been reported (122). The desired dose of cisplatin plus 50 g mannitol is diluted to 1 L with 5% dextrose plus 0.45% sodium chloride, USP. This solution may then be infused at a rate of no greater than 1 mg/min. For patients with known cardiac disease, the dose may be placed in 200 mL of a 10% mannitol solution and infused at a rate of no greater than 1 mg/min. This is followed by 200 mL of additional 10% mannitol. An alternative is to add the drug to 400 mL of 10% mannitol that is then brought up to a 1-L volume with normal saline containing 3 g of magnesium sulfate and administered intravenously over 1 hour (123).

Intraperitoneal cisplatin administration requires that an implantable device (IV port, such as single-lumen venous-access catheter: 9.6F, Port-A-Cath or Bardport) be surgically placed in the IP space. It is important to note that peritoneal or fenestrated catheters can lead to fibrous sheath formation, small bowel obstruction and perforation, and should be avoided (124). Day 2 IP administration requires that cisplatin be mixed in 1 L of normal saline and then warmed to body temperature. The 1-L cisplatin solution is instilled as rapidly as possible into the IP space via the catheter, and should be followed by up to 1 additional liter of saline to the point of mild abdominal discomfort. The cisplatin solution is allowed to remain in the IP cavity (i.e., the fluid is not drained). Concurrently, at least 1 L normal saline must be administered IV along with 40-g mannitol to assure a brisk diuresis to eliminate the cisplatin. Since cisplatin has the potential to be highly emetogenic, it is important to consider an aggressive antiemetic regimen (125,126).

Retrospective analysis by Levin and Hryniuk (127) strongly suggests that the cisplatin efficacy against ovarian cancer

is directly correlated with cisplatin dose intensity (i.e., mg/m^2/wk). Typical high-dose regimens include 20 mg/m^2 daily for 5 days repeated every 3 weeks, 100 to 120 mg/m^2 IV every 3 to 4 weeks, or 100 mg/m^2 on day 1 and day 8 repeated every 20 days (128,129). Holleran and DeGregorio (130) prepared an excellent review of high-dose (200 mg/m^2/course) cisplatin. Dose-limiting toxicities with the higher dose regimens include severe, relatively irreversible neurotoxicity and myelosuppression. Responses have been seen in conventional-dose cisplatin-refractory patients, but they generally are of relatively short duration.

Side Effects and Toxicities.

Dose-related nephrotoxicity is the major dose-limiting toxicity of cisplatin. It is manifested by renal tubular damage resulting in an elevation of the BUN or serum creatinine. The peak detrimental effect on renal function usually occurs between the 10th and 20th days after treatment. The renal damage is usually reversible. Patients concomitantly receiving gentamicin and cephalothin have been shown to be at greater risk of developing acute renal failure (131).

Madias and Harrington (132) have characterized the renal damage of cisplatin as being similar to mercury nephrotoxicity. Pathologically, renal tubular necrosis, degeneration, and interstitial edema without glomerular changes are observed. Although clinically overt renal toxicity may be common, it is usually reversible. However, some degree of long-term damage is likely. The renal-protective effect of hydration and mannitol is well established in animals and humans, and renal impairment can be prevented (122).

Ototoxicity, manifested by high-frequency hearing loss (above the frequency of normal speech), may be seen in as many as 30% of patients treated with cisplatin (133). Hearing impairment may be dose related and can be unilateral or bilateral. Occasional tinnitus (but not vestibular dysfunction) has been reported. The ototoxicity may be partially reduced by adequate hydration and the use of mannitol diuresis. Patients with lower than average threshold before chemotherapy with cisplatin were more likely to experience greater threshold shifts (133).

Neurotoxicity can be a dose-limiting side effect of cisplatin, particularly with high-dose regimens (134). The range of cisplatin-induced neurologic deficits includes peripheral sensory neuropathy, ototoxicity, autonomic neuropathy manifested by orthostatic hypotension and gastric paresis, Lhermitte syndrome, and rarely focal encephalopathy, often accompanied by cortical blindness. Peripheral neuropathy is by far the most common cisplatin-induced neurotoxicity. Neurotoxicity is dose dependent, with symptoms typically developing after cumulative doses of 300 mg/m^2 or greater. A review of published literature (135) found that neurotoxicity occurred in 85% of patients at cumulative doses of 300 mg/m^2 or greater, but occurred in only 15% of patients who had received a cumulative dose below this level. Initial symptoms are usually numbness and tingling in the distal fingers and toes. If cisplatin is continued, proximal extension of the peripheral neuropathy occurs, and the sense of joint position becomes impaired, resulting in more severe neurologic symptoms, including ataxia, gait disturbances, loss of manual dexterity, and wheelchair dependency. Symptoms may begin and progress up to four or more months after discontinuation of cisplatin. In 30% to 50% of patients, cisplatin neuropathy is irreversible.

Symptomatic hypomagnesemia frequently occurs with cisplatin. In a study to determine the effects of magnesium supplementation on cisplatin-induced hypomagnesemia, the administration of magnesium (oral and IV) with cisplatin to one group of patients produced less renal tubular damage and no compromise in efficacy than that seen in a group not supplemented with magnesium (136).

Without adequate antiemetic therapy, most patients who receive cisplatin experience nausea and vomiting. This reaction may be severe and usually starts within the first hour after treatment, and may persist for 24 to 48 hours. Delayed nausea and vomiting, lasting from 3 to 5 days, may also occur. The combination of a 5-HT3 inhibitor (e.g., ondansetron or granisetron) with dexamethasone (10 to 40 mg IV) has reduced the incidence of severe nausea and vomiting by as much as 75% (137). Delayed nausea and vomiting can be eradicated by continuation of oral low-dose dexamethasone (with or without a 5-HT3 inhibitor) for the first 5 days after platinum treatment (138). Other less effective antiemetic regimens to prevent cisplatin-induced nausea and vomiting include prochlorperazine, dexamethasone, and lorazepam; metoclopramide and dexamethasone; metoclopramide and methylprednisolone; or metoclopramide and lorazepam (82,139).

Anaphylactic hypersensitivity reactions consisting of tachycardia, wheezing, hypotension, and facial edema occurring within a few minutes of IV administration have occurred occasionally after a dose of cisplatin given to previously treated patients (140,141). These hypersensitivity reactions have been controlled with corticosteroids, epinephrine, or antihistamines. Wiesenfeld and colleagues (142) reported successful retreatment with cisplatin after apparent allergic reactions in two patients. *In vivo* and *in vitro* tests in one patient could not demonstrate an immunologic basis for the initial reaction. Both patients were successfully rechallenged with cisplatin after only diphenhydramine pretreatment. This suggests a nonallergic cause of the acute hypersensitivity reactions occasionally seen with platinum.

Myelosuppression occurs in 25% to 30% of patients receiving the recommended dose, and is more pronounced at higher doses. Coombs-positive hemolytic anemia also occurs as a result of cisplatin treatment. Cisplatin-induced anemia has been shown to respond to recombinant erythropoietin (143).

Drug Interactions.

When cisplatin is given in combination with other agents, the order of drug sequence can affect the severity of drug-induced myelosuppression. Rowinsky and Donehower (144) conducted a phase 1 study of sequential escalating doses of paclitaxel and cisplatin therapy and determined that myelosuppression was more severe when cisplatin administration preceded paclitaxel than when given after paclitaxel. Another phase 1 study was conducted to evaluate the effects of drug sequence of treatment with cisplatin in combination with topotecan (145). This study also found a significantly higher incidence of myelosuppression when cisplatin was administered first.

Cisplatin-induced nephrotoxicity should be considered whenever this agent is given prior to or in combination with other cytotoxic drugs that are cleared by renal elimination (e.g., bleomycin, ifosfamide, etoposide, methotrexate). Cisplatin reduces the renal clearance of these agents, resulting in an increased accumulation of these drugs. Yee and coworkers (47) observed markedly reduced bleomycin clearance in children who had received six courses of a regimen including cisplatin (cumulative dose 300 mg/m^2). In another case report, fatal bleomycin pulmonary toxicity occurred in a patient with cisplatin-induced acute renal failure (48).

Cisplatin is directly inactivated by mesna and amifostine (50). The FDA has approved amifostine to reduce the cumulative renal toxicity associated with repeated administration of cisplatin in patients with advanced ovarian cancer. In a phase 3 randomized study of ovarian cancer patients, amifostine treatment, prior to IV cisplatin plus cyclophospham, did not appear to reduce cisplatin's anticancer activity (146). However, there are only limited data in other chemotherapeutic settings, and the FDA recommends that amifostine should not be administered to patients in settings where chemotherapy could produce a significant survival advantage or cure except in a clinical trial (147).

Cyclophosphamide

Cyclophosphamide (Cytoxan, Neosar, CTX, CPM, and Endoxan) is an alkylating agent that, before the advent of paclitaxel, was used in the primary chemotherapy of advanced, epithelial-type ovarian and endometrial cancer. At this time, it is uncommonly used in the treatment of gynecologic cancers because of the more effective agents currently available (e.g., paclitaxel). It is occasionally used in the third-line treatment of ovarian cancer and as a second-line agent in the treatment of choriocarcinoma.

Chemistry.

Cyclophosphamide is a cyclic phosphamide ester of nitrogen mustard and is referred to chemically as 2-[bis-(2-chloroethyl)amino]tetrahydro-2H-1,3,2,-oxazaphosphorine 2-oxide monohydrate. Its molecular weight is 279.1. The monohydrate is un-ionized and lipid soluble; in normal saline or water, it is soluble to a maximum of 4% at room temperature.

Mechanism of Action.

Cyclophosphamide, a bifunctional substituted nitrogen mustard, was synthesized in 1958 in an attempt to achieve greater selective toxicity for tumor tissue. The *N*-methyl moiety of nitrogen mustard is replaced with a cyclic phosphamide group, resulting in a stable, inactive compound. The bis-(2-chloroethyl) group cannot ionize until the cyclic phosphamide is opened at the phosphorus-nitrogen linkage.

Activation of cyclophosphamide is a multistep process. The liver microsomal P450 mixed-function oxidase system converts the parent drug to 4-hydroxycyclophosphamide. This metabolite exists in equilibrium with the acyclic tautomer, aldophosphamide. These compounds may be further oxidized by hepatic aldehyde oxidase to the inactive metabolites of carboxyphosphamide and 4-ketocyclophosphamide. Nonenzymatic conversion to the cytotoxic compounds of phosphoramide mustard and acrolein occurs in susceptible peripheral tissues.

Most of the alkylating agents, like cyclophosphamide, are bifunctional, which facilitates their reaction with two cellular molecules. Accordingly, they can cross-link the two opposite strands of DNA to give an interstrand cross-link, react with two sites on the same strand (intrastrand cross-link), or cross-link DNA to protein. The latter type of lesion is generally considered to be innocuous, but the relative significance of the other cross-links is still in contention. DNA intrastrand cross-links are more frequent than interstrand cross-links and are more often considered to be the critical lesions.

These two classes can be differentiated by the structure of the cross-links in DNA. Generally, the entire mustard is involved in the cross-link, with the two mustard “arms” linked usually to the N7 position of guanine. Because these guanines can be separated by several bases in DNA, the linkages represent particularly bulky lesions.

Drug Disposition.

After IV administration, approximately 15% of the drug is excreted unchanged in the urine, and the remainder as metabolites. The plasma half-life of the parent compound after doses of 6 to 80 mg/kg appears to range from 4 to 6.5 hours (148,149). Approximately 50% of the alkylating metabolites (but not parent drug) is bound to plasma proteins.

Although cyclophosphamide is exclusively excreted by the kidneys, because of the un-ionized nature of the intact drug molecule, tubular reabsorption is avid. Hepatic inactivation appears to be the major mechanism of active drug elimination. The mean renal clearance of intact drug is approximately 11 mL/min, or 15% of CrCl, but renal elimination remains the major route of disposition of the more polar, less lipid-soluble metabolites (150). There can be significantly prolonged retention of active (alkylating) metabolites in patients with severe renal failure, and doses should be adjusted accordingly.

Dosage.

Cyclophosphamide is active in many different types of malignancies. The dosing schemes are numerous and depend on the particular disease. Two general categories of treatment schedules exist. In the method generally used to treat ovarian and endometrial cancers, an intermediate dose (600 to 1,000 mg/m^2) is given all at once over a short period. This treatment approach usually involves other drugs, such as cisplatin, carboplatin, or doxorubicin, whose additive toxic effects must be considered in selecting the dose and frequency of cyclophosphamide administration. Adequate hydration for 72 hours before and following high-dose treatment with cyclophosphamide is recommended to reduce cyclophosphamide-induced hemorrhagic cystitis (151).

An alternative continuous low-dose regimen for cyclophosphamide has been developed. Doses of 25 to 50 mg/d are given on a continuous basis. Used in this way, it was originally thought that cyclophosphamide acted as an “accidental” antiangiogenic agent (152). It is usually well tolerated with few side effects. Colleoni and colleagues published a trial of continuous low-dose cyclophosphamide with methotrexate in breast cancer and showed antitumor activity that correlated with vascular endothelial growth factor (VEGF) levels (153). Further, Miscoria and colleagues found an association between progression-free survival and thymidine phosphorylase levels (154). A suggestion has been made that the acrolein metabolite of cyclophosphamide acts as an antiangiogenic agent (155). The use of cyclophosphamide in this way has

come to be known as “metronomic” dosing. In addition to the antiangiogenic effect, metronomic cyclophosphamide may also have an immune regulatory function (156). Ge et al. (157) showed that metronomic cyclophosphamide induced an increase in the number of breast cancer reactive t-cells and that this correlated with disease stabilization in breast cancer.

There have been a large number of trials of the metronomic approach in a range of tumor types, including ovarian cancer. These have been reviewed (158). Activity is frequently reported, but the heterogeneous nature of the trials, the frequent combination with established antiangiogenic agents, and the lack of randomized trials makes the overall role of this approach currently undefined.

Side Effects and Toxicities.

Myelosuppression consisting primarily of leukopenia is the usual dose-limiting toxic effect of cyclophosphamide. Both the nadir and time of bone marrow recovery are rapid at 8 to 14 and 18 to 21 days, respectively. Although this drug has long been considered to be “platelet sparing,” significant thrombocytopenia can also occur at very high doses (>1.5 g/m^2).

Acute, sterile hemorrhagic cystitis, believed to be due to the acrolein metabolite, is an infrequent toxic manifestation, but is occasionally dose limiting. It is understandably more common in poorly hydrated or renally compromised patients. The onset of this complication may be delayed from 24 hours to several weeks. It is detected by gross hematuria or a microscopic hematuria of greater than 20 erythrocytes per high-power field. The bleeding may persist but is usually transient. Prophylactic hydration with intake of at least 3 L/d appears to offer the best protection. With continued therapy, patients characteristically develop a fibrotic “small bladder,” and urinary frequency may become a permanent problem. There is a definite increase in the risk of bladder cancer in these patients. The availability of the sulfhydryl mesna as a prophylactic treatment of patients at high risk for developing cyclophosphamide-induced cystitis has almost completely eliminated this side effect.

A syndrome of inappropriate antidiuretic hormone (SIADH), or “water intoxication,” has been reported after cyclophosphamide treatment. This is more common with IV doses greater than 50 mg/kg and is both a limitation to and consequence of fluid loading (159). Alopecia occurs to some degree in all patients receiving cyclophosphamide and is significant in at least half of all patients treated. Regrowth of hair may occur even with continuing treatment. Gastrointestinal problems are more common with high doses given orally. Anorexia, nausea, and vomiting are all common reactions, but they are usually controlled with IV antiemetic regimens. A rare pulmonary toxic effect has been reported with a pneumonitis picture similar to “busulfan lung.” The typical clinical presentation is that of an interstitial pneumonitis, usually occurring after long-term and continuous low-dose therapy (160). The onset of symptoms is insidious. Pathologically, there can be alveolitis with eventual fibrosis and atypical type II pneumocytes. Steroids may be beneficial. Other toxic effects include testicular atrophy, sometimes with reversible oligospermia and azoospermia. Amenorrhea also has been reported. As with all alkylating agents, drug-induced congenital abnormalities are possible. With high-dose therapy used for bone marrow transplant (120 to 180 mg/kg), cyclophosphamide-associated cardiac toxicity has been reported (161).

Special Precautions.

It is important to keep the patient well hydrated during cyclophosphamide therapy to reduce the potential for hemorrhagic cystitis. It is advisable to administer at least 1 L of additional IV fluids (usually normal saline) to ensure an adequate urine volume to excrete the cyclophosphamide metabolite acrolein, which can otherwise alkylate bladder mucosa and cause hemorrhagic cystitis. The patient should be instructed to drink at least eight glasses of fluid daily during the 2 days after cyclophosphamide administration. In patients prone to developing cystitis, consider administering prophylactic IV mesna, a sulfhydryl-containing compound that can neutralize acrolein.

Drug Interactions.

Cyclophosphamide must be metabolized to be active. Although some cyclophosphamide may be activated by phosphatases and phosphamidases peripherally, most of the drug is metabolized by microsomal enzymes in the liver (162,163). These enzymes may be activated by drugs such as phenobarbital or inhibited by drugs such as proadifen (SKF 525A). Because active and toxic metabolites are generated by the reactions of these enzymes and cyclophosphamide, many potential drug interactions may exist.

Barbiturates and other inducers of hepatic microsomal enzymes, such as phenytoin and chloral hydrate, may increase the rate of hepatic conversion of cyclophosphamide to its toxic metabolites. Similarly, cyclophosphamide may block the metabolism of barbiturates, increasing sedative effects. Although the clinical significance of these reactions is not clear, cyclophosphamide toxicity may be increased by the H_2-histamine blocker cimetidine (164). Cimetidine, but not ranitidine, may increase cyclophosphamide's myelotoxicity through an increase in the concentration time product of its active metabolites (e.g., 4-hydroxycyclophosphamide and phosphoramide mustard) (165). Thus, H_2-blockers like ranitidine may be safer to use than cimetidine when high doses of cyclophosphamide are administered.

Dactinomycin

Dactinomycin (actinomycin D, ACT-D, Cosmegen) has been shown to be active in the treatment of patients with germ cell tumors of the ovary and endometrium, and in gestational trophoblastic disease (166–168).

Chemistry. Dactinomycin has a molecular weight of 1,255 and an empiric formula of $C_{62}H_{86}N_{12}O_{16}$. The drug is an antitumor antibiotic isolated from *Streptomyces parvulus*. The molecular structure includes two peptide loops linked to a three-ring chromophoric phenoxazone ring system (actinocin). The drug is highly soluble in water, forming an amber- to gold-colored solution.

Mechanism of Action.

Dactinomycin becomes anchored into or around a purine-pyrimidine base pair in DNA by intercalation. DNA-dependent ribosomal RNA synthesis and new messenger RNA synthesis is inhibited. The peptide loops appear to allow tight drug binding to DNA because the actinocin (phenoxazone) moiety alone is inactive. This can occur adjacent to any G-C pair in DNA.

Bound dactinomycin molecules dissociate very slowly from DNA owing to electrostatic interactions of the cyclic peptide rings with each strand of the DNA double helix. This process, which stabilizes the intercalative interaction, appears to be crucial for cytotoxicity.

Dactinomycin on a molar basis is one of the most potent antineoplastic agents available. The drug possesses some hypocalcemic activity, similar to mithramycin. Although maximal cell killing is observed in the G_1 phase, the cytotoxic action is thought to be primarily cell cycle-nonspecific. Actively proliferating cells are more sensitive than quiescent cells to the lethal effects of the drug (169).

In that dactinomycin is a natural product, it is not surprising that the primary mode of tumor cell resistance to dactinomycin is mediated through overexpression of P-glycoprotein (170).

Drug Disposition.

Tattersall and colleagues (171) studied the pharmacokinetics of radiolabeled [^{3}H] dactinomycin in patients. They reported that the drug appeared to be only minimally metabolized, and was concentrated in nucleated cells. There was a greater drug uptake into bone marrow than in plasma. Drug penetration into the CNS was not observed. Urinary and fecal

recovery totaled only 30% each after 9 days, and there was significant drug retention in lymphocytes and granulocytes. This may explain the prolonged terminal plasma half-life of 36 hours observed after single dactinomycin doses. There appears to be little metabolism because approximately 90% of excreted drug is collected as the intact molecule. Some monolactone forms of dactinomycin are recovered in the urine.

Using a more specific radioimmunoassay, a much shorter dactinomycin half-life is described ($t_{1/2\alpha}$ = 0.78 minutes, $t_{1/2\beta}$ = 3.5 hours) (172). The discrepancies between these and Tattersall's findings reflect the differences in the assays used.

Administration and Dosage.

Dactinomycin is administered intravenously by slow IV push or, preferably, into the tubing of a freely running IV solution. A 5- to 10-mL flush of 5% dextrose in water (D_5W) or normal saline is recommended before and after IV push administration to assure vein patency and to flush any remaining drug from the tubing.

Dactinomycin is commonly given intravenously in short "pulse" doses of 500 μg/m^2 daily for as long as 5 days in adults. The dose for each 2-week cycle should not exceed 15 μg/kg/d or 400 to 600 μg/m^2/d for 5 days.

A wide variety of dosing regimens have been employed. Several clinical studies have documented equal efficacy and toxicity for single-dose dactinomycin regimens (173,174). In nonmetastatic gestational trophoblastic cancer, a single IV dose of 1.25 mg/m^2 every 14 days produced a 99% remission rate after four courses of therapy (174). Compared with five divided doses of 500 μg/m^2/d, the single-dose method produced slightly greater mild-to-moderate toxic effects.

Side Effects and Toxicities.

Bone marrow depression is the usual dose-limiting toxic effect of dactinomycin. It is usually manifested 7 to 10 days after dosing. All blood elements are affected, but primarily the platelets and leukocytes are depressed. Combined with gastrointestinal reactions, myelosuppression appears to be dose-limiting as well as dose-dependent (175). Immunosuppression is another well-known effect of dactinomycin. Patients should not receive this drug during viral infection because of the risk of developing disseminated disease.

Severe gastrointestinal consequences, such as vomiting, may occasionally represent the acute dose-limiting toxic effects of dactinomycin. Vomiting can persist for 4 to 20 hours, but it can be controlled by combination antiemetic regimens (176). Mucositis may also be severe. It is characterized by severe oral ulcerations and diarrhea in 30% of patients. Reversible alopecia may occur with dactinomycin. A variety of other skin manifestations have been reported, including acneiform changes, erythema, and hyperpigmentation.

Dactinomycin is toxicologically similar to the anthracyclines and characteristically interacts with radiation therapy, producing delayed "radiation recall" skin damage. Previously irradiated or even irritated skin may become reddened and inflamed after drug administration. Frank necrosis is sometimes reported. Oral ulcers may also develop after radiation therapy. These reactions may occur months after radiation therapy. Experimentally, radiation therapy given after dactinomycin does not produce this effect.

Dactinomycin potentiates pulmonary radiation and decreases radiation tolerance by at least 20%. Reintroduction of dactinomycin following pulmonary radiation has resulted in fatal pulmonary fibrosis (177). As noted in the "Special Precautions" section below, dactinomycin is highly ulcerogenic if extravasated.

Special Precautions.

Dactinomycin is extremely damaging to soft tissue, and every effort should be made to assure vein patency during administration. Extravasations characteristically result in immediate pain and swelling followed by indolent, poorly healing necrotic ulcers (176).

Dactinomycin is highly potent and is typically dosed in micrograms per kilogram. Doses must be calculated and

prepared carefully to prevent inadvertent overdosage of this drug. No specific antidote to overdosage is known, although granulocyte colony–stimulating factors may be useful.

Dactinomycin is a potent immunosuppressant and can inhibit the effectiveness of vaccinations given after drug administration. The drug also produces radiation recall skin and soft tissue damage if given after ionizing radiation.

Docetaxel

Docetaxel (Taxotere) is a semisynthetic analog of paclitaxel and has an FDA-approved indication for locally advanced or metastatic breast cancer after failure of prior chemotherapy. It is also FDA approved for locally advanced or metastatic non–small cell lung cancer after failure of prior platinum-based chemotherapy. It has shown marked antitumor activity against a variety of solid tumors, including both platinum-sensitive and platinum-refractory epithelial ovarian cancer (178,179).

Chemistry.

The natural component of docetaxel is 10-deacetyl baccatin III, which is extracted from the needles of the European yew tree (*Taxus baccata* L.) (179). Docetaxel has a molecular weight of 861.9 and the empirical formula $C_{43}H_{53}NO_{14} \cdot 3H_2O$. Unlike paclitaxel, which uses a polyoxyl compound (Cremophor) as a diluent, docetaxel is formulated in Tween 80 and alcohol.

Mechanism of Action.

In a manner similar to paclitaxel, docetaxel promotes microtubule assembly and inhibits the depolymerization of tubulin. However, compared with paclitaxel, the microtubules formed by docetaxel are more slowly reversible, and there are differential effects on tau binding sites and on microtubule-associated proteins. Docetaxel-induced stabilization of microtubules halts cellular division in M phase, thereby preventing cell replication.

Drug Disposition.

The pharmacokinetics of docetaxel when administered as an IV infusion lasting from 1 to 24 hours have been investigated in a number of studies (180). When administered as a typical 1-hour infusion at doses of 70 to 100 mg/m^2, pharmacokinetics reveals triphasic elimination with a plasma AUC of 3.13 to 4.83 mg/mL/h, a peak plasma concentration of 2.57 to 3.67 µg/mL, and a terminal-phase plasma half-life of 13.6 hours. There is very limited renal excretion of docetaxel; the 24-hour urinary excretion was 1.4% of the dose administered. Plasma drug clearance was determined to be 21.3 L/h/m^2 (181).

Administration and Dosage.

All patients receiving docetaxel should be premedicated with oral corticosteroids such as dexamethasone 16 mg/d (e.g., 8 mg b.i.d) for 3 days, beginning 1 day prior to docetaxel administration, to reduce fluid retention and the risk of hypersensitivity reactions.

Docetaxel is commercially available in single-dose 20- and 80-mg vials with accompanying diluent vials. Both the docetaxel vials and the diluent vials should stand at room temperature for approximately 5 minutes before mixing. The entire contents of the diluent vial should be aseptically transferred to the docetaxel vial, and the resulting contents should be gently rotated for 15 seconds to promote complete mixture. The resulting concentration of docetaxel is 10 mg/mL. Foam may be present owing to the Tween 80; however, it should largely dissipate within a few minutes. The infusion solution is prepared by aseptically withdrawing the proper amount of docetaxel with a calibrated syringe and adding it to a

250-mL infusion bag or bottle containing either 0.9% sodium chloride or 5% dextrose solution to produce a final concentration of 0.3 to 0.9 mg/mL. The infusion solution should be mixed by manual rotation and inspected for particulate formation and/or discoloration. Solutions that are cloudy or that contain particulate matter should be discarded.

The recommended dose of docetaxel for chemotherapy in women with metastatic breast cancer ranges from 60 to 100 mg/m^2 IV as a continuous 1-hour infusion every 3 weeks. For non–small cell lung cancer, the recommended dose is 75 mg/m^2 IV as a continuous 1-hour infusion every 3 weeks.

The optimal dosing schedule for docetaxel in gynecologic cancers is presently undefined. A 100-mg/m^2 dose administered as a 1-hour infusion every 3 weeks has been used in phase 2 trials. Other tolerable docetaxel dose schedules that have been identified in phase 1 studies are: 50 mg/m^2/d on days 1 and 8 every 3 weeks; 70 to 90 mg/m^2 by 24-hour continuous IV infusion every 3 weeks; 80 to 100 mg/m^2 by 6-hour infusion every 3 weeks; 14 mg/m^2/d for 5 days by 1-hour infusion every 21 days (182); and 30 to 35 mg/m^2 weekly (183,184). Docetaxel has been administered in combination with cisplatin using the following schedule: docetaxel 85 to 100 mg/m^2 as a 1-hour IV infusion followed (3 hours after completion) by cisplatin 75 mg/m^2 as a 3-hour IV infusion, with cycles repeated every 3 weeks (185).

Side Effects and Toxicities.

The major dose-limiting toxicity of docetaxel is neutropenia, which is noncumulative and generally resolves within 7 to 8 days. The combined results of early phase 2 studies of docetaxel (without steroid premedication) in ovarian cancer revealed that at a dose level of 100 mg/m^2 every 3 weeks, over 90% of patients developed grades 3 to 4 neutropenia, with febrile neutropenia occurring in 8% to 44% of patients (186). The incidence of other grade 3 to 4 toxicities were stomatitis (0% to 5%), diarrhea (6% to 20%), dermatitis (4% to 8%), acute hypersensitivity reactions (7% to 12%), and fluid retention (8% to 12%). Other docetaxel-induced side effects include alopecia, anemia, neurosensory effects (paresthesia, dysesthesia, pain), and asthenia (182).

In early phase 2 studies, slow-onset (i.e., after three to five courses), cumulative fluid retention leading to peripheral or generalized edema with possible development of pleural effusion and/or ascites was a common dose-limiting toxicity. However, a 5-day premedication regimen with corticosteroids, starting the day before docetaxel administration, significantly reduces this side effect. In a retrospective analysis, severe fluid retention occurred in 20% of patients who received no premedication compared with 5% of patients who received steroid prophylaxis. Additionally, the percentage of patients who discontinued treatment secondary to fluid retention was reduced from 32% to 2% (p <0.00001) with the use of a 5-day corticosteroid regimen (182). Steroid prophylaxis also reduces the incidence and severity of dermatologic side effects and hypersensitivity reactions.

The spectrum of docetaxel-induced hypersensitivity reactions is less severe than that associated with paclitaxel. In the absence of prophylactic medication, mild hypersensitivity reaction as characterized by flushing, rash, and pruritus occurs in approximately 5% of docetaxel administrations. Moderate reactions with dyspnea and/or slight hypertension occur in 8% of treatments, and severe reactions (with bronchospasm, angioedema, and/or severe hypertension) occur in less than 2% of docetaxel administrations (187). Initial symptoms of hypersensitivity to docetaxel therapy generally occur within minutes of the start of the first or second course of docetaxel, and resolve rapidly with interruption of the infusion. Patients can be successfully rechallenged with docetaxel therapy following medication with corticosteroids, antihistamines, and H_2-agonists.

Dermatologic toxicities typically appear as maculopapular eruptions and desquamation generally localized to the extremities. Nail changes, including onycholysis, may also occur. Skin changes are largely self-limiting and may be alleviated with glycerin/chlorhexidine ointment or oral pyridoxine. This side effect can often be prevented with prophylactic oral steroids and H_1- and H_2-agonists (188). Recurrent skin toxicity refractory to oral prophylactic medication and pyridoxine therapy may respond to local hypothermia during docetaxel administration (189).

Special Precautions.

Patients with impaired liver function have a significant reduction in docetaxel clearance and an increased risk of life-threatening side effects. Analysis of the overall safety database revealed that patients with moderately impaired liver function (defined as transaminase levels more than 1.5 times the upper limit of normal and alkaline phosphatase more than 2.5 times the upper limit of normal) have a 27% reduction in docetaxel clearance and a 38% increase in the area under the concentration–time curve (182). When compared with patients with normal liver function, patients with at least moderately impaired liver function had a significantly greater incidence of febrile neutropenia (40% vs. 16%) and toxic death (20% vs. 1.4%). Grades 3 to 4 nausea/vomiting, stomatitis, and thrombocytopenia were also increased in patients with impaired liver function (182).

The recommended docetaxel dose level for a patient with moderate hepatic impairment (defined as transaminases between 1.5 and 3.5 times the upper limit of normal and an alkaline phosphatase between 2.5 and 6.0 times the upper limit of normal) is 75 mg/m^2 over 1 hour. No safe docetaxel dose can be recommended for patients with greater than moderate liver impairment (190).

Doxorubicin

Doxorubicin (Adriamycin) is FDA approved for the treatment of many cancers, including sarcoma and breast cancer. In addition, it is a commonly employed agent in the treatment of metastatic endometrial cancer and advanced ovarian cancer.

Chemistry.

Doxorubicin is an anthracycline antibiotic obtained from *Streptomyces peucetius* var. *caesius*. It has a molecular weight of 580. The doxorubicin structure includes a water-soluble basic reducing amino sugar, daunosamine, linked by a glycosidic bond to carbon atom number 7 on the D-ring of the water-insoluble chromophore aglycone, adrimycinone.

Structural changes in the side groups of doxorubicin alter antitumor potency and pharmacokinetic properties. The aglycone is inactive, and modifications in the amino sugar substituents can also alter antitumor or toxic potency (191).

In DNA, the amino sugar projects into the minor groove and can interact electrostatically with negatively charged phosphate groups in the DNA strand to stabilize the aglycone moiety. Doxorubicin can also form complexes with iron or copper by means of the hydroquinone moieties (192). Metal-iron doxorubicin complexes may contribute to cardiotoxicity by enhancing redox cycling of the quinone moiety to produce membrane-damaging oxygen free radicals (193).

Doxorubicin hydrochloride is freely soluble in water, slightly soluble in normal saline, and very slightly soluble in alcohol.

Doxorubicin is also commercially available in a polyethylene glycol (PEG)–coated (pegylated, Stealth) liposomal form (see Liposomal Encapsulated Doxorubicin section below).

Mechanisms of Action. DNA Binding. The anthracyclines, including doxorubicin, probably have several modes of action. The anthracycline portion of the molecule appears to intercalate between stacked nucleotide pairs in the DNA helix by means of P-P–type bonds (194). The drug may also bind ionically around certain base pairs of DNA (adlineation). The overall effect of this is interference with nucleic acid synthesis, specifically an inhibition of DNA synthesis (195). However, preribosomal RNA synthesis is also affected by the drug binding to DNA, preventing DNA-directed RNA and DNA transcription (196).

Mechanisms other than intercalation may also contribute to the antitumor effect of the doxorubicin molecule. The contribution of alkylation to antitumor effects has not been established.

Free Radical Formation. Oxygen free radical intermediates containing an unpaired electron can be formed by doxorubicin. This can react rapidly with oxygen to form superperoxide, and with hydrogen peroxide, highly reactive hydroxyl radicals can form. These radicals damage membrane lipids by peroxidation, break DNA strands by attacking ribose-phosphate bonds, and directly oxidize purine or pyrimidine bases, thiols, and amines (193,197). Free-radical mechanisms have most often been associated with cardiotoxicity.

Doxorubicin appears to be active in all phases of the cell cycle, and although maximally cytotoxic in S phase, it is not phase-specific (198). Cells exposed to lethal doxorubicin concentrations in G_1 can proceed through S phase but are then blocked and die in G_2. Higher concentrations can also produce an S-phase blockade (199).

Inhibition of DNA Topoisomerase II. Topoisomerases are enzymes capable of covalent binding to DNA, forming transient breaks in one strand (TOPO-I) or two strands (TOPO-II). This activity is highly phase-dependent for G_2, and in the case of TOPO-II, normally mediates strand passage to facilitate DNA condensation or decondensation (200). Doxorubicin and other DNA intercalators inhibit the strand-passing activity of TOPO-II by increasing and stabilizing the initial enzyme-DNA (cleavable) complexes. This leads to protein-linked DNA double-strand breaks that are roughly proportional to the cytotoxic potency of the drug *in vitro* (201).

Drug Disposition.

Doxorubicin pharmacokinetics is usually described using a two-compartment or three-compartment open model. The drug is rapidly distributed in body tissues, and about 75% of the drug is bound to plasma proteins, principally albumin (202). In the blood, the free doxorubicin fraction depends on the hematocrit, with more free drug being available in patients with a reduced hematocrit (203). The avid binding to DNA is believed to explain the prolonged terminal elimination half-life of 30 to 40 hours, the large apparent Vd of up to 28 L/kg, and the incomplete (50%) total recovery of drug in urine, bile, and feces (204). Human tissues with high drug concentrations (in descending order) include liver, lymph nodes, muscle, bone marrow, fat, and skin (205). The drug does not distribute into the CNS.

There is a significant distribution of doxorubicin into human breast milk (206). Doxorubicin levels of 0.24 μM and 0.2 μM of doxorubicinol have been measured in human milk. They produce cumulative AUCs in breast milk of 9.9 and 16.5 μM · h, respectively. Both of these values are greater than concurrent plasma AUC values. However, doxorubicin does not appear to pass the placenta consistently. Except for one study reporting low drug levels in placental blood of 0.78 to 1.19 nmol/g and no drug in cord blood plasma, several other trials detected no drug in amniotic fluid after doxorubicin administration to pregnant patients (207–209).

Doxorubicin is extensively metabolized and eliminated primarily as glucuronide conjugates of the parent aglycone or its hydroxylated congener doxorubicinol (204,210). The conjugated metabolites are exclusively excreted in the bile and feces. Overall, biliary excretion accounts for about 40% of an administered dose (211). Approximately 42% of the biliary drug is parent doxorubicin, 22% is doxorubicinol, and 36% comprises other metabolites (211). Only 5% to 10% of the administered drug is excreted in the urine as doxorubicin (40%), doxorubicinol (29%), and other metabolites (31%).

In liver disease, patients with cholestasis have delayed doxorubicin clearance and experience exaggerated toxic reactions from standard doses (212). However, hepatoma patients with cirrhosis or simple hepatocellular enzyme elevation appear to have normal doxorubicin clearance and toxic effects from standard doses (213). Although obesity reduces clearance of doxorubicin in adult cancer patients (214), there were no differences in doxorubicin toxicity between normal, mildly obese, and obese patients.

There is some evidence that repeated doxorubicin dosing alters pharmacokinetics (215,216). In these reports, doxorubicin levels were lower after repeated dosing, which suggests increased drug clearance. However, because neither toxicity nor response rates were altered, the clinical significance of these observations has not been established. Age may also be a factor. In one trial, the highest clearances of doxorubicin were observed in the younger patients (217). These observations suggest that higher peak doxorubicin levels may be achieved in older patients.

The hepatic extraction ratio for doxorubicin in humans is 0.45 to 0.5, and systemic drug levels are about 25% lower

with intra-arterial administration compared with IV dosing (218). Several studies have shown that the pharmacokinetics of intra-arterial drug are similar to those seen after IV doses (205,219). The relatively low hepatic extraction rate and similar overall disposition patterns provide little pharmacokinetic rationale for intra-arterial administration as a means of localizing doxorubicin effects to the liver (220).

Administration and Dosage.

Short IV push infusions and IV bolus injections have been used with doxorubicin. A slow IV push over several minutes with constant monitoring of the patient and blood return can help minimize the chance of serious tissue damage due to extravasation. A 5- to 10-mL flush of normal saline or D_5W before and after administration is strongly recommended to test vein patency and flush any remaining drug from the tubing. Alternatively, injection into the side port of a running IV infusion has also been recommended. The patient should be asked to report immediately any change in sensation during the administration. Old venipuncture sites or infusion sites previously used for administering blood, antibiotics, or other medications should not be used to administer doxorubicin. Heparin locks (unless recently inserted) are not recommended because the drug is chemically incompatible with sodium heparin.

Prolonged infusions increase the incidence and severity of stomatitis and dermatologic reactions. Administration through tunneled central venous catheters or indwelling vascular access ports is mandatory for all prolonged infusions. Careful patient and site monitoring are required, because of the risk of doxorubicin extravasation from central vascular access devices.

Numerous dosing schedules have been reported. The individual doxorubicin dose depends on clinical variables, including the cumulative dose administered to date and the potential for interaction with other drugs or radiation (**Table 14.3**). As a single agent, doses of 60 to 75 mg/m^2 as a single IV injection have been used and repeated no more often than every 3 weeks. An alternative scheme uses 20 to 30 mg/m^2 given daily for 3 consecutive days, repeated in 3 weeks (221). When used in combination therapy, the most commonly used dosage is 40 to 60 mg/m^2 given as a single IV injection every 21 to 28 days.

TABLE 14.3 Intravenous Dosing Guidelines for Doxorubicin

Dose (mg/m^2)[a]	Intravenous Method	Schedule	Average Cumulative Tolerable Dose[c] (mg/m^2)
60 – 75[b]	Bolus	Every 3 weeks	550
30	Bolus	3 successive days, every 3 weeks	550
20	Bolus	Weekly	750
60	96-hour infusion	Every 3 – 4 weeks	1,000

[a] Lower doses should be administered to patients with hepatobiliary dysfunction and for poor bone marrow reserve or performance status.

[b] Allows for greater dose intensity in breast cancer.

[c] Represents average tota l cumulative dose tolerated without clinical evidence of doxorubicin cardiotoxicity.?

Both the dose and rate of dosing (dose intensity) can have therapeutic impacts for different agents and tumors (222). Clinical studies with doxorubicin show that greater dose intensity is associated with enhanced response rates in breast cancer (223). The doses compared in this trial were 70 mg/m^2 every 21 days for 8 cycles versus 35 mg/m^2 every 21 days for 16 cycles.

Dose adjustments are required in a number of clinical settings (**Table 14.4**), specifically in the case of hyperbilirubinemia. A 50% dose reduction is indicated if plasma bilirubin concentration is 1.2 to 3.0 mg/dL, and the dose

must be reduced by 75% if plasma bilirubin concentration reaches 3.1 to 5.0 mg/dL.

TABLE 14.4 Modifications of Doxorubicin Doses

Condition	Recommended Dose Modification
Prior doxorubicin	Limit total cumulative lifetime dose (by IV bolus) to 550 mg/m^2 (224)
Prior chest radiation therapy	Reduce total dose limit to 300–350 mg/m^{2}Obesity Base dose on ideal body weight (214) Hepatobiliary dysfunction Reduce dose for elevated serum bilirubin (give 50% of dose for serum bilirubin of 1.2–1.9 mg/dL, and give 25% of dose for serum bilirubin ≥ 3.0 mg/dL (225)
	Use Indocyanine green disappearance rate as an indicator of doxorubicin clearance
Infusion method	Greater cumulative (total) dose may be afforded by weekly bolus doses or continuous (96-hour) infusions[a] (Legha, 1982)

Note: Average safe cumulative doxorubicin dose is 750 mg/m^2 using standard infusion schedules.

[a]Average safe cumulative doxorubicin dose is 1,000 mg/m^2 when administered with a 96-hour infusion schedule.

Side Effects and Toxicities.

The single acute dose-limiting toxicity for doxorubicin is bone marrow suppression. The most common seen dose-limiting toxicity is leukopenia, with a nadir at 10 to 14 days. Other hematologic toxicities, such as anemia and thrombocytopenia, have been reported, but they are rare and generally less severe. Recovery from myelosuppression is usually prompt, and often resolves within about 1 week after the nadir.

Doxorubicin is known to produce local skin and deep-tissue damage at the site of inadvertent extravasations (226,227). Ulcers may result after 33% of extravasations. The lesions undergo a slow, indolent expansion and occasionally involve tendons and other deep structures. They characteristically do not heal and are associated with prolonged local drug retention (228). Reilly and colleagues (226) recommend early surgical debridement, with skin grafting and tendon repair for serious infiltrations. Numerous pharmacologic antidotes have been evaluated, but few have demonstrated unequivocal clinical efficacy. The application of cold, topical dimethyl sulfoxide (DMSO) is recommended (229).

Cardiac consequences from the drug have included acute effects, such as a rare pericarditis–myocarditis syndrome or electrophysiologic aberrations, and a total dose–related cardiomyopathy (230,231). Nonspecific electrocardiographic changes during infusion or immediately afterward may be seen. These include T-wave flattening, ST depression, supraventricular tachyarrhythmias, and extra systolic contractions (232). These conduction abnormalities are generally transient, not associated with severe morbidity, and do not require dose modification.

Cardiomyopathy from doxorubicin is dose related. It presents initially as a clinical syndrome identical to classic congestive heart failure. It is usually irreversible, but symptoms can be managed with standard medical therapy involving digitalis, glycosides, and diuretics. Potential risk factors for doxorubicin cardiotoxicity include cumulative doses greater than 550 mg/m^2, prior mediastinal irradiation (≥20 Gy), age greater than 70 years, and preexisting cardiovascular diseases, such as prior myocardial infarction or long-standing hypertension (225). Anthracycline-induced cardiomyopathy can also occur 4 to 20 years after the drug is stopped at standard dose limits (233). The administration of anthracyclines incorporated into liposomes is one method that may significantly reduce the risk of cardiac toxicity (see Liposomal Encapsulated Doxorubicin section below) (234).

At total doses under 500 mg/m^2, the incidence of cardiomyopathy is less than 1%; between 501 and 600 mg/m^2, 11% are affected; and the incidence is 30% for doses above 600 mg/m^2. In a retrospective cardiotoxicity study of 4,018 patient records, Von Hoff and associates (224) described an overall incidence of 2.2% for doxorubicin-induced congestive heart failure. In this analysis, performance status, sex, race, and tumor type did not influence the incidence of cardiomyopathy.

However, elderly patients were at greater risk, even after adjustment for the normally decreased cardiac function in this group. The major determinants were the dose, the schedule of administration, and the age of the patient. A weekly doxorubicin dosing schedule was associated with significantly less congestive heart failure than an every-3-weeks dosing schedule. Continuous IV infusions over 96 hours can also significantly lessen doxorubicin cardiotoxicity (235).

Dexrazoxane (Zinecard) is a chemoprotective agent with an FDA-approved indication for reducing doxorubicin-associated cardiomyopathy in women with metastatic breast cancer who have received a cumulative doxorubicin dose of ≥300 mg/m^2 and who, in their physician's opinion, would benefit from further doxorubicin therapy.

There is evidence that doxorubicin is a radiosensitizing or radiomimetic agent and can cause reactivation of tissue reactions in areas previously irradiated (236,237). Radiation recall reactions have also been reported in areas of previous drug infiltration. A particularly sensitive area for serious recall toxicity is the esophagus (238).

Other toxic effects are observed in rapidly proliferating normal tissues. These include marked alopecia in all hairy body areas. Stomatitis may occur at high doses and is more pronounced when the drug is given on consecutive days. It generally begins in the sublingual and lateral tongue regions as a burning sensation with noticeable erythema. The initial inflammation typically progresses to ulceration after a few days. Anal fissures or proctitis have been rarely reported. Nausea and vomiting are common but of moderate intensity. Diarrhea is rare with consecutive daily dosing, and the emetic effects are generally limited to the first day of treatment. Hyperpigmentation of the skin, especially the nail beds, may occur. Extravasations of doxorubicin are known to cause severe ulceration and soft tissue necrosis (226,227). Vein patency should be assured before injection and constantly monitored during administration.

Drug Interactions.

Doxorubicin is believed to interact with numerous other drugs. Most of these effects have been described only in experimental systems, and their clinical significance is, therefore, unknown. However, several potentially significant interactions have been described in cancer patients. Altered doxorubicin disposition is postulated with α-interferon, and substantial doxorubicin dose reductions are required (239). The combination of doxorubicin with H_2-antihistamines, such as ranitidine or cimetidine, may also increase toxicities significantly and necessitate drug dose reduction.

Eribulin

Eribulin is licensed for the third-line treatment of metastatic breast cancer and was also approved for the treatment of unresectable liposarcoma.

Chemistry.

Eribulin is a synthetic derivative of the natural product, Halichondrin B, a product originally isolated from a marine sponge. It acts as a microtubule dynamics inhibitor. The chemical name for eribulin mesylate (the injectable form) is 11,15:18,21:24,28-Triepoxy-7,9-ethano-12,15-methano-9H,15H-furo[3,2-i]furo[2',3':5,6]pyrano[4,3-b][1,4]dioxacyclopentacosin-5(4H)-one, 2-[(2S)-3-amino-2-hydroxypropyl]hexacosahydro-3-methoxy-26-methyl-20,27-bis(methylene)-,(2R,3R,3aS,7R,8aS,9S,10aR,11S,12R,13aR,13bS,15S,18S,21S,24S,26R,28R,29aS)-,methanesulfonate (salt). It has a molecular weight of 826.0 (729.9 for free base). The empirical formula is C40H59NO11·CH4O3S.

Mechanism of Action.

Eribulin binds to tubulin and sequesters it into nonproductive aggregates, thereby inhibiting mitosis and causing a G2/M cell cycle block.

Drug Disposition.

Eribulin is administered intravenously. The majority of the dose is excreted unchanged in the feces, with only about 9% in the urine. There is little metabolism, with about 90% of the drug being excreted unchanged. The Vd is approximately 40 L, and the half-life about 40 hours.

Dosage.

The recommended dose of eribulin for patients with normal hepatic function is 1.4 mg/m^{2,} administered intravenously over 2 to 5 minutes on Days 1 and 8 of a 21-day cycle. Dose reductions to 0.7 mg/m^2 are recommended for patients with mild hepatic impairment, and to 1.1 mg/m^2 for patients with moderate renal impairment.

Further dose reductions are recommended according to the level of myelosuppression encountered during treatment.

Side Effects and Toxicities.

The dose-limiting toxicity of eribulin is myelosuppression. Peripheral neuropathy also occurs. QT prolongation has also been reported. Other adverse events that have been reported in >10% of patients are asthenia, constipation, diarrhea, nausea, and vomiting.

Drug Interactions.

As already noted, there is little CYP-mediated metabolism of eribulin, and no significant drug interactions are expected [H71].

Etoposide

Intravenous etoposide (VP-16) is commonly used in combination chemotherapy regimens for the treatment of patients with germ cell tumors of the ovary (168). Oral etoposide has activity for refractory or recurrent ovarian cancer (240).

Chemistry.

Etoposide is a semisynthetic epipodophyllotoxin derived from the root of *Podophyllum* (the May apple plant, or mandrake). The chemical name is demethylepipodophyllotoxin 9-[4,6-O-(R)-ethylidene-β-D-glucopyranoside]. Etoposide has the molecular formula of $C_{29}H_{32}O_{13}$ and a molecular weight of 588.58. It is highly soluble in methanol and chloroform, slightly soluble in ethanol, and sparingly soluble in water. Because of poor water solubility, the commercial drug is dissolved in an ethanol-based cosolvent system.

Etoposide was originally synthesized from *P. embodi* (241). Structure-activity studies show that the hydroxyl group at the C-4′ position is required for activity, and that alterations at this site can dramatically affect activity.

Mechanism of Action.

There is marked schedule dependence for etoposide cell killing, and cytotoxic effects are maximal in G_2 phase (242). There is also some activity against cells in late S phase, and the drug can halt cell cycle traverse at the S-G_2 interphase (243).

Etoposide produces protein-linked DNA strand breaks by inhibiting DNA TOPO-II enzymes (244). This normal mammalian enzyme mediates double-strand–passing activities in G_2 phase to condense or decondense supercoiled DNA (245). Drug-induced inhibition of TOPO-II is an energy-dependent process that is influenced by dose and duration of exposure.

Etoposide does not bind directly to DNA, but rather stabilizes a transition form of the DNA–TOPO-II complex (244). The number of single and double DNA strand breaks reflects the cytotoxic dose-response curve (246). Etoposide and intercalative drugs such as doxorubicin "poison" TOPO-II enzymes by stabilizing an otherwise transient form of TOPO-II covalently linked with DNA (201). Normal TOPO-II strand-passing activity is thereby blocked, and cell progression out of G_2 phase is halted (200,247). The production of cytotoxicity by etoposide may ultimately involve chromosomal breaks characterized as sister chromatid exchanges (248).

Another postulated etoposide mechanism involves microsomal activation to reactive intermediates capable of generating oxygen-free radicals (246). Nucleoside transport is also inhibited at high drug concentrations, but whether this makes a major contribution to the antitumor effect is unknown (249).

Drug Disposition.

A two-compartment open pharmacokinetic model appears to adequately describe etoposide disposition in cancer patients (250). The terminal half-life of the drug appears to be about 7 hours and is independent of the dose, route, or method of administration (251). Renal excretion appears to account for about 30% of overall drug elimination. Forty-two percent to 66% of radiolabeled drug is recovered in the urine, of which less than half is parent etoposide.

With standard doses of etoposide, no drug is detectable in the cerebrospinal fluid (CSF), and even after doses of 400 to 800 mg/m^2, CSF levels are less than 2% of concurrent plasma levels (252). Despite the low distribution of drug into the CSF, mean levels of 1.4 μg/g (range undetectable to 5.9 μg/g) have been measured in brain tumor tissue (253). The drug also distributes into myometrial carcinoma and normal myometrium, achieving relatively high levels in these tissues (254).

Biliary secretion of parent drug accounts for 2% or less of the dose, although fecal recovery of drug and metabolites is variable, ranging from 1.5% to 16.3% (255). However, patients with obstructive jaundice excrete a larger fraction of the dose in urine (46%) than do unaffected patients (35%), which suggests that there is a slight decrease in hepatic drug metabolism with a commensurate increase in renal clearance (252).

The plasma protein binding of etoposide is normally high, averaging 95% in typical patients (256). The free (unbound) fraction of etoposide can vary from 6% to 37%. Patients with increased bilirubin or decreased albumin may have an increase in the free fraction, even though systemic clearance is unaltered (256). Myelosuppression may also be increased commensurately in these patients. Other conditions that may decrease etoposide clearance include prior cisplatin therapy, obesity, and elevated alkaline phosphatase levels (257).

The absolute oral bioavailability of etoposide gelatin capsules ranges from 25% to 74%, with a mean of 48% (258). Some patients experience a 30% change in overall bioavailability (both increased and decreased) with repeat dosing. Neither food nor other chemotherapeutic agents appear to alter etoposide absorption (259). Wide variations in peak levels and AUC values were also described in this trial.

Administration and Dosage.

Etoposide must be diluted before use with either 0.5% dextrose or 0.9% sodium chloride to give a final concentration of 0.2 to 0.4 mg/mL. Etoposide should be given by IV infusion over a 30- to 60-minute period. Severe hypotension may occur if the drug is given too rapidly. Although not a vesicant, extravasation of the drug should be avoided (260). Examine all solutions for fine precipitates; mix before use. Precipitation may occur if the solution is prepared 0.4 mg/mL. Continuous infusions of etoposide have been used as a means of enhancing efficacy because of its phase-specific mode of antitumor action. Most infusions have used 5-day courses, although 72-hour infusions have also been employed (261,262). Oral administration of etoposide capsules may be useful if patient compliance is high and low-emetogenic drug regimens are used. The capsules may be taken all at once to achieve the desired dose. Neither food nor other chemotherapeutic drugs appear to alter oral absorption of the drug (259).

The variety of doses and schedules that have been used with etoposide are presented in **Table 14.5**. General principles of dosing include more frequent administration to take advantage of cell cycle–dependent cytotoxicity, an approximate

doubling of oral doses due to 50% bioavailability for the gelatin capsules, and significant dose reductions for combinations of etoposide with other myelosuppressive drugs, or for patients with poor bone marrow reserve or poor performance status. In general, etoposide doses can be repeated every 3 to 4 weeks, depending on the leukocyte count. A pharmacokinetic study in patients with obstructive jaundice showed that no significant dose reductions are needed if renal function is normal (263).

TABLE 14.5 Intravenous and Oral Dosing Schedules for Etoposide

Administration Method	Dose		Repeat Dosing Interval (weeks)	Clinical Application
	mg/m²/d	Days		
Short single-dose IV infusion	200 - 250	1	7	Single agent, small cell lung cancer
Short multiple-dose IV infusion	100	1 - 5	3 - 4	Testicular cancer
	100	1, 3, 5	3 - 4	With other drugs
	45	1 - 7	3	Phase I
Continuous IV infusion	125	1 - 5	4	Phase I, single agent
	30	1 - 5	4	With cisplatin in advanced cancer
	80	1 - 5	4	Phase I, good-risk patients
	50	1 - 5	4	Poor-risk patients
	125	1 - 3	4	Adult patients with advanced cancer (240)
	500	1 (24-hour)	3	Small cell lung cancer
Oral	160	1 - 5	3 - 4	Small cell lung cancer
	50	1 - 21	4	Ovarian cancer (243)

Side Effects and Toxicities.

Side effects and toxicities for oral and IV administration of etoposide as a single agent are similar. The principal toxicity of etoposide is dose-related and dose-limiting bone marrow suppression. Leukopenia and thrombocytopenia occur, but leukopenia consistently predominates, with a nadir at approximately 16 days and with recovery usually beginning by days 20 to 22.

Gastrointestinal complaints of nausea, vomiting, or anorexia are usually minor and are more frequent with the oral preparations (264). Other adverse effects include alopecia in 20% to 90% of patients, headache, fever, and hypotension (265). Severe hypotension can occur if the drug is infused too rapidly (<30 minutes) (255). Stomatitis has been reported infrequently. There have been rare instances of generalized allergic reactions and anaphylaxis (266). A few episodes of cardiotoxicity, including myocardial infarction and congestive heart failure, have been described (267). Immune suppression appears to be minimal with this drug (265). Bronchospasm with severe wheezing has been observed rarely, and has usually been responsive to antihistamines and glucocorticosteroids. Chemical phlebitis has also been associated with etoposide, although this reaction is most likely related to solubilizers in the diluent. Diluted solutions of etoposide are not vesicants. For inadvertent extravasations of highly concentrated etoposide solution, hyaluronidase may be effective

(268).

Neurotoxicity has rarely been reported with etoposide. This has consisted of somnolence and fatigue in 3% of patients and peripheral neuropathy in less than 1% of patients. However, the drug may exacerbate preexisting neuropathy caused by vincristine (269). Predisposing factors include advanced age, impaired nutritional status, and poor performance status. Degradation of myelin lamellae has been observed in affected nerves.

5-Fluorouracil and Floxuridine

5-Fluorouracil (5-FU) is a fluorinated pyrimidine differing from the normal DNA substrate, uracil, by a fluorinated number 5 carbon (chemically, 5-fluoro-2,4(1H,3H)-pyrimidinedione). 5-FU has activity as a second-line agent in advanced ovarian and cervical cancers and, in combination with cisplatin, is used as an adjunct to radiation therapy in women with locally advanced cervical cancer.

Chemistry.

Floxuridine (FUDR) is highly similar to its prodrug, 5-FU. The discussion of FUDR in this chapter will be limited to its special application as an intraperitoneally administered agent in salvage therapy for ovarian cancer. 5-FU is light-sensitive and precipitates at low temperatures or, occasionally, with prolonged standing at room temperature. It has the molecular formula of $C_4H_3FN_2O_2$ and a molecular weight of 130.08.

Mechanism of Action.

5-FU acts as a false pyrimidine or antimetabolite to inhibit the formation of the DNA-specific nucleoside base thymidine. There are at least three mechanisms of action: inhibition of TS by 5-fluoro21-deoxyuridine-5′-monophosphate (FdUMP), the active metabolite of 5-FU; incorporation of FUTP into cellular RNA; and incorporation of FUTP into cellular DNA (270). 5-FU is a cell cycle phase–specific agent with cytotoxic effects seen maximally in S phase.

Drug Disposition.

There is disagreement over whether 5-FU is eliminated by a two-compartment or three-compartment model (2,271,272). Fraile and associates (273) demonstrated that plasma levels of 5-FU after oral administration are quite erratic. Schaaf and colleagues (274) documented that the pharmacokinetic characteristics of 5-FU are nonlinear. Doubling of the dose was accompanied by a decrease in nonrenal clearance. The half-life from the high dose was twice as long as that for the low dose of 5-FU. Their data were compatible with a product-inhibition model. Yoshida and coworkers (275) found positive correlations between the dose and serum steady-state levels (C_{SS}) and areas under the concentration–time curves (AUC). Patients who developed toxic reactions had greater C_{SS}s and AUCs. However, there were no correlations between serum levels and patient response to therapy.

5-FU and FUDR are extensively metabolized in the liver (hepatic metabolism can detoxify up to 80% of the total dose). However, there is no absolute documentation that patients with impaired liver function require dose reductions of 5-FU (276); however, patients should be monitored as they may be at increased risk of toxicity. As much as 15% of a dose may be found intact in the urine by 6 hours, with 90% excreted in the first hour. Depressed renal function does not generally require dosage adjustment for 5-FU.

5-FU distributes to all areas of body water by simple diffusion. Significant quantities of the drug may enter the CNS, and after 15 mg/kg given through IV, CSF levels of 6 to 8 × 10^{-6} M are obtained after 30 minutes. These levels persist for several hours and slowly subside. Although distribution to brain tissue is less rapid, abnormal areas, such as those with neoplasms, may more readily take up drug.

5-FU achieves high and persistent levels in effusions after IV administration. Hepatic administration through the portal

vein or artery also achieves high concentrations in the liver parenchyma and produces relatively low systemic levels.

Santini and colleagues (277) showed that therapeutic monitoring of 5-FU levels in patients with head and neck cancer can be used to improve the therapeutic index of the drug (i.e., less toxicity with maximal efficacy).

Administration and Dosage.

Doses of 5-FU to be given by the IV push route do not require further dilution from the commercial solution. Vein patency should be assured before administering a dose, with a 5- to 10-mL flush of normal saline or D_5W and another flush after the dose to rinse the remaining drug from the tubing. For short infusion (less than 24 hours), the rate of administration is not critical, and the dose should be given at a rate compatible with the particular vein selected. The patient should be continuously monitored to guard against extravasation. Most doses can be conveniently given over 1 to 2 minutes in this fashion.

Continuous infusions (over 4 to 5 days) may maximize the efficacy of this cycle-specific drug and lessen hematologic toxicity (278–280). Infusions of the drug may be added to a convenient volume of D_5W or normal saline, and each reconstituted daily dose can be administered over 24 hours. Commonly, the daily dose is added to 1 L, although volume is not critical.

Regimens reported for the use of 5-FU include the use of a loading dose, weekly IV bolus, continuous infusions over 4 to 5 days or over 6 weeks, and oral dosing. 5-FU may be administered intravenously as a bolus, rapid injection on a monthly (425 to 450 mg/m^2 IV on days 1 to 5 every 28 days) or a weekly schedule (500 to 600 mg/m^2 every week for 6 weeks every 8 weeks), or continuous IV infusion (24-hour infusion 2,400 to 2,600 mg/m^2 every week; 96-hour infusion 800 to 1,000 mg/m^2/d; or 120-hour infusion 1,000 mg/m^2/d on days 1 to 5 every 21 to 28 days) (50).

The loading dose scheme calls for one course of 400 to 500 mg/m^2 (12 mg/kg; maximum of 800 mg) daily for 5 days every 28 days, given as a single daily bolus injection or as a 4-day continuous infusion. This is followed by a weekly maintenance regimen. Horton and coresearchers (281) and Jacobs and coworkers (282), however, strongly associated the use of the loading dose with significant morbidity and occasional fatalities, and suggested that it offers no greater antitumor efficacy over a weekly bolus injection of 15 mg/kg given via IV.

Maintenance 5-FU dosing regimens include the following: 200 to 250 mg/m^2 (6 mg/kg) every other day for 4 days, repeated in 4 weeks (if toxicity has resolved); or 500 to 600 mg/m^2 (15 mg/kg), given by IV weekly as a continuous infusion or bolus injection (with and without the loading dose).

By continuous infusion, higher daily doses have been successfully used, and many investigators have reported lessened hematologic toxicity and enhanced efficacy. Most of a dose is eliminated by the liver, and the remainder by the kidney. Therefore, marked dysfunction in either system probably requires a dose reduction.

There are two commonly used dosing regimens for 5-FU combined with leucovorin: 370 mg/m^2/d of 5-FU for 5 days plus leucovorin given as a continuous infusion of 500 mg/m^2/d, beginning 24 hours before the first dose of 5-FU and continuing for 12 hours after completion of therapy; or 5-FU given at doses of 500 to 1,000 mg/m^2 every 2 weeks, preceded by calcium leucovorin at a dose of 20 mg/m^2 given as a 10-minute infusion (283,284).

Side Effects and Toxicities.

The most pronounced and dose-limiting toxic effects of 5-FU are on the normal, rapidly proliferating tissues of the bone marrow and the lining of the gastrointestinal tract. Some nausea and vomiting can be expected. These adverse effects may respond relatively well to antiemetic treatment. Stomatitis, however, is usually an early sign of impending severe toxicity that may become evident after 5 to 8 days of therapy. Symptoms include soreness, erythema, or ulceration of the oral cavity or dysphagia. Other reported gastrointestinal symptoms are diarrhea, proctitis, and esophagitis.

Leukopenia, primarily granulocytopenia and thrombocytopenia, occur with a nadir at 9 to 14 days for the granulocytes and 7 to 14 days for platelets. Patients who are poor candidates for 5-FU therapy are those with a total leukocyte count of 2,000/mm^3 or less or a platelet count of 100,000/mm^3 or less, or those with poor nutritional status at the outset of therapy.

Some degree of alopecia is expected, although hair regrowth has occurred even when successive doses are given. Partial loss of nails and hyperpigmentation of the nail beds and other body areas (e.g., face, hands) have been reported. These may resemble the hyperpigmentation seen in Addison disease. A maculopapular rash may occur on the extremities and sometimes the trunk. The rash is usually reversible. Sunlight may heighten or initiate many dermatologic reactions to 5-FU.

Various series have reported PPEs in association with very long continuous infusion 5-FU (over several weeks). in 42% to 82% of patients. The syndrome is progressive and disrupts treatment (285). This has encouraged the development of prodrugs of 5-FU, such as 5′-deoxy-5-fluorouridine, capecitabine, BOF-A2, ftorafur, UFT, and S-1 (286,287). Although there is no indicated treatment for PPE, the incidence has been reduced to a few percentage points by limiting 5-FU continuous infusion durations to 21 days with at least one additional week off drug. Possible therapies that have yet to be evaluated in clinical trials include DMSO, systemic corticosteroids, and pyridoxine (vitamin B_6) (286,288).

Hyperpigmentation over the veins used for 5-FU administration has been observed (289). In one the veins remained patent, but there was marked darkening of the skin immediately over the vein.

5-FU may also cause an acute cerebellar syndrome that can persist beyond the period of actual treatment (290,291). Neurotoxicity may be evidenced by headache, minor visual disturbances, cerebellar ataxia, or all three. This is a rare complication. The neurotoxic metabolite is probably fluorocitrate.

Cardiotoxicity is a rare but potentially serious toxicity attributable to 5-FU. The incidence of cardiotoxicity may vary from 1.2% to 18% of patients (292) and includes cases of myocardial infarction, angina, dysrhythmias, cardiogenic shock, sudden death, and electrocardiographic changes. The mechanism producing 5-FU–induced cardiotoxicity is unknown.

Special Precautions.

5-FU should never be given to pregnant women. 5-FU may increase the cortisone requirement in patients who have had an adrenalectomy (e.g., for breast cancer), and consideration should be given to increased doses of cortisone for patients receiving 5-FU.

Because dihydropyrimidine dehydrogenase is the rate-limiting enzyme in the metabolism of 5-FU, patients with a familial deficiency of dihydropyrimidine dehydrogenase (familial pyrimidinemia) should not receive 5-FU. The administration of 5-FU to patients with this enzyme deficiency has led to severe toxicity and even death (293,294).

Accidental splashing of 5-FU on the skin or eyes of personnel should be treated with immediate irrigation with saline solution or water. There have been no long-term sequelae of these accidents (295).

Because of the alkaline nature of the drug, admixture with any acidic agents (amino acids, penicillin, multivitamins, insulin, tetracycline) represents a theoretic incompatibility.

Gemcitabine

Gemcitabine (Gemzar) was approved by the FDA in 1995 for treatment of patients with advanced pancreatic cancer, based on an increase in survival and clinical benefit (improvement in pain and performance status). The combination of gemcitabine plus cisplatin is also is FDA-approved and is considered standard therapy for patients with advanced non–small cell lung cancer. Gemcitabine has demonstrated significant activity in advanced ovarian cancer patients and is active against refractory ovarian cancer and cervical cancer, as well as other solid tumors (296–300).

Chemistry.

Gemcitabine is a synthetic nucleoside analog with a structure that is highly similar to deoxycitidine and cytosine arabinoside (ara-C). Gemcitabine HCl is 2′-deoxy-2′,2′-difluorocytidine monohydrochloride (β isomer). The empirical

formula for gemcitabine is $C_9H_{11}F_2N_3O_4 \cdot HCl$, and the agent has a molecular weight of 299.66.

Mechanism of Action.

Gemcitabine is a prodrug and undergoes multiple phosphorylations by deoxycytidine kinase at the intracellular level to form the active diphosphate and triphosphate metabolites. The triphosphate is incorporated into DNA as a fraudulent base pair. Following the insertion of gemcitabine, one additional deoxynucleotide is added to the end of the DNA chain before replication is terminated. This process is known as "masked chain termination" and prevents exonucleases from excising off the fraudulent base pair (301,302). The diphosphate inhibits ribonucleotide reductase and thereby depletes the deoxynucleotide pools that are necessary for DNA synthesis and repair (303). Inactivation of gemcitabine occurs when the drug is metabolized by cytidine deaminase (both intracellulary and extracellulary) to form difluorodeoxyuridine (304).

Drug Disposition.

Following administration of gemcitabine 1,000 mg/m^2 by 30-minute IV infusion, the parent compound undergoes rapid clearance in a diphasic manner. The plasma half-life and clearance are dose, age, and gender dependent. Gemcitabine pharmacokinetics were evaluated in 353 patients with varied solid tumors, using short infusions (<70 minutes) and long infusions (70 to 285 minutes) at various total doses (500 to 3,600 mg/m^2) (305). There is a three- to fourfold interpatient variability in pharmacokinetics. As already noted, gemcitabine is metabolized intracellularly by deoxycytidine kinase to form the active diphosphate and triphosphate metabolites. The drug is inactivated both intracellularly and extracellularly by cytidine deaminase to form difluorodeoxyuridine (dFdU). Of the administered gemcitabine dose, 99% is excreted in the urine either as the parent compound (<10%) or as dFdU (306,307).

Dutch researchers have performed a pharmacokinetic schedule-finding study of gemcitabine plus cisplatin. Gemcitabine 800 mg/m^2 was administered as a 30-minute infusion 4 hours before, 24 hours before, 4 hours after, or 24 hours after administration of cisplatin 50 mg/m^2 by 1-hour IV infusion. Neither of the dosing schedules that used a 4-hour interval between drug administrations resulted in significant pharmacokinetic or pharmacologic differences. However, when gemcitabine was administered 24 hours before cisplatin, there was a twofold decrease in the plasma AUC of platinum. Furthermore, when the order of the drugs was reversed (i.e., cisplatin was administered 24 hours before gemcitabine), there was a 1.5-fold increase in the concentration–time product of the active triphosphate metabolite of gemcitabine within white blood cells. On the basis of these results, the investigators are conducting a phase 2 study of the cisplatin/gemcitabine combination, wherein cisplatin is administered 24 hours prior to gemcitabine (308).

Administration and Dosage.

Gemcitabine should be diluted in 0.9% sodium chloride to a concentration of no greater than 40 mg/mL (higher drug concentrations may result in incomplete dissolution). Gemcitabine is generally administered as a 30-minute IV infusion at a dose of 1,000 mg/m^2; infusion durations of greater than 60 minutes are associated with dose-limiting flu-like symptoms (309).

The standard dosing schedule used for treatment of pancreatic cancer is 1,000 mg/m^2 by 30-minute IV infusion once weekly for 7 weeks for cycle 1, followed by a 1-week rest, then 1,000 mg/m^2 once weekly for 3 weeks, followed by a 1-week rest for subsequent cycles (310).

In vitro studies have shown synergism between gemcitabine and cisplatin in a variety of human cancer cell lines (311,312). It is believed that this synergism is primarily the result of increased platinum–DNA adduct formation (312). An increase in DNA–platinum adducts has also been demonstrated for the combination in the clinical arena (313) [H64]. As noted (see Drug Disposition section), the interval between cisplatin and gemcitabine administration can affect both pharmacokinetic and pharmacologic parameters (308). This combination appears to be especially promising for patients with advanced ovarian cancer.

Side Effects and Toxicities.

Gemcitabine-induced toxicity is highly schedule-dependent; small daily doses are associated with greater toxicity than large doses administered on a weekly basis (314). The dose, schedule, and duration of infusion of gemcitabine directly affects the toxicity profile (314). Infusion durations of greater than 60 minutes are associated with increased myelosuppression and hepatic toxicity, whereas the administration of small daily doses results in dose-limiting flu-like symptoms (304,309). When gemcitabine is administered using the standard weekly dosing schedule, therapy is generally well tolerated, and bone marrow suppression is the major dose-limiting toxicity.

Analysis of safety data from 22 completed clinical trials, in which gemcitabine was administered on a weekly basis to 979 patients, revealed that neutropenia was the most significant hematologic side effect. Six percent of patients experienced grade 4 neutropenia, and an additional 20% experienced grade 3 neutropenia. Grade 4 leukopenia was experienced by less than 1% of patients. Decreases in white blood cell counts were noncumulative, short-lived, and rarely resulted in complications. Only 6 of the 979 patients (1.1%) developed severe infections, and no patient developed a life-threatening infection. Grades 3 and 4 anemia were experienced by 6.8% and 1.3% of patients, respectively, and only 2 of the 979 patients discontinued gemcitabine secondary to anemia. Grades 3 and 4 thrombocytopenia occurred in 4.1% and 1.1% of patients, respectively. Less than 1% of patients received platelet transfusions, and only 4 patients (0.4%) discontinued therapy because of thrombocytopenia (314).

Gemcitabine is associated with a low incidence of hepatic toxicity. Grade 3 elevations in alkaline phosphatase, alanine aminotransferase (ALT), or aspartate aminotransferase (AST) occurred in less than 8% of patients. Grade 4 elevations in these liver enzymes occurred in 2% or less of patients. Grade 3 or 4 increases in bilirubin occurred in 1.8% and 0.8% of patients, respectively. It is noteworthy that one-third of patients in this study population had documented liver metastases (314).

Clinically significant renal toxicity rarely occurs with gemcitabine therapy. However, rare cases of hemolytic uremic syndrome have been reported with gemcitabine therapy. The incidence is believed to be approximately 0.6% (314,315).

Other nonhematologic toxicities that were reported in more than 5% of patients were nausea/vomiting (64.3% overall, 17.1% grade 3, 1.2% grade 4), fever (37.3% overall, 0.7% severe), edema (greater than 20% of patients), flu-like symptoms (18.9%, 0.9% severe), cutaneous reactions (24.8%, 0.2% severe), alopecia (14.1%, 0.4% severe), diarrhea (12.1%, 0.7% severe), somnolence (9.1%, 0.9% severe), infection (8.7%, 1.1% severe), mucositis (8.4%, 0.2% severe), constipation (7.8%, 0.7% severe), and dyspnea (7.7%, 1.2% severe). Nausea and vomiting were rarely dose-limiting, and only 2 (0.2%) patients discontinued gemcitabine therapy because of nausea. Fever was a fairly frequent toxicity and sometimes occurred in the absence of flu-like symptoms or infection. Subcutaneous edema, including peripheral edema and facial edema, occurred in a significant number of patients. Edema was generally mild to moderate in nature; few patients (0.6%) discontinued gemcitabine because of this side effect, and the edema resolved after drug discontinuation. Flu-like symptoms consisted of headache, back pain, chills, myalgia, asthenia, and anorexia, and were generally short-lived. Paracetamol reportedly provided relief to some patients. Cutaneous reactions consisted of erythema in mild cases (15.5%) and dry desquamation, vesiculation, and/or pruritus in moderate cases (9.1%). Only 1 patient developed severe cutaneous toxicity that was characterized as moist desquamation and ulceration. Dyspnea (with or without bronchospasm) occurs in less than 10% of patients following gemcitabine administration. This toxicity generally occurs within a few hours of treatment and resolves within 6 hours (314).

Fatal pulmonary toxicity (acute respiratory distress syndrome) has been reported as a rare side effect of gemcitabine therapy (316). Symptoms include progressive dyspnea, tachypnea, marked hypoxemia, and bilateral interstitial infiltrates consistent with pulmonary edema. Some patients have responded to the termination of gemcitabine therapy and treatment with corticosteroids and diuretics. Prior radiation therapy to the mediastinum may be a risk factor for gemcitabine-induced pulmonary edema (316,317).

Ifosfamide

In combination with cisplatin, ifosfamide (IFEX, Holoxan) has been administered to patients with advanced cancer of the cervix, and in combination chemotherapy, it is a second-line treatment for patients with advanced cancer of the ovary (318,319). It also has activity in advanced or recurrent endometrial cancer (320).

Chemistry.

Chemically, ifosfamide is 3-(2-chloroethyl)-2-[(2-chloroethyl)amino]-tetrahydro- 2H-1,3,2-oxazaphosphorine-2-oxide, and is chemically related to the nitrogen mustards and a structural analog of cyclophosphamide. It differs only in the position of one of the two chloroethyl groups, which is transposed to the endocyclic (ring) nitrogen in ifosfamide. The molecular formula is $C_7H_{15}Cl_2N_2O_2P$, and the compound has a molecular weight of 261.1.

Mechanism of Action.

Ifosfamide is a metabolically activated alkylating agent. Like cyclophosphamide, it must first undergo hydroxylation by microsomal (mixed-function oxidase) enzyme systems (321). The activation of ifosfamide occurs more slowly than that of cyclophosphamide, and there is quantitatively greater oxidation of the chloroethyl side chains with ifosfamide. This leads to a greater production of chloracetaldehyde, a possible neurotoxin.

The activation process generates highly reactive metabolites, particularly 4-hydroxyifosfamide, which are capable of cellular uptake and, ultimately, covalent binding to protein and to DNA (322). Metabolites can spontaneously break down to yield the bladder irritant acrolein and the active alkylating moiety, ifosforamide mustard. Cross-linking of DNA strands proceeds from ifosforamide mustard, but acrolein binds nonspecifically and covalently to bladder epithelium. The DNA–cross-link distance is greater for ifosfamide (seven atoms) compared with cyclophosphamide (five atoms). Furthermore, the aziridine forms more slowly and is less reactive because it lacks a positive charge (323). Chain scission of DNA and inhibition of thymidine uptake also occur with ifosfamide. The primary mechanism of alkylation is not cell cycle-specific.

Drug Disposition. The pharmacokinetics of ifosfamide appears to be qualitatively similar to those of cyclophosphamide. Creaven and coworkers (324) found a plasma half-life of radiolabeled ifosfamide (5,000 mg/m^2) of 13.8 hours, with 82% urinary (radioactivity) recovery.

The plasma decay pattern appears to be biexponential (two-compartment model) for large bolus doses and monoexponential (one-compartment model) with fractionated doses. In contrast to single-dose pharmacokinetics studies, Allen and associates (325) found that with sequential daily administration of 2,400 mg/m^2/d for 3 days, there is monoexponential plasma decay with a half-life of 6.9 hours and a metabolized urinary recovery fraction of 72.8%, in contrast to the biexponential decay (plasma half-life 15.2 hours) of a single-bolus dose of ifosfamide (5,000 mg/m^2). This finding suggests that the metabolic disposition of the drug may be dose-dependent. These half-lives are approximately twice those reported for cyclophosphamide. Of note, a longer ifosfamide half-life may be seen in obese patients who are more than 20% over ideal body weight. The renal clearance rate of ifosfamide is about twice that for cyclophosphamide: 21.3 versus 10.7 mL/min in bolus dosing and 18.7 versus 10.7 mL/min with fractionated doses. Only about half of an ifosfamide dose is metabolized. Compared with about 90% for cyclophosphamide. This reflects a substantial difference in the metabolic clearance capacity for the two analogs. Although more intact (inactive) ifosfamide than cyclophosphamide is renally excreted, urinary alkylating activity persists longer with ifosfamide.

Creaven and coworkers (324) demonstrated that, because unchanged ifosfamide, but not metabolites, penetrates the blood–brain barrier, alkylating activity in the CSF may occur but is probably negligible.

Administration and Dosage.

Ifosfamide is reconstituted by the addition of sterile water to the vial, which should be shaken to dissolve. Ifosfamide may be further diluted to a concentration of 0.6 to 29 mg/mL in 5% dextrose or 0.9% sodium chloride. It is administered intravenously, usually by a short infusion. Ifosfamide may also be administered by slow IV push in a 75-mL minimal

volume of sterile saline solution, but not water, and infused over at least 30 minutes or by continuous infusion over 5 days. Large single doses of ifosfamide produce much more toxicity than fractionated schedules, which are therefore preferred in solid-tumor treatment regimens. Adequate hydration of the patient before and for 72 hours after ifosfamide therapy is recommended to reduce the incidence of drug-induced hemorrhagic cystitis. The use of a concurrent prophylactic agent for hemorrhagic cystitis, such as mesna (Mesnex), is required to prevent severe hematuria from high-dose ifosfamide. At least 2 L of fluid each day is recommended to produce a copious urine output.

Continuous infusions of ifosfamide over 24 hours have also been given every 3 weeks (326). Mesna can be given concurrently in the same infusion container or as a 4-hour intermittent IV bolus (327). However, renal toxicities may be increased with the single, large infusions. Extravasation of the drug should not cause tissue necrosis, but one case report has been described (328).

The FDA-approved dose for testicular cancer is 1,200 mg/m^2/d for 5 consecutive days every 21 days. Other dosage schedules include 2,000 mg/m^2 IV continuous infusion on days 1 to 3 every 21 days as part of the MAID regimen (mesna, Adriamycin, ifosfamide, dacarbazine) for soft tissue sarcoma; 1,000 mg/m^2 on days 1 and 2 every 28 days as part of the ICE regimen (ifosfamide, carboplatin, etoposide) for non-Hodgkin lymphoma; and 1,000 mg/m^2 on days 1 to 3 every 21 to 28 days as part of the TIC regimen (paclitaxel, ifosfamide, carboplatin) for head and neck cancer (50).

Side Effects and Toxicities.

Creaven and associates (324) reviewed the clinical toxicity of ifosfamide administered as a large bolus injection (200 to 10,000 mg/m^2) and in a fractionated 3-day (2,400 mg/m^2/d) schedule. Urinary tract toxicity is the dose-limiting factor with both schedules. The clinical hallmark is hemorrhagic cystitis, which is caused by excretion of active alkylating metabolites into the urinary bladder. Vigorous hydration with oral and IV fluids and concomitant mesna are needed to prevent serious ifosfamide-induced bladder damage. Hydration may also overcome the antidiuretic effects of this drug. Nelson and colleagues (327) used IV furosemide (20 to 40 mg) to maintain adequate urine flow in a phase 1 study of ifosfamide. Diuretic responses usually occurred within 1 hour.

Symptoms of dysuria and urinary frequency appear to parallel those of hematuria. The onset of symptoms is 1 to 2 days after injection, with an average duration of 9 days (range 1 to 41 days) (329). Dose-related ifosfamide-induced nephrotoxicity was detected by elevation of the BUN, producing a subsequent dose-related uremia in 66% of patients receiving 150 mg/kg. Other lesions seen at autopsy (4 of 7 patients) included evidence of acute tubular necrosis and pyelonephritis. At low daily doses, granular cylindruria was seen in all patients, denoting marked tubular damage. The cylindruria cleared within 10 days of drug discontinuance (329). DeFronzo and coresearchers (330) also described glomerular dysfunction and a Fanconi-type picture in a patient treated with ifosfamide. Prior cisplatin therapy may also increase ifosfamide-induced nephrotoxicity (331,332).

Nausea and vomiting are common and are more severe after a rapid injection of large ifosfamide doses. Emesis typically begins within a few hours of administration and persists an average of 3 days (range 1 to 28 days) (329).

Hematologic toxicity from ifosfamide usually involves only a mild-to-moderate degree of leukopenia in most patients. In a review by Creaven and coworkers (324), significant thrombocytopenia was not encountered for any of the dose schedules used.

Lethargy and confusion are seen with high doses of ifosfamide and may be caused by the chloracetaldehyde metabolite. Nelson and associates (327) observed that this lasted from 1 to 8 hours, was spontaneously reversible, and was related to the passage of intact drug into the CNS. Seizures, ataxia, stupor, and weakness have been reported after ifosfamide. These effects may be increased by concomitant neurotoxic drugs, such as certain antiemetics, tranquilizers, narcotics, and antihistamines. There is a single case report of nonconvulsive status epilepticus associated with ifosfamide therapy. The patient responded to discontinuation of the ifosfamide and phenytoin therapy (333). Although alkylating metabolites appear to penetrate the blood–brain barrier, the levels achieved are too low to be useful in the treatment of CNS tumors (324).

Alopecia is usually seen with ifosfamide, especially when large bolus doses are used. In a study by Van Dyk et al.

(329), the average onset of maximal hair loss was 19 days (range 11 to 32 days) after the start of treatment.

Hepatic enzyme elevations have been described in some patients. The elevations in alkaline phosphatase and serum transaminase are transient and typically resolve rapidly without sequelae.

Special Precautions.

The patient must be kept well-hydrated during ifosfamide therapy to reduce the potential for hemorrhagic cystitis. The use of mesna given intravenously or orally is required to prevent hemorrhagic cystitis. **Table 14.6** outlines the recommended mesna schedule for ifosfamide uroprotection.

TABLE 14.6 Dosing Schedules for Mesna Combined with Ifosfamide

Route of Mesna Administration	Dose (mg/kg) as a Percentage of Ifosfamide Dose at Times before and after Ifosfamide		
	15 minutes before	4 hours after	8 hours after
Intravenous	20%	20%	20%
Oral[a]	Not recommended; use IV route	0%	0%

[a]For highly reliable patients with total emetic control, mesna solution can be diluted 1:1 to 1:10 in carbonated cola drinks or in chilled fruit juices (e.g., apple, grape, tomato, and orange juice) and administered orally.?

Patients who have received previous or concurrent therapy with radiation or cytotoxic drugs may require significant ifosfamide dosage reductions. Dose reductions should also be considered for patients with impaired renal function and/or serum albumin concentrations below 3.5 g/dL.

Drug Interactions.

Several drug interactions are possible with ifosfamide. Because the compound undergoes hepatic activation by microsomal enzymes, induction is potentially possible by pretreatment with various enzyme-inducing drugs, such as phenobarbital, phenytoin, and chloral hydrate.

Nephrotoxic drugs like cisplatin may significantly increase ifosfamide renal damage (331). Other drug interactions reported for cyclophosphamide that may also occur with ifosfamide include reactions with metabolic alteration of H_2-antihistamines, such as cimetidine.

Ixabepilone

Ixabepilone is FDA-approved for use as monotherapy in the treatment of metastatic or locally advanced breast cancer after the failure of an anthracycline, a taxane, and capecitabine, or in combination with capecitabine after the failure of an anthracycline and a taxane.

Chemistry.

Ixabepilone is a semisynthetic epothilone microtubule inhibitor. Epothilone is a natural product isolated from a myxobacterium, *Sorangium cellulosum*. Ixabepilone is modified by replacing the naturally occurring lactone in the macrocycle by a lactam, intended to reduce the rate of metabolism of the ring. The chemical name for ixabepilone is (1S,3S,7S,10R,11S,12S,16R)-7,11-dihydroxy-8,8,10,12,16-pentamethyl-3-[(1E)-1-methyl-2-(2-methyl-4-thiazolyl)ethenyl]-17-oxa-4-azabicyclo[14.1.0] heptadecane-5,9-dione, and it has a molecular weight of 506.7.

Mechanism of Action.

Ixabepilone stabilizes αβ-II and αβ-III microtubules leading to the death of proliferating cells via a block in the mitotic phase of the cell cycle. Ixabepilone has a low affinity for the efflux pump proteins MRP1 and P-glycoprotein, which are a known cause of resistance to taxanes. It is also active in human tumor xenografts that overexpress βIII tubulin isoforms or have tubulin mutations conferring resistance to taxanes. Furthermore, it is active in human tumor xenograft models that are resistant to other commonly used anticancer drugs such as anthracyclines and vinca alkaloids.

Drug Disposition.

Following IV injection of ixabepilone, the mean Vd is reported in excess of 1,000 L, indicating a very high tissue distribution. The clearance has been reported as 475 ± 247 mL/min/m^2, the half-life at 14 hours. Plasma protein binding was in the region of 67% to 77%. Ixabepilone is eliminated primarily as the metabolized drug in the feces. Approximately 86% of an administered dose was eliminated in 7 days, with 65% of the dose in the feces and 21% of the dose in the urine. Unchanged ixabepilone was 1.6% of the dose in the feces and 5.6% of the dose in the urine of the recovered dose, respectively. Ixabepilone is extensively metabolized in the liver, and studies with human liver microsomes suggest that CYP3A4 is the primary route.

Dosage.

The recommended dosage of ixabepilone is 40 mg/m^2 administered intravenously over 3 hours every 3 weeks. Dose adjustments are recommended for hematologic and neurologic toxicities. One of the license indications for ixabepilone is for use in combination with capecitabine. Ixabepilone with capecitabine is contraindicated in patients with AST or ALT >2.5 × ULN or bilirubin >1 × ULN because of increased risk of toxicity and neutropenia-related death.

To minimize the chance of hypersensitivity reactions, it is recommended that all patients receive premedication with an H1 and H2 inhibitor. Patients who experience a hypersensitivity reaction should receive treatment with corticosteriods.

Side Effects and Toxicities.

Dose-dependent myelosuppression is seen with grade 4 neutropenia, reported in 36% of patients. Myelosuppression is more severe in patients with hepatic impairment. Peripheral neuropathy is common and has been reported in approximately 65% of patients, with 14% to 21% grade 3/4.

Drug Interactions.

Drug interactions are to be expected with other drugs that are metabolized by (e.g., ketoconazole) or induce (e.g., rifampin) CYP3A4. These two drugs have been shown to increase and decrease the exposure to ixabepilone by +79% and –43%, respectively. It is recommended that strong inhibitors or inducers of CYP3A4 be avoided where possible and dose modifications considered when any strong or weak inducer of inhibitor is used.

Liposomal Encapsulated Doxorubicin

Liposomal doxorubicin (Doxil, Caelyx) is FDA-approved for the treatment of patients with metastatic, refractory ovarian cancer, and AIDS-related Kaposi sarcoma.

Chemistry.

Doxorubicin HCl, which is the established name for (8*S*,10*S*)-10-[(3-amino-2,3,6- trideoxy-α-L-*lyxo*-

hexopyranosyl)oxy]-8-glycolyl-7,8,9,10-tetrahydro-6,8,11-trihydroxy-1- methoxy-5,12-naphthacenedione hydrochloride, has a molecular weight of 579.99 and the molecular formula $C_{27}H_{29}NO_{11} \cdot HCl$. The liposomal carriers are composed of *N*-(carbonyl-methoxypolyethylene glycol 2000)-1,2distearoyl- *sn*-glycero-3-phosphoethanolamine sodium salt (MPEG-DSPE), 3.19 mg/mL; fully hydrogenated soy phosphatidylcholine, 9.58 mg/mL; and cholesterol, 3.19 mg/mL. Greater than 90% of the drug is encapsulated in the liposomes. The liposomal encapsulation of doxorubicin dramatically alters the pharmacokinetic and toxicity profiles of the drug.

Mechanism of Action.

The mechanism of action of doxorubicin mirrors that of doxorubicin. Liposomes are microscopic vesicles composed of a phospholipid bilayer that are capable of encapsulating active drugs. The liposomes of the encapsulated form of doxorubicin are formulated with surface-bound MPEG, a process often referred to as pegylation, to protect liposomes from detection by the mononuclear phagocyte system and to increase blood circulation time (334).

Drug Disposition.

Liposomal doxorubicin is associated with a much longer plasma half-life, slower plasma clearance, and reduced Vd than free doxorubicin. In a pharmacokinetics study performed in 6 patients with solid tumors, the area under the plasma disappearance curve was 1.0 mg/L hour versus 609 mg/L hour when 25 mg/m^2 of doxorubicin was administered as free drug or as a pegylated liposomal form, respectively. The initial half-life was 0.07 versus 3.2 hours, and the terminal half-life was 8.7 versus 45.2 hours for the free and liposomal forms of doxorubicin, respectively. Additionally, the steady-state Vd was 254 L versus 4.1 L for the free and liposomal forms, respectively (335). Liposomal encapsulation of doxorubicin has also been shown to result in fourfold to 16-fold increases in tumor-tissue drug concentrations relative to that achieved following administration of the free form.

Administration and Dosage.

Liposomal doxorubicin must be diluted in 250 mL of 5% dextrose before administration. Because liposomal doxorubicin contains no preservative or bacteriostatic agent, aseptic technique must be strictly observed. Liposomal doxorubicin may be administered as an IV infusion over 30 to 60 minutes. In that liposomal doxorubicin is not a vesicant, extravasation of the drug is not a critical concern. For ovarian cancer patients, liposomal doxorubicin should be administered at a dose of 50 mg/m^2 (every 4 weeks) at an initial rate of 1 mg/min to reduce the risk of infusion reactions. The rate may be increased to a 60-minute infusion if no adverse events are noted; however, in clinical practice, a dose of 40 mg/m^2 is more commonly employed.

Side Effects and Toxicities.

Unlike the parent drug, liposomal doxorubicin is not a vesicant and is associated with minimal cardiotoxicity, alopecia, and nausea/vomiting. However, the liposomal encapsulation results in acute infusion reactions, and an increased rate of PPE and stomatitis (336). PPE is a dose-limiting toxicity that can occur in 26% of patients who receive 50 mg/m^2 every 4 weeks (337). Stomatitis is a second dose-limiting toxicity associated with liposomal doxorubicin. Current methods to prevent PPE and stomatitis include dose reduction and discontinuation (grade 1—redose. If the patient has experienced previous grade 3 or 4 toxicity, delay the treatment by 2 weeks until resolution to grades 0 to 1, and reduce dose by 25% before returning to original dose level; grades 2 to 4—delay up to 2 weeks until resolved, if no resolution to grades 0 to 1, discontinue; grades 3 to 4—after delay and resolution to grades 0 to 1, decrease dose by 25%, if no resolution, discontinue). To help relieve pain from PPE, topical wound care, elevation, and cold compresses may be used as supportive care (288). Topical DMSO has been used to treat skin extravations (99% DMSO four times daily up to 14

days), but has yet to be evaluated in a randomized trial (286). Other possible therapies that have yet to be evaluated in clinical trials include systemic corticosteroids and pyridoxine (vitamin B_6) (288).

Infusion-related reactions occur in less than 10% of patients treated with liposomal doxorubicin and are most common during the first course of treatment. Symptoms may include flushing, shortness of breath, facial swelling, headache, chills, back pain, tightness in the chest and throat, and hypotension. Alopecia has been observed in only 15% of ovarian cancer patients treated with liposomal doxorubicin.

Methotrexate

Methotrexate is an active drug in the first-line treatment of gestational choriocarcinoma, chorioadenoma destruens, and hydatidiform mole. It is used in the prophylaxis and treatment of meningeal leukemia, and in combination with other agents for the treatment of breast cancer, epidermoid cancers of the head and neck, advanced mycosis fungoides, advanced non-Hodgkin lymphoma, lung cancer, and metastatic squamous cell cancer of the cervix.

Chemistry.

Methotrexate is a cell cycle–specific antifolate analog, which differs from folic acid in two substitutions: an amino group for a hydroxyl in the pteridine portion of the molecule and a methyl group on the amino nitrogen between the pteridine nucleus and the benzoyl group of 4-amino-10-methyl folic acid. Chemically, methotrexate is *N*-[4-[[(2,4-diamino-6-pteridinyl)methyl]benzoyl]-L-glutamic acid. It is a weak acid with a molecular weight of 454.45 and a molecular formula of $C_{20}H_{22}N_8O_5$. It is only slightly soluble in water and alcohol. Sodium methotrexate is water soluble and is used in injectable preparations.

Mechanism of Action.

Free intracellular methotrexate tightly binds to dihydrofolate reductase (DHFR), blocking the reduction of dihydrofolate to tetrahydrofolic acid, the active form of folic acid. As a result, thymidylate synthetase and various steps in de novo purine synthesis that require 1-carbon transfer reactions are halted. This in turn arrests DNA, RNA, and protein synthesis.

Amino acid syntheses blocked by methotrexate include those requiring 1-carbon transfer, such as the conversion of glycine to serine and homocysteine to methionine. Experimental studies have shown that thymidylate synthetase is inhibited at methotrexate concentrations of 10^{-8} M or less, but inhibition of purine synthesis requires concentrations of 10^{-7} M or greater (338).

Methotrexate undergoes a variable degree of polyglutamation intracellularly. The polyglutamated forms of the drug are positively charged and do not readily pass through cell membranes. Methotrexate polyglutamates form an intracellular pool of active drug that is retained for long periods, sometimes months, after a single dose (339). The ability of tumor cells to add t-glutamyl residues to methotrexate may be a key determinant of antitumor activity.

The effects of methotrexate are rapidly reversible as free methotrexate leaves the cells. The normal intracellular levels of dihydrofolate are very low (10^{-8} M) but increase greatly after methotrexate administration.

Resistance to methotrexate may develop as a result of elevated DHFR activity or defective transport of methotrexate into malignant cells. Increased DHFR enzyme levels may also result from amplification of the DHFR gene, a process associated with homogeneously staining regions of chromosomes and an unstable inheritance mediated by double minutes or extra chromosomal DNA fragments (340). Certain quinazolines have been shown to be effective inhibitors of thymidylate synthetase and may be useful clinically in overcoming this type of resistance (341). *In vitro* studies and clinical experimentation with high-dose therapy indicate that a major mechanism of resistance is probably secondary to decreased cellular uptake.

Methotrexate is classified as a cell cycle phase–specific antimetabolite with activity mostly in S phase. Experimentally,

methotrexate synchronizes tumor cells in S phase about 36 to 72 hours after administration (342).

The enhanced toxic effect on tumors compared with normal tissue from high-dose methotrexate with leucovorin rescue may be a result of bypassing normal carrier-mediated cell membrane transport of methotrexate. Leucovorin and its metabolite, 5-methyltetrahydrofolate, share a common influx transport site with methotrexate. There appear to be at least two active transport carrier systems involved in the influx and efflux of methotrexate and folates (343). If normal cells are rescued with calcium leucovorin, methotrexate can then exert a relatively greater toxic effect on the tumor cells. Selective rescue of normal cells may be mediated by a slower rate of DNA synthesis relative to the tumor cell or to tissue-specific differences in transmembrane transport.

Drug Disposition.

Orally administered methotrexate is rapidly but incompletely absorbed from the gastrointestinal tract. It reaches peak blood levels in approximately 1 hour. Approximately 50% to 60% of the drug in the blood is bound to plasma proteins. Methotrexate is widely distributed to body tissues. In conventional doses, methotrexate is excreted unchanged in the urine. In high doses, it is partially metabolized to 7-hydromethotrexate, which is only slightly soluble in acidic solutions. About 1% to 11% of a dose is excreted as the 7-hydroxy metabolite, and this may comprise as much as 35% of the drug level in the terminal elimination phase. Only about one-third of an oral dose is absorbed, but IM absorption is almost 100% (344).

The hepatic extraction coefficient for methotrexate appears to be very low, and intra-arterial hepatic doses show metabolism and pharmacokinetics similar to IV doses (345). Methotrexate is both filtered at the glomerulus and actively secreted by the renal tubule. Drugs that interfere with renal excretion of weak acids, such as probenecid, sulfinpyrazone, and salicylates, may be expected to reduce the rate of methotrexate excretion. Probenecid has been used successfully in one study to produce a prolonged elevation of plasma methotrexate levels from otherwise low doses of methotrexate (346).

Plasma decay of methotrexate levels have reportedly been biphasic and possibly triphasic. Huffman and associates (347) reported half-lives after a 30 mg/m^2 dose to be triphasic: 0.750 ± 0.11, 3.49 ± 0.55, and 26.99 ± 4.44 hours, respectively. Stoller and colleagues (348) reported a biphasic plasma decay for high-dose therapy of 2.06 ± 0.16 and 10.4 ± 1.8 hours. Wang and coresearchers (349) reported age-dependent biphasic elimination of high-dose methotrexate.

Patients with pleural effusions may accumulate methotrexate that slowly distributes from this compartment back into the plasma to increase systemic exposure and the risk of toxicity (350). Effusions should be drained before administration of methotrexate.

Administration and Dosage.

Methotrexate may be given by the oral, IM, IV (IV infusion or push), intra-arterial, or intrathecal routes. For treatment of neoplastic disease, oral administration of low-dose methotrexate is preferred because of rapid absorption of the tablet form of the agent. Methotrexate has been administered by numerous dosing schedules. The usual starting doses are adjusted based on clinical response and hematologic monitoring. In general, methotrexate is administered orally or intramuscularly in doses of 15 to 30 mg daily for a 5-day course. Courses are usually repeated three to five times as required, with rest periods of 1 or more weeks between courses until toxicities subside (351). Leucovorin is indicated following treatment with higher doses of methotrexate, to diminish toxicity.

If the IV formulation is administered, the dose should be reduced by 50% for patients with renal insufficiency (BUN ≥30 mg/L). Similar dose reductions should be made for the oral form, although no specific guidelines are available. Methotrexate administration is contraindicated in patients with a CrCl less than 40 mL/min and/or a serum creatinine greater than 2 mg/dL.

Side Effects and Toxicities.

Hematologic effects of methotrexate include leukopenia, thrombocytopenia, and anemia. They occur rapidly and depend on the dose and schedule used. The nadir of hemoglobin depression occurs after 6 to 13 days and of reticulocyte at 2 to 7 days, with rebound between 9 and 19 days. Leukocyte nadir occurs within 4 to 7 days, followed by partial recovery and then, in rare instances, a second decrease in the leukocyte counts occurs during days 12 to 21. The platelet nadir is reached in 5 to 12 days. Hypogammaglobulinemia may also occur after methotrexate administration.

Nausea, vomiting, and anorexia are usually the earliest gastrointestinal symptoms. Gingivitis, glossitis, pharyngitis, stomatitis, and ulcerations with bleeding of the mucosal membranes of the mouth or other portions of the gastrointestinal tract may occur. If ulcerative stomatitis or diarrhea occurs, methotrexate therapy must be interrupted to prevent severe hemorrhagic enteritis or intestinal perforation.

Hepatotoxicity is more common in patients receiving high-dose therapy and in those receiving frequent small doses. Hepatocellular injury is indicated in liver function tests by a rise in SGOT and SGPT, usually within the first 12 hours. Prothrombin times may rise with a decrease in plasma factor VII activity, and indirect hyperbilirubinemia may develop. All of these usually return to normal within 1 week. Hepatocytes appear to be protected by fractionated high-dose methotrexate treatments with leucovorin rescue if treatments are administered at intervals of less than 1 week. This may be due to leucovorin activity remaining from prior doses. Various pathologic hepatic changes can occur, including atrophy, necrosis, fatty changes, fibrosis, and cirrhosis. Liver biopsy is the only reliable means of assessing the degree of methotrexate hepatotoxicity.

Dermatologic side effects include erythematous rashes, pruritus, urticaria, folliculitis, vasculitis, photosensitivity, depigmentation, or hyperpigmentation. Alopecia may occur, with several months being required for regrowth. CNS effects include dizziness, malaise, and blurred vision. Encephalopathy also has been reported. Intrathecal administration has been followed by increased CSF pressure, convulsions, paresis, and a syndrome resembling the Guillain–Barré syndrome (352). Deaths have been reported after intrathecal therapy. Renal failure may occur in patients receiving methotrexate, especially in high doses. This risk may be decreased by alkalinization of the urine to increase methotrexate solubility and by giving large quantities of fluid. Other reactions rarely reported include chills and fever, osteoporosis, and pulmonary reactions, mainly fibrosis (353).

Drug Interactions.

Potential drug interactions have been postulated to occur with other protein-bound drugs, such as salicylates, sulfonamides, phenytoin, and *p*-aminobenzoic acid. These drugs displace methotrexate from its protein-binding site in the blood, causing an increase in the levels of the free drug. However, the overall degree of binding is probably not high enough for major displacement interactions.

Antibiotics used in gut sterilization may also alter methotrexate pharmacokinetics in humans, eliminating the slow phase of excretion (354). Salicylates and probenecid may also compete with methotrexate for renal tubular secretion and increase its serum half-life.

Ethyl alcohol may increase the possibility of methotrexate-induced hepatotoxicity. Oral anticoagulants, such as warfarin, may be greatly potentiated by methotrexate. Methotrexate may alter the liver metabolism of these drugs.

There are several drug interactions described for methotrexate with other chemotherapeutic agents. For example, a clinically significant interaction between methotrexate and L-asparaginase involves the administration of methotrexate 3 to 24 hours before L-asparaginase. The methotrexate treatment is believed to block protein synthesis and reduce asparaginase toxicities, allowing larger doses to be given. Some sequential methotrexate combinations may produce enhanced therapeutic activity. For example, methotrexate given 4 to 9 hours before 5-FU may produce enhanced antitumor activity in breast cancer, but with a commensurate increase in toxic effects (163,355). The mechanism of this interaction involves a significant increase in 5-FU for at least 3 hours (355). The reverse sequence decreases therapeutic activity (356).

Methotrexate activity is enhanced, and thus toxicity increased, when it is used with aspirin, penicillins, nonsteroidal anti-inflammatory agents, cephalosporins, or phenytoin. These agents inhibit the renal excretion of methotrexate (50).

Mitomycin

Mitomycin (Mutamycin, mitomycin C) is a purple antibiotic isolated from *Streptomyces caespitosus* that is indicated for disseminated adenocarcinoma of the stomach or pancreas in combination with other agents and as palliative treatment. It has also proved useful in combination chemotherapy as a third-line agent in the treatment of advanced cervical cancer.

Chemistry.

The chemical name for mitomycin is [1*aR*]6-amino-8-[[(aminocarbonyl)oxy]methyl]- 1,1*a*,2,8,8*a*,8*b*-hexahydro-8*a*-methoxy-5-methylazirino[2′,3′:3,4]-pyrrolo[1,2-*a*]indole-4,7-dione, and it has a molecular weight of 334. Mitomycin is heat stable, is soluble in water and other organic solvents, and has a unique absorption peak at 365 nM (357). In solution, it is slowly inactivated by visible but not ultraviolet light. It is very unstable in acidic and highly basic conditions. The aziridine and carbamate groups on mitomycin are necessary for alkylating activity but not for antibacterial activity. The compound is activated by reduction of the quinone moiety, which releases a methanol residue from the molecule. This allows the aziridine ring to open, exposing an electrophilic carbon at C_1 (alkylating site). The second (cross-linking) site for alkylation is exposed at C_{10} after an enzymatic or chemically mediated loss of the carbamate side chain.

Mechanism of Action.

Mitomycin is activated *in vivo* to an alkylating agent that cross-links complementary DNA strands, halting DNA synthesis. DNA is the major site of mitomycin activity, although at extremely high concentrations, RNA synthesis may also be affected. The active metabolites of mitomycin resulting from reduction of the quinone moiety yield an opened aziridine ring exposing the primary alkylating site at C_1. A second alkylating site at C_{10} is exposed with the enzymatic loss of the carbamate side chain (358). The molecular site of DNA binding has been identified at the N_2 and O_6 positions of adjacent guanines in the minor groove of DNA (359).

Activation of the drug can be mediated by chemical reducing agents, by microsomal enzymes, or even by brief exposure to an acidic pH. The extent of DNA binding appears to be related to the guanine and cytosine content of the particular DNA. Cytotoxicity probably results directly from DNA synthesis inhibition secondary to alkylation.

Oxygen free radicals may also contribute to the cytotoxicity of mitomycin by producing DNA strand breaks (360). Oxygen free radicals are produced by cyclic redox reactions of the quinone moiety. Mitomycin's cytotoxic action is not cell cycle phase–specific, but cytotoxic effects are maximized if cells are treated in late G_1 and early S phase. In addition to the direct cytotoxic effects of the drug, mitomycin also causes chromosomal aberrations (mutagenic activity), and in experimental systems, it is a potent carcinogen and teratogen.

Kennedy and coworkers (361) described selective activation of mitomycin by hypoxic cells, suggesting some drug selectivity for hypoxic tumors. Resistance to mitomycin involves an increase in specific cytosolic proteins (possibly a glutathione transferase) and collateral resistance with anthracyclines and dactinomycin (362,363). The latter type of multidrug resistance is mediated by P-glycoprotein expression, with resultant enhanced drug efflux, as observed in mitomycin C–resistant L-1210 cells (364).

Drug Disposition.

Mitomycin is cleared rapidly from the vascular compartment. Peak serum concentrations of about 1 μg/mL are typically achieved after IV bolus doses of 10 mg/m^2 (365). Less than 10% of the dose is excreted into the urine, and this is complete within a few hours after administration. Mitomycin has also been detected in the bile and feces, although animal studies demonstrate that the highest drug levels occur in the kidneys. Detectable levels were also found in muscle, lung, intestine, stomach, and eye, but not in the brain, spleen, or liver (357).

The primary means of mitomycin elimination is by liver metabolism, but the specific enzymes responsible are

unknown. However, the enzymes responsible for metabolism do not appear to involve the P450 mixed-function oxide family. *In vitro* studies demonstrate drug inactivation on contact with tissue preparations from the spleen, liver, kidney, brain, and heart. This inactivation is further augmented by anaerobic conditions (357).

There is no detectable change in mitomycin pharmacokinetics in patients with altered hepatic function nor when other drugs, including furosemide, are given concurrently (365,366). Schilcher and colleagues (367) showed that the pharmacokinetics of mitomycin do not change after the administration of high doses.

Mitomycin distribution into bile and ascites fluids has been quantitated in patients receiving standard IV doses. The maximum biliary level of 0.5 µg/mL was achieved after 2 hours and was five- to eightfold higher than simultaneous plasma levels during the elimination phase (368). Mitomycin also rapidly penetrates into ascites fluid and reaches maximal concentrations of 0.05 µg/mL 1 hour after administration. This distribution represents about 40% of the total plasma exposure. The drug also appears to concentrate slightly in cervical tissues after IV administration (369).

With intra-arterial administration, the hepatic extraction of mitomycin averages only 23% (370). The calculated relative advantage for hepatic arterial infusions is only 2.5- to 3.6-fold greater than for other methods.

Administration and Dosage.

Sterile water (10 mL) should be added to each 5-mg vial of mitomycin and shaken gently to dissolve. Mitomycin should be administered intravenously to avoid extravasation of the drug. If extravasation occurs, severe local tissue necrosis may occur (371). The drug is usually given by a slow IV push, with continuous patient monitoring to lessen the chance of extravasation. Short infusions in 100 to 150 mL of D_5W or normal saline have also been used. Vein patency should be checked before the administration of any dose, using 5 to 10 mL of fluid that does not contain the drug. The same procedure should follow the dose. This flushes any remaining drug from the tubing and the venipuncture site.

The recommended dose of mitomycin used as a single agent is 20 mg/m^2 given IV every 6 to 8 weeks. In combination with other myelosuppressive drugs, mitomycin doses are typically limited to 10 mg/m^2 every 6 to 8 weeks. Bolus doses greater than 20 mg/m^2 produce severe toxicity without greatly enhancing efficacy.

Repeat dosing of mitomycin should be based on adequate marrow recovery, including leukocytes, platelets, and erythrocytes. Leukocyte count should return to 4,000/mm^3, and platelet count to 100,000/mm^3.

An ambulatory continuous infusion of mitomycin has been administered at 0.75 mg/m^2/d for consecutive 50-day dosing (372). A dosing regimen of 3 mg/m^2/d for 5 days every 4 to 6 weeks has also been used (372). These regimens are believed to deliver greater dose intensity by reducing myelosuppression. Intra-arterial perfusion doses of 20 mg/m^2 have been given every 6 to 8 weeks (373).

Side Effects and Toxicities.

Bone marrow suppression involving platelets, leukocytes, and erythrocytes is the most serious toxicity, and it can continue for 3 to 8 weeks after drug administration is halted (357). Myelosuppression, particularly anemia, can be cumulative. This has been minimized by keeping total lifetime doses under 50 to 60 mg/m^2.

Gastrointestinal disturbances in the form of nausea, vomiting, and anorexia occasionally develop. These reactions are usually not severe and have an onset within 1 to 2 hours after administration. They may persist for several hours. Stomatitis may also occur, but it is generally not severe.

Renal toxicity detected by increasing serum BUN and creatinine levels with glomerular dysfunction is occasionally seen. This does not appear to be dose- or treatment-duration related, and it is usually not severe. However, mitomycin can also induce a microangiopathic hemolytic anemia with progressive renal failure (hemolytic-uremic syndrome) and cardiopulmonary decompensation. This disease is fatal within 3 to 4 weeks of diagnosis, although the onset is typically delayed for months after mitomycin administration (374). The incidence of this toxic effect may approach 10% among patients given large cumulative doses (374). In one series, renal complications from mitomycin developed in 1.6% of 63 patients receiving a total dose of 50 mg/m^2 or less, 11% of 37 patients receiving 50 to 69 mg/m^2, and 28% of 18 patients

receiving total doses greater than 70 mg/m^2 (375). This suggests that a threshold for inducing microangiopathic hemolytic anemia may be a cumulative dose of about 50 mg/m^2 of mitomycin. Signs of the disease include thrombocytopenia, circulating schistocytes, and acute renal failure. Histopathologic examinations of the kidneys reveal fibrin thrombi in arterioles, tubular atrophy, and widespread glomerular necrosis.

Veno-occlusive disease of the liver has been reported after high-dose mitomycin therapy and autologous bone marrow transplantation (376). Signs include progressive hepatic dysfunction, abdominal pain, and ascites. Although this has rarely been observed with low-dose therapy, it appears to be much more frequent after high-dose regimens.

Alopecia may occur after mitomycin therapy, but it is usually not severe. Rarely, purple bands in the nail beds correspond to sequential doses of the drug. Lethargy or weakness may occur and can last from several days to 3 weeks. Fatigue and some drowsiness or confusion have also been observed. Dose-related skin reactions and fever with drug administration are occasionally seen.

Severe soft tissue ulcers may also be expected if the drug escapes the vein during administration. Mitomycin extravasation injuries can result in chronic ulcers that can expand over months (377). Particularly distressing aspects of some mitomycin extravasations include the delayed (3 to 4 months) and sometimes distal occurrence of soft tissue ulceration after uneventful injections in a peripheral vein (377,378). In animals, the only effective antidote to mitomycin skin reactions was topical DMSO (99% DMSO). Mitomycin extravasations may be empirically treated with topical application of 1.5 mL of DMSO every 6 hours for 14 days (379).

Interstitial pneumonia thought to be secondary to mitomycin has been reported in a small number of patients. These patients showed rapid improvement after treatment with corticosteroids (380).

Special Precautions.

Myelosuppression may be cumulative with successive doses of mitomycin and may necessitate dose reductions. Careful monitoring of blood counts is critical. Serious local ulceration may occur if the drug is delivered outside the vein. Extravasation of mitomycin must be avoided.

Clinically significant antitumor drug synergy in humans has yet to be described for mitomycin, although it is probably at least additive in several drug combinations, including the FAM regimen (5-FU, doxorubicin, mitomycin) used in gastrointestinal cancer, the MOB regimen [mitomycin, vincristine (Oncovin), bleomycin] used in carcinoma of the uterine cervix, and megestrol acetate in patients with advanced breast cancer.

Paclitaxel

Paclitaxel (Taxol) is one of the most commonly used drugs in oncology, with FDA approval for primary and subsequent treatment of epithelial ovarian cancer, as salvage therapy for metastatic breast cancer, in second-line treatment of AIDS-related Kaposi sarcoma, and in the treatment of non–small cell lung cancer. It is also active against a variety of other solid tumors, including cervical and endometrial cancer (381–384).

Chemistry.

It is a diterpene plant product derived from the bark of the Pacific yew, *Taxus baccata.* It has a molecular weight of 853.9, is insoluble in water, and has an empirical formula of $C_{47}H_{51}NO_{14}$. Its chemical name is 5β,20-epoxy-1,2α,4,7β,10β,13α-hexahydroxytax-11-en-9-one4, 10-diacetate 2-benzoate 13-ester with (2*R*,3*S*)-*N*-benzoyl-3-phenylisoserine.

Mechanism of Action.

Paclitaxel acts as a mitotic spindle poison. In a manner contrary to known mitotic spindle inhibitors, such as colchicine and podophyllotoxin, paclitaxel promotes assembly of microtubules and stabilizes them, preventing depolymerization. This

inability to depolymerize microtubules prevents cellular replication (144).

Drug Disposition.

Early pharmacokinetic studies using standard doses and a 24-hour infusion suggested that paclitaxel pharmacokinetics were linear; however, with short infusions and/or high dose levels, paclitaxel's nonlinear pharmacokinetics become readily apparent (190). The nonlinearity is due to saturable distribution, metabolism, and elimination. Terminal elimination half-life is largely dependent on the dose and administration schedule. At a dose level of 175 mg/m^2 with a 3-hour infusion, mean pharmacokinetic parameters of paclitaxel include the following: plasma $t_{1/2\alpha}$, 16 minutes; plasma $t_{1/2\beta}$, 140 minutes; plasma $t_{1/2\gamma}$, 18.75 hours; plasma clearance, 12.69 L/h/m^2; plasma AUC, 16.81 μmol/L · h; 48-hour urinary excretion, <10% of dose; and 48-hour fecal excretion, 70% of dose (190).

Clearance is rapid and not due to urinary excretion; the major route of paclitaxel elimination is believed to be via hepatic metabolism and subsequent biliary excretion (382). About 70% to 80% of the drug is eliminated by fecal excretion.

Administration and Dosage.

All patients undergoing paclitaxel therapy should receive premedication to prevent severe hypersensitivity reactions. A recommended regimen is dexamethasone (either 20 mg orally the night before treatment and the morning of treatment or 20 mg IV 30 minutes before paclitaxel delivery) plus diphenhydramine (50 mg) and famotidine (20 mg) IV 30 minutes before chemotherapy (386). For the majority of patients, administration of dexamethasone 20 mg IV 30 to 60 minutes before paclitaxel is sufficient and has been proved effective in preventing hypersensitivity reactions.

Paclitaxel is commercially available as an injection concentrate in 30-mg (5 mL), 100-mg (16.7 mL), and 300-mg (50 mL) multidose vials. Before infusion, paclitaxel must be diluted with 0.9% sodium chloride, 5% dextrose, 5% dextrose and 0.9% sodium chloride injection, or 5% dextrose in Ringer's injection to a final concentration of 0.3 to 1.2 mg/mL. The solution is stable for up to 27 hours at room temperature. Paclitaxel should be administered through an in-line filter with a microporous membrane not greater than 0.22 μ to remove particulates that are present in paclitaxel solutions. Although particulate formation does not indicate loss of drug potency, solutions exhibiting excess particulate matter formation should be discarded. Because of the possibility of leaching of phthalate plasticizers with paclitaxel solutions, only nonpolyvinylchloride (such as polyethylene or polyolefin) IV administration sets should be used.

As a result of an unacceptable level of severe hypersensitivity reactions in early phase I studies (most likely related to the Cremaphor EL vehicle), a 24-hour infusion schedule and a premedication regimen with corticosteroids and histamine H_1- and H_2-antagonists were used in all phase 2 and 3 clinical trials conducted in the United States from 1987 to 1992. Later clinical studies established that a 3-hour paclitaxel infusion schedule can be administered safely without a significant increase in major hypersensitivity reactions and that the shortened infusion schedule is associated with significantly less grade 4 neutropenia than the 24-hour infusion (i.e., 71% vs. 18% for the 24- and 3-hour infusions, respectively) (352). Follow-up studies have determined that a 1-hour infusion schedule is also feasible; however, infusion durations of less than 1 hour are associated with a prohibitively high rate of hypersensitivity reactions (387).

The FDA-approved recommended therapeutic regimen for patients with platinum-refractory ovarian cancer is paclitaxel 135 or 175 mg/m^2 administered IV over 3 hours every 3 weeks, but the optimal regimen has not been clearly established. Paclitaxel has been administered by various other schedules during investigational studies in patients with solid tumors, including 135 to 250 mg/m^2 as a 24-hour continuous infusion every 3 weeks; 212 to 225 mg/m^2 as a 6-hour infusion every 3 weeks; 30 mg/m^2 as a 1-hour infusion daily for 5 days every 3 weeks; 30 mg/m^2 as a 6-hour infusion daily for 5 days every 3 weeks; 120 to 140 mg/m^2 as a 96-hour infusion every 3 weeks; and 150 mg/m^2 as a 120-hour infusion every 3 weeks (144).

Weekly schedules of paclitaxel have been explored extensively, particularly in combination with carboplatin, and this has emerged as a reasonable option for the treatment of ovarian cancer. They are generally better tolerated than the higher dose used with every 3-week dosing (388,389).

Special Precautions.

Before the institution of standard prophylactic medications, the incidence of major hypersensitivity reactions associated with paclitaxel therapy approached 25% to 30%. With premedication, the incidence of severe hypersensitivity reactions has decreased to less than 2%. The majority of paclitaxel-induced hypersensitivity reactions can be categorized as grade 1, with symptoms of dyspnea with bronchospasm, urticaria, and hypotension. Major sensitivity reactions usually occur within the first 10 minutes after the first or second dose of paclitaxel (144). Minor symptoms of flushing and rashes are not predictive of the future development of severe manifestations (144,352). According to National Cancer Institute guidelines for paclitaxel administration, emergency equipment must be available, and medical personnel should be in attendance during paclitaxel infusion, especially during the first 15 minutes of the first and second courses. Vital signs should be periodically monitored during the first several hours of drug infusion. The paclitaxel infusion should be discontinued immediately if symptoms of a major hypersensitivity reaction occur (including respiratory distress, hypotension, generalized urticaria, and angioedema). Severe hypersensitivity reactions may be treated with IV epinephrine, IV diphenhydramine, IV fluids, and nebulized beta-agonists. Steroid therapy may be helpful in the resolution of recurrent symptoms (390). There is strong evidence that patients who develop major hypersensitivity reactions may be successfully retreated with slow, low-dose infusions of paclitaxel after premedication with multiple high doses of corticosteroids and antihistamines (391).

Drug Interactions.

Paclitaxel therapy appears to modify the hematologic toxicity associated with platinum agents. Rowinsky et al. (392) conducted a phase 1 study of sequential escalating doses of paclitaxel and cisplatin therapy, and determined that myelosuppression was more severe when paclitaxel was administered immediately after cisplatin therapy than when given before cisplatin.

Concomitant medications that contain substrates or inhibitors of hepatic enzymes, principally cytochrome P450 isoenzymes CYP_2C_8 and CYP_3A_4, may increase paclitaxel clearance, and caution should be exercised when administering paclitaxel. In a study by Chang et al. (393), the pharmacokinetics of paclitaxel were significantly altered by the concomitant use of anticonvulsants (i.e., phenytoin, carbamazapine, and phenobarbital), and the maximum tolerated doses of paclitaxel in malignant glioma patients were 360 mg/m^2 for those on anticonvulsant therapy versus 240 mg/m^2 for those not receiving anticonvulsants. There was also a significant difference in paclitaxel metabolite and toxicity profiles between the two groups. Central neurotoxicity, rather than neutropenia, was the dose-limiting toxicity in patients on anticonvulsant therapy who received paclitaxel at a dose greater than 350 mg/m^2.

Pemetrexed

Pemetrexed is FDA-approved for combination therapy with cisplatin for malignant pleural mesothelioma, and for single-agent therapy for non–small cell lung cancer. However, it has shown promise as a treatment for ovarian and cervical cancers.

Chemistry.

Pemetrexed (Alimta) is an antifolate antineoplastic agent with the chemical name of L-Glutamic acid, N-[4-[2-(2-amino-4,7-dihydro-4-oxo-1*H*-pyrrolo[2,3-*d*]pyrimidin-5-yl)ethyl]benzoyl]-, disodium salt, heptahydrate. It has a molecular weight of 597.49 and the molecular formula $C_{20}H_{19}N_5Na_2O_6 \cdot 7H_2O$.

Mechanism of Action.

Pemetrexed inhibits the folate-dependent enzymes TS, DHFR, and glycinamide ribonucleotide formyltransferase (GARFT). The inhibition of GARFT, for example, is directly associated with a decrease in the rate of tumor cells (394). Although methotrexate was an early but potent inhibitor of DHFR, the antifolate activity of pemetrexed is quite different. The K_m for pemetrexed is 100th that of methotrexate for folylpolyglutamate synthetase, making it possible to rapidly and completely block TS activity, whereas methotrexate acts in a more gradual and cumulative process, only impacting cellular proliferation at the point where more than 95% of the enzyme is inhibited (394). Additional details regarding the unique mechanism of action of pemetrexed, including features of membrane transport, its maintained activity in loss of transport activity, and its comparison with other antifolates (e.g., 5-FU, methotrexate, raltitrexed) are discussed in more detail elsewhere (394).

Drug Disposition.

Pemetrexed is primarily excreted in the urine and is only minimally metabolized. The elimination half-life is approximately 3.5 hours among patients with normal renal function. Pemetrexed exposure increases with decreasing renal function. Pemetrexed is 81% bound to plasma proteins, and binding is not affected by renal function.

Administration and Dosage.

Pemetrexed is administered IV at 500 mg/m^2 over 10 minutes on day 1 of every 21-day cycle. When used in combination therapy, cisplatin (75 mg/m^2 over 2 hours) should begin 30 minutes after the pemetrexed administration. The premedication regimen with pemetrexed includes corticosteroids (dexamethasone) to reduce skin rash reactions, and folate-containing vitamin supplementation (daily for at least 7 days before pemetrexed administration) to reduce some toxicities.

Side Effects and Toxicities.

The most commonly occurring side effects associated with pemetrexed treatment include hematologic toxicity, fever and infection, stomatitis, pharyngitis, and rash. Although many toxicities appeared to be significantly less frequent among patients receiving folate supplementation (e.g., neutropenia, nausea, vomiting, fever, infection), rates of hypertension (11% vs. 3%), chest pain (8% vs. 6%), and thrombosis/embolism (6% vs. 3%) were higher among those receiving supplementation. Rare cases of colitis have been reported in postmarketing studies.

Topotecan

Topotecan (Hycamtin, topotecan hydrochloride) was approved by the FDA in 1996 for the treatment of ovarian cancer patients after failure of primary chemotherapy. It is also indicated in the treatment of small cell lung cancer after the failure of first-line chemotherapy.

Chemistry.

Topotecan is a semisynthetic analog of camptothecin. The parent compound is derived from the bark of an ornamental tree native to Asia, *Camptotheca acuminata*. Sodium camptothecin was studied in clinical trials in the late 1960s through the early 1970s. However, clinical development of this agent was halted despite evidence of a variety of tumor responses because of severe and unpredictable toxicities (e.g., myelosuppression and hemorrhagic cystitis) (395). Topotecan and other camptothecin analogs (e.g., irinotecan) have been formulated in an effort to overcome unacceptable toxicities and to increase cytotoxicity and water solubility. Topotecan incorporates a stable basic side chain at the 9-position of the A-ring of 10-hydroxycamptothecin, which increases aqueous solubility. The molecular weight is 457.9 (the HCl salt), and the

formula is $C_{23}H_{23}N_3O_5 \cdot HCl$ (the free base has a molecular weight of 421.5). The chemical name of topotecan is (*S*)-10-[(dimethylamino)methyl]-4-ethyl-4,9-dihydroxy-1*H*-pyrano[3′,4′:6,7] indolizino [1,2-*b*]quinoline-3,14-(4*H*,12*H*)-dione monohydrochloride.

Mechanism of Action.

In a manner similar to camptothecin, topotecan's cytotoxicity results from the inhibition of TOPO-I, an enzyme that induces reversible single-strand breaks during DNA replication. Camptothecin analogs bind with and stabilize the transient TOPO-I–DNA complex, preventing religation of the single-strand breakage. The interaction of the ternary topotecan–TOPO-I–DNA complex with replication enzymes results in double-strand DNA breaks and cellular death. Topotecan exists in a pH-dependent equilibrium as both a closed lactone ring and a hydroxy acid; the hydroxy acid is formed by hydrolysis of the lactone ring. The active lactone form predominates at a pH below 7, and at a pH of 6, over 80% of topotecan exists in the lactone form. Slow reaction kinetics studies have shown that the hydroxy acid is inactive and that only the closed lactone bonds with the TOPO-I–DNA complex (396).

Drug Disposition.

After IV administration, plasma pharmacokinetics show that the lactone form, which is active as an inhibitor of TOPO-I, is rapidly converted to the hydroxy acid form. At the end of a brief infusion, approximately half of the dose administered exits as hydroxy acid (397). One hour after administration, less than 30% of the dose remains in the lactone form. Topotecan does not inhibit TOPO-II.

Both forms of topotecan are subject to rapid biphasic elimination. In a summary of pharmacokinetics studies, the mean half-life of topotecan lactone was only 3 hours (range 1.2 to 4.9 hours) (396). Binding to plasma proteins is approximately 35%. Renal excretion appears to account for 40% to 70% of drug clearance (50,151).

When topotecan was administered as a weekly 24-hour IV infusion of 1 to 2 mg/m^2, the plasma steady-state concentration and the AUC increased linearly with dose. The lactone-to–total drug concentration ratio was constant, which suggests that the total drug concentration may be used as a measure of active lactone exposure with weekly, long infusions (398). In addition, comparison of day 1 pharmacokinetics values with blood counts showed that both the topotecan AUC and the lactone AUC were predictive of the level of neutrophil reduction on days 15, 22, and 29 using the sigmoid E_{max} model (398). This led the investigators to suggest that topotecan-induced myelosuppression is noncumulative, and that elimination probably remains unchanged with repeat dosing in individual patients. Other studies have also found a correlation between the topotecan AUC and the level of neutropenia (397,399).

Limited sampling models for topotecan pharmacokinetics have been proposed that may facilitate tailoring of topotecan drug doses in individual patients and large pharmacodynamic studies of topotecan (400,401). Plasma concentrations of the lactone and hydroxy acid forms of topotecan at 2 hours, after a 30-minute infusion, reliably predicted the lactone form AUC, the hydroxy acid AUC, the total topotecan AUC, and the clearance rate.

Administration and Dosage.

Each 4-mg vial of topotecan should be reconstituted with 4 mL of sterile water. The resulting solution can be further diluted with either 0.9% sodium chloride or 5% dextrose. Because the active lactone form of topotecan is subject to a pH-dependent hydrolysis to the inactive hydroxy acid, consideration should be given to maintenance of an acidic pH during drug infusion. When the topotecan lactone is dissolved in 5% dextrose, only approximately 10% is converted to the hydroxy acid (397). Because the product does not contain an antibacterial preservative, it should be used immediately once constituted.

Parenteral topotecan has been administered by IV infusions varying in length from 30 minutes to 21 days (396). The standard FDA-approved dosing regimen is 1.5 $mg/m^2/d \times 5$ days by 30-minute IV infusion every 21 days, for a minimum

of four courses owing to delayed tumor response, as tolerated (in the absence of tumor progression). However, this dosing schedule is associated with a more than 80% incidence of grade IV neutropenia. Many oncologists, therefore, use a dose of 1.25 mg/m^2/d for 5 days and/or administer prophylactic G-CSF. Today, a weekly dosing schedule is more often utilized because of equivalent efficacy, less toxicity, and better acceptability by patients (402,403).

Side Effects and Toxicities.

Toxicity data are available from a phase III, randomized study of topotecan 1.5 mg/m^2/d for 5 days every 21 days versus paclitaxel 175 mg/m^2 IV over 3 hours every 21 days in ovarian cancer patients with progressive or recurrent disease following primary platinum-based chemotherapy (404). Neutropenia was the predominant toxicity in this study: 79% of patients experienced grade 4 neutropenia, 25% of patients experienced febrile neutropenia, and 5% of patients developed sepsis [two patients (2%) died of sepsis]. The onset of grade 4 neutropenia was on days 9 through 15 of a chemotherapy cycle, and it did respond to G-CSF therapy. Thrombocytopenia also occurred frequently: 50% of patients experienced grades 3 to 4 thrombocytopenia (25% experienced grade 4). Grade 4 anemia occurred in 3.6% of patients.

The most common nonhematologic toxicities were cumulative, dose-related alopecia (76%) and nausea/vomiting (10% grades 3 to 4), which was amenable to antiemetic therapy. Other frequent toxicities were fatigue (41%), constipation (43%), diarrhea (40%), abdominal pain (27%), fever in the absence of neutropenia (29%), stomatitis (24%), dyspnea (24%), and asthenia (22%) (404).

Special Precautions.

Because topotecan has a high rate of renal excretion and a modest hepatic clearance, a clinical study was conducted to evaluate the impact of renal and hepatic dysfunction on toxicity in patients undergoing treatment with topotecan on a daily × 5 dosing schedule (405,406). Pharmacokinetic analyses showed clear correlations between CrCl and plasma clearance of both topotecan and topotecan lactone ($r^2 = 0.65$, $p < 0.0001$). Although the standard dose for patients with good renal function is 1.5 mg/m^2/d × 5 days, this study determined that the recommended starting dose for patients with moderate hepatic dysfunction (CrCl of 20 to 39 mL/min) was 0.75 mg/m^2. The investigators urged extreme caution with topotecan administration in patients with more profound renal insufficiency and recommended further dose reductions for heavily pretreated patients (405). Hepatic insufficiency did not appear to exacerbate hematologic toxicity (405). Nonhematologic toxicity appeared to be unaffected by either renal or hepatic insufficiency.

Vinorelbine

Vinorelbine (Navelbine) is a third-generation semisynthetic vinca alkaloid that has been commercially available in the United States since 1994 for treatment of non–small cell lung cancer. Vinorelbine also appears to have significant activity in breast cancer patients (407,408) and moderate activity in patients with cervical or ovarian cancer (409,410), as well as other tumor types (411).

Chemistry.

It has a molecular formula of $C_{45}H_{54}N_4O_8 \cdot 2C_4H_6O_6$ and a molecular weight of 1079.12. Vinorelbine's structure differs from that of the parent compounds, vincristine and vinblastine, in that it contains a nine-member (rather than eight-member) catharanthine ring (412). Its chemical name is 3′,4′-didehydro-4′-deoxy-*C*′-norvincaleukoblastine[*R*-(*R**,*R**)-2,3-dihydroxybutanedioate-(1:2)(salt)].

Mechanism of Action.

Like other vinca alkaloids, vinorelbine is classified as a "spindle poison" because it interacts with tubulin with resulting inhibition of microtubule assembly and cellular division during mitosis (413). Vinelorbine blocks cell cycle progression specifically in G_2 and M phases (151).

Drug Disposition.

The pharmacokinetics of vinorelbine show large interpatient variability and are best described by a triphasic model. Following IV administration of a 30-mg/m^2 dose, a peak plasma level of 1,000 ng/mL is achieved, but the plasma level declines to 100 ng/mL within 2 hours. Vinorelbine rapidly binds to platelets (78% of total dose) and plasma proteins (13.5%), and only 1.7% is available as free drug (413). The drug readily diffuses into other tissues, and has a large Vd (75.61 L/kg). The terminal half-life is approximately 45 hours (414).

The primary means of vinorelbine clearance appears to be hepatic metabolism. Approximately 18% and 46% is recovered in the urine and feces, respectively; however, recovery was incomplete in pharmacokinetic studies (415,416).

Administration and Dosage.

Vinorelbine is a vesicant and requires careful administration. The drug should be diluted in a syringe or IV bag to a concentration of 1.5 to 3.0 mg/mL (syringe) or 0.5 to 2 mg/mL (IV bag). When using a syringe or IV bag, vinorelbine should be diluted with dextrose (5%) or sodium chloride (0.9%). When using an IV bag, it may also be diluted with sodium chloride (0.45%), Ringer injection, or lactated Ringer injection. Diluted vinorelbine should be administered over 6 to 10 minutes into a side port of a free-flowing IV line closest to the IV bag. Following vinorelbine administration, the vein should be flushed with at least 75 to 125 mL of IV solution. Longer IV infusions (e.g., 20 minutes) are associated with a higher incidence of phlebitis (417).

Vinorelbine solution is incompatible with fluorouracil, mitomycin, and thiotepa. It is also incompatible with several antibiotics (including a number of cephalosporins, amphotericin B, ampicillin, piperacillin, and trimethoprim-sulfamethoxazole), acyclovir, furosemide, ganciclovir, methylprednisolone, and sodium bicarbonate (418).

Vinorelbine is generally administered at a dose of 30 mg/m^2 every week. This dosing schedule has been used in combination chemotherapeutic regimens; however, the recommended dosing schedule in combination with cisplatin (100 mg/m^2 every 4 weeks) is weekly administration of vinorelbine at a dose of 25 mg/m^2. Attempts to increase vinorelbine dose intensity using a daily × 3 every 21 days dosing schedule with or without G-CSF have not been successful (419,420). However, Weiss et al. (421) have reported that continuous infusion of vinorelbine at doses of 8 to 10 mg/m^2/d with concurrent administration of G-CSF results in a twofold increase in vinorelbine dose intensity without increasing toxicity.

Side Effects and Toxicities.

The primary dose-limiting toxicity of vinorelbine is myelosuppression, chiefly granulocytopenia (36% of patients, <500 cells/mm^3). A safety summary of data from North American clinical trials reported that when vinorelbine was administered at a dose of 30 mg/m^2/week to patients with breast cancer and non–small cell lung cancer, 64% of patients experienced grades 3 to 4 granulocytopenia, 50% experienced grades 3 to 4 leukopenia, and 9% developed grades 3 to 4 anemia. Despite the high incidence of granulocytopenia, most events were uncomplicated, and only 7% of patients required hospitalization for fever and/or infection. The death rate due to sepsis was 1% to 2%. Myelosuppression was noncumulative, and the incidence of grades 3 and 4 granulocytopenia declined during later cycles of vinorelbine therapy. The granulocyte nadir typically occurred on day 14 of treatment, with recovery of the granulocyte count within 7 days (422).

Vinorelbine therapy is frequently associated with transient increases in liver enzymes, especially alkaline phosphatase. Virtually all patients experience a rise in alkaline phosphatase, with approximately 25% developing grade 3 toxicity and an

additional 2% experiencing grade 4 elevations. Increases in AST and ALT also occur in more than half of all patients. However, most patients with liver enzyme increases remain asymptomatic and do not require dose modification of vinorelbine. Total bilirubin can also be elevated: 10% of patients experience some degree of increased bilirubin, with 2% experiencing grade 4 elevation. Because of the high incidence of liver and bone metastases in the study population (breast cancer and non–small cell lung cancer patients), the proportion of these toxicities that is directly attributable to vinorelbine therapy is unknown (422).

Other common toxicities associated with vinorelbine when administered as a single agent at a dose of 30 mg/m^2/wk by a 20-minute IV infusion include nausea (38% overall, 2% severe), vomiting (17% overall, 2% severe), constipation (31%, 3% severe), asthenia (29%, 5% severe), injection site reactions (26%, 2% severe), anorexia (15%, 1% severe), diarrhea (15%, 1% severe), stomatitis (14%, 0% severe), pain (13%, 2% severe), paresthesia (13%, <1% severe), fever (11%, 1% severe), and alopecia (10%, <1% severe) (422). Vinorelbine-induced nausea and vomiting are generally mild and are readily controlled with standard antiemetic medication (422). Injection site reactions include erythema, warmth, pain, and phlebitis. Repeated administration of vinorelbine can result in discoloration of the vein. As discussed above, shortening the injection duration to 6 to 10 minutes significantly reduces the incidence of injection site reactions (417).

Injection site pain and pain of unspecified etiology has been reported with administration of vinorelbine as a single agent (422). In addition, acute tumor pain has been reported in several cancer patients who received treatment with vinorelbine plus a platinum-containing agent (either carboplatin or cisplatin) (423,424).

Pulmonary toxicity is an infrequent side effect of vinorelbine. Approximately 5% of patients experience dyspnea. Some cases of dyspnea are characterized by rapid onset during administration and resolve with bronchodilator therapy. Other cases occur usually within 1 hour of vinorelbine infusion and are characterized by life-threatening progressive dyspnea and the development of interstitial infiltrates (422,425). The coadministration of mitomycin may increase the pulmonary toxicity of vinorelbine (425).

Rare side effects of vinorelbine include pancreatitis, PPE (with prolonged infusions), paralytic ileus, and syndrome of inappropriate ADH secretion (381,426–428).

Special Precautions.

Vinorelbine extravasation can result in severe local irritation, tissue necrosis, and phlebitis. If extravasation occurs, the injection should be halted immediately, and any remaining portion of the dose should be injected into a different vein. Specific antidotes for vinorelbine extravasation have not been studied; however, vinblastine extravasation reactions may be ameliorated with the use of corticosteroid injections followed by cold compresses (382).

Drug Interactions.

In that vinca alkaloids are metabolized by the cytochrome P450 3A system, coadministration of strong P450 inhibitors, such as erythromycin and ketoconazole, could potentially reduce vinorelbine clearance and increase toxicity (429,430). Doxorubicin and etoposide are also metabolized by the P450 system, and coadministration of these drugs with vinorelbine could potentially affect vinorelbine metabolism (429).

Mitomycin is known to exacerbate vinca alkaloid–induced pulmonary toxicity (431), and the combination of high-dose vinorelbine (50 mg/m^2 on days 1 and 21) plus mitomycin (15 mg/m^2 on day 1) has been associated with life-threatening acute pulmonary toxicity characterized by rapid onset of severe, progressive dyspnea and the development of bilateral interstitial infiltrates (425).

The combination of paclitaxel and vinorelbine has been associated with severe neurotoxicity including grade 4 motor neuropathy, irreversible ototoxicity, and vocal cord paresis (432,433). In one report of clinical experience in five patients with preexisting, mild-to-moderate, paclitaxel-induced sensory neuropathy, the combination of vinorelbine 25 to 30 mg/m^2 followed by paclitaxel 150 mg/m^2 by 3-hour infusion every 2 weeks resulted in severe, slowly reversing motor neuropathy in all five patients. Four of the five patients required the use of a wheelchair (432).

CHAPTER 15 Immunotherapy of Gynecologic Malignancies

Paul J. Sabbatini, Kunle Odunsi, Jacobus Pfisterer and Dmitriy Zamarin

Patients with ovarian cancer are particularly well-suited for participation in studies evaluating immune-based treatment strategies, due, in part, to the natural history of this disease. The historical data indicates that 70% of patients with advanced disease are in complete clinical remission following initial cytoreductive surgery and platinum- and taxane-based primary chemotherapy (1). However, only 30% of optimally debulked stage III patients will remain disease-free, and there is a median progression-free interval of approximately 24 months (2). Despite the high relapse rate, many patients return to a complete or partial clinical remission following additional chemotherapy, but ever-shortening intervals of response are seen (3). Despite this chronic course of relapse and response, in a study evaluating intraperitoneal (IP) therapy as part of primary treatment, the median survival of optimally debulked patients exceed 60 months (4). Neither higher doses, nor protracted schedules, nor non–cross-resistant consolidation chemotherapy has provided additional benefits. Ovarian cancer patients with minimal disease burdens are therefore appropriate candidates for clinical trials evaluating immune-based therapy.

With regard to other gynecologic malignancies, a significant proportion of immune strategies being evaluated in patients with cervical cancer target human papillomavirus, and this subject is covered separately in Chapter 20(5). The evaluation of immune-based approaches for the treatment of endometrial cancer has been limited, but interest is growing (6). Targets such as human trophoblast cell surface marker (TROP-2), Wilms Tumor Gene (WT-1), and a variety of cancer testis (CT) antigens have been shown to be expressed in endometrial cancers, which has prompted early stage trials with dendritic cell (DC) vaccines and adoptive cellular therapy as two examples (7,8). In addition, contemporary data show enhanced efficacy with PD-1 blockade in patients having tumors with mismatch repair deficiency, which includes patients with endometrioid uterine carcinoma (9).

CANCER IMMUNOLOGY: OVERVIEW

The immune system evolved to fight foreign invaders such as bacteria, viruses, and parasites. However, strong evidence suggests that it also plays a crucial role in controlling or rejecting incipient cancers. William B. Coley (10) first observed regression in patients with sarcoma contracting “accidental erysipelas” as early as 1893. Because patients with competent immune systems still develop cancers, and spontaneous remission of tumors is rare, enthusiasm for the effectiveness of immune system control has waxed and waned over the decades. The fact that animal models with a variety of deficiencies in immunologic components consistently develop carcinoma has allowed the concept of immunosurveillance to be sustained and developed (11,12). Observations in patients with ovarian cancer strongly support a role for immune system involvement in patient outcome. For example, 5-year overall survival (OS) in epithelial ovarian cancer has been correlated with the presence or absence of tumor-infiltrating lymphocytes (TIL) (38% vs. 4.5%, $p < 0.001$) (13). A second study

also showed improved survival in patients with increased frequencies of intraepithelial $CD8^+$ TIL (55 vs. 26 months; HR = 0.33; 95% CI, 0.18 to 0.60; $p = 0.0003$) (14). Finally, data show that cancer cells and TILs in ovarian high-grade serous carcinoma suggest that expression of programmed cell death (PD-1) and PD-ligand 1 (PDL-1) may have prognostic impact, particularly when this feature is expressed at higher levels (15). In contrast, patients with increased numbers of immune suppressive $CD4^+$ CD25HI regulatory T cells (Tregs) have reduced survival (15). The process is made more complex when we recognize that not only can the immune system protect the host against tumor development, but it is also thought to select cancer cells of lower immunogenicity that can escape early immunity because of changes in gene expression. This actually leads to an outgrowth of tumors with the capacity to escape recognition, and this process has been termed immunoediting (16). The immunoediting or "immune sculpting" process, therefore, is responsible for shaping the immunogenicity of the tumors that will eventually form. Considering the effectors of the immune system in the context of both of these processes is important in order to develop immune-directed therapies with the greatest chance of success (17,18).

The mechanism by which tumors escape from immune surveillance is complex (19). An alteration in nearly all known effectors required for immune activation has been proposed as being responsible for immune evasion. In some cases, antigen presentation is downregulated, or gene deletions or rearrangements may cause reduced expression of the major histocompatibility (MHC I) complex, thus preventing T-lymphocyte activation (20,21). Tumors can also secrete proteins that inhibit T-cell effector action or that promote the development of regulatory T cells that suppress immune function (22). It has been shown that certain melanomas can actually remodel their stromal microenvironment so as to resemble lymphoid tissue, recruiting regulatory cells to promote tolerance and allow tumor progression (23). Other mechanisms include the downregulation of intracellular adhesion molecules (24), changes in molecules responsible for apoptosis signaling (25), or the development of peripheral tolerance (26). Due to the increasing number of interacting mechanisms with putative activity enabling immune escape, approaches directed against multiple mechanisms will likely be needed to eradicate immune-tolerant tumor cells (27).

Innate Immunity

The immune system is broadly divided into two arms: innate and active immunity, but there are multiple examples of cross-communication between them. Recent data, for example, show that neutrophil survival is influenced by T-cell responses (28). *Innate immunity* is present at birth and does not require adaptation to react against microorganisms or tumors. It includes physical barriers (mucous membranes, skin), chemical components (complement, hydrolytic enzymes), and multiple other cellular components. Natural killer cells are lymphocytes programmed to recognize and destroy tissues that have been altered or placed under stress; for example, by viruses or by malignant transformation (29). They do not have antigen-specific receptors, but instead have inhibiting receptors that can recognize MHC class I molecules on normal cells, which prevents their activation (30). MHC I expression is aberrant or absent on many virus- and tumor-infected cells (31). Another component includes macrophages, which play many roles in immunity and inflammation, including production of a multitude of soluble secreted proinflammatory proteins; these proteins act as growth factors for other cells of the immune system, for neovasculature, and for cancer cells. The growth factors include *cytokines* and *chemokines*, and they support the growth, movement, and survival of immune and inflammatory cells. Macrophages play important roles in tissue remodeling during wound healing, mediating inflammatory responses, sampling molecules from the environment through internalization, and presenting antigens to stimulate T cells. Macrophages can also play a counterproductive role through production of molecules that promote tumor growth and angiogenesis (e.g., vascular endothelial growth factor [VEGF] and basic fibroblast growth factor) (32). Macrophages can also inhibit immune responses through production of cytokines and other molecules that downregulate immunity, such as prostaglandins E2, arginase I, and transforming growth factor-β. Thus, the role of macrophages in tumors is complex, and provides an additional means of communication between traditionally defined innate and acquired immunity effectors (33). DCs have some properties that are similar to macrophages, including production of cytokines and sampling of molecules from the

environment. Most importantly, DCs are one of the key links between the innate immune system and the adaptive or acquired immune system through presentation of antigens (professional antigen-presenting cells [APC]) to initiate T-cell activation.

Adaptive Immunity

Adaptive immunity is characterized by adaptation to antigens; for example, antigens of infectious pathogens (or potentially cancer). This arm of the immune system is not mature or activated at birth, but rather adapts through maturation in response to antigens of pathogens. It is characterized by receptors encoded by the immunoglobulin (Ig) gene family. These receptors have the capacity to rearrange, creating enormous diversity ($>10^{11-12}$ different receptors). This provides a system that generates enormous specificity, recognizing and responding to a wide range of antigens that have not previously been encountered.

The two major cell types of acquired immunity are *T lymphocytes* (T cells) and *B lymphocytes* (B cells). T cells have the capacity to recognize antigens sequestered in different compartments within cells; for example, antigens generated in the cytoplasm or nucleus by viral infections (34). T cells recognize antigens as short peptides, 8 to 16 amino acids in length. These peptides must be complexed with and presented by specialized antigen-presenting molecules, the MHC molecules, to T-cell receptors (TCRs). In humans, MHC molecules are the human leukocyte antigens (HLAs) expressed on virtually every cell in the body. On the other hand, B cells produce secreted *antibodies* that can recognize soluble and cell surface molecules. Both T cells and B cells initially develop with a limited range of receptors for immune recognition. However, in response to antigen (e.g., from a virus or cancer cell) presented by a professional APC, T cells or B cells that have receptors with the best "fit" to the antigen itself (for B cells) or antigen/MHC complex (for T cells) are stimulated to proliferate, and this subpopulation is quickly expanded (35).

Humoral Immunity

B cells usually recognize antigens in their natural configuration (34). An individual host has a repertoire of B cells that are capable of generating antibodies against the full range of pathogens encountered in the environment. To do this, the total population of B lymphocytes expresses a diverse repertoire of immunoglobulins. Each B cell expresses immunoglobulin against a single antigenic determinant; the immunoglobulin is expressed at the cell surface of the B cell, where it acts as a specific receptor to transduce signals in response to that antigen (36). Once activated, the B cell creates an individual monoclonal antibody (mAb). The diversity of specificities in different B cells is generated by rearrangements of the immunoglobulin genes, and new antibody specificities continue to be generated in response to new antigens (37). During development, B cells with high-avidity immunoglobulins against ubiquitous self-antigens are eliminated. This elimination of B cells reactive with autoantigens is not absolute, however, as a broad array of antibodies against autoantigens is found in the blood of humans. Peripheral blood B cells consist of naïve and relatively short-lived B cells, long-lived memory B cells resulting from maturation in response to antigenic stimulation, and a small population of B cells expressing germline immunoglobulins that have not undergone rearrangement (these are found in the $CD5^+$ B-cell population) (14).

B cells are mobile, and after developing in the bone marrow, they migrate through the peripheral blood to B-cell-rich areas in lymphoid organs; for example, the follicles of lymph nodes, spleen, and gastrointestinal tract. Many B cells continue recirculating in the blood. If cognate antigen is encountered in lymphoid organs, the B lymphocyte migrates to the T-cell-rich areas, where appropriate T-cell help can be provided to promote increased antibody diversity and increased affinity through immunoglobulin gene rearrangements (38). This T-cell help does not have to be induced by the same antigen. Chemical conjugation of the antibody-recognized antigen to highly immunogenic bacterial or xenogeneic proteins, or, alternatively, expression of the antigen in bacterial or viral vectors, is a widely used approach to ensure adequate T-cell help in vaccines. The result of T-cell help is generation of plasma cells, the most mature form of B cell with the highest capacity for antibody production. In addition, T-cell help promotes formation of germinal centers in lymphoid organs

where hypermutation in immunoglobulin genes and class and subclass switching occur to generate antibodies with higher affinities for antigen. Class switching refers to changes in antibody class during an immune response, with the IgM class of antibodies appearing first, generally followed by antibodies of the IgG class (different subclasses of IgG antibodies have different blood half-lives and different capacities for effector functions, such as fixation of complement or binding to Fc receptors). The consequence is plasma cells secreting increasingly higher affinity IgG antibodies as the immune response matures over time (39). In addition, some B cells that generally recognize nonprotein antigens. For example, carbohydrate or glycolipid antigens can be stimulated to proliferate in the absence of T-cell help. The immunoglobulin variable region (called the Fv region) determines antibody specificity and is located in the Fab domain of immunoglobulins. This region mediates effective binding to antigens. However, the constant region (Fc), where antibody class and subclass are determined, is equally critical. Binding of antibody to antigen results in a conformational change in the Fc portion, leading to activation of several effector mechanisms, including complement activation (discussed below). IgM antibodies are synthesized early in the response. If T-cell help is available, antibody responses mature through immunoglobulin gene rearrangements into the higher affinity IgG classes. These are capable of improved binding to antigen as well as receptors on the bone marrow–derived cells for the Fc domain, expanding potential effector functions. The responses to most nonprotein antigens are IgM class and generally do not mature to IgG responses. The IgM pentamer structure is specialized to increase avidity of binding to multimeric antigens and to efficiently activate effector functions such as complement (40). Activation of complement, which includes blood components with different enzymatic properties, results in opsonization (coating of pathogens by complement components), recognition by complement receptors on macrophages, monocytes, neutrophils, and DCs, with subsequent activation of these cells leading to phagocytosis and/or killing. In addition, complement can form a membrane attack complex, which creates holes in membranes of target pathogens and cancer cells, producing complement-dependent cytotoxicity (CDC) (41,42). IgG antibodies are synthesized following immunoglobulin gene rearrangements, with switches in Fc domains, as the B cell matures in response to T-cell help. IgG antibodies usually have higher affinity, and can be found in the extracellular space as well as in the blood. IgG1 and IgG3 antibodies in humans are especially effective at activating complement and also at sensitizing pathogens for killing by NK cells, macrophages, and other cells with complement receptors and immunoglobulin Fc receptors (43).

Opsonization for ingestion and destruction by phagocytes can occur through complement activation, but also occurs directly as a consequence of engagement of Fc receptors on phagocytic cells. Antibodies complexed to antigen bind to Fc receptors, which can lead to activation signals through activating Fc receptors (e.g., FcRIII), but activation can be countered by IgG binding to the inhibitory Fc receptor, FcRIIB. Fc receptors, which are bound effectively by IgG1 and IgG3 subclasses of human antibodies, are expressed on monocytes, macrophages, NK cells, neutrophils, mast cells, and other cells. Cross-linking of Fc receptors leads to activation of the cells, in some cases leading to antibody-dependent cell-mediated cytotoxicity (ADCC) of tumor cells through production of cytotoxic molecules; for example, perforin and granzyme by NK cells and reactive molecular species by macrophages (44–46). Monoclonal antibodies are commonly used for cancer therapy. Antitumor effects can be mediated in part by antibody binding to critical molecules on the surface of tumor cells; for example, by inhibiting tumor cell attachment or growth receptors. Generally, however, interactions of antibodies with cell antigens are not very effective unless Fc receptor–mediated effector mechanisms are also activated.

Cellular Immunity

T lymphocytes recognize processed (digested) molecules that complex with MHC molecules within APCs. The antigen/MHC molecules are then trafficked to the cell surface for recognition by TCRs, which are encoded by genes of the immunoglobulin family. Similar to generation of antibodies, great diversity of TCRs is generated by rearrangements of these immunoglobulin family genes. Each monoclonal TCR must bind to its cognate antigen/MHC complex (CD4 cells bind to MHC class II molecules, and CD8 cells bind to MHC class I molecules) presented on the surface of APCs (47,48). Signaling from the TCR following engagement of antigen/MHC complex is insufficient to activate the T cell. Additional signals are required (costimulatory signals or “signal 2”). The most important costimulatory signal in T cells comes from

the T-cell surface molecule CD28, which engages B7 molecules (CD80 and CD86) on APCs (49–51). Engagement of TCR by antigen/MHC in conjunction with CD28 engagement of B7 is sufficient to activate naïve T cells. Within several days following T-cell activation, a second molecule, CTLA-4, appears on the T-cell surface to provide a brake to the T-cell response. CTLA-4 also binds B7 molecules, but with much higher affinity, therefore displacing CD28 activation signals. CTLA-4 signaling leads to downregulation of the T-cell response. The manipulation of CTLA-4 activity has been shown to have therapeutic efficacy, with initial data showing tumor responses in patients with melanoma (52,53). Other studies have shown responses in a variety of tumor types, including gynecologic cancers (54). PD-1, a co-inhibitory immune signal receptor, has also shown promising activity in patients with platinum-resistant ovarian cancer (55). A variety of other costimulatory molecules are upregulated on the surface of activated T cells, including OX40 and 4–1 BB (CD137), which promote survival of T cells and help generate long-lived T-cell memory responses (56,57). Once T cells are activated by professional APCs (primarily DCs), they gain a variety of effector functions, including the production of cytokines and cytotoxic molecules, which lead to the death of target cells.

Antigen-Presenting Cells

Dendritic cells are the prototype of professional APCs and are the critical link between innate immunity and acquired immunity. These are phagocytic cells that sit on epidermal surfaces, including skin and mucosal membranes, constantly sampling their environment to search for infectious organisms. Although DCs continuously ingest molecules from their environment, uptake of antigen is insufficient to activate DCs. Rather, DCs have a set of receptors, most notably the toll-like receptors (TLRs), which can recognize lipid-containing molecules and CpG-rich DNA and poly-U RNA sequences produced specifically by microbial organisms. Engagement of TLR signals for activation of the DC, with increased expression of MHC and B7 molecules, and movement of cells with captured antigen to draining lymph nodes. It is in draining lymph nodes that DCs activate appropriate T cells that recognize the specific antigens presented by MHC molecules. Subsequently, activated T cells can travel from the draining lymph node to distant sites of infection or tumor to carry out the effector functions. One of the central problems for cancer immunology is that DCs may ingest and process cancer antigens, but without activation through TLRs or other receptors, the DCs remain incapable of activating T cells (because of insufficient expression of costimulatory molecules, such as B7) and do not move to draining lymph nodes. In fact, insufficiently activated DCs presenting antigens can induce anergy, a form of immune tolerance in which T cells become paralyzed and incapable of responding to cognate antigens. This is one of the mechanisms used to maintain immune tolerance to self, to prevent autoimmunity, but it also presents a major hurdle for cancer immunity. Cancer cells do not have any readily apparent mechanism to activate DCs, although several self-molecules, including heat shock protein, hyaluronate, and uric acid crystals, have been suggested to cause activation.

Helper and Regulatory T Cells

Several types of T cells are activated by DCs, and the type is influenced by whether antigens are presented by MHC class I or MHC class II molecules on APCs. MHC class I molecules complexed with antigen stimulate $CD8^+$ T cells that are cytotoxic and kill target cells (infected cells or tumor cells). Antigens presented by class II MHC molecules stimulate $CD4^+$ helper T cells. Helper T cells produce chemokines and cytokines to help recruit and orchestrate other components of the immune system. Helper T cells come in several types, and different cytokines in the milieu determine what type of T cell is generated. Each type of helper T cell mediates different types of immune responses with different characteristics. Th1 T cells produce interferon (IFN)-γ to activate cytotoxic T cells and macrophages for *cellular immune responses*. On the other hand, Th2 helper T cells produce interleukin (IL)-4 and other cytokines that favor antibody responses, or *humoral immunity*. The newly discovered Th17 $CD4^+$ T cell produces IL-17 to mediate inflammatory autoimmune diseases, such as arthritis, colitis, and encephalitis, and may play a role in cancer pathogenesis, either by promoting cancer progression or by destroying tumors. Another type of $CD4^+$ T cell restricted by MHC II presentation negatively regulates immune

responses. These are regulatory T cells or Tregs. Tregs recognize self-antigens, are dependent on IL-2, and produce inhibitory molecules such as IL-10 and transforming growth factor-β. Th1 cellular immunity may be particularly effective at attacking tumors in tissues, whereas humoral immunity may have an advantage in controlling circulating metastatic tumor cells. Infiltration of ovarian cancers and other cancers by Treg cells is associated with a poorer prognosis (52,58).

CANCER IMMUNITY AND IMMUNOTHERAPY

Studies over the past 3 decades have shown that the immune system can recognize and destroy cancers, but this typically involves interactions between multiple arms of the immune system. For instance, simple recognition by T cells, antibodies, or NK cells is usually not sufficient to reject cancers. Cytotoxic T cells and NK cells produce soluble and cell surface molecules that induce death of target tumor cells. Helper T cells can produce cytokines and chemokines that recruit not only cytotoxic T cells or B cells to make antibodies, but also inflammatory cells that mediate tissue destruction. Checkpoints are responsible for the maintenance of the effector response. Antibodies can activate NK cells, macrophages, or other cells that have receptors for the antibodies' Fc domain, leading to activation of the recruited cells, a mechanism implicated in the antitumor effects of monoclonal antibody therapies. Antibodies can also activate complement proteins in the blood that can directly kill tumor cells and activate inflammatory cells at the tumor site.

There is evolving and expansive data confirming that the immune system can recognize antigens on tumor cells and that immunity may be sufficient to destroy tumors, and this provides the impetus to develop new strategies for *immunotherapy*. These approaches can be broadly divided into three groups. First, *immune modulation* uses more broad approaches to treat cancer. Traditional examples include cytokines such as IL-2, IL-12, or IFNs, and more recently, more targeted approaches such as those interfering with CTLA-4 or PD-1 (53). Secondly, *passive therapy* refers to the transfer of specific components from the acquired immune system to the host with cancer. The best examples are monoclonal antibodies directed against antigens expressed on the surface of cancer cells such as rituximab against the CD20 antigen, or trastuzumab (Herceptin) directed toward the HER 2 receptor in breast cancer. It should be noted that although the antitumor effects of trastuzumab probably involve, in part, inhibition of signaling by the HER2 tyrosine kinase oncogene, evidence strongly supports a major role for immune activation of Fc receptor–positive cells by both rituximab and trastuzumab (59). Another example of passive immunotherapy is adoptive cellular therapy, in which cells from the blood or bone marrow donor are purified, cultured, and/or manipulated outside the body and reinfused into the same patient (autologous) or a different patient (allogeneic). Cellular therapy has particularly focused on T cells and, more recently, on NK cells. Finally, *active immunization* refers to vaccines that trigger an immune response in the patient. Both passive and active immunotherapy must be directed against specific antigens on cancer cells, and the notion of an integrated immune response with effectors that include antibodies and T cells, as well as some component of immunomodulation, is increasingly becoming the goal of immunotherapeutic strategies (60).

With regard to potential targets, ongoing advances utilizing newer technologies including serologic analysis of recombinant cDNA expression libraries (SEREX) (61,62), robust applications of bioinformatics (63), and seromic profiling techniques (64) have allowed further characterization of tumor-associated antigens in multiple tumor types. There are over 2,000 candidate tumor-associated antigens and they are generally classified as follows (65): (1) differentiation antigens (66), (2) mutational antigens (67) (which are altered forms of proteins), (3) amplification antigens (68), (4) splice variant antigens (69), (5) glycolipid antigens (70), (6) viral antigens (71), and (7) CT antigens (72). Representative examples of each group are seen in **Table 15.1**.

TABLE 15.1 Antigens for Immunotherapy

Antigen Category	Representative Examples
Differentiation antigens	Tyrosinase (66), Melan-Mart-1 (73), gp-100 (74)

Mutational antigens	CD4 (67), β-catenin (75), caspase (76)
Amplification antigens	Her2/neu (68), P53 (77)
Slice variant antigens	NY-CO-37/PDZ 45 (69), ING1 (78)
Glycolipid antigens	MUC1 (70)
Viral antigens	HPV (71)
CT antigens	MAGE (72), NY-ESO-1 (79), LAGE-1 (80)

CT, cancer testis.

In addition to selecting the appropriate targets, it is necessary to select the strategy to be used for immunotherapy. Multiple approaches have been considered from giving the effector cells directly to including antigens of a variety of types given alone or with adjuvants, administering modified or unmodified tumor cell lysates (autologous or allogeneic), priming DCs with a variety of agents, making tumor hybrids with APCs, or administering DNA alone or in a recombinant fashion. A sample of cancer vaccine strategies are listed in **Table 15.2**.

TABLE 15.2 Examples of Vaccine Approaches

I. Antigens alone, with, or without adjuvants Peptides Protein Gangliosides Immunoglobulin idiotypes
II. Dendritic cells Peptides, immunoglobulin idiotype Tumor lysates DNA or RNA Protein
III. Tumor cells unmodified or modified Autologous Allogeneic Mixed autologous–allogeneic
IV. Tumor–APCs hybrid
V. DNA alone (naked DNA)
VI. Recombinant viruses (adenovirus, vaccinia, others)
VII. Bacteria (e.g., Listeria)

A critical component of any immune approach is a consideration of immune escape. Tumors escape destruction by the immune system *via* a variety of active, regulatory mechanisms. These include downregulation of MHC and tumor antigen loss (81), stimulation of the inhibitory receptors on T cells such as CTLA-4 (82), PD-1, and LAG-3 (83), tumor overproduction of indoleamine 2,3-dioxygenase (IDO) (84), induction of increased tumor infiltration by regulatory $CD4^+$ $CD25^+$ $CD25^+$ T cells (T_{regs}) (85), and also certain types of natural killer T (NKT) cells that inhibit tumor immune destruction (86). Overcoming these mechanisms is the goal of immunomodulation.

IMMUNOMODULATION

Multiple potential difficulties remain in developing new immunotherapy approaches, including insufficient activation of DCs

by cancer cells, inhibition of responses by Treg cells, and both intrinsic and extrinsic mechanisms that downregulate T-cell responses; for example, signaling through CTLA-4. These checkpoints all participate in dampening immune responses against cancer. Modulating immune checkpoints by activation of effector cells, depletion of Tregs, or activation of professional APCs could substantially improve the therapeutic efficacy of vaccines or adoptively transferred T cells. The development of functional antibodies is now enabling effective immunomodulation as shown in **Figure 15.1**. Passive therapy with monoclonal antibodies or with adoptive cellular treatments may also prove capable of bypassing some of these checkpoints.

Dendritic Cell Activation

The main mechanism of immune stimulation by CD 40 ligands is activation of DCs resulting in increased survival, upregulation of costimulatory molecules, and secretion of critical cytokines to T-cell priming such as IL-12. This promotes antigen presentation, priming, and cross-priming of $CD4^+$ and $CD8^+$ effector T cells (87). However, agonistic anti-CD40 antibody is best used in combination with vaccines or toll-like receptor agonists (87,88), because alone it can accelerate the deletion of tumor-specific cytotoxic lymphocytes (89). Additional value of CD40 ligation is provided by the fact that ovarian cancers, like many tumors, express the CD40 receptor (90–93) and respond to CD40 agonists with apoptosis and growth inhibition *in vitro* and *in vivo* (94).

Effector T-cell Activation

T-cell activation is triggered through the TCR by recognition of the cognate antigen complexed with MHC. This activation is regulated by complex signals downstream of CD28 family immune receptors, which include costimulatory (CD28 and ICOS) and inhibitory receptors (CTLA-4, PD-1, and BTLA). PD-1 and CTLA-4 are induced on T cells following a TCR signal, and result in cell cycle arrest and termination of T-cell activation. The use of blocking CTLA-4 or PD-1 mAbs can

sustain the activation and proliferation of tumor-specific T cells, preventing anergy or exhaustion, thereby permitting the development of an effective tumor-specific immune response.

CTLA-4 Blockade

CTLA-4 is the best characterized of the inhibitory B7 receptors. As with CD28, CTLA-4 also binds CD80 and 86 expressed by APCs, but provides inhibitory signals to the T cell, serving as a negative feedback loop. CTLA-4 knockout mice develop uncontrolled lymphoproliferation with early lethality. Furthermore, administration of CTLA-4 blockade significantly enhanced antitumor immunity in a variety of mouse models and with various therapeutic combinations including vaccine, TLR agonists, chemotherapy and radiation therapy. Although Treg constitutively express CTLA-4, CTLA-4 blockade had no effect on the number or function of Treg in cancer patients. CTLA-4 blockade activates CD4 and $CD8^+$ T effector cells by removing an inhibitory checkpoint on proliferation and function (95,96). The combination of direct enhancement of Teff cell function and inhibition of Treg activity is important for mediating the full therapeutic effects of anti-CTLA-4 antibodies during cancer immunotherapy (97).

On the basis of these data, multiple clinical studies have been undertaken to assess the efficacy of a CTLA-4 antagonist antibody in the setting of human cancer. The initial clinical data emerged from studies in patients with melanoma (98). Randomized phase III trials showed an OS advantage for ipilimumab over conventional chemotherapy in patients with melanoma, and regulatory approval was obtained in 2011 (53,99). In patients with melanoma, the most common grade 3 to 4 adverse events were colitis/enterocolitis (increased frequency of diarrhea/stools), dermatitis, and hypophysitis. Significant progress has been made in standardizing treatment approaches to the unique adverse events common to checkpoint blockade (9,100).

Ipilimumab has been evaluated in patients with gynecologic cancers, although the experience remains limited. For example, 11 patients with ovarian carcinoma, previously vaccinated with GM-CSF modified, irradiated autologous tumor cells (GVAX), received ipilimumab (1 month to 3 years following GVAX). Significant antitumor effects were observed in a minority of the patients. One patient achieved a dramatic fall in CA-125 levels several months after an initial dose of ipilimumab. Nine additional infusions of the anti-CTLA-4 antibody spaced at 3- to 5-month intervals over nearly 4 years maintained disease control, with grade 1 rash as the only adverse event (101). In contrast to the melanoma cohort, a single dose of 3 mg/kg ipilimumab triggered two cases of grade 3 gastrointestinal inflammation among the nine ovarian carcinoma patients, associated with significant diarrhea. Endoscopic biopsies revealed mucosal damage associated with abundant granulocytes, macrophages, $CD4^+$ and $CD8^+$ T cells, and $FoxP3^+$ Treg. The remaining seven patients showed only minor inflammatory toxicities including papular rash or urticarial-like reactions at sites of prior vaccination (101). Tumor regression in these patients correlated with the $CD8^+$/Treg ratio, suggesting that other forms of therapy targeting Treg depletion may provide an effective treatment when combined with the tumor vaccine and CTLA-4 antibody approaches (101). A phase II clinical trial of ipilimumab in relapsed platinum-sensitive ovarian cancer with measurable disease is ongoing (NCT01611558).

PD-1 Blockade

Programmed death receptor-1 is a negative regulator of cell activation, primarily expressed on both B and T lymphocytes, which binds PD-L1 and PD-L2 ligands. PD-L2 is restricted to professional APCs, whereas PD-L1 is expressed on many tissues, and plays a pivotal role in maintaining peripheral tolerance (102). A variety of epithelial cancers express PD-L1 (103–105) including ovarian carcinoma cells as well as tumor-infiltrating tolerogenic DCs and myeloid-derived suppressor cells (MDSCs) (106,107). Furthermore, expression levels correlate with disease course. Although PD-1 signaling can occur at very low levels of receptor expression, functional significance has recently been attributed to elevated levels of PD-1. During conditions characterized by chronic antigen persistence (such as in chronic viral infections), antigen-specific effector T cells expressing high levels of PD-1 were demonstrated to be functionally exhausted; that is, unable to

proliferate, secrete IL-2, or kill target cells (108). It has been shown that TILs in metastatic melanoma and other tumors express higher levels of PD-1 than $CD4^+$ and $CD8^+$ cells in the peripheral blood of healthy patients, and exhibit phenotypic and functional characteristics of exhausted T cells with impaired effector function. These findings suggest that the tumor microenvironment can lead to upregulation of PD-1 on tumor-reactive T cells and contribute to impaired antitumor immune responses (109). Constitutive or inducible expression of PD-L1 by tumors conferred resistance to immunotherapy in mice. This is related to failure of antigen-specific $CD8^+$ cytotoxic T lymphocytes (CTLs) to destroy tumor cells without impairing CTL function (110).

Following evidence that PD-1 blockade through gene therapy approaches in the tumor microenvironment activates antitumor immunity (111), antibodies blocking PD-L1 or PD-1 were found to enhance the efficacy of immune therapy (110,112). Demonstrations of clinical efficacy of the PD-1/PDL-1 antagonists have resulted in regulatory approval for multiple tumor types, including melanoma, renal cell carcinoma, non–small cell lung cancer, and bladder cancer. The data for PDL-1 inhibitors in gynecologic cancer, while limited, is increasing, and this continues to be an area of active investigation. A phase I trial of nivolumab in patients with platinum-resistant ovarian cancer showed an overall response rate of 15% with durable complete responses with overall disease control rate of 45% (55). A second phase Ib study evaluating pembrolizumab in 26 previously treated PDL-1 + ovarian cancer patients showed 1 patient with complete response (CR) and 2 with partial response (PR) (113). Finally, a study of the PDL-1 antagonist avelumab showed an overall response rate of 10.7% and a disease control rate of 54.7% (114).

Despite their similarities, the regulatory roles of CTLA-4 and PD-1 differ. For example, CTLA-4 ligation does not inhibit PI3-kinase signaling, whereas PD-1 engagement blocks the induction of PI3K activity. PD-1-mediated signaling blocks T-cell activation more effectively than CTLA-4–mediated signaling. In addition, PD-1 signaling may be related to T-cell apoptosis. Whereas the ligands for CTLA-4, CD80, and CD86 are primarily expressed by mature APCs, PD-L1 (on tumor cells or myeloid cells) and PD-1 (on effector T cells) are significantly upregulated in the tumor microenvironment. The effects of PD-1 blockade are therefore more pronounced in the tumor than in periphery. Thus, given the differing but potentially synergistic mechanisms, combination therapy of PD-1 and CTLA4 blockade has been evaluated and was recently shown to be beneficial in patients with melanoma (115). A clinical trial for patients with ovarian cancer (NCT01772004) is ongoing (116).

T Regulatory Cell Depletion

$CD4^+$ $CD25^+$ $Foxp3^+$ T regulatory cells are responsible for maintaining peripheral tolerance by inhibiting T-cell activity. A number of Treg-depleting strategies have been investigated (117–121). An example is the use of low-dose oral or intravenous cyclophosphamide (122,123). Other strategies for Treg depletion are through targeting the IL-2 receptor alpha chain, also known as CD25. In mouse models, the use of anti-CD25 monoclonal antibody before vaccination led to complete tumor rejection and establishment of long-lasting tumor immunity, with no autoimmune complications (124,125). Administration of anti-CD25 antibody linked to a potent proinflammatory toxin showed significant but transient reduction in $CD4^+$ $CD25^+$ Treg cells in patients with metastatic melanoma (126). Another clinical approach of targeting CD25 is through Denileukin diftitox, a fusion protein of IL-2 and diphtheria toxin that targets CD25-expressing cells used in patients with melanoma, ovarian cancer, and renal cell carcinoma (127–130). Although effective in short-term infusions, these conjugates are quite immunogenic and induce neutralizing antibodies, which hamper their long-term application. Another agent is Daclizumab, which is an FDA-approved humanized IgG1-kappa mAb that binds specifically to CD25 (131). It has been used in autoimmune disorders (132,133), acute graft-versus-host disease (134), and in cancer patients with $CD25^+$ T-cell malignancies (135,136).

An alternative strategy has been suggested through the use of an anti-CCR4 antibody, which selectively depletes regulatory T cells from humans (137,138). Several phase 1 studies on the anti-CCR4 antibody mogamulizumab in patients with solid tumors are currently ongoing. The NCT01929486 trial is evaluating mogamulizumab as a single agent; the NCT02301130 and NCT02705105 trials are examining mogamulizumab in combination with immune checkpoint blocking

antibodies such as tremelimumab, durvalumab, and nivolumab; and the NCT02444793 trial is evaluating mogamulizumab in combination with the 4–1 BB agonist PF-05082566.
